Proceedings of Forum Acusticum - Euronoise 2025

11th Convention of the European Acoustics Association

Edited by

Daniel de la Prida, Jaime Ramis and María Machimbarrena

Chair: Antonio Pedrero
General Secretary: María Machimbarrena

Sociedad Española de Acústica

ISSN 3005-7124
ISBN 978-84-87985-35-5

ORGANIZING COMMITTEE

Honorary President: Antonio Pérez-López (SEA)

Chairman
Antonio Pedrero (SEA)

General Secretary
María Machimbarrena (SEA)

Technical Chairman
Luis A. Azpicueta (UC3M)

Exhibition Chairman
Miguel Ausejo (SEA)

Publications Chairmen
Daniel de la Prida (UPM)
Jaime Ramis (UA)

Forum Laboris Chairman
Roberto San Millán (URJC)

Summer School Chairwomen
Belén Casla (SEA)
Mª Ángeles Navacerrada (SEA)
Laura Estévez (ULE)

Volunteer Coordinators
Juan Negreira (Saint-Gobain Ecophon)
Salvador Luna (UMA)
Cristina Quintero (UMA)

Social Media Coordinator
Lucía Schröder (UMA)

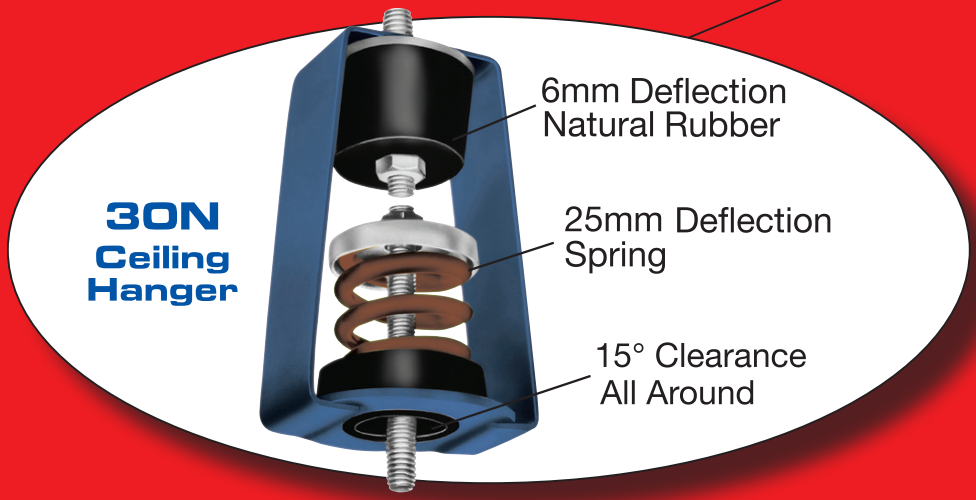
Local Committee
Carolina Gijón (UMA)

CONGRESS COMMITTEE

Ariana Astolfi (EAA)
María Campo (UMA)
Jesús Carbajo (UA)
Teresa Carrascal (IETCC-CSIC)
Alexander Díaz-Chyla (UPM)
Ricardo Hernández (UCA)
Ramón Peral (UMH)
Pedro Poveda (UA)
Samuel Quintana (UCLM)
Carlos Romero (Salford Univ.)
Pedro Salcedo (UMA)
Rosa Mª Alsina (URL)
André Fiebig (EAA)
Fernando Ruiz Vega (UMA)

INTERNATIONAL ADVISORY BOARD

Jorge Arenas
Francesco Asdrubali
Marion Burgess
Torsten Dau
Kristian Jambrošić
Manfred Kaltenbacher
Catherine Lavandier
Luigi Maffei
Carolina Monteiro
Etienne Parizet
Jorge Patrício
Jean-Dominique Polack
Monika Rychtáriková
Brigitte Schulte-Fortkamp
Michael Taroudakis
Nilda Vechiatti
Michael Vorländer
Jo Webb
Jerzy Wiciak



Conference organizer and venue
REVOLUTION EVENTS
Palacio de Ferias y Congresos de Málaga (FYCMA)

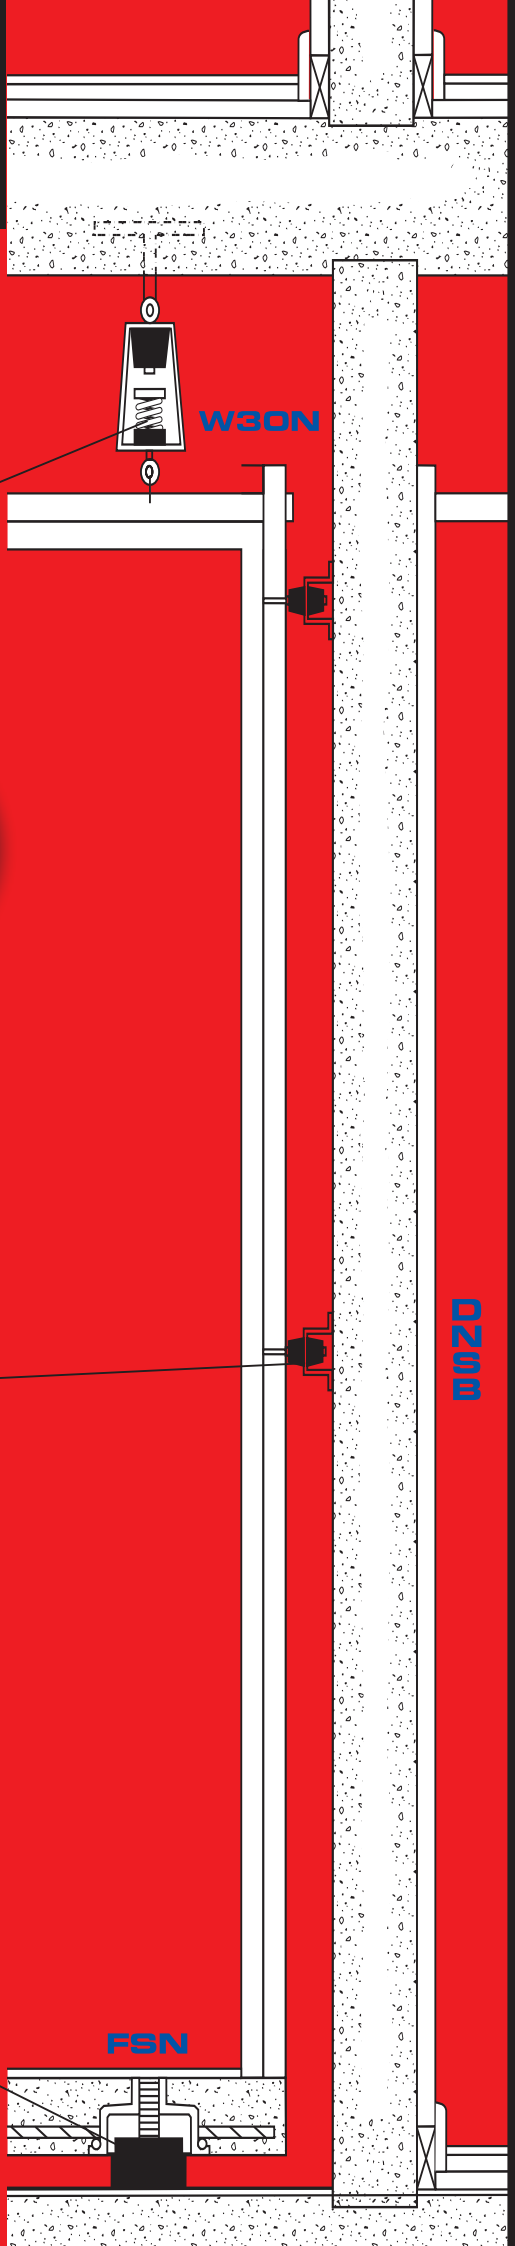
MASON INDUSTRIES, INC.



Manufacturers of Noise and Vibration Control Products

We have been designing and improving acoustical isolation products for over sixty years by studying the market and listening to requirements and suggestions from the acoustical fraternity.

350 Rabro Drive, Hauppauge, NY, USA 11788

MAIN THEME ORGANIZERS

AA01 - Active Control of Sound and Vibration
Jordan Cheer
Teresa Bravo

AA02 - Bio-Acoustics
Bill Davis
David Waddington
Helen Whitehead
Ester Vidaña Vila

AA03 - Building Acoustics
Amelia Romero
Chiara Scrosati
Teresa Carrascal
Carolina Monteiro

AA04 - Education, Public Outreach and History in Acoustics
Montserrat Pàmies-Vilà
Nuria Campillo-Davó

AA05 - Environmental Acoustics
Miguel Arana
Guillermo del Rey
Judicäel Picaut

AA06 - Electro-Acoustics
Hervé Lissek
Libor Rufer
Petr Honzík
Vittorio Ferrari

AA07 - Flow Acoustics
Stefan Becker
Daniele Ragni
Roberto Camussi

AA08 - Industrial Machinery, Equipment Noise and Vibration
Francesco Pompoli
Jaime Ramis

AA09 - Machine Learning and AI in Acoustics
Dick Botteldooren
Rosa María Alsina
Manuel Sobreira

AA10 - Materials and Metamaterials
Jean-Philippe Groby
Rubén Picó

AA11 - Musical Acoustics
Vasileios Chatziioannou
Michele Ducceschi
Vincent Debut

AA12 - Physical Acoustics and Ultrasound
Lynda Chehami
Óscar Martínez-Graullera
Noé Jiménez

AA13 - Physiological and Audiological Acoustics
Deborah Vickers
Maria Milagros J. Fumero
Miriam Isabel Marrufo Pérez

AA14 - Psychoacoustics
Piotr Majdak
Nicola Prodi
Philipp Aichinger

AA15 - Room Acoustics
Monika Rychtáriková
Ingo Witew
Mélanie Nolan

AA16 - Signal Processing
Efrén Fernández Grande
Boaz Rafaelly
Frank Zotter

AA17 - Soundscape, Environmental Quality, Health and Well-Being
André Fiebig
Jerónimo Vida

AA18 - Speech
Laureano Moro-Velázquez
Eugenia San Segundo
Nick Cummins
Phillip Aichinger

AA19 - Numerical, Computational and Theoretical Acoustics
Luis Godinho
Maarten Hornikx
Stefan Schoder
Marcus Mäder

AA20 - Transportation Noise and Vibration
Stephanos Theodossiades
Eduardo Latorre
Ramón Peral

AA21 - Sound Quality and Product Design
Elif Özcan Vieira
Patrick Susini
Georgios Marentakis
Doriana del Palú

AA22 - Underwater Acoustics
Dídac Diego-Tortosa
María Campo

AA23 - Vibro-Acoustics
Jose Roberto de Franca Arruda
Robert Arcos
Arnau Clot
Oriol Guash

AA24 - Virtual Acoustics
Brian Katz
Arcadio Reyes Lecuona
José Javier López Monfort

SESSION ORGANIZERS

Abhayapala T.
A09.06/A16.03 Machine learning for array processing

Aichinger P.
A14.01 Psychoacoustics - General
A18.01 Speech - General

Alsina-Pagès R.M.
A08.07/A09.05 Artificial intelligence for industrial applications
A09.01 Machine learning and AI in acoustics - General
A17.04 Soundscape methods, monitoring and metrics

Altinsoy E.
A14.06 Development of semantic attributes based on psychoacoustic modelling

Amado Mendes P.
A05.07 Outdoor sound propagation
A10.10/A19.08 Numerical methods for wave propagation in complex media

Anda S.
A08.03 Advances in machinery noise and vibration control
A20.02 Automotive noise and vibration

Andreopoulou A.
A16.07/A24.11 Processing/individualization/interpolation of HRIRs or BRIRs

Antunes S.
A03.04 Ground borne noise

Arana M.
A05.01 Environmental acoustics - General
A05.04 Wind turbine noise

Arcos R.
A20.05 Railway noise and vibration
A23.01 Vibroacoustics

Arenas J.
A08.04/A10.04 Materials and systems for noise and vibration reduction

Aspöck L.
A19.07 Validation and benchmarks in computational acoustics

Aspuru Soloaga I.
A17.04 Soundscape methods, monitoring and metrics

Astolfi A.
A15.02 Speech production and perception in rooms

Atamer S.
A14.06 Development of semantic attributes based on psychoacoustic modelling

Aumond P.
A09.07 Events detection and localization, and acoustic scenes, using ML techniques

Ausiello L.
A11.03 Consistency of musical instrument making

Avallone F.
A07.05/A19.06 Methods for advanced computational aeroacoustics

Bai M.R.
A01.06 Signal processing for active control

Barbancho A.M.
A11.05 Instruments, hyperinstruments and beyond

Barros A.
A05.03 Environmental noise perception

Battarra M.
A08.05 NVH damage detection, condition monitoring, diagnostics of machinery

Becker S.
A07.01 Flow acoustics - General
A07.04 Fluid structures acoustic coupling

Bellows S.
A16.06 Source directivity: capturing, processing, and evaluating its effects

Bellucci P.
A05.06 Recent advances in noise mitigation methods
A20.06 Noise barriers and mitigation techniques for road traffic and railway

Ben Tahar M.
A12.02 NDT & SHM Applications

Bernardini G.
A07.05/A19.06 Methods for advanced computational aeroacoustics

Berzborn M.
A15.11/A16.05 Sound field reconstruction in rooms and enclosures

Bottalico P.
A15.02 Speech production and perception in rooms

Botteldooren D.
A09.01 Machine learning and artificial intelligence in acoustics - General

Bravo T.
A01.05/A06.07 Active metamaterials
A10.08 Modeling acoustic wave propagation in viscothermal structures

Brinkmann F.
A24.09/A24.13 Motion and rendering

Camacho J.
A12.03 Biomedical ultrasound

Campillo-Davo N.
A04.01 Education, Public outreach and history in acoustics - General
A04.02 Online resources and simulations
A04.05 Yesterday, today and tomorrow of research in acoustics
A20.04 Tyre/road noise

Campo-Valera M.
A22.03 Communication, positioning and acoustic sensor systems
A22.05 Geophysics and Distributed Acoustic Sensing (DAS)

Camussi R.
A07.01 Flow acoustics - General
A07.02 Aeroacoustics of aircraft and urban air vehicles

Carbajo San Martín J.
A08.04/A10.04 Materials and systems for noise and vibration reduction

Carlosena A.
A06.06 Acoustic-based sensors, actuators and microsystems

Carrascal T.
A03.01 Building acoustics - General
A03.02 Acoustic regulations, classification schemes and standards
A03.08 Reducing neighbour noise by acoustic retrofit in housing

Casalino D.
A07.02 Aeroacoustics of aircraft and urban air vehicles

Chatziioannou V.
A11.01 Musical acoustics - General
A11.04 Articulated musical instrument modelling

Chazot J.D.
A19.01 Numerical, computational and theoretical acoustics - General

Chehami L.
A12.02 NDT & SHM Applications

Chevillotte F.
A10.07/A15.07 Characterization of acoustic materials

Chmelík V.
A03.09 Acoustic and thermal retrofit of office building stock in EU

Cobos M.
A09.06/A16.03 Machine learning for array processing

Cosarinsky G.
A12.02 NDT & SHM Applications

Cuenca J.
A10.03 Metamaterials for noise and vibration reduction

Cummins N.
A18.01 Speech - General

D'Orazio D.
A15.03 Modern offices: challenges and solutions

Dalmont J.P.
A11.03 Consistency of musical instrument making

Davies B.
A02.01 Bio-acoustics - General

Dazel O.
A10.06/A19.05 Numerical methods for acoustic materials and metamaterials

de la Prida D.
A14.07 Robust and unbiased psychoacoustical experimentation
A15.10 Modeling room impulse responses with machine learning

De Marqui Jr C.
A01.05/A06.07 Active metamaterials

Debut V.
A11.01 Musical acoustics - General

Deckers E.
A10.03 Metamaterials for noise and vibration reduction

Declercq N.
A12.01 Physical acoustics and ultrasound - General

Del Palú D.
A21.03 Listening experience in sound-driven design

Del Val L.
A16.04 Airborne sonar

Delle Monache S.
A21.04 Methodologies for sound-driven design and education

Deng J.
A10.05/A23.05 Metamaterials and acoustic black holes in vibro-acoustics

Díaz A.
A03.10 Acoustic consultancy projects and BIM

Diego-Tortosa D.
A22.03 Communication, positioning and acoustic sensor systems
A22.05 Geophysics and Distributed Acoustic Sensing (DAS)

Diviacco P.
A22.04 Traffic ship noises

Ducceschi M.
A11.01 Musical acoustics - General

Duocastella M.
A12.07 Acousto-optics

Dupont S.
A12.07 Acousto-optics

Durand S.
A06.02 Microphones (theory, measurement, MEMS, etc.)

Ech-Cherif El-Kettani M.
A12.02 NDT & SHM Applications

Encina Llamas G.
A18.04 Speech perception pathologies

Engel M.S.
A14.06 Semantic attributes based on psychoacoustic modelling
A17.02 Restorative soundscapes

Estévez-Mauriz L.
A05.05 Urban sound planning
A20.03 Road traffic noise and vibration

Fernández-Grande E.
A15.11/A16.05 Sound field reconstruction in rooms and enclosures

Ferrari V.
A06.06 Acoustic-based sensors, actuators and microsystems

Plenary Sessions

Plenary Session 1

Sounds of the Ocean: understanding marine life and its interactions with sound

Author: Ana Širović
Affiliation: Norwegian University of Science and Technology, Norway
Date: Monday, June 23rd

Biography:

Ana Širović is a marine bioacoustician and a professor at the Norwegian University of Science and Technology (NTNU) in Trondheim, Norway. Originally from Croatia, she obtained a Bachelor's degree from the University of California Santa Barbara and a PhD in Oceanography from the Scripps Institution of Oceanography at the University of California San Diego in the United States. She is interested in the development and use of new methods to improve understanding of highly exploited and endangered marine species. She also conducts research on ambient sound and the effects of anthropogenic noise on marine life. Her group uses acoustic tools to answer ecological, population-level questions relevant to the management of animal resources. Prior to joining NTNU, Prof. Širović was a faculty member at Texas A&M University at Galveston and Alaska Pacific University, and a research oceanographer at the Scripps Institution of Oceanography. She is the recipient of the Medwin prize from the Acoustical Society of America and the US Antarctic Service Medal.

Abstract:

Sound allows us to investigate the ocean on a much finer time scales than other methods of study as it is feasible to collect continuous underwater recordings over months or years at a time. At the same time, sound is critical for successful functioning of many marine animals. It helps them find food and mates, fend off threats, and sense their environment. I will present case studies that highlight how we have been gaining valuable ecological and biological knowledge about baleen whale and fish species through long-term passive acoustic monitoring effort. Some of these highlights include an improved understanding of animal occurrence and coupling of the occurrence of predators and prey into dynamic ecosystem patterns dynamics, leading ultimately to a fuller understanding of their roles in the ocean. In addition, I will reflect on the concerns that increases in ocean sound levels raise regarding functioning of marine life and ecosystems, again highlighting the issues via several case studies. Effects of exposure to seismic noise studies also show mixed impact across taxa. In lab-based experiments, we found that exposures to sounds of seismic airguns on red drum (Sciaenops ocellatus) juveniles did not induce an increase in water-borne and tissue-measured steroid hormone levels. Pile driving noise often results in hearing impairment in marine mammals and injury in fishes. Currently, impacts from other industrial noise sources are poorly documented across taxa. One such source of increasing interest is offshore wind farms. In 2023 and 2024, we conducted microcosm and mesocosm experiments to investigate the response of plankton community to sounds of operational wind farms. Our preliminary results indicate impacts across trophic levels. Overall, given the limited number of species used in noise impact experiments, development of categorizing principles and modeled response pathways will be necessary to better elucidate mechanistic framework for observed impacts. Combined with multi-stressor impact assessment framework and integration and interplay of effects across ecosystems, improved understanding of underlying impact mechanisms should contribute to a better understanding and ultimately a more efficient management of marine resources.

AI for Acoustics: Recognition, Captioning, Visualization, Separation and Generation of Everyday Sounds

Author: Prof. Mark Plumbley
Affiliation: University of Surrey, UK
Date: Tuesday, June 24th

Biography:

Prof. Mark Plumbley is Professor of Signal Processing at the Centre for Vision, Speech and Signal Processing (CVSSP) at the University of Surrey, in Guildford, UK. He is an expert on analysis and processing of audio, using a wide range of signal processing and machine learning methods. He led the first international data challenge on Detection and Classification of Acoustic Scenes and Events (DCASE), and is a co-editor of the book "Computational Analysis of Sound Scenes and Events" (Springer, 2018). He currently holds a 5-year EPSRC Fellowship "AI for Sound" on automatic recognition of everyday sounds. He is a Member of the IEEE Signal Processing Society Technical Committee on Audio and Acoustic Signal Processing, and a Fellow of the IET and IEEE.

Abstract:

The last few years has seen a rapid increase of interest in the application of AI to everyday sounds. Starting a decade ago with acoustic scene classification and sound event detection, the challenges and workshops on Detection and Classification of Acoustic Scenes and Events (DCASE) have brought together researchers from academia and industry to establish a new research community. In this talk, I will highlight some of the work taking place in this area at the University of Surrey, including pretrained audio neural networks (PANNs), audio captioning, audio visualization, audio source separation and audio generation (AudioLDM). I will also mention some cross-cutting issues such as dataset collection, algorithm efficiency, and large language models (LLMs), and discuss how we might design future AI applications for acoustics, to benefit of people and society.

Plenary Sessions

Plenary Session 3

Standardizing soundscape perception and other tales

Author: Francesco Aletta
Affiliation: University College London, UK
Date: Wednesday, June 25th

Biography:

Dr Francesco Aletta is a Lecturer in Building Physics and Soundscape at Institute for Environmental Design and Engineering, University College London (UCL). His research focuses on environmental acoustics and soundscape studies. Francesco is committed to advancing soundscape research through his contribution to the ISO 12913 series on soundscapes, which provides a comprehensive framework for assessing and managing urban sound environments. Francesco's research has informed international policy discussions. He authored a United Nations Environment Programme report in 2022, addressing emerging environmental concerns related to noise and its impact on public health and urban environments. His work is frequently referred in policy documents and guidelines aimed at promoting healthier and more sustainable sound environments globally. As part of his standardization efforts, Francesco coordinated the Soundscape Attributes Translation Project, an international collaboration of more than 100 scholars worldwide. He is also an active member of editorial boards for leading journals, including the Journal of the Acoustical Society of America (Coordinating Editor for TC Noise), and member of the organizing committee of several international conferences, including the Urban Sound Symposium, and the Lancet UK Public Health Science Conference. Francesco is a member of the Italian Acoustical Society (AIA), the Acoustical Society of America (ASA), and serves as secretary of the Technical Committee Noise of the European Acoustics Association (EAA). With over 200 publications, 6,000 citations and multiple awards, including the ASA Science Communication Award in 2023, Francesco aims to contribute to the global discourse on soundscape design, urban acoustics, and public health.

Abstract:

The way we experience soundscapes is deeply personal, shaped by cultural, environmental, and psychological factors. Yet, as urbanization accelerates and noise management becomes a global priority, the need for standardized approaches to assessing and designing soundscapes has never been greater. This keynote explores the evolving efforts to establish frameworks for soundscape perception, from the development of international standards to the challenges of ensuring their widespread adoption. While standardization provides a necessary foundation for consistency, the reality of soundscape experience is far from universal. People from different cultural and linguistic backgrounds perceive, interpret, and encode sounds in diverse ways, highlighting the limitations of rigid frameworks. Addressing this complexity requires a balance between structured methodologies and adaptability to local contexts. Advances in cross-cultural research and translation efforts are helping to refine these approaches, making soundscape assessment more inclusive and representative. At the same time, new methods for quantifying soundscape quality are emerging, offering ways to integrate perceptual and contextual dimensions into meaningful metrics. These developments not only enhance our ability to compare and evaluate soundscapes but also provide valuable tools for urban planners, policymakers, and designers to create environments that support well-being. This talk will explore the intersection of standardization, perception, and measurement, reflecting on how soundscapes can be assessed in a way that respects both scientific rigor and human experience.

Plenary Sessions

Plenary Session 4

Sculpting sound fields with acoustic holograms

Author: Dr. Noé Jiménez
Affiliation: Spanish Research Council (CSIC), Spain
Date: Thursday, June 26th

Biography:

Noé Jiménez is a Senior Scientist at the CSIC since 2024. He develops his work at the Institute of Instrumentation for Molecular Imaging, a joint centre of the Universitat Politècnica de València (UPV) and the CSIC. He is a Telecommunications Engineer, holds a Master's degree in acoustics and a PhD (2015) from the UPV. He has been a Ramón y Cajal senior researcher, Juan de la Cierva - Incorporation, Juan de la Cierva - Training, has worked at the CNRS (France) as a postdoctoral researcher for two years, and has made stays at Columbia University (NYC, USA), the University of Salford (UK), and the University of Le Mans (France). He has over 15 years' experience in developing imaging and therapeutic ultrasound systems, wavefront shaping techniques and acoustic metamaterials. His recent research interest ranges from the application of acoustic metamaterials for biomedical ultrasound applications, novel therapeutic ultrasound techniques, acoustic holograms, and acoustic vortices.

Abstract:

Using optical holograms, we can modulate light wavefronts to generate visible images. Can we do the same with sound waves? Acoustic holograms can render sonic images, shaping the areas where mechanical waves present a high amplitude, and areas where the media is at rest. In this plenary talk, we will present an overview of the use of acoustic holograms, and how they can be applied in biomedical ultrasound applications, in particular in emerging therapeutic applications of focused ultrasound, but also in other fields like audible engineering acoustics or contactless particle trapping, to tailor sound waves in unprecedented ways.

Effect of measurement positions on structure-borne noise levels in buildings subject to railway vibrations
C. Guigou Carter and P. Ropars 495

Methodology for assessing structural noise annoyance in buildings caused by rail traffic. Comparative analysis between Portugal and Spain
S. Antunes and J. Patricio 503

Building Base Isolation Design: Quantification Of Vibration Transmission Using Power Flow Analysis
H. Masoumi and J. Talbot 511

Mitigating ground-borne vibrations with a box-in-box solution: feasibility and challenges in a real case study
I. Arana Goenaga, P. V. Rodríguez, A. Isnardo Iglesias, S. F. Frasson Quaresma and H. Masoumi 519

Impact noise horizontally with 80 mm concrete slab and upper 80 mm polystyrene splitted with continuous polystyrene beneath
B. M. Larsen 527

Session A03.05 Structure -borne sound and noise from building services

Preparatory Work Toward Experimental Estimation Of Water Excitation Terms In Wastewater Systems
Y. Aoki, S. Öhler and B. Kaltbeitzel 533

FH-IPTOOLS: Predicting wastewater noise in timber construction – a project introduction
T. Kruse, A. Mayr, U. Schanda and F. Schöpfer 541

From Classification to Prediction: Applying EN14366-1 to Freshwater Systems
L. Däuble, J. Scheck and B. Zeitler 547

On-Site Application of Noise Reduction Technologies for Bathroom Drainage in Apartment Buildings
G.-G. Song, J.-Y. Chung and A.-H. Jo 555

Session A03.07 Acoustics of wooden buildings

Improvement of the airborne and impact sound insulation of a timber stud wall
J. Scheck, U. Schüttler, C. Fichtel and B. Zeitler 561

Sound insulation performance of timber floors with elastically mounted and suspended layers
J. Lietzén, L. Talus, A. Lahdensivu, A. Lopetegi and A. Aldalur 567

Impact Sound Insulation of CLT Floors: Evaluation of Small Scale Specimens and Correlation with Large Scale Systems
M. Puljizevic, T. Poljansek and M. Grasic 577

Influence of gravel on flanking transmission in CLT buildings
A. Dijckmans and C. Crispin 585

Prediction of flanking sound transmission across periodic cross-laminated timber junctions with area couplings
S. Moons, R. Lanoye and E. P. B. Reynders 593

Experimental Modal Analysis of a Cross-Laminated Timber L-Junction with a View Towards Predicting Flanking Sound Transmission
S. Vallely, A. Esposito and S. Schoenwald 601

Load effects in flanking transmission of CLT structures with resilient interlayer
V. Pettoni Possenti, C. Crispin, A. Dijckmans and L. Barbaresi 611

Modelling Cross-Laminated Timber Plate Connections: A Numerical Investigation On Flanking Sound Transmission Through Angle Brackets
A. Esposito, S. Vallely and S. Schoenwald 619

Suggestion for a round robin test on the measurement of vibration reduction indices on CLT junctions
F. Schöpfer, U. Schanda and C. Chateauvieux-Hellwig 627

Detailed analysis of different software for sound insulation calculations of various structures
K. Hagberg, E. Nilsson and D. Bard 631

Rainfall sound insulation of (lightweight) wooden roof constructions
A. Stenitzer, B. Nusser, C. Lux and H. Müllner 641

Acoustic Comfort Of Lightweight Timber Walls: Correlation Between Subjective Evaluations And Objective Measurements
F. Morandi, A. Speranza, P. Brugnara, F. Cappelletti and A. Gasparella 649

Initial Results of the Research Project Sound and Vibration Protection for Long Span Timber Floors
M. Schneider, J. Ruf, M. Marxt and B. Zeitler 655

Session A03.08 Reducing neighbour noise by acoustic retrofit in housing

Improving sound insulation of old timber floor constructions 1917/1937 in multi-storey housing – Field case study & perspectives
B. Rasmussen 665

Acoustic Insulation in plasterboard systems with Mineral Wool
P. Belenguer Rubio and P. González De La Peña 673

In-situ evaluation of concrete interlayer adhesion by vibration in garaje floors
D. Caballol Bartolomé, A. Pérez Raposo and F. Gil Carrillo 683

Noise Reduction Mat Performance of Apartment Houses according to Slab Conditions
J.-Y. Chung, G.-G. Song, A. Cho and S. Jeong 689

Communication between Caregivers and Children Regarding Inter-floor Noise in Multi-family Housing: A Korean Study
M. Kwon and W. Yang 693

Session A03.09 Acoustic and thermal retrofit of office building stock in EU

ActaReBuild MSCA-DN project - Acoustic and Thermal Retrofit of Office Building Stock in EU
V. Chmelík and M. Rychtáriková 699

Mycelium composites combining different waste sources for sustainable acoustic solutions
T. S. Gomez, L. M. Garcia, N. Escobar, M. D. L. A. Navacerrada and C. Glorieux 705

Exploration of use of Membrane-Type Metamaterial Layer for Application in Building Acoustics
R. Zeng, E. Deckers, C. Glorieux, D. Urbán and B. Chmielewski 713

Effect of Load Plate Mass on Dynamic Stiffness Determination
D. Urbán and M. Neusser 721

Evaluating Recycled PET Filaments As A Sustainable Sound Absorbing Material For Building Retrofitting
J. Garcia, D. Tonetti, E. A. Piana and O. Jiricek 727

Building Envelope Assessment of Airtightness Using an Acoustic Camera: A Case Study in Valladolid, Spain
A. Elsaei, M. Machimbarrena, A. Meiss and S. Herguedas 733

Development of acoustic resonators using recycled plastics
J. Potocar, M. Maaroufi, S. Uncik, C. Glorieux and M. Rychtáriková 741

Rethinking material cycles: Combining mycelium and paper waste for the development of sound absorbers
A. M. Kubiak, T. S. Gomez, C. Glorieux, M. D. L. A. Navacerrada, N. Vasileva Nicheva and D. Sanz Arauz 747

Session A03.10 Acoustic consultancy projects and BIM

IFC Open BIM for noise emission evaluation of the HVAC systems
C. C. Mastino, A. Di Bella, J. Vaičiūnas, P. Raffaello, M. Zavari and M. Piga 755

Building Information Modeling: Example of use IDS file and bSDD data base for acoustic evaluation
C. C. Mastino, A. Di Bella, A. Sygulska, P. Raffaello, A. Frattolillo, M. Zavari and V. Da Pos 761

Acoustic calculations and workflow based on list of acoustically distinguishable spaces
A. Fürjes 767

Introduction of a Grasshopper workflow for the integration of the acoustic analysis in a multi-domain BIM model
A. Gerbotto, L. Shtrepi, F. Favoino and A. Astolfi 775

Session A03.11/A05.11 Heat pump sounds in residential settings: challenges and solutions

Machine Learning-Based Prediction of Air Source Heat Pump Noise Annoyance
V. Acun, S. Graetzer and A. Torija Martinez 781

Characterisation and control of aero-acoustical inflow noise sources of the evaporator fan in Heat Pumps
F. Lörcher and S. Hub 789

Improve heat pump placement considering frequency resolved acoustic directivity data: creation of an open database
C. Reichl, F. Bessac, G. Klein, L. Stöckl and M. Czuka 797

The role of measurement locations in low-frequency noise assessment
L. Čurović and J. Prezelj 803

In-Situ Transfer Path Analysis of a Roof Mounted Air Source Heat Pump
L. Barton, J. Hargreaves, V. Acun, A. Torija Martinez, S. Graetzer and D. Waddington 811

Simulation-based analysis of the sound emissions of decentral air-to-water heat pumps in renovated multi-family buildings
W. Monteleone and F. Ochs 819

A Risk-Based Framework For Acoustic Assessment Of ASHPS - From Domestic To Commercial Applications
J. Harvie-Clark, J. Hill, N. Dobinson and R. Hinton 827

Session A03.12 Ventilation noise in dwellings: challenges, measurements, and solutions

Scalability of Ventilation and Noise Insulation methods for assessing a full-scale Metawindow
G. Fusaro, L. Barbaresi and M. Garai 837

A Silencer Design for a Mechanical Heat Recovery Unit
D. Mullally and J. Kennedy 841

Evaluation of Acoustic Performance in Smart Ventilated Windows with Integrated Heat Storage
A. Gerbotto, L. Shtrepi, F. Favoino and A. Astolfi 845

Session A04.01 Education, Public outreach and history in acoustics - General

The teaching of acoustics at the higher technical school of architecture of Madrid in 1855
A. Díaz Chyla 853

Acoustics in music education: Empowering Music Teachers as STEM Ambassadors
M. Pàmies-Vilà 859

From sounds to architectural design: Acousmatic Spaces
A. Sentop Dumen and Y. Celiker-Cenger 867

Acoustic multi-component monitoring of ecosystems: training for mangroves' conservation in Africa
C. Nhancale, Z. Valgi Macheve, A. Rapino, A. J. Nhampossa, M. Polizzi and P. F. Moretti 875

Session A04.02 Online resources and simulations for teaching and learning acoustics

MOOCs for introductory courses in acoustics at the University of Le Mans: assessment and prospects
J.-P. Dalmont 883

Interactive simulation apps for teaching acoustical phenomena and vibration effects
M. Maeder, M. Buba, M. Dogu, M. T. Bárány, T. Breitkreutz, L. Heggemann, L. E. Roca Paz, S. Kersten and J. D. Schmid 885

Open Educational Resources For Acoustics And Audio Signal Processing Using Jupyter Notebooks And Pyfar
F. Brinkmann, M. Berzborn, A. Heimes, A. Hoyer, X. Karakonstantis, S. Kersten, T. Lübeck, P. Palenda, C. Andrade, J. M. Arend, N. Hahn, T. Jüterbock, N. Meyer-Kahlen, A. Paskiewicz, S. J. Schlecht, F. Schultz and S. Weinzierl 889

Application of room acoustics simulation software in university teaching
L. Aspöck, P. Palenda, J. Fels and M. Vorländer 895

Session A04.05 Yesterday, today and tomorrow of research in acoustics

Al-Ándalus. Spreading acoustic knowledge from Spain to Western Europe
W. A. Montano Rodríguez 901

Music studies in 1254 at the University of Salamanca. An al-Ándalus legacy
W. A. Montano Rodríguez 909

20 years of research on acoustics and vibrations at Miguel Hernandez University of Elche
R. Peral-Orts, N. Campillo-Davo, H. Campello-Vicente, M. Fabra-Rodriguez, D. Abellan-Lopez, D. Clar-Garcia and E. Velasco-Sanchez 915

Psychoacoustics, the long way to be considered into international standards
K. Genuit 921

A historical overview of Higini Arau's proposal for calculating reverberation time (1988)
J. Álvarez, R. Graus and H. Martín-Nieva 925

From acoustic testing and modeling towards multi-physical digital twins: use cases and demonstrators
L. Van Belle, D. Panagiotopoulos, V. Cool, H. Denayer, C. Claeys, W. Desmet, B. Pluymers, K. Gryllias, F. Naets and E. Deckers 933

Session A05.01 Environmental acoustics - General

Case Study: Noise Source Analysis Through Environmental Noise Measurements
O. Odeh, M. Bite and D. Kocsis 943

Obtaining noise levels from projected overpressure levels generated by blasting operations
M. Glisser and B. Vásquez 949

Experimental Assessment of Outdoor Leisure Noise: Sampling Methodology and Annoyance Indicators
A. Hidalgo Otamendi and A. Hernandez 955

Practical noise immission modeling for concerts in stadiums: Santiago Bernabeu - Real Madrid (Spain)
C. V. Viloria-Yzquier, E. García-Calderón and R. San Millán-Castillo 961

Comparative analysis between CNOSSOS-EU and interim methods
M. Ausejo Prieto, R. García Morales and I. Soto Molina 969

Need of a National Noise Strategy in Spain and approach to develop it
M. Á. González García, I. Soto Molina and C. Soriano Pastor 975

Preliminary evaluation of a low-cost device for binaural recording and soundscape monitoring
J. M. Navarro Ruiz and M. Masullo 983

Assessing Acoustic Dynamics in Alpine Ecosystems: The Nivolet Pass Case Study
G. Guagliumi, F. Angelini, R. Benocci and G. Zambon 991

Evaluating Background Noise Criteria For Estimating Outdoor-To-Indoor Levels Via A Statistical Learning Modelling Framework
M. E. Terzakis, C. Van Hoorickx, M. Hornikx, F. Naim, D. Fecht, A. L. Hansell and J. Gulliver 999

Towards the Worlds largest Noise Complaint Database
E. King, E. Murphy, T. Messerer and T. Messerer 1007

Assessment And Analysis Of Vibration Impacts From Underground Railway Tunnelling And Excavation In Sydney, Australia
A. Miller, J. Parnell, V. A. Menon and D. Hanson 1011

Immision Directivity in the frequency domain
J. Murovec, L. Čurović, A. Železnik and J. Prezelj 1019

Session A05.03 Environmental noise perception

Measurement Of The Sound Field Over A Green Roof Using Simultaneous Sound Pressure Recordings
J. Alvarez Chaia, A. Alva and A. M. Lacasta 1029

Optimizing the traffic induced annoyance by public participation; Interaction between questionnaires, model calculations, and measurements
W. Van Keulen 1037

The alleviating role of residential green on road traffic noise annoyance: Insights from the RESTORE project
C. Kawai, J. Dopico, B. Schäffer, M. García-Martín, N. Kolecka, S. Tobias, D. Vienneau, M. Röösli, M. Brink and J. M. Wunderli 1041

Clustering individuals based on performance in audio-visual testing
T. Van Renterghem 1045

Exploring soundscape perception through the italian language: a study on descriptive words for noise and sound
M. Ferretti, D. Chiarella, A. Cinini and P. Cutugno 1051

Key Aspects for Survey Data Processing and Statistical Analysis when Modelling Exposure-Annoyance Relationships
M. Brink, B. Schäffer and D. Schreckenberg 1059

Exploring the acoustic environments of Barcelona's Superblocks: perceptions from soundwalks
A. R. Esperidião, A. Potenza, E. Vidaña-Vila, M. Freixes, A. Radicchi, A. Iarozinski Neto and R. M. Alsina-Pagès 1063

Session A05.04 Wind turbine noise

OFF-COUSTICS: Predicting The Underwater Acoustic Footprint Of Offshore Wind Turbines
E. Eerrer, L. Botero-Bolivar, O. A. Marino, M. De Frutos, D. Huergo, A. Ballout, E. Jané, H. Marbona and G. Rubio . 1073

Long-term Wind Farm Noise assessment over different meteorological conditions
K. Lowe, M. Amatriain and S. Broneske 1079

Optimizing Electricity Production in Wind Farms with Noise Mitigation Strategies
Á. Grilo Bensusan 1087

Noise and vibration measurements emitted by wind towers
G. Iannace, L. Fredianelli, A. Akbaba, G. Ciaburro and F. Artuso 1095

Wind turbine directional tonality
M. Amatriain and M. Arana 1099

Session A05.05 Urban sound planning

Guidelines For An Institutional Proposal For The Creation Of A Noise And Vibration Observatory In Uruguay
L. Marisquirena, E. González and P. Gianoli 1109

Characteristics determining the attractiveness of urban green spaces: Insights from the RESTORE project
J. M. Wunderli, C. Kawai, J. Dopico, M. Röösli, D. Vienneau, M. Brink, S. Tobias and B. Schäffer 1115

Necessary steps to advance research on healthy urban sound planning
T. Haselhoff and S. Moebus 1119

Development of a tool for noise management in LEZs
J. I. Riesco García, S. Herrero, L. Garcia, R. Díez, R. Paredes, A. E. Espinel Valdivieso and M. Lora 1123

Soundscape evaluation of residential outdoor spaces based on a subjective questionnaire and objective acoustical measures
M. Isenegger, T. Steiner, G. Heini, L. Bartha, U. Sturm and A. Taghipour 1131

A Spatial Processing Framework For Mapping Areas Benefiting From Urban Morphology And Building Design In Airport Regions
G. Wuite, M. Lugten, R. Vassallo and A. Van Timmeren 1139

Enhancing Urban Acoustic Comfort: The Role of Free Surfaces, Green Spaces and Water Bodies in Mitigating Road Traffic Noise
C. V. Fiorini, V. Battistini, M. Calanna, L. Quaranta, C. Guattari, A. Tarsitano and A. Vallati 1147

Bringing Soundscape Auralizations To The Urban City Planning
J. Llorca-Bofí, H. H. Au-Yeung, M. Lippold and C. Reicher 1155

Session A05.06 Recent advances in noise mitigation methods

The LIFE SILENT Project: advancing sustainable solutions to mitigate noise in urban environments
P. Bellucci, F. Ciarallo, M. Garai, G. Licitra, T. Onorato and F. G. Praticò 1161

Challenges in Producing Innovative Low-Noise Asphalt Mixtures with Recycled Materials and Additives: Insights from the LIFE SILENT Project
M. Diamantini, P. Bellucci, G. Chidichimo and F. G. Praticò 1169

How sustainable are innovative noise mitigation road pavements? An LCA approach
A. Altobello, F. V. Catania, M. Busti, C. Ravagnan and A. Tani 1173

European Projects For Noise Quality In Florence
A. Melloni, G. Pecchioni and R. Bellomini 1181

Managing environmental noise by bringing together continuous monitoring and simulation models
L. Conde Santos, A. Carvalho, J. Preto, P. Valério, C. Leão and G. Covas 1185

Low-Height Noise Barriers For Railways: Measurement Standardization And Metamaterials Application On Noise Reduction
D. De Salvio, P. Guidorzi and M. Garai 1193

Analysis Of Complex Scenarios In The Noise Mitigation Of Main Infrastructures In Italy In Life Silent Project
M. Cerchiai, M. Bolognese, A. Panci, D. Vatteroni, D. Palazzuoli and G. Licitra 1197

Using Microphones in Outdoor Pass-By Noise Testing for Vehicle Speed Measurement
F. Lo Castro, M. L. Ariza Alvarez, M. De Luca and S. Iarossi 1201

LCA approach to evaluate the sustainability of innovative low-height noise barriers
M. Montesi, A. Tranzi, M. Fantozzi, M. Garai and C. Micheletti 1209

LIFE SILENT: Implementation Of The Solutions Developed In The Pilot Site
C. Relandini, M. Fantozzi, S. Relandini and L. Peruzzi 1217

Environmental Noise Reduction Using Geometric Ground Shaping: Results from Scale Model Experiments
T. Shaked, S. Fishkin, A. Hauptman and F. Nir 1223

Session A05.07 Outdoor sound propagation

Self-shielding windows : scale model measurements and numerical simulations
T. Van Renterghem and P. Thomas 1233

Predicting the effects of ground impedance in long-range low-frequency propagation with the Semi-Analytic Finite-Element (SAFE) Method
R. Castro Mota, P. Williams, R. Kirby and S. Jacob 1239

Improvements in Measuring Acoustic Impedance of Outdoor Ground Surfaces
A. Fuchs and M. Haider 1243

Assessing forest acoustics: A comparison of in-situ and scale model acoustic impulse responses
S. Feng, F. Stevens and A. Chadwick 1251

Key Updates In ISO 9613-2:2024 – What's New In Outdoor Noise Prediction Standards?
O. Odeh, A. Khayyat and D. Kocsis 1259

Session A05.08 Advances in noise mapping

Noise Pollution in Spain: Towards a comprehensive assessment
I. Soto Molina, M. Á. González García, C. Soriano Pastor and R. M. Arce Ruiz 1267

Road Traffic Noise Modelling Near Highway Street Using The CNOSSOS-EU Method
K. Katw, B. Tóthmérész and D. Kocsis 1275

Identifying noise action plan priority locations in Ireland
S. Shilton and T. Dolan 1285

Quality Assurance and Modeling Limitations in Noise Emission Control Using ISO 9613-2 and ISO 17534
J. Schaal and D. Zollitsch 1293

Comparative analysis of strategic noise maps: using heat maps to find why two CNOSSOS-EU implementations (iNoise and CadnaA) differ
A. L. Peña 1301

Defra's Noise Modelling System: A new approach to nationwide modelling in support of research and evidence
J. Trow and H. Notley 1307

CNOSSOS Environmental Noise Analysis By Cloud-Based Model Refinement And Calculation
H. Stapelfeldt and I. Naegelen 1315

Overview of research supporting development of a national noise modelling system for England
S. Shilton, J. Trow, M. Wilczek, K. Fedyk, H. Stapelfeldt, R. Wong, B. Peeters and M. Toward 1321

A Comparative Study of Methods for the Distribution of Populations in Residential Buildings for Noise MAPPING PURPOSES
Y. P. Alvarez Ruiz, T. Jiménez Pérez, V. Puyana Romero, M. Sequera Soto, R. Gey Flores and J. L. Cueto-Ancela 1329

An Open-Source Tool For Aircraft Noise Modeling In The Context Of Spain's Global Noise Assessment (Under Development)
I. Soto Molina and R. M. Arce Ruiz 1333

Can road traffic noise annoyance maps describe the lack of mental well-being in an urban area?
A. Montenegro, A. Zumelzu, G. Leal and G. Licitra 1341

Comparison Of Different Urban Traffic Representations For Road Traffic Noise Indicators Estimation
Y. Gao, S. Baclet, P. Aumond, R. Rumpler and A. Can 1349

Delivering National Scale Noise Calculations with CNOSSOS-EU through cloud computing and software optimisation
H. Stapelfeldt, J. Trow and J. Madden 1357

Comparison of input data collection methods for road traffic noise models in residential area
E. Ascari, L. Fredianelli, M. Cerchiai, G. Licitra, C. A. Neagoe, A.-M. Mitu, T. Sireteanu, D.-C. Baldovin, D. Profumo and S. Kanka 1363

Effect of traffic flow on urban noise modelling
V. Gómez Escobar, S. Palomeque Váquez and G. Rey Gozalo 1369

Session A05.10/A14.09 Advanced air mobility noise

Noise Impact Range Assessment using UAM Noise Hemisphere
S.-M. Lee and C. H. Haan 1375

On-field measurements following the EASA Guidelines on Noise Measurements of Unmanned Aircraft Systems lighter that 600 kg
P. Miguel-Ayala, L. Estévez-Mauriz, C. Ramos-Romero and A. Torija Martinez 1379

Rotor Noise Interference Mechanisms For Side-By-Side Co-Rotating Configurations
T. Pagliaroli, P. Candeloro, F. Del Duchetto, J. Yin and K.-S. Rossignol 1387

Integrated U-space Societal Acceptance Assessment: Energy-based and Perception-based Acoustic Metrics
C. Ramos-Romero, M. J. B. Lotinga and A. Torija Martinez 1395

Noise impact of drone parcel delivery scenario over Madrid
I. Legriffon, E. Ruaud, J. Kuljanin and E. Ganic 1403

The effects of time-variant characteristics of unmanned aircraft system noise on reported annoyance
Z. Podwinska, C. Ramos-Romero, M. C. Green and A. Torija Martinez 1409

Review of the effects of drone noise on people
J. Li, B. R.C. Molesworth and M. Burgess 1417

A novel procedure to minimize the acoustic and environmental impact of eVTOL vehicles for intra-city mission profiles
C. Poggi, G. Bernardini and M. Gennaretti 1421

Differences in sound emission level of multi-rotor UAS during hover and cruise
J. Meister, J. Jäggi, T. Van Renterghem and R. Pieren 1429

Prediction of Environmental Noise from Rotorcraft using a Noise Hemisphere with Time-Domain Data
Y. Jo and S.-Y. Wie 1435

Influence of surface roughness on the aerodynamic, aeroacoustic and psychoacoustic performances of drone propellers
G. Capobianchi, A. Di Marco, E. De Paola and L. G. Stoica 1439

Mid-Fidelity Framework for Rotor Noise Prediction and Perception in Maneuvering flight
M. Picillo, M. Barbarino and F. Avallone 1447

Psychoacoustic Characterization Of An Isolated Propeller At Different Inflow Turbulence Conditions And Collective Pitch Angles
R. Merino-Martinez and L. N. Quaroni 1457

Machine Learning-Based Modelling Of UAV Noise Metrics In Real Conditions
C. I. Andino Cappagli, A. Amiri-Simkooei, S. Luesutthiviboon, T. Meiser, A. Morin, M. Zajacík, M. Rollo and M. Snellen 1465

Assessment of the Psychoacoustic Performance of the VENUS Project Distributed Electric Propellers Configuration
A. Di Marco, L. G. Stoica and G. Capobianchi 1473

Comparative Drone Noise Flight Test Campaign Using Conventional Precision Microphones and an Artificial Head
G. Fasulo, F. Petrosino, M. Barbarino and L. Federico 1481

Exploring socio-spatial pattern of noise impact of advanced air mobility – A case study in West Yorkshire, England
L. Jiang 1489

UAS-NoiseCheck - A System Implementing the EASA Guidelines on Drone Noise Measurement
M. Blass, S. Grebien and F. Graf 1495

Noise Modeling of UAM around Vertiports by Sound Barrier
S.-M. Lee and C. H. Haan 1501

Session A05.11 Heat pump sounds in residential settings: challenges and solutions

Session A06.02 Microphones (theory, measurement, applications, MEMS technology, etc.)

Nonlinear Behavior of Condenser Microphones: Analytical Modeling and Experimental Validation
J. Placek and P. Honzík 1507

Characterization of Planar Circular and Square MEMS Microphone Arrays for Low-Power Acoustic Applications
R. Moreno, J. Ortigoso-Narro, M. Raiola, L. A. Azpicueta-Ruiz and D. De La Prida 1515

Pressure-Comparison Calibration Of MEMS Microphones In The Reverberation Chamber
F. Saba, M. Campo-Valera, M. Corallo and G. Durando 1523

Noise Source Direction Estimation using Flow-Sensing MEMS Microphones
T. Röck, M. Hagmüller and F. Zotter 1529

Amplitude modulation discrimination in cochlear implant listeners: Effects of carrier frequency and 'interfering' modulated signals
N. Haywood, B. Moore, B. Williges, P. Boyle, M. Salorio-Corbetto, J. Schlittenlacher, C. Harbottle and D. Vickers 1537

Session A06.03 Loudspeakers and headphones (theory, measurement, applications, MEMS technology, etc.)

Acoustic metamaterials for attenuating unwanted wave phenomena in loudspeaker enclosures
B. Chojnacki, A. Chojak, W. Binek, J. Pawlik and J. Idczak 1543

Flat and curved parametric acoustic loudspeakers measured with exponential sine sweeps
A. Fantinelli and M. Arnela 1547

Influence of coil winding material on the performance of electrodynamic loudspeakers
J. Martinez-Iranzo, C. Martinez-Pia, J. Carbajo San Martín, P. Poveda Martinez, J. Ramis-Soriano and E. G. Segovia-Eulogio 1553

Optimization of Cavities and Suspensions in Underwater Acoustic Projectors: Analytical and Experimental Study
J. Martinez-Iranzo, J. Carbajo San Martín, P. Poveda Martinez, J. Ramis-Soriano, E. G. Segovia-Eulogio and C. Martinez-Pia 1559

Investigating Spatial Aliasing and Fresnel Zones of Line and Planar Sources for Sound Reinforcement
L. Gölles and F. Zotter 1565

A Simulation Framework for Piezoelectric MEMS Speakers: Modeling, Integration, and Validation
F. Bachl and S. Horvath 1573

Mechanically-open and acoustically-closed MEMS loudspeakers for in-ear applications
C. Gazzola, F. Perli, F. Cerini, S. Adorno, P. Lotton, M. Melon and A. Corigliano 1581

Impact of Impedance Mismatch on Crosstalk Cancellation with Micro-Speaker Arrays
F. Veronesi, F. Fazi and J. Hollebon 1585

Development of a omnidirectional cylindrical sound source with a Corona Discharge Transducer
H. Lissek, T. Wang and R. Vesal 1593

Session A06.06 Acoustic-based sensors, actuators and microsystems for diverse applications

On biotelemetry's bidirectional acoustic tag
G. Batet, D. Sarria, S. Gomariz, I. Masmitja and J. Del Rio 1603

Low Order Lateral Modes Of Plate Transducers As Basis For Effective And Reproducible Acoustofluidic Devices
A. Fuchsluger, A. De Pastina and B. Jakoby 1607

Acoustic Levitation in Air: novel techniques and applications
A. Marzo 1609

Piezoelectric MEMS Temperature Sensor based on Acoustic Flexural Plate Waves
S. Bertelli, A. Nastro, M. Baù, M. Ferrari, L. Rufer, S. Basrour and V. Ferrari 1613

Productization challenges of acoustic MEMS sensors and actuators
A. Lagosh, A. Piot, S. Nayak, R. T. Rocha and H. Campanella 1619

Comparative Study of the Frequency Response of Smartwatch Sensors for Human Movement Assessment
M. Centeno-Cerrato, C. Polvorinos-Fernandez, G. De Arcas, L. Sigcha and I. Pavón 1625

Session A06.07 Active metamaterials

Session A07.01 Flow acoustics - General

Comparison of wavepacket models for supersonic twin jets against near-field pressure measurements
I. Padilla-Montero, D. Rodríguez, V. Jaunet and P. Jordan 1637

Matching Pursuit decomposition of jet near-field pressure data
R. Camussi, M. Mancinelli and E. De Paola 1645

Impact Of The Nozzle Exhaust Temperature On The Near-Field Noise Emitted By Subsonic Jets
S. Meloni, G. Palma, R. Camussi and C. Bogey 1653

Revisiting the effects of mean velocity profiles shape on sound propagation through two-dimensional ducts
L. Bonomo, J. A. Cordioli and E. Brambley 1661

GPU-based aeroacoustic simulation of low-speed axial fans across their characteristic fan curves
A. Verza, P. Altmann and L. Erbig 1669

Investigating the Acoustic Radiation of Coherent Structures in a Subsonic Jet
Y. Fang, Z. Song, X. Yang and J. Liu 1677

Session A07.02 Aeroacoustics of aircraft and urban air vehicles

Aeroacoustics of UAV propellers with unequally spaced blades
D. Usov, A. Filippone, C. Poggi and G. Bernardini 1683

Flow characterisation using PIV to optimise microphone windscreens for on-board self-noise measurements of a multicopter (UAV) under different flight conditions
J. Benz, C. Heigl, D. Gruetzner, F. Czwielong, A. Gruender, J. Franke and S. Becker 1689

Anechoic Noise Characterization Of Sub-7kg Multi-Rotor Drones: Configuration Effects And Spl Scaling Models
R. Cao, Z. Zhang, Z. Peng, Z. Ma, W. Chen, P. Zhou and X. Zhang 1697

Numerical Investigation on Tonal Noise Directivity in Distributed Propulsion Systems
A. Zarri and F. De Prenter 1705

Effects of boundary layer ingestion on ducted propeller noise
M. Daroukh, F. Ahmed, T. Le Garrec, M. Azarpeyvand and E. Manoha 1711

Wall Pressure Fluctuations and Impact on the Noise from Distributed Electric Propellers
L. G. Stoica, E. De Paola, G. Capobianchi, A. Di Marco and R. Camussi 1719

Analytical Investigation Of Rotor-Strut Potential Interaction Noise
R. Zamponi, A. Zarri and J. Christophe 1725

Hovering small-scale low Reynolds number rotor-beam source localization using both nearfield and farfield measurements
H. Parisot-Dupuis, B. Mellot, N.' Gariglio and F. Méry 1729

On the Impact of Turbulent Inflow on the Noise Generated by a Propeller Operating at Low Reynolds Number
M. Ali, A. Piccolo, R. Zamponi, D. Ragni and F. Avallone 1737

A Study Of Urban Air Mobility Rotor Noise At Moderate Reynolds Numbers With Collective Pitch Control
C. Tinney, J. Valdez and Y. Zhao-Dubuc 1745

Session A07.03 Active and passive noise reduction technologies

On the Interaction of Grazing Acoustic Waves and Turbulent Boundary Layer over Acoustic Liners
A. Paduano, F. Scarano, D. Casalino, J. A. Cordioli and F. Avallone 1755

Relevance of radiator installation on the efficacy of noise reduction strategies in an industrial engine cooling fan
F. Bellelli, R. Arina and F. Avallone 1763

Rotor Noise Control Using Coaxial Co-Rotating Rotors
C. Tinney, Y. Zhao-Dubuc and J. Valdez 1771

Further Investigation of the Simplified Septa Acoustic Liner Concept
B. Howerton and J. Kreitzman 1779

Turbulence effect on the acoustic boundary layer of perforated acoustic liners
A. Schulz and D. Ronneberger 1787

On the impact of the orifice geometrical features on the performance of an acoustic liner
F. Avallone, A. Khedr, A. Paduano, F. Scarano, L. Meirelles and J. A. Cordioli 1793

Experimental Investigation into the Suppression of Propeller Noise Using Over-Tip-Rotor Liners
S. Palleja Cabre, J. Ballgjati, C. Paruchuri, P. Joseph and F. Avallone 1801

Identification of an actuation manifold for open-loop control of subsonic jet noise with acoustic-based excitation
L. Franceschelli, M. Raiola, A. Ianiro and S. Discetti 1809

Numerical Investigation on Noise Reduction of Distributed Propellers by Phase Synchronization
Z. Yang, M. Meinke, D. Krug and W. Schröder 1817

Mitigation Strategies For Acoustic Reflections Generated By An Axisymmetric Wind Tunnel Nozzle
L. N. Quaroni and R. Merino-Martinez 1825

Session A07.04 Fluid structures acoustic coupling

Suppression of an aeroacoustic feedback mechanism in a complex pipeline
E. Quaranta and M. Smith 1835

Impact of resonance loading on the sound generation from in-duct point sources
M. Behn and U. Tapken 1843

Parametric study of turbulence ingestion noise for marine propellers
R. Lavanant, B. Cotté, G. Serre and J.-F. Mercier 1851

Effects of inflow conditions on turbulence-ingestion noise prediction
A. Piccolo and R. Zamponi 1859

A Vibro-Acoustic Calibration for the FEM Simulation of a Thin-Walled Duct System and Fan Housing
P. Heidegger, F. Czwielong, S. Schoder, S. Becker and M. Kaltenbacher 1867

Shape Optimisation For The Aeroacoustics, Aerodynamics And Heat Transfer Of Round Holes
Y. Wang, J. Guzman-Inigo and A. Morgans 1871

Flow-acoustic coupling in vortex whistle
M. Amielh, D. Mazzoni, Y. Pley and J.-J. Lasserre 1879

Session A07.05 Methods for advanced computational aeroacoustics

Session A07.06 Modern experimental techniques in aeroacoustics

Experimental Investigation of Rotor Shielding Effects on Axial Flow Fan Using Interstage Array
M. Adhikary, A. Pereira, M. Jacob, R. A. Blazquez Navarro and J. Thisse 1891

Stochastic approach for estimating the sound power of tonal mode components in flow ducts based on azimuthal mode analysis
M. Behn and U. Tapken 1899

Instrumentation and measurement validation approach for an aero-acoustic circular testrig based on temporal, frequency, and modal criteria
J. Derré, N. Aujogue and P. Rodríguez Garcia 1907

Numerical assessment of a mode detection array for azimuthal decomposition
H. Vincent, A. Pereira and M. Jacob 1915

Application of atmospheric wind filter arrays for acoustic monitoring UAVs
R. R. Subramanyam, C. Gerasch and S. Jacob 1923

Session A08.03 Advances in machinery noise and vibration control

A Study On The Transfer Characteristics Of The In-Wheel Motor System Based On EV Platform
S. Park, J. Lee, M. Lee, J. Woo, J. Jung, S. Lee and B. Sohn 1933

Relationship among Noise, Cavitation Structure and Erosion Risk in Industrial Centrifugal Pumps with a Fan-type Inducer
S. Narimatsu, H. Utsumi, S. Ejiri and M. Miyabe 1939

The influence of helix angle and gears width on the noise radiated by a gearbox
F. Mori, A. Santoni, N. Zuccherini Martello, R. Grimaldi, S. Chiari and P. Fausti 1949

LpScan – A project to standardize sound power determination from sound pressure scans
F. Heisterkamp, V. Wittstock and D. Brosig 1953

Analytical and Experimental Investigation of Stator Assembly Vibrations in Electric Motors
P. Andreou, A. Z. Hajjaj, M. Mohammadpour and S. Theodossiades 1961

Psychoacoustic investigation of the sound radiation of rotary drilling rigs
J. Riedel, G. Beer, F. Froschmeir, T. Uhlemann and S. Becker 1965

Acoustic measurements and employee feedback: addressing noise in industrial work environments – a case study
P. Van Dort 1969

Comparison Of Control Logic Driving Inverter Compressors In Refrigerators And Potential Impact On Customer Sound Quality Assessment
P. Kosowski, S. Atamer and M. E. Altinsoy 1977

Double And Single Elastic Support For Large Generator Sets
S. Anda 1985

Combined thermal and acoustic design of enclosures for outdoor applications
E. A. Piana, J. J. Garcia, D. Tonetti and R. Spezie 1991

Active Structural Acoustic Control With Remote Microphone Technique For Noise Radiated By A Thin Plate
F. Mori, A. Santoni, C. Marescotti, P. Fausti, F. Pompoli, P. Nataletti and P. Bonfiglio 1997

Design of a tripod vibration actuator for active reduction methods
S. Wrona, F. Caroppo, R. Scarano and M. Pawelczyk 2001

Noise measurements performance guarantee on a Floating Liquified Natural Gas plant
B. Crivelli and D. Vincent 2007

Session A08.04/A10.04 Materials and systems for noise and vibration reduction

Experimental Approaches for the Characterization of the Vibroacoustic Behaviour of a Domestic Coffee Apparatus
F. Castellini, A. Cavallo, M. Rossoni, F. Ripamonti, G. Colombo, R. Corradi and G. Cimmino 2013

Development of Sustainable Sound Absorbing Panels Made of Jute Fibers
F. Pompoli, P. Dagø, C. Marescotti, A. Santoni and P. Fausti 2021

Low-frequency acoustic and vibroacoustic treatments to reduce sound transmission within ducts
C. Lagarrigue, D. Lecoq, J. Perchaud and M. Fruchart 2025

Towards a unified approach to characterize ventilated acoustic metamaterials
F. Martellotta, C. Rubino, S. Liuzzi, F. Bianco and C. Scrosati 2031

Demonstrating the effectiveness of a multi-layer thin mineral sound absorber for courtyard noise reduction
B. Van Damme, J. M. Wunderli, L. Zambila and T. Cavalieri 2035

A Study on the Prediction Method of Bush Dynamic Characteristics in Used and High Frequency Domain
Y. E. Ahn 2039

Measurements Of The Acoustic Properties Of Mycelium-Based Materials Using An Impedance Tube
G. Wersényi, Z. Németh and A. Schweighardt 2045

Recycled materials as absorbent layer in acoustic ceilings: non-woven polypropylene
M. Galindo, E. Alberdie, M. A. Sánchez-Burgos, F. J. Nieves and I. Flores-Colen 2051

Session A08.05 NVH damage detection, condition monitoring, diagnostics of machinery

A Vibration Based Health Monitoring System For An Automatic Packaging Machine
I. Rizioli, G. Cristofori, M. Battarra and E. Mucchi 2061

A mathematical model based digital twin for gearboxes operating at variable speeds
S. Hashim, S. K. Mishra and P. Shakya 2065

A new feature extraction framework for source-free domain adaptation in bearing fault diagnosis
S. Arunagiri, S. K. Mishra and P. Shakya 2073

Analysis of Defects in Rolling Bearings Using Vibroacoustic and Ultrasonic Techniques
E. Voltolini, M. Monaco, E. Armelloni, M. Cocconcelli, A. Toscani, F. Immovilli and E. Manconi 2079

Tool Wear Prediction in CNC Turning Operations using Ultrasonic Microphone Arrays and CNNs
J. Steckel, A. Aerts, E. Verreycken, D. Laurijssen and W. Daems 2087

Session A08.06 Innovative noise barriers to enhance acoustic comfort

Session A08.07 Artificial intelligence for industrial applications

Session A09.01 Machine learning and artificial intelligence in acoustics - General

Neural Network-Based Solutions for the Linearized Euler Equations in Outdoor Sound Propagation
H. Juliust, K. Baumann, A. Schady, S. Gharbi and F. Dietrich 2099

Utilizing Large Language Models for Optimizing Sound Selection in Dementia Care Environments
A. Talebzadeh 2107

Comparative analysis on the use of linear and non-linear methods for auditory attention decoding (AAD)
I. García Ugarte, R. Eguinoa, C. Vidaurre, D. Paternain and R. San Martín 2113

Comparison of Deep Learning and Psychoacoustic Models to Predict UAV Noise Impact in Soundscapes
M. W. Ellis, M. C. Green, M. J. B. Lotinga and A. Torija Martinez 2121

Open-Source System for Multilingual Translation and Cloned Speech Synthesis
M. Cámara, J. Gutierrez, M. P. Daza and J. L. Blanco 2129

A model for improving the performance of large language models on soundscape description tasks
Z. Yuan and D. Botteldooren 2137

Sound environments classification of an university campus using unsupervised machine learning techniques
J. Montoya Belmonte, A. Pita Lozano and J. M. Navarro Ruiz 2143

Session A09.03/A02.07 AI and machine learning in bioacoustics

Automated Ecoacoustic Monitoring: Evaluating Classifier Performance For Common Cuckoo (Cuculus Canorus) Detection
H. Whitehead, W. Davies, S. Gashchak and M. Wood 2149

Clustering and Novel Class Recognition: Evaluating Bioacoustic Deep Learning Feature Extractors
V. Kather, B. Ghani and D. Stowell 2153

Development of an Ear Tag System for Diagnosing Swine Respiratory Diseases Using Long Short-Term Memory Networks
Y. Matoba, S. Ishimitsu, S. Yumoto, O. Mikama, Y. Ogawa, H. Inoue, M. Ishida and D. Tanaka 2161

Automated Data Curation for Self-Supervised Learning in Underwater Acoustic Analysis
H. Hummel, S. Bhulai, B. Ghani and R. Van Der Mei 2165

Preliminary Results on Audio Event Classification Applied to a University Square in Milan (Italy) Before an Urban Regeneration Project
A. Potenza, E. Vidaña-Vila, A. Afify, R. Benocci, R. M. Alsina-Pagès and G. Zambon 2171

Hardware acceleration of Convolutional Neural Network for Lung Ultrasound segmentation
A. Rubio, M. Muñoz, G. Cosarinsky and J. F. Cruza 2179

Cross-Domain Transfer Learning for Segmentation of Lung Ultrasound images
M. Muñoz, A. Rubio, G. Cosarinsky and J. Camacho 2185

Session A09.05/A08.07 Artificial intelligence for industrial applications

Reinforcement Learning To Enhance Computational Fluid Dynamic Simulations With Acoustics
D. Huergo, M. De Frutos, O. A. Marino, E. Jané, G. Rubio and E. Ferrer 2193

Soundscape system based on passenger emotion and conversation perception of autonomous vehicles
K.-J. Chang, J. Kang, D. Park, G. Cho and C. W. Ahn 2201

Automatic classification of packaging waste at source using acoustic technology
M. Arnela, E. Vidaña-Vila, A. Fantinelli, A. Moñux-Bernal, J. Vaquerizo-Serrano, S. Rubio-Garcia and J. C. Socoró ... 2207

Deep Learning-Aided Design Of A Broadband Low-Frequency Meta-Absorber For Room Acoustic Applications
O. Ogun and J. Kennedy 2213

Detection of Operational Regimerelated Faults in Air Compressor Systems Using Acoustic Analysis and Machine Learning
A. Hvastja and J. Prezelj 2221

Monitoring of Manufacturing process, using unsupervised Sound Event Classification with application of Sound Directivity
J. Prezelj, A. Hvastja and T. Berlec 2225

Fault Detection in C-EPS Bearings Based on Unsupervised Learning
H. Jo, J. Park, I.-J. Cho, J. Seo, S.-S. Yoo, S. Lee, S.-J. Bang, J.-L. Oh, C.-H. Jung and S.-Z. Cho 2233

Deep learning for ultrasound surface echo detection with matrix arrays
M. Larrea, M. Muñoz, A. Rubio, J. F. Cruza and G. Cosarinsky 2241

Session A09.06 Machine learning for array processing

Session A09.07 Events detection and localization, and acoustic scenes, using ML techniques

Does Source Directivity Influence Neural Network-Based Speech Position Estimation?
R. A. Viveros-Munoz and S. Guajardo-Herrera 2253

Speech position estimation using neural networks from acoustic signals of hearing aids
S. Guajardo-Herrera and R. A. Viveros-Munoz 2259

Leveraging Pre-Trained Foundational Audio Models for Acoustic Event Detection in Driving Scenarios
M. Moghimi, P. Healy, C. Castorena, F. J. Ferri and M. Cobos 2263

Exploring the Potentialities of Machine Learning Techniques for the Analysis and the Forecast of Road Traffic Noise Levels
D. Rossi, A. Mascolo, D. Singh and C. Guarnaccia 2271

Urban sound classification on the edge: exploring the accuracy-efficiency trade-off
L. Cassens, M. Kroesen, S. Calvert and S. Van Cranenburgh 2279

Automatic detection of roadway noise using AI classifiers and sound level features
E. Betton-Ployon, A. Kacem, J. Mars and N. Martin 2285

Enhanced Environmental Sound Event Classification through Transfer Learning with CLAP Model
F. Artuso, G. Pompei, A. Akbaba, G. Iannace, F. D'Alessandro, F. Fidecaro, G. Licitra and L. Fredianelli 2289

A Comparative Analysis of Interior vs. Exterior Vehicle Microphone Placement for Acoustic Event Detection in Driving Environments
C. Castorena, L. Banchero, J. A. De Rus, F. Vacalebri, S. Roger, J. M. Mossi, J. J. López, F. J. Ferri and M. Cobos ... 2295

Session A09.08 Artificial intelligence in musical acoustics

Session A10.02 Acoustic, vibroacoustic and elastic metamaterials

High bulk modulus pentamodes: the three-dimensional metal water
S. Cominelli, G. Brambilla, M. Verbicaro, M. Pozzi, G. Cazzulani and F. Braghin 2305

Increasing Helmholtz resonator stability against non-linear resistance increments using chamfers
D. Jun, J. Plasek, M. Rychtáriková, Z. Fisarova and C. Glorieux 2309

Switching Room Acoustics with causality-driven dual-function passive metamaterials for broadband sound absorption and diffusion
E. Ballestero, Y. Meng, P. Sheng, V. Tournat, V. Romero-García and J.-P. Groby 2315

Rotatable Phononic Crystal with Multiresonant Scatterers for acoustic switching applications
D. Ramírez-Solana, V. Sangiorgio, R. Picó, J. Redondo, M. Gulzari and M. P. Fanti 2317

Additive Manufacture of Flexible Lattice Absorbers for Enhanced Low Frequency Performance
C. Neill and J. Kennedy 2323

Tunable Envelope Solitons in a Piezoelectric Metamaterial Obeying the Nonlinear Schrödinger Equation
C. Wang and A. Erturk 2327

Optimizing locally resonant elements distribution on isotropic plate for increased sound insulation and mass reduction
K. Chojnacka 2331

Initial Analytical Attempts to Handle the Sound Absorption using Segmented Oblique Perforations
T. D'Orazio, D. Ramos, L. Godinho, C. Guattari and F. Asdrubali 2335

Transfer matrix modelling of folded quarter-wavelength resonators with 90° bends
F. De Bie, H. Denayer and E. Deckers 2341

Session A10.03 Metamaterials for noise and vibration reduction: novel applications and experimental methods

Reduced-order modeling analysis of random geometric changes on the vibroacoustic behavior of metamaterials
Y. Pillot, R. Boukadia, L. Van Belle and E. Deckers 2347

Shape optimization of inertia-amplified mechanical resonators for vibration damping of mounted plate
L. Mardini, A. Bergamini, E. Deckers, C. Claeys and B. Van Damme 2355

Design and experimental characterization of multi-modal metamaterial panels achieving broadband sound transmission and radiation reduction
D. Giannini, L. Van Belle, E. Deckers and E. P. B. Reynders 2361

Psychoacoustical design optimization for acoustic metamaterials using global sensitivity analysis
J. Zhang, J. Cuenca, L. De Ryck, L. Van Belle and E. Deckers 2369

Numerical And Experimental Study Of Acoustic Performance Of Phononic Crystals-Based Ventilated Noise Barriers For Traffic Noise
N. Ahsan, N. Herrera, L. Sangiuliano, P. Amado Mendes and L. Godinho 2375

Validating the use of acoustic metamaterials in industrial applications for low-frequency noise reduction
E. Cierco, M. Janer, D. Suárez and P. V. Rodríguez 2383

Reciprocity Driven Omni-directional Absorption
J. P. Escudero, J.-P. Groby and V. Pagneux 2389

Experimental and Numerical Analysis of Sonic Crystal Noise Barriers with Hybrid Scatterers
N. Herrera-Leon, N. Ahsan, L. Godinho, L. Sangiuliano and P. Amado Mendes 2393

Comparative Analysis of Lightweight Metamaterial Partitions for Enhanced Acoustic Performance and Perceptual Sound Evaluation
M. Ribera, B. Van Damme, A. Pereira, P. Amado Mendes, J. Zhang and L. Godinho 2401

Hierarchical labyrinthine metamaterials for low frequency noise absorption applications
E. Pérez Compte, F. Nistri, L. Zambila, A. Bergamini, A. Gliozzi, L. Shtrepi and F. Bosia 2407

The Influence Of Sample Size On The Results Of Sound Insulation Measurement Conducted In Small Coupled Reverberation Rooms
D. Mlynarczyk, K. Baruch-Mazur and A. Szelag 2411

Injection moulded locally resonant rings for vibration mitigation in pipes
K. Steijvers, U. Arasan, C. Claeys, L. Van Belle and E. Deckers 2415

On the Relationships Between Manufacturing Parameters, Geometrical Accuracy, and Vibrational Properties of Selective Laser Sintered PA-12 Beams
A. Kryuchkov, M. Pavan, C. Claeys and E. Deckers 2423

Quantifying the impact of injection molding process parameters on the vibroacoustic performance of manufactured locally resonant metamaterials
A. Karaman, L. Van Belle and E. Deckers 2431

Using 3D printed labyrinthine inclusions to improve the low-frequency performance of a thin, conventional sound absorbing panel
M. Niedzielczyk and T. G. Zielinski 2439

Rainbow Trapping Resonator Array for High-Level Sound Absorption
A. Cavanagh, O. Umnova and D. Akiwate 2447

Session A10.04 Materials and systems for noise and vibration reduction

Session A10.05/A23.05 Metamaterials and acoustic black holes in vibro-acoustics

Additive acoustic black holes to suppress acoustic energy in a resonant cavity
J. Deng, O. Guasch and X. Chen 2457

Predicting the acoustic response of a resonant cavity coupled to sonic black holes by means of patch transfer functions
P. De Campos Muradas Cerântola, L. Maxit, O. Guasch and J. Deng 2461

Ultra-thin and Ultra-lightweight Meta-panel for Broadband Noise Insulation
J. Kim and W. Jeon 2469

Ventilated acoustic metamaterial for noise reduction in a duct with non-uniform cross sections
D. Kim, J. Kim and W. Jeon 2471

Design of a metamaterial plate with acoustic black hole absorbers and its application to floating raft system
S. Hao, H. Li and Q. Ding 2473

Effects of acoustic black hole pillars on the acoustic energy of a water-filled cavity
J. Li, J. Deng and O. Guasch 2481

Vibration control in a honeycomb sandwich metapanel made up of periodic cells with an ABH-like thickness profile
S. Avetisov, F. Gautier, A. Pelat, S. Sorokin, G. Gabard, M. Versaevel and J. Mardjono 2485

Absorption and scattering of bending waves by an Acoustic Black Hole embedded in a honeycomb sandwich panel
A. Besse, O. Aklouche, F. Ablitzer, A. Pelat and F. Gautier 2489

Efficiency of an Acoustic Black hole embedded into a honeycomb sandwich panel
A. Besse, O. Aklouche, F. Ablitzer, A. Pelat and F. Gautier 2493

Session A10.06 Numerical methods for acoustic materials and metamaterials

Session A10.07/A15.07 Characterization of acoustic materials

Uncertainties in parameter estimation of porous media in tube measurements
Z. Chen and N. Xiang 2501

Characterisation of acoustic metamaterials allowing airflow
G. Memoli, M. Puttock-Brown, J. Eccles, B. Pearce and E. Greenland 2505

Multi-Density Inversion Characterisation Method for Fibrous Material
A. Santoni, F. Pompoli, C. Marescotti and P. Fausti 2511

Measurements and simulations of a double-porosity material under variation of perforation parameters
M. Isenegger, T. Graf, M. Sonderegger, A. Bonnard, S. Fleischli and A. Taghipour 2515

A novel algorithm for estimating Biot parameters in acoustic simulation of fibrous materials based on raw material composition
M.-T. Hoang, M. Tiengo and E. Harry 2523

A multi-modal analysis of anisotropy in porous media
M. Nolan, S. Félix and J.-P. Groby 2529

Combining absorption coefficient measurements in reverberation rooms with different volumes
H. Bietz and V. Wittstock 2533

Analysis of the relationship between sound field isotropy and errors in the results of Sabine's absorption coefficient
M. Berzborn and M. Vorländer 2541

Estimating the Impedance of a Material Sample at Low Frequencies
A. Prinn, R. Maestro-Vallejo, M. L. López Ibañez, M. Larrosa-Navarro and E. Latorre Iglesias 2549

The measurement of the sound absorption of an array of baffles
J. L. Davy, M. Debevc, D. Truett, J. Payne and J. Watson 2557

A data-driven two-microphone method for measuring the sound absorption of finite absorbers
L. Emmerich, P. Aste, E. Brandão, M. Nolan, J. Cuenca, U. P. Svensson, M. Maeder, S. Marburg and E. Zea 2563

Diffusion Equation-Based Estimation Of Spatially Non-Uniform Surface Absorption Coefficients
A. Prinn and E. Habets 2569

Comparative analysis of acoustic absorption testing methods for different Layers of Cotton Wadding
M. Mastoori, A. M. Lacasta, I. R. Cantalapiedra, F. Merli and C. Buratti 2577

An experimental data set focused on methodologies for the in situ characterization of acoustic materials
J. V. Pontalti, E. Brandão, W. D.'A. Fonseca, P. H. Mareze, G. Netto and E. Fernandez-Grande 2585

Measurement Of Sound Absorption Of Wood Chip-Based Materials For Noise Barriers: Effects Of Testing And Casting Conditions
L. Shtrepi, V. Buggè, S. Fasana, M. Zerbinatti and A. Astolfi 2593

Sound absorption prediction of high-density foam-formed softwood fibers
J. Heldmann, J. Cucharero Moya and T. Lokki 2599

Characterization Of The Sound Absorption Properties Of A Fibrous Biomaterial: A Key Input For Room Acoustic Simulation Software
J. Garcia, P. Alloza and E. A. Piana 2605

Characterization of the Acoustic Behavior of Raw Earth Coatings
M. Ziapkoff, P. Glé, A. Héllouin-De-Ménibus, T. Blinet and C. Guigou Carter 2611

Streaming over Micro-Perforated walls submitted to acoustic plane wave
D. Mazzoni, M. Amielh, L. Genevay, T. Bravo and C. Maury 2619

Method for assessing the impact of aging of selected building materials on their acoustic properties
E. Nowicka 2627

Influence Of Moisture Content On The Acoustic Properties Of Textile Materials
L. Euler, A. Mehrem and E. Shabalina 2631

Study of some influences on the acoustic behaviour of disintegrated samples of used cigarettes
C. Moreno González, V. Gómez Escobar and G. Rey Gozalo 2635

A practical approach to the determination of reproducibility precision (σtarget) in the field of sound absorption measurements: Evaluation of Proficiency Testing data according to ISO 354:2003
P. Rosario and J. L. Martínez 2641

Acoustic characteristics of a hydroponic material
G. Iannace, A. Bevilacqua, A. Trematerra and G. Amadasi 2647

Session A10.08 Modeling acoustic wave propagation in viscothermal structures, including porous materials

Boundary Element Method with visco-thermal losses: development, improvements and applications
V. Cutanda Henriquez 2653

Low-drag rainbow-trapping filters for broadband sound dissipation in a low-speed ducted flow
C. Maury, T. Bravo, F. Ali, D. Mazzoni and M. Amielh 2655

Tunable Microperforated Panel Acoustic Absorbers with Coupling Effects Under Grazing Flow
Y. Li and Y. S. Choy 2663

Modelling Sound Absorption Of Vegetal Wools: Consideration Of Fibre Polydispersity
L. Mutel, C. Piégay, P. Glé, E. Gourdon and C. Segovia 2671

Evaluation Of Methods For Modelling The Impact Of Flame-Retardant Treatments On The Acoustic Performance Of Hemp Wools
C. Piégay, T. Schatzmayr Welp Sa, H. Bossert, L. Mutel, S. Marceau, P. Glé and C. Segovia 2677

Multi-functional rainbow trapping filters for particle acoustic agglomeration
T. Bravo, C. Maury, M. Amielh and D. Mazzoni 2683

Multi-resonant material based on channels with contrasting tortuosity
T. G. Zielinski and M.-A. Galland 2691

Session A10.09/A12.10 Acoustic wave propagation in complex media

Numerical simulations of elastic wave propagation in solid materials containing a random distribution of spherical particles
T. Bertels, T. Valier-Brasier and J.-M. Conoir 2701

Dynamic Wave Manipulation in Spatiotemporal Interfaces and Slabs for Acoustic Control
R. Picó, J. Galiana Nieves, J. Redondo and V. J. Sánchez-Morcillo 2705

Ultrasonic Hologram for Bi-directional Diffusion by Phase Controlling the Scattering Coefficients
E. Ballestero, J. Rodríguez-Sendra, V. Romero-García, J.-P. Groby and N. Jiménez 2709

Conditions for weak scattering and the Born approximation in beams with multiple resonators
M. Lázaro, R. Wiltshaw, R. Craster and V. Romero-García 2713

Session A10.10 Numerical methods for wave propagation in complex media

Session A11.01 Musical acoustics - General

Acoustical Behaviour of Vent Holes on Brasswind Instruments
M. Aragó Bishop, A. Myers and M. Campbell 2721

Embouchure Parameter Variations Across Brass Musicians Of Different Levels Of Proficiency
P. Amann, V. Chatziioannou, P. Nicolay and R. Willmann 2727

Modal approaches for modelling nonlinear acoustics in 2D axisymmetric domains: application to brass instruments
F. Soares, B. Cochelin, V. Fréour, C. Vergez and K. Arimoto 2733

Estimating Sound Radiation Characteristics of Complex-Shaped Plates Using Reduced Sets of Elementary Sources
F. Soares and V. Debut 2739

Effects of Different Auditory Monitoring Conditions on Vocal Intonation Accuracy
A. P. Pietrzak 2747

Absolute Pitch among non-global possessors - Timbre and Categorization
É. Resende De Souza 2751

A measurement system to capture the player's control in the natural playing condition of single-reed musical instruments: Application to the performance log of a beginner player
T. Shoji, Y. Wada, Y. Takahashi and K. Arimoto 2757

Session A11.02/A09.08 Artificial intelligence in musical acoustics

A procedure for evaluating the softness of sound played on the Clarinets
N. Yasui 2763

Psychoacoustic Analysis of Viscoellastically Damped Membranes Using Physics-Informed Machine Learning
C. F. Martínez Orellanos and R. Bader 2767

The Revolution is Here: Deep Audio Processing Redefines Offline and Real-Time Audio Experiences
B.-Y. Yossi, T. Yami and F. Nir 2775

Individual violin sound identification using audio features and machine learning
H. Pauget Ballesteros, P. Lalitte and C. Fritz 2783

A Data-Driven Transfer Matrix Model for the Design of Saxophone Mouthpieces
G. Greco, X. Luan, A. Bernardini, F. Antonacci and A. Sarti 2787

Session A11.03 Consistency of musical instrument making

Evaluating the Reproducibility of Impedance Measurements of Wind Instruments
J.-P. Dalmont, A. Ernoult, J. Cabaret, H. Boutin, T. Colinot, V. Fréour and R. Viala 2797

Assessing the consistency of numerical models for wind instrument impedance
A. Ernoult, J. Cabaret, J. Chabassier, T. Colinot, J.-P. Dalmont, J.-B. Doc, V. Fréour and R. Viala 2801

Is it possible to predict single cane reed mouthpiece interaction by measuring the reed alone?
A. Gaillard, M. Tahon, C. Urban, E. Brasseur and B. Gazengel 2807

Reproducibility in the construction of traditional wooden and 3D-printed plastic soundboards for string instruments
S. Labraña, V. Correa, A. Montoya and C. Espinoza 2815

Design, Construction, and Acoustic Characterization of a Fully Functional 3D-Printed Guitar
C. Espinoza, C. Adasme, V. Correa and J. Baeza 2821

Perceptual Comparison Between a Low-Cost Guitar and a 3D-Printed Guitar
C. Espinoza, T. Ibanez, C. Adasme, M. Denzer, C. Díaz and T. Moreno 2827

Numerical design of a trumpet lead pipe: from the numerical model to the evaluation of the hardware prototype
J.-F. Petiot, V. Fréour and K. Arimoto 2833

Session A11.04 Articulated musical instrument modelling

Real-time bowing parameter sensing methods for articulated bow-string physical modelling
E. Ó Néill, M. Van Walstijn and M. Ortiz 2843

A two-register haptic interface for articulated control of harpsichord physical models
M. Hamilton, R. Russo, C. Webb and M. Ducceschi 2851

Real-time demonstrators to exhibit, investigate and teach transient behaviors in nonlinear dynamics, focused on musical instruments
T. Colinot 2859

Influence of the basins of attraction in the register jumps of the clarinet
N. Szwarcberg, T. Colinot, C. Vergez and M. Jousserand 2863

Imaging based saxophone reed modelling
D. Tonetti and E. A. Piana 2871

Vocal tract turbulence and recorder sound – a CFD approach
N. Nordblom and R. Bader 2877

Dynamical Behavior of a Brass Instrument Around a Double Hopf Bifurcation
M. Pégeot, T. Colinot, J.-B. Doc, V. Fréour and C. Vergez 2885

Session A11.05 Instruments, hyperinstruments and beyond

Musical Acoustics students faced with the challenge of building new musical instruments
A. M. Barbancho, I. Barbancho and L. J. Tardón 2891

What do bells made from lunar regoliths sound like?
A. M. Barbancho, I. Barbancho, L. J. Tardón and C. Traginer 2897

Acoustic Design of a Dual-Purpose Sound Tube Organ
E. Pérez, S. Guillén, A. M. Barbancho, I. Barbancho and L. J. Tardón 2905

Enhancing Music Visualization with Haptic Feedback to Ease Perception for DHH Listeners
N. Mauri, M. Sacchetto, P. Bagnus, C. Nicora, M. Zanoni, A. Bianco and C. Rottondi 2913

MeloPad, a portable device for music composition based on the Bela audio and interaction platform
J. Thieme and L. Molina-Tanco 2921

Alfonso and Theresa: Merging Traditional Lutherie with Modern Electronics in the Design of an Expanded Lute and Contrabass
C. Betancur Gutierrez and L. Valentin 2929

Session A11.06 Networked music performances and virtual environments

Session A12.01 Physical acoustics and ultrasound - General

Ultrasonic Imaging for Quantifying Microplastic Concentrations in Liquids
O. Martinez-Graullera, P. Moreno, C. Pinillos Boralla, J. Huecas, R. Shaporin, M. Parrilla and L. Elvira 2943

Ultrasonic intensification reactor applied to the agri-food and pharmaceutical industry
R. Fernández-Clement, F. J. Pastor-Rodríguez, F. J. Navarro-Brull, P. Poveda Martinez and R. Gómez 2949

Preliminary Study On Theoretical Corrections To The Equation Of State In Single-Bubble Sonoluminescence And Extension Of The Minimum Radius Stage
R. Fernández-Clement, P. Poveda Martinez and R. Gómez 2955

Session A12.02 NDT & SHM Applications

Modelling of the Acoustic Emission (AE) wave propagation using the AE transmitting sensors' responses
V.-D. Le, M. Perrin, L. Espinosa, M.-L. Pastor and Y. Le-Maoult 2965

Adaptive 3D Plane Wave Imaging through interfaces
G. Cosarinsky, A. Rubio, M. Muñoz, J. F. Cruza and J. Camacho 2973

Ultrasonic pulse-echo system for measuring the inter-plate distance of an irradiated fuel element
R. Mrabti, E. Le Clézio, T. Delaunay, Y. Calzavara and G. Despaux 2981

Impact of phase anisotropy-related shifts on the contrast of defect localization images in reverberant plates
L. Chehami, O. Bouchakour, E. Moulin and E. Farha 2989

Viscoelastic Model: The Memory Of Cement
J. Gosalbez, V. J. Ruiz, J. Madrigal, R. Miralles, I. Bosch, J. Quiroga and J. Payá 2995

Acoustic Resonance Spectroscopy Using FBG Sensors Embedded in Mortars
J. Gosalbez, V. J. Ruiz, J. Madrigal, A. M. Macian, J. E. Carcel and J. Payá 3003

Characterization of the adhesion quality in an aeronautical assembly by acoustic microscopy
Y. Ezziani, D. Leduc, P. Marechal, M. Ech-Cherif El-Kettani, M. Ducousseau and N. Cuvillier 3009

Ultrasonic maging of layer on substrate structures using high-frequency acoustic field correlation
N. Ben Jafela, L. Chehami, M. Duquennoy, E. Moulin, N. Smagin, D. Fall and Z. Oumekloul 3017

Session A12.03 Biomedical ultrasound

Can acoustic vortices fragment kidney stones?
S. Maldonado-Ortega, E. González-Mateo, A. Cebrecos, C. D. Vera-Donoso, A. Carrión, F. Camarena and N. Jiménez . 3025

Blood-brain-barrier opening in small animals using focused ultrasound
J. Limens-Pinaque, J. Rodríguez-Sendra, J. J. Rodríguez-García, A. Arándiga, J. L. Alonso-Ramos, D. Panadero Soler, N. Jiménez, P. Rico, S. Canals and F. Camarena 3029

Non-Invasive and Low-Cost Photoacoustic/Ultrasound Dual-Modal Imaging System for Carotid Plaque Imaging
A. Ariza-Carrasco, J. G. Muñoz, J. F. Cruza, L. Elvira, J. L. Herraiz, J. M. Udías, M. A. De Laciñana, J. Rodriguez-Pardo, P. Ibáñez García and M. Pérez-Liva 3035

Impact of spatiotemporal excitation parameters in laser diode-based photoacoustic microscopy
J. Á. Navarro-Calvo, I. Pi-Martín, V. Company-Rubio, A. Arándiga, A. Cebrecos and J. J. García-Garrigós 3039

Designing Acoustic Holograms Without Ionising Radiation For Wearable Transcranial Ultrasound Therapy Devices
A. Eroles-Simó, V. Vegas-Luque, A. Carrión, J. A. Pineda-Pardo, J. J. Rodríguez-García, J. L. Alonso-Ramos, F. Camarena and N. Jiménez 3043

Generating acoustic holograms beyond the hyperbolic approximation
V. Vegas-Luque, D. Andrés, A. Eroles-Simó, J. J. Rodríguez-García, F. Camarena and N. Jiménez 3049

Sparse Arrays for 3D Ultrasound Microstructure Imaging
O. Martinez-Graullera, J. Camacho, J. Huecas, G. Cosarinsky, L. Elvira and A. Ibañez 3053

Modular and flexible hardware architecture for real-time 3D ultrasound imaging
J. F. Cruza, R. Mateos, R. G. Bueno, G. Montaldo and J. Camacho 3059

Numerical Framework for Deep Learning Photoacoustics Image Reconstruction
J. G. Muñoz, A. Ariza-Carrasco, J. F. Cruza, L. Elvira, J. Camacho, J. M. Udías, M. A. De Laciñana, J. Rodriguez-Pardo, P. Ibáñez García and M. Pérez-Liva 3067

Session A12.07 Acousto-optics

Towards broadband lateral BAW excitation in a low-velocity anisotropic substrate
K. B. Yushkov, N. Naumenko and V. Y. Molchanov 3073

Uncertainty relations for broadband ultrasonic waveforms: the case of acousto-optic femtosecond laser pulse shaping
K. B. Yushkov and V. Y. Molchanov 3075

Characterization of optoelectronic oscillator based on collinear acousto-optic cell
E. Kostyleva, S. Mantsevich, N. Polikarpova and E. Dyakonov 3077

Acousto-optic spatial frequency filter with phase control for reconfigurable dark optical traps
V. Y. Molchanov, A. Chizhikov, D. Obydennov and K. B. Yushkov 3081

Tailored ultrasound fields for acousto-optic light control directly within a sample
J. Torres-Durall and M. Duocastella 3083

Enhancing Eye Imaging Modalities with Acousto-optic Interaction
I. Grulkowski and D. Ruminski 3089

Recording neuronal activity in 3D using calcium and voltage genetically encoded indicators
W. Akemann, J. Morizet and L. Bourdieu 3093

Design and Validation of an Acousto-Optic Tunable Filter for Spectro-Polarimetry Analysis
S. Dupont, J. Vanhamel and J.-C. Kastelik 3097

Optimization algorithm for AOTF parameter characterization
J. Vanhamel, A. Pavlov and S. Dupont 3103

Exploiting the Acousto-Optic Effect for Advanced Optical Microscopy
M. Duocastella, C. Alexandropoulos, J. Torres-Durall, B. Mestre-Tora, L. Rodriguez-Sune and M. Colom 3109

Session A12.10 Acoustic wave propagation in complex media

Session A13.04 Advancements and challenges in military acoustics: physiological and audiological perspectives

Two hybrid directivity models of muzzle blasts to describe the frequency and distance dependency
P. Bechtel, C. Kleinhenrich and K.-W. Hirsch 3117

Virtual and experimental acoustical comfort testers for earplugs
F. Sgard, K. Carillo, S. Kersten, R. Richert and O. Doutres 3125

Auditory damage risk due to indoor and outdoor shooting
F. Van Der Eerden, E. Van Pruissen, E. Salomons, P. De Krom and A. Van Heijningen 3133

Beyond the Standard Audiogram: The Need for Comprehensive Assessment of Combat Noise Auditory Trauma
S. Chordekar, D. Brand, C. Adelman, R. Frankael, N. Horev and F. Nir 3141

Squad-level operational performance under varying hearing protection devices and simulated hearing loss
B. Sheffield, R. Bieber, S. Turcios and D. Brungart 3145

Impact of Acoustic Test Fixture Ear Stiffness on Earplug Attenuation of Impulsive Sounds
C. Ruzyla, C. Blondé-Weinmann, P. Hamery, F. Sgard and S. Roth 3153

Sound Attenuation with Double Hearing Protection: A Comparison of Real-Ear and Behavioral Hearing Threshold Measurements
A. Hauptman, S. Chordekar, C. Dirks, L. Fostick and F. Nir 3157

Evaluation Of A Novel Sound Enhancing Connecting Tube Apparatus For Improving Sound Localization Of Occluded Ears
A. Benn, L. Grushko, G. Banta and F. Nir 3163

Design and Analysis of Mobile Microphone Arrays for Acoustic Drone Tracking
M. Blass and F. Graf 3173

Acoustic Detection of Drones: A Machine Learning and Psychoacoustic Approach
D. Tejera Berengué, G. Corral García, F. Zhu-Zhou, M. Zurera-Rosa, R. Gil-Pita and M. Utrilla-Manso 3181

Investigating the Impacts of Cockpit Noise Exposure on Human Decision-Making
E. Fox, A. Cook, F. Mobley, G. Bowers, H. Gallagher and Z. Ennis 3189

Comparison of REAT and insertion loss measurements using headphone audiometry
V. Zimpfer, P. Hamery and C. Blondé-Weinmann 3197

The Relationship Between Damage Risk Criteria for Impulse Noise Explained by Simple Acoustical Descriptors
M. Weger 3201

Session A13.05 Asymmetric hearing loss - clinical solutions and functionality

Speech intelligibility in noise of single-sided deaf cochlear implant users for near and distant talkers
T. Wesarg 3211

Effect of reducing the static interaural time difference in bimodal listeners
S. Zirn, S. Roth, F.-U. Mueller, W. Hemmert and J. Angermeier 3215

A comparative study of four directional microphones and directivity steering for bimodal cochlear implant users
H. C. Stronks, N. Langerak, A. J. Schrijver, R. Koning, J. Briaire and J. Frijns 3219

Better-Ear-Listening vs. Combined Bilateral Information Across Ears in Asymmetric Hearing
B. Williges, N. Sadok, D. Arweiler-Harbeck and T. Jürgens 3227

Speech perception and sound localization in CI subjects with electric-acoustic stimulation and contralateral normal hearing
T. Weissgerber, M. Bandeira, T. Stöver and U. Baumann 3231

Session A13.06 Audiology diagnostic techniques

Evaluating Test Time in Simultaneously Recorded ABRs
S. G. B. Kristensen, S. Laugesen, T. Dau and J. A. Undurraga Lucero 3237

Diagnosing hearing loss using air- and bone-conducted parallel auditory brainstem responses
M. Polonenko and R. Maddox 3243

The binaural interaction component is enhanced with chirps relative to clicks and produces better behavioral lateralization
K. A. Walker, C. A. Sammeth, M. Mavandi, N. T. Greene and D. J. Tollin 3247

A Pilot Study on Assessing Auditory Masking Using Auditory Steady- State Responses
A. Sergeeva and P. Kidmose 3255

How frequency-based processing may help clinicians improve sound quality perception in cochlear implant users?
L. Villejoubert, L. Picinali, K. Faulkner and D. Vickers 3263

Evaluation of Hyperacusis and Loudness Estimates as part of an Extended Audiological Test Battery
L. Vinceslas, V. Drga, J. L. Verhey and I. Yasin 3267

Advancing Objective Assessment of Spectral Discrimination using EEG: Amplitude Roving Minimizes Loudness Confounds
M. Rekswinkel, J. Hjortkjær, A. Kressner and J. A. Undurraga Lucero 3275

Neural Responses Akin to ABRS Measured During Natural Speech Listening for Hearing Aid Assessment
F. L. Bachmann, J. P. Kulasingham, K. Eskelund, M. Enqvist, J. Hjortkjær, E. Alickovic and H. Innes-Brown 3281

Optimising Parameters For Measuring The Acoustic Change Complex With Amplitude-Modulated Stimuli Using A Clinical Evoked-Potential System
W. Ellis, D. Vickers, N. Haywood, N. Mehta, M. Keshavarzi and E. De Groote 3287

Alterations in steady-state synchronisation between Acute and Chronic Tinnitus suggests reduction in the neural correlates of tinnitus over time
A. Umashankar, W. Sedley, K. Alter and P. Gander 3295

Numerical analysis of minimum resonance bandwidths in input impedances of human ear canals
R. Roden and M. Blau 3303

Single-Trial Electroencephalographic Analysis of Front-Back Confusions in Free-Field and Headphone-Based Listening Conditions
N. Marggraf-Turley, M. Shiell, N. Pontoppidan, D. Cappotto and L. Picinali 3307

Evaluation of Microphone Nonlinearities in Probes for Measurement of Otoacoustic Emissions
P. Honzík and V. Vencovský 3309

Methodology For The Neurocognitive Study Of Acoustic-Perceptual Abilities And Linguistic Function In Preterm Infants
R. Hernández-Molina, C. Varo Varo, V. M. Rodríguez-Montaño, R. Pérez Vargas, F. Fernández-Zacarías, V. Puyana Romero, T. Denisenko, J. L. Cueto-Ancela and P. Zafra Rodríguez 3315

Session A14.01 Psychoacoustics - General

Binaural fusion as a special case of auditory object formation
J. Aronoff, J. Lapapa, P. Bk, I. Oyebamiji and N. Gustafson 3321

Modeling fluctuation strength based on the Sottek Hearing Model
R. Sottek 3325

Does a frequency mismatch between infrasound and modulator affect their interaction?
B. Friedrich and J. Verhey 3333

A Study On Sound Level Differences In Working Modes Of A Refrigerator With An Inverter Compressor
P. Kosowski, S. Atamer and M. E. Altinsoy 3337

Does Audibility Mediate The Effects Of Binaural Beats On Working Memory And Mental Workload?
K. Van Den Bosch, C. Schmidt Von Wolkahof and T. Sarampalis 3345

Psychoacoustics of Remixing Music: Catering to Hard-of-Hearing and Normal-Hearing Audiences for Enhanced Experiences
F. Nir, T. Yami and B.-Y. Yossi 3349

Impact of real and synthetic lip-sync-related visual cues on speech intelligibility in a highly reverberant conference hall
A. Galletto, A. Guastamacchia, F. Riente, L. Shtrepi, G. Puglisi, A. Albera, F. Pellerey and A. Astolfi 3355

Modelling the interaction of infrasound and low-frequency sounds
J. Verhey and B. Friedrich 3361

Association Between Speech in Noise Performance and Inferred Cochlear Response Functions
L. Vinceslas, V. Drga, J. Verhey and I. Yasin 3365

Humming and rumbling: Experiments and model predictions
M. Gottschalk and J. Verhey 3373

Verified implementations of the Sottek psychoacoustic Hearing Model standardised sound quality metrics (ECMA-418-2 Loudness, Tonality and Roughness)
M. J. B. Lotinga, M. Torjussen and G. Felix Greco 3377

Evaluation Of The Episodic Audiovisual Memory In A Gamified Experiment
G. Wersényi 3385

Session A14.04 Spatial hearing: modeling and applications

Distance perception of nearby sources located around the subject in echoic rooms
N. Kopco and G. Andrejková 3393

Towards predicting binaural audio quality in listeners with normal and impaired hearing
T. Biberger and S. Ewert 3399

Comparing Measures of Information in Head-Related Transfer Functions
N. Meyer-Kahlen, K. Pollack and P. Lladó 3405

Subjective evaluation of the first incoming reflection - revisiting and extending Barron's study
A. Neidhardt, T. Surdu, P. Lladó and E. De Sena 3413

On comparing auditory models and perceptual assessment when rating head-related transfer functions
R. Daugintis, M. Geronazzo and L. Picinali 3421

Vertical Sound Localization: Influence of Age, Ear Size, Sex, and Hair
V. I. Schneider, B. Bugl and A. Sehr 3425

Vertical Sound Localization: Precision and Robustness to Reverberation in a Large-Scale Study
B. Bugl, V. I. Schneider and A. Sehr 3431

Spiking neural networks for sound localization: A new perspective on auditory spatial perception
Q. Liu, S. Laurent, H. Wuthrich and H. Lissek 3435

Does Source Directivity Influence Human Perception of Speech Position?
C. E. Contreras-Saavedra and R. A. Viveros-Munoz 3443

Binaural Localization Model for Speech in Noise
V. Tokala, E. Grinstein, R. Brooks, M. Brookes, S. Doclo, J. Jensen and P. A. Naylor 3449

Spatial Audio Models' Inventory To Cover The Attributes From The Spatial Audio Quality Inventory
P. Lladó, A. Neidhardt, F. Brinkmann and E. De Sena 3457

Spatial release from masking and listening effort: differences between binaural and free-field presentation
N. La Magna, K. Poole and L. Picinali 3465

Session A14.06 Development of semantic attributes based on psychoacoustic modelling

Estimation of interpretable non-linear Sound Quality Metrics using Kolmogorov-Arnold Networks (KANs)
T. Lobato and F. Kamp 3471

Psychoacoustic Modelling of AVAS Sounds: Consumer-Centric Semantic Attribute Development for Electric Vehicles
B. Kullukcu, M. S. Engel, S. Atamer and M. E. Altinsoy 3477

Auditory-Perceptual and Emotional Matching with Psychoacoustic Indicators of Urban Soundscapes
M. S. Engel, M. L. D. U. Carvalho and M. E. Altinsoy 3485

Comparative Analysis of Acceleration Sounds from Electric and Internal Combustion Vehicles Using Discomfort Indices
N. Misaki and S. Ishimitsu 3493

Quantifying and Mitigating Motion Sickness in Autonomous Vehicles through Psychoacoustic Modeling and Neurophysiological Insights
J. Y. Jeon, H. Lee, M. Ji, B. B. Santika, S. U. Choi and H. Moon 3499

Session A14.07 New trends and research for robust and unbiased psychoacoustical experimentation

On the need for homogeneous and standardized methodologies for perceptual testing in acoustics
D. De La Prida, M. Larrosa-Navarro, L. A. Azpicueta-Ruiz and A. Pedrero 3505

Rendering complex acoustic scenes for perception experiments
L. Aspöck, M. Vorländer and J. Fels 3513

Footstep Sounds Recording and Evaluation in Outdoor Environments
A. D'Adamo, K. Srinivasan, D. De La Prida, L. A. Azpicueta-Ruiz and A. Tajadura-Jimenez 3517

Robustness of an equal loudness paradigm to stimuli, environment and participants
M. Geluykens, H. Müllner, V. Chmelík and M. Rychtáriková 3525

Influence of participant training on the discriminability of clarity changes
M. Larrosa-Navarro, D. De La Prida and A. Pedrero 3533

Experimental Design Considerations for Proximity Perception of Binaural Action Sounds in Anechoic and Reverberant Environments
M. M. Rahmani, M. Roel Lesur, D. De La Prida, L. A. Azpicueta-Ruiz, J. R. Diaz Duran, A. D'Adamo and A. Tajadura-Jimenez
3541

The Impact of Looming Sound Duration on Peripersonal Space Measurement
M. M. Rahmani, M. Roel Lesur and A. Tajadura-Jimenez 3549

Optimal Pairwise Comparison Procedures for Subjectic Evaluations
J. Webb and L. Picinali 3557

Session A14.08 Virtual acoustics and binaural AR in hearing research: challenges of a new paradigm

Session A14.09 Advanced air mobility noise

Session A14.10 Psychological and physiological experiments for noise annoyance, acoustic comfort, and soundscape evaluation

Development and psychoacoustic evaluation of a curving noise classification method
M. Isenegger, L. Bartha, S. Emmenegger, C. Jeckelmann-Imhof and A. Taghipour 3567

Spatial Analysis of Axial Fan Psychoacoustic Metrics
N. Cerkovnik and J. Prezelj 3575

Measuring Human Noise Sensitivity: Psychometric Evaluation in an Online Survey
E. Song, W. Ellermeier, C. Marquis Favre, K. Zimmer, S. H. Park and R. Strebel 3583

An Approach for Evaluating Time-varying Annoyance Caused by Railway Noise
J. Egeler, C. Huth, A. Schlesinger, M. Liepert, C. Ende, D. J. Meyer, T. Koch, J. Bartnitzek, L. Höhle, B. Schlüter and R. Böhme 3589

Association of stress biomarkers with road traffic noise exposure and residential green: Insights from the RESTORE study
B. Schäffer, J. Dopico, M. Brink, D. Vienneau, M. Röösli, T. M. Binz, S. Tobias, N. Bauer and J. M. Wunderli 3597

Experimental Design to Map Brain Areas Involved in Sound Recognition Process
J. Donnerer, M. Kaltenbacher and C. Adams 3601

Annoyance of shooting sounds: Re-evaluation of ISO/PAS 1996-3 penalty procedure
A. Kuusinen, E. Rantanen and V. Hongisto 3605

Drone pass-by noise perception across various urban environments settings
N. Gravina, M. Masullo and L. Maffei 3609

Diversity in Sound Perception in Survey to Noise Sensitive People and Relevance for Experimental and Field Studies
C. Rosas-Pérez, L. Galbrun, S. R. Payne and M. E. Stewart 3613

The Role Of Sound Valence In Shaping Taste Perception Across Different Sound Environments
N. F. F. Istiani, M. Masullo, G. Ruggiero and L. Maffei 3621

Investigation into the Effect of Horizontal Source Direction on Psychoacoustic Annoyance
S. Dickinson and H. Lee 3627

Session A15.01 Room acoustics - General

Measurement of room acoustic parameters with an omnidirectional parametric loudspeaker in an converted chapel for choral music performance
M. Arnela, G. Quaranta, M. Avelar and L. H. Sant'Ana 3637

Speech Intelligibility Evaluation and Acoustic Performance of the Madrid Assembly Plenary Hall Combining Traditional and AI-based Methods
E. García-Medina, M. Centeno-Cerrato, J. Trujillo and C. Asensio 3645

Large public database of room acoustic responses
A. Fürjes 3653

Effect of Installation Method and Thickness on the Sound Absorption Performance of Melamine Foam
Y. Chun, S. Kim and S. Lee 3655

Acoustic characterization of Theater Ribeiro Conceição (Lamego, Portugal)
M. Gomes, A. Carvalho and A. Costa 3657

Acoustic characteristics of Gugak (Korean music) practice rooms
J. Jeong and Y. Kim 3665

Technology-Enhanced Methods For Indoor Acoustic 3D Modelling
E. Gómez Parrado, C. Aguado Tienda and Á. Grilo Bensusan 3669

Acoustic design of Church of Our Lady of Fatima in Poland
A. Sygulska 3677

Comparative Analysis of the Acoustic Modeling using Various Room Acoustic Simulation Software
C. H. Haan and C.-H. Han 3681

Quantum-inspired Reverberation using Ray Tracing Method
J. Tudoce, A. Reserbat-Plantey, R. Yamada and M. Lewenstein 3685

Acoustic analysis of a single-nave hall with an apse in the Cellars of Diocletian's Palace in Split
M. Nosil Mešić, Z. Veršić, M. Horvat and K. Jambrošić 3689

Echoes In Iberian Bullrings
M. Martín-Castizo, M. Galindo and S. Girón 3697

Session A15.02 Speech production and perception in rooms

Acoustic refurbishments in a university lecture room: Effects on speaker's comfort and voice strain
N. Cansu, G. Öhlund-Wistbacka, E. Arvidsson, J. Christensson, S. Holmqvist-Jämsén, R. Rydell and V. Lyberg-Åhlander 3707

Sensory-Driven Voice Modulation: Effects of Auralized Acoustics and Visual VR on Voice Outcomes
C. J. Nudelman, A. Tunuguntla, N. Ha, I. Rogala, K. House-Henry, B. Lopez, R. Perez Guerrero and P. Bottalico 3711

The effect of different simulated reverberant environments on cochlear implant users' binaural fusion
J. Aronoff, P. Bk and N. Gustafson 3719

Contribution of auditory detection thresholds to speech recognition in temporally and spectrally degraded environments for older adults
D. Fogerty and J. Dubno 3723

The role of speech directivity in speech perception
B. Monson 3727

On-axis sound pressure levels and sound power of normal speech for speech intelligibility, privacy and security
C. Hopkins, S. Graetzer and G. Seiffert 3731

Investigation on the acoustic conditions of active classrooms in accordance with the students and classroom activities
Y.-J. Choi 3735

Assessing sound levels of student activity in primary school classrooms
C. Visentin and N. Prodi 3741

Speech intelligibility and acoustic conditions in university classrooms for the teaching of Quechua as a second language
H. D. Lazarte Reátegui, W. A. Montano Rodríguez, H. S. Guerrero Arias, M. F. Siguas García, V. L. Palomino Franco and K. L. Huamani Quiquinlla 3745

Binaural speech intelligibility in practice
N. Prodi and M. Begotti 3749

Session A15.03 Modern offices: challenges and solutions

Effects of music on cognitive performance: from the workplace to the laboratory to open-plan offices
A. Smith 3757

Noise in open-plan offices: A holistic research strategy
A. Smith, J. Langer and J. Taylour 3761

Objective method for predicting office noise annoyance
V. Hongisto, R. Alakoivu, J. Keränen and J. Laukka 3769

Enhancing Acoustic Design in Open-Plan Offices: Practical Applications of the Simplified ISO 3382-3 Prediction Model
R. Machner, H. Brokmann and A. Klein 3773

Airborne Sound Insulation In Five Office Buildings According To Requirements Of Italian Regulations And Well Building Standard
S. Di Blasio, F. Ferilli, L. Andreozzi, I. Gualdana, E. Stigliano and E. Siciliano 3779

Optimizing Acoustic Privacy in Open-Plan Offices: A Simulation-Based Study of Desk Partition Designs and Material Choices
G. Fratoni and D. D'Orazio 3787

Sound Absorbing Furniture As A Strategy For Acoustic Comfort Optimization
C. Rubino, S. Liuzzi and F. Martellotta 3793

Do frequencies below 160 Hz play a role in speech privacy between rooms?
A. Kuusinen, E. Rantanen and V. Hongisto 3797

Class A booth reduces stress due to office noise
V. Hongisto, J. Keränen, E. Rantanen and J. Radun 3801

How did the addition of soundproof pods influence office employees' experience?
J. Radun, S. Pitkänen, R. Alakoivu, J. Laukka, H. Maula, A. Sivula and V. Hongisto 3805

Session A15.04/A24.06 Virtual reconstructions in archaeoacoustic research

Acoustical features of the Üç Şerefeli Mosque in Edirne (the mosque with three balconies)
Z. Sü Gül 3811

Virtual acoustic completion of the unfinished baroque church of Santuari del Miracle in the Catalan region of Solsonès
M. Arnela, M. Rebollo-Arjona, R. Scoczynski Ribeiro and R. M. Alsina-Pagès 3819

Exploring the Past using Dynamic Auralization of Cultural Heritage: A Case Study on the Theatre of Tyndaris
L. Lavagna, A. Farina, A. Farina, L. Shtrepi and A. Astolfi 3827

Analysis of the reconstructed acoustic environment of a Portuguese Romanic Cathedral in the XVIth century by numerical modelling
P. Amado Mendes, L. Godinho, D. Mateus, A. Pereira, D. Ramos and A. Gaspar 3831

An archaeoacoustic study of the Hoftheater's (1808-1847) history
B. Postma, M. U. Schumann and B. F. G. Katz 3839

Acoustic Characterization Of The "Cueva Del Pájaro Azul": Architectural Reference Of The Sound Heritage Of Gadir
D. Payo, V. M. Rodríguez-Montaño, F. Fernández-Zacarías and R. Hernández-Molina 3847

Measurement and Auralization of Paleoacoustics landscapes in Chauvet Cave
L. Valentin, J. Abel, J. Berger, C. Chafe, J. Chowning, C. Fritz, N. Farzaneh, M. Kolar, R. Michon, S. Martin, P. Svensson and M. Wright 3855

From Measurement to Music: Reviving the Acoustic Heritage of St. Michael's Church, Coventry, UK
I. Ali-Maclachlan, H. Roberts, B. West, S. Hall and J. Savan 3865

Comparison Between the Acoustic Texture Obtained Through In Situ Measurements and That Calculated From Virtual Models of a Pre-Romanesque Church
L. Carrero-Muriel, D. De La Prida, M. Larrosa-Navarro and A. Pedrero 3873

Survey And Acoustic Correction Of The Boboli Amphitheater Using Of Audio-Visual Model
L. Magnini, V. Amodeo, D. Masci, P. Ruggieri, S. Secchi and G. Verdiani 3881

Session A15.05 Acoustic comfort in hospitals

Space For Music: Elements To Incorporate Into Healthcare Designs
A. Ferrentino, C. Rius and R. Torrents Pairo 3889

Impact Of Spatial Organization On Noise Levels In Open-Bay Neonatal Intensive Care Units
V. M. Rodríguez-Montaño, J. L. Beira Jiménez and R. Hernández-Molina 3897

Environmental Noise in Hospitals: a Rapid Review of Trends and Possible Developments
V. Amodeo and S. Secchi 3905

Towards new metrics to characterize the acoustic environment in Intensive Care Units
E. De Ruiter, E. Fasllija, D. Gommers and E. Özcan 3913

Looking at sound together: using VR with Dutch Hospitals - a case study
C. Van Wezel 3921

Sound in Clinical Environments (SILENTS): Overview of a mixed methods intervention to improve acoustic comfort in a hospital ward in London (UK)
C. Rosas-Pérez, A. Hall, C. J.H. Cook, J. Drever, M. Cobianchi and H. Skene 3925

Noise Assessment Within Healthcare Facilities: Annoyance And Intrusiveness Of Sound Sources
D. De Salvio, V. Amodeo, M. Garai and S. Secchi 3933

Preliminary study of a University Hospital outdoor noise environment based on monitoring and soundscape
A. Nora, D. De Salvio, G. Fusaro and L. Barbaresi 3939

Session A15.06 Acoustic and multidomain comfort in learning spaces

Linking Speech Clarity, Reverberation, And Distance For Classroom Design Optimization
D. Mironovs 3949

Case Study: Remodeling of open plan Dutch school - acoustic design and operational challenges
B. Scherpenhuyzen, C. Campbell and J. Vugts 3953

A possible single number universal classroom acoustic criterion
S. Dance 3961

Virtual Reality for Performance Preparation
C. J. Wingfield, Y. G. Gonzales Redman, C. J. Nudelman and P. Bottalico 3965

Children's listening perception and cognitive performance at school
C. Pavarin, I. Pittana, I. Pavanello, P. Ruggeri, A. Di Bella, P. Scimemi, P. Romagnoni and F. Cappelletti 3973

EEG Insights into the Impact of Noise and Dysphonic Speech on Children's Listening Effort and Sentence Comprehension
S. Murgia, M. M. Flaherty and P. Bottalico 3981

Evaluating Noise-Related Stressors in Italian Schools: Aligning Acoustic Environments with the Needs of Neurodivergent Students
A. Marzi, F. Bettarello, M. Caniato and A. Gasparella 3987

Multi-domain sensation and preference of children at primary school: a case study
I. Pittana, C. Pavarin, I. Pavanello, A. Di Bella, P. Scimemi, P. Romagnoni and F. Cappelletti 3993

Combined effect of IAQ and acoustics on calculation in university classrooms
M. Pellegatti, C. Visentin, S. Torresin, F. Babich and N. Prodi 4001

Teachers' Indoor Environmental Satisfaction And Sound Exposure In Enclosed And Flexible Learning Spaces
J. Radun, M. Veermans, S. Rantanen and V. Hongisto 4005

Vocal behavior in different room acoustic conditions, noise, and with sound field amplification system use
N. Cansu, G. Öhlund-Wistbacka, S. Holmqvist-Jämsén, R. Rydell and V. Lyberg-Åhlander 4009

An Acoustic Survey Of Korean School Classrooms
Y.-J. Choi, D.-H. Kim, H.-J. Lim and H.-J. Kim 4013

Session A15.07 Characterization of acoustic materials

Session A15.09 Sound reflections in concert halls

The Support parameters for measurement of sound reflections on concert hall stages
A. C. Gade 4021

On the influence of sound scattering in room acoustic modelling
A. Pereira, A. Gaspar, L. Godinho, D. Mateus and P. Amado Mendes 4029

Robust 3D Localisation of Anomalies in Reverberation Time Signals
T. Rittenschober and A. Decloux 4035

Development of a 3D tool to visualise the lateral energy component within each sound reflection in concert halls
J. Sanz Soriano, C. Day and J. Ó. García Gómez 4043

Forget about the seat dip effect – you have other problems! Early reflections to compensate for broadband grazing incidence attenuation
N. Rummler, E. Green, Y. Jurkiewicz and E. Kahle 4051

Computer-based Construction of Self-similar Acoustic Reflectors
J. O.'K. O'Keefe 4057

Session A15.10 Modeling and estimation of room impulse responses with machine learning

Deep, data-driven modeling of room acoustics: literature review and research perspectives
T. Van Waterschoot 4065

Complex Room Geometry Inference via Acoustic Echoes
I. Yeon and J.-W. Choi 4073

DiffusionRIR: Room Impulse Response Interpolation using Diffusion Models
S. Della Torre, M. Pezzoli, F. Antonacci and S. Gannot 4079

Latent FXLMS: Accelerating Active Noise Control with Neural Adaptive Filters
K. Sarkar, A. Lu, M. Mittal, Y. Zhuang, R. Corey and A. Singer 4087

Evaluating Acoustic Characteristics used by Conditional GANs for Room Impulse Response Modeling
G. Atienza, F. Pastor-Naranjo, D. De La Prida, L. A. Azpicueta-Ruiz, V. Naranjo and G. Piñero 4095

Session A15.11/A16.05 Sound field reconstruction in rooms and enclosures

Tracking of Spatially Dynamic Room Impulse Responses Along Locally Linearized Trajectories
K. Macwilliam, T. Dietzen and T. Van Waterschoot 4103

Experimental Validation of Sound Field Estimation Methods Using Moving Microphones
J. Brunnström, M. B. Møller, T. Van Waterschoot, M. Moonen and J. Østergaard 4111

Introduction of the boostlet transform for acoustic signal processing
E. Zea, M. Laudato and J. Andén 4119

Frequency and spatial limitations of sound field reconstruction methods for navigable reproduction
A. Figueroa-Duran, N. Meyer-Kahlen, S. A. Verburg, T. Lokki and E. Fernandez-Grande 4127

Spatially extended reconstruction of room impulse responses using a generalizable wave model
E. Fernandez-Grande, A. Figueroa-Duran and S. A. Verburg 4135

Stochastic Variational Inference of Directional Decay Times in a Reverberation Room
M. Berzborn and M. Vorländer 4139

Towards Analytical Waveform Transitions in Space-Time Across Different Boundary Conditions
E. Zea, E. Fernandez-Grande and C. E. Yarman 4145

The performance of the cable robot sound field characterisation measurement system
R. Prislan, M. Repek and D. Svenšek 4153

Sound source localization in small-volume industrial reverberant cavities through the Steered Response Power PHAT-β
K. Rousou, D. Panagiotopoulos, D. Chronopoulos and E. Deckers 4161

Session A15.12/A19.09 Numerical methods for room acoustics

A neural network for predicting with the diffusion equation: a case study of long rooms
I. Fichera, A. Deleforge, C. Foy, J.-D. Pascal, C. Prax, M. Tonelli, C. Van Hoorickx and M. Hornikx 4171

Using spherical array receivers to extract scattering coefficients of room surfaces
D. Xie and M. Hornikx 4179

On the Accuracy of the Image Source Method in the Presence of Two Adjacent Impedance Walls
Z. Xu, E. Habets and A. Prinn 4185

Sweeping echoes management in image-method based open-source software
A. Andrijasevic and M. Horvat 4193

Simulation method for shoebox-shaped rooms with absorbing ceilings
U. P. Svensson, K. H. Reigstad and M. Skålevik 4201

Room Modeling In COMSOL Using Finite Elements Method
R. Maestro-Vallejo, E. Latorre Iglesias, M. L. López Ibañez and A. Melis 4207

Evaluating the Applicability of Statistical Reverberation Theory in Rooms with Varying Compactness and Material distributions
W. Wittebol, H. Wang and M. Hornikx 4215

From Theory to Reality: Assessing Predictive Models for Reverberation Time in Built Environments
M. Caniato and F. Bettarello 4223

Towards a community hub for open-source room acoustics software
S. Willemsen, H. Teymoori, I. Fichera, H. Wang, A. Nolte, A. Serebrenik and M. Hornikx 4229

A zero-phase parametric equalization for microphone and loudspeaker impulse response
V. Popa, B. Moroșanu and H. S. Ionita 4237

Session A16.02 Spatial audio signal processing - capture, encoding and enhancement

Cross-Spectral Analysis of Higher-Order Ambisonic Signals for Investigating the Spatial and Statistical Properties of Captured Sound Fields
N. Hahn, F. Fazi, M. Orita, B. Bacila and P. Nelson 4243

Increasing the spatial aliasing frequency of circular arrays via beamformer order reduction
F. Fazi and N. Hahn 4251

Steerable Neural Directional Filtering
W. Huang, M. M. Halimeh, S. R. Chetupalli, O. Thiergart and E. Habets 4259

Dynamic room impulse response measurements with a robotic arm
S. A. Verburg, O. Díaz Gaztelumendi, Y. Pene and E. Fernandez-Grande 4267

Multi-channel Processing for Patient Identification and Audio Analysis in the Context of Group Music Therapy
A. Epure, T. Dietzen and T. Van Waterschoot 4275

Correction of azimuth ambiguities of the GCC algorithm in a uniform circular array
A. Resino Viñas, G. Corral García, D. Tejera Berengué, F. Zhu-Zhou and M. Zurera-Rosa 4283

Tracking of Intermittent and Moving Speakers : Dataset and Metrics
T. Iatariene, A. Guérin and R. Serizel 4291

Relative Transfer Matrix-Based Binaural Signal Denoising of Head-Mounted Microphone Array Recordings
M. Kumar, A. Bastine, L. Birnie, S. Arcos Holzinger, P. Samarasinghe and T. Abhayapala 4299

Neural Network Solvers for Binaural Encoding with Perception-Based Losses
O. Berebi, Z. Ben-Hur, D. Alon and B. Rafaely 4307

Binaural Signal Matching with Wearable Arrays for Near-Field Sources
S. Goldring, Z. Ben-Hur, D. Alon and B. Rafaely 4315

Ambisonics Encoder for Wearable Array with Improved Binaural Reproduction
Y. Gayer, V. Tourbabin, Z. Ben-Hur, D. Alon and B. Rafaely 4321

Session A16.03/A09.06 Machine learning for array processing

Learning Magnitude Distribution of Sound Fields via Conditioned Autoencoder
S. Koyama and K. Ishizuka 4329

Universal auditory scene analysis model for source separation, event localization, and detection
D. Lee and J.-W. Choi 4337

Learning from data-driven sound field estimation using complex-valued neural networks
V. Paul, N. Hahn and P. Nelson 4343

Exploiting Spatial Information for Anomaly Detection in Industrial Machines Using Autoencoders
C. Luzón-Álvarez, A. M. Torres-Aranda, F. J. Ferri and M. Cobos 4351

Acoustic Scene Description Using Acoustic Imaging And Machine Learning
E. Tiffeneau, Q. Leclère and S. Bouley 4357

Elevation and Azimuth Frequency Invariant Beamforming using Autograd and Concentric Circular Microphone Arrays
J. Ortigoso-Narro, J. A. Belloch, M. Morales-Cespedes and M. Cobos 4365

Point Neuron Learning for broadband array processing
A. Bastine, T. Abhayapala and P. Samarasinghe 4373

Deep Learning-Driven Object Tracking for Enhanced Acoustic Beamforming in Dynamic Environments
J. Ortigoso-Narro, J. A. Belloch and M. Cobos 4381

Complex-valued neural networks for the reproduction of linearly superposed sound fields
I. Lambert, V. Paul and P. Nelson 4389

Interpolation of Modal Displacement in Thin Plates Using Physics-Informed Neural Networks
R. Malvermi, F. Zese, M. Pezzoli, F. Antonacci and A. Sarti 4397

Enhancing the Geometrical Calibration of Microphones Arrays : Solutions and Experimental Validation
M. Hartenstein, P. Luizard, H. Moingeon, C. Pinhède, M. Pachebat, C. Ollivon, F. Ollivier and F. Silva 4405

Session A16.04 Airborne sonar

Spatial Characterization of Noise Generated by a Drone in Hovering Flight
A. Izquierdo, L. Del Val, J. J. Villacorta and J. Retortillo 4415

Detection and spatial localization of xylophagous insects in wood structures with acoustic arrays
L. Del Val, A. Izquierdo, J. J. Villacorta and R. D. Martínez 4421

Plant Health Monitoring using Acoustics
J. Vande Velde, B. Da Silva, A. Touhafi and L. Segers 4427

Compressed Sensing for Data Acquisition in Air Imaging Sonar Sensor
A. Sharifa and J. Steckel 4435

Advancing Direction Estimation for Acoustic Drone Detection in Noisy Outdoor Environments
M. Varela and W.-D. Wirth 4443

Pedestrian Detection Using an Active Acoustic Array Embedded in a Car
J. J. Villacorta, A. Izquierdo, L. Del Val and A. Martin 4449

Session A16.05 Sound field reconstruction in rooms and enclosures

Session A16.06 Source directivity: capturing, processing, and evaluating its effects

A robotic system for space-time characterization of parametric acoustic sound sources
A. Fantinelli, M. Arnela, E. Brandão and E. Fernandez-Grande 4457

Sound source directivity estimation via a spherical wave decomposition of the radiated field : application to human voice directivity measurements
M. Hartenstein, P. Luizard, H. Moingeon, C. Pinhède, M. Pachebat, C. Ollivon, F. Ollivier and F. Silva 4465

Impact of leg diffraction and scattering on voice directivity patterns
S. Bellows, B. F. G. Katz and T. Leishman 4473

Analytic expressions for the low-frequency acoustic center of dipole radiators
S. Bellows 4481

Investigating the effects of sound source occlusion in a real dynamic scenario
T. Surdu, L. Treybig, F. Klein, R. R. Ramachandra Rao and S. Werner 4489

Session A16.07 Processing/individualization/interpolation of HRIRs or BRIRs

Session A17.01 Soundscape, environmental quality, health and well-being - General

Soundscaping as a Multidisciplinary Activity
M. Cobussen 4501

Virtual Reality Applications in Urban Soundscape Assessment: An Overview
Ö. Gök Tokgöz and M. E. Altinsoy 4507

Walking vs. Standing: How Dynamic Visuals Impact Soundscape Perception
K. Guo and J. Kang 4515

An Approach To Sensory Heritage Policy Through Soundscape And Smellscape
P. Lindborg, L. H. Lam, Y. C. Kam and J. Xiao 4519

Meta-analyses in noise and health: to update or not?
E. Van Kempen, M. Reedijk, K. Rijs and C. De Bruijn 4525

Up-to-Date Epidemiological Evidence on Health Effects from Transportation Noise for Burden of Disease Assessment
M. Röösli, N. Engelmann, X. Jiang and D. Vienneau 4533

Umbrella+ Review And Discussion Of The Evidence, Gaps, & Research Needs For Quantifying Transportation Noise Impacts On All-Cause Mortality
S. N. Clark, B. Fenech, J. Gulliver, C. Jephcote, O. Williams and C. Clark 4539

Progress In The Translation Of ISO/TS 12913-2:2018 Soundscape Model Into Spanish: New Insights From The Satp Project In Chile
J. Vida Manzano, R. García Quesada, J. A. Almagro Pastor, E. Suárez Silva and J. Cárdenas Mansilla 4547

Linguistic Representations of Soundscapes: Perceptions and Descriptions in Urban and Mountain Contexts in Trentino-South Tyrol
G. Gozzi, S. Torresin and L. Badan 4555

Towards The Creation Of An Ibero-American Urban Soundscape Network For Collaboration, Preservation And Promotion Of Sound Environments
F. Rodriguez-Manzo, E. Suárez Silva and J. Vida Manzano 4563

Inhabiting Gaudí: Integrating Objective and Subjective Acoustic Evaluations for Human Comfort
R. M. Alsina-Pagès, M. Arnela and M. Freixes 4571

Soundscape Analysis And Contribution To Forming Place Identity And Satisfaction Of Users
Z. Al-Bayyar, T. B. Dahham and P. N. D. Yorukoglu 4577

Interventions And Acoustic Nuances In The Soundwalks With Daumal And ISO 12913 Methods In Elche, Cuenca And Faro
F. Daumal I Domènech, J. Vida Manzano, S. Herguedas and S. Silva Antunes 4583

Citizen Science To Analyse The Relationship Between Sounds And Spirituality In A Monastery
E. Vidaña-Vila, A. Ramos Esperidião, M. Freixes, J. Cabó, A. Iarozinski Neto and R. M. Alsina-Pagès 4591

PEMS: People Experience of Mountain Soundscapes
B. Di Donato and I. Mcgregor 4599

Session A17.02 Restorative soundscapes - Sound quality, health and well-being

Tranquillity Islands: Designing restorative soundscapes in urban environments
G. Watts 4609

Silenzi in Quota – An Initiative Promoting Soundscape Protection in Mountainous Natural Areas
T. Oberman, S. Torresin, R. Keller, G. Gozzi and J. Kang 4615

Field study on the restorative potential of small green and blue spaces in densely populated areas
M. Schuck, E. Lüer and A. Fiebig 4621

A citizen science approach to collect combined noise exposure and survey data
L. Dekoninck, P. Thomas and T. Van Renterghem 4629

Restorative Urban Spaces In Europe: Comparisons Of Criteria And Approaches In Germany And Italy
M. Masullo, R. A. Toma, A. Fiebig, S. Sibilio and L. Maffei 4635

A Simple Structured Approach to Urban Greenspace Acoustic Design
B. W. Hohmann 4641

Acoustic quality layers: A systematic review to understand acoustic quality spaces
H. A. Dogan Iseri and A. Ozcevik Bilen 4649

The Influence of Soundwalk Direction on Healthy Street Metrics
Z. S. Ozturk, J. Kang and F. Aletta 4657

Comparison of methodological approaches for investigating urban parks soundscape restoration: A case study of Curitiba, Brazil
M. S. Engel, K. F. K. Maciel, B. Szeremeta and P. H. T. Zannin 4661

Perceptions Of Chinese Temples Through Soundscape And Smellscape: A Case Study At Wong Tai Sin
L. H. Lam, R. Yue, Y. C. Kam and P. Lindborg 4667

Listening to the High-Tech City and its Vehicles: Auditory Perception of Electric Vehicles Embedded in Shenzhen's Urban Soundscape
Q. Xiang, Z. Liu and M. Z. Sagesser 4673

Restorative Soundscape Design for Resting Places in Purpose-Built Vehicles: Enhancing Relaxation and Well-being through Audio-Visual Environments
J. Y. Jeon, H. Lee, B. B. Santika, D. Park and J. Kim 4681

Mitigating Noise Annoyance Through Green Spaces: Health Impacts in European Urban Environments
X. Jiang, J. Fons-Esteve, M. Sáinz De La Maza, N. Blanes Guàrdia, E. Peris, M. Röösli and D. Vienneau 4685

Courtyard trees and aircraft noise: Investigating the effect of Urban Greenery on aircraft noise perception using Virtual Reality (VR)
R. Vassallo, G. Wuite and M. Lugten 4691

Session A17.03 Soundscape practice and interventions

Soundscape Practice And Interventions: A Framework
J. Kang, X. Fang, F. Aletta, A. Mitchell, T. Oberman, G. Cerwén, X. Chen, J. Xiao and P. Mittal 4699

Defining urban soundscape design means and tools
M. Haberl, T. Kusitzky and S. Alves 4707

Architecture as Soundscape Intervention Design Process and Strategies
M. Gold, G. W. Siebein and K. Siebein 4713

Exploring Soundscape Methods and Interventions in Urban and Suburban Soundscapes
G. W. Siebein, K. Siebein, M. Gold, G. Siebein Jr and M. Roa 4721

A Tale of Two Cities: Soundscape Analysis and Planning
G. W. Siebein, K. Siebein, M. Gold, G. Siebein Jr and M. Roa 4725

The Soundscape of an ICU
K. Siebein, G. W. Siebein, L. Lorusso, D. Rittenbacher, T. Orozco, J. Miller, M. Vetterick and I. Jones 4731

Measuring short-term changes in perceived soundscapes due to localized interventions
G. Memoli, L. Chisari, M. Boerger, J. Eccles, V. Apicella and B. Carambia 4739

Listening to the Built Environment: Cultural and Social Urban Soundscape
L. Tsaih, S.-I. Juan, R. Ghadiri, J. C.-P. Chen, T.-Y. Yu, V. Prawira, C.-H. Chen and Y.-T. Yen 4747

The Sonic (Re)Design Of Urban Places: Auditory Transformations In The Hague (Nl) And Kiruna (S)
M. Cobussen, S. Östersjö, P. Craenen, J. Bennett, R. Zentschnig, I. Ruipérez Canales and J. Berg 4755

Exploring green façades as complex systems and their relationships with soundscape quality through a system thinking approach
S. Torresin, F. Aletta, E. Gasparri, K. Zhou, T. Astell-Burt, A. Brambilla, T. Parkinson, S. Yuksel Dicle and A. Kuru . 4761

Towards Designing Pleasant Urban Soundscape: An Acoustic Metamaterial-Based Multi-Objective Psychoacoustic Analysis
X. Fang, P. Mittal, T. Oberman, F. Aletta, S. Subramanian and J. Kang 4767

Sonic Citizenship and the feeling of awe in urban space
S. Raahede Lundgård, M. Koldkjær Højlund and L. Stenfeldt 4773

The Soundscape of Animal Care Facilities
K. Siebein, G. W. Siebein, S. Boman and H. Lewis 4781

Session A17.04 Soundscape methods, monitoring and metrics

The Prediction Of Environmental Noise, Using Arcmap, (NMSIM-GIS) And ISO 9613, For Commercial Jet Boat Operations
J. Pearse, J. Lee, B. Donohue and G. Watts 4791

Noise in the High-Tech City: Listening to Shenzhen Through a Participatory Phone-Based App
X. Fu, S. Li and M. Z. Sagesser 4799

Introducing NORBAERT – an open source software to facilitate the research on complex networks from the acoustic environment
T. Haselhoff, M. Jedrusiak, F. Weichert and S. Moebus 4807

A revised Web Application for Interactive Exploration and Visualization of ISO 12913 Soundscape Datasets
M. Erdmann, S. Versümer and J. Steffens 4813

Proposal For A Scale To Measure Psychosocial Cobenefits Of Natural Soundscape In Urban Areas
K. Herranz-Pascual, P. Anchustegui, I. Aspuru Soloaga and I. Iraurgi 4817

Polish version of soundscape attributes: translation process and preliminary validation results
J. Dumanowski, J. Felcyn and A. Preis 4823

Comparison of Text-Based and Graphical Methods for Soundscape Assessment
Y. Kim, D. Kim and J. Ryu 4827

Effects of audio-visual interactions on the soundscape in urban shopping streets
J.-Y. Jeon, G. Kim and J.-Y. Hong 4833

Comparative Analysis of Visual and Auditory Perceptions in Urban Environments Using Mental Mapping
G. Kim, J.-Y. Jeon and J.-Y. Hong 4835

Clustering analysis of human perceptual responses to birdsongs
J.-Y. Hong, K. Ooi, B. Lam, Z.-T. Ong and W.-S. Gan 4839

Developing a linguistic corpora-based soundscape questionnaire: addressing translation challenges in the ISO Standard
M. Ferretti, D. Chiarella, A. Cinini and P. Cutugno 4843

The role of pleasantness mapping in a University campus for studying soundscape subjective perception in evolving environments
A. Mascolo, D. Rossi, M. Grimaldi and C. Guarnaccia 4847

Psychoacoustic Assessment of loud vehicles recorded by a noise radar
A. Fiebig, M. Diechmann, P. Kolingba-Froidevaux, A. Mundt and M. Schuck 4855

Soundscape analysis according to ISO/TS 12913-2:2018: A case study for areas of high heritage value in Coimbra
L. Oliveira, A. Pereira, P. Amado Mendes and L. Godinho 4863

Collaborative learning in the diagnosis of the soundscape of the Historic Center of Morelia, Mexico
F. Rodriguez-Manzo and J. Á. García-Márquez 4869

Questionnaires and Acoustic Measurements in Longyearbyen Area During Winter and Summer Seasons
J. Wiciak, D. Mlynarczyk, P. Malecki and J. Piechowicz 4877

NoiseSens - a system for identifying noise offenders in road traffic
F. Fuhrmann, R. Ladstädter, M. Blass, A. Maly, A. Gregorac and F. Graf 4883

Session A17.05 Indoor soundscapes

Comparing Teachers' And Students' Perceptions Of School Soundscapes Through A Questionnaire-Based Study
H. Kurukose Cal, F. Aletta, J. Kang and P. Clarke 4889

A Systematic Review Of Perceptual Attributes For Indoor Soundscape Assessment In Primary School Classrooms
S. Syed, S. Torresin and C. Visentin 4897

Cross-modal effects on assessments of soundscape and IAQ in university classrooms
M. Pellegatti, C. Visentin, S. Torresin, F. Babich, P. W. Wargocki and N. Prodi 4905

Adaptive Comfort: Similarities and Differences Between the Acoustic and Thermal Domains
S. Yuksel Dicle, F. Aletta and J. Kang 4909

Thermo-Acoustic Perception In An Open-Plan Office: Influence Of Ventilation, Gender, And Headphones Under Similar Thermal Conditions
L. P. De Souza, A. P. Melo and R. Lamberts 4917

Characterizing New Modalities Of Shared Offices: A Diary-Interview Methodology To Inform Audio Augmented Reality Approaches
C. Boukhemia, N. Misdariis and M. Lagrange 4925

Noise Perception And Cognitive Effort In The New Civic Central Library Of Torino
A. Astolfi, M. Modica, I. Grozeva, D. Cetani, V. Martinelli, L. Shtrepi, L. Lavagna, A. Griginis, C. Pintore and M. Zampini 4933

Prison soundscapes and health effects: Insights from the literature
J. Chieng, L. Woodland, O. Williams and B. Fenech 4941

Soundscape attribute for the assessment of the acoustical environment in apartments
S. Lee, D. Kim and J. Ryu 4949

Clustering residential sound based on soundscape attributes
J. Kim and J. Ryu 4953

Effects of adding a natural and a mechanical sound to a polyclinic soundscape on spatial knowledge performance
D. Dalir 4959

Radiation and Spatial Characteristics of Masking Speaker Reproduced Sound in Residential Spaces and Its Impact on Masking Performance
D. Kim, S. Kim, Y. Kim, C. Yun, C. Eom and J. Ryu 4967

Auditory Processing-Driven Soundscape Design for Dementia: A Systematic Framework for Environmental Intervention
A. Talebzadeh, P. Devos and D. Botteldooren 4971

The Role of Salient Sounds in everyday indoor Soundscapes
S. Versümer, J. Steffens and P. Blättermann 4975

Soundscape experience mapping: A deep listening approach for eliciting older adults' perceptions of indoor soundscapes
T. Deacon, G. Bibbó, A. Singh and M. Plumbley 4983

Contribution to the measurement and assessment of indoor university soundscapes: a classroom experience
J. Vida Manzano, R. García Quesada and J. A. Almagro Pastor 4991

Session A17.06 Soundscape and inclusion, from theory to practice

Diversity In Soundscapes Studies: A Monochromatic Case On Nature
K. Van Den Bosch, K. Chatburn and A. Talebzadeh 5001

Multispecies Soundscape Character: Conceptualising Soundscape Character For/From Multiple Perspectives
U. Ruiz Arana and G. Cerwén 5007

Listening To Hospitals: Towards An Assessment Tool Of Audio Data Ethics For ICUs
A. Giglio, S. Lenzi, S. Spagnol and E. Özcan 5015

Characterizing the soundscape of Oncology Hospital Spaces at University Hospital 'Mother Teresa' (UHCT): Assessment of Patients and Staff
E. Alimadhi, E. Fasllija and A. Cani 5023

Rehabilitation exercises using spatial sound
K. Piątek and D. Mlynarczyk 5031

Exploring pedestrian perceptions of safety through Shared Space soundscapes
F. Pereira, R. Almeida, D. Machado, E. Sousa, W. L. Martens and E. Freitas 5037

Diversity Of Responses And Potential Conflicts In Inclusive Urban Sound Design – Preliminary Results From Interviews In Brighton (UK)
M. Cobianchi, L. Lavia and J. Drever 5045

Sunday Soundscapes: Foreign Domestic Helpers' Acoustic Contributions to Hong Kong's Public Spaces
R. Yue, P. Lindborg, L. H. Lam, A. L. Lin and Y. C. Kam 5053

Session A17.07 Hospital soundscape

The role of critical alarms in the ICU acoustic environment: A Pilot Study
E. Fasllija, E. De Ruiter, D. Gommers and E. Özcan 5061

Impacts of soundscape on healthcare workers' wellbeing
P. J. Lee and Z. Song 5069

Nurses' Interpretation Of ICU Soundscape: An Annotated Sound Level Measurement At Erasmus Medical Center
E. Özcan, K. Bogers, D. Gommers and S. Spagnol 5075

Session A18.01 Speech - General

Masker Type And Speaker Voice Cues Determine Masking Of Speech By A Single Talker
L. Rachman and D. Baskent 5085

Rhythm instruction to enhance ESP students' prosody: An acoustic study
L. Quesada Vázquez 5091

Slicer - A Tool for Efficient Stimuli Extraction from Large Speech Corpora
L. Eckert, S. Wepner and B. Schuppler 5101

The avatars speech intelligibility: comparison between two different speech generation methodologies for facial animation
F. Cioffi, M. Masullo, A. Pascale and L. Maffei 5105

The effect of congruence of virtual image and reverberation-induced speech on speech intelligibility
N. Hodoshima, K. Hamamoto, M. Mizumachi and K.-I. Sakakibara 5111

Session A18.02 Forensic phonetics and acoustics

Acoustic And Comparative Analysis In The Process Of Trans-Voice Hormonal Treatment
J. Alonso Nogales 5117

Digital Voices: An Analysis Of Speech Intelligibility Through Mobile Devices
R. Pérez Vargas and V. M. Rodríguez-Montaño 5125

Human-Machine Speaker Identification According To TOBI Principles
F. Bernal Ortiz 5131

Perception Of Audio Deepfakes In Spanish And Japanese: Effects Of Language, Speaking Style, And Voice Familiarity
A. López-Jareño, J. J. Romero, E. San Segundo and X. Wang 5139

Speech Clarity And Topic Relevance: Forensic Analysis In Varying Acoustic Environments
R. Pérez Vargas 5147

Perceptual evaluation of synthetic voice detection with dysphonic speakers
J. J. Romero, A. López-Jareño, E. San Segundo and J. Delgado 5153

Session A18.03 Speech production pathologies

Texture Analysis In Recurrence Plots For Pathological Voice Recognition
H. Fandiño-Toro, D. Torricelli and J.A. Gómez-García 5163

Automatic Speech Recognition for a Dysarthric Child Speaking Austrian German
L. Eckert and B. Schuppler 5167

Discriminating Parkinson's Disease from Normophonic Voices Using a SincNet model
J.A. Gómez-García, H. Fandiño-Toro and D. Torricelli 5175

Explainable Feature Selection for Dementia Recognition from Acoustic and Linguistic Cues
A. Gallardo-Antolín, I. Oiza-Zapata, J. Ferreiros-López, F. Fernández-Martínez and R. San-Segundo 5179

Session A18.04 Speech perception pathologies

Comparison Of DNN-Based And Traditional Hearing-Aid Algorithms For Sensorineural Hearing-Loss
M. Wouters, C. Wen, A. Fráter and S. Verhulst 5189

Modelling of distortions created by temporal interactions between pulses in CI users
F. Guérit, C. Garcia and R. P. Carlyon 5193

Perceptual evaluation of deep learning-based speech enhancement for hearing aids
M. Baig, E. Gusó, J. Luberadzka and U. Sayin 5197

Audio-Visual Feature Synchronization for Robust Speech Enhancement in Hearing Aids
N. Saleem, M. Gogate, K. Dashtipour, A. Hussain, U. Anwar, A. Adetomi, A. Tughrul and A. Hussain 5205

Assessing Speech Processing HA/CI Advancements for Naturalistic Field Testing: Advancements with the CCi-MOBILE Research Platform
J. H.L. Hansen, J. N. Saba, H. A.F. Younis, T. Lawson, S. O. Okei and H.-T. Chiang 5213

Session A18.05 Speech technologies: diarization, emotion, enhancement

Localize, Filter, Segment: Towards Multi-Microphone Speaker Segmentation
T. Mariotte 5221

Temporal Segmentation Strategy to Improve Speech-Based Anger Detection using YAMNet
F. Zhu-Zhou, R. Gil-Pita, D. Tejera Berengué, G. Corral García, M. Zurera-Rosa and M. Utrilla-Manso 5229

Towards Interpretable Emotion Recognition: Identifying Key Features with Machine Learning
Y. Kaloga and I. Kodrasi 5237

Developing a novel multimodal speech enhancement intelligibility evaluation metric: Addressing the limitation of traditional objective measures
A. Hussain, M. Gogate, K. Dashtipour, N. Saleem, A. Goman, A. Tughrul, A. Sheikh and A. Hussain 5247

Session A19.01 Numerical, computational and theoretical acoustics - General

Optimizing Volume Penalization for Acoustic FDTD Simulations: Modeling Errors and Parameter Selection
Y. Schubert and M. Lemke 5257

Generation of sound waves by nonlinearly evolving two-dimensional coherent structures on a turbulent subsonic mixing layer
Z. Zhang, W. Ji and X. Wu 5261

Data-driven discovery of nonlinear wave equations in weak formulation
A. Furmanová, V. Hruška and T. Filipska 5269

Uncertainties and Efficiency of Bayesian Decay Analysis
N. Xiang and Z. Sü Gül 5275

Acoustic Field Reconstruction in Tubes via Physics-Informed Neural Networks
X. Luan, K. Yokota and G. Scavone 5279

Machine learning for modelling band structure properties
A. Furmanová, V. Hruška and A. Bajicová 5287

Session A19.02 Numerical methods for acoustics and vibration

Identification of acoustic characteristic of tweeter loudspeakers for car cabin sound quality simulations
E. Garofalo, G. Costa, G. Isacchi, S. Talucci, M. Olivieri, M. Ebri and F. Ripamonti 5293

Development and comparative analysis of novel Component Mode Synthesis Methods for structural and acoustic applications
S. El Kadmiri Pedraza, S. Algermissen and H. P. Monner 5301

Reduced-order transient simulations of the convected wave equation with perfectly matched layers
Y. Cai, G. Gabard, S. Van Ophem, W. Desmet and E. Deckers 5309

Application of Craig-Bampton reduction in vibro-acoustic coupling
S. El Kadmiri Pedraza, S. Algermissen and H. P. Monner 5317

Applicability of the Discontinuous Galerkin method for outdoor noise propagation simulations
F. Kraxberger, J. Heinz, A. Wurzinger, M. Kaltenbacher, S. Schoder and C. Adams 5325

Isogeometric FEM/BEM approach for a coupled acoustic fluid-structural interaction systems
A. M. Shaaban and S. Marburg 5329

On the usage of acoustic radiation modes for Krylov subspace reduction of acoustic finite element models in the time domain
S. Van Ophem 5333

Reconstruction Of Radiated Acoustic Fields Using 3D Laser Vibrometry And FEM Simulation: A Comparative Study Of Interpolation Approaches
P. Nieradka, M. Veloso, J. Jóska, B. Chmielewski, M. Kozupa and G. Kmita 5337

Investigation of the influence of slip-operators on ultrasound pulse-based sound generation principles
D. Mayrhofer, T. Wilczacki and M. Kaltenbacher 5343

Investigation of Memory Efficient Convolutional Truncation Methods for the 2D Time Domain Boundary Element Method
D. Kılıçarslan, D. Panagiotopoulos and E. Deckers 5351

Using open software modeling tools for innovative transducer designs
M. Moszyński, I. Pérez Arjona and V. Espinosa Roselló 5359

An Absorbing Boundary Condition Formulation For Fast Frequency Sweep Of Unbounded Acoustic Finite Element Problems
P. Mariotti, H. Mao, S. Schopper and R. Rumpler 5363

Session A19.05/A10.06 Numerical methods for acoustic materials and metamaterials

Design and Optimisation of a Multi-Layer Porous Barrier with Tunable Resonators
L. Sousa, L. Godinho and P. Amado Mendes 5373

Periodic boundary conditions in finite difference time domain
J. Galiana Nieves, R. Picó, D. Ramírez-Solana and J. Redondo 5381

Non reciprocity in spatiotemporal sonic crystals
J. Galiana Nieves, J. Redondo, V. J. Sánchez-Morcillo and R. Picó 5389

A meshfree approach for sound wave propagation in periodic media with multi-layer porous inclusions
L. Godinho, N. Herrera-Leon, P. Amado Mendes, A. Pereira and J. Redondo 5395

Model-based auralization of vibro-acoustic metamaterial partitions
L. Van Belle, F. Di Giusto and E. Deckers 5399

Geometrical optimisation of an acoustic metamaterial for low-frequency sound absorption
M. L. López Ibañez, A. Melis, J. Muñoz-Paniagua, C. Díaz and E. Latorre Iglesias 5407

Investigation of Stop Band Behavior in complex finite Vibroacoustic Metamaterial Structures using a Power-based Method
H. Atzrodt, A. Maniam, N. Kleinfeller and S. Rieß 5415

Session A19.06/A07.05 Methods for advanced computational aeroacoustics

Separating aerodynamic from acoustic-induced velocity on a portion of an acoustic liner through modal decomposition methods
F. Scarano, B. Lyu, A. Paduano and F. Avallone 5423

Prediction of in-duct aeroacoustic noise of a mechanical ventilation system
R. Sevenois 5431

Acoustic Propagation Through Diffuse Interfaces
A. Ballout, O. A. Marino, G. Rubio and E. Ferrer 5437

An Advanced Boundary Integral Formulation for Sound Scattered by Deforming Bodies
B. De Rubeis, M. Gennaretti, G. Bernardini and C. Poggi 5441

Sound source identification based on balance of acoustic energy
J. Kreuzinger and F. Schwertfirm 5449

Stability investigations of solid wall immersed boundary schemes for the linearized Euler equations in multidimensions
M. G.S. Izsak and H.-J. Kaltenbach 5453

Numerical And Experimental Zig-Zag Trip Effects On A Low Reynolds Number Propeller
M. Lattari, A. Beck, G. C. Vicente, F. D. Silva, J. P. L. C. Salazar, J. A. Cordioli and C. J. Deschamps 5463

Session A19.07 Validation and benchmarks in computational acoustics

Validation study of broadband numerical methods for room acoustic simulations and binaural rendering in a furnished room
H. Sampedro Llopis, S. Guðjónsson, M. Cosnefroy, H. Hafsteinsson and F. Pind 5471

Benchmarking Room Acoustic Sound Particle Simulations incorporating Uncertainty-Based Diffraction: Challenges and Strategies
I. Herrero-Durá, T. Judd, S. Weigand, J. Hörmeyer and J. Schaal 5477

Acoustic characteristics of an open-fan model from semi-analytical predictions and wind tunnel measurements
C. Polacsek, V. Daydé-Thomas, S. Fauqueux, J. Mardjono and M. Descamps 5485

Comparing Open Source Room Acoustics Simulation Tools: Performance and Usability Insights
L. Dijkman, N. Hoekstra and M. Hornikx 5493

Input data for room acoustic simulations: ray-based vs hybrid models of a rectangular room
G. Fratoni and D. D'Orazio 5501

Testing of commercial software to generate simulated impulse responses for Personal Sound Zones systems
D. De La Prida, G. Piñero, L. Fuster and L. A. Azpicueta-Ruiz 5505

Measures of validation for computational room acoustics
A. Prinn, Z. Xu and E. Habets 5513

Numerical validation of VLES-LBM for predicting aerodynamic and acoustic phenomena in propeller-wing ultra-tight separation distances
M. Lattari, A. Beck, L. T. Moresco, F. D. Silva, J. P. L. C. Salazar, J. A. Cordioli and C. J. Deschamps 5521

Unlocking the Potential of Open Research Software in Acoustics: lessons learned from the Nantes workshop
M. Hornikx, H. Wang, I. Fichera, S. Willemsen and L. Paganini 5529

Session A19.08/A10.10 Numerical methods for wave propagation in complex media

Streamlined model of porous media for Finite Difference Time Domain schemes
P. Camblor Iglesias, L. Godinho and J. Redondo 5539

Inspection of welding joints using elastoacoustic signals via topological derivative
C. Placinta, S. Muñoz and M.-L. Rapún 5547

Numerical Quantification Of The Bivalve Presence In Granular Sediments On Coastal Seabeds
A. Prieto and P. Rubial 5553

DG-Trefftz method with radiating boundary conditions imposed via the NtD map: Analysis on a waveguide
P. Monk, M. Pena and V. Selgas 5555

A 3D finite element model of ultrasonic waves travelling through pervious concrete
A. Spalvier, N. Pérez, P. Garcén, L. Hernández and G. Cetrangolo 5559

Generalized plane wave quasi-trefftz spaces for wave propagation in inhomogeneous media
I. Fontana and L.-M. Imbert-Gerard 5565

Efficient Simulation Of Time-Domain Acoustic Wave Propagation In Unbounded And Penetrable Media
V. Dominguez, M. Ganesh and F. Le Louër 5573

On the Acoustic Investigation of Complex Buildings materials by Physics Informed Neural Networks (PINN)
S. Ryehan, I. Z. Soma and J. Naumann 5581

Session A19.09 Numerical methods for room acoustics

Session A20.01 Transportation noise and vibration - General

A source model for airborne noise from ship traffic in fairways
A. Genell and A. Gustafson 5593

Rolling resistance and Rolling noise assessment of bituminous mixtures
M. Ramón Martínez, V. Fernández Vázquez, F. J. Terán Sierra, Á. M. Martínez García-Hoz and S. Expósito Paje 5601

Analysing the Effect of undetected flights in the comparison of measured and modelled aircraft noise
R. Van Der Grift, A. S. Jayanthi, M. Snellen and A. Amiri-Simkooei 5607

IOTA: A positional data processing software for aircraft noise simulations
T. Ramseier, M. Gligorijevic, S. Plüss and B. Schäffer 5615

Session A20.02 Automotive noise and vibration

Modeling of the load transmissibility up to 300Hz of an vehicle air suspension
J. Jang, J. Lee, S. Park, J. Jung, S. Lee and B. Sohn 5623

Comparing Measured Pass-by Levels of Accelerating Battery Electric Cars and Combustion Engine Cars
A. Heusser, J. Jäggi, M. Elser, S. Grunder and R. Pieren 5627

Psychoacoustic assessment of synthetic sounds for electric vehicles in a virtual reality experiment
P. Bazilinskyy, M. S. Alam and R. Merino-Martinez 5635

The use of virtual reality for the subjective evaluation of vehicle cabin interior refinement levels
E. Harry and R. M. Kirby 5643

The determination and ranking of interior cabin noise sources via advanced matrix manipulation
E. Harry and R. Morris-Kirby 5647

XAI based Frequency-Time feature Extraction and development of an optimal evaluation method for C-EPS
J. Park, H. Jo, I.-J. Cho, J. Seo, S.-S. Yoo, S. Lee, S.-J. Bang, J.-L. Oh, C. Jeong and S.-Z. Cho 5653

Research on Integrated Virtual Component Sound System
B. Kang, H. Jo, J. Seo, K. Park and K. Baek 5661

Session A20.03 Road traffic noise and vibration

Loudspeaker Array-Based Auralization of Electric Vehicle Noise in Living Environments
L. Müller, J. Ahrens and W. Kropp 5669

Comprehensive Frequency Spectrum Analysis of Metro Rail Noise for Environmental and Acoustic Insights
V. Laxmi and H. Phuleria 5677

Model-Based Approaches for Acoustic Pavement Characterization
U. Pachale, F. Georgiou, J. Jäggi, D. Wöllstein, A. Heusser and R. Pieren 5681

Evaluation Of Road Noise Prediction Models In Ireland: A Comparison Of CNOSSOS-EU And CRTN Source Models
P. Redondo Martinez and E. King 5685

Impact of the choice of road traffic speed data on modelled environmental noise
A. Sheehan, S. Beevers, A. Beddows and J. Gulliver 5693

Microscopic and Dynamic Road Traffic Noise Model Coupled with a Vehicle Recognition and Tracking Video Analysis Tool
D. Rossi, A. Pascale, A. Mascolo, M. Coelho and C. Guarnaccia 5701

Experimental Assessment of Different Car Driving Styles and Their Role in Road Traffic Noise Annoyance Reduction
M. Czuka, A. Fiebig, M. Schuck, M. Conter, C. Moshona, M. Chudalla and F. Strigari 5709

A case study of prediction accuracy of ASJ RTN-Model 2023 on Japanese general roads
K. Yamauchi and K. Yoshimura 5717

Comparison of a Stochastic and Microscopic Road Traffic Noise Models Using Variable Level of Aggregation of Traffic Flows
A. Mascolo, D. Rossi, M. Nigro, B. Gauvreau and C. Guarnaccia 5725

Acceleration Noise From Electric Cars Matters
S. Baclet and R. Rumpler 5733

Design of Vibration Isolation system for Multiple number of Spacecrafts Transportation Container
D. S. Srivastava, S. Sahu, B. P V and R. V. Nadagouda 5741

Relative importance of road traffic in the temporal structure of city noise
J. M. Barrigón Morillas, D. Montes-Gonzáez, G. Rey Gozalo and R. Vílchez-Gómez 5747

Challenges In Real-Time Low-Cost Vehicle Recognition Systems For CNOSSOS-EU Input
L. Fiorella, D. Profumo, F. Petrongolo, G. De León, F. Artuso, L. Fredianelli, G. Licitra and E. Ascari 5755

Audio-Video Acquisition System For Dynamic Road Pavement Monitoring
F. Petrongolo, L. Fiorella, G. De León, D. Profumo, F. Artuso, A. Monticelli, F. D'Alessandro, E. Ascari, G. Licitra and L. Fredianelli 5761

Session A20.04 Tyre/road noise

New road surface source correction factors for Nord2000 calculations in Sweden
A. Genell and A. Gustafson 5771

Image-based prediction of noise: a two-step conceptual model
F. G. Praticò and V. N.K. Mypati 5779

Machine Learning techniques for tyre rolling noise on rubberized asphalt roads
S. Kanka, F. Artuso, A. Moro, F. Fidecaro and G. Licitra 5785

In-situ evaluation of tyre/road noise of a pavement based on footwear waste
N. Campillo-Davo, R. Peral-Orts, H. Campello-Vicente, M. Fabra-Rodriguez, D. Abellan-Lopez, A. B. Muñoz-Milan, B. Mateu-Romero and F. Aran-Ais 5791

Long-term tyre/road noise comparison of different road surfaces measured by CPX method
P. Markova, B. Hablovicova and V. Krivanek 5797

Influence of velocity on the frequency spectra of SMA 11 road surface measured by CPX method
B. Hablovicova, P. Markova and V. Krivanek 5803

Session A20.05 Railway noise and vibration

Method for Railway Noise Event Detection: experiment using Medusas sensors
M. Hellot, M. Sineau and C. Mietlicki 5811

GENIFER feasability study - Assessing railway noise instantaneous annoyance with in-situ listening test
M. Hellot, R. Mafféis, M. Sineau, A.-S. Evrard and J.-P. Regairaz 5817

VibraSIG - Modeling railway structure-borne noise and vibrations and implementation in QGIS geographic information software
R. Walther 5825

Framework for the assessment of uncertainty of high-speed train pantograph aerodynamic noise predictions
E. Latorre Iglesias, G. García Barrios, M. L. López Ibañez, A. Melis, J. Muñoz Paniagua and D. Thompson 5831

BIM-Based Noise Protection Planning in Railway Infrastructure
J. Bartnitzek, L. Höhle, J. Egeler, A. Schlesinger, M. Liepert, C. Huth, C. Ende, D. J. Meyer, T. Koch, B. Schlüter and R. Böhme 5839

The influence of nonlinear behaviour of reinforced concrete structures on numerical modelling for vibration
M. Österreicher 5845

A method for track-independent railway vehicle characterization as ground-borne vibration sources based on blocked forces
R. Arcos, A. Clot, Y. Shafieyoon and J. Meggitt 5851

Study of the effect of ballast properties and wheel geometry on rolling noise
E. M. Sánchez Orgaz, V. T. Andrés, J. Martínez Casas and F. D. Denia 5859

Session A20.06 Noise barriers and mitigation techniques for road traffic and railway

The design of a sonic crystal noise barrier for an evolving urban area
G. Fusaro and M. Garai 5865

Noise barriers: what really matters and what doesn't?
J. P. Clairbois, P. Houtave and M. Garai 5869

Assessment of efficiency of WHIStop diffractor for road traffic noise abatement
E. King, S. Horsman and M. Manohare 5875

The ECODRIVE Project: Traffic Management and Control Measures to Mitigate Road Traffic Noise
T. Onorato and P. Bellucci 5883

Session A20.07 Aircraft noise

AAVT: A Tool To Run Virtual Surveys With Passing Aircraft
G. Isherwood, J. Eccles and G. Memoli 5893

Exposure-response relationships between aircraft noise and annoyance or sleep disturbance for Dutch civil and military airports
M. Reedijk, R. Van Poll, J. Hoekstra, W. Swart, J. Van Der Kassteele, A. Sahai and D. Houthuijs 5901

Sound Characteristics and Perception Study of new Generation of Turbofan Aircraft
R. Aalmoes, N. Sieben and S. Nolet 5907

Indoor and Outdoor Noise perception of communities near Schiphol Airport
N. Sieben and R. Aalmoes 5915

Krueger flap noise generation on a semi-span aircraft model
L. Sanders and M. Pott-Pollenske 5923

Aircraft Noise-Induced Annoyance Analysis Using Psychoacoustic Listening Experiments
R. Merino-Martinez and V. S. Buzetelu 5929

Evaluation Of Audio-Visual Parameters In The Perceived Aircraft Noise Annoyance In Virtual Reality Experiments
S. A. Priboi and R. Merino-Martinez 5937

Low-Noise Propeller Optimization Via Blade Sweep And Uneven Spacing
F. Fruncillo, P. Luchini and F. Giannetti 5945

Community And Cabin Noise Assessment Of A 19-Seater Hydrogen-Electric Airliner
M. Barbarino, G. Fasulo, A. Pagano, A. Visingardi, F. Morlando, F. Petrosino, M. Zupanič and J. Drofelnik 5953

Exploring Acoustic Signatures of Different Aircraft Types and Operations Using Advanced Data Analysis
I. Besnea, A. Amiri-Simkooei, I. Dedoussi and M. Snellen 5961

Session A21.02 Applied sound-driven design

Mitigating Motion Sickness in Electric Vehicles Through Active Sound Design
S. Kim, J. Yang and M. E. Altinsoy 5971

Sound design in beauty tech: improving the sounds of hair dryers
A. Bhatara, A. Suwanto, S. Romagny and D. Morizet 5975

Design and evaluation of the SoundAsleep app: the impact of emotional states on sound preferences for sleep
S. Hallak, A. Choubey and S. Pauletto 5983

SoundAI: Exploring culture-sensitive and environmentally-conscious applications for AI-supported sound-driven design
E. Özcan, S. Mora, F. Duarte and S. Lenzi 5991

From Research to Practice: A Collaborative Approach to Tackling Alarm Fatigue in ICUs
I. Bostan, R. Van Egmond, D. Gommers and E. Özcan 5999

Experimental Evidence Shows that Auditory Icon Clinical Alerts Work Better than Tones
J. Edworthy 6007

Session A21.03 Listening experience in sound-driven design

Rotary Engine Essence Utilization for In-Car Sounds Driven Design
M. Yamamoto, S. Ishimitsu, Y. Mitsuda, S. Fujikawa, K. Iwata, M. Kikuchi, M. Matsumoto, S. Kodama and H. Inaki . 6013

Listening and talking about sound: exploring effective descriptors for everyday sounds with non-expert listeners
D. Larsson Holmgren, N. Misdariis and S. Pauletto 6019

Exploring the benefits and boundaries of auditory representations in service design
A. Kuštrak Korper, J. Blomkvist and V. Rodrigues 6029

Investigating strategies in a sound design for sustainability exercise in an educational setting
G. Marentakis and S. Delle Monache 6033

A Design Guideline For Gamified Intervention For Managing Hyperacusis: Insights From Expert Interview
Q. Liu, T. Wang, H. Yang and E. Özcan 6041

Session A21.04 Methodologies for sound-driven design and education

From framework to practice: Les_Sons, a product sound tool for design education
S. Delle Monache, T. Delfrap, N. Misdariis, D. Murray-Rust and E. Özcan 6051

Designing Sounds For Exhibitions: Tools To Enhance Sound-Driven Design Strategies
M. Riva and R. Trocchianesi 6059

Sound-Driven Design in Astronomy: the long-term impact of design and evaluation activities on the development of astronomical data sonification tools
S. Pauletto and N. Misdariis 6067

Acoustic Design Case Studies Of Educational Spaces For Neurodivergent Individuals
F. Bettarello, M. Di Prisco, G. Scavuzzo and M. Caniato 6075

Session A22.02/A02.02 Underwater soundscape and noise: modelling, measurements and effects

Comparative analysis of three underwater soundscapes
J. Ramis-Soriano, P. Poveda Martinez, J. Carbajo San Martín, A. Forcada Almarcha, C. Valle Pérez and N. Ullah 6083

Numerical modeling of low frequency sound propagation in three dimensional shallow marine environment with solid seabed
P. Klin and U. Tinivella 6091

Acoustic indicators of ecosystems' and energy dynamics in marine environments
A. Pomaro and P. F. Moretti 6095

An Optimized MATLAB Software Package for the Analysis and Characterization of Underwater Sound Produced by Wind Farms
J. A. Díaz, S. Neves and E. Delory 6101

Advanced far-field vibro-acoustic modeling of underwater pile driving for offshore noise mitigation
J. Perchaud, M. Fruchart and C. Lagarrigue 6107

The Hidden Patterns of Marine Soundscapes:A Better Approach for Identifying and Counting Sources of Sound in Marine Areas of Special Conservation
F. L. Rosa González, J. P. Lüke, S. Garcia Beitia and J. Almunia Portoles 6113

New Methods For Studying Underwater Noise Effects On Microscopic Sessile Marine Invertebrates: Challenges And Perspectives
L. Manni, G. Sabbadin, S. Domenichi, L. Ballarin, V. Zaffaroni-Caorsi and G. Zambon 6117

On the problem of underwater sound mapping in shallow waters: a case study
A. Aguirre, E. Robles Arnao and E. Ruiz 6125

Acoustic characterization of Panarea's hydrothermal system
S. Viola, D. Bonanno, L. S. Di Mauro, D. Diego-Tortosa, C. Gomez Garcia, A. Idrissi, G. Riccobene and S. Sanfilippo . 6131

Vibro-Acoustic Study Of A Small Glass Walled Fish Tank: An Experimental And Theoretical Approach
N. Ullah, J. Carbajo San Martín, P. Poveda Martinez and J. Ramis-Soriano 6135

Underwater noise survey in the Turku Archipelago
V. Hongisto, R. Alakoivu, O. Outinen, J. Sahlsten and O. Loisa 6143

Methodology For Underwater Noise Level Measurement From Dredging Activities
S. Nuñez Gutierrez and D.P. Ruiz Padillo 6147

An Open Dataset for Exploring Underwater Soundscapes and Vessel Noise in Barcelona, Constanța and Lagoon of Venice Basins
I. Nou-Plana, A. Teaca, F. Gazzada, M. Freixes, G. Zambon and R. M. Alsina-Pagès 6155

Streamlining Underwater Acoustic Propagation Modeling with a Python-Based Interface
I. Urtiaga Chasco and A. Hernández Guerra 6163

Sounds generated by a fixed offshore oil and gas platform during production periods
N. Pérez Gimeno, J. L. Cueto-Ancela and E. Nava Baro 6169

Acoustic study of diving sperm whales during a week of continuous monitoring in the western Ionian Sea
V. Sciacca, A. S. Briguglio, F. Caruso, L. S. Di Mauro, F. Filiciotto, C. Pellegrino, G. Riccobene, F. Simeone and S. Viola 6177

The Marine Soundscape of Kongsfjorden, Svalbard: Two-Year Study on Spectral Variability and Environmental Drivers
V. Sciacca, M. Azzaro, G. De Vincenzi, F. Giglio, P. Giordano, L. Langone, S. Miserocchi, F. Paladini De Mendoza and F. Filiciotto 6181

Exploratory Study On The Acoustic Characterization Of Transit And Trawling Noise From Fishing Vessels In The Strait Of Sicily
S. Ferri, G. Sorrentino, R. Grammauta, G. Milisenda and F. Caruso 6185

The Project KNOWHALE: Improving Knowledge On Fin Whale Acoustic Occurrence And Behaviour In The Central Mediterranean Sea
G. De Vincenzi, F. Caruso, S. Ferri, F. Filiciotto, L. Beranzoli, V. Cardin, S. Miserocchi, T. Sgroi and V. Sciacca 6191

SOS Bass project: acute and chronic effect of vessel noise disturbance on farmed fish
D. Bertotto, F. Filiciotto, T. Gaggero, L. Marinelli, C. Guérineau, M. Bortoletti, A. Meloni, F. Colotto, V. Sciacca and P. Mongillo 6195

Communicating in noisy waters: how shipping noise and environmental conditions affect blue and fin whale calling activity
Z. Groenewoud, M. Baumgartner and A. Širović 6199

Session A22.03 Communication, positioning and acoustic sensor systems

Time synchronization of long-term underwater acoustic observations: the challenge of autonomous hydrophones without global clock baseline
D. Nazarpour, P. F. Moretti, S. Buogo and A. Pomaro 6205

Design Of An Autonomous Low-Cost Acoustic Acquisition System Based On Intensimetric Sensors For Underwater Acoustics Scenarios
J. D. Pastor Sar, J. Carbajo San Martín, P. Poveda Martinez, J. Ramis-Soriano and E. G. Segovia-Eulogio 6213

Design And Fabrication Of An Acoustic Leaky-Wave Antenna For Underwater Applications
A. Fernández-Garrido, M. Campo-Valera, R. Picó, E. Abdo-Sánchez and R. Asorey-Cacheda 6221

Studies On The Conceptual Design Of An Acoustic Sensors Array For Neutrinos Event Triggering
C. A. Quiroz Rangel, M. Ardid, D. Diego-Tortosa, G. Riccobene and S. Viola 6227

Session A22.04 Traffic ship noises

Interacting Multiple Model Target Tracking Algorithm for Underwater Maneuvering Targets Based on Transformer
Y. Liu, T. Ji, X. Ma, X. Wang, C. Feng, P. Li and Y. Hu 6235

The Spatio-Temporal And Frequency Modeling Of Deep-Sea Surface Reverberation Caused By Different Waveforms
X. Wang, X. Pei, X. Ma, C. Feng and Y. Liu 6243

The Italian Ocean Sound monitoring sub-system for the 'Italian Integrated Environmental Research Infrastructures System (ITINERIS)' project
S. Sanfilippo, D. Bonanno, L. S. Di Mauro, D. Diego-Tortosa, A. Idrissi, G. Riccobene and S. Viola 6251

Impact of Maritime Traffic Noise on Juvenile Dicentrarchus labrax
P. Giner Tarazona, I. Pérez Arjona, J. Ramis-Soriano, V. Espinosa Roselló, M. Mauro, P. Poveda Martinez, V. Arizza, M. Vazzana, A. Vizzini and R. De Luca 6259

The characteristic spectrum of vessels in different European basins
G. Zambon, F. Gazzada, I. Nou-Plana and R. M. Alsina-Pagès 6263

Modeling of a ship sound recorded by an ocean bottom seismometer
S. Pinson 6269

Ship Propeller Non-Cavitating Noise In Non-Uniform Flow
M. Brun, S. Pinson, J. Carpentier and J.-A. Astolfi 6275

The OceanSoundModel: a GUI for shipping noise predictions
O. C. Rodríguez, S. Jesus, H. Chognot and L. O. Júnior 6283

Session A22.05 Geophysics and Distributed Acoustic Sensing (DAS) capabilities

Trans-dimensional Bayesian matched-field inversion for seabed geoacoustic profiles
S. Dosso and J. Bonnel 6293

Optimization Of Sparse Sampling And Interpolation For Seismic Data Compression Using A Genetic Algorithm
N. Giovanardi, L. Lobato, J. Leal Filho and S. Paul 6297

Advances in Optoacoustic Technologies for Monitoring the Ionian Sea
D. Diego-Tortosa, S. Aurnia, G. Cappelli, M.-A. Gutscher, C. Gomez Garcia, A. Idrissi, L. Quetel, G. Riccobene, A. Tricomi and S. Viola 6303

Assessment On The Potential Of Distributed Acoustic Sensing In The Gulf Of Catania
A. Idrissi, D. Diego-Tortosa, L. S. Di Mauro, F. Grenga, C. Gomez Garcia, G. Laudani, G. Riccobene, S. Sanfilippo, A. Tricomi and S. Viola 6311

Pre-stack Seismic Data Compression Using U-net-Based Predictors
J. Leal Filho and S. Paul 6319

Underwater sound detection with taut, vertically suspended fibre-optic cable and distributed acoustic sensing

TOPOLOGY OPTIMISATION OF MICROPHONE ARRAYS FOR REMOTE MICROPHONE VIRTUAL SENSING IN DIFFUSE SOUND FIELDS

Achilles Kappis* **Jordan Cheer**
Institute of Sound and Vibration Research, University of Southampton, Southampton, UK

ABSTRACT

Past research has shown that virtual sensing techniques can enhance the performance of active noise control systems by projecting the control points towards remote locations of interest. However, accurate sound field estimation using virtual sensing is critical to the performance of such active control systems and depends on both signal processing and the physical microphone array. Typically, microphone placement is determined by practical considerations such as convenience, spatial constraints and cost, resulting in limited exploration of optimal microphone positioning. The current study employs a genetic algorithm to identify optimal microphone array configurations for accurate estimation of the pressure in a diffuse sound field, utilising the Remote Microphone Technique. The optimality criterion is defined as the estimation performance or the robustness of the derived topologies to practical uncertainties. The resulting optimal configurations are evaluated against a conventional uniform linear microphone array, which consist of sub-array elements capable of utilising both pressure and pressure gradient information for enhanced estimation accuracy.

Keywords: *Virtual sensing*, *Remote Microphone Technique*, *Microphone arrays*

1. INTRODUCTION

Virtual Sensing (VS) has been effectively integrated in to local Active Noise Control (ANC) systems such as the active headrest and has been shown to improve control performance [1, 2].However, this is reliant on accurate estimation of the sound field at the remote location of interest [1, 3]. In general, VS studies have focused on the use of physical microphone arrays with rather straightforward geometries, such as linear or circular arrays [4, 5]. Additionally, in many practical applications, microphone placement is dictated by constraints in the system such as limited space availability and convenience. Thus, limited research has been undertaken investigating more complex or flexible microphone positioning that is solely based on providing optimal estimation performance. The problem of finding the optimal combination of sensor positions, in the ANC context, has been investigated in the past [6] with the use of Genetic Algorithms (GAs) providing promising results [5]. However, in most of the studies presented in the literature the optimal configuration was generated by selecting the combination of microphone positions out of a predefined set. The current work constitutes a preliminary study to investigate the suitability of using a GA to calculate the optimal microphone configurations from a continuous set of available positions. The Remote Microphone Technique (RMT) is used as the VS method employed for the estimation. The estimation error over a grid of virtual microphones and the robustness to uncertainties are used as performance metrics for the calculated microphone configurations and the solutions are compared to a uniform linear array consisting of sub-arrays capable of incorporating pressure and pressure gradient for the estimation of the pressure at the virtual microphones [7–9].

2. REMOTE MICROPHONE TECHNIQUE

2.1 Virtual sensing formulation

The block diagram of a generalised virtual sensing system using the RMT is shown in Fig. 1. The sound field is generated by N_v primary sources with complex strengths $\boldsymbol{v} = \left[v_1, v_2, \ldots, v_{\mathrm{N_v}}\right]^\mathrm{T}$, with $[\,\cdot\,]^\mathrm{T}$ denoting transposition. The source strengths correspond to realisations of uncorrelated wide sense stationary random processes. The signals at the monitoring microphones, $\boldsymbol{d}_\mathrm{m} = \left[m_1, m_2, \ldots, m_{\mathrm{N_m}}\right]^\mathrm{T}$ and at the virtual microphones, $\boldsymbol{d}_\epsilon = \left[\epsilon_1, \epsilon_2, \ldots, \epsilon_{\mathrm{N}_\epsilon}\right]^\mathrm{T}$, are given by

$$\boldsymbol{d}_\mathrm{m} = \boldsymbol{P}_\mathrm{m}\boldsymbol{v} \tag{1a}$$

$$\boldsymbol{d}_\epsilon = \boldsymbol{P}_\epsilon\boldsymbol{v}, \tag{1b}$$

with $\boldsymbol{P}_\mathrm{m} \in \mathbb{C}^{\mathrm{N_m}\times\mathrm{N_v}}$ and $\boldsymbol{P}_\epsilon \in \mathbb{C}^{\mathrm{N}_\epsilon\times\mathrm{N_v}}$ denoting the frequency response functions from the sources to the monitoring and virtual microphones respectively. The sound field at the virtual microphone positions is estimated by applying the observation filter $\hat{\boldsymbol{O}}$ to the monitoring microphone signals. The estimation error is then given by

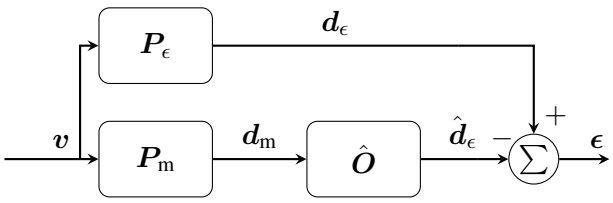

Figure 1. Block diagram of a generalised virtual sensing system. The sound field at the error microphones, $\boldsymbol{d}_\epsilon$, is estimated by applying the observation filter $\hat{\boldsymbol{O}}$ to the signals measured at the monitoring microphones $\boldsymbol{d}_\mathrm{m}$.

$$\boldsymbol{\epsilon} = \boldsymbol{d}_\epsilon - \hat{\boldsymbol{d}}_\epsilon = \boldsymbol{d}_\epsilon - \hat{\boldsymbol{O}}\boldsymbol{d}_\mathrm{m} = \boldsymbol{P}_\epsilon\boldsymbol{v} - \hat{\boldsymbol{O}}\boldsymbol{P}_\mathrm{m}\boldsymbol{v}. \tag{2}$$

The optimal filter, in the least squares sense, is calculated by minimising the cost function [3]

$$\begin{aligned} J_2 &= \mathrm{E}\left[\boldsymbol{d}_\epsilon^\mathrm{H}\boldsymbol{d}_\epsilon\right] \\ &= \mathrm{tr}\left\{\boldsymbol{S}_{\epsilon\epsilon} - \boldsymbol{S}_{\mathrm{m}\epsilon}\hat{\boldsymbol{O}}^\mathrm{H} - \hat{\boldsymbol{O}}\boldsymbol{S}_{\mathrm{m}\epsilon}^\mathrm{H} + \hat{\boldsymbol{O}}\boldsymbol{S}_\mathrm{mm}\hat{\boldsymbol{O}}^\mathrm{H}\right\}, \end{aligned} \tag{3}$$

where $\mathrm{E}[\,\cdot\,]$ denotes the expectation operator, $[\,\cdot\,]^\mathrm{H}$ denotes Hermitian conjugation, the quantities $\boldsymbol{S}_{\epsilon\epsilon}$ and $\boldsymbol{S}_\mathrm{mm}$ correspond to the monitoring and virtual microphone power spectral density matrices respectively and $\boldsymbol{S}_{\mathrm{m}\epsilon}$ is the cross spectral density matrix between the monitoring and virtual microphones. These matrices can be calculated with the help of the power spectral density matrix of the source signals, $\boldsymbol{S}_\mathrm{vv}$, as

$$\boldsymbol{S}_{\epsilon\epsilon} = \mathrm{E}\left[\boldsymbol{d}_\epsilon\boldsymbol{d}_\epsilon^\mathrm{H}\right] = \boldsymbol{P}_\epsilon\boldsymbol{S}_\mathrm{vv}\boldsymbol{P}_\epsilon^\mathrm{H} \tag{4a}$$

$$\boldsymbol{S}_\mathrm{mm} = \mathrm{E}\left[\boldsymbol{d}_\mathrm{m}\boldsymbol{d}_\mathrm{m}^\mathrm{H}\right] = \boldsymbol{P}_\mathrm{m}\boldsymbol{S}_\mathrm{vv}\boldsymbol{P}_\mathrm{m}^\mathrm{H} \tag{4b}$$

$$\boldsymbol{S}_{\mathrm{m}\epsilon} = \mathrm{E}\left[\boldsymbol{d}_\epsilon\boldsymbol{d}_\mathrm{m}^\mathrm{H}\right] = \boldsymbol{P}_\epsilon\boldsymbol{S}_\mathrm{vv}\boldsymbol{P}_\mathrm{m}^\mathrm{H} \tag{4c}$$

$$\boldsymbol{S}_\mathrm{vv} = \mathrm{E}\left[\boldsymbol{v}\boldsymbol{v}^\mathrm{H}\right]. \tag{4d}$$

The unconstrained solution to (3) is then given by [3]

$$\hat{\boldsymbol{O}}_\mathrm{opt} = \boldsymbol{S}_{\mathrm{m}\epsilon}\boldsymbol{S}_\mathrm{mm}^{-1} = \boldsymbol{P}_\epsilon\boldsymbol{S}_\mathrm{vv}\boldsymbol{P}_\mathrm{m}^\mathrm{H}\left(\boldsymbol{P}_\mathrm{m}\boldsymbol{S}_\mathrm{vv}\boldsymbol{P}_\mathrm{m}^\mathrm{H}\right)^{-1}, \tag{5}$$

where $[\,\cdot\,]^{-1}$ denotes matrix inversion. The assumption of uncorrelated sources with equal strengths simplifies the source power spectral density matrix to a scaled identity matrix which can be omitted without loss of generality. This formulation enables the calculation of the filter's expected performance without generating multiple sound field realisations, making it suitable for repetitive calculations, such as those required for the optimisation with a GA used in the this study.

2.2 Performance metrics

The monitoring microphone array configurations calculated with the GA are evaluated based on two metrics, the estimation performance and the robustness to uncertainties. The metric used to evaluate the performance of the estimation is the normalised mean squared estimation error. For a single virtual microphone this is given by

$$L_\epsilon = 10\log_{10}\left(\frac{\mathrm{E}\left[\epsilon\epsilon^*\right]}{\mathrm{E}[d_\epsilon d_\epsilon^*]}\right), \tag{6}$$

where $[\,\cdot\,]^*$ denotes complex conjugation. The estimation error gives negative values for good estimation performance with $-\infty$ denoting perfect estimation.

The robustness of the configurations is reported by the condition number of the monitoring microphone power spectral density matrix, $\kappa\left(\boldsymbol{S}_\mathrm{mm}\right)$. Higher condition numbers signify higher sensitivity to uncertainties with the theoretical maximum value being ∞ for singular matrices and the lowest is unity, for a scaled identity matrix.

3. GENETIC ALGORITHM

A GA is used in this work to perform a search of the microphone positions that will provide optimal estimation performance under certain constraints. The search is performed over a constrained two-dimensional continuous spatial domain with MATLAB's built-in GA algorithm. When non-linear constraints, such as those used in this study are included, the underlying algorithm used is the Augmented Lagrangian Genetic Algorithm (ALGA) [10]. A Lagrangian consisting of the fitness values of the individuals complemented by the sum of a scaled transformation of the constraints is minimised in each generation, and the original problem is approximately solved. The high level flowchart diagram describing the algorithm is shown in Fig. 2, and the steps and their associated parameters are described below.

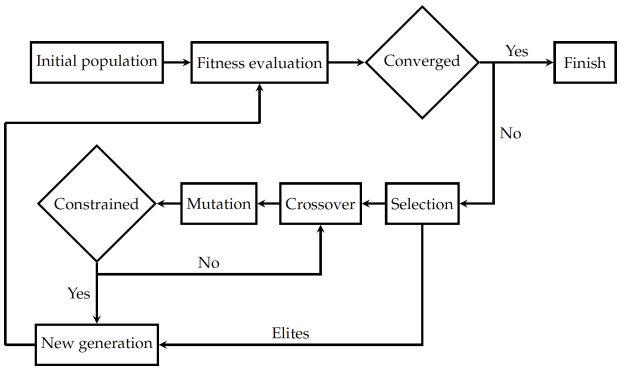

Figure 2. Flowchart diagram describing the genetic algorithm used in the current study.

Population and coding scheme The parameters to be optimised are the positions of the monitoring microphones. The number of microphones is fixed to eight and their x and y coordinates are interleaved in a vector of the form $\boldsymbol{x} = \left[x_1, y_1, x_2, y_2, \ldots, x_{\mathrm{N_m}}, y_{\mathrm{N_m}}\right]$ which constitutes one individual in the population, with one generation consisting of 100 individuals. The population of the first generation is drawn at random from a uniform distribution scaled and shifted to satisfy any imposed constraints.

Fitness function The fitness function defines the performance of each individual. In the current study, two distinct fitness functions are used. The function evaluating the performance of the configurations is defined as the sum of the estimation error values over a spatial virtual microphone grid, given by

$$J_{\mathrm{GA}} = \sum_{i=1}^{N_\epsilon} L_{\epsilon_i}. \tag{7}$$

For the optimisation of the robustness of the configurations, the condition number is used as the fitness function and is directly calculated using the corresponding built-in function in MATLAB. Smaller values denote better performance for both functions so the optimisation is formulated as a minimisation problem.

Selection After the fitness of each individual in a generation has been evaluated, the individuals are ordered based on a scale associated with their performance rank instead of their fitness score. The values are proportional to $\frac{1}{\sqrt{r}}$, where r is the rank of each individual. Ordering the individuals based on their rank removes the effect of the spread of the score values on the convergence of the search [11].

Elitism To ensure useful information is not lost from one generation to the next, the notion of *elitism* is used. The five individuals that scored highest are passed directly to the next generation. This ensures that the best fitness value of each generation cannot be worse than the previous and facilitates convergence to an optimal solution.

Crossover To traverse the search domain, individuals in new generations are created by combining elements of the parameter vectors of solutions in the current generation. After initial trials the percentage of the individuals in the new generation resulting from crossover was set to 80% which provides a good tradeoff between domain search and variability of solutions. For each individual created by crossover five candidates are picked at random and the two with the highest fitness score are chosen as the "parents". To decide which part of the vector will be picked from each parent two integers, n and m in the range from zero up to the number of parameters are picked at random. Elements with indices less than n and greater than m are picked from the first parent and the rest from the second parent.

Mutation The new generation individuals that are not created through crossover result from mutation, which is

the process of applying random changes to some of the values in the parameter vectors of current generation individuals. To perform the mutation, a direction in the space of the parameter vector is picked and scaled at random. If any imposed constraints are not satisfied the direction and scale are adapted.

Constraints and bounds The minimum value of the estimation error given by Eq. (7) has been constrained to be great than -30dB for each virtual microphone, which aims to discourage solutions that achieve effective estimation on average across all positions by achieving extremely low error at a small number of microphone positions.

The values describing the coordinates of the microphones have been constrained to satisfy two conditions. Firstly, the microphones must not be located outside of a specified area to avoid overly favourable positioning overlapping with the virtual microphone grid. Secondly, the minimum allowed distance between the microphones is constrained to be approximately 0.0354m. This constraint serves a twofold purpose: first, to avoid overlapping microphones, and second, to ensure comparability with the "conventional" array against which the solutions are compared.

Termination conditions The optimisation is performed until 300 generations are evaluated, or the best fitness value change is smaller than 10^{-1} for 100 successive generations. At this point, the parameter vector associated with the best fitness values is returned as the optimal solution.

4. SIMULATIONS

4.1 Simulation setup

The GA was used in a scenario where monitoring microphones could be positioned over a rectangular spatial domain with side equal to 0.5m. A rectangular $0.5\text{m}\times0.25\text{m}$ grid of 10×10 virtual microphones was used to evaluate the fitness function of Eq. (7). The complete geometry of the optimisation problem is presented in Fig. 3.

To facilitate comparison with a past study [9], a two element Uniform Linear Array (ULA) of inter-element distance of 0.1m was implemented and positioned parallel to the x Cartesian axis, as shown in Fig. 3. Each array element consists of a sub-array with two pairs of microphones, one orientated parallel to the x-axis and one to the y-axis. The distance between the two microphones of each pair is 0.05m.

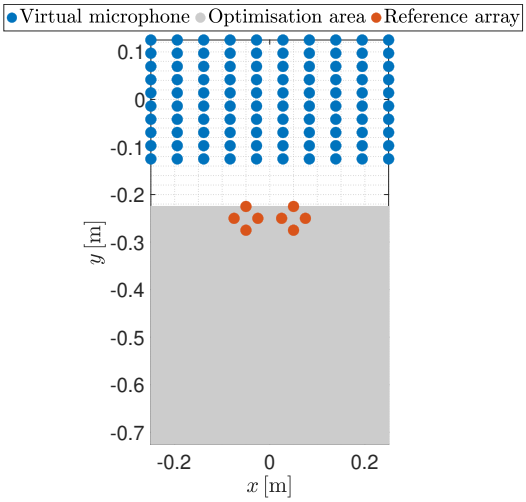

Figure 3. Geometry of the optimisation problem. Virtua microphones are denoted with blue dots and the microphones of the reference linear array with red dots. The grey square denotes the area the algorithm uses for the candidate monitoring configurations.

A diffuse sound field was generated by a constellation of 501 ideal point sources on the surface of a sphere with radius of 10m arranged on a Fibonacci lattice. At low frequencies, the impact of the microphone topology is obscured by the increased performance due to high coherence between the monitoring and virtual microphones [2, 4]. For this reason, the optimisation was performed at a frequency of $f = 1\text{kHz}$, although the performance has been assessed over a broader frequency range.

4.2 Optimising estimation performance

First, the GA was used to calculate microphone configurations that provide optimal performance by minimising the fitness function of Eq. (7). The optimisation was performed five times and the spatial distribution of the estimation error over the virtual microphone grid at the optimisation frequency is presented in Fig. 4, along with the performance of the reference ULA. The black line indicates the area over which the estimation error is less than -10 dB.

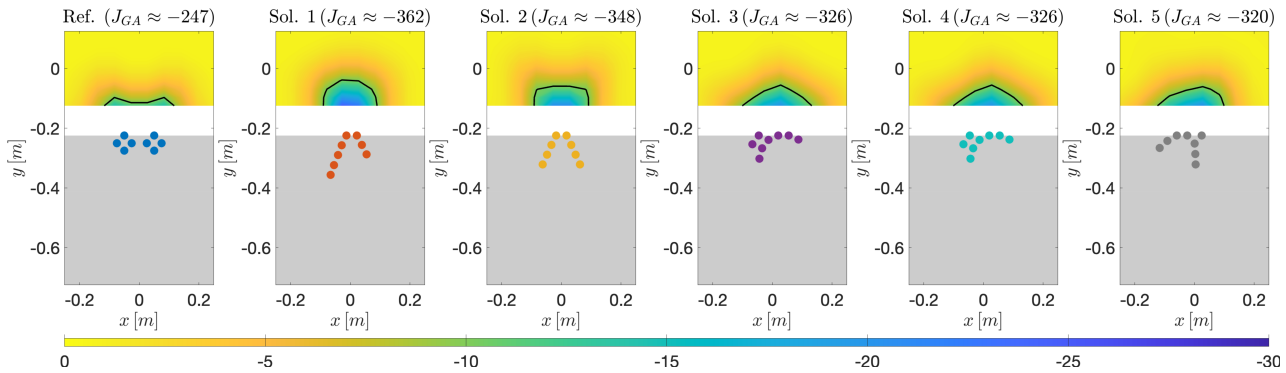

Figure 4. Spatial estimation error distribution for the microphone configurations calculated with the GA at the frequency of 1 kHz. The solid line (–) indicates the area over which the estimation error is less than -10 dB.

The configurations obtained with the GA yield significantly lower fitness values than the reference design. For the GA setups, areas with estimation errors below -10 dB consistently extend further from the microphone array, and the lowest error achieved is consistently lower than that of the reference arrangement.

Distinct patterns are observed in the topologies of the solutions. The configurations with the best fitness scores, solutions 1 and 2, consist of linear sub-arrays oriented toward the estimation area, extending the -10 dB error zone along their axes [5,9]. The other configurations utilise the same mechanism, to a lesser extent, combined with microphone placement near the virtual microphone grid to achieve a low fitness value, resulting in slightly worse estimation spread over a larger area.

The performance gain achieved with the calculated configurations comes at the cost of increased sensitivity to uncertainties, which is reflected in the condition numbers associated with the arrays. Fig. 5 presents the condition numbers for the calculated arrays at frequencies from 50 Hz to 2 kHz. The condition numbers range from about 10^6 for the reference array to approximately 2.5×10^7 for the solution with the lowest fitness score at the optimisation frequency, with the span increasing significantly at lower frequencies. Additionally, it is important to highlight the large range of the fitness scores being 42 dB at the frequency of 1 kHz.

4.3 Optimisation with constrained condition number

An additional constraint on the upper bound of the condition number was introduced to control the sensitivity of

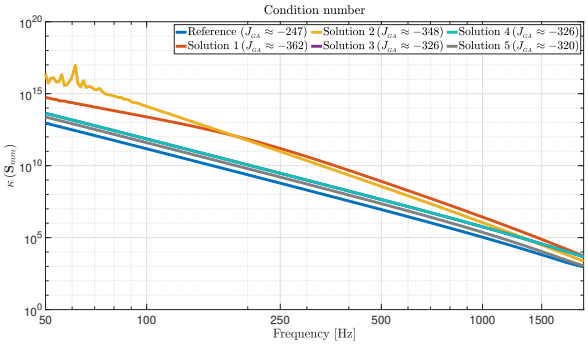

Figure 5. The condition number for the arrays calculated with the genetic algorithm for frequencies from 50Hz to 2kHz.

the calculated arrays. Additionally, solutions 2 and 3 of Fig. 4 were included in the initial population. The optimisation was performed five times for each of the condition numbers from 10^3 to 10^8 with a geometric step of 10. The spatial distribution of the estimation error for the configurations associated with the lowest fitness score from each trial are shown in Fig. 6.

Even with the condition number constrained to low values, the optimised arrays achieve lower function scores than the reference array. The spacing between microphones is larger under strict condition constraints and decreases with more relaxed bounds. The topologies exhibit significant similarities; for condition bounds up to 10^5, the primary difference between configurations is the micro-

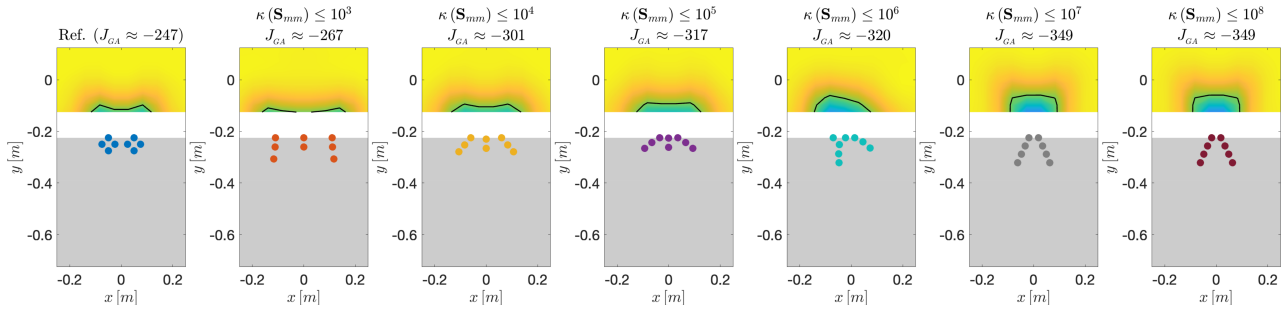

Figure 6. Spatial estimation error distribution for the microphone configurations associated with the lowest fitness score when the condition number is constrained. The solid line (–) indicates the area over which the estimation error is less than -10 dB.

phone spacing. At higher condition constraints, the optimal configurations resemble those calculated without any constraint on the condition, indicating that further relaxation of the bound is unlikely to yield significant performance benefits.

Fig. 7 presents the condition numbers of the microphone configurations of Fig. 6. The conditioning of the arrays is consistent with the imposed constraints up to approximately the optimisation frequency. For constraint values of 10^6 and higher, the configurations with the best fitness scores are those introduced in the initial population, and their condition does not reach the bound. Notably, among the two configurations, only the one returned for $\kappa(\boldsymbol{S}_{\text{mm}}) \leq 10^6$ satisfies this constraint. When the constraint is relaxed, the configuration that achieves the best score is returned instead.

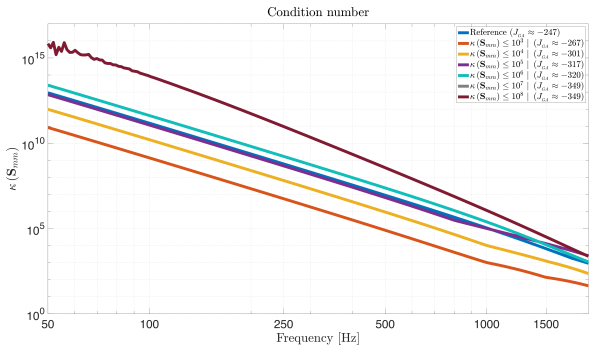

Figure 7. Conditioning of the microphone configurations associated with the lowest fitness score when the condition is constrained.

It is important to investigate the consistency of the GA in calculating the optimal arrays presented in Fig. 6. Fig. 8 presents the spread of the fitness scores for the calculated arrays at each constraint value, revealing a score range of the order of 40 dB for all configurations, consistent with the range for the unconstrained optimisation. The vertical overlap of the boxes indicates that, for a specified constraint, a calculated array may perform worse than those derived with more relaxed condition bounds, which contradicts the purpose of the optimisation.

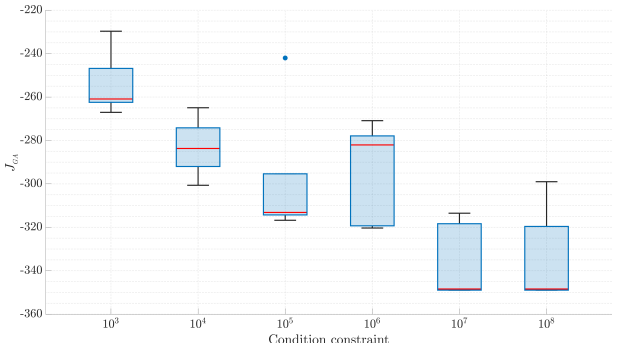

Figure 8. Fitness score spread for the calculated arrays for each condition constraint value.

4.4 Optimisation with constrained estimation error

An alternative approach to the optimisation is to constrain the estimation error to be lower than a specified bound and minimise the condition number. Five trials

were performed with the total estimation error over the virtual microphone grid being upper bounded by values from -100 dB to -400 dB in steps of 50 dB. The same two arrays were included in the initial population for these trials too.

The spatial distribution of the error for the arrays associated with the lowest condition numbers is shown in Fig. 9. The titles indicate the constraint and the actual value achieved by the array. It can be seen that when the bound was set very low, no feasible solution was found and the array that was closest to satisfying the constraint was returend. The minimisation of the condition number leads to distinctively different arrays compared to those acquired by minimising the error, with inconsistencies in the performance. The array associated with the $J_{\text{GA}} \leq -300$ dB has a condition number of about 3.4×10^4, while the array in Fig. 6 associated with a condition number bound of 10^4 achieves an error of $J_{\text{GA}} \approx -301$.

The range and median of the condition number associated with the calculated arrays for each constraint value are presented in Fig. 10. The spread of the values is significant when the consistency in the estimation error is taken into account. The results suggest that the same error values can be achieved with arrays whose conditioning differs significantly from each other. In contrast to the results obtained for the error minimisation, no significant overlap is observed between the condition numbers of the arrays calculated for each constraint bound.

5. SUMMARY

In this study, the applicability of a genetic algorithm for the calculation of optimal microphone configurations used to estimate the pressure in a tonal diffuse sound field at some location remote from the array was investigated.

The sum of estimation errors over a spatial grid of virtual microphones was used as the optimisation criterion. Microphone arrangements with similar topological patterns demonstrated performance gains compared to a reference linear array composed of sub-arrays capable of incorporating pressure and pressure gradient information into the estimation process [9]. However, the performance gains were accompanied by increased sensitivity to uncertainties, as assessed via the numerical conditioning.

Further optimisation trials were conducted with constraints on the condition number or the sum of estimation errors over the grid. Significant inconsistencies were observed in the results, with similar error metrics resulting from distinctly different array topologies. Overall, the range of the fitness values associated with the calculated configurations was found to be excessive with significant overlap for different constraint values in certain situations. Further refinement of the algorithm and its parameters is required if the method is to be used for the calculation of optimal microphone configurations.

CONTROL OF TRANSVERSE VIBRATIONS IN VERTICALLY INSTALLED ROTATING SHAFTS THROUGH ACTIVE BEARINGS

Jaewon Song[1] **Byeongil Kim**[1*]
[1] Department of Mechanical Engineering, Yeungnam University, Republic of Korea

ABSTRACT

Machines with vertical shafts, such as generators and electric motors, must address vibration-induced noise and heat. Vertical hydroelectric generators, in particular, are prone to vibrations from water flow and component imbalances, leading to reduced efficiency, early wear, and potential system failure. Controlling shaft vibrations is essential for maintenance and stable operation. This study aims to address these issues by applying active control technology to reduce vibrations in vertical shafts, utilizing active bearings and the NLMS algorithm. To validate the study, simulations were conducted using MATLAB/SIMULINK, and the system was mathematically modeled using the FEM approach. Experiments were conducted at 600 RPM, inspired by the rotational speed of the Porjus U9 generator, and additional analysis was performed across a speed range from 100 RPM to 800 RPM to compare shaft displacement orbits with simulation results. Through this comparison, the reliability of the simulation model was evaluated, and the effectiveness of active control in reducing vibrations was successfully demonstrated. These results suggest that active bearings have the potential to resolve vibration issues in machines with vertical shafts, such as generators and electric motors, thereby extending their operational lifespan.

Keywords: active bearing, finite element method, normalized least mean square algorithm, vertically driven shaft, transverse vibration.

1. INTRODUCTION

Machines equipped with vertically oriented shafts such as hydroelectric generators and electric motors are frequently subject to vibration-related challenges. In particular, vertical hydroelectric generators experience significant transverse vibrations due to water flow disturbances and internal imbalances in components. These vibrations can result in increased noise, heat generation, mechanical wear, and, ultimately, a decrease in system efficiency and reliability. Over time, excessive vibrations may lead to premature failure of critical components, posing serious maintenance and operational risks. Among the various solutions proposed to mitigate these problems, active vibration control technology has emerged as a promising approach. In contrast to passive methods, active control strategies can adapt to varying operational conditions and effectively suppress unwanted vibrations in real time. This study focuses on applying such a method specifically, the use of active bearings combined with the Normalized Least Mean Square (NLMS) algorithm to control transverse vibrations in vertically installed rotating shafts. To evaluate the proposed method, a mathematical model of the system was developed using the Finite Element Method (FEM), and simulations were conducted using MATLAB and SIMULINK environments. The system behavior was analyzed under a rotational speed of 600 RPM, chosen based on the operational characteristics of the Porjus U9 hydroelectric generator. Additionally, a parametric analysis was carried out across a range of speeds (100–800 RPM) to assess vibration responses and compare shaft displacement orbits with simulation results. Through this analysis, the accuracy and reliability of the proposed model were validated, and the effectiveness of the active control strategy was confirmed. The findings of this research highlight the potential of active bearings as a viable solution for reducing vibrations in vertical shaft systems. This

approach not only contributes to the enhancement of machine performance but also extends the operational lifespan of equipment such as generators and electric motors.

2. MODELLING OF ROTOR

In this chapter, we employed the FEM(Finite Element Method) to construct a model of a vertical shaft system comprising a generator and a turbine. The model comprises 15 nodes and 14 elements. Figure 1 below provides a visual representation of this model.

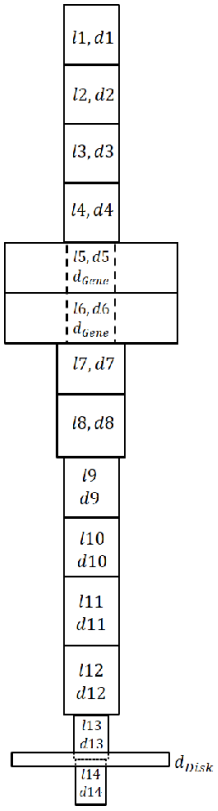

Figure 1. Porjus U9 rotor finite element model.

2.1 Finite element method

For modeling using the finite element method, the shaft model was structured with 14 elements and 15 nodes. The matrices utilized for modeling include the mass, stiffness, and damping matrices. These matrices are detailed as follows.

$$M_i^e = \frac{\rho A_i l_i}{420}\begin{bmatrix} 156+\left(\frac{m_d}{\rho A_i l_i/420}\right) & & & sym \\ 22l_i & 4l_i^2+\left(\frac{I_d}{\rho A_i l_i/420}\right) & & \\ 54 & 13l_i & 156 & \\ -13l_i & -3l_i^2 & -22l_i & 4l_i^2 \end{bmatrix} \quad (1)$$

$$K_i^e = \frac{2EI_i}{l_i^3}\begin{bmatrix} 6+\left(\frac{k_i}{2EI_i/l_i^3}\right) & & & sym \\ 3l_i & 2l_i^2 & & \\ -6 & -3l_i & 6 & \\ 3l_i & l_i^2 & -3l_i & 2l_i^2 \end{bmatrix} \quad (2)$$

$$G_i^e = \begin{bmatrix} 0 & & & sym \\ 0 & I_p\Omega & & \\ 0 & 0 & 0 & \\ 0 & 0 & 0 & 0 \end{bmatrix} \quad (3)$$

2.2 Modelling of active bearing

The active bearing system comprises a rubber grommet and a piezo actuator, illustrated in Figure 2. The modeling process involved utilizing linearized stiffness, with the damping effects from oil films in the bearings disregarded. Furthermore, considering the significant rigidity of the housing, it was treated as a rigid body. In Figure 1, the upper bearing of the turbine has been replaced with an active bearing.

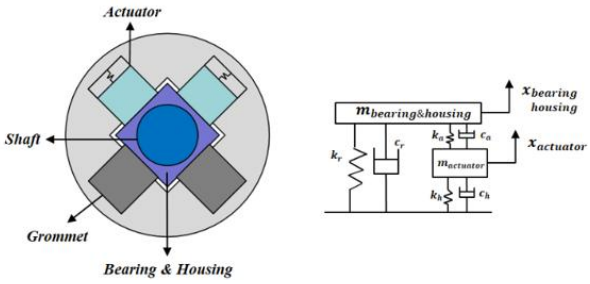

Figure 2. Structure and dynamic model of the active bearing

$m_{bearing\&hosing}$ refers to the mass of the housing attached to the rotor. k_r , c_r express the stiffness and damping of the rubber grommet. Also, $m_{actuator}$ represents the actuator mass. k_a and k_h represent the stiffness of the actuator and the spring located below the actuator, respectively, and c_a and c_h also represent the damping of the actuator and the spring located below the actuator. $x_{bearinghosing}$ and $x_{actuator}$ mean the displacement of the bearing housing and the actuator, respectively.

3. SIMULATION RESULTS

In this study, simulations were conducted at the nominal speed of 600 rpm. The overall system response obtained from the simulation-based control is presented in Figure 3.

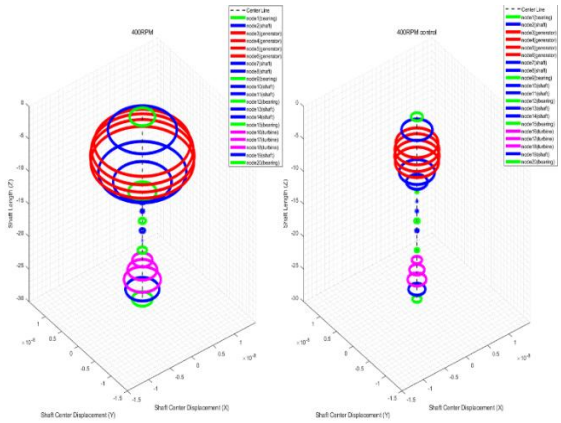

Figure 3. Comparison of system response before and after control at 600 rpm.

The control result at Node 12, which corresponds to the displacement measurement point in the actual experimental setup, is shown below.

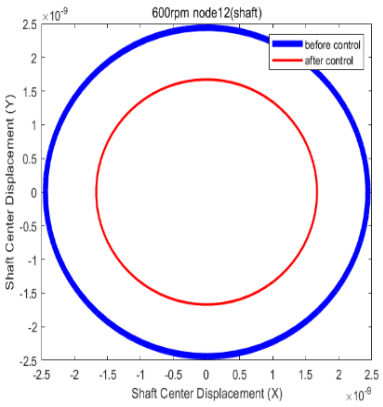

Figure 4. Shaft orbit at 600 rpm before and after control.

In the simulation, it was confirmed that the use of active bearing control effectively reduced vibrations, with a 31.54% reduction in amplitude observed after control.

4. EXPERIMENTAL RESULTS

4.1 Experimental setup

Figure 5 shows the experimental setup for evaluating the active bearing system. It consists of an unbalanced disk and two actuator-sensor modules mounted on a vertical shaft. The actuators apply control forces in the X and Y directions, while the sensors measure shaft displacement. All components are mounted on a rigid frame to reduce external disturbances.

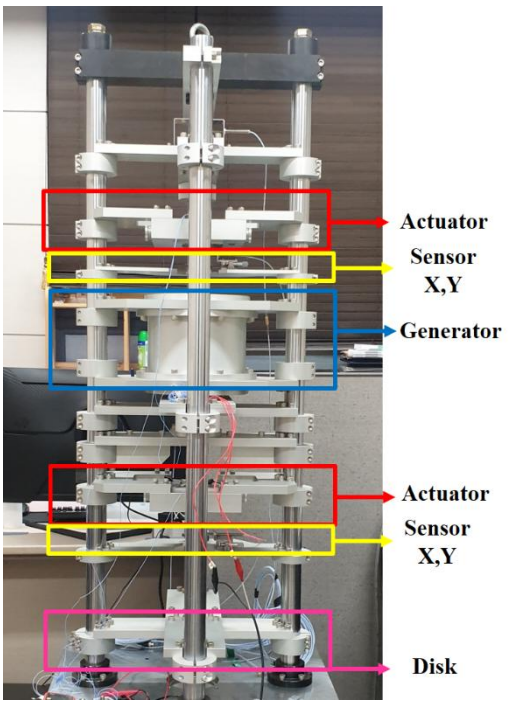

Figure 5. Experimental setup

Acceleration sensors in the X and Y directions send signals to Simulink via the d-SPACE platform. The NLMS algorithm processes the signals to generate control inputs, which are applied to piezoelectric actuators for real-time vibration suppression.

4.2 Experimental Results

Similar to the simulation results, the displacement response at 600 rpm was measured. The orbit plots before and after control are shown in the figure below.

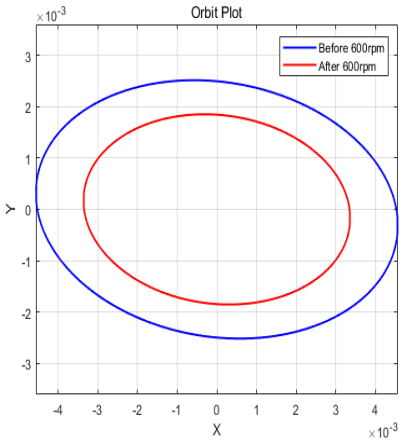

Figure 6. Shaft orbit at 600 rpm before and after control.

A 26.31% reduction in orbit amplitude was observed after applying the control.

5. CONCLUSION

In this study, an active vibration control method combining active bearings and the Normalized Least Mean Square (NLMS) algorithm was proposed to suppress transverse vibrations in vertically oriented rotating shaft systems. A vertical shaft model, including a generator and turbine, was developed using the Finite Element Method (FEM), and simulations were performed at 600 rpm using MATLAB and Simulink. The simulation results confirmed that the proposed method effectively reduced vibration amplitudes. To verify the practical effectiveness of the method, an experimental setup was constructed, featuring piezoelectric actuators and acceleration sensors. A real-time control loop was implemented using the d-SPACE system and Simulink, incorporating the NLMS algorithm. The experimental results showed a similar trend to the simulation, demonstrating significant vibration reduction at 600 rpm. These findings validate the potential of active bearings as a robust solution for vibration control in vertical rotor systems. The proposed approach can enhance operational stability and extend the service life of equipment such as hydroelectric generators and vertical electric motors.

ACTIVE STRUCTURAL ACOUSTIC CONTROL (ASAC) FOR VIBRATING PLATES WITH OPENINGS IN VIBRO-ACOUSTIC SYSTEMS

Khaled Said Ahmed Maamoun[1,2*] **Stanislaw Wrona**[1] **Marek Pawelczyk**[1]
Hamid Reza Karimi[2]

ABSTRACT

Active Structural Acoustic Control (ASAC) is a well-established technique for managing noise and vibration in vibro-acoustic systems. This study investigates the application of ASAC to vibrating plates with corner openings, a configuration that presents unique challenges due to localized stress concentrations and complex vibro-acoustic coupling. The placement and configuration of inertial actuators, which are integral to ASAC systems, are experimentally analyzed to optimize performance. The results show that the position of the opening significantly influences the overall system response, making the placement of inertial actuators unique to each configuration. Changing the location of the opening alters the vibrational and acoustic characteristics of the plate, requiring a tailored actuator arrangement for effective control. For fully clamped plates, placing actuators near the edges reduces their effectiveness in suppressing sound due to the high stress concentrations and limited vibrational energy at these regions. Additionally, positioning actuators around the openings introduces greater instability and nonlinearities into the system, further complicating the control dynamics. These findings highlight the necessity of considering both the opening location and actuator placement to optimize performance in vibro-acoustic systems.

1. INTRODUCTION

Openings in plate structures play a vital role in numerous engineering applications, particularly in vibro-acoustic coupled systems. These structures are widely employed across various domains, including household appliances, manufacturing, and vehicle engineering [1]. The shape, location, and relative position of openings concerning the noise source in such systems significantly influence the system's sound power response. For systems where openings are located in high-stress areas of vibrating plates, such as plate corners, additional sound power resonances are expected. Therefore, special attention is required to effectively address these systems [2]. Different techniques are employed to improve sound reduction in such systems, including both passive and active control methods [3].

Active Structural Acoustic Control (ASAC) plays a crucial role in mitigating noise transmission in various engineering applications by actively controlling structural vibrations. When properly implemented, ASAC can not only attenuate noise in localized regions but also achieve global noise reduction [4, 5]. It is generally implemented using a combination of passive noise barriers, vibration actuators, sensors, and a control system, as outlined in [6]. ASAC mitigates noise transmission through a structure by actively controlling its vibrations.

The authors in [7] theoretically evaluated a radiation-mode-based ASAC system for an enclosure with vent openings. However, their study was limited to tonal disturbances and did not explore practical real-world applications. A feedforward ASAC algorithm was later implemented on the lining panels of an aircraft cabin using a low-cost microcontroller, achieving a tonal noise reduction of 23 dB [8]. In [9], the authors examined the ef-

fectiveness of a tonal ASAC strategy that employs an experimentally identified radiation matrix to regulate sound power radiation, demonstrating superior performance over conventional active vibration control methods. However, their study did not consider broadband excitation.

Despite these advancements, the existing literature indicates a notable research gap in ASAC applications for systems with openings compared to fully enclosed structures. This highlights the need for further investigation to enhance ASAC effectiveness in such configurations.

The filtered-x least-mean-square (FxLMS) algorithm is the most popular active control algorithm due to its stability and simple structure [10]. The reference signal to the controller is filtered through the model of the secondary path between the actuator and the error sensors, ensuring effective noise attenuation. More features and have been added to FxLMS to enhance its characteristics, such as the Leaky FxLMS that introduces a small leakage factor to prevent coefficient drift and instability, making it more robust in nonstationary environments [11]. The Normalized FxLMS (NFxLMS) algorithm adjusts the step size based on the filtered reference signal power, ensuring faster convergence and better stability in varying input conditions [12].

The selection of the inertial actuator location on vibrating plates is crucial, as it directly affects the control system's ability to reduce noise [13]. Various studies have addressed this placement problem. Some studies optimize actuator placement based on vibration response [14], while others incorporate radiated sound into the cost function [15, 16]. The main contributions of this paper are twofold: i) an analysis of ASAC's effectiveness in mitigating noise from vibro-acoustic systems with openings, and ii) an investigation into the optimal placement of inertial actuators on vibrating plates, specifically considering corner regions with high stress concentrations.

The reminder of the paper is organized as follows: Section 2 is introduction of the experimental setup. Section 3 presents the results and the discussion. Finally, the conclusion is presented in Section 4.

2. EXPERIMENTAL SETUP

The experimental setup is designed to provide flexibility in testing actuators at various positions. The test plate can be replaced to evaluate systems with openings located at different corners. The laboratory room measures 5.8 meters in length and 3.5 meters in width. While the walls are lined with sound-absorbing materials, the presence of equipment and other objects within the room gives it acoustic characteristics more representative of a typical real-world environment rather than those of a dedicated acoustic chamber. The setup comprises a rectangular steel plate mounted on a concrete enclosure containing a loudspeaker. The plate is composed of steel with a density $\rho = 7850\,\mathrm{kg/m^3}$, Young's modulus $E = 210 \times 10^9\,\mathrm{Pa}$. The dimensions of the plate are $a = 0.42\,\mathrm{m}$, $b = 0.39\,\mathrm{m}$, and $h = 0.001\,\mathrm{m}$, representing its length, width, and thickness, respectively. The loudspeaker generates a random, band-limited noise signal with a position fixed at (0.3 m, 0.1 m, -0.3 m) for all the considered configurations. The concrete enclosure offers substantial sound attenuation, ensuring that the majority of the acoustic energy exiting the enclosure propagates through the plate and the circular opening. The active control system employs three Beyerdynamic MM1 error microphones and three DAEX32EP-4 inertial actuators, as illustrated in Fig. 1.

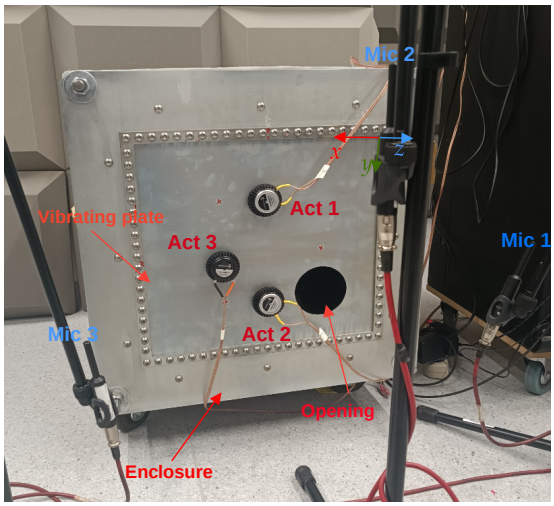

Figure 1: An overview of the experimental setup, showing a vibrating plate that contains a circular opening of a radius 0.05 m with center coordinates at (0.105 m, 0.265 m). Actuators (Act 1, Act 2, and Act 3) are mounted on the plate at (0.2 m, 0.1 m), (0.27 m, 0.2 m), and (0.2, 0.295 m), respectively. Microphones (Mic 1, Mic 2, and Mic 3) are positioned at the coordinates (-0.18 m, 0.12 m, 0.25 m), (0.21 m, -0.1 m, 0.4 m), and (0.53 m, 0.24 m, 0.25 m), respectively.

2.1 Algorithm

For active control, a feedforward multichannel FxLMS algorithm with a leakage factor is employed due to its simplicity and robustness [3], as illustrated in Fig. 2. The system normalizes based on the power of a single reference signal. The reference signal, denoted as $R(n)$, can be artificially generated or obtained via a reference microphone. The adaptive filter coefficients, represented by the vector W, consist of K elements generating the control signals $Y(n)$, while the canceling signals are given by $\hat{Y}(n)$.

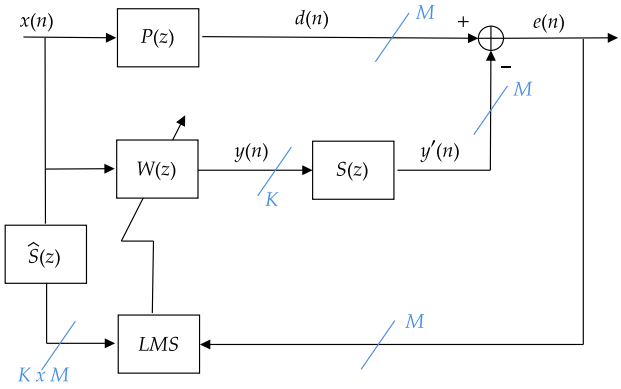

Figure 2: Block diagram of a single-reference multichannel feedforward FxLMS algorithm. M and K denote the number of outputs and secondary sources, respectively.

Since the secondary path matrix S is not directly available, it is approximated using an estimate $\hat{S}$. The $K \times M$ secondary paths are modeled as FIR filter impulse responses and adapted using the NLMS algorithm. The adaptive filter coefficients $W_k(n)$ are updated as:

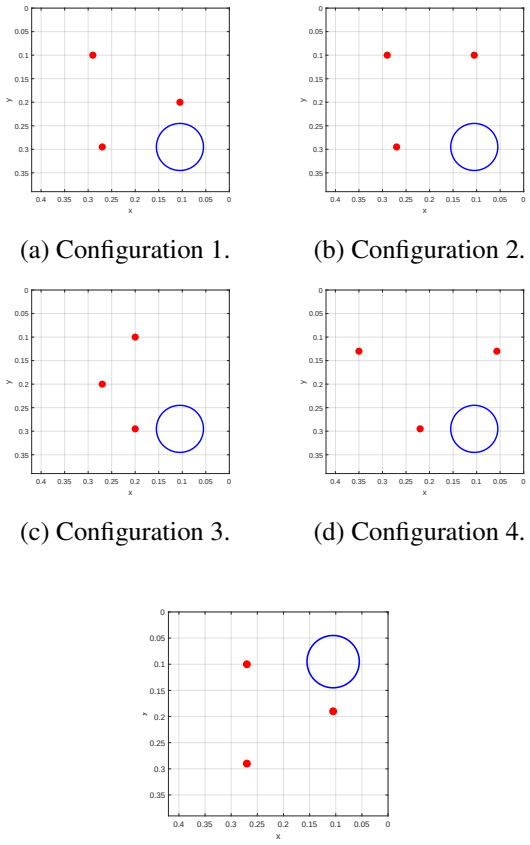
$$W_k(n+1) = (1-\eta(n)\beta)W_k(n)+\eta(n)\sum_{m=1}^{M} R'_{km}(n)E_m(n), \tag{1}$$

where $R'_{km}(n)$ is the filtered reference signal, $E_m(n)$ is the error signal, and $\eta(n)$ is the normalized step size expressed as follows:

$$\eta(n) = \frac{\mu}{\sum_{k=1}^{K}\sum_{m=1}^{M}\|R'_{km}(n)\|^2}, \tag{2}$$

where μ is the fixed step size, $\|\cdot\|$ denotes the L^2-norm, and β is a leakage regularization factor.

In real-time operation, the total system latency from ADC input to DAC output is approximately 2.16 ms, which is close to the acceptable threshold for active control applications. This delay results from the combined effects of the output buffer (0.33 ms), the group delay introduced by IIR filters during downsampling (to 3 kHz) and upsampling (0.83 ms), and the inherent processing delay of the ADC and DAC at a 48 kHz sampling rate. The system is implemented using the Analog Devices SC598 with an SHARC+ core, integrated with the EVSOMCRR-EZKIT development board [17], featuring a 4-channel, 24-bit ADC and a 12-channel, 24-bit DAC.



3. RESULTS AND DISCUSSION

This study investigates the effect of actuator positioning on the performance of vibro-acoustic systems by evaluating four distinct actuator arrangements, as illustrated in Fig.3. The selected configurations are designed to reflect both critical and potentially optimal actuator placements, informed by the physical characteristics of the system [2, 15].

The mass of the actuators is approximately 140 g, which can alter the system's response even without control. Fig. 4 compares the power spectral density (PSD) of the three error microphones for the four configurations under consideration.

The difference between Configuration 1 and Configuration 4 is particularly noticeable in the frequency range between 150 Hz and 200 Hz. This is due to the fact that, in Configuration 4, the actuator masses are positioned near the edges of the clamped plate, regions of high stress, resulting in a higher sound power response.

In contrast, Configuration 1 places two of the three actuators closer to the opening, which helps to reduce vibrations in that region, thereby minimizing the radiated sound power. Moreover, Configurations 2 and 3 exhibit similar performance, as the actuators are more concentrated near the center of the plate. To assess the reduction achieved through active control, the four configurations are compared to the average microphone response in the absence of control. As shown in Fig. 5, ASAC effectively minimizes the system's sound power response, indicating that it is not only effective in reducing radiated sound but also in mitigating noise leakage through the opening. The actuator placement near the clamped edges in Configuration 4 restricts the system's ability to vibrate actively. The displacement is constrained, and this helps generate anti-noise waves that counteract sound leakage through

(a) Configuration 1. (b) Configuration 2.

(c) Configuration 3. (d) Configuration 4.

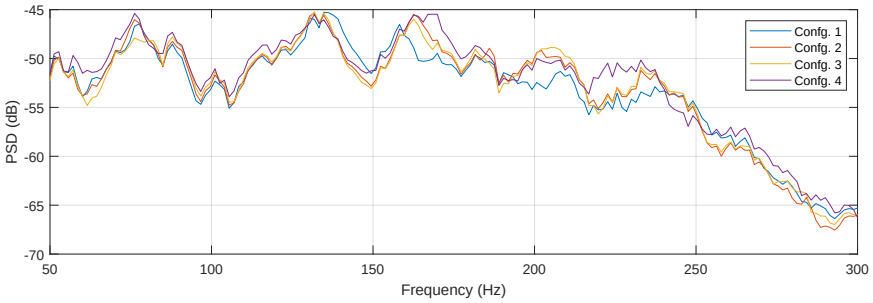
(e) Configuration 5.

Figure 3: An overview of the four configurations of the actuators' arrangements.

the opening.

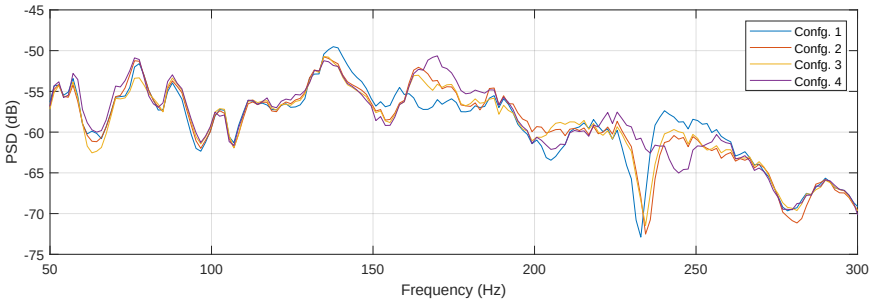
Configuration 3 demonstrates the best performance across the considered frequency range. This is attributed to one actuator being positioned closer to the opening—allowing greater flexibility for displacement—combined with a central actuator arrangement that provides a balanced response across most mode shapes. Configurations 1 and 2 may be advantageous when targeting specific resonances. For instance, Configuration 2 positions the actuators closer to the anti-nodal regions of the third and fourth mode shapes of the rectangular plate [2], making it more effective in that frequency range.

To evaluate the influence of the relative position of the opening with respect to the excitation source, as well as the effect of actuator arrangement, Configuration 5 is tested and compared with Configuration 1. This comparison is considered fair, as both configurations share a similar actuator arrangement, as illustrated in Fig. 6.



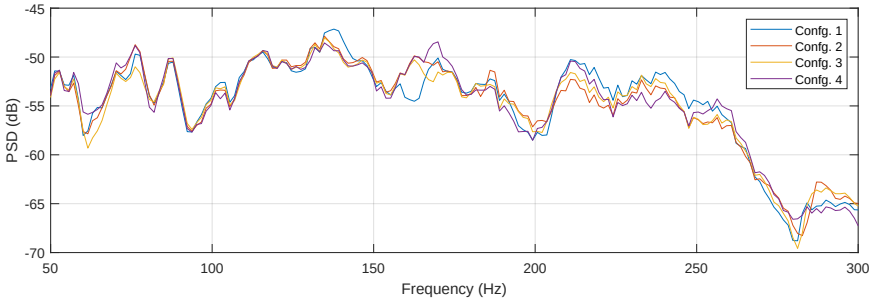
Configuration 5 exhibits lower sound power levels compared to Configuration 4, particularly in the frequency range between 135 Hz and 200 Hz. This improvement is attributed to the fact that the opening in Configuration 5 is positioned farther from the internal noise source, resulting in reduced sound leakage through the opening. When ASAC is applied, Configuration 5 demonstrates enhanced control performance due to the revised opening location, which makes the actuator placement—particularly that of Act 1 and 3—more favorable for inducing effective vibrational displacement near the aperture. As a result, despite having the same actuator arrangement as Configuration 1, the system achieves over 5 dB additional noise reduction in the frequency ranges of 70–125 Hz and 170–200 Hz due to the relocated opening.

4. CONCLUSION



This study experimentally examined the application of Active Structural Acoustic Control (ASAC) in vibro-acoustic systems with structural openings, focusing on the influence of inertial actuator placement and opening location on control effectiveness. Five actuator configurations were evaluated on a fully clamped vibrating plate to assess how spatial arrangement and structural characteristics impact both passive and active noise control performance.

The results demonstrate that actuator positioning significantly affects the system's vibrational and acoustic response. Configurations with actuators placed near the clamped edges—regions of high stress and low vibrational energy—showed limited effectiveness in both passive damping and active control. In contrast, configurations with actuators distributed closer to the plate center or near the opening, such as Configuration 3, provided more balanced control across the frequency range, benefiting from greater displacement flexibility and improved mode shape engagement. Moreover, Configuration 5 revealed that relocating the opening farther from the noise source, even with the same actuator arrangement as Configuration 1, can lead to an additional 5 dB reduction in key frequency ranges. This highlights that the opening's position, in relation to the excitation source and actuators, plays a crucial role in minimizing sound leakage and enhancing ASAC performance.



These findings underscore the importance of tailoring

A COMPARISON BETWEEN SPATIAL INTERPOLATION APPROACHES IN A HEAD-TRACKED ACTIVE HEADREST SYSTEM

Chung Kwan Lai* **Jordan Cheer**
Institute of Sound and Vibration Research (ISVR)
University of Southampton, United Kingdom.

ABSTRACT

The integration of head-tracking can improve the achievable performance of active noise control headrest systems by allowing the mismatch between the plant model used by the controller and the physical plant response to be reduced. Although previous studies have shown that the performance improvement achieved through head-tracking is limited by the resolution of the tracking system, this limitation can be addressed by either interpolating between plant models obtained at different head positions and then calculating the required controller, or interpolating between a set of pre-computed controllers optimised for different head positions. The differences in performance between the two approaches to interpolation, however, have not been explored, despite various interpolation strategies being previously utilised in head-tracked active control systems discussed in the literature. This paper presents a comparison between the two approaches to spatial interpolation for a head-tracked active headrest system. Assuming a tonal disturbance, it is shown through numerical simulations that the performance benefit brought by spatial interpolation differs between the two approaches to interpolation.

Keywords: *active headrest system, local active noise control, head-tracker, interpolation*

1. INTRODUCTION

The use of active noise control to provide local control of sound at a listener's ears dates back to the 1950s [1], however, it has recently attracted renewed interest due to the potential for integrating head-tracking techniques to extend the bandwidth of effective control [2]. In the context of an active headrest system [3], where secondary loudspeakers are typically placed near the headrest, a head-tracker can be used to detect the current position of the user's head and update either the plant model, which is then used to compute the controller, or the precomputed controller itself, both of which would be obtained during a calibration stage. In either case, this updating process can reduce the mismatch between the physical and assumed responses for the physical head position, thereby improving control performance in response to head movements. While it is ideal for the head-tracker and corresponding system updates to be as accurate as possible to maximise the control performance, such an approach may not be feasible in practice, as this would require a lengthy calibration process to measure the plant responses and optimal controllers for many head positions. Previous research has been conducted to determine how the tracking accuracy influences the performance and stability of an active headrest system and ultimately to define the required tracking accuracy for a given level and bandwidth of performance [4, 5]. However, rather than utilising an extremely fine tracking resolution, an alternative approach is to interpolate between the responses [6] for a coarser tracking resolution to improve their accuracy. Although it seems relatively straightforward that the performance of the active headrest system will depend on the accuracy provided by the interpolation algorithm used, there are in fact two approaches to interpolation: in the first case, the plant responses corresponding to the coarse measurement grid are interpolated directly and the optimal controller is then calculated using the interpolated plant responses; in the second case, the interpolation is instead performed between the optimal controllers calculated for each head position

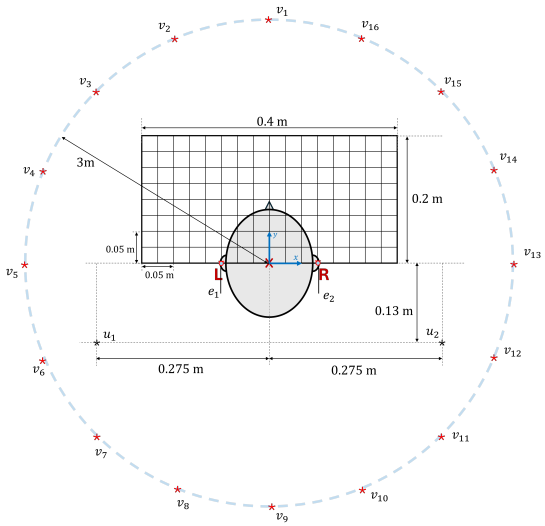

Figure 1: Configuration for the active headrest where the head translates in the sway (left/right) and surge (front/back) direction within a $(0.4\text{ m} \times 0.2\text{ m})$ translational grid. The minimum grid spacing for the translational grid is 0.025 m.

on the coarse measurement grid. This paper presents a comparison between the control performance for the two proposed approaches to interpolation applied to an active headrest system. Sec. 2 describes the active headrest and introduces the two spatial interpolation approaches; Sec. 3 describes the interpolation algorithm used to realise the interpolation in both cases; Sec. 4 presents the results from the simulation study; and conclusions are drawn in Sec. 5.

2. FORMULATION OF ACTIVE HEADREST CONTROL PROBLEM

Fig. 1 illustrates the numerically simulated configuration of the active headrest, which employs a boundary element model of the KU100 head [7] implemented in COMSOL to represent the user's head. Two monopole point sources, driven by control signals u_1 and u_2, simulate the secondary sources in the active headrest; whilst the disturbance sound field is generated by 16 incoherent primary sources, driven by the complex source strengths $v_1 - v_{16}$, positioned around the head, as depicted in Fig. 1. The feedforward control strategy used to minimise the signals at the user's ears is shown in Fig. 2, where each diagram illustrates a different interpolation approach for updating the control filter, $\mathbf{W}$, based on the current location of the head. Assuming that the disturbance signal is tonal, the cost function that aims to minimise the error signals located at the user's ears can be expressed in the frequency domain, as

$$\begin{aligned} J &= \mathbb{E}\left[\mathbf{e}^{\mathrm{H}}\mathbf{e} + \beta\mathbf{u}^{\mathrm{H}}\mathbf{u}\right] \\ &= \mathrm{tr}\left\{\mathbb{E}\left[\mathbf{e}\mathbf{e}^{\mathrm{H}} + \beta\mathbf{u}\mathbf{u}^{\mathrm{H}}\right]\right\} \end{aligned} \tag{1}$$

where $\mathbf{e}$ and $\mathbf{u}$ denote complex vectors of the error signals and control signals, respectively, and $\beta = 0$ is the regularization parameter. Based on the block diagram shown in Fig. 2, the complex vector of error signals is given by

$$\mathbf{e} = \mathbf{d} + \mathbf{G}\mathbf{u} = \mathbf{d} + \mathbf{G}\mathbf{W}\mathbf{x}, \tag{2}$$

where $\mathbf{W}$ and $\mathbf{G}$ are matrices of control filters and the physical plant responses, respectively, and $\mathbf{x}$ is the complex vector of reference signals. Assuming that the physical plant responses are perfectly known, the optimal control filter matrix can therefore be derived as [8]

$$\mathbf{W}_{opt} = -\left[\mathbf{G}^{\mathrm{H}}\mathbf{G} + \beta\mathbf{I}\right]^{-1}\mathbf{G}^{\mathrm{H}}\mathbf{S}_{xd}\mathbf{S}_{xx}^{-1}, \tag{3}$$

where $\mathbf{S}_{xd}$ is the spectral density matrix between the disturbance and reference signals, and $\mathbf{S}_{xx} = \mathbf{I}$ is the spectral density matrix of the reference signals, following the general notation $\mathbf{S}_{xy} = \mathbb{E}\left[\mathbf{y}\mathbf{x}^{\mathrm{H}}\right]$.

During the initial calibration phase, the plant responses were directly obtained for a subset of head positions within a discrete translational grid of $(0.4\text{ m} \times 0.2\text{ m})$, marked by the red crosses in Fig. 3. The corresponding optimal control filters for these head positions were then calculated using Eqn. (3). The use of a coarser resolution reflects the practical constraints encountered on calibration complexity and duration. For the remaining grid points, the control filter can be determined utilising the two different approaches to interpolation, as outlined in Fig. 2. In the controller-based interpolation approach, as shown in Fig. 2a, the control filter is calculated by directly interpolating between the optimal control filters computed for the head positions included in the calibration process, and the interpolated control filter is denoted as $\underset{\sim}{\mathbf{W}}$. In contrast, in the plant-based interpolation strategy, as shown in Fig. 2b, the plant model and spectral density at the target head position are first estimated by interpolating between the responses measured in the calibration, and then the control filters are calculated using the interpolated responses, as

$$\mathbf{W}_o = -\left[\underset{\sim}{\mathbf{G}}^{\mathrm{H}}\underset{\sim}{\mathbf{G}} + \beta\mathbf{I}\right]^{-1}\underset{\sim}{\mathbf{G}}^{\mathrm{H}}\underset{\sim}{\mathbf{S}}_{xd}\mathbf{S}_{xx}^{-1}, \tag{4}$$

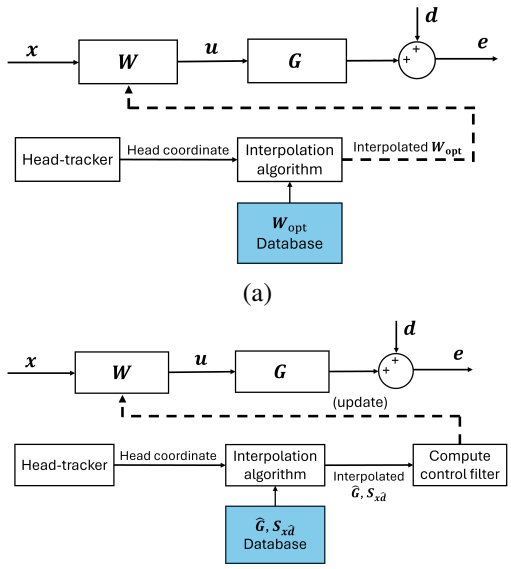

Figure 2: The multichannel feedforward control system used in the head-tracker equipped active headrest system, featuring (a): controller-based interpolation and (b): plant-based interpolation architecture.

where $\underset{\sim}{\mathbf{G}}$ and $\underset{\sim}{\mathbf{S}}_{xd}$ denote the interpolated plant model and spectral density matrices respectively.

To compare the performance of the two approaches to interpolation, the control performance of the active headrest system at the interpolated grid points can be assessed by computing the attenuation performance at the i-th error microphone, given by

$$L_{e,i} = -10\log_{10}\left|\frac{\mathbf{S}_{e_i e_i}}{\mathbf{S}_{d_i d_i}}\right|. \tag{5}$$

3. SPATIAL INTERPOLATION BASED ON KERNEL RIDGE REGRESSION

While various interpolation algorithms are available, to compare the two approaches to interpolation described in the previous section, the Kernel-ridge interpolation method will be utilised. This algorithm has recently been applied to sound-field estimation and a spatial active noise control system [9, 10], and is described in this section.

Consider a general complex matrix $\underset{\sim}{\mathbf{H}}(\boldsymbol{\psi}) \in \mathbb{C}^{(I\times J)}$, where $\boldsymbol{\psi}$ represents the vector of head coordinates, and

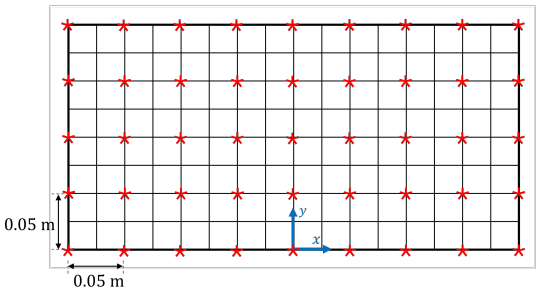

Figure 3: Head positions within the translational grid, marked by red crosses, indicate locations where plant responses were directly measured during the calibration phase.

the element at the i-th row and j-th column is denoted by $\underset{\sim}{h}_{ij}(\boldsymbol{\psi})$. In this context, $\underset{\sim}{\mathbf{H}}$ may represent either the control filter $\underset{\sim}{\mathbf{W}}$, plant model $\underset{\sim}{\mathbf{G}}$, or spectral density $\underset{\sim}{\mathbf{S}}_{xd}$, depending on the interpolation approach being utilised. During the calibration phase, the matrix is measured at discrete grid positions, which are denoted as $\hat{\mathbf{H}}(\boldsymbol{\psi}_n)$ for the n-th position. The goal of interpolation is to estimate each element of $\underset{\sim}{\mathbf{H}}$ at an arbitrary position $\boldsymbol{\psi}$ using the corresponding elements from the pre-measured matrices $\hat{\mathbf{H}}$ at the known positions $\boldsymbol{\psi}_n$. Each element of $\underset{\sim}{\mathbf{H}}$ can be calculated according to the interpolation function given as $\underset{\sim}{h}_{ij}(\boldsymbol{\psi}) = \boldsymbol{\phi}^{\mathrm{H}}(\boldsymbol{\psi})\mathbf{f}$, where $\boldsymbol{\phi}(\boldsymbol{\psi})$ is the input feature vector that is a function of head coordinates $\boldsymbol{\psi}$, and $\mathbf{f}$ is the complex weighting vector containing the coefficients that determine the contribution of each feature vector components. The cost function, which minimises the sum of squared errors between the interpolated and pre-measured elements across all discrete head positions, is defined as

$$\begin{aligned} J_{ij} &= \sum_{n=1}^{N}\left|\underset{\sim}{h}_{ij}(\boldsymbol{\psi}_n) - \hat{h}_{ij}(\boldsymbol{\psi}_n)\right|^2 + \lambda\mathbf{f}^{\mathrm{H}}\mathbf{f} \\ &= \left(\boldsymbol{\Phi}\mathbf{f} - \hat{\mathbf{h}}_{ij}\right)^{\mathrm{H}}\left(\boldsymbol{\Phi}\mathbf{f} - \hat{\mathbf{h}}_{ij}\right) + \lambda\mathbf{f}^{\mathrm{H}}\mathbf{f}, \end{aligned} \tag{6}$$

where N is the total number of discrete grid points used during the calibration phase, and

$$\boldsymbol{\Phi} = \left[\boldsymbol{\phi}^{\mathrm{H}}(\boldsymbol{\psi}_1)\ \boldsymbol{\phi}^{\mathrm{H}}(\boldsymbol{\psi}_2)\ \cdots\ \boldsymbol{\phi}^{\mathrm{H}}(\boldsymbol{\psi}_N)\right]^{\mathrm{T}}, \tag{7}$$

$$\hat{\mathbf{h}}_{ij} = \left[\hat{h}_{ij}(\boldsymbol{\psi}_1)\ \hat{h}_{ij}(\boldsymbol{\psi}_2)\ \cdots\ \hat{h}_{ij}(\boldsymbol{\psi}_N)\right]^{\mathrm{T}}, \tag{8}$$

are the generic input feature matrix and the vector of pre-measured elements across all grid points, respectively, and

λ is the regularisation factor. The optimal $\mathbf{f}$ is therefore given as

$$\mathbf{f}_{opt} = \left[\mathbf{\Phi}^{\mathrm{H}}\mathbf{\Phi} + \lambda\mathbf{I}\right]^{-1}\mathbf{\Phi}^{\mathrm{H}}\hat{\mathbf{h}}_{ij}. \tag{9}$$

However, the value of $\mathbf{f}_{opt}$ depends on the choice of $\mathbf{\Phi}$, which may involve a much higher number of dimensions than the number of grid points. Instead, the cost function can be kernelized to overcome the dimensionality curse imposed by the generic input feature vector [11]. By letting $\mathbf{f} = \mathbf{\Phi}^{\mathrm{H}}\boldsymbol{\alpha}$, where $\boldsymbol{\alpha}$ is the intermediate complex variable vector, the cost function from Eqn. (6) can be expressed in terms of $\boldsymbol{\alpha}$ to give

$$J_{ij} = \boldsymbol{\alpha}^{\mathrm{H}}\left[(\mathbf{K}\mathbf{K} + \lambda\mathbf{K})\right]\boldsymbol{\alpha} - \boldsymbol{\alpha}^{\mathrm{H}}\mathbf{K}\hat{\mathbf{h}}_{ij} - \hat{\mathbf{h}}_{ij}^{\mathrm{H}}\mathbf{K}\boldsymbol{\alpha} + \hat{\mathbf{h}}_{ij}^{\mathrm{H}}\hat{\mathbf{h}}_{ij}, \tag{10}$$

where $\mathbf{K} = \mathbf{\Phi}\mathbf{\Phi}^{\mathrm{H}}$ is the Gram matrix, which is Hermitian and semi-positive-definite i.e. $\mathbf{K} = \mathbf{K}^{\mathrm{H}}$, given by

$$\mathbf{K} = \begin{bmatrix} \kappa(\boldsymbol{\psi}_1, \boldsymbol{\psi}_1) & \kappa(\boldsymbol{\psi}_1, \boldsymbol{\psi}_2) & \cdots & \kappa(\boldsymbol{\psi}_1, \boldsymbol{\psi}_N) \\ \kappa(\boldsymbol{\psi}_2, \boldsymbol{\psi}_1) & \kappa(\boldsymbol{\psi}_2, \boldsymbol{\psi}_2) & \cdots & \kappa(\boldsymbol{\psi}_3, \boldsymbol{\psi}_N) \\ \vdots & \vdots & \ddots & \vdots \\ \kappa(\boldsymbol{\psi}_N, \boldsymbol{\psi}_1) & \kappa(\boldsymbol{\psi}_N, \boldsymbol{\psi}_2) & \cdots & \kappa(\boldsymbol{\psi}_N, \boldsymbol{\psi}_N) \end{bmatrix}, \tag{11}$$

and $\kappa(\boldsymbol{\psi}_m, \boldsymbol{\psi}_n) = \boldsymbol{\phi}^{\mathrm{H}}(\boldsymbol{\psi}_m)\boldsymbol{\phi}(\boldsymbol{\psi}_n)$ is denoted as a kernel function. The optimal value of $\boldsymbol{\alpha}$ that minimises Eqn. (10) can then be obtained as

$$\boldsymbol{\alpha}_{opt} = \left(\mathbf{K} + \lambda\mathbf{I}\right)^{-1}\hat{\mathbf{h}}_{ij}. \tag{12}$$

Finally, the interpolated element at an arbitrary position $\boldsymbol{\psi}$ can then be evaluated as

$$\underset{\sim}{h}_{ij}(\boldsymbol{\psi}) = \boldsymbol{\kappa}(\boldsymbol{\psi})\left(\mathbf{K} + \lambda\mathbf{I}\right)^{-1}\hat{\mathbf{h}}_{ij}, \tag{13}$$

where

$$\boldsymbol{\kappa}(\boldsymbol{\psi}) = \left[\kappa(\boldsymbol{\psi}, \boldsymbol{\psi}_1)\ \kappa(\boldsymbol{\psi}, \boldsymbol{\psi}_2)\ \cdots\ \kappa(\boldsymbol{\psi}, \boldsymbol{\psi}_N)\right] \tag{14}$$

is known as the reproducing Kernel vector.

To gain a preliminary understanding of how different kernel functions affect the controller's performance, two different kernel functions have been used here for interpolation. The first, derived from previous work [10], is constrained by the 3D Helmholtz equation and is given by

$$\begin{aligned}\kappa(\boldsymbol{\psi}_m, \boldsymbol{\psi}_n) &= \mathrm{sinc}(k||\boldsymbol{\psi}_m - \boldsymbol{\psi}_n||_2) \\ &= \frac{\sin(k||\boldsymbol{\psi}_m - \boldsymbol{\psi}_n||_2)}{k||\boldsymbol{\psi}_m - \boldsymbol{\psi}_n||_2},\end{aligned} \tag{15}$$

where $k = \omega/c_0$ is the acoustic wavenumber, and $||\cdot||_2$ denotes the l_2-norm. The second kernel function, adapted from [12], is a Gaussian kernel scaled according to the wavenumber, defined as

$$\kappa(\boldsymbol{\psi}_m, \boldsymbol{\psi}_n) = \exp\left(-k^2||\boldsymbol{\psi}_m - \boldsymbol{\psi}_n||_2^2\right). \tag{16}$$

To evaluate the accuracy of the interpolation, the overall interpolation error between the interpolated matrix $\underset{\sim}{\mathbf{H}}$ and the true matrix $\mathbf{H}$ at the interpolated head position $\boldsymbol{\psi}$ is defined as

$$L_{\mathbf{H}}(\boldsymbol{\psi}) = 10\log_{10}\left|\frac{\sum_{i,j}\left|h_{ij}(\boldsymbol{\psi}) - \underset{\sim}{h}_{ij}(\boldsymbol{\psi})\right|^2}{\sum_{i,j}\left|h_{ij}(\boldsymbol{\psi})\right|^2}\right|. \tag{17}$$

4. COMPARISON BETWEEN SPATIAL INTERPOLATION APPROACHES

This section evaluates the interpolation accuracy for the interpolation algorithm introduced in Sec. 3 and the performance of the active headrest system is then presented in Sec. 4.2, with a comparison between the two interpolation approaches described in Sec. 2.

4.1 Interpolation accuracy

Fig. 4 and Fig. 5 present the overall interpolation error, calculated according to Eqn. (17), for the $\mathbf{G}$, $\mathbf{S}_{xd}$, and $\mathbf{W}$ matrices at all head positions requiring interpolation, corresponding to the unmarked grid points in Fig. 3. To improve the conditioning of the Gram matrix inversion in Eqn. (11), the regularisation parameter for all cases was set to $\lambda = 1 \times 10^{-6}$. When the Helmholtz kernel function from Eqn. (15) is used to interpolate the $\mathbf{G}$ and $\mathbf{S}_{xd}$ matrices, the interpolation error, shown in Fig. 4a, remains below -30 dB across all frequencies. Notably, the error for $\mathbf{S}_{xd}$ is significantly lower than that for $\mathbf{G}$ at all frequencies, highlighting how interpolation accuracy varies between different matrices. In contrast, when using the Gaussian kernel function from Eqn. (16), as shown in Fig. 4b, the estimation error increases with frequency, exceeding -20 dB at some head positions around 900 Hz. This difference arises from the nature of the kernel function itself, as discussed in [10], where the Helmholtz kernel function is better suited for the interpolation of responses that are physically related to the acoustic sound field, such as the acoustic response. While both the plant $\mathbf{G}$ and spectral density $\mathbf{S}_{xd}$ correspond to the secondary and primary acoustic responses, respectively, the differences in interpolation accuracy between the two may arise

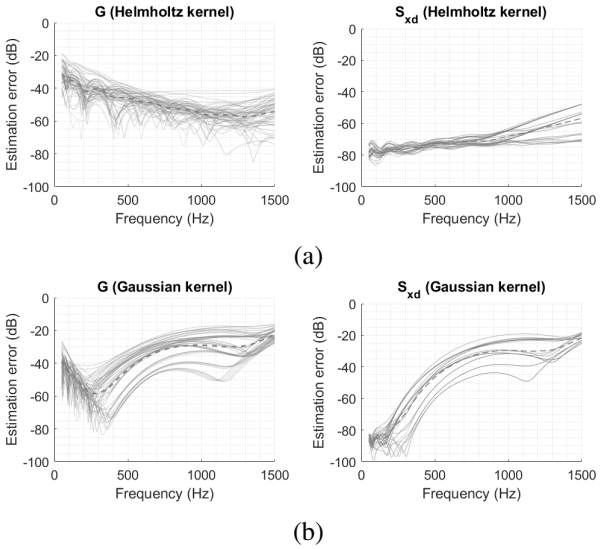

Figure 4: The overall interpolation error, evaluated using Eqn. (17), for the $\mathbf{G}$ and $\mathbf{S}_{xd}$ matrices as a function of frequency at head positions requiring interpolation. Solid lines represent errors for all head positions requiring interpolation using the (a) Helmholtz kernel from Eqn. (15) and the (b) Gaussian kernel from Eqn. (16), while the dotted line indicates the average interpolation error.

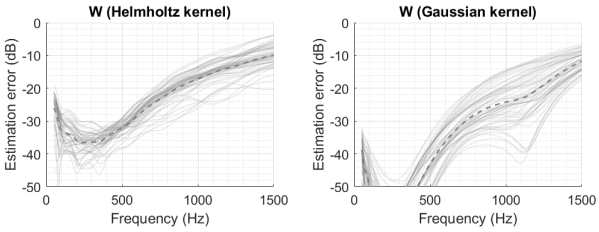
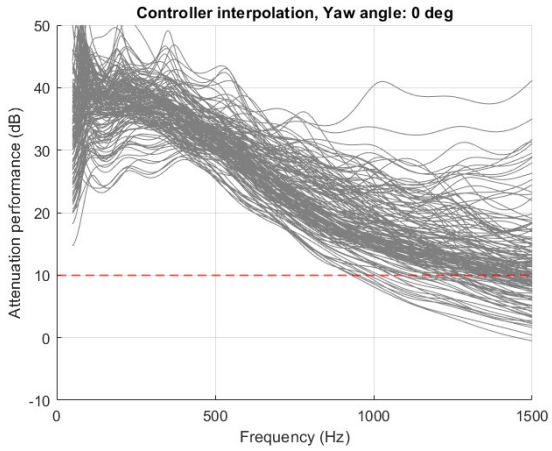
from the fact that the head scattering effect varies more spatially in the near-field compared to the far-field. When both the Helmholtz and Gaussian kernel functions are used to interpolate the control filter, the overall interpolation error, as shown in Fig. 5, is significantly lower compared to that of $\mathbf{G}$ and $\mathbf{S}_{xd}$, and increases with frequency. Even though the control filter is directly related to the plant responses, as shown in Eqn. (3), the individual elements of the controller matrix result from the interaction between all elements of the plant due to the matrix inverse and multiplication operation, which results in a lower interpolation accuracy. These results offer valuable insights into how the performance of the active headrest system varies between the spatial interpolation approaches, as further discussed in Sec. 4.2.

4.2 Control performance comparison between spatial interpolation approaches

Fig. 6 and Fig. 7 present the attenuation performance plots for the left error microphone as a function of frequency





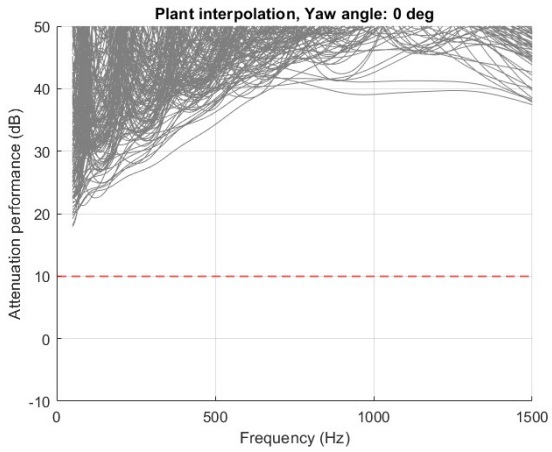


Figure 5: The overall interpolation error, evaluated using Eqn. (17), for the control filter $\mathbf{W}$ as a function of frequency at head positions requiring interpolation. Solid lines represent errors for all head positions requiring interpolation using the (a) Helmholtz kernel from Eqn. (15) and the (b) Gaussian kernel from Eqn. (16), while the dotted line indicates the average interpolation error.

for all head positions requiring interpolation. Depending on the interpolation approach being applied, interpolation is performed on either the plant responses or precomputed controllers obtained from the marked grid points in Fig. 3. When the controller-based interpolation strategy using the Kernel function from Eqn. (15) is applied (Fig. 6a), the attenuation performance generally decreases with increasing frequency, with less than 10 dB performance being achieved for some head positions at around 900 Hz. In contrast, the attenuation performance is significantly improved when the plant-based interpolation strategy (Fig. 6b) is used, with attenuation levels in excess of 20 dB being achieved across all frequencies. This is likely due to the differences in interpolation accuracy between the plant and controller matrices, as discussed in Sec. 4.1, which results in an upper-frequency limit beyond which the performance achieved by interpolating the controller is limited. When the Gaussian kernel from Eqn. (16) is used in the interpolation algorithm, the performance of both interpolation approaches degrades with increasing frequency. The results for the controller-based approach (Fig. 7a) show a slight improvement compared to those obtained using the Helmholtz kernel function (Fig. 6a) for some head positions. Although the plant-based interpolation approach still performs better than the controller-based interpolation approach, the results still highlight the importance of selecting the appropriate kernel function when performing spatial interpolation.

5. CONCLUSIONS

Although integrating head-tracking techniques into active noise control headrest systems has been shown to significant enhance control performance, the performance remains constrained by the resolution of head-tracking, which is limited by the calibration procedure. This limitation can be addressed by applying spatial interpolation techniques to estimate the either the controller or the plant responses at head positions that have not been explicitly calibrated. However, the effectiveness of interpolation depends on both the chosen interpolation approach and the utilised interpolation algorithm. This paper has presented two interpolation approaches: one that interpolates between plant models obtained at different head positions before computing the corresponding controller, and another that interpolates directly between a set of precomputed optimal controllers. In both cases the kernel ridge interpolation algorithm has been utilised with different kernel functions being explored. The results from numerical simulations of an active headrest system with head-tracking have demonstrated that when utilising the kernel ridge interpolation algorithm, a significant improvement in control performance is achieved when utilising the plant-based interpolation approach. It has also been shown that the kernel function has a significant impact on the achieved performance, with the Helmholtz kernel function providing a significant performance advantage when utilised with the plant-model interpolation approach, but providing somewhat inferior performance when applied to the controller-based interpolation approach.

STABILITY ANALYSIS OF STEPWISE SIMULTANEOUS PERTURBATION STOCHASTIC APPROXIMATION FOR ACTIVE NOISE CONTROL

Chao Liang[1*] **Francesco Ripamonti**[1] **Hamid Reza Karimi**[1]
[1] Department of Mechanical Engineering, Politecnico di Milano, 20156, Milan, Italy

ABSTRACT

Active noise control (ANC) is particularly effective in mitigating low-frequency noise, with its primary objective being to achieve maximum noise reduction while minimizing both measurement and computational costs. The filtered-x least mean square (FxLMS) algorithm has been widely adopted due to its effective balance between performance, ease of implementation, and computational efficiency. However, FxLMS relies on accurate secondary path estimation, which can be computationally intensive and time consuming. Recently, as a model-free method, the simultaneous perturbation stochastic approximation (SPSA) algorithm has been successfully applied in broadband, multi-channel, and time-varying environments. Despite its demonstrated effectiveness in noise reduction, the stability of SPSA has received limited attention. Following a recently proposed stepwise SPSA extension, which significantly enhances the stability of classical SPSA, this work investigates its stability characteristics with respect to key algorithmic parameters. The analysis provides insights into the parameter selection process, enabling efficient noise reduction while ensuring stability.

Keywords: *active noise control, stepwise SPSA, stability analysis, parameter optimization*

1. INTRODUCTION

The filtered-x least mean square (FxLMS) algorithm has been widely adopted in industrial active noise control (ANC) applications due to its effectiveness and implementation simplicity [1–3]. However, its performance is highly dependent on an accurate model of the secondary path, making it less suitable for time-varying environments.

As an alternative, simultaneous perturbation stochastic approximation (SPSA) provides a model-free approach to ANC. It updates the controller by estimating the gradient of the loss function using only function evaluations, thereby eliminating the need for explicit secondary-path modeling [4]. This characteristic enables SPSA to better adapt to changes in the acoustic environment.

SPSA has been applied in various ANC scenarios, including early adaptive systems [5], feedback control for periodic disturbances [6], time-varying environments [7], cross-correlation-based enhancements [8,9], second-order variants for faster convergence [10], and multi-channel extensions [11]. Despite these developments, SPSA's performance remains sensitive to parameter tuning, particularly the step size a and the perturbation coefficient c, where inappropriate settings may result in instability.

While prior research has primarily focused on the noise reduction performance of SPSA-based ANC, limited attention has been paid to its stability characteristics. Recently, stepwise SPSA (S-SPSA) was introduced to improve the robustness of the algorithm with respect to the selection of a and c [12]. This paper builds upon that foundation by further analyzing the influence of key algorithmic parameters on system stability and performance.

2. ALGORITHM DESCRIPTION

As illustrated in Fig. 1, the reference signal $x(n)$ passes through the primary path $P(n)$, generating the primary noise $d(n)$, where n denotes the discrete time index. To attenuate $d(n)$, the adaptive filter with weights $\boldsymbol{w}(n)$ gen-

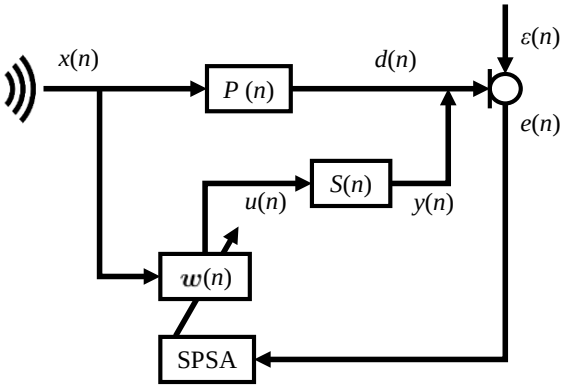

Figure 1: Block diagram of the ANC system using SPSA.

erates a control signal $u(n)$, which passes through the secondary path $S(n)$ to produce the anti-noise signal $y(n)$. The residual error $e(n)$, which also includes background noise $\varepsilon(n)$, is given by

$$e(n) = d(n) - y(n) + \varepsilon(n). \tag{1}$$

SPSA:

To minimize the energy of the residual error, SPSA iteratively updates the filter coefficients using

$$\boldsymbol{w}(k+1) = \boldsymbol{w}(k) - a\hat{\boldsymbol{g}}(\boldsymbol{w}(k)), \tag{2}$$

where k is the block index, a is the step size, and $\hat{\boldsymbol{g}}(\boldsymbol{w}(k))$ denotes the estimated gradient of the loss function.

The gradient is estimated by applying the perturbation $c\boldsymbol{\Delta}(k)$ to the weights $\boldsymbol{w}(k)$ and evaluating the loss function over two consecutive segments within a data block of length 2λ:

$$J^+ = J(\boldsymbol{w}(k) + c\boldsymbol{\Delta}(k)) = \frac{1}{2}\sum_{n=1}^{\lambda} e^2(n), \tag{3}$$

$$J^- = J(\boldsymbol{w}(k) - c\boldsymbol{\Delta}(k)) = \frac{1}{2}\sum_{n=\lambda+1}^{2\lambda} e^2(n), \tag{4}$$

where J is the loss function defined as the sum of squared error signals, c is the perturbation coefficient, $\boldsymbol{\Delta}(k)$ is a random perturbation vector, and 2λ is the block length. This structure ensures that the gradient approximation is based on distinct error responses to positive and negative perturbations, allowing for an efficient stochastic update.

The gradient is then estimated as:

$$\hat{\boldsymbol{g}}(\boldsymbol{w}(k)) = \frac{J^+ - J^-}{2c\boldsymbol{\Delta}(k)}. \tag{5}$$

S-SPSA:

To improve stability and convergence, the stepwise SPSA (S-SPSA) divides each block into $2m$ equal-length segments. Each segment has a length of λ/m. The loss functions for the i-th segment are defined as:

$$J_i^{s+} = \frac{1}{2}\sum_{n=(i-1)\frac{\lambda}{m}+1}^{i\frac{\lambda}{m}} e^2(n), \tag{6}$$

$$J_i^{s-} = \frac{1}{2}\sum_{n=(i-1)\frac{\lambda}{m}+\lambda+1}^{i\frac{\lambda}{m}+\lambda} e^2(n). \tag{7}$$

Each segment computes its own gradient independently:

$$\hat{\boldsymbol{g}}_i^s = \frac{J_i^{s+} - J_i^{s-}}{2c\boldsymbol{\Delta}_i(k)}, \quad \hat{\boldsymbol{g}}_i^s \in R^{\frac{L}{m}}, \tag{8}$$

where $\boldsymbol{\Delta}_i(k)$ is the i-th subvector of the perturbation vector $\boldsymbol{\Delta}(k)$, such that:

$$\boldsymbol{\Delta}(k) = \left[\boldsymbol{\Delta}_1^T(k), \boldsymbol{\Delta}_2^T(k), \ldots, \boldsymbol{\Delta}_m^T(k)\right]^T.$$

Finally, each sub-filter $\boldsymbol{w}_i(k)$ is updated independently as:

$$\boldsymbol{w}_i(k+1) = \boldsymbol{w}_i(k) - a\hat{\boldsymbol{g}}_i^s(\boldsymbol{w}(k)). \tag{9}$$

3. NUMERICAL SIMULATION AND RESULT DISCUSSION

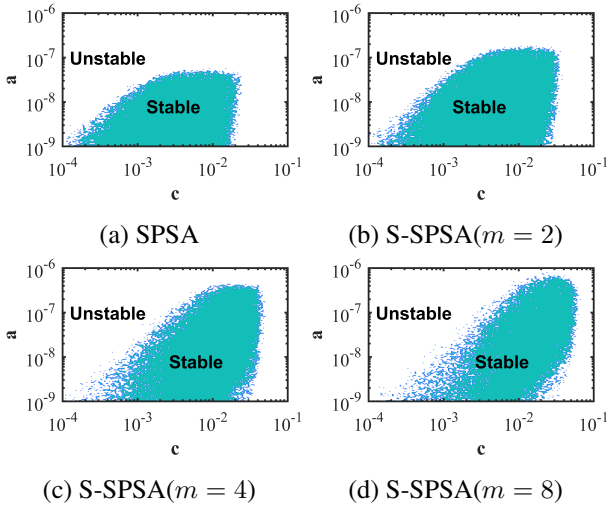
To investigate the influence of parameters on the stability of the algorithms, numerical simulations are conducted using the following default configuration. The sampling rate is set to 16 kHz. The adaptive filter $\boldsymbol{w}(n)$ has a length of $L = 1024$, and the block length is set to $2\lambda = 4000$. For the S-SPSA, each block is divided into $2m$ segments, where $m = 2$.

The reference signal $x(n)$ consists of a sum of tonal components with equal amplitude $A = 1$, at frequencies of 150 Hz, 200 Hz, ..., up to 700 Hz. Gaussian white noise $\varepsilon(n)$ is added as background interference, yielding a signal-to-noise ratio (SNR) of 10 dB between the original primary noise $d(n)$ and the background noise. The

primary and secondary paths are measured experimentally using a Kundt's tube and their frequency responses cover the range from 100 Hz to 750 Hz.

To evaluate the performance of active noise control, the attenuation of noise is quantified using the average noise reduction (ANR), defined as:

$$\mathrm{ANR}(n) = 10\log_{10}\frac{\sum_{i=n-l+1}^{n} e^2(i)}{\sum_{i=n-l+1}^{n}(d(i)+\varepsilon(i))^2}, \quad (10)$$



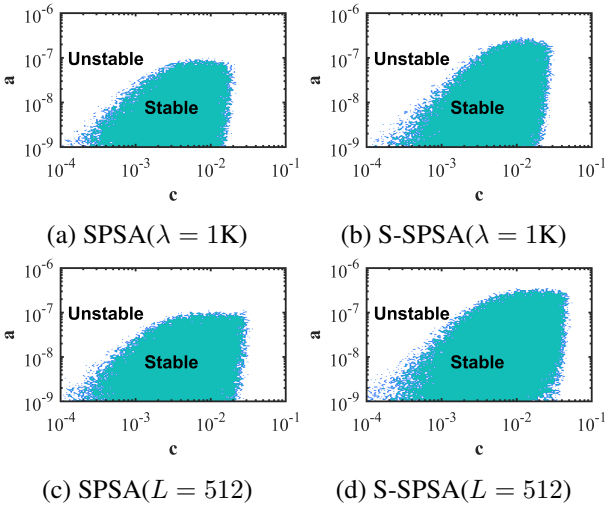
where the window length is set to $l = 2000$ samples.

3.1 Stability Comparison

To evaluate algorithmic stability, each simulation runs for 60 seconds. The system is considered *unstable* if one of the following conditions is met:

$$\begin{cases} \sum_{n=1}^{2\lambda} e^2(n) > 2\sum_{n=1}^{2\lambda} d^2(n), \\ \mathrm{ANR}(t = 60\,\mathrm{s}) \geq 0, \end{cases} \quad (11)$$

and is defined as *stable* otherwise.



(a) SPSA (b) S-SPSA($m = 2$)

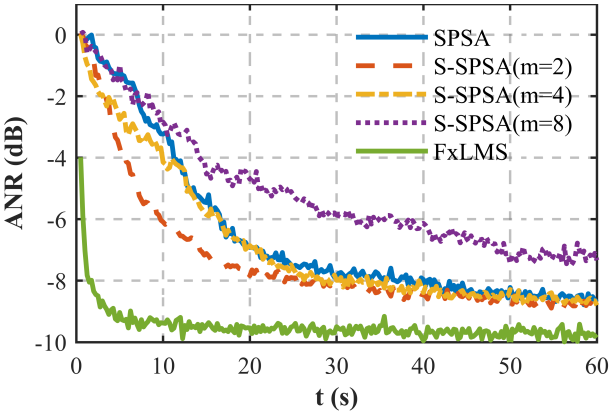
(c) S-SPSA($m = 4$) (d) S-SPSA($m = 8$)

Figure 2: Stability of the algorithms with respect to the parameter m.

As shown in Fig. 2, green regions indicate parameter combinations that lead to stable operation. Compared to the standard SPSA, the stepwise variant S-SPSA with $m = 2$ notably expands the stability region. Further increasing the segment number to $m = 4$ and $m = 8$ raises the upper bounds of stable values for both step size a and perturbation coefficient c. However, S-SPSA with $m = 8$ exhibits a narrower overall stability region, indicating that $m = 2$ and $m = 4$ have better stability.

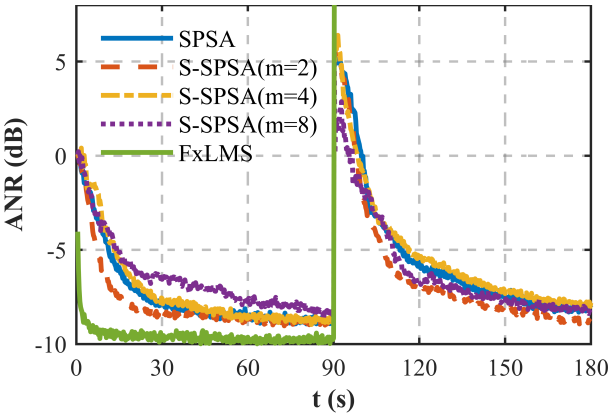
In Fig. 3, S-SPSA again demonstrates a broader stable region than conventional SPSA. Compared to Fig. 2a and Fig. 2b, it can be observed that reducing either the block length λ or filter length L increases the upper stability boundary for the step size a, implying improved robustness under smaller system dimensions.

(a) SPSA($\lambda = 1$K) (b) S-SPSA($\lambda = 1$K)



(c) SPSA($L = 512$) (d) S-SPSA($L = 512$)

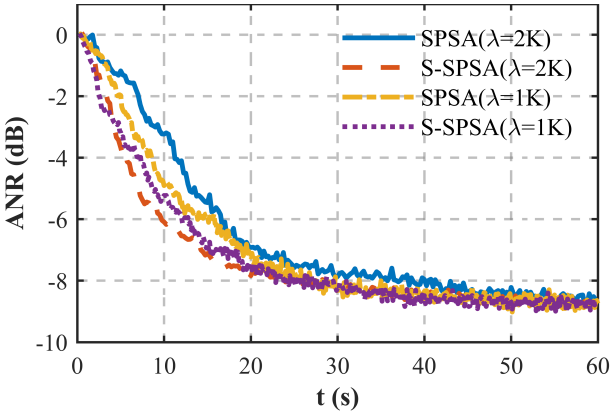
Figure 3: Stability of the algorithms with respect to the parameters λ and L.



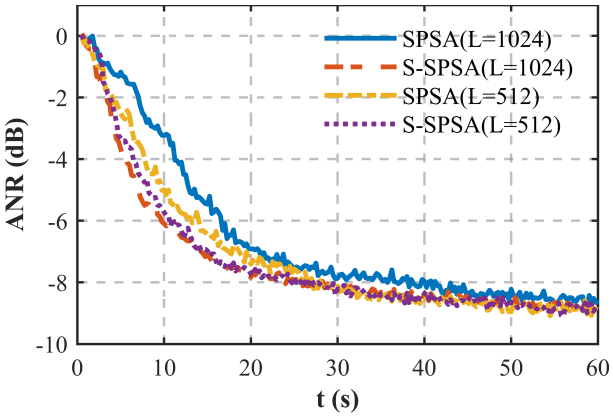
3.2 Performance Comparison

The tracking performance of the algorithms is assessed using the ANR metric, defined in Eq. (10), with optimal parameters a and c. As depicted in Fig. 4a, the convergence behavior of standard SPSA, S-SPSA with $m = 2, 4, 8$, and FxLMS is evaluated over 60 seconds. S-SPSA with $m = 4$ closely approximates the performance of standard SPSA, stabilizing at an ANR of approximately -8.7 dB. The variant with $m = 2$ exhibits the fastest initial convergence among S-SPSA configurations, reaching -6 dB within 10 seconds, while $m = 8$ converges more slowly, stabilizing at a slightly higher ANR of -7.3 dB. In contrast, FxLMS demonstrates superior performance, achieving an ANR below -8 dB within 5 seconds and maintaining a steady-state value near -10 dB.

The robustness of these algorithms to abrupt changes is examined in Fig. 4b, where the secondary path is reversed at $t = 90$ s. After this point, FxLMS diverges



(a) Convergence performance of algorithms



(b) Robustness to secondary path reversal at $t = 90$ s

Figure 4: ANR performance with the parameter m

(a) ANR versus block length λ

(b) ANR versus filter length L

Figure 5: ANR performance with respect to the parameters λ and L

sharply to instability. Conversely, SPSA and S-SPSA variants exhibit adaptivity; their ANR values increase temporarily to over 0 dB but recover gradually over the subsequent 90 seconds.

The influence of block length λ and filter length L on performance is shown in Fig. 5. At $\lambda = 1$K and $L = 512$, the ANR differences across SPSA and S-SPSA diminish, suggesting that shorter block and filter lengths lessen the impact of m on noise reduction performance.

4. CONCLUSION

This paper investigates the impact of the segment number m, half block length λ, and filter length L on the stability and noise reduction performance of the SPSA and S-SPSA algorithms. The results demonstrate that increasing m generally raises the upper stability bound for the step size a, while configurations with $m = 2$ or $m = 4$ are recommended due to their stability and noise attenuation performance.

Additionally, smaller values of λ and L not only enhance algorithmic stability by allowing for larger values of a, but also reduce the performance gap between SPSA and S-SPSA variants. These findings suggest that appropriate segmentation and parameter selection are crucial for robust and efficient adaptive noise control using perturbation-based optimization.

SPATIAL PSYCHOACOUSTIC ANALYSIS OF PERCEPTUAL ERROR SHAPING IN LOCAL ACTIVE NOISE CONTROL

Christian Blöcher[1*] **Alois Sontacchi**[1] **Thomas Hatheier**[2]

ABSTRACT

To address the frequency-dependent nature of human auditory perception, error shaping can be incorporated into traditional feedforward Filtered-Reference Least-Mean-Squares (FxLMS) local Active Noise Control (ANC) schemes by applying A-weighting to the LMS input signals. Several publications have compared the psychoacoustic properties of noise residuals produced by such Filtered-Error LMS (FeLMS) and FxLMS ANC systems at the point of cancellation. This paper expands previous studies by additionally investigating the surrounding sound field. In a co-simulation, both algorithms are evaluated for fullband and bandlimited control for an active headrest system with two built-in loudspeakers and a head and torso simulator (HATS) positioned in front of the headrest. With white, pink, and real-world driving noise as innovation signals, the sound field after adaptation is evaluated for HATS rotations and transitions to the front, utilizing psychoacoustic- and speech metrics. While the FeLMS algorithm generally produces more coloration for head movements from the reference position than the FxLMS algorithm, performance for synthetic signals is otherwise similar. However, for driving noise, it achieves greater loudness reduction and improved speech intelligibility. The spatial extent of noise control is enlarged for bandlimited compared to fullband ANC systems at the cost of reduced performance near the reference position.

1. INTRODUCTION

Active Noise Control (ANC) aims at reducing unwanted noise by superimposing a destructively interfering anti-noise played via loudspeakers. The optimization goal of traditional feedforward ANC schemes relying on the Filtered-Reference Least-Mean-Squares (FxLMS) approach is the minimization of the error signal energy [1]. This corresponds to a maximization of the mean noise reduction across the entire controlled frequency spectrum. However, since this criterion ignores the frequency-dependent nature of human auditory perception [2], the achieved noise reduction may be suboptimal. A simple, yet effective way of incorporating the frequency characteristic of our hearing system is perceptual error shaping. In a Filtered-Error LMS (FeLMS) ANC approach [3], a psychoacoustic rating filter, such as A-weighting, can be applied to the LMS input signals to guide the focus of the adaptation towards frequency regions in which our hearing is more sensitive [4]. Previous publications have compared the psychoacoustic properties of noise residuals produced by perceptually motivated FeLMS ANC approaches and FxLMS systems at the point of cancellation [5] or for headphone applications [6]. This paper extends the evaluation by additionally investigating the psychoacoustic properties of the surrounding sound field. In a co-simulation, both FxLMS and FeLMS algorithms are evaluated for fullband and bandlimited local control in an active headrest system for use in vehicles, utilizing both synthetic and real-world innovation signals.

The rest of this paper is organized as follows. Section 2 details the co-simulation by describing the physical measurement setup, specifying the utilized innovation signals, and highlighting the investigated ANC algorithms and adaptation procedure. Section 3 features the metrics used in the spatial psychoacoustic evaluation, before results are presented in section 4. To conclude, section 5 summarizes the findings and provides an outlook.

Figure 2. Placement of the HATS in front of the headrest at the reference position.

2. CO-SIMULATION

2.1 Measurement Setup

The evaluation took place within a co-simulation based on the physical setup depicted in Fig. 1, extending the approach described in [7]. In an anechoic room, a Brüel & Kjær 4128C HATS was positioned in front of an active headrest situated in the center of a circular arrangement of eight Genelec 8020B loudspeakers with a radius of $1.45\,\mathrm{m}$. While these loudspeakers served as the primary sources, two loudspeakers integrated into the headrest in close proximity to the HATS' ears were utilized as secondary sources. To model this scenario within the co-simulation, both the acoustic primary paths between the loudspeakers in the circular arrangement and the HATS, and the acoustic secondary paths between the headrest loudspeakers and the HATS were measured at a sample rate of $44.1\,\mathrm{kHz}$ using the method of multiple exponential sine sweeps [8]. Starting from the neutral HATS position shown in Fig. 2 as a reference position, the measurement procedure was repeated for rotations of the HATS of up to $30°$ to the left in $1°$ steps and lateral transitions of the HATS of up to $15\,\mathrm{cm}$ to the front in $0.5\,\mathrm{cm}$ steps. To ensure the accuracy of the re-positioning of the HATS, rotations were executed using a motorized turntable and the HATS' position was verified using an optical tracking system (OptiTrack Motive with 6 Flex3 cameras, mean error $\leq 0.5\,\mathrm{mm}$) for both rotations and transitions.

2.2 Innovation Signals

For the co-simulation, both synthetic and real-world innovation signals were utilized. As synthetic test signals, $75\,\mathrm{s}$ of mono white and pink noise were generated at a sample rate of $44.1\,\mathrm{kHz}$. Additionally, a recording of driving noise captured using an NTi MA2230 measurement microphone in a car (combustion engine, $80\,\mathrm{km/h}$) was cut to the same duration. To achieve a diffuse presentation, all innovation signals were processed using the IEM Plugin Suite's [1] Granular Encoder [9] as described by Holzmüller et al. [10] and decoded to the eight-channel loudspeaker arrangement using the AllRAD approach [11]. After application of the primary path transfer functions for the reference position, all spatialized innovation signals were normalized to produce a level of $70\,\mathrm{dB(A)}$ at the HATS. Subsequently, the spatialized signals at the HATS were generated from the normalized innovation signals for all measurement positions.

2.3 Evaluated ANC Systems

Fig. 3 illustrates the extension of the FxLMS algorithm into an FeLMS ANC system, as detailed in [3], for the evaluated setup. In an FxLMS system, the broadband disturbances $\mathbf{d}(n)$ at the HATS' microphones, modeled as the reference signals $\mathbf{x}(n)$ filtered by the respective primary paths $\mathbf{P}(z)$, are superimposed with the control signals $\mathbf{y}(n)$, resulting in the error signals $\mathbf{e}(n)$. With the control signals generated by filtering $\mathbf{x}(n)$ with a set of adaptive linear filters $\mathbf{W}(z)$ and applying the secondary paths $\mathbf{S}(z)$, the error signal at HATS microphone m can be expressed as

$$e_m(n) = d_m(n) + \sum_{i,j} \left(\mathbf{w}_{i,j}^T(n)\,\mathbf{x}_i(n)\right) * \mathbf{s}_{j,m}(n), \quad (1)$$

[1] https://plugins.iem.at

where $*$ indicates the convolution operation, $\mathbf{s}_{j,m}$ denotes the impulse response of $S_{j,m}(z)$ between secondary loudspeaker j and HATS microphone m, $\mathbf{x}_i(n) = [x_{i,0}(n), x_{i,1}(n), ..., x_{i,N-1}(n)]^T$ is the reference signal vector at primary loudspeaker i, and $\mathbf{w}_{i,j}(n) = [w_{i,j,0}(n), w_{i,j,1}(n), ..., w_{i,j,N-1}(n)]^T$ is the coefficient vector of $W_{i,j}(z)$, controlling the reference signal at primary loudspeaker i via secondary loudspeaker j, with filter order N at time n.

The filter coefficients are updated via the LMS algorithm, which takes the error signals $\mathbf{e}(n)$ and the filtered reference signals $\mathbf{r}(n)$ as inputs. Instead of the typical approach of filtering $\mathbf{x}(n)$ via an offline estimate of the secondary paths $\hat{\mathbf{S}}(z)$, in this simulation we can substitute $\hat{\mathbf{S}}(z)$ with our actual secondary paths $\mathbf{S}(z)$. The update equation for the filter coefficients $\mathbf{w}_{i,j}(n)$ is expressed as

$$\mathbf{w}_{i,j}(n+1) = \mathbf{w}_{i,j}(n) - \mu\, \mathbf{r}_{i,j}^T(n)\, \mathbf{e}(n), \qquad (2)$$

where $\mathbf{r}_{i,j} = [\mathbf{r}_{i,j,0}(n), \mathbf{r}_{i,j,1}(n), ..., \mathbf{r}_{i,j,N-1}(n)]^T$ denotes the filtered reference signal vectors for reference signal i, filtered with the secondary paths $\mathbf{S}_j(z)$ from secondary loudspeaker j to both HATS microphones, and μ is the adaptation step size.

In an FeLMS system both LMS input signals are additionally filtered with a weighting filter $H(z)$. Here, $H(z)$ denotes an A-weighting of the LMS input signals, implemented as a 7th order digital IIR filter derived via the improved matched z-transform method [12]. With $\mathbf{r_f}(n)$ and $\mathbf{e_f}(n)$ denoting the perceptually filtered versions of $\mathbf{r}(n)$ and $\mathbf{e}(n)$, Eqn. (2) becomes:

$$\mathbf{w}_{i,j}(n+1) = \mathbf{w}_{i,j}(n) - \mu\, \mathbf{r_f}^T_{i,j}(n)\, \mathbf{e_f}(n). \qquad (3)$$

To improve the convergence behavior of both ANC systems, the Normalized LMS (NLMS) algorithm [13] is employed, normalizing the adaptation step size by the time-smoothed total maximum energy over all $\mathbf{r}_{i,j}(n)$ and $\mathbf{r_f}_{i,j}(n)$, respectively.

As previous studies have shown, that the perceived spatial extent of ANC systems increases when limiting the control bandwidth [10], the evaluation of both FxNLMS and FeNLMS algorithms was conducted for both fullband and bandlimited ANC systems, i.e. at sample rates $f_{s,anc} = \{44.1\,\text{kHz}; 4410\,\text{Hz}\}$ with respective control filter lengths of 512 and 51 taps ($\hat{=}\,12\,\text{ms}$).

2.4 Adaptation

The adaptation for all ANC systems, bandwidth conditions, and innovation signals was conducted for the reference position only. Step sizes for all conditions were set individually to ensure convergence after 70 s of the innovation signal.

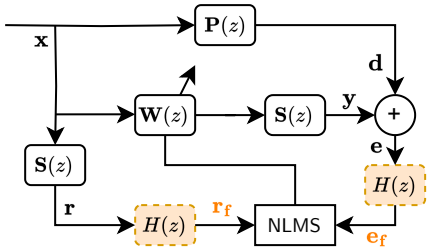

Figure 3. Extension of the FxNLMS algorithm into an FeNLMS system via added weighting filters $H(z)$ (orange) for the evaluated setup.

Fig. 4 shows the semitone-smoothed error power spectral densities (PSD) for the left HATS channel at the reference position both without ANC and after the adaptation process for all conditions. At the point of cancellation, substantial noise reduction is achieved by both FxNLMS and FeNLMS algorithms for white and pink noise in both bandwidth conditions. The FeNLMS PSDs show a bathtub-shaped frequency characteristic due to the applied A-weighting with a slight amplification of very low frequencies, while the FxNLMS algorithm tends to focus more on the reduction of higher frequency components. However, for driving noise, only the FeNLMS algorithm manages to achieve substantial noise reduction, while the FxNLMS algorithm only reduces very low frequency components and some harmonics caused by the car's combustion engine. The error PSDs for the bandlimited condition are in good agreement with the fullband condition up to just below the systems' Nyquist frequency at 2205 Hz, except for the FxNLMS algorithm for white noise, which achieves greater noise reduction in the controlled frequency range in the bandlimited condition.

3. EVALUATION

In order to evaluate the controlled sound field for rotations and transitions of the HATS extending from the sweet spot at the reference position, the control- and innovation signals were superimposed at all measurement positions. For each condition, the spatialized control signals were generated by filtering the normalized innovation signals with the respective converged adaptive filter and then applying the

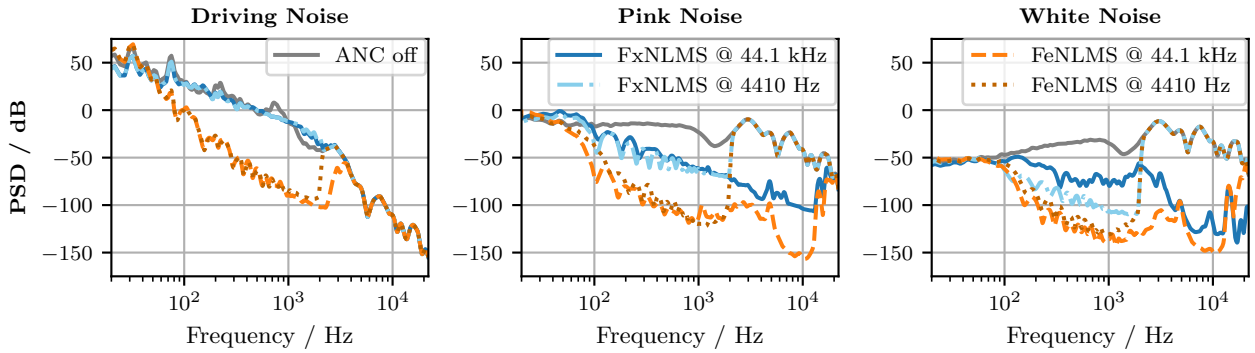

Figure 4. Error power spectral densities (PSD) at the reference position at left HATS channel for all control conditions after convergence. To prevent obscuring any data points, legend items are distributed among subplots.

corresponding secondary paths. The duration of the generated stimuli was 10 s. Afterwards, the following metrics were calculated in MATLAB R2024a at all measurement positions for both the uncontrolled spatialized innovation signals and all control conditions.

RMS. The monaural root mean square (RMS) value for the left HATS channel. Lower is better.

Loudness. The binaural loudness calculated using MATLAB's Audio Toolbox implementation of the Moore-Glasberg model [14] for signals captured at the eardrum. Lower is better.

Sharpness. The monaural acoustic sharpness of the left HATS channel computed using MATLAB's Audio Toolbox implementation of the model in DIN 45692 [15]. Lower is better.

PEMO-Q. The monaural Perceptual Similarity Measure (PSM) calculated by the PEMO-Q [2] [16] between the signal at the left HATS channel at the reference position and all other measurement positions. The PSM is calculated from the correlation between internal representations of level-normalized reference and test signals based on the Oldenburg Perception Model (PEMO). Higher is better.

MBSTOI. The reference-based Modified Binaural Short-Time Objective Intelligibility (MBSTOI) [3] [17] evaluated for a potential communication scenario, in which the adaptation of the ANC filters is paused, and the headrest loudspeakers are used to also play speech signals. To limit potential speaker-related biases the mean MBSTOI was calculated over the first sentence of each of the six speech samples provided in the EBU SQUAM material [4] in English, German, and French, uttered by male and female speakers. With the speech samples spatialized to the HATS using the secondary transfer paths and normalized to 55 dB(A), the MBSTOI was calculated from the speech samples in noise with the reference condition of speech samples spatialized to the HATS without any innovation signal present. Higher is better.

For monaural metrics, only signals at the left HATS channel were evaluated, because for rotations of the HATS greater fluctuations caused by the control signals can be expected at the ipsilateral ear, while for transitions to the front there is little difference between the channels due to the symmetric arrangement of the measurement setup.

4. RESULTS

The evaluated metrics for all ANC and innovation signal conditions are displayed in Fig. 5 for HATS rotations, and in Fig. 6 for transitions of the HATS. Prior to an in-depth discussion of the results, it is possible to discern several general trends from the data. For white noise there is little difference between algorithms, except for sharpness close to the reference position and coloration compared to the reference position expressed via the PEMO-Q values. For white and pink noise, and a translation of 2 cm to 5 cm, an interference effect is visible as the HATS exits the acoustic shadow provided by the headrest against the mid-to-back primary loudspeakers. For driving noise, there is virtually no difference per algorithm between bandwidth conditions due to the strong spectral tilt of the innovation signal. For

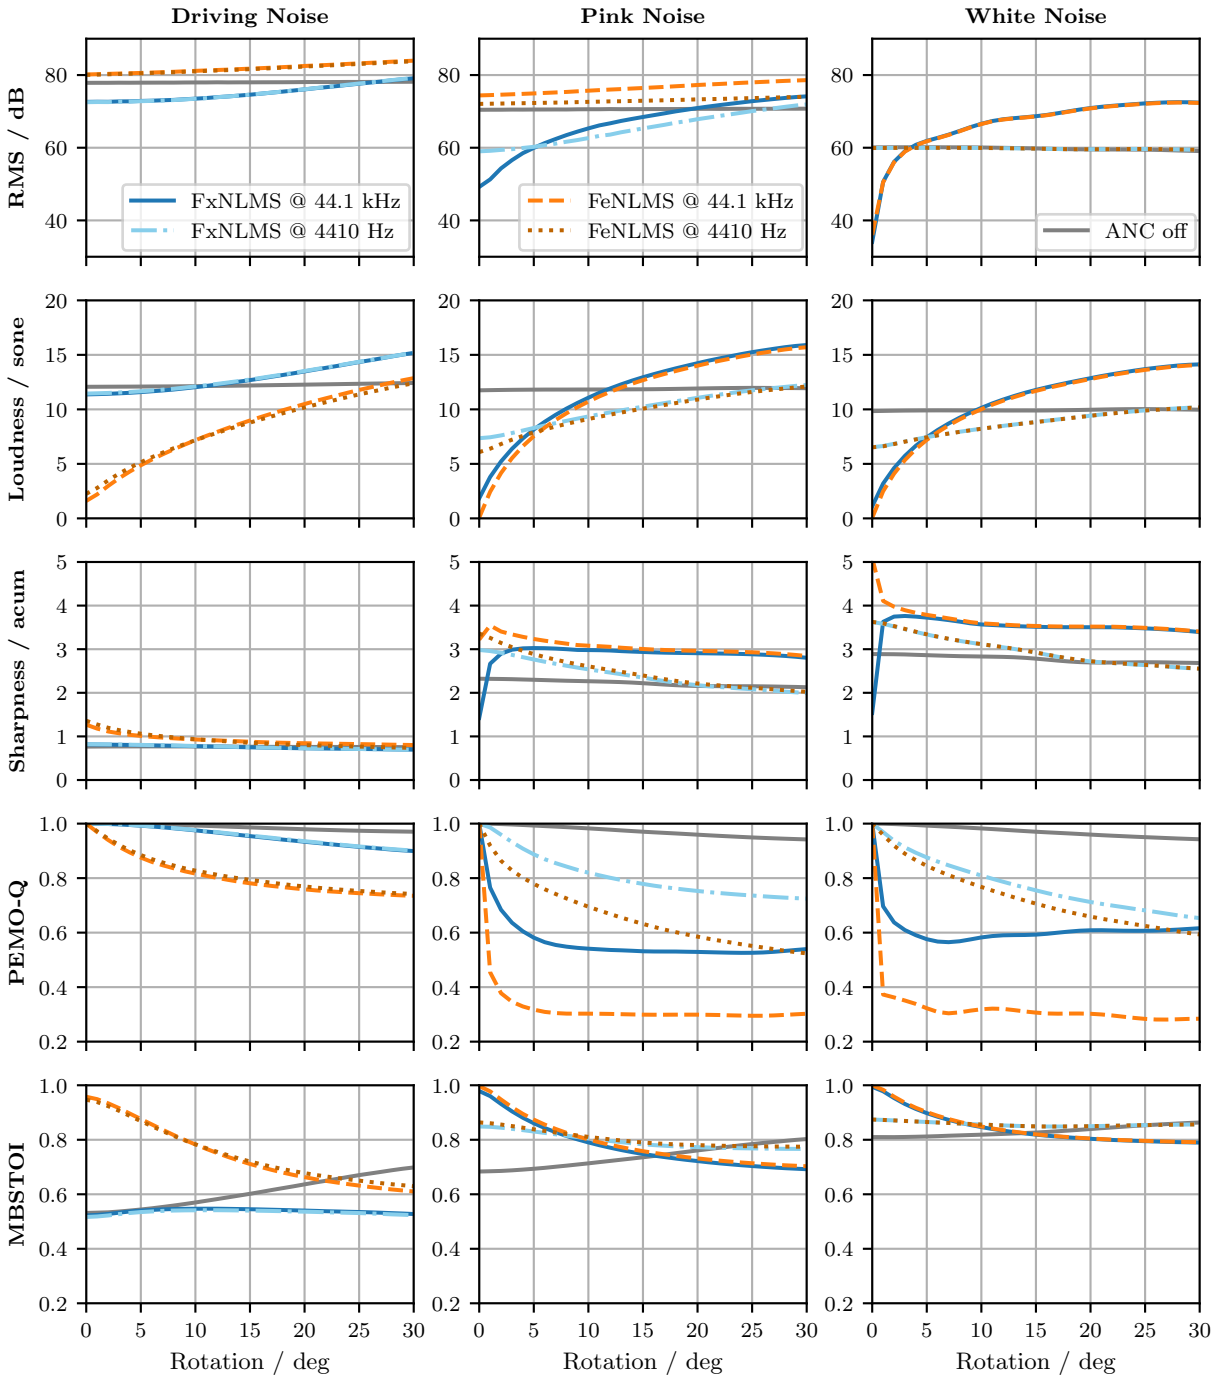

Figure 5. Evaluated metrics (rows) for all innovation signals (columns) as a function of HATS *rotation* from the reference position without ANC, and for fullband and bandlimited FxNLMS and FeNLMS ANC systems. To prevent obscuring any data points, legend items are distributed among subplots.

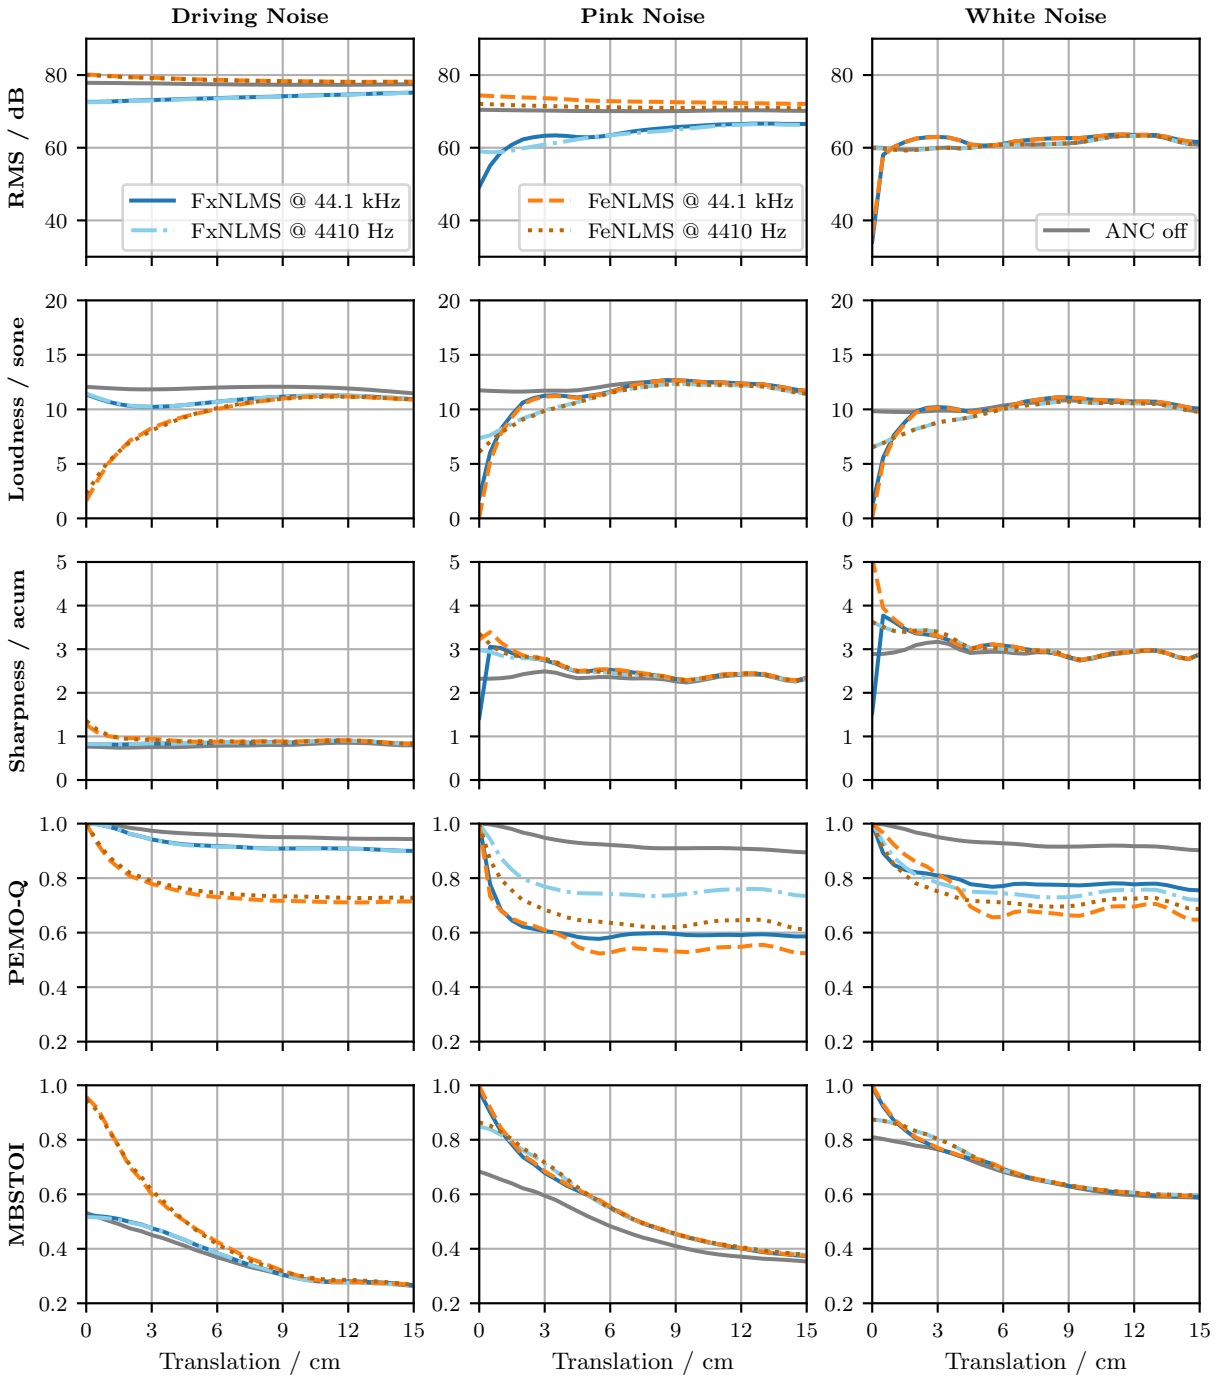

Figure 6. Evaluated metrics (rows) for all innovation signals (columns) as a function of HATS *translation* from the reference position without ANC, and for fullband and bandlimited FxNLMS and FeNLMS ANC systems. To prevent obscuring any data points, legend items are distributed among subplots.

the other innovation signals, compared to the fullband condition, the bandlimited condition generally results in smaller deviations from the data without ANC close to the reference position. The effects of the bandlimited condition also decrease more gradually with increasing rotation and translation from the reference position.

RMS. For white noise, both fullband ANC systems achieve a substantial reduction at the reference position but produce increased RMS values from 4° rotation and from 1 cm to 11 cm translation. The bandlimited ANC systems cause virtually no change in RMS. For pink noise, both FxNLMS systems manage a reduction in RMS that decreases for increasing rotation and translation, with the fullband condition performing better only near the reference position. Both FeNLMS systems cause an increase in RMS, that increases with rotation and slightly decreases with translation. For driving noise, these general trends between algorithms remain. While the FxNLMS systems achieve less reduction in RMS at the reference position compared to pink noise, the decrease in reduction for rotation and translation is more gradual.

Loudness. For white noise, similar trends are visible for the fullband condition as in the RMS results with the area of effect extending slightly further. Not visible in the RMS data, the bandlimited condition achieves some loudness reduction up to 25° rotation and 6 cm translation. Contrary to the RMS results, the FeNLMS algorithm achieves loudness reduction for both pink and driving noise, due to the focus on perceptually relevant frequency regions. While for pink noise, the FeNLMS systems achieve higher loudness reduction at the reference position, similar loudness reduction to the results for white noise is achieved for all conditions for head movements. For driving noise, the FeNLMS algorithm achieves a substantial loudness decrease at the reference position, while the FxNLMS algorithm barely reduces the loudness of the innovation signal. Loudness reduction extends up to 25° rotation and 10 cm translation for the FeNLMS systems, while loudness is increased by the FxNLMS systems from 10° rotation but remains stable across translation.

Sharpness. For white and pink noise, sharpness is reduced at the reference position by the fullband FxNLMS system but increased for all other ANC conditions. For rotations, sharpness remains increased over the condition without ANC for fullband control but reduces to the uncontrolled value for bandlimited control at 17° rotation. For transitions, sharpness reduces to match the value without ANC at 7 cm for all ANC conditions. For driving noise, sharpness is only slightly increased for the FeNLMS algorithm near the reference position.

PEMO-Q. Only slight changes are observed for all uncontrolled innovation signals. For all innovation signals, the sound field produced by the FeNLMS algorithm exhibits lower perceptual similarity to the reference position per bandwidth condition than that produced by the FxNLMS algorithm, with larger differences visible for rotation of the HATS. For fullband control, and white and pink noise, rotations of only 2° already cause a drop in perceptual similarity before values remain constant from 5°, indicating substantial coloration compared to the reference position, especially for the FeNLMS algorithm. An ongoing, more gradual decrease is visible for bandlimited conditions and driving noise. Across translations, the decline in perceptual similarity is less steep and values remain mostly constant from 5 cm translation for all conditions.

MBSTOI. Since the speech audio is played back via the headrest loudspeakers, intelligibility without ANC increases with rotation, because the ipsilateral ear moves towards the left loudspeaker. Similarly, intelligibility decreases with translation, because the HATS moves away from the loudspeakers. For white and pink noise, both fullband ANC systems enable perfect intelligibility at the reference position that decreases to levels observed without ANC by 12° rotation and 3 cm translation for white noise, and 15° rotation for pink noise. For larger rotation, intelligibility values fall below those of the uncontrolled condition. The bandlimited ANC systems cause slightly lower intelligibility at the reference position, but show a more gradual decline with increased rotation, extending the area of effect to 20°. Across translations, intelligibility is the same for all ANC systems from 5 cm. For driving noise, only the FeNLMS algorithm causes a substantial increase in intelligibility with the effect extending to 20° rotation and 8 cm translation.

5. CONCLUSION

In a co-simulation of an active headrest system, a perceptually motivated FeNLMS algorithm using A-weighting was compared to an FxNLMS algorithm for fullband and bandlimited control with white, pink, and driving noise as innovation signals. Extending from the point of cancellation, the sound field produced by the ANC measures was evaluated for head rotations and transitions to the front based on RMS, binaural loudness, sharpness, PEMO-Q, and MBSTOI.

While the FeNLMS algorithm increases RMS values for pink and driving noise, the adaptation focus on per-

ceptually relevant frequency regions causes a substantial reduction in loudness surrounding the point of cancellation.

For white and pink noise, there is only little difference between both algorithms in loudness and speech intelligibility, but the FeNLMS algorithm causes an increase in sharpness at the reference position and an increased coloration for head movements. However, for driving noise, the FeNLMS algorithm achieves vastly better loudness reduction and an increase in speech intelligibility.

While for white and pink noise, both algorithms perform better at the point of cancellation for the fullband condition when examining RMS, loudness, and MBSTOI, differences from the uncontrolled condition decrease more gradually for the bandlimited ANC systems. Further supported by the lower sharpness change and reduced coloration for head movements, an increased spatial extent is suggested for bandlimited control. For driving noise, the bandlimited ANC systems perform equally well as the fullband systems.

Future work will focus on the conduction of listening experiments to verify the simulation results.

ABSTRACT

The acoustic quality inside vehicles has become a key factor in the overall evaluation of cars, particularly in luxury models. As a result, improving in-cabin communication and overall acoustic comfort has gained significant attention from the automotive industry. Recently technologies, such as Active Road Noise Cancellation (ARNC), have been extensively explored to reduce unwanted noise, effectively lowering acoustic pressure within the vehicle cabin. Beyond noise reduction, these algorithms have the potential to significantly enhance in-vehicle speech intelligibility. In this study, we investigate the impact of ARNC algorithms on person-to-person speech communication, simulating conversations between passengers. Experimental measurements have been conducted in a four-seat vehicle model equipped with a state-of-the-art ARNC system. Passenger communication has been simulated by convolving reference speech signals with measured acoustic impulse responses within the vehicle cabin. Additionally, we compare different metrics to assess speech intelligibility between front and rear seats, evaluating the effectiveness of the ARNC algorithm. The results demonstrate the potential of ARNC in enhancing in-vehicle speech intelligibility, offering valuable insights for future advancements in automotive audio technology.

1. INTRODUCTION

The ability to communicate effectively within a car is crucial for both comfort and safety, making acoustic optimization a key area of research and development [1, 2]. Traditionally, improving acoustic comfort in a vehicle has relied on passive noise control techniques, such as by improving insulation materials, acoustic glazing, and optimized cabin structures. Although these methods effectively reduce overall noise levels, they are often limited by weight, cost, and design limitations. Furthermore, passive solutions are typically more effective at high frequencies, while their insulating properties tend to degrade at lower frequencies, making them less effective against road-induced low-frequency noise.

As an alternative, active solutions have gained significant attention, encompassing a variety of approaches based on advanced signal processing, including personalized audio zones (commonly referred to as ”private bubbles”) and Active Road Noise Cancellation (ARNC). The latter, in particular, aims to reduce low-frequency road noise by generating anti-noise signals, typically through the vehicle’s audio system. Although ARNC has been developed primarily to enhance passenger comfort by reducing background noise levels, its potential impact on speech intelligibility within the vehicle has not yet been fully explored.

In this paper, we assess the indirect benefits of ARNC on the in-car speech intelligibility by analyzing how reduced road noise contributes to clearer in-vehicle communication. We present a series of experimental measurements along with objective and subjective evaluations, aiming to provide insights into the role of ARNC not only as a comfort-enhancing or weight-reduction technology,

but also as a potential enabler of improved speech communication among vehicle occupants.

The rest of the paper is structured as follows. Sec. 2 present the context and background of ARNC and speech intelligibility. In Sec. 3 we present the methodology and experimental scenario to evaluate the impact of ARNC in passanger-to-passanger communications. Results are provided in Sec. 4 along with objective metrics and subjective evaluations. In Sec. 5 we draw final conclusions and considerations.

2. BACKGROUND AND PROBLEM FORMULATION

2.1 Active Road Noise Cancellation

Active Road Noise Cancellation (ARNC) refers to the application of Active Noise Cancellation (ANC) techniques to mitigate low-frequency road noise inside vehicle cabins. ANC techniques actively generate anti-noise signals to counteract unwanted sound waves, leveraging the principle of destructive interference [3, 4]. Unlike passive solutions, which rely on insulating materials and structural modifications, active techniques require an external power source and the implementation of a control strategy.

Most control systems are based on the well-known Filtered-x Least Mean Squares (FxLMS) algorithm [5, 6], which is an extension of the LMS algorithm [7] belonging to the gradient descent [8] family of optimization techniques. These techniques minimize a cost function by iteratively moving in the direction of its negative gradient [9]. FxLMS is a hybrid-feedforward control strategy based on adaptive filtering [7] that iteratively adjusts the filter coefficients to minimize the residual error, i.e., the sound pressure level at the cancellation position. The algorithm employs reference sensors, error microphones, and actuators to find the optimal solution and apply the control action.

A typical ARNC architecture adopted accelerometers mounted on the chassis or suspension system as reference sensors to detect road-induced vibrations before they propagate into the cabin. To measure the residual error, microphones are strategically placed within the cabin. Finally, actuators are typically the loudspeakers of the car's sound system [10].

The ARNC system operates by modeling two main paths: the primary and the secondary [11]. The primary path refers to the sound propagation from the road to the cabin, while the secondary path represents the transfer function from the actuators to the microphones within the cabin. The FxLMS algorithm continuously adapts to these paths to optimize noise cancellation, accounting for plant variations.

2.2 Speech Intelligibility

Speech intelligibility within a vehicle cabin is a critical aspect of passenger communication, particularly in the presence of road noise [12, 13]. High noise levels can mask speech signals, reducing the ability of passengers to understand each other clearly. The assessment of speech intelligibility in noisy environments typically relies on both objective and subjective evaluation methods.

Several metrics are commonly used to quantify speech intelligibility. The Short-Time Objective Intelligibility (STOI) [14] metric provides a prediction of intelligibility by analyzing the correlation between clean and degraded speech signals. The Signal-to-Noise Ratio (SNR) [15] quantifies the relative level of speech against background noise, with higher values indicating improved clarity.

In this paper, we leverage these metrics to quantify the impact of ARNC on speech intelligibility, comparing objective measurements in different road conditions to assess its role in improving in-vehicle communication.

3. METHODOLOGY

In this study, a speaker located in the rear right seat of a car has been simulated, and the impact of an ARNC system on speech intelligibility at the front right passenger position has been assessed. To achieve this, a state-of-the-art active noise cancellation system based on the Filtered-x Least Mean Squares algorithm has been implemented.

3.1 Experimental scenario

In order to evaluate the potential benefits of an Active Road Noise Cancellation (ARNC) system on in-vehicle speech intelligibility, an FxLMS-based algorithm was implemented and tested on the vehicle. The car was instrumented with accelerometers placed at carefully selected locations, while microphones were positioned inside the cabin, near the right front passenger's ears.

We adopted the mouth simulator of a Head and Torso Simulator (HATS) [16] placed on the right rear passenger seat to simulate human speeches. Specifically, the impulse responses (IRs) from the artificial mouth to the left and right microphones at the co-driver's seat, with an occupant

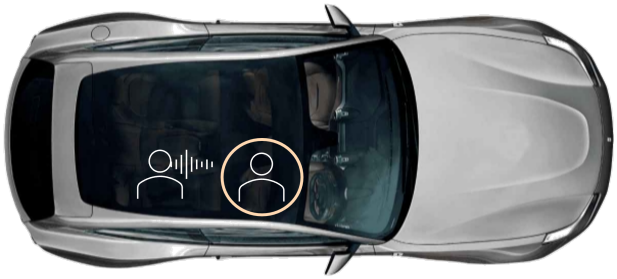

Figure 1. Measurement setup. Speaker at the rear-right seat and listener at the front-right seat along with the ARNC system.

in place, were measured in an anechoic chamber to characterize the acoustic transmission path through the Exponential Sine Sweep (ESS) method [17]. A schematic representation of the experimental setup is shown in Fig. 1. Notice that, in this study we assume the left-right microphones coincide with the co-driver ears, thus the measured IRs correspond to the transfer function from the rear-right talker to the ears of listener position under test.

Firstly, road noise measurements were performed on different road surfaces and at various speeds with the ARNC system deactivated. Then, the same measurements were repeated with the ARNC system enabled. In the rest of the paper, we will refer to those measurements as "*ARNC OFF*" and "*ARNC ON*", respectively. Therefore, this process provided road noise signals at the right front passenger's ears, both with and without active noise cancellation.

Moreover, a speech source at the rear-right passenger seat was simulated by convolving different clean speech signals with the previously measured IRs. The test signal was carefully designed to include both female and male speech segments, with progressively decreasing amplitude levels of $0\,\mathrm{dBFS}$, $-6\,\mathrm{dBFS}$, and $-12\,\mathrm{dBFS}$, respectively.

Finally, the resulting simulated speech signals at the right front passenger's ears were superimposed onto the road noise recordings, both with *ARNC OFF* and *ARNC ON*, allowing for a direct comparison of speech intelligibility under different noise conditions.

4. RESULTS

The impact of the ARNC system in terms of speech intelligibility has been evaluated with objective analysis and perceptual subjective analysis. The former, with the computation of different metrics. The latter, with the evaluation of two different perceptual listening tests. The following sections provide detailed explanations of the results along with insights and interpretations.

4.1 Objective analysis

To quantify the impact of the ARNC system on in-vehicle communication, we compute two different metrics presented in the literature of speech intelligibility, as explained in Sec. 2.2.

First of all, the Short-Time Objective Intelligibility (STOI) has been computed as reported in [14]:

$$STOI = \frac{1}{JM} \sum_{j,m} STOI_{j,m} \quad , \tag{1}$$

where:

$$STOI_{j,m} = \frac{(\boldsymbol{x}_{j,m} - \mu_{\boldsymbol{x}_{j,m}})^T \quad (\bar{\boldsymbol{y}}_{j,m} - \mu_{\bar{\boldsymbol{y}}_{j,m}})}{||\boldsymbol{x}_{j,m} - \mu_{\boldsymbol{x}_{j,m}}|| \quad ||\bar{\boldsymbol{y}}_{j,m} - \mu_{\bar{\boldsymbol{y}}_{j,m}}||}, \tag{2}$$

with

- J is the total number of one-third octave bands
- M denotes the total number of temporal frames
- $\boldsymbol{x}_{j,m}$ represents the clean speech short-time temporal envelope in the $j-th$ frequency band and $m-th$ time frame
- $\bar{\boldsymbol{y}}_{j,m}$ represents the normalized degraded speech envelope in the $j-th$ frequency band and $m-th$ time frame after applying a one-frame temporal clipping
- $\mu_{\boldsymbol{x}_{j,m}}$ and $\mu_{\bar{\boldsymbol{y}}_{j,m}}$ denote the sample average of $\boldsymbol{x}_{j,m}$ and $\bar{\boldsymbol{y}}_{j,m}$

The STOI index has been computed for each speech segment and evaluated at the three amplitude levels. Inspecting the results, we notice that for each segment the ARNC provides an improvement in terms of intelligibility with an increase up to $5\,\%$, and in general higher then $1.1\,\%$. However, to provide a single index for both ears position, the following binaural definition, denoted as BSTOI, has been formulated:

$$BSTOI = \sqrt{\frac{STOI_L^2 + STOI_R^2}{2}}, \tag{3}$$

where $STOI_L$ and $STOI_R$ represent the $STOI$ index computed at the left and right ear microphones position,

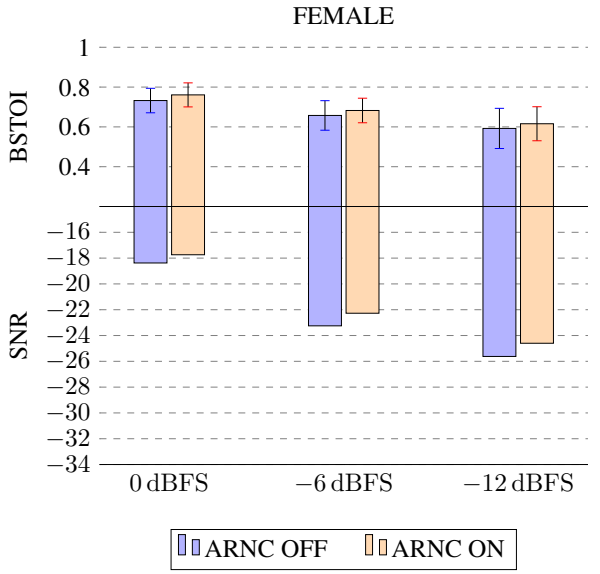

Figure 2. Average and standard deviation of BSTOI and average SNR for Female speakers at different dBFS values.

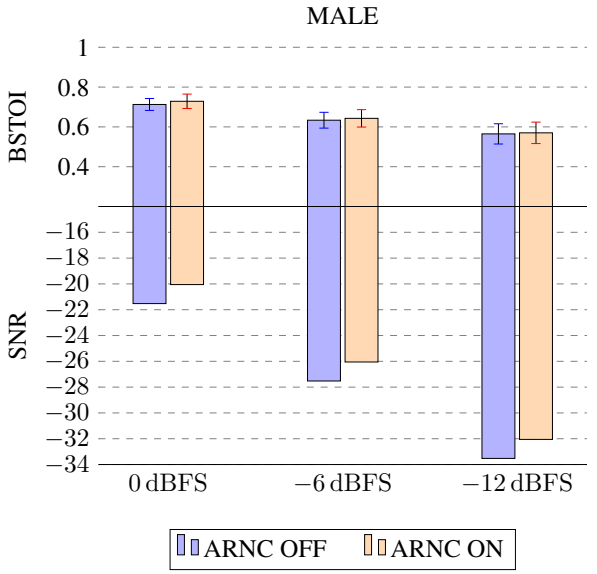

Figure 3. Average and standard deviation of BSTOI and average SNR for Male speakers at different dBFS values.

respectively. Therefore, as for STOI, also BSTOI values are in the range $[0, 1]$, with 1 referring to the highest intelligibility score.

Similarly, the Signal-to-Noise Ratio (SNR) has been computed in dB for all the speech segments and the different amplitude levels as follows:

$$SNR = 10 \log_{10} \left(\frac{P_{signal}}{P_{noise}} \right), \tag{4}$$

where P_{signal} and P_{noise} denote the power of the signal and the noise, respectively. Moreover, we consider as SNR the mean values between the two microphones at the ear positions. It is worth noticing that in our scenario SNR values are negative due to the predominance of the noise compared to the signals.

Fig. 2 and 3 depict the average BSTOI (in the positive y-axis) and SNR data (in the negative y-axis) computed among female and male speakers, respectively, for each different dBFS values.

In general, female speech signals achieve higher values of BSTOI and SNR with respect to the male speech signals, both with ARNC system ON and OFF. This is due to the higher frequency content of female speeches, which is less affected by road noise. Indeed, male voices exhibit more spectral overlap with road noise, which is more dominant at low frequencies, resulting in lower scores, in general. Enabling the ARNC system for female speakers results in an increase of the BSTOI higher than 1.3% for all the three amplitude levels, with a maximum increase of 3.4%. For the case of male speakers, all amplitude levels show an increase of the index higher than 0.3%, with a maximum delta of 2%. In terms of SNR instead, we have a maximum increase of 1% for female speakers, while for the male case a maximum delta of 1.5% is registered.

Finally, the standard deviation of the BSTOI index between females decreases when the ARNC system is activated, indicating more uniform values, while an increment can be observed for the case of male speakers. Therefore, it can be noticed that the ARNC system provides an increase in terms of intelligibility for all the examined cases.

4.2 Subjective analysis

The benefits of the ARNC system on speech intelligibility has been evaluated also through a subjective evaluation campaign. Specifically, two blind tests were conducted:

- **Test 1:** A-B comparison of each speech signal with ARNC system enabled and disabled
- **Test 2:** Progressively increasing level test of speech signals.

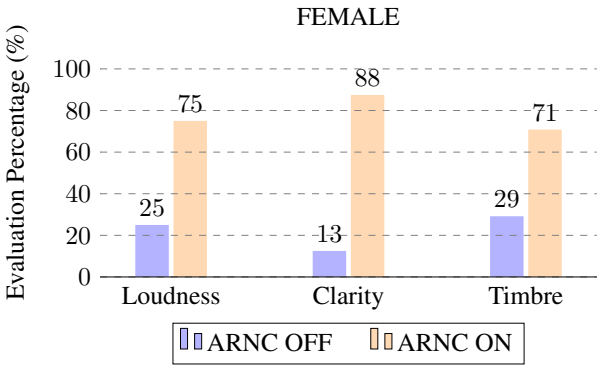

Figure 4. Average KPIs results of the A-B comparison for Female speech signals.

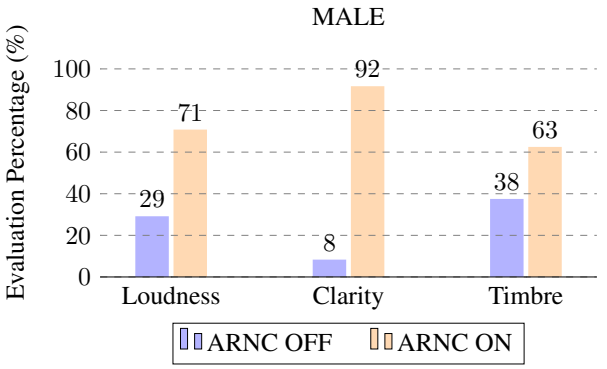

Figure 5. Average KPIs results of the A-B comparison for Male speech signals.

4.2.1 A-B comparison

For this experiment, we focus on four test signals from the simulated speech signals with background road noise described in Sec. 3.1. In particular, we considered the two female and the two male speakers. For each of the selected speech, signal A and signal B have been randomly generated considering *ARNC ON* and *ARNC OFF* conditions.

The blind listening test was conducted on 12 expert-listeners using Audeze high-quality professional headphones [18], and they were given the ability to switch between signal A and signal B for each of the four speech frames. Therefore, for each frame the listeners were asked to express their preference between A and B based on the following three key performance indicators (KPIs):

- Loudness
- Clarity
- Timbre

where *Loudness* refers to the highest perceived loudness of the speech, *Clarity* relies on the precise articulation and correct pronunciation perceived, and *Timbre* evaluated the perceived quality of the speech.

The average evaluation results expressed in percentage between female and male speakers are depicted in Fig. 4 and Fig. 5, respectively. In both cases, the same trend can be noticed with an overall preference to the *ARNC ON* condition for all the three KPIs. Therefore, the activation of the ARNC system implies a perceptual benefits on the rear-to-front speech intelligibility.

It is worth nothing that, considering the *ARNC ON* condition, the *Loudness* and *Timbre* indeces collect higher results for the female speakers with respect to male ones, respectively with $4\,\%$ and $5\,\%$ of difference. Conversely, the *Clarity* with *ARNC ON* has been selected by $92\,\%$ for the case of male speaker, lowering to $88\,\%$ for female speakers. Such results depend on the frequency range of the male and female speech. With lower frequency contents, the male spectra is more affected by the frequency range of the road noises, thus the presence of an ARNC system affects the speech *Clarity*.

The stacked bar plot depicted in Fig. 6 represents the detailed results for the two female speakers (refer to F1 and F2) and the two male speakers (refer to M1 and M2). Interestingly, the sujbective results between *ARNC OFF* and *ARNC ON* present higher variance for the female case with respect to the male one. Such result confirms the impact of the ARNC system to the lower frequency range. Indeed, assessors considered easier the A-B test for male with respect to female speakers. Interestingly, although an overall preference for the case with the algorithm enabled can also be seen for the *Timbre* index, it has been described as the most difficult KPI to be evaluated by the majority of the listeners.

4.2.2 Progressively increasing level test

To further assess the impact of the ARNC system on in-vehicle speech intelligibility, an additional blind test was conducted. In this experiment, the same four speech frames used in the A-B comparison test of Sec. 4.2.1 have been evaluated. However, for each of the speech frames under consideration, assessors have been asked to listen to a progressively increasing level of the speech frames both with *ARNC OFF* and with *ARNC ON*, thus highlighting

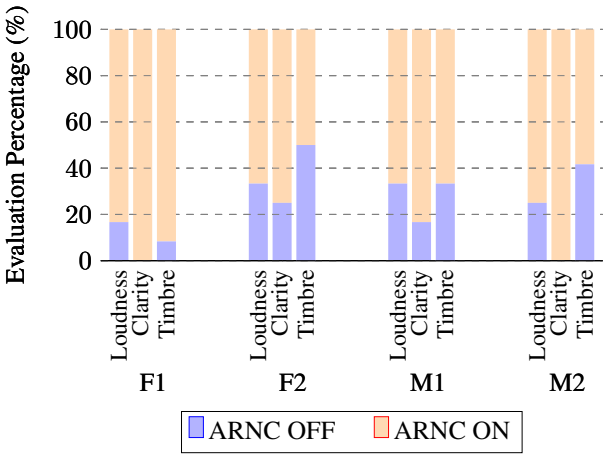

Figure 6. Overall KPIs results of the A-B comparison for Female (F1 and F2) and Male (M1 and M2) speech signals.

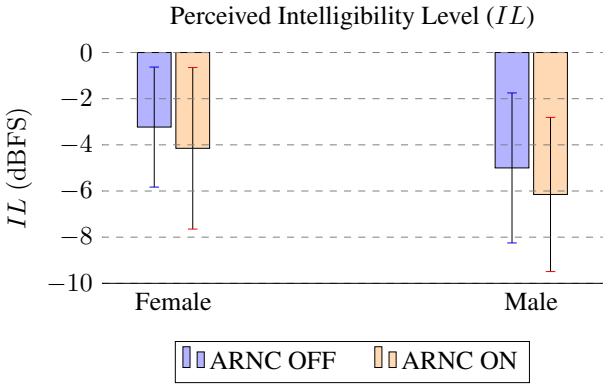

Figure 7. Results of perceived intelligibility level (IL). Avarage and standard deviation are shown with respect to Female and Male speeches with for the case of *ARNC OFF* and *ARNC ON*.

when the signals were intelligible. In particular, the simulated speech has been initially set to a level of -20 dBFS, thus progressively increasing the level at each repetition with a step of 2 dBFS of increments up to 0 dBFS.

A group of 13 expert-listener was selected for the blind test. Assessors have been instructed to stop the audio playback as soon as they were able to understand all the words in each frame, thus identifying a level of perceived intelligibility expressed in dBFS and for the sake of simplicity denoted as IL (intelligibility level). The average results of the perceived IL along with the standard deviation are depicted in Fig. 7 for the case of *ARNC OFF* and *ARNC ON* and differentiating between male and female frames.

In general, assessors were able to fully comprehend the speech content at a lower level in the case of *ARNC ON*, thus confirming the benefits of the road noise reduction for the intelligibility. In particular, the delta level of perceived IL between *ARNC OFF* and *ARNC ON* is equal to 2 dBFS for male speeches and decreases to 1.77 dBFS for female speakers.

It is worth noticing that independently of the ARNC system, male talkers achieved a lower IL then female speeches. The former with -4.15 dBFS and -6.15 dBFS of IL for the case of *ARNC OFF* and *ARNC ON*, respectively. For female speeches, the average results reduced to -3.23 dBFS and -5 dBFS, respectively. Therefore, the delta IL between the disabled and enabled ARNC system increases from 1.77 dBFS for female speakers to 2 dBFS for male speakers. As expected, such result confirms the benefits of the ARNC system in terms of speech intelligibility signals with lower frequency contents that overlap with the ARNC operating frequency range. Moreover, notice that the outcome of this listening test is aligned with Fig. 4 and Fig. 5 of the A-B listening test in Sec. 4.2.1, where male speeches with *ARNC ON* achieved a higher *Clarity* score compared to the female counterpart test.

Another interesting interpretation of the advantages of the ARNC system provided by the results of the devised progressively increasing level test lies in allowing the rear passengers to speak at a lower level but keeping the same speech intelligibility at the front passengers when the ARNC system is enabled.

5. CONCLUSIONS

In this study, the benefits of an Active Road Noise Cancellation (ARNC) algorithm on in-vehicle passenger-to-passenger speech intelligibility have been evaluated through both objective and subjective assessments. Road noise measurements were conducted at the front-right passenger's ear positions in a vehicle instrumented with accelerometers and microphones, using a state-of-the-art ARNC algorithm.

To simulate a speaker inside the vehicle, a Head and Torso Simulator was placed on the rear right-seat, and the impulse response from its artificial mouth to the microphones at the front passenger's ear position has been

measured. A reference speech signal, consisting of both male and female voices at different amplitude levels, was then convolved with the measured impulse responses to replicate how speech from the rear passenger seat would be perceived by the front passenger. Finally, this processed speech signal was superimposed with the previously recorded road noise, both with and without the ARNC system enabled.

Speech intelligibility was assessed using two objective metrics, specifically STOI and SNR, at both ears. Additionally, two blind listening tests were conducted with more than 10 expert-listeners. Specifically, both objective and subjective assessments revealed an increase in speech intelligibility when the ARNC algorithm is enabled, with a stronger perceptual improve for the case of male speakers, where the frequency content of the voice has a major overlap with the one of the road noise. Therefore, results of devised experiments consistently demonstrated the positive impact of the ARNC system on in-vehicle speech intelligibility, confirming its potential in enhancing communication within the vehicle cabin.

MOMENTUM ALGORITHM AND ITS APPLICATION TO ACTIVE CONTROL OF HVAC COMPRESSOR NOISE IN AUTONOMOUS BUS

Sang-Kwon Lee[1*] **Junseok Choi**[1]
Doyeon Kim[1] **Seongyeol Kim**[1]
[1] Department of Mechanical Engineering, Inha University, South Korea

ABSTRACT

The compressor is used for a heating, ventilation, and air-conditioning (HVAC) system which provide air conditioning for each passenger in autonomous bus. The sound radiated from the compressor of the HVAC system is a high-frequency annoyance noise caused by vibroacoustic noise due to the shell vibration of the compressor. The dominant frequency components of the vibroacoustic noise are harmonics of the rotation frequency of the reciprocating compressor. The HVAC system generates vibroacoustic noise dominantly in the frequen-cy range between 100 and 600 Hz. Such noise is not only distinctly perceptible but also contributes to passenger discomfort and negatively impacts the perceived quality of the vehicle. The aim of this paper is to attenuate the vibroacoustic noise of the HVAC system by developing an active noise control (ANC) system. Generally, the widely recognized filtered-X least mean squared (FXLMS) algorithm has been successfully implemented to active noise control of reciprocating compressor. However, its performance was found lacking outside the peak frequency of compressor operation noise. To address this, the momentum algorithm was employed to enhance ANC performance. The momentum algorithm has a lower residual error and faster convergence rate compared to the FXLMS algorithm. As a consequence, the implementation of the momentum based ANC algorithm resulted in enhanced noise reduction not only at the peak frequencies, which correspond to the compressor operation frequency, but also in frequency ranges outside these peak frequencies.

1. INTRODUCTION

HVAC noise profoundly affects passenger riding comfort within electric vehicle cabins. Consequently, extensive re-search efforts have been devoted to analyzing and reduc-ing these noises. Contrasting with typical vehicle HVAC systems, the HVAC system under autonomous bus seats is structurally akin to refrigerator systems, incorporating com-ponents like compressors, evaporators, condensers, and fans. This similarity allows for the application of noise con-trol techniques used in refrigerator systems to be effectively employed in autonomous car seat HVAC systems as shown in Fig.1. Among these HVAC parts, the shell vibration of the compressor generates noise that is harmonic to the rotation frequency of the reciprocating compressor. The hybrid technique, a combination of passive and active techniques, can be used to obtain a reduction in the overall frequency range for this dominant noise.

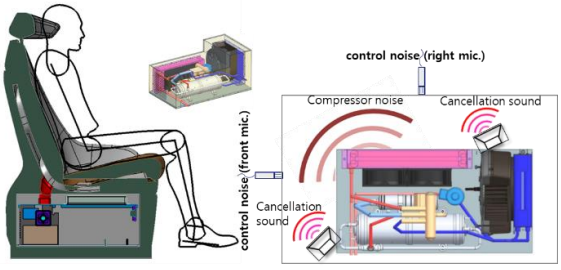

Figure 1. HVAC system of autonomous bus seat.

ANC stands out as a technique for suppressing low-frequency noise, offering the advantage of effective noise reduction without additional weight or space consumption

unlike many passive methods [1]. On the other hand, passive strategies such as sound absorbing materials are more suited for high-frequency noise reduction [2]. For example, the vibration absorber can be designed to reduce such structural vibration in the high-frequency range [3]. ANC operates by producing 'anti-noise' of equal ampli-tude but opposite phase to the primary noise. Adaptive filter-ing, often employing the LMS algorithm, is a cornerstone of ANC systems for addressing time-varying noise characteris-tics [4]. Despite its effectiveness, there are space con-straints within the system that limit the speaker size, affecting low-frequency noise reduction. Therefore, the low-frequency component of the output can be filtered out [5]. In this study, on the other hand, a frequency range between 200 Hz and 600 Hz is targeted for this ANC application since the speaker to be used has a diameter of 2.25 inches. However, this frequency range is relatively high for the ANC ap-plication because the generation of a signal that is out of phase of the high-frequency primary noise signal is chal-lenging due to its short wavelength. Hence, the ANC algo-rithm requires fast convergence. For the ANC algorithm, the FXLMS algorithm is widely used because it is robust and requires low computation. However, the convergence speed of the LMS algorithm is poor due to a phenomenon called eigenvalue spread [6]. The performance of the LMS algo-rithm can be improved using the momentum algorithm [7] with a small increase in computational burden In this study, the momentum algorithm based ANC algorithm will be de-veloped for the HVAC system for autonomous bus seats.

2. FXLMS ALGORITHM

The fundamental objective of the Least Mean Square (LMS) algorithm is to compute the optimal filter coefficients that minimize the mean square error. This optimization employs the iterative steepest descent method, where each iteration proceeds in the direction opposite to the gradient of the error surface [4].

$$\boldsymbol{w}(n+1) = \boldsymbol{w}(n) + \mu(-\nabla_n) \tag{1}$$

The error signal, $e(n)$, is defined as the difference between the desired signal (in this case, noise to be canceled), $d(n)$, and the output signal, $y(n) = x(n)\boldsymbol{w}(n)$.

$$e(n) = d(n) - x(n)\boldsymbol{w}(n) \tag{2}$$

Accordingly, the gradient of the squared error is expressed as

$$\nabla e^2(n) = -2e(n)x(n) \tag{3}$$

Substituting Eq. (3) into Eq. (1), the final form of the LMS algorithm is obtained.

$$\boldsymbol{w}(n+1) = \boldsymbol{w}(n) + \mu x(n) e(n) \tag{4}$$

Here, μ denotes the convergence factor, crucial for the stability and steady-state performance of the algorithm. The algorithm employs a time-varying step size, calculated to be inversely proportional to both the power of the reference signal ($\widehat{P_x}$) and the filter length (L). This is expressed as

$$\mu(n) = \frac{\alpha}{L\widehat{P_x}(n)} \tag{5}$$

Here, the normalized step size α falls within the range of $0 < \alpha < 2$. The power of the reference signal is estimated using the formula.

$$\widehat{P_x}(n) = \frac{1}{M}\sum_{m=0}^{M-1} x^2(n-m) \tag{6}$$

To mitigate divergence issues due to insufficient spectral excitation, a leaky mechanism is integrated into the weight update process. The leaky LMS algorithm is thus formulated as follows.

$$\boldsymbol{w}(n+1) = \nu\boldsymbol{w}(n) + \mu x(n) e(n) \tag{7}$$

In this context, ν denotes the leakage factor, constrained within the range $0 < \nu \leq 1$. Adjusting the leakage factor involves a trade-off between robustness and performance loss [1]. In practical implementations involving electronic components such as microphones, filters, and amplifiers, the signal path from the loudspeaker to the error microphone, termed the secondary path, significantly influences the ANC system's efficacy. Burgess [8] proposed compensating for the secondary path effect to enhance system performance. This is achieved by filtering the reference signal with a filter that mimics the secondary path, leading to the development of the filtered-X LMS (FXLMS) algorithm. The error signal in the FXLMS context is redefined as follows.

$$\hat{x}(n) = s(n) * x(n) \tag{8}$$

where $s(n)$ is the impulse response of the secondary path, $*$ denotes linear convolution. The gradient of squared error can be rewritten as

$$\nabla e(n) = -2\hat{x}(n)e(n). \quad (9)$$

The FXLMS algorithm iteratively updates the filter weights to achieve optimum noise cancellation.

$$\boldsymbol{w}(n+1) = \nu\boldsymbol{w}(n) + \mu\hat{x}(n)e(n) \quad (10)$$

Since the transfer function, $S(z)$ of the secondary path is typically unknown, it can be estimated via a separate LMS algorithm. The adaptive filter output is computed by linear convolution between the optimum filter and the reference signal.

$$y(n) = \sum_{l=0}^{L} w_l(n)\hat{x}(n-l) \quad (11)$$

The block diagram of the FXLMS algorithm is shown in Fig. 2.

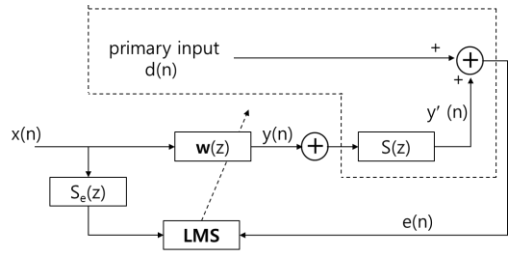

Figure 2. Block diagram of ANC system using FXLMS algorithm.

In this representation, $\hat{S}(z)$ denotes the estimated transfer function of the secondary path, $P(z)$ represents the primary path, and $W(z)$ symbolizes the time-varying adaptive filter.

3. THEORY OF THE MOMENTUM ALGORITHM

The momentum algorithm can also be derived from gradient descent method, where the gradient of gradient descent descends along the surface of cost function ξ which is error surface in the context of ANC. The system can resemble to dynamic system with a mass moving along the error surface. The direction of movement at this time is determined by potential $\nabla\xi$, and can be expressed as [9]

$$\frac{d\boldsymbol{w}}{dt} = \nabla\xi \quad (12)$$

Therefore, in (12), while a local minimum is achieved when $\nabla\xi(\boldsymbol{w}) = 0$, it is not the only equation where a minimum point occurs exactly at $\nabla\xi(\boldsymbol{w}) = 0$ but also governs the system movement. In other words, the system does not converge directly to the target point but rather oscillates and gradually converges. This can be considered as a simple oscillator that takes into account the oscillations that occur. Using this, the resulting second-order differential equation is as

$$\eta\frac{d^2\boldsymbol{w}}{dt^2} = -\nabla\xi(\boldsymbol{w}) - b\frac{d\boldsymbol{w}}{dt} \quad (13)$$

If $\eta \geq 0$, it considers the mass of the particle, and if $b \geq 0$, t considers the damping that occurs during the system's change process. When $\nabla\xi(\boldsymbol{w}) = 0$ as in (12), it reaches a minimum point in the differential equation. When η converges to 0, it results in (12). If η is positive, the trajectory represented by (13) gradually changes direction in the direction indicated by $-\nabla\xi(\boldsymbol{w})$, showing evidence of momentum [9]. A simple finite difference approximation in (13) is as

$$\eta\frac{\boldsymbol{w}(t+\Delta t)-2\boldsymbol{w}(t)+\boldsymbol{w}(t-\Delta t)}{(\Delta t)^2} \approx -\nabla\xi(\boldsymbol{w}(t)) - b\frac{\boldsymbol{w}(t+\Delta t)-\boldsymbol{w}(t)}{\Delta t} \quad (14)$$

In summary,

$$\boldsymbol{w}(t+\Delta t) = \boldsymbol{w}(t) - \alpha\nabla\xi\big(\boldsymbol{w}(t)\big) + \beta(\boldsymbol{w}(t) - \boldsymbol{w}(t-\Delta t)) \quad (15)$$

In the ANC system, signals are processed as discrete signals rather than continuous signals, so $t = n, \Delta t = 1$. Therefore, equation (15) can be rearranged for discrete signals as

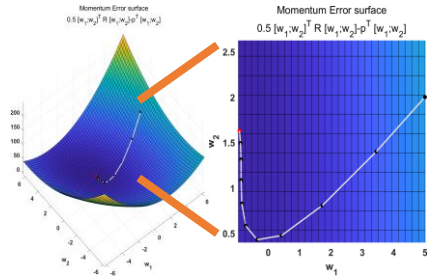
$$\boldsymbol{w}(n+1) = \boldsymbol{w}(n) - \alpha\nabla\xi\big(\boldsymbol{w}(n)\big) + \beta\big(\boldsymbol{w}(n) - \boldsymbol{w}(n-1)\big) \quad (16)$$

This algorithm is defined as Polyak's heavy ball method. With slight modifications, a related method called Nesterov's optimization can also be obtained. If ξ is a convex quadratic equation, the approach in (16) (allowing for adaptive choices of α and β that vary with each iteration) is called the Chebyshev iteration method. Additionally, (16) can be redefined as

$$\begin{aligned}\boldsymbol{v}(n) &= \boldsymbol{w}(n+1) - \boldsymbol{w}(n) \\ &= -\alpha\nabla\xi\big(\boldsymbol{w}(n)\big) + \beta\big(\boldsymbol{w}(n) - \boldsymbol{w}(n-1)\big) \\ &= -\alpha\nabla\xi\big(\boldsymbol{w}(n)\big) + \beta\boldsymbol{v}(n-1)\end{aligned} \quad (17)$$

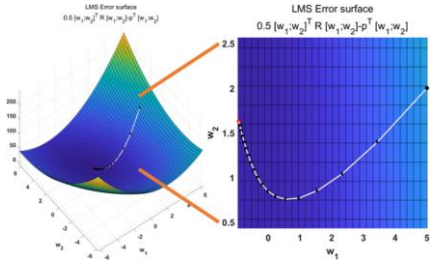
In (17), we can divide it into two equations as follows.

$$\begin{cases} \boldsymbol{w}(n+1) = \boldsymbol{w}(n) + \boldsymbol{v}(n) \\ \boldsymbol{v}(n) = -\alpha \nabla \xi\big(\boldsymbol{w}(n)\big) + \beta \boldsymbol{v}(n-1) \end{cases} \quad (18)$$



Here, $\boldsymbol{v}$ is the accumulated gradient, $\boldsymbol{\alpha}$ is the step size, and β represents inertia, where $0 < \beta < 1$ and typically $\beta = 0.9$ is used. Additionally, $\nabla \xi(\boldsymbol{w}(n))$can be expressed as $\nabla \xi(n)$ in (12), and $\nabla \xi(\boldsymbol{w}(n))$ in (18) can be expressed by (9) as

$$\nabla \xi(\boldsymbol{w}(n)) = 2[\nabla \mathrm{e}(n)]\mathrm{e}(n) = -2\boldsymbol{x}(n)e(n) \quad (19)$$



By (19), (18) can be expressed as

$$\begin{cases} \boldsymbol{w}(n+1) = \boldsymbol{w}(n) + \boldsymbol{v}(n) \\ \boldsymbol{v}(n) = \mu \boldsymbol{x}(n)e(n) + \beta \boldsymbol{v}(n-1) \end{cases} \quad (20)$$

μ represents the step size. In other words, μ is a convergence coefficient that is crucial for stability and steady-state performance, much like in the LMS algorithm.

(a) Convergence of the momentum algorithm along the error surface.

(b) Convergence of the LMS algorithm along the error surface.

Figure 3. Comparison of convergence performance the momentum and LMS algorithm along the error surface.

Therefore, the convergence performance depends on this μ value, and an appropriate μ value must be found. For an arbitutary cost function, the convergence pergormance of two algorithms along the error surface was compared and its results are illustrated in Fig. 3.

4. ANC OF HVAC COMPRESSOR NOISE

4.1 Flow Chart of Algorithm

The ANC system employed in this study is characterized as a single reference with a multiple output configuration (1x2x2), as delineated in Fig. 4. The system acquires a reference signal through an accelerometer stuck to the compressor's shell. Two small size speakers were useded for ANC. One speaker positioned at the front side of compressor and the other one is right side. The error signals were captured by microphones strategically placed in the near field of the front and right sides of the HVAC system. These reference and error signals are crucial in the computation of filter coefficients, a process executed utilizing Eq. (10) and Eq. (20). It should be noted that the reference signal undergoes a filtration process before its integration into the algorithm, facilitated by modeled secondary filters. These filters represent transfer functions that cover the characteristics of various electronic components, such as analog filters and amplifiers, as well as the acoustic pathway extending from the speakers to the error microphones. Subsequently, the derived optimal filter coefficients are convolved with the reference signal in accordance with Eq. (11). This process yields the output signal $y(n)$, which functions as the anti-noise of the targeted noise signal $d(n)$.

4.2 Experimental Setup of the HVAC ANC System

The experimental setup entailed the utilization of a notebook computer interfaced with the dSPACE Autobox I/O board as shown in Fig. 5. The dSPACE Autobox plays a crucial role in this setup, facilitating the conversion of signals from analog to digital and vice versa. Additionally, it executes the embedded MATLAB Simulink code designated for Active Noise Control (ANC).
The signals collected from the error microphones and the accelerometer cannot be employed in their raw form due to the indeterminate frequency content. Consequently, it becomes essential to subject these signals to a low-pass filtering process. This step aids in determining the appropriate sampling frequency. The low-pass filters are configured with a cut-off frequency of 400 Hz in this study, marginally exceeding the highest frequency target for ANC.

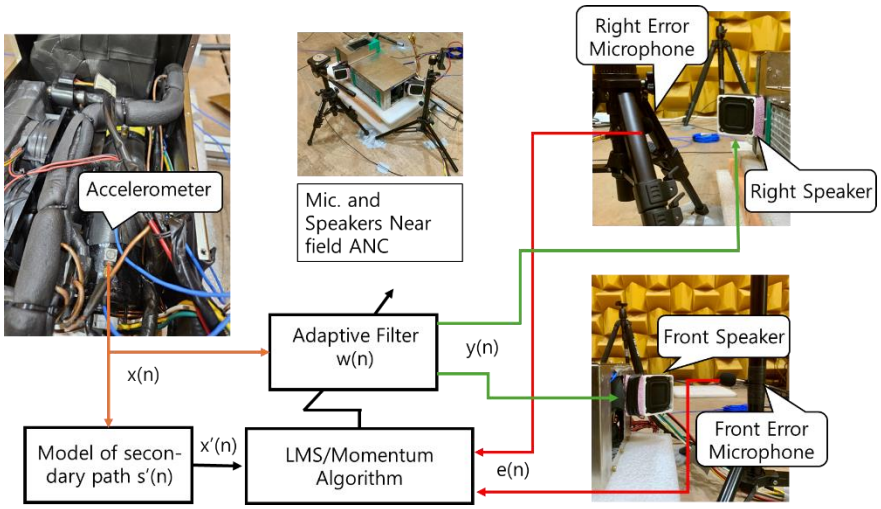


Figure 4. Block diagram of ANC system using FXLMS algorithm.

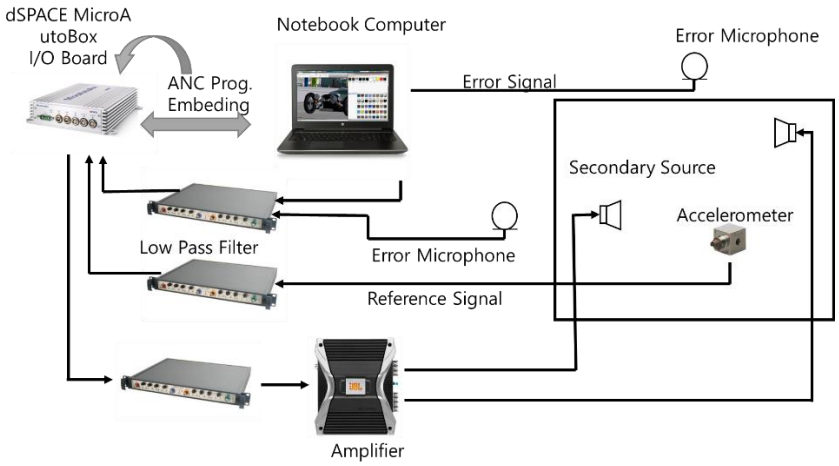

Figure 5. Experimental setup for the implementation of ANC system.

To prevent the occurrence of aliasing which distorts the signal, the sampling frequency must be at least twice the frequency content of the signal according to the Nyquist-Shannon sampling theorem. In this instance, a sampling frequency of 2048 Hz is selected, exceeding the double threshold of the signal's frequency content. Moreover, the output signal $y(n)$, directed towards the speakers, requires filtering to correct any reconstruction errors that may arise during the digital-to-analog (A/D) conversion process. Therefore, the cut-off frequency for this reconstruction filter is set at 400 Hz to eliminate the reconstruction error during the A/D conversion and to prevent the algorithm from diverging due to exciting the speakers outside the target frequency range (100-400 Hz). Finally, this signal is amplified using an amplifier to effectively drive the loudspeakers.

4.3 Placement of Error Microphones

To measure the basic SPL (sound pressure level) of HVAC system, five microphones have been installed within a 1-meter distance from the center of HVAC system in accordance with the stipulated standards [10] as shown in Fig. 6. According to the results of measured SPL, overall A-

weighted SPL in frequency range (0-5000 Hz) was as listed in Tab. 1.

Table 1. A-weighted sound pressure level of all microphones.

Microphones	Front	Right	Left	Rear	Top
Average SPL	80.1 dB	83.2 dB	75.8 dB	77.1 dB	78.3 dB

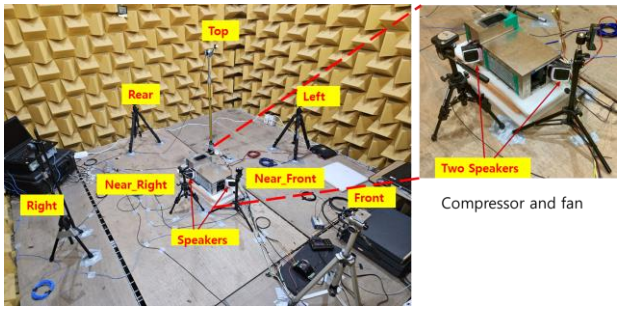

Figure 6. Setup of seven microhones and two speakers for ANC of HVAC system.

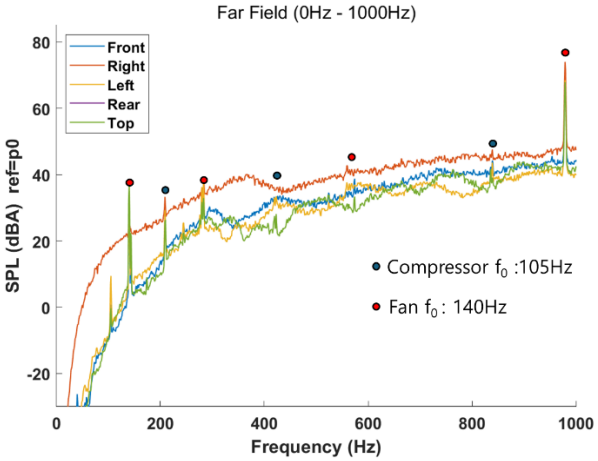

Figure 7. Frequency analysis of the sound pressure measured at the five microphones.

The major frequencies of the measured noise are associated to the rotating frequency of compressor shaft (105Hz) and cooling fan (140Hz) and their harmonics as shown in Fig.7. For the active cancellation of vibroacoustic noise radiated from shell of compressor and fan at nearfield, the error $e(n)$ microphones were installed at the front and the right of test compressor respectively. Two secondary speakers were also installed near to the test compressor as shown in Fig. 6. The frequency band that ANC is possible is from 100Hz to 400Hz due to size limit of secondary speaker and wave length of sound.

4.4 Selection of the Reference Signal

The ordinary coherence function is commonly employed to assess the extent of linear association between two signals, such as input and output signals [11]. The coherence value, therefore, is an important parameter for the performance evaluation of the ANC system [1]. Thus, magnitude-squared coherence can be defined as

$$C_{dx}(f) = |\gamma_{dx}(f)|^2 = \frac{|S_{dx}(f)|^2}{S_{dd}(f)S_{xx}(f)} \quad (21)$$

where f denotes the frequency of interest, $S_{dx}(f)$ is the cross-power spectrum, and $S_{dd}(f)$ and $S_{xx}(f)$ are the autopower spectra of $d(n)$ and $x(n)$, respectively. The coherence values between the accelerometer signal in the z direction and front, right microphone approached unity at the operational frequency of the compressor and its harmonics. This indicates a high degree of correlation, suggesting that the vibroacoustic noise emanating from the compressor can be effectively controlled.

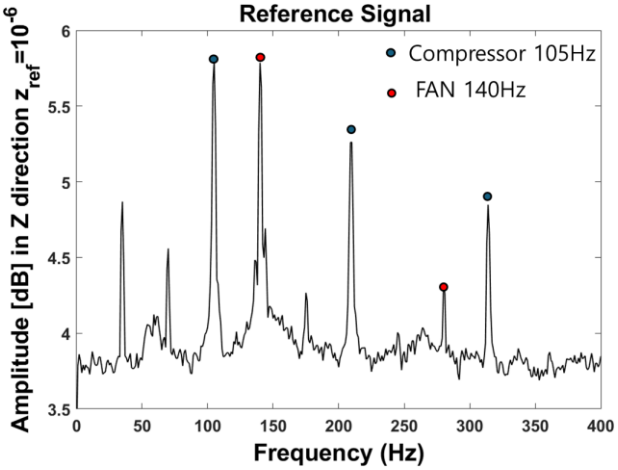

Figure 8. Fourier transform of the reference signal.

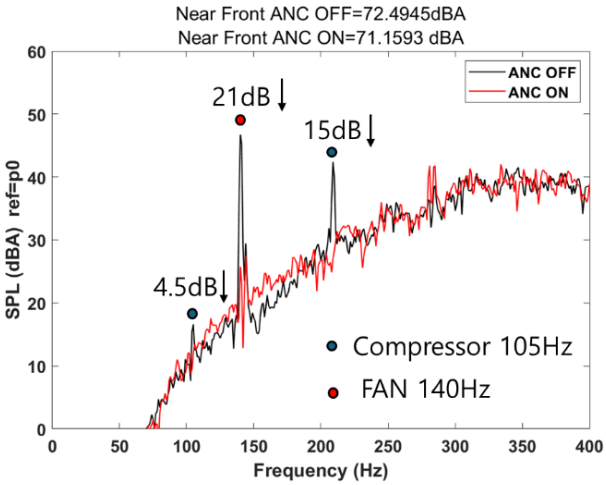
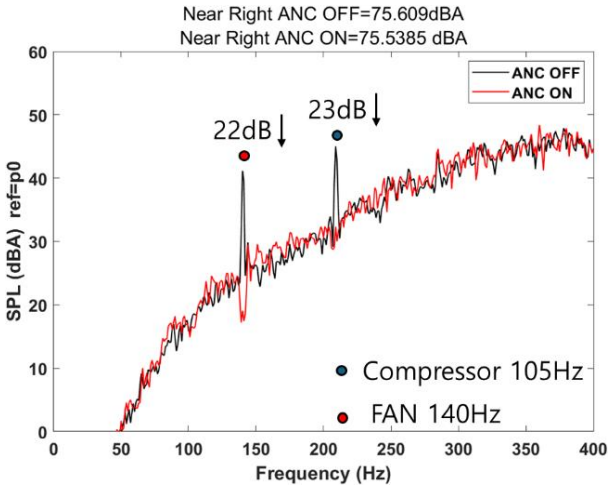
This indicates a high degree of correlation, suggesting that the vibroacoustic noise emanating from the compressor can be effectively controlled. According to the coherence results, the accelerometer data specifically collected in the z-axis



direction has been employed as the reference signal $x(n)$ as shown in Fig. 4. The Fourier transform of this reference signal is presented in Fig.8, offering a detailed spectral representation. The peaks in the graph denote the operation frequency of the compressor and fan.\

4.5 Measurement of Secondary Paths

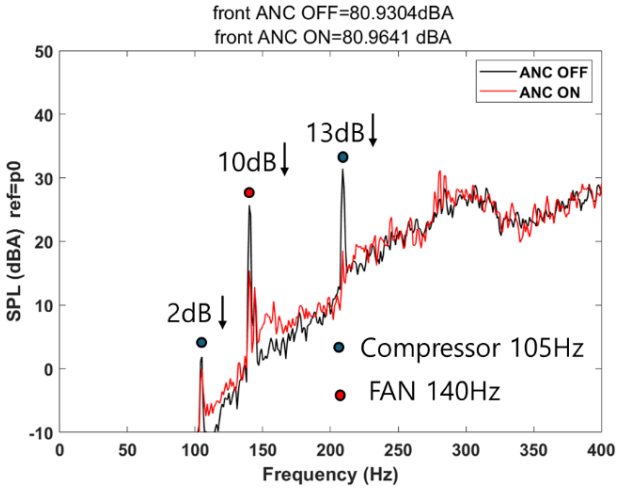


The estimation of the secondary path models, which are the transfer functions between speakers and error microphones, is based on the assumption that these models are time-invariant. Consequently, an offline modeling technique has been implemented to determine these filter coefficients. Broadband white noise, recognized as the ideal signal for such estimations due to its encompassing frequency range, is utilized in this process. This white noise is inputted into the speakers, and the consequent sound pressure is measured by the error microphones. Utilizing adaptive filter algorithms in this context facilitates the determination of the filter coefficients for the secondary paths, thereby allowing for a precise model estimation [12-13].

4.6 Results of the ANC

In this study, the momentum algorithm was used for the ANC of compressor and fan noise. The discrete Fourier transforms (DFTs) of the signals captured by the error microphones are graphically represented in Fig. 9. Within this figure, it is evident that the momentum algorithm exhibits excellent performance, particularly in terms of reducing the peak frequencies. For the front and right microphone, the performance of the peak reduction across the frequency spectrum is notably similar.

(a) Fourier transform of the front error microphone.



(b) Fourier transform of the right error microphone.

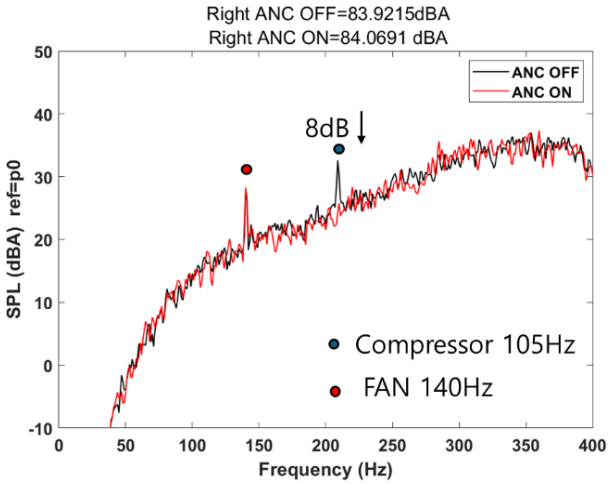


Figure 9. Fourier transform of the error microphones data without and with ANC.

The attenuation level of fan noise is up to 22dB at 140Hz and that of compressornoise is up to 23dB .

Attenuation levels of noise measured by front and right microphone are depicted as shown in Fig.10. Consequently Uncontrolled noise measured at far field microphones was also attended through ANC of near field noise.

(a) Fourier transform of the front error microphone.

(b) Fourier transform of the right error microphone.

Figure 10. Fourier transform of the far field microphones data without and with ANC.

5. CONCLUSIONS

In this study, we present the implementation of a momentum algorithm within the HVAC system of an autonomous bus seat. The HVAC system is a significant source of vibroacoustic noise, predominantly within the 100 to 400 Hz frequency range. This noise is primarily due to the vibration of the compressor's shell at the rotation frequency and its harmonics, resulting in prominent peaks in the frequency response. To control these disruptive noises, an ANC system has been developed. The reference signal for the ANC system was derived from an accelerometer stuck to the compressor's shell. Noise level of HVAC system is attenuated up to 20dB at near filed and 10dB at far field respectively. The study concludes that the momentum algorithm is excellent in reducing the overall noise levels of the HVAC system.

EMPIRICAL STUDY ON ACTIVE NOISE CONTROL IN UAVS

Jonas Steiner[1*] **Florian Hilgemann**[1] **Peter Jax**[1]
[1] Institute of Communication Systems, RWTH Aachen University, Aachen, Germany

ABSTRACT

Unmanned aerial vehicles (UAVs) are known for their characteristic noise emissions, which are inevitable during operation, but often perceived as annoying. Current research on UAV noise mitigation focuses on passive technology, but active noise control (ANC), commonly used in headphones and related applications, might prove to be more effective. However, ANC algorithms require comprehensive knowledge of acoustic transfer paths, across all operational modes of the UAV. Commercially available UAVs lack components such as microphones and loudspeakers as required by ANC applications. The purpose of this work is to investigate the estimation accuracy achievable with a simplified linear time-invariant (LTI) model of the generally non-linear aerodynamic system of UAV sound emission. For this, a prototype UAV-ANC system, which extends a UAV with added microphones and loudspeakers, is considered. Extensive measurements are conducted in a controlled indoors environment to assess the applicability of state-of-art system identification methods for estimating the associated acoustic transfer paths. These transfer path estimates can be used to determine the efficacy of ANC algorithms in the considered application through simulation. They are made available online for research purposes.

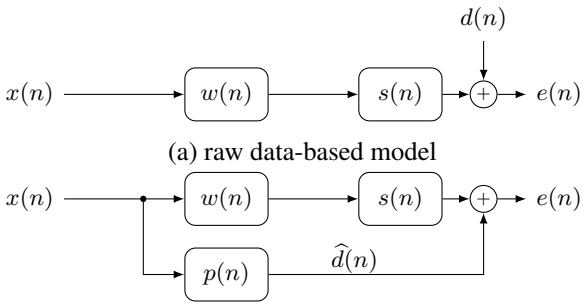
1. INTRODUCTION

The sound produced by UAV quadrocopters is an undesirable byproduct of rotor-based propulsion systems. The subjective impact of this sound depends on the frequency of occurrence of UAV flyby events as well as on the sound pressure level of the noise [1]. Participants of that study perceived scenes that feature UAV noise as highly annoying. The reduction of UAV noise is vital as it has the potential to improve the acceptance of UAV technology, e.g., in urban delivery tasks.



Currently, the mitigation of drone noise receives scientific and practical interest. As an example, In [2], a looped rotor blade that reduces the sound pressure level (SPL) at the blade passing frequency (BPF) by four decibels was proposed. However, the thrust force of the less noisy rotor was also significantly reduced. Another method for reducing the perceived SPL is ANC, which is typically used in headphones [3], and was proposed as a suitable means of mitigating UAV noise [4, 5]. One advantage of active approaches is that they do not interfere with the rotor design.

The working principle of ANC is based on destructive interference, which requires accurate knowledge on the acoustic sound propagation with respect to both, magnitude and phase. In classical ANC applications such as ANC headphones, this sound propagation is modeled using LTI models of the electro-acoustic transfer paths. While these transfer paths were studied thoroughly in headphone applications, fewer results are available for UAVs. For instance, the reproduction of rotor noise was studied using analytic [6] and data driven methods [7], but these approaches lack accurate information about amplitude and phase required by ANC.

This paper presents a database of spatially distributed noise measurements of a commercially available UAV, together with simultaneously recorded reference signals in proximity of the UAV. Impulse responses with corresponding raw data that reflect the primary- and secondary paths are made available online [1]. The main purpose of this data is the analysis of the transfer paths for ANC ap-

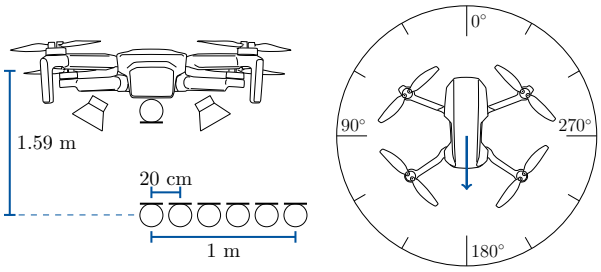
plications. For this, the prediction error of a conventional system identification algorithm on the measurement data is analyzed, and a case study of a basic feed-forward ANC system is included. The study brings insight into UAV transfer path modeling and highlights the potential and difficulties of real-world spatial ANC for UAVs.

2. SYSTEM OVERVIEW

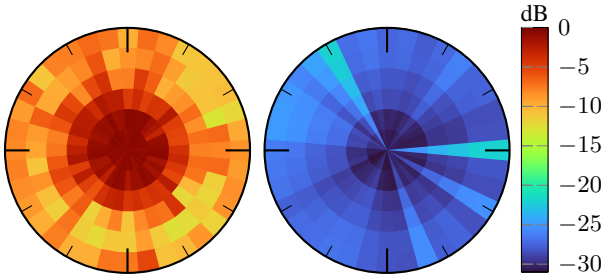
The system at hand consists of four main components: a reference microphone and loudspeakers close to the UAV, error microphones further away, and a signal processor. In general, the primary path $p(n)$ models sound propagation from a microphone collocated towards the primary noise source, in this case, the reference microphone signal $x(n)$, to a point in space where noise cancellation is desired. The signal at this point is denoted by $d(n)$ or $e(n)$ when the ANC system is disabled or enabled, and is picked up by one of the error microphones. The secondary path $s(n)$ models the sound propagation to the same point but originating from a loudspeaker that is used to generate the anti-phase signal which achieves the noise reduction [8]. For this analysis, the path-based model from Fig. 1b, which estimates $d(n)$ by the means of the linear model $p(n)$, will be compared with the raw data-based model from Fig. 1a, which uses recordings of $d(n)$ and therefore does not require $p(n)$ explicitly. The latter raw-data approach could turn out as favorable because modeling inaccuracies cannot occur. In practice, the reference signal $x(n)$ is afflicted with acoustic feedback from the loudspeaker, which is not considered here for the sake of a simplified evaluation. In headphone applications, ANC is required to attenuate broadband signals with limited a priori knowledge of the signal source characteristics [8]. Therefore, the objective is to minimize the expected broadband SPL of the remaining noise signal. With UAVs, an estimate of the excitation signal can be measured and exploited in a band limited ANC approach focused on reducing the SPL at the BPF.



To define electro-acoustic transfer paths, a commercially available drone was extended by loudspeakers and microphones. Generally, the objective is to derive an optimal finite impulse response (FIR) filter $w(n)$ that causes cancellation of the disturbance signal $d(n)$, reducing the signal power of the remaining error signal $e(n)$.

3. MEASUREMENT SETUP

The measurements were done in two parts. In the first part, the propagation of UAV noise was measured, while in the second part, the sound emitted by the loudspeakers was recorded. The objective of each measurement was to gather signal components required for deriving the optimal FIR filters $w(n)$ and subsequent simulation. While the secondary path estimation can be done with optimized excitation signals [9], the primary paths are required to be estimated using the UAV noise, which is inherently tonal (Fig. 2) and therefore not suited for broadband estimation. This excitation complicates the identification of $p(n)$, which could degrade the ANC performance.



3.1 Measurement Equipment

The measurements were carried out in a controlled indoors environment that follows the base reference ITU-R BS.1116-2 [10], but is subject to adverse acoustic effects such as room echos. A DJI mini 2 SE is equipped with a DPA 4061 omnidirectional condenser type microphone with a pop-filter to protect against wind noise, placed directly on the bottom of the chassis. A RME 12-mic microphone amplifier was used together with the RME MADIface USB as an audio interface running at a sampling frequency of 48 kHz. Six error microphones of the same make and model were placed in a linear array on top of a Head Acoustics HRT I high-precision turntable, to fa-

(a) Front view. (b) Top-down view.

Figure 3: Measurement setup.

(a) primary paths. (b) secondary paths.

Figure 4: Relative approximation error.

cilitate the measurement of $d(n)$ inside a disk directly underneath the DJI mini. These microphones allow to gather the required measurement data, but are unavailable in practice. Multiple independent measurements were performed with varying rotations of the turntable. As secondary sources five Fostex 6301b active studio monitors were placed in proximity to the DJI mini. The error microphones were spaced 20 cm apart. The DJI mini was placed 1.59 m above the microphone array (Fig. 3).

3.2 UAV Noise Measurements

During the UAV noise measurements the loudspeaker array was not present. Measurements were taken at multiples of 10° of turntable angle spanning the entire disk. Figure 3b shows the coordinate system used for the angles. The DJI mini was fixed by a construction mounted to its top, such that arbitrary rotational speeds could be utilized without requiring stable flight conditions. This way, scenarios such as hovering, take off and landing could be simulated by assigning the same rotational speed to all rotors. Here, 10 different rotational speeds were selected, such that the BPF varied between 93 Hz and 233 Hz. For each configuration of angle and rotational speed the reference microphone and all six error microphones were recorded for two seconds. The estimated primary paths have been obtained using the MMSE method [11] and are available as FIR filters of length 8192 (corresp. 170 ms).

3.3 Loudspeaker Measurements

The loudspeakers were placed in a cross-shaped arrangement tightly below the DJI mini. One central loudspeaker was placed directly underneath the DJI mini, with loudspeakers at each of its four sides angled away from the center at about 30°. Exponential sweeps [9] with a duration of 10 s were played back over each of the five loudspeakers in individual measurements. Again, all measurements were repeated for each multiple of 10° of turntable angle. All secondary paths were obtained using the spectral division method with suitable regularization and are available as FIR filters of length 8192.

3.4 Analysis of Estimation Accuracy

One issue with the primary path estimate is the tonal characteristic of the UAV noise, visible in Fig. 2. With a narrow-band excitation signal it is generally not possible to obtain the underlying broadband transfer function. However, the transfer path estimates can be analyzed objectively by their relative estimation error. This measure has no issue with small band excitation, as the same frequencies used for identification are used in the evaluation. A high approximation error indicates insufficient model order or a general lack of applicability of linear models. Figure 4 shows the normalized approximation error in decibels for each primary path estimate at a BPF of 137 Hz, as well as the accuracy of the secondary path estimates averaged over the five speakers. It clearly shows that the estimation of secondary paths is more accurate compared to the primary path. Rotor-induced wind noise is present at the error microphones but not in the reference microphone signal. This deteriorates the estimation accuracy underneath the UAV as can be seen in Fig. 4a, where the approximation error decreases with the radius.

4. CASE STUDY

The case study considers an ANC system which uses five secondary sources and is optimized for one error microphone directly underneath the UAV for a turntable rotation of 0°. The two system models described in section 2, are tested and compared using different rotational speeds. The optimal filters $w(n)$ were determined using the well

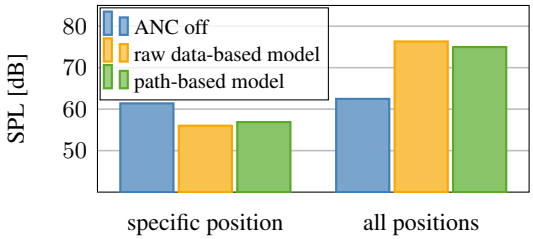


Figure 5: SPL comparison.

known minimum mean squared error approach [11] using a filter length of 8192 samples. The simulation results for a BPF of 137 Hz are presented in Fig. 5, showing the SPL in a third-octave band centered at the BPF at the target location and averaged over all virtual microphone positions. The data includes comparisons of both considered systems to the scenario without ANC. Peak SPL at the target location is reduced by 9 dB and 7 dB using the raw data-based and path-based models, respectively. This evaluation is likely more favorable than a real application, as the secondary path estimates employed for the filter design were also used in the subsequent simulation. Despite this success at the target location, the overall SPL is increased highly using any of the described methods.

5. CONCLUSION

This paper describes a database which contains spatially distributed quadrocopter noise for ANC applications. The data is available online and facilitates the design and simulation of UAV-ANC algorithms. Experiments on reducing the UAV noise within a region of interest were conducted. It was shown that a relatively simple system equipped with a single reference microphone and five secondary loudspeakers, designed to minimize the SPL at a single error microphone, can reduce drone noise at the target location, but is generally not suited for spatial noise reduction.

Multi-Channel Acoustic Switch via Activation of Evanescent or Propagation Bloch Wave Modes

Heow Pueh Lee* **Kian Meng Lim** **Yapeng Li**
Department of Mechanical Engineering, National University of Singapore, Singapore

ABSTRACT*

Sonic crystals exhibit interesting phenomena, enabling flexible manipulation of acoustic waves. By leveraging the complex band structure, we propose a wave profile decomposition method to quantitatively predict wave propagation behaviors, revealing that acoustic wave attenuation is influenced by the sound source profile. While earlier studies have demonstrated the feasibility of acoustic switches, the realization of an adjustable multi-channel switch remains unexplored. To address this, a unit cell featuring five Helmholtz resonators is designed to modify sound source profiles by adjusting the orientations of the resonators. This unit cell is connected to three one-dimensional sonic crystals with cylindrical cores to form a multichannel acoustic switch. The ON state of a channel is achieved by activating propagating Bloch wave modes, whereas the OFF state corresponds to the activation of evanescent Bloch wave modes. To enable switching functionality across different frequencies, the orientations of the Helmholtz resonators are optimized to produce desired acoustic source profiles at the outputs. Both experimental and numerical investigations confirm the switching mechanism arising from the activation of evanescent and propagating Bloch wave modes, offering a versatile and tunable platform for advanced acoustic control.

1. INTRODUCTION

Switches and rectification devices constitute essential components for managing energy flow in various applications, including acoustics and vibration control systems. Different operational principles have been explored to design efficient acoustic or vibration switches.
Based on nonlinear mechanism, Boechler et al. demonstrated an acoustic switching and rectification approach using a one-dimensional granular crystal featuring a defect positioned near one end. By exploiting nonlinear Hertzian contact, which induces bifurcations and chaos, vibration energy originating from frequencies within band gaps is redistributed into lower frequencies within the granular crystal's propagation band [1]. Similarly, Li et al. introduced an acoustic switch based on a driven chain of spherical particles exhibiting nonlinear contact forces, where the output signal is modulated by adjusting the amplitude of a low-frequency control wave [2]. Devaux et al. developed a one-way acoustic switch employing acoustic radiation pressure effects at a water-air interface, effectively controlling directional acoustic propagation [3]. Vanhille and Campos-Pozuelo designed a three-channel acoustic switch based on bubbly-liquid channels. In this mechanism, acoustic waves traveling through the bubbly-liquid medium experience significant attenuation due to the presence of bubbles. By strategically positioning acoustic pressure antinodes to relocate bubbles away from the propagation path, acoustic energy can selectively pass through bubble-free channels [4]. Alagoz et al. proposed another approach, utilizing destructive interference between control waves and input waves, thereby facilitating wave-to-wave acoustic switching [5].
The closure of a sonic crystal (SC) band gap can facilitate the transition from an OFF state to an ON state. For instance, Zhu proposed an acoustic wave switch based on phononic crystals with meta-fluid inclusions that were constructed by alternately stacking sound-hard sub-layers. By altering the orientation of these sub-layers, the anisotropic density of the inclusions is modified, and the opened band gap induces an OFF state in the meta-fluid

phononic crystals [6]. Similarly, Babaee et al. employed an array of elastomeric helices in air; in its undeformed configuration, the system exhibits distinct band gaps characterized by strong wave attenuation. When the helices are axially stretched, these band gaps are suppressed, thereby allowing sound to propagate [7]. In another approach, Bilal et al. realized a phononic transistor-like device by utilizing magnetic coupling to adjust the band gap frequency [8]. Cao et al. designed a Kirigami metashell featuring Archimedean spirals, where deformation of the spiral branches closes the band gap, thus switching the metashell to an ON state [9]. Xue et al. introduced an acoustic switch based on a compressible p-type triply periodic minimal surface structure that can be deformed to either open or close the band gap, thereby controlling the OFF or ON state [10]. Finally, Jia-Hao He et al. [11] developed a bidirectionally tunable, multiconfiguration acoustic diode that controls its ON and OFF states by varying the orientation of square scatterers, and Yuanyuan et al. designed a tunable soft chiral-ligament phononic crystal where unit cell deformations adjust the band gaps [12].

2. DEPENDENCE OF TRANSMISSION LOSS ON SOUND SOURCE PROFILE

In this section, we quantitatively examine the relationship between wave attenuation behaviors, the sound source profile and the complex band structure. A one-dimension SC is studied in the following. The one-dimensional SC under investigation consists of a channel filled with air (density: ρ=1.23 kg/m³, sound speed: c=343 m/s) and N periodically arranged rigid cylinders with a radius of r=15 mm. The channel's width is w=60 mm. Figure 1 (a) illustrates the unit cell of the SC, demonstrating periodicity along the x-axis with a lattice constant of a= 60 mm. Sound hard walls are enforced on the upper and lower sides, and Bloch-Floquet periodic boundary conditions are imposed on the left and right boundaries of the unit cell. Figure 1 (b) shows the complex band structure. The influence of the sound source profiles on wave propagation behaviors are studied. The first three Bloch wave modes at 3.0 kHz are illustrated in the left panels of Figure 1 (c). In the right panel of Figure 1 (c), '+' represents that the phase of sound source is π/2 rad and '−' represents that the phase is -π/2 rad. The contours represent the acoustic pressure fields when the SC is excited by these sound sources. The sound source profile is adjusted according to the Bloch wave modes on the left panel. The resulting acoustic pressure fields in the first cell of the SCs (as shown in the right panels of Figure 1 (c)) closely resemble the Bloch wave modes depicted in the left panels.

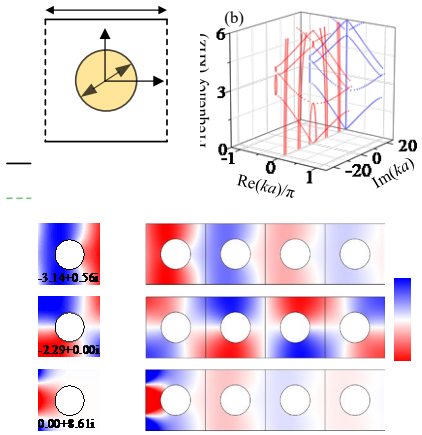

Figure 1. (a) Schematic of the unit cell. (b) Complex band structure. (c) Complex band structure in the Re (ka)-frequency plane (left panel) and Im(ka)-frequency plane (right panel). (c) The first three Bloch wave modes at 3.0 kHz and acoustic pressure fields for three different cases of sound source. The number on the downside of the left panel denotes the value of ka.

Figure 1 (c) demonstrates the feasibility of activating different Bloch wave modes by adjusting the profile of the sound source. Activating a propagating Bloch wave mode enable a large acoustic pressure at the other end of the SC. After sorting the eigen wavenumbers in descending order based on their imaginary part, the m-th order Bloch wave mode can be defined as the mode associated with the m-th eigen wavenumber. Assuming the m-th order Bloch wave mode participates in wave propagation, the acoustic pressure profiles on the left and right boundaries of the unit cell are represented by $p_{m,\mathrm{L}}(y)$ and $p_{m,\mathrm{R}}(y)$, respectively. According to the Bloch-Floquet periodic boundary condition, $p_{m,\mathrm{R}} = p_{m,\mathrm{L}} \exp(-\mathrm{i}k_m a)$ (a is the lattice constant, k_m is the m-th eigen wavenumber). Suppose that a prescribed acoustic pressure is applied on the left boundary of a one-dimensional SC and the profile is $p_{\mathrm{S}}(y)$, this sound source profile can be decomposition into the profiles ($p_{m,\mathrm{L}}(y)$ and (m=1,2,⋯, M)) from different order of Bloch wave modes, expressed as:

$$p_{\mathrm{S}} = p_{\mathrm{L}}^{(1)} = \sum_{m=1}^{M} w_{1,m} p_{m,\mathrm{L}}\,, \tag{1}$$

where $p_{\mathrm{L}}^{(1)}$ represent the acoustic pressure profile on the left boundary of the first unit cell, and M represents that profiles from the first M Bloch wave modes are utilized.

Performing Gram-Schmidt orth-normalization on $p_{m,\mathrm{L}}$ will derive M different basis orthotropic profiles $\hat{p}_{m,\mathrm{L}}$. $p_{m,\mathrm{L}}$ and $\hat{p}_{m,\mathrm{L}}$ are related by:

$$\mathbf{p} = \mathbf{A}\hat{\mathbf{p}}, \tag{2}$$

where $\mathbf{p}$ and $\hat{\mathbf{p}}$ are expressed in column vector forms, expressed as $[p_{1,\mathrm{L}}, p_{2,\mathrm{L}}, ..., p_{M,\mathrm{L}}]^{\mathrm{T}}$ and $[\hat{p}_{1,\mathrm{L}}, \hat{p}_{2,\mathrm{L}}, ..., \hat{p}_{M,\mathrm{L}}]^{\mathrm{T}}$, respectively. $\mathbf{A}$ is a $M \times M$ matrix that transfers orthotropic basis $\hat{p}_{m,\mathrm{L}}$ to basis $p_{m,\mathrm{L}}$ by using Gram-Schmidt orth-normalization, and $A_{i,j} = \langle p_{i,\mathrm{L}}, \hat{p}_{j,\mathrm{L}} \rangle$. According to the Bloch-Floquet periodic boundary condition, the TL can be calculated as:

$$\begin{aligned} \mathrm{TL}^N(\hat{\mathbf{w}}_1) &= -20\log(\left\|\hat{\mathbf{w}}_1\mathbf{A}^{-1}\mathbf{D}^N\mathbf{A}\right\|_2) \\ &= -20\log(\left\|\bar{\mathbf{w}}_1\mathbf{D}^N\mathbf{A}\right\|_2) \end{aligned}, \tag{3}$$

where $\mathrm{TL}^N(\hat{\mathbf{w}}_1)$ represent the TL of a SC with N unit cells and excited by a sound source with a profile of $p_{\mathrm{S}} = \hat{\mathbf{w}}_1\hat{\mathbf{p}}$. In Equation (3), $\|\hat{\mathbf{w}}_1\|_2$ is 1 and $\bar{\mathbf{w}}_1$ is $\hat{\mathbf{w}}_1\mathbf{A}^{-1}$ with $\|\hat{\mathbf{w}}_1\|_2 = 1$.

3. DESIGN METHOD OF THE ACOUSTIC SWITCH

In this section, we propose a design methodology for an acoustic switch. For brevity, the design principle is demonstrated using a single-channel acoustic switch, as illustrated in Figure 2 (a). This configuration comprises a one-dimensional SC with the acoustic switch cell positioned at the left end, where a plane wave is incident. The detailed structure of the acoustic switch is depicted in Figure 2 (b). Central to the switch cell is a C-split resonator—although other scatterer configurations may also be employed—which is characterized by an outer radius of r=15 mm, a thickness (dr) of 2 mm, and a split width of w=2 mm. A plane wave sound source, designated as $p_{\mathrm{in}}(y)$, is applied at the left boundary of the switch cell. As the acoustic waves propagate through the switch cell, the output acoustic pressure profile, $p_{\mathrm{out}}(y)$, is altered. Based on the criteria discussed in Section 2, if $p_{\mathrm{out}}(y)$ excites propagating Bloch wave modes, the acoustic waves continue to propagate through the subsequent SC, thereby placing the switch in the ON state. Conversely, if $p_{\mathrm{out}}(y)$ triggers evanescent Bloch wave modes, the acoustic wave is inhibited from propagating, resulting in an OFF state. By adjusting the orientation (θ) of the C-split resonator, the output acoustic pressure profile can be effectively modulated, thereby controlling the switching state. This approach highlights the feasibility of using geometric and orientation adjustments to achieve tunable acoustic wave manipulation in engineered sonic crystals.

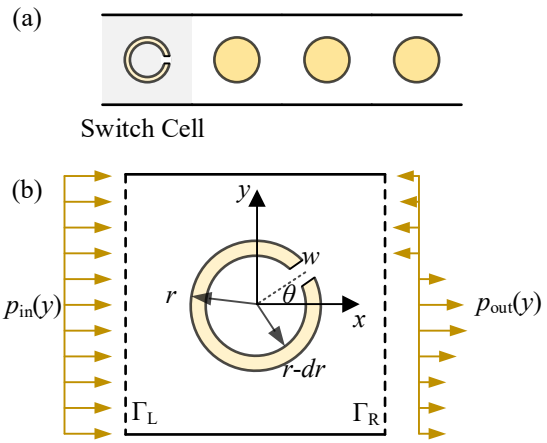

Figure 2. (a) Schematic of the acoustic switch. The cell on the left end is the switch cell. (b) Detail illustration of the switch cell. The switch cell contains a C-split.

According to the design principle—where the activation of evanescent or propagating Bloch wave modes hinges on accurately predicting the output acoustic pressure profile from a given input—the key is to model the wave propagation within the switch cell precisely. Here, we analyze the switch cell illustrated in Figure 2 (b). The left boundary is treated as an acoustic pressure boundary, while the boundaries of the C-split resonator and the upper and lower boundaries are considered sound-hard wall boundaries. Consequently, determining the overall acoustic pressure profile also requires specifying the acoustic boundary condition on the right side (Γ_{R}), which serves as the interface between the switch cell and the sonic crystal. Before defining the precise boundary condition on Γ_{R}, we first examine the acoustic pressure and the normal acoustic velocity at the different interfaces depicted in Figure 3.

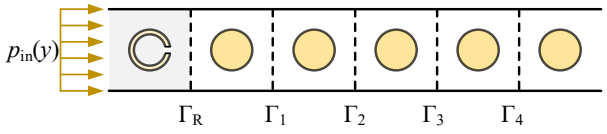

Figure 3. Different interfaces in the acoustic switch.

According to Equation (1), the acoustic pressure and acoustic norm velocity can be decoupled as:

$$p_{\mathrm{R}} = \sum_{m=1}^{M} w_{1,m} p_{m,\mathrm{L}}, \quad v_{\mathrm{R}} = \sum_{m=1}^{M} w_{1,m} v_{m,\mathrm{L}}. \tag{4}$$

After acoustic waves propagate through several unit cells of the sonic crystal, the acoustic pressure and velocity at the

nth interface are characterized by the Bloch-Floquet periodic boundary conditions. The acoustic pressure and velocity can be expressed as follows:

$$\begin{aligned} p_n &= \sum_{m=1}^{M} w_{1,m} p_{m,\mathrm{L}} \exp(-in\,\mathrm{Re}(k_m a)) \exp(-n\,\mathrm{Im}(k_m a)) \\ v_n &= \sum_{m=1}^{M} w_{1,m} v_{m,\mathrm{L}} \exp(-in\,\mathrm{Re}(k_m a)) \exp(-n\,\mathrm{Im}(k_m a)) \end{aligned} . \quad (5)$$

As n increases, the contribution of the evanescent component diminishes, and both the acoustic pressure and acoustic velocity converge to their steady-state values:

$$\begin{aligned} p_n &\approx w_{1,1} p_{1,\mathrm{L}} \exp(-in\,\mathrm{Re}(k_1 a)) \\ v_n &\approx w_{1,1} v_{1,\mathrm{L}} \exp(-in\,\mathrm{Re}(k_m a)) \end{aligned} . \quad (6)$$

This result indicates that the acoustic impedance converges to a constant profile, expressed as:

$$Z = \frac{p_n}{v_n} = \frac{p_{1,\mathrm{L}}}{v_{1,\mathrm{L}}}, \quad (7)$$

where $p_{1,\mathrm{L}}$ is acoustic pressure profile of the propagating Bloch wave mode, and $v_{1,\mathrm{L}}$ is velocity profile of the propagating Bloch wave mode. Hence, we define the propagating Bloch mode impedance as $Z_{\mathrm{PB}} = p_{1,\mathrm{L}} / v_{1,\mathrm{L}}$.

After applying the Bloch mode impedance boundary condition to the right boundary of the switch cell, we can compute the output acoustic pressure profile, $p_{\mathrm{out}}(y)$, for a prescribed input profile. Using Equation (3), the transmission loss (TL) of the acoustic switch can then be determined based on this output pressure profile. To validate the capability of the Propagating Bloch Impedance (PBI) boundary condition in predicting the switch cell's output profile, we examine cases with rotation angles of 0° and 90°. In both scenarios, different SC unit cells are analyzed, as depicted in Figure 4 (a) and Figure 4 (c). Figure 4 (b) and Figure 4 (d) present a comparison between the TL calculated via Equation (3) and that obtained from the commercial software COMSOL. The strong correlation between these results indicates that the PBI boundary condition reliably predicts the output acoustic profile and that the predictive model based on Equation (3) accurately estimates the TL.

Next, we determine the rotation angle of the acoustic switch by solving the following optimization problem:

$$\begin{aligned} \min_{\theta_{\mathrm{ON}},\theta_{\mathrm{OFF}}} \quad & \mathrm{TL}(\theta_{\mathrm{ON}}, f_0) - \mathrm{TL}(\theta_{\mathrm{OFF}}, f_0) \\ s.t. \quad & \theta_{\mathrm{ON}}, \theta_{\mathrm{OFF}} \in [0,\, 180^\circ] \end{aligned} . \quad (8)$$

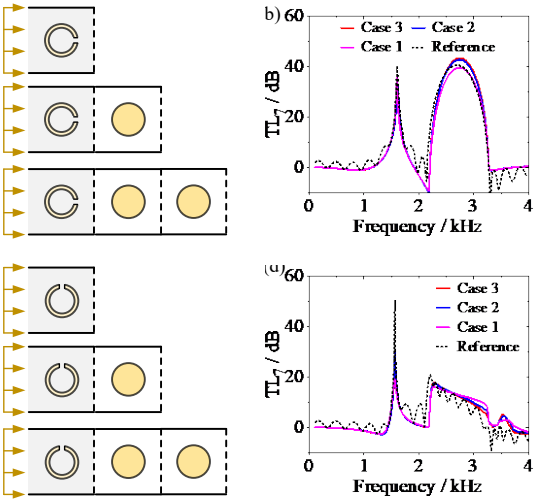

Figure 4. (a) Numerical model to calculate the output acoustic pressure profile $p_{\mathrm{out}}(y)$ of the switch cell when the rotation angle θ is 0°. (b) Comparison of the TL calculated with predicated pressure profile $p_{\mathrm{out}}(y)$ and reference from COMSOL (θ is 0°). (c) Numerical model to calculate the output acoustic pressure profile $p_{\mathrm{out}}(y)$ of the switch cell when the rotation angle θ is 90°. (d) Comparison of the TL calculated with predicated pressure profile $p_{\mathrm{out}}(y)$ and reference from COMSOL. (θ is 90°). PBI indicates propagating Bloch impedance boundary condition. Case 1, 2, and 3 indicates there are zero, one or two unit cells of SC in the prediction model.

where θ_{ON} and θ_{OFF} is the rotation angle when the switch is in ON state and OFF state, respectively. f_0 is working frequency. By setting f_0 as 3.0 kHz, and solving Equation (8) with the PSO algorithm, we derive that θ_{ON} is 100.7°, and θ_{OFF} is 0°. Figure 5 shows the acoustic pressure field when the rotation angle is in OFF (upper panel) state or ON (lower panel) state.

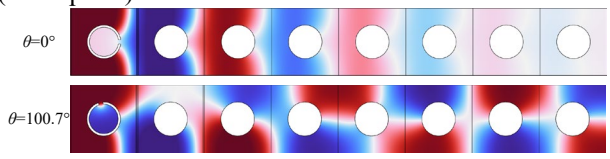

Figure 5. Acoustic pressure of the acoustic switch when the rotation angle is θ_{OFF}= 0° (upper panel) and is θ_{ON}= 100.7° (lower panel).

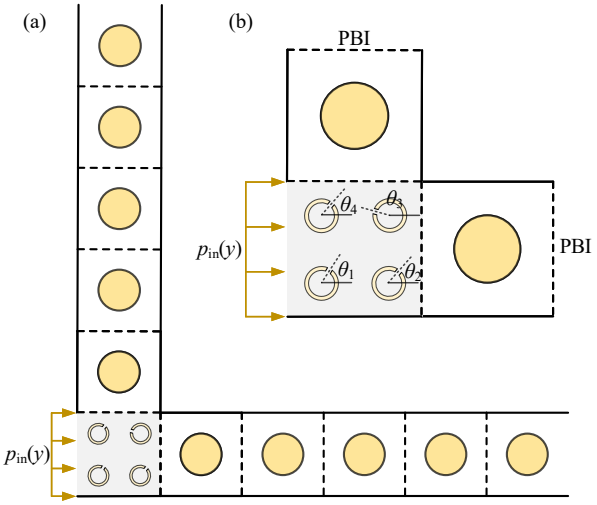

Figure 6. (a) Two-channel acoustic switch. (b) Numerical model to predict the output acoustic pressure profile and TL.

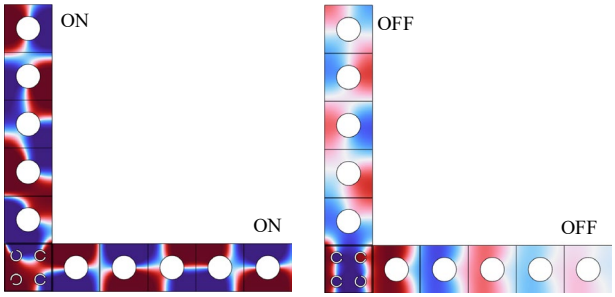

Figure 7. Acoustic pressure of the acoustic switch when both branches are in ON state (left panel with **θ**=[209.6°, 0°, 0°, 107.5°]) or OFF state (right panel with **θ**=[0°, 102.87°, 0°, 0°]).

For a multichannel acoustic switch, as illustrated in Figure 6 (a), Figure 6 (b) shows the corresponding numerical model used to predict the acoustic pressure profiles. In the switch unit cell, four C-split resonators with individually adjustable rotation angles are employed. By varying the orientations of these resonators, the output acoustic pressure profiles directed to the upper sonic crystal (SC) and the left SC can be independently controlled. Here, TL_U represents the transmission loss of the upper SC branch, while TL_L represents the transmission loss of the left branch. To simultaneously control both branches such that they are in the same ON or OFF state, the following optimization problem can be formulated:

$$\begin{aligned} \min_{\theta_{ON},\theta_{OFF}} \quad & \left[\mathrm{TL_L}(\boldsymbol{\theta}_1, f_0) - \mathrm{TL_L}(\boldsymbol{\theta}_2, f_0)\right] \\ & + \left[\mathrm{TL_U}(\boldsymbol{\theta}_1, f_0) - \mathrm{TL_U}(\boldsymbol{\theta}_2, f_0)\right] \\ s.t. \quad & \boldsymbol{\theta}_1 = [\theta_{1,1}, \theta_{1,2}, \theta_{1,3}, \theta_{1,4}] \in [0, 360^\circ] \\ & \boldsymbol{\theta}_2 = [\theta_{2,1}, \theta_{2,2}, \theta_{2,3}, \theta_{2,4}] \in [0, 360^\circ] \end{aligned}, \tag{9}$$

And the design results in shown in Figure 7.

To derive a double-channel switch that one is in ON state and the other is in OFF state, we define he optimization problem as follows:

$$\begin{aligned} \min_{\theta_{ON},\theta_{OFF}} \quad & \left[\mathrm{TL_L}(\boldsymbol{\theta}_1, f_0) - \mathrm{TL_L}(\boldsymbol{\theta}_2, f_0)\right] \\ & + \left[\mathrm{TL_U}(\boldsymbol{\theta}_2, f_0) - \mathrm{TL_U}(\boldsymbol{\theta}_1, f_0)\right] \\ s.t. \quad & \boldsymbol{\theta}_1 = [\theta_{1,1}, \theta_{1,2}, \theta_{1,3}, \theta_{1,4}] \in [0, 360^\circ] \\ & \boldsymbol{\theta}_2 = [\theta_{2,1}, \theta_{2,2}, \theta_{2,3}, \theta_{2,4}] \in [0, 360^\circ] \end{aligned}, \tag{10}$$

And the design results in shown in Figure 8.

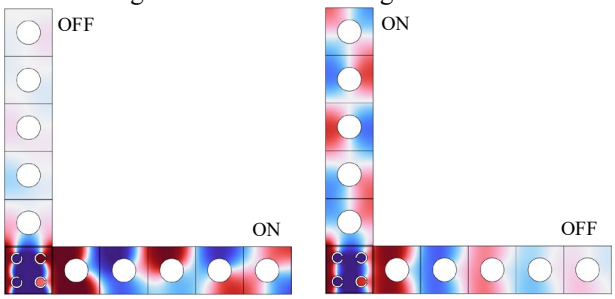

Figure 8. Acoustic pressure of the acoustic switch when the two branches have opposite states. Left panel with **θ**=[42.9°, 0°, 0°, 41.9°] and right panel with **θ**=[0°, 0°, 198.5°, 0°]).

ON-DEMAND NOISE MITIGATION WITH TIME-MODULATED ACTIVE ACOUSTIC METAMATERIALS

Bogdan-Ioan Popa*
Department of Mechanical Engineering, University of Michigan, USA

ABSTRACT

It is generally accepted that active metamaterials could, in principle, address long-standing challenges in noise mitigation. However, the research of active structures capable to meet these challenges has been slow due to issues of stability and scalability. This work shows that 2D active metamaterials composed of arrangements of sensor-driver pairs can be configured to be excellent sound absorbers very well matched to the background fluid and thus scatter-free. The property is achieved by programming the metamaterial effective mass density and bulk modulus to be complex numbers with matching phases. Moreover, the metamaterials can be switched from being opaque absorbers to transparent media on very small time scales by time-modulating their effective material properties without adverse effects such as ensuing instability. Furthermore, the metamaterial unit cells are completely independent of each other thus promoting scalability.

Keywords: *active acoustic metamaterial, noise control, time modulation, programmable metamaterial*

1. INTRODUCTION

Noise has long been correlated with an increased incidence in cardiovascular diseases [1] making noise mitigation an important area of research. Numerous passive absorbers have been proposed but they tend to be either ineffective, too bulky, narrow band, or scatter sound instead of dissipating it [2, 3]. It has been proposed that metamaterials can advance this strategically important field due to their increased degrees of freedom on sound manipulation. Passive metamaterials have been tried first, but they suffered from the same limitations as conventional passive sound dissipation methods [4]. It was soon realized that active metamaterials can overcome these limitations [5]. A particularly promising active metamaterial architecture consists of arrangements of sensor-driver pairs realizing effective acoustic properties dictated by the chosen transfer function (or gain) between each pair of sensors and drivers [6–8]. These gains are typically set in electronic circuits programmable in real time [9–13]. The advantages of this approach are its scalability promoted by the independence of the sensor-driver pairs (i.e., there is no connection between different pairs) and very low response time and thus broadband operation stemming from the gains being computed apriori for a desired functionality [14] and not adaptively as in conventional controls-based systems [3]. It has recently been shown that active metamaterials composed of sensor-driver pairs achieve very large sound dissipation with minimal scattering [13]. However, the effect has been studied in the steady state regime in which the effective properties of the metamaterial are fixed. Whether switching these properties on-demand can be done in a stable manner is unknown.

Here we show experimentally that active metamaterials following the sensor-driver architecture can be switched instantaneously from scatter-free opaque absorbers to transparent media without adverse effects. To act as a sound absorber, the fabricated metamaterial is designed to mimic the acoustic behavior of a continuous medium with bulk modulus and mass density having complex values with matching phases. We show that these effective properties can be time modulated to switch from

complex to real quantities matching the properties of air on very short time scales thus realizing the remarkable transition from absorber to transparent medium.

2. ACTIVE METAMATERIAL DESIGN

The goal of this work is to realize a time-modulated 2D active acoustic absorbing medium that does not scatter impinging sound. The medium is represented by the red box placed in the air-filled acoustic waveguide shown in Fig. 1a and composed of two parallel plates driven at the fundamental mode by an external speaker placed on the side of the waveguide. The air has bulk modulus B_0, mass density ρ_0, speed of sound c_0 and characteristic impedance Z_0.

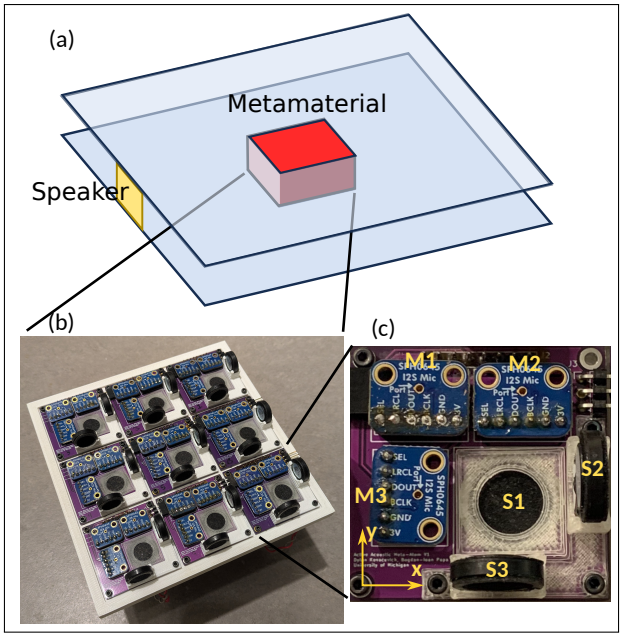

Figure 1. (a) Schematic of the experimental setup showing a homogeneous fluid of bulk modulus B and mass density ρ placed in a 2D waveguide and ensonified by an external speaker. (b) Active metamaterial programmed to realize the B and ρ of the desired fluid. (c) Photo of unit cell showing the labeled microphones Mi and speakers Si, where $i = \overline{1,3}$.

The medium is a very good absorber matched with the background as long as its bulk modulus B and mass density ρ are complex quantities having the following expressions.

$$B = B_0 e^{j\phi}, \quad \rho = \rho_0 e^{-j\phi}, \tag{1}$$

where ϕ is a real phase. Under these conditions, the characteristic impedance of the metamaterial matches that of air ($Z = \sqrt{B\rho} = Z_0$) and the speed of sound inside the metamaterial is complex ($c = \sqrt{B/\rho} = c_0 e^{j\phi}$). High absorption is achieved when the imaginary part of c is large.

This continuous medium is realized with an active metamaterial composed of the 3 by 3 arrangement of active cells illustrated in Fig. 1b. The metamaterial is under a good approximation flat, protruding very little inside the waveguide and thus it is not impeding the flow of air. Consequently, in its off state, the metamaterial has the effective properties of air.

It has been shown that active cells composed of multiple sensor-driver pairs can fully program the effective bulk modulus, mass density tensor, and two Willis coupling vectors depending on the nature of the sensor and driver in each pair [5, 13]. In particular, the bulk modulus is controlled by a monopole sensor capturing the local pressure p and driving a monopole driver whose amplitude is proportional to p. Similarly, each component $\rho_{\alpha\beta}$ of the mass density tensor ($\alpha, \beta \in \{x, y\}$ in 2D) is controlled by a dipole sensor capturing the local particle velocity u_α and driving a particle velocity source parallel to direction β with amplitude proportional to u_α.

Figure 1c shows a 2D metamaterial cell realizing three sensor-driver pairs to control the bulk modulus and all components of the mass density tensor. In this approach, the pressure and particle velocity components are obtained with three microphones Mi sensing the acoustic pressures $p_{\mathrm{M}i}$ and driving the three speakers Si, where $i = \overline{1,3}$. One speaker is horizontal, acting as a monopole pressure source, and two speakers are vertical, acting as dipole sources in the x and y directions. The sensed monopole and dipole quantities p, u_x, and u_y as well as the amplitude of the sound generated by these speakers $A^{\mathrm{S}i}$ are shown in Table 1. The proportionality terms between the sensed and driven quantities (g^m, g_x^{dx}, g_y^{dx}, g_y^{dy}, and g_x^{dy}) are set by a Teensy 4 microcontroller connecting the microphones and speakers of each cell.

Closed-form expressions relating these gain terms to the desired effective material properties B and ρ given by Eqn. (1) are derived elsewhere [13, 14] and implemented in the microcontroller.

In its active state the metamaterial is programmed to have B and ρ given by Eqn. (1), where $\phi = 30°$. As we

Table 1. Driven versus sensed quantities.

Sensed	Driven
$p = \frac{p_{M1}+p_{M2}+p_{M3}}{3}$	$A^{S1} = g^m p$
$u_x = -\frac{\int (p_{M1}-p_{M2})dt}{\rho_0 d}$	$A^{S2} = g_x^{dx} u_x + g_y^{dx} u_y$
$u_y = -\frac{\int (p_{M3}-p_{M1})dt}{\rho_0 d}$	$A^{S3} = g_x^{dy} u_y + g_y^{dy} u_x$

will see in the next section, this phase produces a very large absorption. The microcontroller in each cell can reduce the gains g shown in Table 1 to zero essentially instantaneously.

3. RESULTS

The metamaterial is ensonified by a speaker at 1200 Hz. We programed the metamaterial to switch from the opaque, high absorption state ($\phi = 30°$) to the transparent state ($\phi = 0°$) and back every 1.67 ms, i.e. two acoustic periods at 1200 Hz. Figure 2 shows the time domain acoustic pressure fields measured inside and outside the metamaterial at two time instances separated by 1.67 ms with and without the metamaterial inside the waveguide.

The external speaker excites cylindrical waves in the empty waveguide (Fig. 2 top). The two time instances illustrated in the figure are chosen approximately two acoustic periods apart and thus the two measured acoustic pressure distributions are essentially the same.

The bottom panels represent the acoustic fields measured in the waveguide with the metamaterial inside. The black squares in the figure represent the position of the metamaterial. The same two instances separated by two acoustic periods shows the metamaterial behavior $\phi = 30°$ (absorber state) and $\phi = 0°$ (transparent state), respectively.

In the absorber configuration, the metamaterial dissipates almost all the incident energy as indicated by the very low amplitude pressure inside the structure and behind it (the shadow region). In all other directions, the acoustic pressure looks essentially the same as that measured in the empty waveguide at the same time instant, which confirms the metamaterial's expected scatter-free behavior.

In its transparent state, the metamaterial behaves essentially as air, i.e., the measured fields look like those measured in the empty waveguide, confirming that the effective B and ρ match those of air.

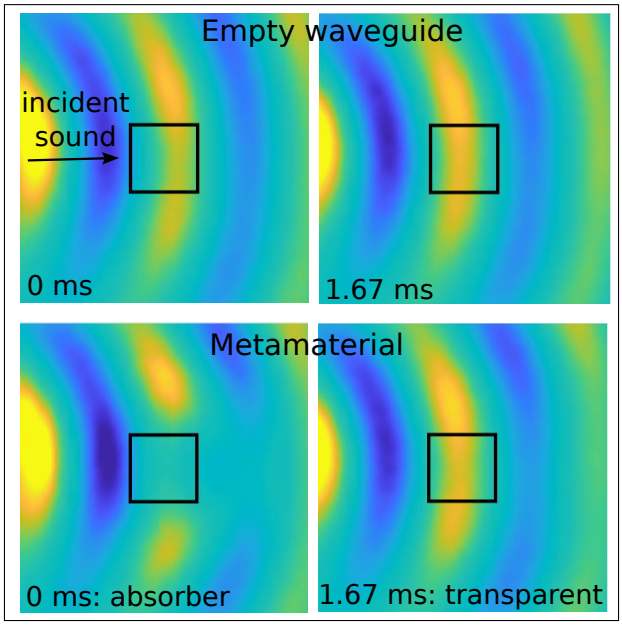

Figure 2. Time domain acoustic pressure measured in the empty waveguide (top) and with the time-modulated programmable metamaterial (bottom). The right pressure fields (transparent state) were measured 1.67 ms later than the left fields (absorber state), i.e. half the modulation period.

4. CONCLUSIONS

This work shows that active metamaterials with carefully tailored effective bulk modulus and mass density behave as highly effective, compact sound absorbers. The metamaterial demonstrated here is composed of independent unit cells composed of sensor-driver pairs that promote scalability, i.e., adding more cells increases the area covered by the metamaterial absorbers without having to change the existing cells. More importantly, the gain between the sensors and drivers in each pair are precomputed from a desired set of effective acoustic properties leading to low dispersion. This approach contrasts with conventional controls methods used in existing noise cancellation devices that use complex, adaptive transfer functions realized with centralized controllers.

Remarkably, this work shows that the fabricated metamaterial can switch functionality essentially instantaneously without any adverse effects such as ensuing instability. This property has been demonstrated experimentally by repeatedly switching the metamaterial from its ab-

sorber to transparent configurations. Active metamaterials based on sensor-driver pairs are thus ideal for noise mitigation, but also for other applications that require very fast time modulation of material parameters recently associated with interesting physical phenomena.

ABSTRACT

The emergence of topological states in condensed matter physics has provided reliable mechanisms for waveguiding in phononic crystals and metamaterials. This study introduces a strategy for dynamic wave localization using space-time programmable topological interface states in piezoelectric metamaterials. By dynamically tuning inductive shunt circuits, we induce and modulate interface states in space and time without physical changes in the host structure. By modulating electrical properties, the topological interface can be dynamically moved along the beam, enabling efficient energy transfer. The numerical results clarify the effects of modulation smoothness on wave localization for cases with and without structural damping, identifying the optimal conditions for robust energy transfer.

Keywords: *piezoelectricity, programmable metamaterial, topological interface states, structural damping*

1. INTRODUCTION

The discovery of topological states in condensed matter physics has led to innovative methods for manipulating waves in metamaterials [1, 2]. The topological protection of these states, which confine mechanical waves to edges or interfaces between regions with distinct topological properties [3], provides robustness against backscattering caused by imperfections or disturbances along the propagation path [4]. In contrast to their electronic counterparts [5], acoustic and elastic systems offer greater flexibility in the design, fabrication, and detection of diverse topological phenomena [6]. In this context, breaking the spatial inversion symmetry while maintaining the time-reversal symmetry can be achieved in the subwavelength regime by manipulating piezoelectric inductive shunt circuits [7]. In this sense, connecting two metamaterials with distinct Zak phases allows the emergence of a topological interface state that presents significant vibration energy localization [8].

Recent years have seen significant interest in exploring metamaterials with adaptable and programmable characteristics, particularly due to their potential for versatile control over wave propagation. [9]. Recent studies have concentrated on multi-coupling domains to improve reconfigurability. Within this context, piezoelectric materials have become a popular choice due to their versatility in controlling wave behavior. This is achieved by adjusting digitally controlled analog and digital shunt circuits, as opposed to traditional analog shunts. This advancement has enabled the experimental implementation of programmable metamaterials [10, 11]. This advanced control strategy enables the design of materials with spatiotemporal modulation, enhancing metamaterials by adding an extra dimension of tunability through dynamic adjustments of their properties in both space and time [12].

In this work, we build upon a recently introduced approach that utilizes space-time modulation of trivial de-

fects [13, 14] and extend it to programmable topological interfaces within an electromechanically coupled metamaterial beam. By applying cosine-based modulations to the electrical properties of the unit cells, we demonstrate that the topological interface can be dynamically repositioned along the beam, enabling efficient energy transfer while preventing energy leakage. Additionally, we discuss the effects of structural damping on the modulation performance and energy availability for further operations.

2. MODEL DESCRIPTION

Fig. 1 depicts the electromechanical metamaterial, which consists of a thin conductive substructure sandwiched by two oppositely poled piezoelectric layers. The outer surfaces of the thin and conductive electrodes covering each piezoelectric layer are periodically segmented, and each segment is connected to an inductive shunt circuit, characterizing a local resonator with the equivalent in-series piezoelectric capacitance. The unit cell highlighted in Fig. 1 comprises four consecutive local resonators with the outer and inner inductances set as L_1 (blue inductances) and L_2 (red inductances), respectively. Thus, the unit cell has a mirror symmetry regarding the central point. A dimerization parameter δ is defined to generate $L_1 = L_r(1+\delta)$ and $L_2 = L_r(1-\delta)$, where L_r is a reference inductance.

The metamaterial beam is discretized into one-dimensional finite elements based on the Euler-Bernoulli assumptions. A third-degree polynomial is employed to approximate the transverse displacement field within each element that has two degrees of freedom per node, denoted as transverse displacement (w) and rotation about the y direction (θ) [15]. In the electrical domain, the non-zero electric field component is assumed to be uniform in the thickness direction of the piezoelectric layers. Consequently, one electrical degree of freedom is sufficient to model the voltage output in each electrode's segment. The structural dissipation is included using Rayleigh's proportional damping model. Consequently, the behavior of the piezoelectric metamaterial beam is governed by the following finite elements equations [16],

$$\mathbf{M}\ddot{\mathbf{u}} + \mathbf{D}\dot{\mathbf{u}} + \mathbf{K}\mathbf{u} - \boldsymbol{\Theta}\mathbf{v} = \mathbf{F} \tag{1a}$$

$$\mathbf{C_p}\mathbf{v} + \mathbf{q} + \boldsymbol{\Theta}^t\mathbf{u} = \mathbf{0} \tag{1b}$$

where $\mathbf{M}$ is the global mass matrix ($n_m \times n_m$), $\mathbf{K}$ is the global stiffness matrix ($n_m \times n_m$), $\mathbf{D}$ is the structural damping matrix ($n_m \times n_m$), $\mathbf{F}$ is the vector of external mechanical inputs ($n_m \times 1$), $\boldsymbol{\Theta}$ is the electromechanical coupling matrix ($n_m \times n_e$), $\mathbf{C_p}$ is the capacitance matrix ($n_m \times n_e$), $\mathbf{v}$ is the vector of voltage output from each electrode segment ($n_e \times 1$), $\mathbf{q}$ is the vector of electrical charges ($n_e \times 1$), $\mathbf{u}$ is the vector of mechanical degrees of freedom ($n_m \times 1$), which contains the transverse displacements and rotations (about the y direction) associated to each node, and n_m and n_e are the number of mechanical and electrical degrees of freedom, respectively. The over-dots represent the derivative with respect to time t.

When considering time-varying inductances in each shunt circuit, the voltage output from each electrode segment is determined by $\mathbf{v}(t) = \dot{\mathbf{L}}_c(t)\dot{\mathbf{q}} + \mathbf{L_c}(t)\ddot{\mathbf{q}}$, where $\mathbf{L_c}$ is a diagonal matrix ($n_e \times n_e$) that contains the inductances connected to each segment of electrode. In this case, the matrix representation of Eqs. 1 is

$$\begin{bmatrix} \mathbf{M} & -\boldsymbol{\Theta}\mathbf{L_c} \\ \mathbf{0} & \mathbf{C_p}\mathbf{L_c} \end{bmatrix} \begin{bmatrix} \ddot{\mathbf{u}} \\ \ddot{\mathbf{q}} \end{bmatrix} + \begin{bmatrix} \mathbf{D} & -\boldsymbol{\Theta}\dot{\mathbf{L}}_\mathbf{c} \\ \mathbf{0} & \mathbf{C_p}\dot{\mathbf{L}}_\mathbf{c} \end{bmatrix} \begin{bmatrix} \dot{\mathbf{u}} \\ \dot{\mathbf{q}} \end{bmatrix} + \begin{bmatrix} \mathbf{K} & \mathbf{0} \\ \boldsymbol{\Theta}^t & \mathbf{I} \end{bmatrix} \begin{bmatrix} \mathbf{u} \\ \mathbf{q} \end{bmatrix} = \begin{bmatrix} \mathbf{F} \\ \mathbf{0} \end{bmatrix} \tag{2}$$

where $\mathbf{I}$ is the identity matrix ($n_e \times n_e$). Equation 2 represents a multiphysical problem, wherein the mechanical and electrical domains are coupled through the electromechanical coupling matrix $\boldsymbol{\Theta}$ (off-diagonal elements of the matrices). In each unit cell, the combination of the inductive shunt L_{c_j} and the effective capacitance of the piezoelectric bimorph C_{p_j} forms a capacitive-inductive circuit whose resonance frequency is $\omega_{n_j} = 1/\sqrt{C_{p_j} L_{c_j}}$.

In Fig. 1, each electrode segment has length l_s and width b equal to 20 mm. The substructure has thickness h_s of 1 mm, the elastic modulus is $c_s = 69$ GPa, and mass density $\rho_s = 2700\,\mathrm{kg/m^3}$. The substructure is sandwiched by two PMN-PT piezoelectric layers, each with a thickness h_p of 0.6 mm. The elastic modulus of the PMN-PT crystal at a constant electric field is $\bar{c}_{11}^E$ of 21.8GPa, an effective piezoelectric stress constant $\bar{e}_{31}$ of $-14.1\,\mathrm{C/m^2}$, a permittivity component at a constant strain $\bar{\epsilon}_{33}^S$ of 33 nF/m, and a mass density ρ_p of $8120\,\mathrm{kg/m^3}$.

The angular frequency axis in the results is normalized by the velocity of the longitudinal wave considering the composite material's average properties. Accordingly, the normalized frequency assumes $\Omega = \omega l_s/(2\pi\sqrt{Y_{avg}\rho_{avg}})$, where $Y_{avg} = v_f/Y_s + (1-v_f)/Y_p$ and $\rho_{avg} = v_f\rho_s + (1-v_f)\rho_p$ are the average modulus and the average mass density, respectively, while

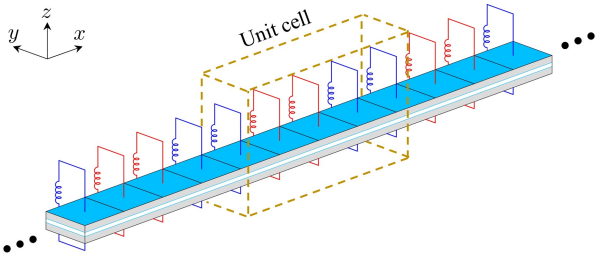

Figure 1. Scheme of the locally resonant electromechanical metamaterial, where the light gray and white regions represent the piezoelectric and substructure layers, the blue regions represent the electrodes. The highlighted region depicts the unit cell, where the blue and red inductances are associated with L_1 and L_2, respectively.

$v_f = h_s/(h_s + 2h_p)$ is the volume fraction of the substructure and $Y_p = 1/s_{11}^E$ is the piezoelectric elastic modulus. In addition, the finite element mesh for the numerical calculations is assumed as 12 elements per unit cell, which gives approximately 1.1 mm for each element. This value corresponds to 3% of the smallest wavelength analyzed, which can capture the studied dynamic behavior effectively.

3. RESULTS

Fig. 2 depicts the band structure for three unit cells, one tuned with $\delta = 0$ (Fig. 2(a)) and tuned with $\delta = \pm 0.05$ (Fig. 2(b)), where $L_r = 0.576$ H. The unit cells tuned with $\delta = 0.05$ are named UCA in this work while the ones tuned with $\delta = -0.05$ are UCB. The numerical procedures combine the Bloch-Floquet periodic conditions with the finite element matrices where the electrical outputs are considered internal degrees of freedom (for more details, see [13]). An inverse eigenproblem (i.e., $\omega(\kappa)$) is solved for each wavenumber κ. According to the presented results, the homogeneous unit cell (i.e., $\delta = 0$) features a locally resonant band gap between $\Omega_l = 0.0153$ and $\Omega_u = 0.0169$. In addition, a folding point appears at $\Omega_f = 0.0150$ (red circle in Fig. 2(a)). The folding point opens to generate a band gap in the subwavelength region (green region) for the non-homogeneous unit cell (i.e., $\delta \neq 0$). Although the band structures of the unit cells tuned with $\delta \pm 0.05$ are identical, they have distinct topological properties due to band transition and inversion, which characterizes a topologically non-trivial band gap [17].

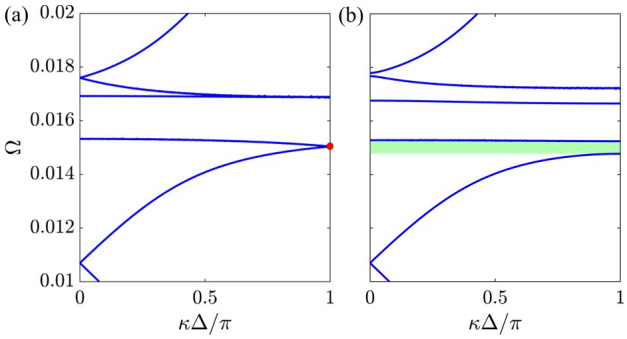

Figure 2. Dispersion relation of the unit cell tuned with $\delta = 0$ (a) and $\delta = \pm 0.05$. The red circle indicates the folding point whereas the green region highlights the non-trivial band gap.

The emergence of a topological interface mode is examined through the harmonic response of a finite piezoelectric metamaterial beam consisting of 16 unit cells — 8 unit cells UCA to the right and 8 unit cells UCB to the left, creating an interface between them. A harmonic point excitation, denoted as $\bar{F}(L/2, \Omega)$ (where L represents the total length of the metastructure), is applied at the interface position. The corresponding harmonic transverse displacements, $\bar{w}(x, \Omega)$, are obtained along the metastructure as well as the amplitude of the transfer functions $20\log_{10}|\hat{w}(x, \Omega)/\hat{F}|$ (dB, reference 1 m/N). Fig. 3(a) shows the harmonic response as a function of space and frequency for the periodic configuration (the metamaterial beam with 16 unit cells tuned with $\delta = 0.05$). Fig. 3(b) displays the harmonic response for the topological metamaterial (metamaterial with 8 unit cells tuned with $\delta = 0.05$ and 8 unit cells tuned with $\delta = -0.05$). Three attenuation zones are observed in the responses of the periodic configuration and the topological metamaterial beam. These consist of two Bragg band gaps and a locally resonant band gap situated between them, which is consistent with the dispersion previously presented for the unit cells. Figure 3(b) displays a resonance peak within the first non-trivial Bragg band gap (green region depicted in Fig. 2(b)), which corresponds to the topological interface state.

After examining the behavior of a topological metamaterial with a fixed interface, we now investigate its pro-

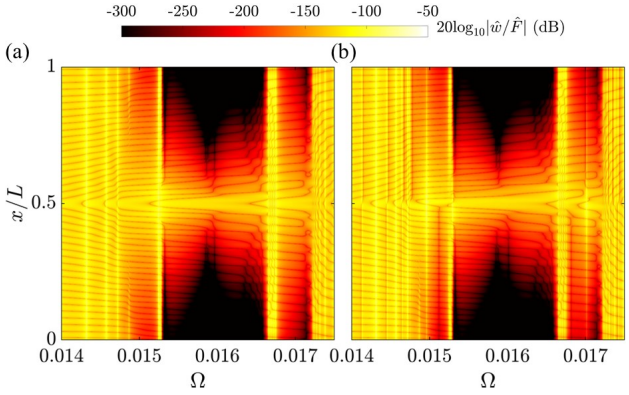

Figure 3. Maps displaying harmonic responses as a function of both spatial position and frequency for the periodic metastructure without topological interface (a) and for the topological metastructure with topological interface (b).

grammable counterpart. We perform the space-time wave localization by dynamically modulating the interface in both space and time. This approach involves transforming one of the unit cells adjacent to the interface into its topological counterpart while keeping the others unchanged. As a result, the interface can only shift between successive unit cell boundaries within a single modulation cycle. In this framework, modifying a unit cell initially set to $\delta = 0.05$ ($\delta = -0.05$) requires that the inner electromechanical resonators are changed from Ω_{t_1} (Ω_{t_2}) to Ω_{t_2} (Ω_{t_1}), while simultaneously updating the outer electromechanical resonators from Ω_{t_2} (Ω_{t_1}) to Ω_{t_1} (Ω_{t_2}). Consequently, vibrational energy is expected to be transferred from the initial interface location to the final interface position.

The essential mechanism for achieving a perfect energy transfer across successive unit cell boundaries involves the smooth and synchronized adjustment of each local resonator's frequency. In this study, cosine functions are employed to modulate the local resonant frequency, affecting the inductance of each shunt circuit during space-time transitions. These functions are of interest in this application since they present zero-time derivatives at the beginning and end of the transition intervals and are continuous throughout the entire domain. For convenience, we denote the unit cells on the left and right of the topological interface with the indices j and $j+1$, respectively. If the interface is intended to move to the right (left) side, then the unit cell represented by $m = j+1$ ($m = j$) is topologically converted. Furthermore, consider Ω_{m_1} and Ω_{m_2} as the frequencies of local resonators, which are initially tuned to Ω_{t_1} and Ω_{t_2} within the unit cell m to be converted, respectively. Therefore, the variation of the locally resonant frequencies defined by Ω_{m_1} from $\Omega_{m_1}/\Omega_{t_1} = 1$ to $\Omega_{m_1}/\Omega_{t_1} = \Omega_{t_2}/\Omega_{t_1} = \eta$ is governed by the following law during the time interval $t_{i_j} \leq t \leq t_{f_j}$:

$$\frac{\Omega_{m_1}}{\Omega_{t_1}}(t) = \frac{(1+\eta)}{2} - \frac{(\eta-1)}{2}\cos\left(\frac{t-t_{i_j}}{t_{f_j}-t_{i_j}}\pi\right) \quad (3)$$

simultaneously, the change in locally resonant frequencies defined by Ω_{m_2} from $\Omega_{m_2}/\Omega_{t_1} = \eta$ to $\Omega_{m_2}/\Omega_{t_1} = 1$:

$$\frac{\Omega_{m_2}}{\Omega_{t_1}}(t) = \frac{(1+\eta)}{2} + \frac{(\eta-1)}{2}\cos\left(\frac{t-t_{i_j}}{t_{f_j}-t_{i_j}}\pi\right) \quad (4)$$

where t_{i_j} and t_{f_j} are, respectively, the initial and final time steps of the transition. Likewise, the transition about the mth unit cell can be characterized through $\delta_m(t) = (\Omega_{m_2}(t)^2 - \Omega_{m_1}(t)^2)/(\Omega_{m_2}(t)^2 + \Omega_{m_1}(t)^2)$. The rate of change of the frequencies of the local resonator, $d\Omega_{m_1}/dt$ and $d\Omega_{m_2}/dt$, affects the energy transfer over space and time. To control the transition smoothness, we define the transition interval as integer multiples N_j of the excitation period T, i.e., $\Delta\tau_j = t_{f_j} - t_{i_j} = N_j T$. In the case involving more unit cells, e.g., the interface displacement from the boundary between the jth and $(j+1)$th unit cells to the boundary between the $(j+3)$th and $(j+4)$th unit cells, the time values must be chosen so that $t_{i_{j+2}} \geq t_{f_{j+1}}$ and $t_{i_{j+3}} \geq t_{f_{j+2}}$, which means that the next transition only begins when the previous has been finished.

The feasibility of the previously discussed strategy is illustrated through simulations in the time domain. The Newmark method at a constant time step configured with $\gamma = 0.5$ and $\beta = 0.25$ (average constant acceleration scheme) [18] was employed to conceive multiple transition scenarios. A point force excitation is applied at the interface position and modeled as a sine burst (sinusoidal envelope) with a central frequency of $\Omega = 0.01496$ (corresponding to the frequency of the topological interface mode). The force magnitude is 0.1 N with a duration of 100 periods (i.e., $100T$, where T corresponds to one period). The interface is initially assumed at the center of the beam, between unit cells 8 and 9. Equations 3 and 4 are used to create the programmable topological interface from the center of the beam to the location between unit cells 12 and 13.

In the first transition unit cell 9 is changed from $\delta = -0.05$ to $\delta = 0.05$, i.e., the inductors are time modulated from the $L_2L_1L_1L_2$ configuration to $L_1L_2L_2L_1$ and, therefore, the space-time vibration energy localization around the new interface position (between unit cells 9 and 10) is observed. Subsequently, unit cell 10 is modified from $\delta = -0.05$ to $\delta = 0.05$ configuration, resulting in space-time vibration energy localization around the new interface position between unit cells 10 and 11. Later, the electrical inductances of the unit cell 11 are updated, resulting in the new tuning $\delta = 0.05$ and, consequently, changing the interface to the new position between unit cells 11 and 12. Finally, unit cell 12 is gradually changed from $\delta = -0.05$ to $\delta = 0.05$, creating a new interface between unit cells 12 and 13 and, finally, vibration energy localization around the new topological interface position.

Fig. 4 displays the transitions for two cases. The first one, displayed in Fig. 4(a), assumes an undamped configuration and $N = 100$. The white dots delimit the modulation intervals, where the stages II to V represent the time modulation of the inductors of unit cells 9 to 12, respectively. The perfect space-time vibration energy transfer along each smooth transition is observed in Fig. 4(a), where the energy initially confined around the center of the metamaterial beam is gradually and perfectly transferred to the final interface position. Fig. 4(b) shows the result for a damped configuration, i.e., $\zeta = 0.002$. Even considering that the amplitude of motion is reduced over time due to dissipation effects, vibration energy is localized at the final interface position. Although not shown in this work, there is a trade-off between modulation speed and the available energy in the final state in the presence of damping [14].

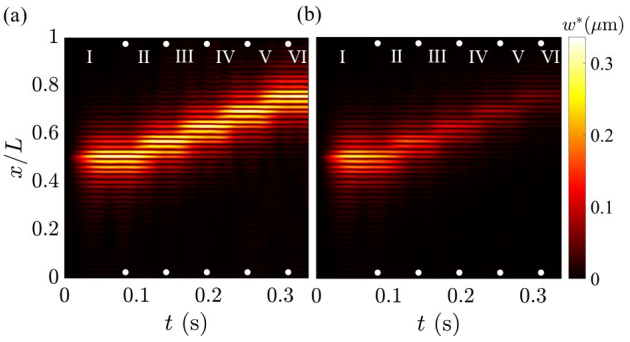

Figure 4. Multiple smooth modulations for the undamped (a) and damped (b) cases.

4. CONCLUSIONS

This study introduced a framework for space-time wave localization using programmable topological interface states in electromechanically coupled metamaterials. Energy transfer between programmable interfaces was successfully demonstrated by smoothly modulating inductive shunt circuits in an undamped metastructure. Although the amount of vibration energy was reduced throughout the modulations, successful modulations could be observed in the presence of structural damping.

ABSTRACT

Low-frequency noise in commercial passenger vehicles is difficult to mitigate, as conventional methods often rely on heavy, bulky materials with limited effectiveness at these frequencies. This study investigates the application of plasmacoustic metalayer-enabled transducers for in-cabin noise control. The system employs ten 18x18 cm transducers, strategically distributed within the cabin, and evaluated under static conditions. The transducers, using the corona discharge mechanism, employ active impedance control to regulate the acoustics, enabling direct sound field management through interaction between ionized air and surrounding air particles. These transducers are lightweight and feature a slim form factor, achieving inertia-free operation and an extended bandwidth of sound control. Experimental results demonstrate broadband global noise reduction exceeding 3 dB across an operating frequency range of up to 700 Hz, effectively suppressing low-frequency resonant peaks and attenuating direct sound when transducers are placed along noise propagation paths. These findings highlight the potential for side panels and rear benches integrated with plasmacoustic technology to provide scalable and efficient global noise control solutions in passenger vehicles, reducing weight and eliminating the use of unsustainable materials.

1. INTRODUCTION

Active noise reduction techniques have advanced significantly over recent decades and have been implemented in commercially mature products. Effective noise cancellation can be achieved across broad frequency ranges in acoustically controlled environments, such as ear canals or waveguides, such as exhaust and ventilation ducts [1–3]. However, active noise reduction remains challenging in generic three-dimensional spaces, where passive solutions, including porous and resonant absorbers, presently dominate. These passive materials often require substantial mass and volume to achieve the desired performance in the lower frequency range [4], limiting their applicability in vehicle cabins, where the added weight affects performance. Active methods, such as active noise cancellation (ANC) [5] and active sound absorption [6, 7], present promising alternatives by improving acoustics without compromising vehicle performance to the same degree.

ANC systems in vehicles typically employ multichannel adaptive feedforward techniques, predominantly using the filtered-x LMS algorithm [8]. These systems rely on multiple reference and error sensors, usually microphones and accelerometers, placed throughout the cabin, along with loudspeakers integrated into the vehicle's interior - typically as part of its audio entertainment system. ANC effectively reduces low frequency engine and exhaust noise, when good corelation of the noise at source and target locations can be measured. Reducing road and wind noise is more challenging due to difficulties in obtaining accurate reference signals, thus necessitating additional sensors and processing powers. Enhancements like remote microphone sensing and passenger head tracking [9] improve performance, but can increase complexity and costs while limiting the effective spatial noise control

area. More research is required to expand the capabilities of the ANC and expand the noise reduction zone.

Active sound absorption modifies the acoustic properties by equipping small surface areas with active transducers designed for perfect or partial sound absorption. Recent research introduced plasmacoustic metalayers [10], which utilize ionized air layers controlled by alternating electric fields, enabling sound absorption without mechanical parts. The tests demonstrated perfect absorption at normal incidence over a bandwidth exceeding 1 kHz, achieved through a compact design adaptable to various shapes and sizes without affecting performance.

In the previous work [11], a respectable reduction in low-frequency broadband noise was achieved in a simplified rectangular volume using just a few plasmacoustic transducers if the volume presents a significant degree of reverberation. Further numerical simulations of more realistic spaces, such as a real vehicle cabin, have indicated that although a larger number of transducers may be needed to achieve similar noise reduction performance, the proportion of the so-called active absorbing area still remains low (below 3%) and can be practically realized. In this work, we attempt to achieve a significant noise reduction in a real vehicle cabin by deploying the prototype plasmacoustic active sound absorption (PASA) system in the vehicle cabin interior.

2. SETUP OF THE EXPERIMENT

2.1 Plasmacoustic transducer

The plasmacoustic transducer used in the experimental setup is illustrated in Figure 1. It consists of two electrodes that create a corona discharge. The corona electrode is a thin tungsten wire arranged in a parallel back-and-forth pattern and secured within a rigid plastic frame. The second electrode, called collector, is made from a perforated metallic plate with a high open-area ratio, ensuring minimal acoustic obstruction. The electrode system is enclosed with an acoustically transparent ozone filter. The gap between the electrode is approximately 5 mm and follows a patented geometry. The active area established between these electrodes measures 180×180 mm^2. The device operates within a voltage range of 5 to 8 kV. The ionized particles generated by the discharge interact with the surrounding air, transferring energy from the discharge zone. A detailed explanation of the operating principles is provided in previous work [10, 12]. Each transducer is powered with a compact electronic control unit (ECU),

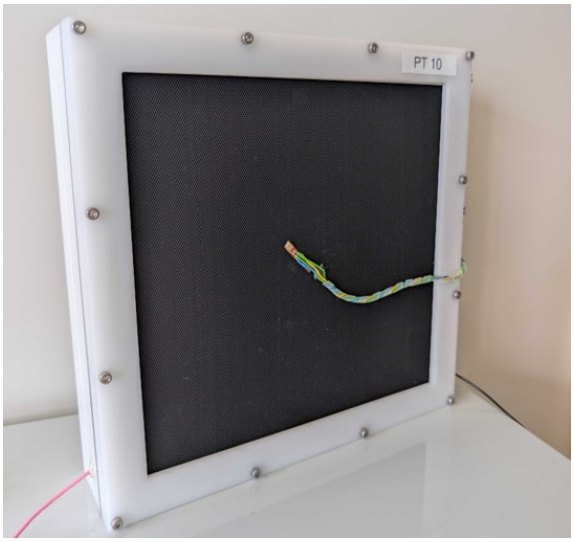

Figure 1. Assembled plasmacoustic transducer covered with the ozone filter. A control microphone is fixed in the middle of the transducer's surface.

which combines a high-voltage amplifier with an embedded electronic controller. The microphone measures the total sound pressure on the front surface of the transducer, providing input to the control algorithm. The closed-loop control aims to establish a target acoustic impedance condition over the active area of the plasmacoustic transducer. In this experiment, the controller was set to achieve an impedance close to the characteristic impedance of air:

$$Z_0 = \rho c, \tag{1}$$

where $\rho = 1.23\ kg/m^3$ is the density of the air and $c = 343\ m/s$ is the speed of sound in the air. The control transfer function is derived analytically [10], discretized and executed on the controller with a sampling frequency of 100 kHz. Thus, each of the plasmacoustic transducers is driven with an independent single-input single-output control system.

2.2 Test environment

The experiment was carried out in the Tesla Model 3 cabin of the model year 2022 as shown in Fig. 2. No changes were made to the original trim or other interior components. This vehicle model was chosen because it represents a midsize BEV deployed with a typical acoustic package. At the same time, its interior design, offering a

number of flat surfaces, allows for a simpler installation of prototype plasma transducers.

Figure 2. Vehicle under test with 10 plasmacoustic transducers placed in the cabin above; schematic locations of the microphones (red dots) and plasmacoustic transducers (blue rectangles) below.

Measurements were performed under static conditions. The sound field in the cabin is excited by a loudspeaker placed in the corner of the trunk. In this configuration, when playing back a broadband noise signal, different low-frequency acoustic modes of the cabin can be excited. Additionally, noise is filtered by the car's trim while passing from the trunk into the cabin, which resembles a dynamic noise spectrum. Sound pressure spectra are captured by measurement microphones that are attached to the headrests of the four seats.

Ten 180×180 mm^2 plasmacoustic transducers are placed in the vehicle cabin (blue rectangles in Fig. 2). They provide a total active area of approximately 0.32 m^2 and 1.5% of the entire surface of the cabin. Four transducers are placed on the dashboard (see Fig. 2), four other are distributed on the back seat shelf, and two are attached to the left and right back doors. Those locations are chosen as reasonable candidates for an actual deployment of the system. The ECUs are connected to the transducers from the outside of the car.

3. EFFECTIVE NOISE REDUCTION

Noise reduction performance is evaluated by comparing the noise spectra at different microphone locations when the PASA system is off and on. These frequency responses with the PASA system in passive and active modes are presented in Fig. 3.

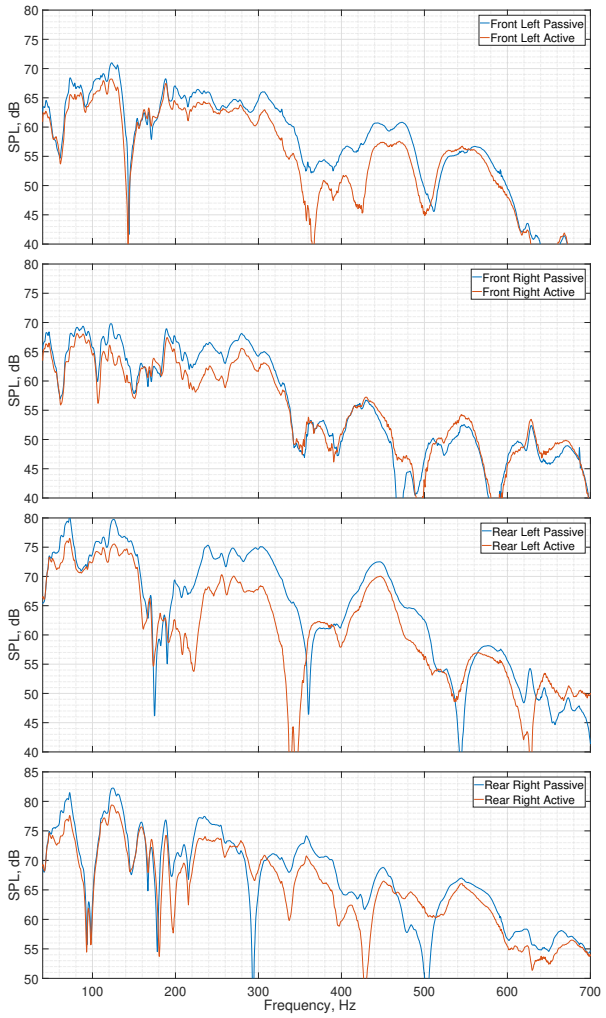

Figure 3. Measured frequency responses at different microphone locations in the vehicle cabin labeled by a seat position. Blue - PASA system is turned off; red - PASA system targets Z_0 impedance.

As discussed in the Introduction, realistic three-dimensional spaces rarely exhibit a high level of reverberation. Typically, they experience considerable acoustic

losses as a result of the vibration of lightweight structural components and air leaks. As a result, only a few first low-frequency cabin modes with limited amplitudes can be identified in the 40 to 140 Hz range. It is also worth noting that the front seat microphones are positioned near the center of the cabin, which is close to a pressure node of the first resonance. Nevertheless, the active plasmacoustic transducers effectively dampen these low-frequency modes. This effect is observable at all measurement locations, though it is more pronounced at the rear seats, where the microphones are placed closer to the cabin boundaries.

At higher frequencies, the cabin also shows limited reverberation. In this range, the mechanism by which the PASA system reduces acoustic noise changes. In addition to dampening the resonances of the cabin, plasmacoustic transducers absorb the direct noise propagating past the panels. As a result, a broad level of noise reduction is observed rather than reduction at the resonant peaks. Overall, while performance varies across frequency bands and measurement positions, the dominant spectral components are attenuated throughout the entire measured frequency range, from 40 to 700 Hz. The global noise reduction achieved well exceeds that possible by traditional ANC techniques, whose effect is limited to specific control locations.

4. CONCLUSIONS

In this study, the PASA system has demonstrated its potential to reduce acoustic noise in compact three-dimensional environments such as vehicle cabins. The application of a plasmacoustic metalayer significantly extends the operational bandwidth of a single device for local acoustic impedance control. Although a realistic environment with considerable inherent damping requires a larger active surface area, effective control can still be achieved with a relatively small number of transducers. In this experiment, only 1.5% of the interior surface area of the cabin was covered by an actively controlled impedance surface provided by the PASA system. With transducers distributed throughout the cabin and tuned to achieve a target impedance close to Z_0, the PASA system successfully reduced noise levels in the 40 to 700 Hz frequency range. Different sound absorption mechanisms dominate in different frequency bands: at low frequencies, resonant peaks are suppressed, whereas at higher frequencies, noise is reduced through the absorption of direct sound. In the latter case, placing transducers in close proximity to potential noise sources enhances effectiveness. Therefore, the ability of plasmacoustic transducers to attenuate higher-frequency direct sound depends on their position relative to the excitation source. This is an important consideration in dynamic driving conditions due to the spatially distributed nature of the noise sources. In summary, the active sound absorption system based on plasmacoustic transducers offers a broadband, global, light-weight, and environmentally sustainable form of active noise reduction, potentially deployable at a significantly lower cost of ownership than conventional active road noise cancellation techniques, which require multiple drivetrain-mounted accelerometers and higher, networked computational demands.

5. CURRENT STATUS AND OUTLOOK

Figure 4. Exterior aesthetics of a commercial version of a plasmacoustic transducer.

Sonexos will be manufacturing a plasmacoustic transducer "Plasmapanel®" featuring reduced operating voltages and enhanced long-term reliability. As illustrated in Fig. 4, the transducer comprises electrodes enclosed within a hermetically sealed plastic housing. The front face of the enclosure is acoustically transparent, enabling effective sound transmission, while maintaining the electrode assembly in a controlled gas environment. This configuration significantly reduces the required operating voltages and protects electrodes from corrosion. Multiple Plasmapanel® units can be assembled into arrays, providing flexible scaling of the active surface area to achieve specific noise reduction targets.

ABSTRACT

The ”plasmacoustic metalayer” concept relies on the use of a Corona Discharge Transducer (CDT), transparent towards fluid flows and to light. When used as an actuator within an active control system, it allows manipulating sound waves in transmission/reflection/absorption without resorting to a membrane or any other mechanical intermediate, contrarily to conventional loudspeakers. Moreover, owing to its non-resonant nature, the CDT is an obvious candidate for the development of broadband active acoustic metamaterials, especially since it is transparent to sound in a ”passive” mode.

This presentation aims to showcase some examples of active plasmacoustic metamaterials concepts, through numerical simulations and experimental validations, at the unit-cell level. These preliminary results will allow drawing conclusions on the applicability of the CDT to achieve broadband active acoustic metamaterials, and identifying routes for further development of the concept.

Keywords: acoustic metamaterials, plasmacoustic metalayers, active control

1. INTRODUCTION

Acoustic metamaterials have emerged in the early 2000's inspired by the literature on their electromagnetic counterparts. In its general definition, an acoustic metamaterial is an artificial structure consisting of miniature engineered elements (cavities, ducts, membranes, etc.), assembled in such a way so that the whole exhibits physical properties that mimic or even go beyond physical phenomena occurring in nature. The most important feature of these unit-cells is their subwavelength dimension, namely their size should much smaller than the wavelengths they interact with [1].

However, most of the reported architectures rely on resonant structures (Helmholtz resonators, coiled-space cavities, membranes) [2–4]. Therefore, the resulting anomalous/negative properties are limited to a narrow frequency bandwidth, if not at a single frequency. Also, their inherent losses negatively impact their “transmissibility” capacities (the amount of acoustic energy that can be effectively transmitted “forward” by the artificial structure), and therefore preclude any practical application. More generally, passive linear metamaterials are bound to the Kramers-Kronig relations, eventually leading to trade-offs in terms of bandwidth of operation and transmissibility.

In a view to overpassing the inherent limitations of passive structures, active acoustic metamaterial concepts have been recently investigated. In this paradigm, the unit-cells are composed of electroacoustic transducers (loudspeakers and microphones) connected by a control platform, in a view to adapting their dynamic response to ongoing sound waves. Thanks to such a tunability, it is possible to observe exotic time-varying properties such as time-reversal for sound focusing, non-Hermitian media, acoustic circulators, acoustic diodes, and many other interesting topological phenomena, that were not possible with passive constructions. But conventional loudspeakers are still intherently resonant, thus limited in terms of bandwidth of operation, and more importantly, they are prone to introduce significant losses against which the control should devote a significant par of energy to function. Last, they rely on (opaque) membrane radiators, that cannot avoid scattering (loudspeakers are obstacles to the propagation of sound in a metamaterial structure).

The Plasmacoustic Metalayer recently developed by

Sergeev et al [6, 7] allows interacting with exogenous sound waves in a membraneless manner, thanks to a Corona Discharge Transducer (CDT) [5]. Besides its almost transparency to fluid flows (and light), which makes it non-scattering and lossless in its passive form, the main asset for metamaterial applications is its non-resonant characteristics. In active mode, it has been capable to exhibit almost ideal sound absorption over an ultrabroadband frequency range (20 Hz-2000 Hz), owing to the absence of mechanical interface known to bound the bandwidth of operation in conventional loudspeaker-based active control systems. Moreover, further use of the concept in transmission configuration have been demonstrated, showing also variable broadband reflection/transmission modules and phases. This makes the Plasmacoustic Metamalayer a most promising candidate as unit-cell for active metamaterial applications.

This paper introduces the Plasmacoustic Metamaterial (PM) concept, by leveraging some examples of active sound reflection/transmission results achieved by the plasmacoustic metalayer concept. These examples will be discussed in the light of their application as plasmacoustic metamaterial unit-cells (PMUC), that are the heart of a research project submitted for funding to the Swiss National Science Foundation.

2. THE CORONA-DISCHARGE ELECTROACOUSTIC TRANSDUCER

2.1 Corona discharge transducer in a "wire-to-grid" configuration

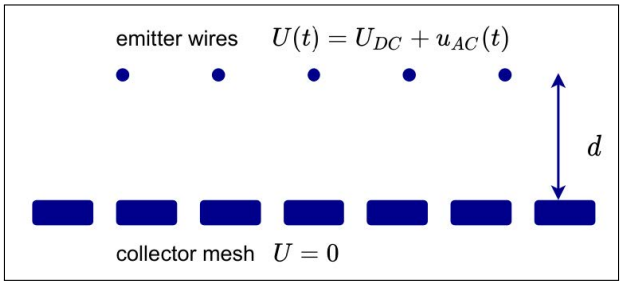

Figure 1. Sketch representing a cut view of the electrode pair: corona electrode (emitter wires)/collector electrode (grounded perforated grid)

Corona discharge transducers (CDT) allow for sound generation due to the ionization of molecules in the surrounding fluid, moved by an intense oscillating electric field. In the "wire-to-grid" configuration, the transducer is constituted by a pair of electrodes (forming two parallel planes, as illustrated in the sketch of Fig. 1): the first one is a perforated metallic grid connected to the ground, and is designated the "collector electrode"; the second one, designated "corona electrode", is made of an ultra thin wire (diameter of the order of 100 μm), arranged in a pattern of parallel lines along a same plane parallel and distant of d to the collector plane, put at a sufficiently high voltage so as to trigger the extraction of electrons from surrounding molecules. The breakdown voltage, above which ionization is possible, is designated U_0 and is of the order of a few kV.

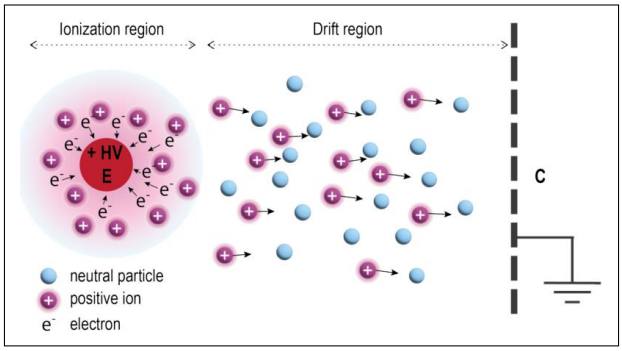

Figure 2. Corona discharge principle

When applying an offset voltage U_{DC} higher than U_0, positive ions are accelerated inside the ionization region towards the collector electrode. They then collide with the neutral particles present in the drift region, which are then moved, giving rise to an "ionic wind" (constant flow).

If an alternating voltage $u_{ac}(t)$, of the order of 1 kV, is superimposed to U_{DC} (while total voltage $U_{DC} + u_{ac}$ still remains higher than the breakdown voltage, as well as not exceeding a value above which arcing may occur), the transducer generates acceleration/deceleration of the surrounding fluid layers, responsible for sound generation.

The preceding studies show that this corona discharge transducer configuration could be modelled as the combination of two volumic sound sources, one monopolar "heat" source H (due to the heat release at the corona electrodes), and another dipolar "force" source F (relative to the electrostatic force moving the surrounding fluid back and forth).

An extremely simple electroacoustic model can be deduced from the coupling equations between the plasma generation and actuation, and the generated sound field.

Indeed, it has been shown that the offset voltage U_{DC} can be linked to the current I flowing through the corona wire according to the Townsend formula:

$$I = CU_{DC}(U_{DC} - U_0) \tag{1}$$

where C is a constant that depends on the transducer geometry, and that can be experimentally determined. It is then possible to express the two sources H and F as a function of the voltage feeding the transducer [5, 6]:

$$\begin{aligned} H &= C(3U_{DC}^2 - U_{DC}U_0)u_{ac}\ [\mathrm{W}] \\ F &= \frac{C.d}{\mu_i}(2U_{DC} - U_0)u_{ac}[\mathrm{N}] \end{aligned} \tag{2}$$

where μ_i designates ions mobility, and d is the distance between the two electrodes (or the plasma thickness). It can be seen that the two sound sources are interdependent. Their individual influence is independent on frequency but on the constant parameters U_0, U_{DC}, C, d and μ_i, and not directly on the transducer cross-section area S. However, the lateral dimensions of the CDT is likely to change the current-voltage law (Eq. (1)), thus C.

In the following, we define the the heat source power density $h = \frac{H}{S.d}$ (in W/m^3), and the dipolar force source density $f = \frac{F}{S.d}$ (in N/m^3), where S is the transducer effective cross-section area, to be used in the expression of the sound fields generated by the CDT.

3. THE PLASMACOUSTIC METALAYER AS A METAMATERIAL UNIT-CELL

Let's consider a 1D waveguide along dimension x being the host of the PMUC, as illustrated in Fig. 3. In the PM paradigm, we will consider a unit-cell integrating a CDT, one ore more microphones (either one on the front side when backed by a rigid cavity, or with at least 2 microphones, one on each sides of the transducer in an open configuration), a control hardware and a power amplifier capable to manage the high voltage DC and the acoustic control voltage u_{ac}, as illustrated on Fig. 3. For the sake of simplicity, the controller part includes the power amplifier, to deliver a given voltage u_{ac} to the transducer.

In the configuration where the CDT is centered at the origing $x = 0$ and oriented so that the collector electrode is located towards the left (with respect to the chosen direction of axis x of the waveguide) and the corona electrode being on the right side, a given ac voltage u_{ac} will give rise to a dipolar force source that will generate out-of-phase (wrt. u_{ac}) sound pressures towards the increasing x direction, while generating in-phase (wrt. u_{ac}) sound pressures towards the decreasing x direction. The different contribnutions to the acoustic field generated by the CDT will then be (distinguised between negative and positive x half-domains):

$$\text{for } x < 0 : \begin{cases} p_h(x) = \dfrac{dc_0}{2C_pT_0}he^{jkx} \\ p_f(x) = \dfrac{d}{2}fe^{jkx} \\ v_h(x) = -\dfrac{d}{2\rho_0C_pT_0}he^{jkx} \\ v_f(x) = -\dfrac{d}{2\rho_0c_0}fe^{jkx} \end{cases} \tag{3}$$

$$\text{for } x > 0 : \begin{cases} p_h(x) = \dfrac{dc_0}{2C_pT_0}he^{-jkx} \\ p_f(x) = -\dfrac{d}{2}fe^{-jkx} \\ v_h(x) = \dfrac{d}{2\rho_0C_pT_0}he^{-jkx} \\ v_f(x) = -\dfrac{d}{2\rho_0c_0}fe^{-jkx} \end{cases} \tag{4}$$

If we consider an exogenous sound field $p_{ac}(x) = p_{ac}^+e^{-jkx} + p_{ac}^-e^{+jkx}$, and the associated particle velocity $v_{ac}(x) = \frac{1}{\rho_0c_0}\left(p_{ac}^+e^{-jkx} - p_{ac}^-e^{+jkx}\right)$, we can derive the total pressure fields on both sides of the unit-cell as:

$$x < 0 : \begin{cases} p_t(x) = p_{ac}^+e^{-jkx} \\ \qquad + \left(p_{ac}^- + \dfrac{dc_0}{2C_pT_0}h + \dfrac{d}{2}f\right)e^{jkx} \\ v_t(x) = \dfrac{1}{\rho_0c_0}\left[p_{ac+}e^{-jkx}\right. \\ \qquad \left. - \left(p_{ac}^- + \dfrac{dc_0}{2C_pT_0}h + \dfrac{d}{2}f\right)e^{jkx}\right] \end{cases} \tag{5}$$

$$x > 0 : \begin{cases} p_t(x) = p_{ac}^-e^{jkx} \\ \qquad + \left(p_{ac}^+ + \dfrac{dc_0}{2C_pT_0}h - \dfrac{d}{2}f\right)e^{-jkx} \\ v_t(x) = \dfrac{1}{\rho_0c_0}\left[-p_{ac}^-e^{jkx}\right. \\ \qquad \left. + \left(p_{ac}^+ + \dfrac{dc_0}{2C_pT_0}h - \dfrac{d}{2}f\right)e^{-jkx}\right] \end{cases} \tag{6}$$

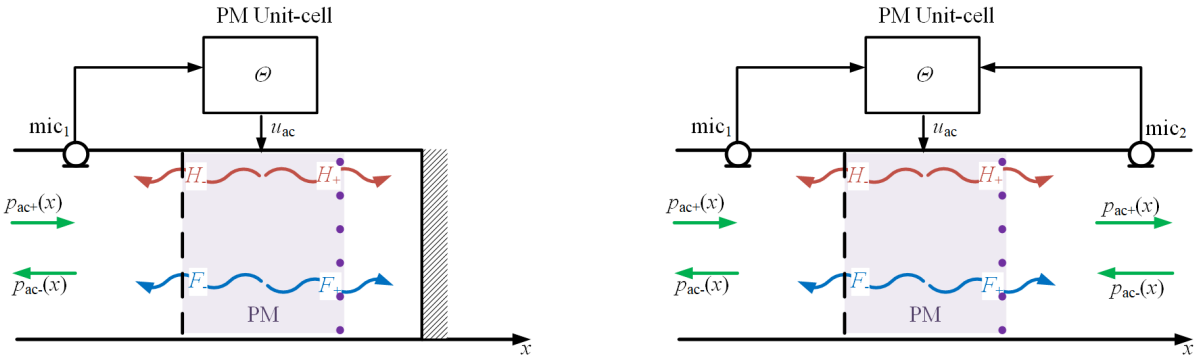

Figure 3. Realizations of a PMUC in a 1D waveguide: left: PMUC backed by a rigid termination; right: PMUC open on both sides

In these sets of equations, h and f are intricate as they both depend on u_{ac}. Still, the control of u_{ac} as a function of one ore more microphone inputs allows achieving interesting acoustic properties over the PMUC. The following section intends to present some of the applications.

4. EXAMPLES OF PLASMACOUSTIC METAMATERIAL UNIT-CELL REALIZATIONS

4.1 PMUC in reflection

The first realization of a PMUC in reflection is reported in [6]. In this experience, the PMUC is in the backed configuration (see Fig. 3-left), with a control microphone located at position $-x_0$ (the PMUC center being at the origin $x = 0$). In this configuration, the left-handed side of the PMUC can simplify, taking into account the reflection at the back wall distant of l from the PMUC center. Accounting for the actual (measurable) specific impedance $Z_l = \frac{p_t(x=l)}{v_t(x=l)}$ at the wall ($x = l$), we derive the reflection coefficient $R = \frac{Z_l - Z_c}{Z_l + Z_c}$ and then the relationships on the left side ($x < 0$) become:

$$\begin{cases} p_t(x) = p_{ac}^+ e^{-jkx} + \Big(R p_{ac}^+ \\ \quad + \dfrac{dc_0}{2C_pT_0}(1 - Re^{-2jkl})h \\ \quad + \dfrac{d}{2} f(1 - Re^{-2jkl})\Big)e^{jkx} \\ v_t(x) = \dfrac{1}{\rho_0 c_0}\Big[p_{ac}^+ e^{-jkx} - \Big(R p_{ac}^+ \\ \quad + \dfrac{dc_0}{2C_pT_0}(1 + Re^{-2jkl})h \\ \quad + \dfrac{d}{2}(1 - Re^{-2jkl})f\Big)\, e^{jkx}\Big] \end{cases} \tag{7}$$

By prescribing a target specific impedance $Z_t(-x_0) = \frac{p_t(-x_0)}{v_t(-x_0)}$ at the control microphone position, we can deduce the transfer function $\Theta(\omega) = \frac{u_{ac}}{p_t(-x_0)}$ to drive the PMUC in order to achieve the targeted impedance:

$$\begin{cases} \Theta(\omega) = \dfrac{1}{A}\dfrac{Z_c}{Z_t}\left(\dfrac{Z_t - Z_{ac}(-x_0)}{Z + Z_{ac}(-x_0)}\right) \\ A = \dfrac{d}{2}\left(f + \dfrac{c_0 h}{C_p T_0}\right)e^{-jkx_0} \\ \quad + \dfrac{d}{2}\left(\dfrac{c_0 h}{C_p T_0} - f\right)Re^{-jk(x_0+2l)} \\ Z_{ac}(-x_0) = \dfrac{p_{ac}(-x_0)}{v_{ac}(-x_0)} \end{cases} \tag{8}$$

In this study, we target a control in reflection with adjustable amplitude and phase, the target impedance being set so as to achieve target reflection coefficient $R_t =$

$|R_t|e^{j\angle(R_t)}$. In that view, we define a dimensionless factor $\zeta \in [01]$ to define a virtual acoustic termination ζZ_l, and a virtual depth of the cavity $l + \Delta l$ leading to an additional delay in the control loop. In this control strategy, the target impedance becomes:

$$Z_t = Z_c \frac{\zeta Z_l + jZ_c \tan(k(l + x_0 + \Delta l))}{Z_c + j\zeta Z_l \tan(k(l + x_0 + \Delta l))} \quad (9)$$

An experimental prototype of PMUC in absorption has been built with lateral dimensions $50\,\mathrm{mm} \times 50\,\mathrm{mm}$ and inter-electrode gap of $6\,\mathrm{mm}$, and placed in a rectangular tube of same cross-section and length $1.1\,\mathrm{m}$, with a back cavity length l =15 mm. The PCB 130D20 quarter-inch ICP microphone used for the control is located at position $x_0 = -10\,\mathrm{mm}$ and input a Speedgoat IO-334 working at $50\,\mathrm{kHz}$. Finally a TREK 615-10 high voltage AC/DC amplifier drives the PMUC with amplification gain of 1000 (accounted for in the transfer function Θ).

The reflection coefficient is measured after ISO 10534-2 standard [12], with two PCB 130D20 ICP microphones distant of $50\,\mathrm{mm}$ from each others, the signals of which are processed by a B&K Pulse Multichannel Analyzer to estimate the transfer functions H_{12} and derive the reflection coefficient in the different control cases.

We measured the reflection coefficient (in amplitude and phase) for two scenarios: one where we set the coefficient ζ to achieve different reflection amplitude of [0.9 0.7 0.4] while keeping $\Delta l = 0\,\mathrm{m}$ (see Fig. 4), and another where we keep the reflection amplitude to 0.4 while adding a virtual cavity depths of [3.7 cm, 9.7 cm, 14.7 cm], namely by adding a delay of [0.22 ms, 0.56 ms, 0.85 ms] (see Fig. 5).

We can then assign any reflection coefficient amplitude and phase to the PMUC in the backed configuration, which gives a unique possibility to control the reflection gratings over a 2D metasurface with an ultra-thin unit-cell (in the range of $1\,\mathrm{cm}$ in the current prototype, but it can be made even thinner), without having to employ acoustic or mechanical resonators with frequency-dependent thickness as reported in the current literature (space-coiling channels [8], Helmholtz resonators [9], or membrane-capped cavities [10]).

4.2 PMUC in transmission

Preliminary investigations on the use of a PMUC in open configuration for active noise reduction have been recently undertaken. In this study, the PMUC consists of a square

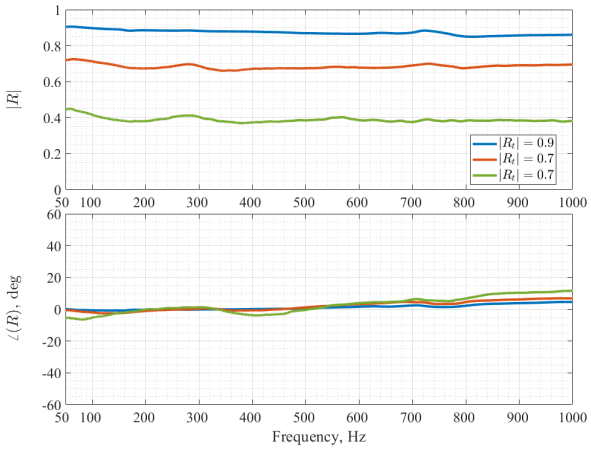

Figure 4. Reflection coefficient measured on the PMUC in an impedance tube with variable amplitude, while the phase is set to 0 degree (source: Sergeev et al [6])

CDT of size $50\,\mathrm{mm} \times 50\,\mathrm{mm}$ and inter-electrodes gap $d = 6\,\mathrm{mm}$, surrounded by two PCB 130D20 quarter-inch ICP microphones as control microphones, distant of x_0 to the center of the CDT. The PMUC is inserted in the middle of an impedance tube with same square cross-section and total length $2\,\mathrm{m}$. One extremity is loaded with a $500\,\mathrm{mm}$ long melamin wedge to ensure anechoic condition, the other hosting a loudspeaker used as the sound source. The PMUC is controlled with a Speedgoat Baseline Real-Time Target Machine to assign the targeted control law. The acoustic properties of the PMUC are measured with two pairs of PCB 378B02 half-inch ICP microphones, the signals and the transfer functions being processed with a 4-channels B&K Pulse Sound and Vibration Analyzer. The Transfer Matrix Method [13] is employed to derive the PMUC transmission properties, such as the effective propagation constant $\gamma = \alpha + j\beta$, transmission loss, or the effective impedance matrix of the small insertion of size $d + 2x_0$.

In this study, the control strategy consisted in synthesizing a target 2-port acoustic circuit comprising a series impedance Z_t, following the same methodology as the one employed for the PMUC with back-cavity configuration. Here it is important to stress on the fact that the PMUC will result in both series impedance and shunt admittance Y_t since the monopolar and dipolar sound

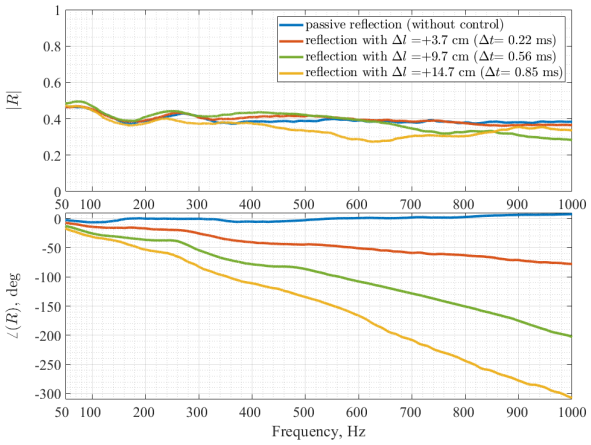

Figure 5. Reflection coefficient measured on the PMUC in an impedance tube with variable delays (source: Sergeev et al [6])

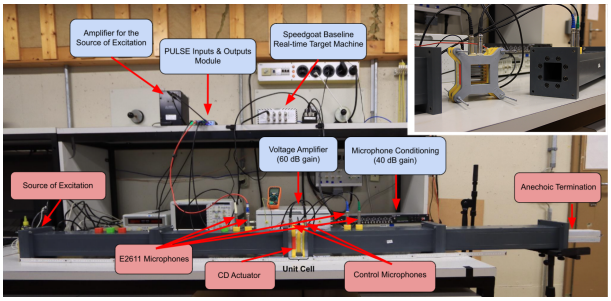

Figure 6. Setup of the PMUC assessment in transmission

sources are intricated. Nevertheless the choice has been made here to ignore the shunt admittance and verify that the control still allows achieving the series impedance, and see how much it is impacted by the resulting admittance. Therefore, the heat source h is set to 0 in the sound field expressions of Eqs. (5) and (6), in order to derive the target control law $\Theta(\omega)$, so as to deliver a prescribed particle velocity as $v_t = \dfrac{p_t(-x_0) - p_t(+x_0)}{Z_t}$.

We decided to assign two target impedances here. The first one corresponds to a layer of porous material wth porosity of 0.75 and flow resistance $1.5\,\mathrm{MPa\,s\,m^{-4}}$ and of thickness $d + 2x_0 = 64\,\mathrm{mm}$, modeled as series resistance R_t (also taking into account the "natural" mass of air $M_p = \rho_0(d + 2x_0)$ without the PMUC, while neglecting the "natural" compliance). The second one targets a single-degree-of-freedom resonator consisting of an acoustic mass M_t and compliance C_t (also taking into account the "natural" mass of air without the PMUC, while neglecting the "natural" compliance). The target impedance in these two cases are

$$\begin{cases} Z_{t,\text{porous}} = R_t + j\omega M_p \\ Z_{t,\text{membrane}} = j\omega(M_p + M_t) + \dfrac{1}{j\omega C_t} \end{cases} \tag{10}$$

where $M_p = 76.8\,\mathrm{g\,m^{-2}}$, $R_t = 0.1\,\mathrm{Pa\,s\,m^{-3}}$, M_t =331 $\mathrm{g\,m^{-2}}$ and $C_t = 6.510^{-6}\ \mathrm{m^{-1}\ N^{-1}}$. The results in terms of achieved normalized impedance $z = \frac{Z}{Z_c}$ are represented on Fig. 7 and Fig. 8.

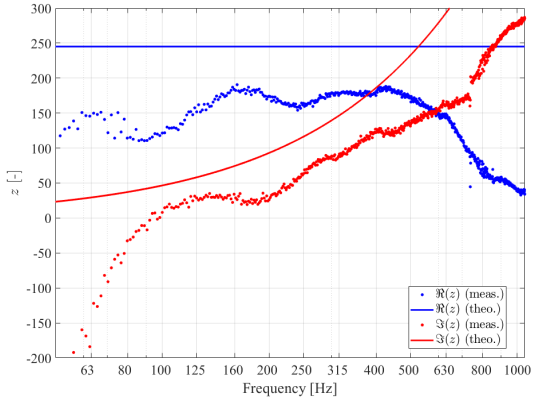

Figure 7. Normalized acoustic impedance (blue: real part; red: imaginary part) when targeting a porous layer (points: measurements; lines: target)

We can observe that the achieved impedance differs from the target one, mainly due to the assumption after which the the CDT is mainly dipolar. However, the behaviour at low frequencies fits reasonably well the target in the second case, while the achieved resistance of the first case is significantly lower than the target. The effect of the monopolar source explains the mismatch with the target, especially at high frequencies.

From these measurements, it is also possible to derive the transmission loss $TL = 10.\log_{10}\left(\dfrac{I_i}{I_t}\right)$ and the propagation contant $\gamma = \alpha + j\beta$. The examples for the case where the target impedance is the one of a porours layer are given in Fig. 9 and Fig. 10

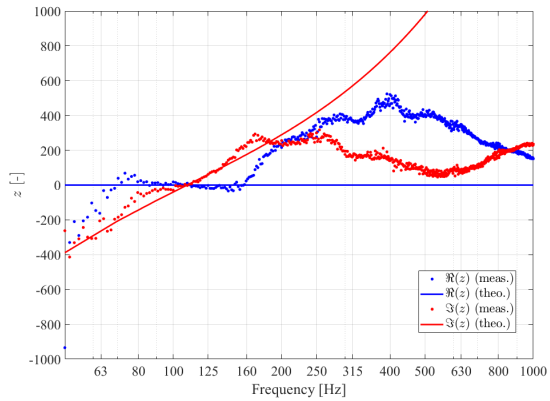

Figure 8. Normalized acoustic impedance (blue: real part; red: imaginary part) when targeting a membrane (points: measurements; lines: target)

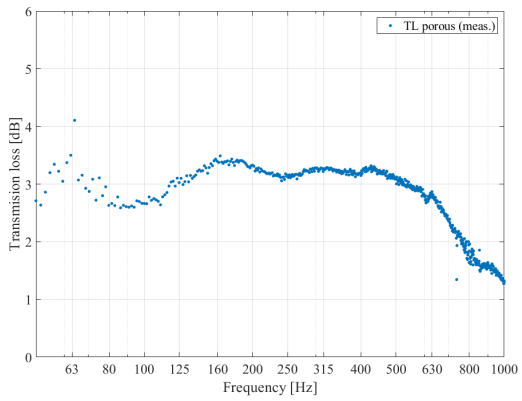

Figure 9. Transmission loss when targeting a porous layer $Z_t = R_t + j\omega M_p$

5. CONCLUSION AND PERSPECTIVES

We have shown that the PMUC allows achieving a wide range of acoustic properties, either in reflection when backed with a closed cavity, or in transmission when open on both ends. The achieved performance is aligned with the targeted one in the case where the PMUC is closed at one side, but differs in the open configuration, due to the intrication of monopolar/dipolar sound sources.

In a follow-up study, we will develop alternative control strategies that allow separating monopolar and dipolar components of the CDT, thus enabling full control on the 2-ports acoustic properties.

ABSTRACT

To tackle the issue of adaptability to in-situ conditions while providing efficient acoustic absorption in a large frequency bandwidth, impedance control of loudspeakers has been brought as a solution. To control the impedance of a loudspeaker, one should place microphones collocated to the loudspeaker, supplied with a processor that calculates the needed electrical current to send to the loudspeaker's coil to target a specific impedance. This concept has long been considered in the framework of linear dynamics, however the extension to nonlinear dynamics is a current subject of interest. In this study, nonlinear dynamics are enforced through a feedforward control tracking a setpoint defined by a numeric exosystem. The use of the exosystem allows to synthesize uncommon behaviors such as nonpolynomial nonlinear restoring forces. However, nonlinear resonators may present many stable equilibrium points for a single frequency, which may be targeted via the choice of the initial conditions. The choice of the initial conditions in electroacoustics is challenging and would permit better sound absorption. In this study, a method for targeting the equilibrium point of a nonlinear dynamical system in the framework of electroacoustic resonators is presented, and its experimental implementation is demonstrated, leading to many potential acoustic applications.

1. INTRODUCTION

An electroacoustic resonator (ER) is a loudspeaker collocated to microphones and equipped with a processor running a controller that takes into input the measured pressure, and provides as an output the electrical current to enforce to the loudspeaker [1, 2]. The benefits of an ER lies in its efficiency in a bandwidth around its resonance frequency, leading to the possibility of efficient acoustic absorption at low frequencies. The resonance frequency can be tuned through digital programming of the controller. As this concept is widely studied for linear behaviors enforced to the loudspeaker [3], enforcing nonlinear behavior using a digital control at low excitation amplitudes stands as a current subject of interest [4–7]. A nonlinear resonator offers larger frequency bandwidth of efficiency and features nonlinear phenomena useful of the mitigation of vibrations. However, a nonlinear system may present multiple co-existing equilibrium points at a single frequency, which do not have similar efficiency results in acoustic absorption [7, 8]. indeed, the system converges towards a specific equilibrium point depending on the initial conditions. As a result, the acoustic absorption capabilities of a nonlinear resonator, compared to a linear resonator, lies in the initial conditions. In this study, a nonlinear ER created by a digitally programmed controller is used for the mitigation of acoustic vibrations. As the choice of the initial conditions proves to be difficult, the choice of the equilibrium point might be done in the digital programming. The method for targeting a specific

equilibrium point is presented.

2. THE DIGITAL CONTROL ENFORCING NONLINEAR BEHAVIOR

The linear dynamics are enforced through the infinite input response method, which can not be used to enforce nonlinear dynamics efficiently [4]. As a result, the nonlinear dynamics are enforced through a real-time based feed-forward controller tracking a setpoint defined by an Exosystem (ES).

Considering a loudspeaker collocated with microphones, the ER is created by assuming that the loudspeaker's response is dominated by its first mode, along with the hypothesis of low amplitudes (to keep the resonator in its linear regime) and low frequencies (to keep the excitation frequencies close to the ER's first mode).
The ES simulates the targeted behavior of the loudspeaker under the measured pressure. The ES model contains the dynamic to enforce, and is supplied with the measured pressure. Its numerical resolution can be realized using classical numerical schemes for solving ordinary differential equations. Once the targeted displacement, speed and acceleration are predicted, the electrical current is calculated using the feed-forward controller containing the loudspeaker's model driven by the predictions. The equations of the control are presented in Eqn. (1):

$$\dot{X}(t) = A(X(t), t, f_{ext}(t), u_d(t)) \tag{1a}$$

$$u_d(t) = \varphi(\dot{X}_d(t), X_d(t), t, f^m_{ext}(t)) \tag{1b}$$

$$\dot{X}_d(t) = F(X_d(t), t, f^m_{ext}(t)) \tag{1c}$$

where Eqn. (1a) is the equation of the system to control, here the loudspeaker. The variable X stands for the loudspeaker's modal coordinate of its first mode, t is the time, f_{ext} represents the external forces applied on the loudspeaker's membrane (the pressure), and u_d is the control variable allowing to apply the control, here the electrical current. The Eqn. (1b) is the equation that permits to determine the electrical current to send to the loudspeaker, which is obtained by inversion of the system Eqn. (1a). The variable f^m_{ext} represents the measured external forces. The calculation is done using the variable X_d standing for the desired modal coordinate provided by solving the ES Eqn. (1c). The ES Eqn. (1c) provides the nonlinear desired behavior by solving it using numerical schemes. These control equations are evaluated at each time step.

3. TARGETING SPECIFIC EQUILIBRIUM POINTS

By forcing the ES to target specific equilibrium points, the feed-forward controller then tracks the setpoint to enforce the ES behavior to the loudspeaker. As a result, modifying the basin of attraction of the ES to raise the size of the set of initial conditions to all the set of initial conditions leads to enforcing the targeted equilibrium point.

This goal can be achieved by adding synthetic variables to the ES equation to control the basin of attraction of the solution. Three methods are considered: adding a synthetic desired displacement X^s_d, or a desired speed $\dot{X}^s_d$, or an additional external force f^s_{ext}.
The form of the synthetic added variable should be selected to force the system onto an equilibrium point, and then set to 0 in order to maintain a passive behavior of the ER.

4. NUMERICAL SIMULATION OF THE CONTROL

To demonstrate that the method allows to choose a specific equilibrium point, numerical simulations are conducted. The control is simulated with and without the added synthetic variables, and solved using a fourth order Runge-Kutta with the following control equations:

$$M_0\ddot{x}(t) + R_0\dot{x}(t) + K_0x(t) = f_{ext}(t) - Blu_d(t) \tag{2a}$$

$$u_d(t) = \frac{1}{Bl}(-M_0\ddot{x}_d(t) - R_0\dot{x}_d(t) - K_0x_d(t) + f^m_{ext}(t)) \tag{2b}$$

$$M_d\ddot{x}_d(t) + R_d\dot{x}_d(t) + K_dx_d(t) + K_d\beta x_d(t)^3 = f^m_{ext}(t) \tag{2c}$$

with $\dot{\bullet}$ corresponds to a time derivative. The parameters M_0, R_0, K_0 stand for the modal mass, damping and stiffness of the loudspeaker without electrical current, and M_d, R_d and K_d represent the desired modal mass, damping and stiffness of the ES model. The parameter β is the nonlinear constant coefficient of the cubic nonlinearity. The simulations are conducted with the parameters $M_d = M_0 = 3.89 \times 10^{-4}$ kg, $R_d = R_0/8 = 3.29 \times 10^{-2}$ kg.s^{-1}, $K_d = K_0 = 4.34 \times 10^3$ kg.s^{-2} and $\beta = 10^{10}$ m^{-2}. The excitation is chosen to be a mono-harmonic sine excitation of amplitude 1.5 Pa. The initial conditions are taken as $(x_d(0), \dot{x}_d(0)) = (0, 0)$. The sampling frequency is chosen to be 50 kHz, with a 20 seconds duration of the

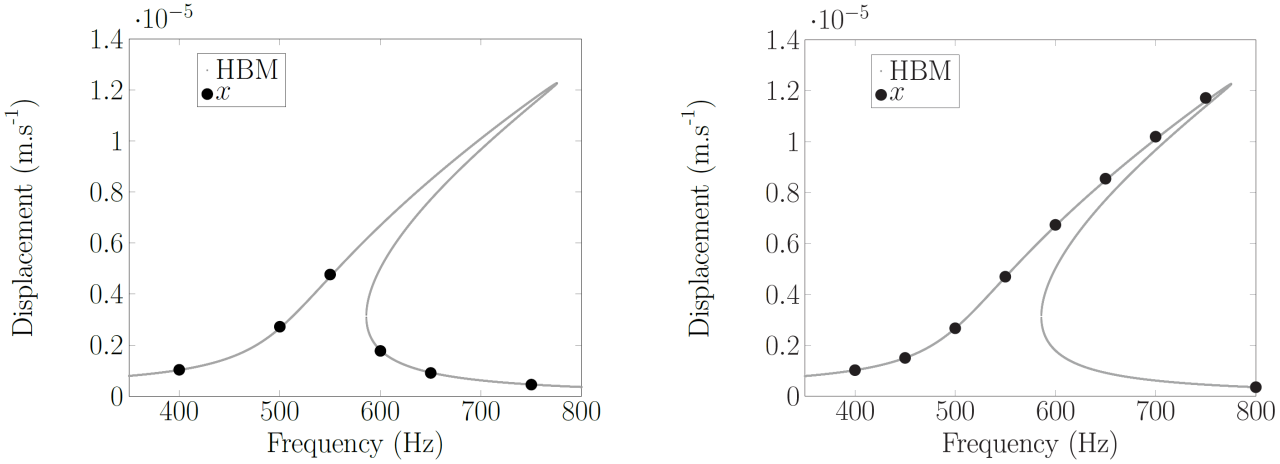

Figure 1: Comparison of the analytical solution of Eq. (1c) obtained with a Harmonic Balance Method (HBM) and the obtained equilibrium point with the numerical simulation of the control with (a) the classical control; (b) the added synthetic variables.

mono-harmonic sine excitation.
The synthetic added variable is chosen as an added external force of the form:

$$f_{ext}^{s} = 200\big(1 - \tanh(t-2)\big) \tag{3}$$

The results of the simulations are presented in Fig. 2. The obtained equilibrium point after 15 seconds of simulation is represented as a black dot. The numerical solutions are compared with a Harmonic Balance Solution (HBM) of the ES equation. One can observe in Fig. 2a that the control without the added synthetic variables targets the lower energy equilibrium point. However, with initial conditions at (0,0), and with the added synthetic variable in Fig. 2b, the control enforces the higher energy equilibrium point. It is due to the control of the basin of attraction of the ES equation with the added variable.
Numerical simulations validates the method, demonstrating its ability to drive the system towards a higher energy equilibrium point, which offers improved acoustic absorption capabilities. The results showed that without the synthetic control variable, the system naturally settled at a lower energy equilibrium point, while the added external synthetic force successfully guided the system toward the desired state.

5. CONCLUSION

In this study, we introduced a novel digital control strategy to enforce nonlinear behaviors in electroacoustic resonators for enhanced acoustic absorption. By leveraging an exosystem to generate targeted nonlinear dynamics, the feed-forward controller successfully tracks and enforces the desired equilibrium state of the loudspeaker. A key challenge of nonlinear systems, the coexistence of multiple equilibrium points with varying efficiency, was addressed by incorporating synthetic variables into the ES equation. This approach effectively reshaped the system's basin of attraction, enabling the selection of a specific equilibrium point through digital programming rather than relying on initial conditions. The proposed approach paves the way for digitally controlled nonlinear resonators with tunable properties, opening new possibilities for vibration and noise mitigation in advanced engineering systems.

DEEP OBSERVATION FILTER FOR VIRTUAL SENSING IN LOCAL ACTIVE NOISE CONTROL

Felix Holzmüller* **Alois Sontacchi**
Institute of Electronic Music and Acoustics
University of Music and Performing Arts Graz, Austria

ABSTRACT

Local active noise control (ANC) algorithms are often based on adaptive filters, requiring an error signal to operate. For optimal performance, this error signal should be captured at a position as close as possible to the desired point of cancellation. However, in many situations, this is not feasible without invading the listener's space. In such cases, virtual sensing algorithms such as the remote microphone technique (RMT) can be employed to estimate the signal using nearby sensors and domain knowledge. The RMT relies on filters, calculated in a training phase based on recorded scenarios. To ensure sufficient performance under varied acoustic conditions and geometrical configurations, a suitable filter set must be selected during operation from a pre-calculated database encompassing all potential scenarios. This paper proposes a novel approach for an online estimation of the observation filter in the RMT, based on a convolutional neural network. By providing correlation metrics and coordinates as input features, efficient asynchronous computation on external processing units is possible. Handling various acoustic scenarios with variable virtual error microphone position, this approach renders the use of any filter selection logic obsolete.

1. INTRODUCTION

Active noise control (ANC) is a widely used technique for noise reduction [1]. Secondary sources emit control signals that mimic the primary disturbances at a point of interest with an inverse phase. When executed properly, this approach can lead to a substantial reduction in noise through destructive interference. While global ANC approaches aim to reduce disturbances throughout the entire space, local ANC targets selected points of cancellation. The latter technique has been shown to control a larger frequency bandwidth with fewer transducers [2]. An inherent issue of local ANC is its limited spatial extent, often referred to as "zone of quiet" [3–5], which corresponds to the area where at least 10 dB noise reduction can be achieved. The extent of this region usually scales inversely with the controlled bandwidth in diffuse sound fields [3, 5]. Outside this zone of quiet, the ANC system can actually increase the sound pressure [3]. Another position-dependent issue arises when considering common ANC system architectures. Many implementations are based on adaptive filters [6–8] to compensate for slight changes in the scenario during operation. However, adaptive filters for ANC usually require the residual error signals and transfer functions between the secondary sources and the points of cancellation [1, 9]. A mismatch between the estimated and actual error signals or transfer paths can lead to a deterioration in noise reduction performance or even render the system unstable [10, 11].

As it is often not possible to place sensors at the desired points of cancellation without invading the listener's space [12], so-called *virtual sensing* techniques [13–15] are employed to estimate the signal of virtual error microphones at the points of cancellation, using signals from nearby physical microphones and domain knowledge. Due to the limited spatial extent of local ANC and the sensitivity of certain virtual sensing algorithms to changes in the

acoustic scenario [16], a large variety of filters for different situations is calculated in advance and either switched [11] or interpolated [17] during operation to account for time-variant changes.

The dependency on position and acoustic scenario spans a multivariate space, requiring a large database of precomputed filters as well as a filter-selection mechanism during operation. Recently, neural networks have been utilized to handle some of these challenges - for example for modelling secondary paths [18], selecting filters from a database with a classifier network [19], or applying physically informed neural networks for virtual sensing in simple, static acoustic scenarios [20].

We propose a method for the online estimation of the observation filter in the *remote microphone technique* (RMT) [14] with variable virtual microphone position, based on a lightweight convolutional neural network (CNN). The underlying RMT is explained in section 2 before describing the proposed approach in section 3. It is tested for different source and receiver configurations in sections 4 and 5, followed by a conclusion and outlook in section 6. Code and data are openly accessible [21].

2. REMOTE MICROPHONE TECHNIQUE

The RMT [14] is a commonly used technique for virtual sensing. It is based on the assumption that the residual noise $e[n]$ at the listener's position can be decomposed into contributions from the primary noise sources $d_e[n]$ and the control signals $u[n]$, filtered by the transfer function $G_e(z)$ between the secondary sources and the listener's position. The residual error is expressed as

$$E(z) = D_e(z) + G_e(z)U(z)\,, \tag{1}$$

with $E(z)$, $D_e(z)$, and $U(z)$ being the z-transform of $e[n]$, $d_e[n]$, and $u[n]$, respectively. For simplicity, it is assumed that only a single $d_e[n]$, $e[n]$, and $u[n]$ exist, forming an acoustic single-input-single-output system.

On the other hand, the R physical remote microphones also record a mixture $\mathbf{m}[n] = \begin{bmatrix} m_0[n] & m_1[n] & \dots & m_{R-1}[n] \end{bmatrix}^T$ of primary disturbances $\mathbf{d}_m[n] = \begin{bmatrix} d_{m,0}[n] & d_{m,1}[n] & \dots & d_{m,R-1}[n] \end{bmatrix}^T$ and control signal $u[n]$, filtered by the transfer paths $\mathbf{G}_m(z) = \begin{bmatrix} G_{m,0}(z) & G_{m,1}(z) & \dots & G_{m,R-1}(z) \end{bmatrix}^T$ between the secondary sources and remote microphones. Using these definitions, the remote microphone signals in z-domain are expressed as

$$\mathbf{M}(z) = \mathbf{D}_m(z) + \mathbf{G_m}(z)U(z)\,. \tag{2}$$

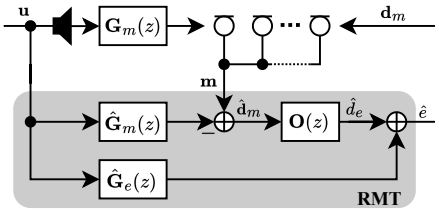

Figure 1. Block diagram of the remote microphone technique (RMT).

A block diagram of the RMT is shown in figure 1. By subtracting the filtered control signal from the remote microphone signals, the primary disturbances at the remote positions

$$\mathbf{D}_m(z) = \mathbf{M}(z) - \mathbf{G}_m(z)U(z) \tag{3}$$

can be extracted. As the actual secondary paths $\mathbf{G}_m(z)$ are usually unknown, a modelled $\hat{\mathbf{G}}_m(z)$ is used to calculate $\hat{\mathbf{D}}_m(z)$. The latter signals are then processed by a so-called *observation filter* $\mathbf{O}(z) = \begin{bmatrix} O_0(z) & O_1(z) & \dots & O_{R-1}(z) \end{bmatrix}$ to get an estimate for the primary disturbances at the virtual error microphone

$$\hat{D}_e(z) = \mathbf{O}(z)\hat{\mathbf{D}}_m(z)\,. \tag{4}$$

Finally, the control signal $U(z)$, filtered by a model for the secondary path $\hat{G}_e(z)$ to the virtual error position, is added to get an estimate for the residual error signal

$$\hat{E}(z) = \hat{D}_e(z) + \hat{G}_e(z)U(z)\,. \tag{5}$$

The secondary paths $\hat{\mathbf{G}}_m(z)$ and $\hat{G}_e(z)$ can be estimated relatively easily by measuring the transfer function between secondary loudspeakers and the remote microphones or a temporarily placed microphone at the virtual position, respectively. The observation filter is computed in a training phase using recordings of the primary disturbances at the remote and virtual microphone positions. The filters themselves are estimated for example via cross-correlations [22] or cross spectral densities (CSDs) [23] between remote and virtual error microphones, forming an inverse problem. To cover several virtual microphone positions and acoustic scenarios, different filter sets must be obtained and switched during operation [23].

In the next section, an approach to estimate the observation filter during operation using a CNN is described. The neural network is capable of estimating filter coefficients for variable virtual microphone positions as well as various primary source configurations.

3. NEURAL OBSERVATION FILTER

We propose an approach to estimate the finite impulse response (FIR) coefficients for the observation filter using a CNN. An overview of the system architecture is shown in figure 2.

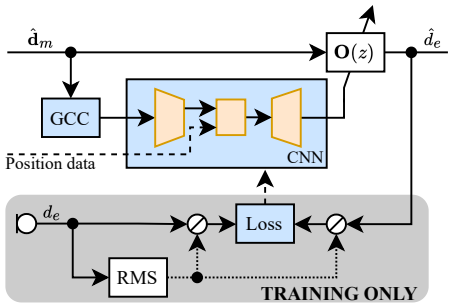

Figure 2. Architecture of the proposed deep observation filter.

3.1 Input features: GCC-PHAT

Applying a neural network to a raw audio signal is generally associated with high computational complexity [24]. As ANC with virtual sensing is often deployed on embedded and low-power hardware, we chose to pre-process the inputs by calculating the generalized cross-correlation functions (GCC) [25] between all unique combinations of remote microphones. A similar approach is commonly used in acoustic beamforming applications [26]. This approach enables us to update the observation filter coefficients asynchronously to the filter process itself.

The GCC $r_{x_1x_2}[k]$ with lag k between two signals $x_1[n]$ and $x_2[n]$ is calculated as

$$r_{x_1x_2}[k] \xleftarrow{\text{IDFT}} \psi(f) S_{x_1x_2}(f)\,, \tag{6}$$

where $S_{x_1x_2}(f)$ refers to the CSD between $x_1[n]$ and $x_2[n]$, f to a frequency index, and $\xleftarrow{\text{IDFT}}$ to an inverse discrete Fourier transform (IDFT). $\psi(f)$ is an additional frequency weighting to sharpen peaks in the GCC [25]. A widely used weighting is the so-called *phase transform* (GCC-PHAT) [25]

$$\psi_{\text{PHAT}}(f) = \frac{1}{\left|S_{x_1x_2}(f)\right|}\,. \tag{7}$$

This measure has proven to be useful in a pilot study [27] and is also applied in the here presented model. To further reduce the number of input parameters for the neural network, only the values of the GCC covering the microphone array aperture around zero lag are considered [1].

The GCC-PHAT is computed online during operation to account for time-variant changes. Let $\tilde{S}_{x_1x_2,t}(f)$ be the CSD estimated using only the signals in a current time frame t. An exponentially weighted moving average

$$\hat{S}_{x_1x_2,t}(f) = \alpha\tilde{S}_{x_1x_2,t}(f) + (1-\alpha)\hat{S}_{x_1x_2,t-1}(f) \tag{8}$$

with smoothing factor α is applied to average over a larger time scope as well as to put an emphasis on recent values in order to track time-variant changes.

Additionally, the neural network receives the Cartesian coordinates of the virtual error microphone as well. These coordinates can be obtained for example by head-tracking systems [23, 28] in real-world applications.

3.2 Model architecture

The network itself has an encoder-decoder-like architecture. In this publication, four remote microphones with an aperture of less than 30 cm are used for virtual sensing. This means, that six GCCs for the unique microphone combinations with 29 values each [2] are computed and used as input for the neural network.

The encoder consists of four sequential stages, compressing the temporal input dimension while expanding channels. Each stage comprises two 1D convolutional layers with a padding of 1. Kernel size and stride are configured to compress the temporal dimension.

The encoding stage operates independently of the virtual microphone position. To track the virtual microphone's position, the output of the encoder is flattened and concatenated with the three Cartesian coordinates before being passed to two linear layers. The output of these bottleneck layers is then reshaped and expanded again in the decoder. The latter consist, similarly to the encoder, of four stages with two transposed 1D convolutional layers each. The layer parameters are adjusted such that the output shape corresponds to 4 sets of FIR filters with 65 coefficients each. All layers use leaky ReLU activation functions. An overview of the model architecture with its parameters is provided in table 1. The CNN has in total 366.94 k parameters and requires 1.34 M operations per inference.

[1] E.g. if the maximum time-of-flight between microphones in the array corresponds to 10 samples, only the 21 central values of the GCC are used.

[2] $\left\lceil \frac{0.3\,\text{m}}{343\,\text{m/s}} \cdot 16\,000\,\text{samples/s} \right\rceil = \pm 14$ samples around zero lag

4. TRAINING

To train and assess the model, a synthetic dataset is created in pyroomacoustics [29]. Four remote microphones are positioned at the Cartesian coordinates $(0.1, 0.1, 0.1)$, $(0.1, -0.1, -0.1)$, $(-0.1, 0.1, -0.1)$, $(-0.1, -0.1, 0.1)$ m, forming as tetrahedral arrangement with an aperture of 28.3 cm. A single virtual microphone is placed near the origin of coordinates. Its exact position is randomly varied for each scene with a distance of up to 5 cm from the centre of the tetrahedron. A single primary source is positioned at a distance of 1 m with random direction of arrival in free field conditions. The source emits coloured broadband noise with a power spectral density proportional to $1/f^{\beta}$, where $\beta \in [0; 2]$ and the root mean square (RMS) level between -40 dB and -10 dB are randomly selected. All random variables are drawn from uniform distributions. In total, 50 000 scenes were generated, each lasting 10 s at a sample rate of 16 kHz and a speed of sound of $c = 343$ m/s. The dataset has been split for training and validation with an 80/20 ratio.

Table 1. Structure of the neural network, consisting of 1D convolutional (Conv1d), linear, and transposed 1D convolutional layers (ConvT1d).

Layer	Shape		Kernel	Stride	Pad
	In	Out			
Conv1d	6×29	16×29	3	1	1
Conv1d	16×29	16×14	4	2	1
Conv1d	16×14	32×14	3	1	1
Conv1d	32×14	32×7	4	2	1
Conv1d	32×7	64×7	3	1	1

ConvT1d	16×33	16×33	3	1	1
ConvT1d	16×33	4×65	3	2	1
ConvT1d	4×65	4×65	3	1	1

The network is trained by minimizing the mean squared error (MSE) loss between the predicted primary disturbances $\hat{d}_e[n]$ at the virtual microphone and the known target signal $d_e[n]$. Since the MSE is calculated in time domain, phase errors which are critical for ANC are inherently accounted for. For a level invariant loss [30], the signals are normalized by the target signal's RMS value.

The CSDs for the GCC are estimated using Welch's method [31] with a FFT size of 128, 50 % overlap and a Hann window. The GCC estimates are exponentially weighted as described in equation (5) with $\alpha = 0.01$ as all presented scenes are stationary. Given the aperture of the remote microphone arrangement, only the central 29 values of the GCCs between the six unique microphone combinations are used as input for the neural network as described in section 3.2.

The observation filter is modelled as FIR filter using the overlap-save method. For this simple anechoic scenario, a filter length of 65 taps is chosen. The overlap-save algorithm operates with a segment length of 128 samples and a stepsize of 64 samples. Coefficients are updated every 500 ms, meaning that the neural network is inferred twice per second. To enhance robustness, the network is trained to estimate past samples of the primary disturbances instead of the current ones, as seen in the *delayed RMT* [22, 32]. With a delay of 25 samples, all relevant parts of the FIR coefficients are shifted into a causal region.

The model has been trained using the Adam optimizer [33] at a learning rate of 1e−4. A weight decay of 1e−8 was applied to prevent overfitting and exceedingly large filter coefficients. Training was conducted for 1000 epochs in PyTorch with a batch size of 100, requiring approximately 16 h on a single NVIDIA GeForce RTX 3080 GPU.

5. RESULTS

The presented model is evaluated regarding the influence of position information, as well as for different primary disturbance directions and virtual microphone positions. It is assessed using a normalized mean square error (NMSE)

$$NMSE = 10\log_{10}\left(\frac{\sum_{n=0}^{\infty}\epsilon[n]^2}{\sum_{n=0}^{\infty}d_e[n]^2}\right) \tag{9}$$

as single-value broadband metric, where

$$\epsilon[n] = d_e[n] - \hat{d}_e[n]\,. \tag{10}$$

The estimation error [23]

$$E(f) = 10\log_{10}\left(\frac{S_{\epsilon\epsilon}(f)}{S_{d_e d_e}(f)}\right), \tag{11}$$

based on the power spectral densities $S_{\epsilon\epsilon}(f)$ and $S_{d_e d_e}(f)$ of $\epsilon[n]$ and $d[n]$, respectively, is used to analyse the spectral properties of the presented approach.

5.1 Availability of position data

In a first experiment, the potential improvement in estimation accuracy by providing the virtual microphone position is assessed. As mentioned in section 3.2, the position of the virtual error microphone is provided in Cartesian coordinates both during training and validation. As a baseline for comparison, the same model is validated without accurate position data by supplying only the centre coordinates of the microphone arrangement as virtual microphone position, regardless of its actual location. Additionally, another model is trained and validated entirely without valid position data as well. All experiments are performed on the same dataset.

Table 2. Mean validation NMSE in dB with standard deviation (SD) with and without provided coordinates of the virtual microphone.

Position data	NMSE in dB	
	Mean	**SD**
train+val	**-33.53**	9.90
train only	-17.67	14.35
none	-13.42	12.24

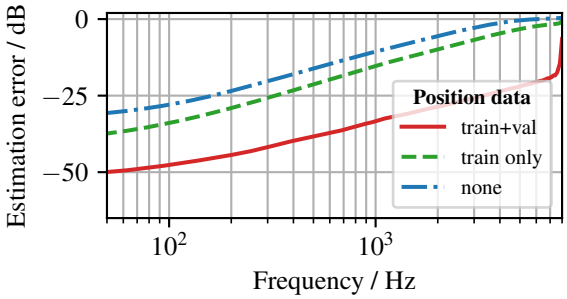

Figure 3. Validation estimation error in dB for models trained and validated with and without accurate position data of the virtual microphone.

As seen in table 2, the NMSE increases by more than 15 dB when the network is supplied with inaccurate position data during validation. This result is expected, as other authors have demonstrated that accurate tracking of the (virtual) error microphone position can significantly improve ANC performance [11, 13, 23]. If the network is even trained without position data, the mean NMSE rises further, but its variance slightly decreases. The mean estimation error in frequency domain in figure 3 can provide more insights into the model's characteristics. It performs best towards low frequencies with an estimation error around −50 dB, but still maintains less than −20 dB error even at the upper end of the assessed spectrum. The spectral tilt can be attributed to the spectral distribution of the primary disturbances during training, which emphasises low frequencies, ranging from brown to white noise. The estimation error for the conditions without accurate tracking data exhibits a constant bias across the whole assessed spectrum, indicating that accurate tracking information enhances performance even towards very low frequencies.

5.2 Virtual error position

In a second evaluation, the effect of the actual position of the virtual error microphone on estimation performance is investigated. For this analysis, the validation set is divided into five distinct subsets based on the distance r of the virtual microphone from the centre of the arrangement. Table 3 shows only a minor decline in estimation performance and a slight increase in variance as the virtual microphone moves away from the centre. The mean NMSE rises by approximately 0.5 dB to 1 dB per cm of distance from the centre. Larger deviations occur at both the start and end of

the assessed range, meaning the increase of NMSE is not strictly proportional to absolute distance.

Table 3. Mean validation NMSE in dB with standard deviation (SD) for different virtual position distance r from the tetrahedron's centre.

Range	NMSE in dB	
	Mean	**SD**
$r \in [0.0, 1.0)$ cm	**-35.02**	9.55
$r \in [1.0, 2.0)$ cm	-34.07	9.57
$r \in [2.0, 3.0)$ cm	-33.48	10.00
$r \in [3.0, 4.0)$ cm	-33.05	9.97
$r \in [4.0, 5.0)$ cm	-32.06	10.14

5.3 Primary source direction

Finally, the influence of the primary disturbance direction is examined. Two extreme cases are considered:

1. Sound arriving from the direction of a remote microphone, and
2. Sound propagating along the normal vector of the tetrahedron's surfaces.

For both cases, a tolerance margin of 10° is applied to the direction of arrival.

As table 4 shows, only minor differences in NMSE are observed depending on the primary source direction. The difference in mean NMSE is not statistically significant ($p = 0.762$) according to an independent samples t-test. This suggests that estimation performance is unaffected by the primary disturbance direction.

6. CONCLUSION

In this article, a neural network-based method for estimating the observation filter in the remote microphone technique for local active noise control has been presented. It features an encoder-decoder-like architecture implemented as a convolutional neural network.

For efficient operation, the neural network receives GCCs between all remote microphones, along with the coordinates of the virtual microphone, as input features. It computes the FIR coefficients of the observation filter, which can be used in conventional filter architectures. With

Table 4. Mean validation NMSE in dB with standard deviation (SD) for primary sources in direction of a single remote microphone or normally to the tetrahedron surfaces with 10° tolerance.

Direction	NMSE in dB	
	Mean	**SD**
mic	-34.31	9.36
surface	**-34.58**	9.62

this structure, filtering can be performed on low-latency hardware while allowing asynchronous coefficient estimation on an external (co-)processor or neural processing unit (NPU) for optimal performance.

It has been demonstrated that supplying the network with accurate position information of the virtual microphone significantly enhances estimation accuracy. The lowest NMSE is achieved when the virtual microphone is positioned near the centre of the tested arrangement, whereas NMSE only slightly increases with distance from the centre. However, no statistically significant differences dependant on the primary source direction could be observed.

In future studies, the presented model will be expanded to handle time-variant scenarios with moving virtual positions and primary disturbances. It is anticipated that recurrent architectures will yield noticeable improvements for these cases. Additionally, the model's capability to process scenarios with multiple primary sources and narrowband signals will be evaluated, especially in conjunction with an adaptive ANC algorithm to assess noise reduction performance.

ACTIVE NOISE CONTROL WITH EXTENDED QUIET ZONES USING TIME-DOMAIN UNDERDETERMINED MULTICHANNEL INVERSE FILTERS AND KERNEL INTERPOLATION

Michael Anthony[1*] **Mingsian R. Bai**[1]
[1] Department of Electrical Engineering, National Tsing Hua University, Taiwan

ABSTRACT

This paper proposes a novel Active Noise Control (ANC) framework that exploits time-domain underdetermined multichannel inverse filters (TUMIF) with kernel-based sound field interpolation to enhance the spatial coverage of noise suppression. While TUMIF is effective in reducing noise at the measured control points, its performance degrades elsewhere, limiting its application in extended spatial regions. To solve this problem, a kernel ridge regression method is used to interpolate the Acoustic Transfer Functions (ATFs) of the secondary loudspeakers and the unmeasured control points, based on the Helmholtz equation. The interpolated control points enable the creation of extended quiet zones with a limited number of measured control points. The simulation results showed that the proposed approach achieved significant broadband noise reduction in an extended control region.

Keywords: *active noise control, sound field interpolation, kernel method.*

1. INTRODUCTION

Active Noise Control (ANC) is an effective technique for reducing unwanted noise, especially in the low frequency range, by generating anti-noise signals through secondary loudspeakers [1]. Adaptive filtering techniques, such as the widely used filtered-x least mean squares (FxLMS), handle time-varying issues but suffer from increasing computational complexity as the number of secondary loudspeakers and control points increases [1–2]. Moreover, these approaches are constrained by the overdetermined inverse filtering problem, which limits their achievable noise reduction performance. To address this, time-domain underdetermined multichannel inverse filtering (TUMIF) is introduced [3].

A major limitation of traditional ANC systems is that noise cancellation is confined to measured control points, with performance deteriorating in between these locations [4]. Broader quiet zones can be achieved by increasing the amount of measured control points. However, measuring a large number of measured control points is often impractical due to the time-consuming calibration process and physical constraints in real-world environment [5]. To overcome this challenge, the kernel ridge regression method [6] is proposed to estimate the Acoustic Transfer Functions (ATFs) at unmeasured locations, so-called interpolated control points. These interpolated control points enable broader noise suppression without requiring additional physical sensors.

In this work, we propose a novel ANC framework that integrates TUMIF with kernel interpolation to achieve spatially extended noise control. This combination enhances the noise suppression at interpolated control points while maintaining the performance at measured control points.

Single-channel feedforward ANC system can be seen as a model-matching problem as illustrated in Fig. 1. Under the assumption that both the secondary path $g[n]$ and the controller $c[n]$ are FIR systems, their linear convolution should match the primary path $m[n]$ such that the residual error signal $e[n]$ tends to zero, with n denoting the discrete time index. Let L_p, L_s, and L_c be the impulse response length of, respectively, primary path, secondary path, and controller, the matrix form of the linear convolution relation is modeled as

$$\mathbf{G}\mathbf{c} = -\mathbf{m} \tag{1}$$

where

$$\mathbf{m} = [m[0] \quad m[1] \quad \cdots \quad m[L_p - 1]]^T \tag{2}$$

$$\mathbf{c} = [c[0] \quad c[1] \quad \cdots \quad c[L_c - 1]]^T \tag{3}$$

$$\mathbf{G} = \begin{bmatrix} g[0] & 0 & \cdots & 0 \\ g[1] & g[0] & & \vdots \\ \vdots & g[1] & \ddots & \\ g[L_s-1] & \vdots & & 0 \\ 0 & g[L_s-1] & & g[0] \\ \vdots & 0 & \ddots & g[1] \\ & \vdots & & \vdots \\ 0 & 0 & \cdots & g[L_s-1] \end{bmatrix} \tag{4}$$

Note that $L_p = L_s + L_c - 1$ and $\mathbf{G}$ is a $L_p \times L_c$ convolution matrix. The least square (LS) solution is computed as:

$$\mathbf{c}_{LS} = -\mathbf{G}^{+}\mathbf{m} = -\left(\mathbf{G}^T\mathbf{G}\right)^{-1}\mathbf{G}^T\mathbf{m} \tag{5}$$

The fact that Eqn. (1) is an overdetermined system ($L_p > L_c$) generally leads to a non-zero minimum residual error. The TUMIF approach [3] has proven effective in mitigating this problem by introducing additional secondary loudspeakers.

3. PROPOSED METHOD

The proposed method is divided into two stages: calibration stage and testing stage. At the calibration stage, the ATFs between J microphones and K secondary loudspeakers G_F are measured. ATFs at interpolated control points $\hat{G}_F$ are estimated using kernel ridge regression based on the measured one and then inverse transformed into time-domain impulse reponses (IRs). Both the interpolated and measured IRs are fed onto TUMIF to compute the coefficients of the controllers $\mathbf{c}$. The microphones are detached at the testing stage and the proposed ANC framework suppresses unwanted noise in a widened region, resulting in broader quiet zones.

3.1 Sensor interpolation using kernel method

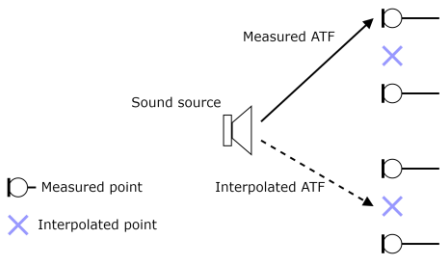

Figure 2. Block diagram of the sensor interpolation problem.

As shown in Fig. 2, kernel interpolation is utilized to estimate the ATFs in between measured control points, as written as the following optimization problem:

$$\min_{G_F} \mathfrak{I} = \sum_{j=1}^{J} \left|\hat{G}_F(\mathbf{r}_j) - G_F(\mathbf{r}_j)\right|^2 + \alpha \left\|\hat{G}_F\right\|_{\mathcal{H}}^2 \tag{6}$$

where $\hat{G}_F(\mathbf{r}_j)$ and $G_F(\mathbf{r}_j)$ are, respectively, the interpolated and measured ATFs at position vector $\mathbf{r}_j$ of the j microphone, α is the regularization parameter, and $\|\bullet\|_{\mathcal{H}}^2$ is the squared L_2-norm within the Hilbert space $\mathcal{H}$. By deriving the reproducing kernel, the solution of Eqn. (6) can be obtained as [6]

$$\hat{G}_F(\mathbf{r}) = \kappa^T(\mathbf{r})\left(\mathbf{K} + \alpha\mathbf{I}_J\right)^{-1}\mathbf{G}_F \tag{7}$$

where

$$\mathbf{K} = \begin{bmatrix} j_0\left(k\|\mathbf{r}_1 - \mathbf{r}_1\|_2\right) & \cdots & j_0\left(k\|\mathbf{r}_1 - \mathbf{r}_J\|_2\right) \\ \vdots & \ddots & \vdots \\ j_0\left(k\|\mathbf{r}_J - \mathbf{r}_1\|_2\right) & \cdots & j_0\left(k\|\mathbf{r}_J - \mathbf{r}_J\|_2\right) \end{bmatrix} \tag{8}$$

$$\kappa^T(\mathbf{r}) = \left[j_0\left(k\|\mathbf{r} - \mathbf{r}_1\|_2\right) \quad \cdots \quad j_0\left(k\|\mathbf{r} - \mathbf{r}_J\|_2\right)\right] \tag{9}$$

are the Gram matrix and kernel function, respectively, in which k is the wave number, $\mathbf{I}_J$ denotes the $J \times J$

identity matrix, $\mathbf{r}$ is position vector of the interpolated control point, and $j_0(\bullet) = \sin(\bullet)/(\bullet)$ denotes the zeroth-order spherical Bessel function, also known as the sinc function.

3.2 TUMIF

Let J_t be the total number of both interpolated and measured control points. The multichannel version of Eqn. (1) can be formulated as

$$\begin{bmatrix} \mathbf{G}_{11} & \cdots & \mathbf{G}_{1K} \\ \vdots & \ddots & \vdots \\ \mathbf{G}_{J_t 1} & \cdots & \mathbf{G}_{J_t K} \end{bmatrix} \begin{bmatrix} \mathbf{c}_1 \\ \vdots \\ \mathbf{c}_K \end{bmatrix} = \begin{bmatrix} -\mathbf{m}_1 \\ \vdots \\ -\mathbf{m}_{J_t} \end{bmatrix} \tag{10}$$

where

$$\mathbf{m}_j = [m_j[0] \quad m_j[1] \quad \cdots \quad m_j[L_p - 1]]^T \tag{11}$$

$$\mathbf{c}_k = [c_k[0] \quad c_k[1] \quad \cdots \quad c_k[L_c - 1]]^T \tag{12}$$

$$\mathbf{G}_{jk} = \begin{bmatrix} g_{jk}[0] & \cdots & 0 \\ g_{jk}[1] & & \vdots \\ \vdots & \ddots & 0 \\ g_{jk}[L_s - 1] & & g_{jk}[0] \\ 0 & \ddots & g_{jk}[1] \\ \vdots & & \vdots \\ 0 & \cdots & g_{jk}[L_s - 1] \end{bmatrix} \tag{13}$$

for $j = 1, 2, \ldots, J_t$ and $k = 1, 2, \ldots, K$.

An underdetermined system can be established if the following requirement is satisfied:

$$L_p = L_s + L_c - 1 < KL_c \tag{14}$$

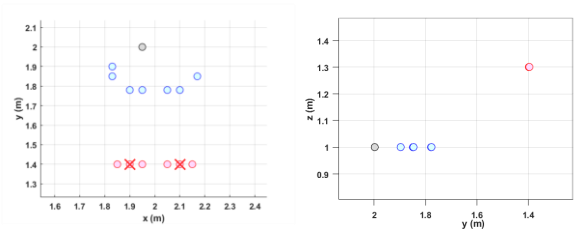
or

$$L_c > \frac{L_s - 1}{K - 1} \tag{15}$$

By satisfying Eqn. (15), exact solutions that result in zero residual errors exist. It also follows that an infinite number of exact solutions exists, providing additional freedom to achieve other objectives [3]. The minimum-norm solution can be wriitten as

$$\mathbf{c}_{LS} = -\mathbf{G}^{+}\mathbf{m} = -\mathbf{G}^T\left(\mathbf{G}\mathbf{G}^T\right)^{-1}\mathbf{m} \tag{16}$$

However, the Gram matrix $\mathbf{G}^T\mathbf{G}$ may be ill-posed at some frequencies, resulting in high gain controllers. This problem can be mitigated, at some cost in model fitting performance, by using the TIKR approach [7]



$$\mathbf{c}_{TIKR} = -\left(\mathbf{G}^T\mathbf{G} + \beta^2\mathbf{I}\right)^{-1}\mathbf{G}^T\mathbf{m} \tag{17}$$

where β is the regularization parameter.

4. SIMULATION

4.1 Simulation setup

A $4 \times 4 \times 3$ m^3 rectangular room is considered in this simulation. Fig. 3(a) illustrates the location of primary loudspeaker (grey circle), secondary loudspeakers (blue circles), measured control points (red circles), and interpolated control points (red crosses). As displayed in Fig. 3(b), the loudspeakers are located one meter above the ground and another 30 cm higher for the microphones to mimic laptop user behavior. The ATFs are generated by using Image Source Method (ISM) [8] with a reverberation time (T60) of 120 ms and white noise is used as the primary noise.

(a) (b)

Figure 3. Loudspeakers and microphones placement (a) x and y axes and (b) y and z axes.

The control points are numbered incrementally to the right starting from the first red circle on the left. The kernel interpolation parameter α and regularization parameter β are set as, respectively, 10^2 and 10^{-4}. The L_p, L_s, and L_c are configured as, respectively, 1024, 512, and 1024.

In order to verify the performance, MSNR [9] is used as the evaluation metric which is defined as

$$MSNR = 10\log_{10}\frac{\sum_{n=0}^{N}\left|d_j[n]\right|^2}{\sum_{n=0}^{N}\left|e_j[n]\right|^2} \tag{18}$$

where $d_j[n]$ and $e_j[n]$ represent the primary noise signal and and the error signal at the j-th control point. The larger the MSNR, the better the noise control performance.

4.2 Simulation results

Tab. 1 presents the MSNR values measured on each control point, comparing the performance of the proposed method with TUMIF. The combination of TUMIF and kernel interpolation achieves better performance at the unmeasured control points while maintaining its effectiveness at the measured control points. The power spectrum density (PSD) is plotted in Fig. 4, demonstrating that the proposed method controls noise more effectively than TUMIF.

Table 1. Comparison of MSNR (dB).

Control points	TUMIF	Proposed method
Measured #1	28.88	31.12
Unmeasured #2	-27.72	8.49
Measured #3	27.63	26.68
Measured #4	28.15	27.32
Unmeasured #5	-22.5	4.22
Measured #6	29.43	30.52

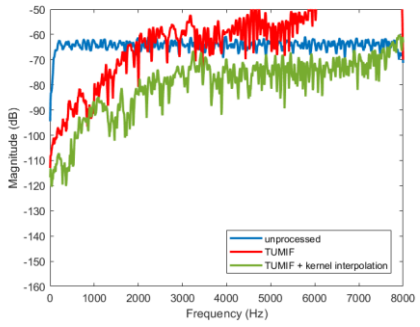


Figure 4. Power Spectrum Density (PSD) at unmeasured control point #2.

5. CONCLUSIONS

This study explored the integration of TUMIF with kernel interpolation to extend the quiet zone beyond measured control points. While TUMIF effectively suppresses noise at these points, its performance degrades at unmeasured locations. Kernel ridge regression was employed to interpolate ATFs, enabling broader noise suppression without additional physical microphones. Simulations demonstrated significant noise reduction at both measured and unmeasured control points for the proposed method, leading to an extended quiet zone. Real-time validation will be conducted in future work.

SPATIALLY SELECTIVE ACTIVE NOISE CONTROL FOR OPEN-FITTING HEARABLES WITH ACAUSAL OPTIMIZATION

Tong Xiao* **Simon Doclo**
Department of Medical Physics and Acoustics and Cluster of Excellence Hearing4all,
Carl von Ossietzky Universität Oldenburg, Germany

ABSTRACT

Recent advances in active noise control have enabled the development of hearables with spatial selectivity, which actively suppress undesired noise while preserving desired sound from specific directions. In this work, we propose an improved approach to spatially selective active noise control that incorporates acausal relative impulse responses into the optimization process, resulting in significantly improved performance over the causal design. We evaluate the system through simulations using a pair of open-fitting hearables with spatially localized speech and noise sources in an anechoic environment. Performance is evaluated in terms of speech distortion, noise reduction, and signal-to-noise ratio improvement across different delays and degrees of acausality. Results show that the proposed acausal optimization consistently outperforms the causal approach across all metrics and scenarios, as acausal filters more effectively characterize the response of the desired source.

Keywords: active noise control, spatial selectivity, causality, beamforming

1. INTRODUCTION

Active noise control (ANC) hearables create a quiet environment by using secondary sources to generate anti-noise, which minimizes sound at specific positions when superimposed on the primary noise (leakage) [1, 2]. Based on their fit, hearables can be categorized as closed-fitting (completely occluding the ear), open-fitting (partially occluding the ear), and open-ear (no occlusion, e.g., smart glasses). Open-fitting and open-ear designs, in particular, reduce the occlusion effect and improve the physical comfort. Recent research focuses on designing intelligent ANC hearables with spatial selectivity, particularly for complex acoustic environments like cocktail-party scenarios involving multiple sound sources from different directions [3–5]. In these scenarios, listeners may wish to focus on desired sounds from a specific direction (e.g., the front) while blocking out undesired sounds from other directions.

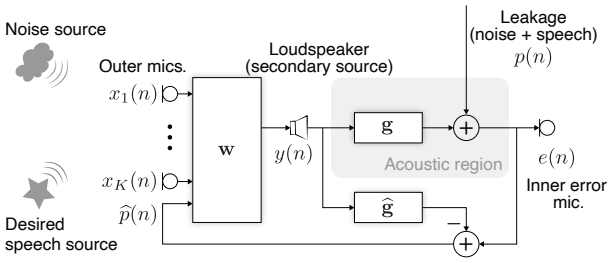

Figure 1: Block diagram of an ANC system with K outer microphones, one inner error microphone and one loudspeaker (i.e., secondary source). The control filter is denoted by $\mathbf{w}$, the secondary path is denoted by $\mathbf{g}$, and its estimate by $\widehat{\mathbf{g}}$.

Modern ANC hearables are commonly equipped with multiple microphones, i.e., microphones on the exterior of the hearable and error microphones in the interior close to the eardrum. On the one hand, conventional ANC algorithms suppress all leakage measured by the inner error microphones, including desired speech. On the other hand, multi-microphone noise reduction algorithms perform spatial filtering by reducing all noise while preserving speech from the desired direction [6–8]. However, these algorithms typically ignore the leakage and do not

exploit the inner error microphones. Recent advancements have proposed integrating spatial filtering into an ANC system so that sounds from a desired direction are preserved and sounds from undesired directions are actively suppressed [9–17]. A recent study demonstrated that, when the speech component from an outer reference microphone signal is desired, a small delay is required to satisfy causality. The optimal delay is the acoustic delay between the reference microphone and the inner error microphone for the desired source [17]. These findings were derived using a system with *causal* relative impulse responses (ReIRs). However, under more flexible design constraints, *acausal* ReIRs may give a better performance.

In this paper, we present an improved approach to spatially selective ANC (SSANC) that leverages *acausal* ReIRs in the optimization process, thereby substantially improving performance over the causal optimization approach. We analyze the signal distortion, noise reduction, and signal-to-noise ratio (SNR) improvement of the inner error microphone signal when the speech component of an outer microphone signal is desired. We identify both the optimal range of delays and the optimal degree of acausality based on these evaluation metrics. These insights guide the design of a more effective SSANC for open-fitting hearables.

2. SIGNAL MODEL

As shown in Fig. 1, we consider a hearable with K outer microphones. Without loss of generality, we consider one loudspeaker as the secondary source and one inner error microphone, resulting in a total of $K+1$ microphones. We assume that the acoustic feedback paths between the loudspeaker and the outer microphones are known, such that acoustic feedback can be canceled. In addition, we assume that an estimate of the secondary path between the loudspeaker and the inner error microphone is available. Subscripts $(\cdot)_s$ and $(\cdot)_v$ denote the speech and noise components in signals, respectively.

The inner error microphone signal $e(n)$, with n the discrete time index, is given by

$$e(n) = p(n) + (\mathbf{G}\mathbf{w})^{\mathcal{T}}\mathbf{x}(n), \tag{1}$$

where $(\cdot)^{\mathcal{T}}$ denotes the transpose operator. The leakage (including noise and desired speech) at the inner error microphone is denoted by $p(n)$, and the anti-noise component at the inner error microphone is given by $(\mathbf{G}\mathbf{w})^{\mathcal{T}}\mathbf{x}(n)$, where $\mathbf{w}$ is the stacked control filter, $\mathbf{x}(n)$ is the stacked input vector, and $\mathbf{G}$ represents the secondary path convolution matrix. The stacked control filter $\mathbf{w}$ is defined as

$$\mathbf{w} = [\mathbf{w}_1^{\mathcal{T}} \quad \mathbf{w}_2^{\mathcal{T}} \quad \dots \quad \mathbf{w}_{K+1}^{\mathcal{T}}]^{\mathcal{T}} \in \mathbb{R}^{(K+1)L_w}, \tag{2a}$$

$$\mathbf{w}_k = [w_{k,0}\ w_{k,1}\ \dots\ w_{k,L_w-1}]^{\mathcal{T}} \in \mathbb{R}^{L_w}, \tag{2b}$$

where L_w denotes the control filter length for each channel. The convolution matrix of the secondary path is defined as

$$\mathbf{G} = \text{blkdiag}\,(\mathbb{G}\dots\mathbb{G}) \in \mathbb{R}^{(K+1)L\times(K+1)L_w}, \tag{3a}$$

$$\mathbb{G} = \begin{bmatrix} g_0 & \cdots & 0 \\ \vdots & \ddots & \vdots \\ g_{L_g-1} & \ddots & g_0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & g_{L_g-1} \end{bmatrix} \in \mathbb{R}^{L\times L_w}, \tag{3b}$$

where $L = L_g + L_w - 1$, and L_g denotes the secondary path filter length. As input signals to the control filter we consider the K outer microphone signals $\mathbf{x}_k(n)$, $k = 1,\dots,K$, and an estimate of the leakage $\widehat{\mathbf{p}}(n)$, i.e., the stacked input vector $\mathbf{x}(n)$ is defined as

$$\mathbf{x}(n) = [\mathbf{x}_1^{\mathcal{T}}(n)\ \dots\ \mathbf{x}_K^{\mathcal{T}}(n)\ \widehat{\mathbf{p}}^{\mathcal{T}}(n)]^{\mathcal{T}} \in \mathbb{R}^{(K+1)L}, \tag{4}$$

with

$$\mathbf{x}_k(n) = [x_k(n)\ \dots\ x_k(n-L+1)]^{\mathcal{T}}, \tag{5a}$$

$$\widehat{\mathbf{p}}(n) = [\,\widehat{p}(n)\ \dots\ \widehat{p}(n-L+1)]^{\mathcal{T}}. \tag{5b}$$

The estimated leakage $\widehat{p}(n)$ can be computed from the inner error microphone signal $e(n)$, the loudspeaker signal vector $\mathbf{y}(n) = [y(n)\dots y(n-L_g+1)]^{\mathcal{T}}$, and an estimate of the secondary path $\widehat{\mathbf{g}}$ as

$$\widehat{p}(n) = e(n) - \widehat{\mathbf{g}}^{\mathcal{T}}\mathbf{y}(n). \tag{6}$$

Assuming a perfect estimate of the secondary path to be available, i.e., $\widehat{\mathbf{g}} = \mathbf{g} = [g_0\ g_1\ \dots\ g_{L_g-1}]^{\mathcal{T}}$, the leakage can be written as $p(n) = \widehat{p}(n) = \mathbf{q}^{\mathcal{T}}\mathbf{x}(n)$, with

$$\mathbf{q} = [\mathbf{0}^{\mathcal{T}}\ \dots\ \mathbf{0}^{\mathcal{T}}\ \boldsymbol{\delta}^{\mathcal{T}}]^{\mathcal{T}} \in \mathbb{R}^{(K+1)L}, \tag{7a}$$

$$\boldsymbol{\delta} = [1\quad 0\quad \dots\quad 0\,]^{\mathcal{T}} \in \mathbb{R}^{L}. \tag{7b}$$

Hence, the inner error microphone signal in (1) can be rewritten as

$$e(n) = (\mathbf{q} + \mathbf{G}\mathbf{w})^{\mathcal{T}}\mathbf{x}(n). \tag{8}$$

Assuming that the speech and the noise components are uncorrelated, then we have

$$e_s(n) = (\mathbf{q} + \mathbf{G}\mathbf{w})^{\mathcal{T}}\mathbf{x}_s(n), \tag{9a}$$

$$e_v(n) = (\mathbf{q} + \mathbf{G}\mathbf{w})^{\mathcal{T}}\mathbf{x}_v(n). \tag{9b}$$

3. ACAUSAL OPTIMIZATION

In the SSANC system, the objective is to minimize the power of the inner error microphone signal while preserving the delayed desired speech component of an outer reference microphone signal. This can be achieved by imposing the constraint

$$e_s(n) = x_{\mathrm{ref},s}(n-\Delta). \tag{10}$$

For each channel, the speech component can be represented as the convolution of the speech component of the reference microphone signal and an acausal ReIR filter, that is,

$$x_{k,s}(n) = \sum_{l=-L_a}^{L_h-1} h_k(l)\, x_{\mathrm{ref},s}(n-l), \tag{11}$$

where the ReIR has L_a-tap anti-causal part and L_h-tap causal part. The stacked input vector for all the channels can then be written as

$$\mathbf{x}_s(n) = \mathbf{H}^{\mathcal{T}}\, \mathbf{x}_{\mathrm{ref},s}(n), \tag{12}$$

where

$$\mathbf{H} = [\mathbf{H}_1 \dots \mathbf{H}_{K+1}] \in \mathbb{R}^{(L_a+L_h+L-1)\times(K+1)L}, \tag{13a}$$

$$\mathbf{H}_k = \begin{bmatrix} h_{k,-L_a} & \cdots & 0 \\ \vdots & \ddots & \vdots \\ h_{k,L_h-1} & \ddots & 0 \\ 0 & \ddots & h_{k,-L_a} \\ \vdots & \ddots & \vdots \\ 0 & \cdots & h_{k,L_h-1} \end{bmatrix} \in \mathbb{R}^{(L_a+L_h+L-1)\times L}, \tag{13b}$$

$$\mathbf{x}_{\mathrm{ref},s}(n) = [x_{\mathrm{ref},s}(n+L_a) \dots x_{\mathrm{ref},s}(n-L_h-L+2)]^{\mathcal{T}} \in \mathbb{R}^{L_a+L_h+L-1}, \tag{13c}$$

and $\mathbf{x}_s(n) \in \mathbb{R}^{(K+1)L}$ is similarly defined as (4).

We rewrite (10) as

$$e_s(n) = \boldsymbol{\delta}_\Delta^{\mathcal{T}} \mathbf{x}_{\mathrm{ref},s}(n), \tag{14}$$

where

$$\boldsymbol{\delta}_\Delta = [\underbrace{0 \dots 0}_{L_a}\ \underbrace{0 \dots 0}_{\Delta}\ \underbrace{1\, 0 \dots 0}_{L_h+L-1-\Delta}]^{\mathcal{T}} \in \mathbb{R}^{L_a+L_h+L-1}. \tag{15}$$

Thus, using (9a), (12) and (14), we reformulate (10) as

$$\mathbf{H}(\mathbf{q}+\mathbf{G}\mathbf{w}) = \boldsymbol{\delta}_\Delta. \tag{16}$$

It is important to note that although the ReIRs, e.g., $\mathbf{H}$ and $\boldsymbol{\delta}_\Delta$, are modeled to be *acausal*, the SSANC control filter $\mathbf{w}$ for generating the anti-noise is still *causal*.

Therefore, the optimization problem for an SSANC system can be defined as

$$\underset{\mathbf{w}}{\text{minimize}} \quad \mathcal{E}\left\{e^2(n)\right\} + \beta \mathbf{w}^{\mathcal{T}}\mathbf{w} \tag{17a}$$

$$\text{subject to} \quad \mathbf{H}(\mathbf{q}+\mathbf{G}\mathbf{w}) = \boldsymbol{\delta}_\Delta, \tag{17b}$$

where $\mathcal{E}\{\cdot\}$ denotes the mathematical expectation operator. β denotes a regularization factor. The solution is found to be

$$\begin{aligned}\mathbf{w} = &-\left[\mathbf{I}-\boldsymbol{\Phi}_{\mathbf{rr}}^{-1}\mathbf{G}^{\mathcal{T}}\mathbf{H}^{\mathcal{T}}\left(\mathbf{H}\mathbf{G}\boldsymbol{\Phi}_{\mathbf{rr}}^{-1}\mathbf{G}^{\mathcal{T}}\mathbf{H}^{\mathcal{T}}+\rho\mathbf{I}\right)^{-1}\mathbf{H}\mathbf{G}\right]\boldsymbol{\Phi}_{\mathbf{rr}}^{-1}\boldsymbol{\phi} \\ &+\boldsymbol{\Phi}_{\mathbf{rr}}^{-1}\mathbf{G}^{\mathcal{T}}\mathbf{H}^{\mathcal{T}}\left(\mathbf{H}\mathbf{G}\boldsymbol{\Phi}_{\mathbf{rr}}^{-1}\mathbf{G}^{\mathcal{T}}\mathbf{H}^{\mathcal{T}}+\rho\mathbf{I}\right)^{-1}(\boldsymbol{\delta}_\Delta-\mathbf{H}\mathbf{q}),\end{aligned} \tag{18}$$

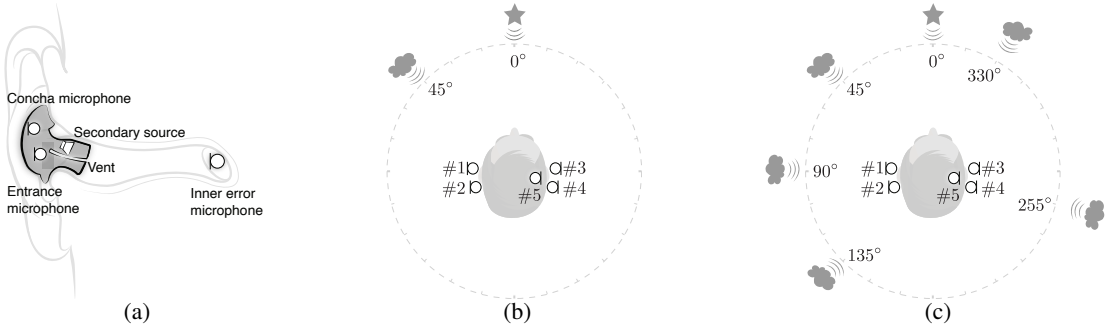
where

$$\boldsymbol{\Phi}_{\mathbf{xx}} = \mathcal{E}\left\{\mathbf{x}(n)\mathbf{x}^{\mathcal{T}}(n)\right\}, \tag{19a}$$

$$\boldsymbol{\Phi}_{\mathbf{rr}} = \mathbf{G}^{\mathcal{T}}\boldsymbol{\Phi}_{\mathbf{xx}}\mathbf{G} + \beta\mathbf{I}, \tag{19b}$$

$$\boldsymbol{\phi} = \mathbf{G}^{\mathcal{T}}\boldsymbol{\Phi}_{\mathbf{xx}}\mathbf{q}, \tag{19c}$$

and ρ denotes a small regularization factor, $\mathbf{I}$ denotes the identity matrix.



It should be noted that the solution is similar to the previous studies [15, 17]. The major difference is that the ReIR matrix $\mathbf{H}$ is acausal now containing L_a-tap anti-causal part of the ReIR for all channels. When $L_a = 0$, the solution becomes causal, as in the previous approach.

4. SIMULATIONS

4.1 Setup

For the simulation, we considered a pair of open-fitting hearables [18, 19] inserted into both ears of a GRAS 45BB-12 KEMAR Head & Torso simulator, as shown in Fig. 2(a). We used four outer microphones (entrance microphones and concha microphones at the left and right ears, labeled as #1– #4), one inner error microphone (located at the right ear, labeled as #5), and the outer receiver at the right ear as the secondary source. The inner error microphone was assumed to be at the eardrum.

Two acoustic scenarios were considered. In the first scenario, as shown in Fig. 2(b), we considered a desired speech source at 0° and an undesired speech source at 45°

(a) (b) (c)

Figure 2: (a) Illustration of the open-fitting hearable. (b) First acoustic scenario. A desired speech source is at $0°$, and one undesired speech source is at $45°$. (c) Second acoustic scenario. The desired speech source is at $0°$, and five babble noise sources are at $45°$, $90°$, $135°$, $255°$ and $330°$.

("p361_005" and "p243_018" from the VCTK dataset [20], respectively). In the second scenario, as shown in Fig. 2(c), the same desired speech source remained at $0°$, and five noise sources were placed at $45°$, $90°$, $135°$, $255°$ and $330°$ (babble noise from the NOISEX-92 database [21]). The desired speech and noise components in all microphone signals were generated by convolving source signals with measured anechoic impulse responses from the database [19]. All signals were 5 seconds in duration and sampled at 16 kHz. The desired speech and noise components were mixed such that the signal-to-noise ratio (SNR) of the leakage at the inner error microphone was set to -5 dB. In the second scenario, all noise sources contributed the same energy. As the secondary path estimate we used the measured impulse response between the outer receiver and the inner error microphone at the right ear (from [19]).

We set the filter lengths to $L_w = 600$, $L_g = 280$, and $L_h = 262$. The acausal ReIRs were computed using the least-mean-squares adaptive filter (after convergence) from microphone signals simulated with white noise at $0°$, using the entrance microphone #3 as the reference microphone. Similar to the previous studies [15, 17], we were only interested in the frequency range above 100 Hz. Therefore, a minimum-phase high-pass filter with a cut-off frequency at 100 Hz was applied to the desired signal $x_{\mathrm{ref},s}(n-\Delta)$. The effects of delay ($\Delta$) and acausality ($L_a$) on system performance were investigated.

4.2 Evaluation metrics

The following three metrics are used for evaluation. The intelligibility-weighted spectral distortion is used to assess the amount of speech distortion [9, 22, 23]. It is defined as

$$\mathrm{SD}_{\mathrm{intellig}}\,(\mathrm{dB}) = \sum_{b=1}^{B} I(\omega_b)\, 10\log_{10}\frac{\mathcal{P}_{\epsilon}(\omega_b)}{\mathcal{P}_{\mathrm{ref},s}(\omega_b)}, \quad (20)$$

where the band importance function $I(\omega_b)$ expresses the importance of the b-th one-third octave band for intelligibility [24], and B denotes the total number of bands. $\mathcal{P}_{\epsilon}(\omega_b)$ is the power spectral density of $\epsilon(n)$ in the b-th band, where $\epsilon(n) = e_s(n) - x_{\mathrm{ref},s}(n-\Delta)$. $\mathcal{P}_{\mathrm{ref},s}(\omega_b)$ is the power spectral density of $x_{\mathrm{ref},s}(n-\Delta)$ in the b-th band.

The noise reduction is defined as the difference between the power of the noise component of the leakage $p_v(n)$ (without control) and the noise component of the inner error microphone signal $e_v(n)$ (with control), i.e.,

$$\mathrm{NR}\,(\mathrm{dB}) = 10\log_{10}\sum_{n=1}^{N} p_v^2(n) - 10\log_{10}\sum_{n=1}^{N} e_v^2(n), \quad (21)$$

where N denotes the total signal length.

The SNR improvement (ΔSNR) is defined as

$$\Delta\mathrm{SNR}\,(\mathrm{dB}) = 10\log_{10}\frac{\sum_{n=1}^{N} e_s^2(n)}{\sum_{n=1}^{N} e_v^2(n)} - 10\log_{10}\frac{\sum_{n=1}^{N} p_s^2(n)}{\sum_{n=1}^{N} p_v^2(n)}. \quad (22)$$

4.3 Performance for different delays

First, we investigate the effect of delay Δ on performance. The speech distortion, the noise reduction and the SNR improvement are shown in Fig. 3 for different delays ranging from zero to 80 samples (5 ms) for the first scenario.

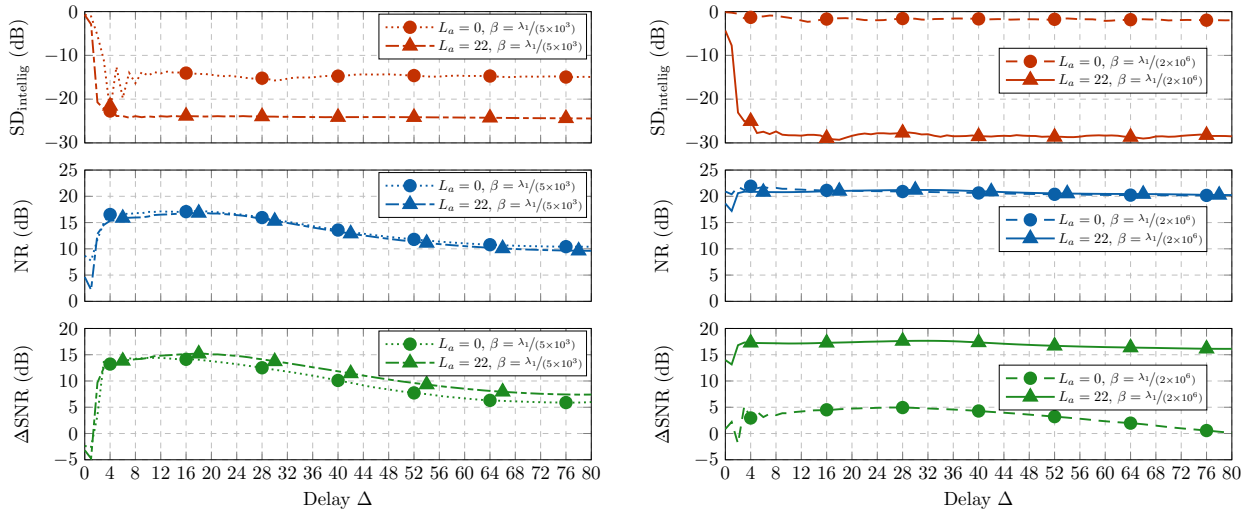


Figure 3: Speech distortion, noise reduction, and SNR improvement for the first simulation scenario for different delay Δ when (a) $L_a = 0$ and $L_a = 22$, with $\beta = \lambda_{\max}(\mathbf{G}^T\mathbf{\Phi_{xx}}\mathbf{G})/(5\times10^3) = \lambda_1/(5\times10^3)$, (b) $L_a = 0$ and $L_a = 22$, with $\beta = \lambda_1/(2\times10^6)$. In all cases, $\rho = \lambda_{\max}(\mathbf{HG}\mathbf{\Phi_{rr}}^{-1}\mathbf{G}^T\mathbf{H}^T)/(1\times10^5)$.

Four design choices are considered. When $L_a = 0$, $\beta = \lambda_{\max}(\mathbf{G}^T\mathbf{\Phi_{xx}}\mathbf{G})/(5\times10^3) = \lambda_1/(5\times10^3)$ and $\rho = \lambda_{\max}(\mathbf{HG}\mathbf{\Phi_{rr}}^{-1}\mathbf{G}^T\mathbf{H}^T)/(1\times10^5)$ as shown in Fig. 3(a), where $\lambda_{\max}(\cdot)$ denotes the largest eigenvalue, this design corresponds to the previous causal optimization [15, 17]. It can be observed that there is very high speech distortion, low noise reduction and low SNR improvement for $\Delta < 4$. This is due to the delays between the reference microphone and the inner error microphone from the desired source, which has a 4-sample delay. The causality constraint requires the delay to be at least four samples. For $4 \leq \Delta \leq 30$, the speech distortion is about -15 dB, the noise reduction has about 15–17 dB, and the SNR improvement is about 14 dB. However, further increases in delay result in degraded noise reduction, which in turn leads to reduced SNR improvement. These results agree with the previous findings.

When $L_a = 22$ with the same β and ρ as shown in Fig. 3(a), it can be observed that the speech distortion is reduced to a much lower level for $\Delta \geq 4$, reaching about -24 dB. However, the noise reduction and the SNR improvement do not show significant benefits compared to the previous results.

The main advantage of acausal optimization is its ability to achieve better performance with a smaller β value, i.e., when less constraint is imposed on the secondary source. The results are shown in Fig. 3(b) when $\beta = \lambda_1/(2\times10^6)$. In the causal case ($L_a = 0$), the system

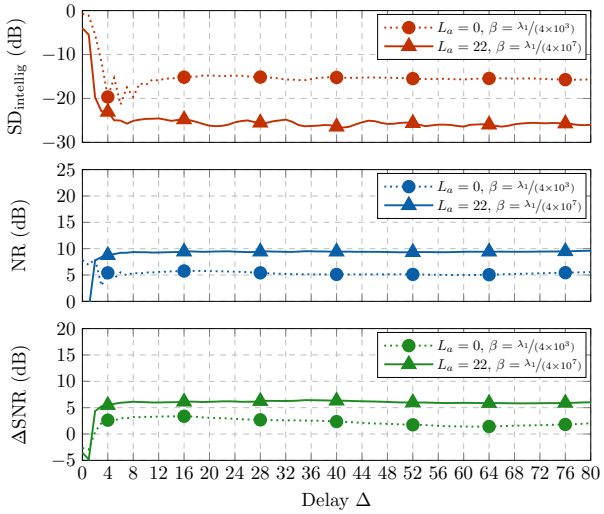

Figure 4: Speech distortion, noise reduction, and SNR improvement for the second simulation scenario for different delay Δ when $L_a = 0$, $\beta = \lambda_1/(4\times10^3)$, and when $L_a = 22$, $\beta = \lambda_1/(4\times10^7)$. In both cases, $\rho = \lambda_{\max}(\mathbf{HG}\mathbf{\Phi_{rr}}^{-1}\mathbf{G}^T\mathbf{H}^T)/(2\times10^5)$.

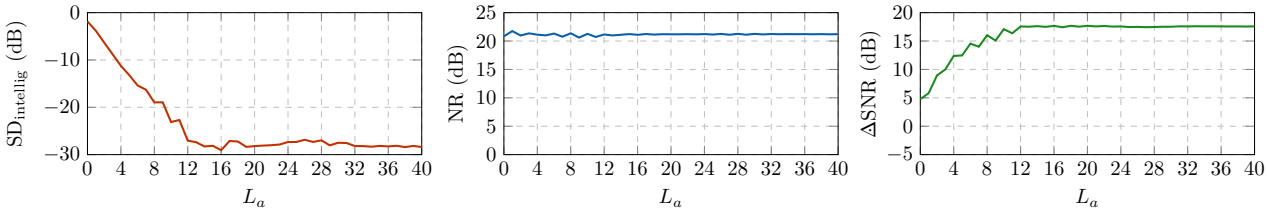

Figure 5: Speech distortion, noise reduction, and SNR improvement for the first simulation scenario for different L_a values when $\Delta = 32$, $\beta = \lambda_1/(2\times10^6)$ and $\rho = \lambda_{\max}(\mathbf{H}\mathbf{G}\mathbf{\Phi}_{\mathbf{rr}}^{-1}\mathbf{G}^{\mathcal{T}}\mathbf{H}^{\mathcal{T}})/(1\times10^5)$.

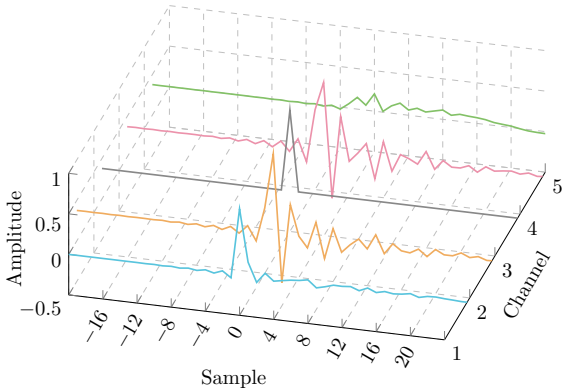

Figure 6: Acausal ReIRs for all five channels.

achieves a high level of noise reduction (21 dB), but at the cost of significant speech distortion (approximately -2 dB), resulting in an SNR improvement of just under 5 dB. In this configuration, the SSANC system fails to operate as intended and instead behaves similarly to conventional ANC, reducing both speech and noise components of the leakage. In contrast, the acausal design ($L_a = 22$) achieves much lower speech distortion (around -28 dB for most delays), maintains a similar level of noise reduction (21 dB), and delivers an SNR improvement exceeding 17 dB for most delays. Furthermore, the acausal approach yields consistent performance across varying delays, reducing the sensitivity to delay selection and thus imposing fewer constraints on the system compared to the causal design, which requires careful tuning of delay parameters.

The results for the second scenario are shown in Fig. 4. The performance reduces overall compared to the first scenario, which is expected since the scenario is much more challenging. However, the general trend remains the same. The speech distortion is reduced from about -15 dB to about -26 dB, the noise reduction increases from approximately 6 dB to around 9.5 dB, and the SNR improvement is increased from about 3 dB to about 6 dB.

4.4 Performance for different degrees of acausality

The results above show the performance for the causal design ($L_a = 0$) and one acausal design ($L_a = 22$). We now investigate the effect of different degrees of acausality, i.e., different lengths of anti-causal part L_a on performance. For this analysis, we use the first scenario and fix the delay to $\Delta = 32$ (2 ms), with $\beta = \lambda_1/(2\times10^6)$ and $\rho = \lambda_{\max}(\mathbf{H}\mathbf{G}\mathbf{\Phi}_{\mathbf{rr}}^{-1}\mathbf{G}^{\mathcal{T}}\mathbf{H}^{\mathcal{T}})/(1\times10^5)$. The results for different L_a values are shown in Fig. 5.

It can be observed that noise reduction remains consistent across all L_a values. However, speech distortion is high when L_a is small. As L_a increases, the speech distortion decreases and stabilizes when L_a reaches approximately 12. The SNR improvement follows a similar trend.

By examining the ReIRs for all five channels, as depicted in Fig. 6, it can be observed that the amplitude of the impulse responses also stabilizes around $L_a = 12$. Thus, using acausal filters to model the response from the desired source enables the SSANC system to achieve better performance than that of a purely causal design.

5. CONCLUSION

This paper has presented an improved approach to spatially selective active noise control that incorporates acausal relative impulse responses into the optimization process, leading to a substantial performance improvement over the causal optimization approach. Using a pair of open-fitting hearables in two acoustic scenarios, we demonstrated that the speech distortion under acausal optimization remains consistently lower than that of the causal optimization. Furthermore, both noise reduction and SNR improvement are significantly higher with acausal optimization. This indicates that acausal relative impulse responses offer a more accurate representation of the desired source, leading to improved noise control performance.

USING THE MASKING CURVE OF A MASKER SIGNAL TO APPROXIMATE THE SPECTRAL SHAPE OF A TARGET SPEECH SIGNAL*

Pierre Laffitte[1*] **Sankha Subhra Bhattacharjee**[1] **Jesper Rindom Jensen**[1]
Mads Græsbøll Christensen[1]
[1] **Audio Analysis Lab, Aalborg University, Denmark**

ABSTRACT

This work attempts to provide a novel look at speech privacy preservation, by proposing a solution based on sound masking as an alternative or a complement to traditional sound control and noise cancellation methods. We propose a framework for generating a masker signal whose masking curve approximates the spectral shape of the target speech to be masked. The approximation is done by Gradient Descent-based optimization, to minimize the distance between the magnitude spectrum of the target speech and the masker. The results show that the proposed algorithm exhibits the desired effect, reducing the measured annoyance when other metrics are kept constant. Although proper implementation in a real-world system is out of the scope of this paper, it serves to validate the theoretical background proposed here.

Keywords: *psychacoustic annoyance, signal masking, block processing, numerical optimization*

1. INTRODUCTION

Unwanted noise in open-plan offices, healthcare facilities, and residential spaces disrupts concentration, compromises confidentiality, and increases stress. Sound masking technology mitigates these effects by generating a low-level, unobtrusive background sound that conceals conversations and auditory distractions, enhancing privacy and acoustic comfort. It is widely applicable in both controlled sound zones and open acoustic spaces [1–6]. As an alternative, traditional noise control methods, such as active noise control [7, 8] and sound zone control [9, 10], though effective under optimal conditions, rely on precise reference signals or *a priori* information that are often impractical to obtain. In contrast, sound masking leverages the natural masking effect, where one sound renders another less perceptible, without requiring detailed information about the acoustic channels. While most studies evaluate the psychological impact of various fixed masking signals — such as white noise, pink noise, or speech-shaped noise [11] — few explore the creation of a masker tailored to the specific acoustic environment. This work focuses on generating a dynamic masker designed to optimize both privacy and listening comfort by adapting to the characteristics of the speech to be masked.

2. RELATED WORK

Research on masking sounds for privacy dates back to the 1970s [12, 13]. Early approaches often relied on predefined noise types such as white, pink, babble, or speech-shaped noise [5]. Other sounds, like nature sounds [4,6] or music [6, 14], have been explored, but pink noise remains the most common. To evaluate masker efficiency, metrics like the speech transmission index (STI) [4–6, 15] and articulation index (AI) [16] are frequently used. However, we opted for the short-time objective intelligibility (STOI) [17], designed to better handle time-frequency processing. The key premise of this work is that optimal masking requires tailoring the sound to the speech being masked. While constant noisy sounds are more efficient for masking, they are less tolerable. Psychoacoustic research re-

veals that masking is a frequency-dependent phenomenon [18]. By reducing energy in spectral regions that do not contribute to masking and ensuring enough energy where it does, we can maintain masking efficiency while minimizing annoyance. The Masking Curve [18] describes a signal's masking capability across the frequency spectrum, providing a threshold dB value for each frequency that a given signal can mask. This psychoacoustic approach forms the foundation of our method, balancing intelligibility reduction and listener comfort.

3. PROBLEM FORMULATION

We aim to mask a speech signal $x(n)$ with a masker signal $y(n)$, such that the mixture $x(n) + y(n)$ is unintelligible. To avoid trivial solutions where louder maskers provide better masking, we fix the masker energy $E_y = C$, where C is a constant determined by practical considerations (e.g., desired SNR limits). Since the speech signal $x(n)$ typically has a non-flat spectrum, the masker $y(n)$ does not need uniform energy across all frequencies to effectively mask it. The total masker energy, expressed as:

$$E_y = \sum_{-f_s/2}^{f_s/2} S_{xx}(f) \tag{1}$$

can be minimized by reducing spectral components where little or no masking energy is required. Psychoacoustic research shows that the masking effect is governed by frequency and energy [18]. A masker's energy spectral density $Y(f)$ defines its masked threshold $\nu(f)$ —the minimum energy level required to mask a signal at each frequency. To create a masker $y(n)$ that matches the target speech spectral shape, we iteratively adjust $y(n)$ to minimize the distance between $X(f)$ and $\nu(f)$: This leads to the optimization problem:

$$\min_{y(n)} (\|X(f) - \nu(f)\|)^2 \tag{2}$$

where $\nu(f)$ is nonlinearly dependent on $y(n)$ [18]. To avoid intelligibility leakage, we reset the phase to zero at each frame, simplifying the problem to spectral magnitude only. A block diagram of the process is shown in Fig. 1.

4. PROPOSED METHOD

To achieve this, we choose to generate a control signal $\epsilon(n)$ and shape its spectrum by multiplying it with a

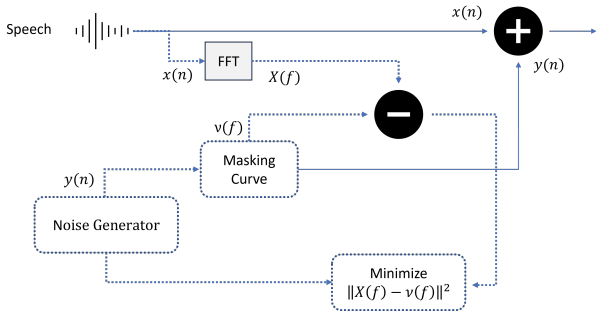

Figure 1: Optimization framework to produce a masker signal, using its masking curve to approximate the speech' spectrum. Dashed lines represents the optimization loop.

weight vector $\vec{W}$ in the frequency domain. The masking curve $\nu(f)$ then depends directly on the resulting time domain signal. The STOI and PA metrics being based on third-octave bands, we choose $\vec{W}$ to have a component along each third octave band, meaning that each filter weight represents an octave band. Our objective is to find the set of filter weights $\vec{W}$ which minimizes the distance between the target speech spectrum and the masked threshold of our masker:

$$\min_{\vec{W}} \sum_{k}^{M} (\|X_k - \nu_k\|)^2 \tag{3}$$

$\tilde{X_k}$ is the k-th third octave band amplitude of the windowed speech frame and ν_k is the masked threshold for the k-th third-octave band with M the total number of bands. When the optimization is finished, the final weight vector $\vec{W}$ is used to filter a raw masker sound, at a power determined by the pre-defined Masker to Signal Ratio (MSR).

4.1 Block processing

We use block-based processing; the target speech to be masked is windowed in the time domain, and each windowed block of signal is then analyzed in the frequency domain. The windowing process uses a classic Hanning window, e.g.,

$$\tilde{x}(x) = \omega(n)x(n) \tag{4}$$

where $\omega(n)$ is the Hanning window function, $x(n)$ the sampled input signal and $\tilde{x}(n)$ the windowed signal frame.

The Hanning window exhibits constant overlap-add property (COLA) thereby allowing reconstruction of the signal in the time-domain after frequency-domain processing [19]. Since this process is block based, each block is adjusted to the desired MSR value, resulting in a fluctuating energy, following the envelope of the input speech maskee.

4.2 Optimization

We frame the problem as an unconstrained optimization problem in which we try to minimize the error or distance between a desired variable and an estimated variable. The desired variable is defined as the speech spectrum, $X(f)$, and the estimated variable is the masking curve calculated from the produced masker, $\nu(f)$. The cost function is the l_2-norm of the difference

$$J(\mathbf{W}) = \sum_{k}^{M} (\|X_k - \nu_k\|)^2 \tag{5}$$

which for simplicity is assumed to be convex. To find a global minimum for this function, we use the gradient descent method. Since there is no closed-form solution to the derivative of our error function, we employ a numerical optimization scheme, namely the Finite Difference Method (FDM). In this method, the derivative is approximated by

$$\frac{df}{dx} = \frac{f(x+h) - f(x-h)}{2h} \tag{6}$$

following a rewriting of Taylor's first order decomposition of differentiable functions. For our cost function $J(\mathbf{W})$, this gives the following gradient computation:

$$\Delta = \frac{J(\mathbf{W} + \epsilon) - J(\mathbf{W} - \epsilon)}{2\epsilon} \tag{7}$$

The update equation for weight vector $\mathbf{W}$ is then:

$$\mathbf{W}_{i+1} = \mathbf{W}_i - l_{\text{rate}}\Delta \tag{8}$$

where l_{rate} is a hyper-parameter whose value is chosen empirically.

4.3 Smoothing filter

Once the optimal third-octave band weights are found, we design a filter whose frequency response matches these weights. Applying this filter to the raw masker sound shapes its frequency domain according to the weight values.

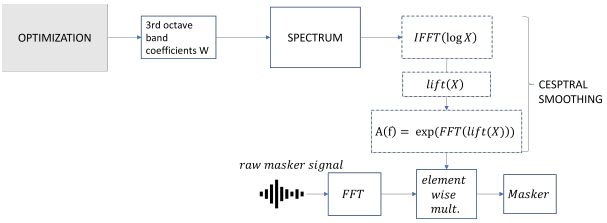

Figure 2: Cepstral windowing method used to smooth the spectrum before converting it to a filter for the raw masker sound

We call this the smoothing filter because we want to avoid a rough masking sound or one that resembles the original speech too closely, as that would compromise intelligibility. To achieve this, we transpose the weights from the third-octave basis to a linear frequency axis, take the cepstrum, and apply a "liftering" filter to retain only the slow spectral variations.

We then return to the frequency domain via the Fourier transform, taking the exponential to reverse the log transformation of the cepstrum. This produces a smoothed spectrogram, which we use to derive the filter for the raw masker sound by taking the inverse Fourier transform.

$$S(f) = \exp(FFT(w * IFFT(\log(FFT(x))))) \tag{9}$$

where w is the "lifter" (i.e. the filter), we apply to the cesptrum to only keep the first few values.

This spectral smoothing technique is called the "cepstral windowing method", for which a graphical description is given in Fig. 2 and is explained in [19].

4.4 Metrics

In this work, we rely on three metrics to evaluate the performance of our framework, which correspond to the two subjective criteria in which we are interested, namely the intelligibility of the speech and the annoyance of the noise.

4.4.1 STOI

Short-term objective intelligence (STOI) is a metric proposed to measure the objective intelligibility of a given speech signal. The subjective evaluation carried out in [17] shows that the STOI objective metric correlates with perceived annoyance. A value of STOI of 0.20 correspond

roughly to a subjective intelligibility score of less than 10%, with a correlation coefficient of 0.95. We noticed from our experimental results that the STOI function does not distinguish very well between two different maskers at low values of intelligibilities, for instance when increasing the volume of the masker. That is, the function exhibits a bit of saturation in the low range (below 0.20), while another metric such as CSII was able to make clearer distinctions between maskers. This is why we chose to also use CSII in addition to STOI.

4.4.2 CSII

Proposed to measure the intelligibility of a speech signal [20], Coherence Speech Intelligibility Index (CSII) computes speech intelligibility, by eq.(14) [20]. According to the paper's finding, a CSII value of 0.10 corresponds roughly to a subjective intelligibility score of less than 10%, with a correlation coefficient of 0.98.

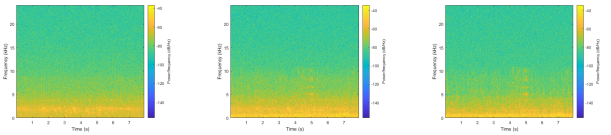
4.4.3 Annoyance

We consider the Annoyance derived in [21] to measure the degree of annoyance incurred by the masker, given by:

$$PA = N_5(1 + \sqrt{\omega_S^2 + \omega_{FR}^2}) \tag{10}$$

where $\omega_S = (S - 1.75) \times 0.25 \log(N_5 + 10)$ and $\omega_{FR} = \frac{2.18}{N_5^{0.4}}(0.4F + 0.6R)$ and the following variables are defined as follows:

- N_5 relates the perceived loudness of the signal
- S is the sharpness (in acum)
- R measures the roughness (in asper)
- F measures the fluctuation strength (in vascil)



It was shown [21] that this objective annoyance metric correlates with the perceived annoyance.

4.5 Masker signal composition

It was reported in [11] that babble noise is the least annoying type of masker when compared to white noise, pink noise, and speech-shaped noise, so we decided to use it as our masker sound. Additionally, in order to add content/energy in some parts of the spectrum, we added nature sounds to complement the babble sound, which were mostly field recordings from the forest, containing sounds of a river flowing, the rain, and birds chirping. Different combinations of raw sounds were tested, using different mixing proportions, as shown in table 1. Sound a consists of nature sounds and white noise, sound b consists of nature sounds, babble sounds and white noise, sound c consists of babble sounds and white noise, while sound d (noise) was composed of white noise only.

Table 1: Proportion of the raw sounds in the different masking sounds generated and used as input to the optimization process. 'noise' denotes white noise, 'bab' stands for babble noise and 'nat' stands for nature sounds.

sound	noise	bab.1	bab.2	bab.3	nat.1	nat.2	nat.3
a (1)	0.1	0	0	0	0.5	0.5	0.5
b (6)	0.1	0.5	0.5	0.5	0.5	0.5	0.5
c (8)	0.1	0.5	0.5	0.5	0	0	0
d (noise)	1	0	0	0	0	0	0

(a) 'a' (b) 'b' (c) 'c'

Figure 3: Spectra of 'a' (left), 'b' (center), and 'c' (right)

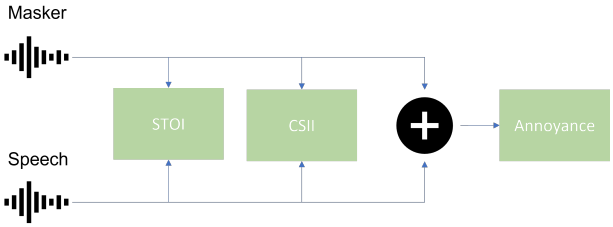


Figure 4: Experimental setup

The spectra of each of the raw masker sounds are given in fig.3; with sound 'a' at the top, sound 'b' second to top, and sound 'c' at the bottom. One can see some sonic patterns in the spectrum; at second 5, for example, between 5 kHz and 10 kHz for sounds 6 and 8. The same pattern is not visible in sound 1, however sound 'a'and sound 'b' seem to share similar content in the 1 kHz-2 kHz frequency band. Similarly, sound 'b' and 8 have similar content in the 0-1 kHz band. sound 'b' seem to be the sound sharing patterns with most other sounds, which is

confirmed by the information provided in Table1. In that sense, sound 'b' is the closest to white noise because it is the "fullest" in frequency.

5. RESULTS

This section presents the measured Intelligibility (STOI and CSII) as well as the annoyance of the masker generated by the proposed methods.

The masker and the input speech are combined to simulate the resulting acoustic signal heard in practice. Annoyance is computed on this signal, while the clean input speech and the masker are used to calculate the intelligibility metrics, as shown in Fig. 4.

All experiments were conducted with a fixed Masker to Signal Ratio (MSR) of -3 dB, meaning the masker power is adjusted at each frame according to the input speech power. This value was chosen as it produced reasonable intelligibility levels.

5.1 Hyper parameter selection

5.1.1 Window length

We tested analysis windows of 25 ms, 50 ms, 100 ms, 200 ms, and 400 ms at an MSR of -6 dB for four masker sounds (Table 1). A 100 ms window consistently provided the best balance between low annoyance and low intelligibility. At -6 dB, it produced the lowest annoyance for sounds 6 and 8, the second lowest for white noise (by only 0.3), and a mid-range value for sound 1. At -3 dB, the 100 ms window again gave competitive annoyance levels, remaining close to the lowest values across all sounds. Intelligibility variations were small at -6 dB, staying low (under 0.2 for STOI and 0.10 for CSII), except for sound 1, where the 100 ms window produced the lowest scores—both below the 10% word recognition threshold (as explained in 2). At -3 dB, the 100 ms window again yielded the lowest STOI and CSII scores for sound 1 and remained highly competitive for other sounds. These results lead us to conclude that a 100 ms window is the most suitable for our experiment.

5.1.2 Number of Cepstral Coefficients

The number of cepstral coefficients for spectral smoothing affects the signal reconstruction and thus the masker, by controlling spectrum smoothness. We tested various coefficient counts to assess their impact on intelligibility and annoyance.

Table 2: Effect of window length at MSR of -6dB.

	Sound 'a'			Sound 'b'			Sound 'c'			Noise		
Window	STOI	CSII	PA	STOI	CSII	PA	STOI	CSII	PA	STOI	CSII	PA
25ms	0.15	0.12	99.8	0.10	0.06	93.2	0.11	0.06	87.2	0.10	0.08	99.8
50ms	0.15	0.10	94.1	0.10	0.05	88.4	0.11	0.06	83.1	0.11	0.07	95.6
100ms	0.11	0.05	75.7	0.11	0.07	61.2	0.13	0.08	58.8	0.10	0.07	68.0
200ms	0.14	0.09	73.7	0.11	0.05	66.7	0.11	0.05	64.7	0.11	0.06	68.8
400ms	0.18	0.10	67.9	0.15	0.05	62.9	0.15	0.05	60.3	0.16	0.07	67.7

Table 3: Effect of window length at MSR of -3dB.

	Sound 'a'			Sound 'b'			Sound 'c'			Noise		
Window	STOI	CSII	PA	STOI	CSII	PA	STOI	CSII	PA	STOI	CSII	PA
25ms	0.27	0.45	75.0	0.16	0.13	77.8	0.17	0.13	76.6	0.21	0.36	76.5
50ms	0.18	0.18	80.4	0.16	0.12	66.2	0.16	0.12	66.4	0.18	0.26	67.5
100ms	0.14	0.10	64.8	0.15	0.12	52.1	0.18	0.17	50.6	0.15	0.14	58.1
200ms	0.17	0.14	62.6	0.14	0.09	51.7	0.15	0.08	52.6	0.15	0.11	59.5
400ms	0.24	0.14	54.9	0.25	0.19	50.4	0.24	0.14	49.8	0.23	0.21	57.6

Table 4 show the metrics for three different raw masker sounds. In most cases, intelligibility was only slightly affected, except for the CSII values for sound 'c'. The general trend is that for sounds 6 and 8, higher coefficients lead to higher intelligibility and lower annoyance. For sound 'a', intelligibility remains constant while annoyance decreases with more coefficients. In contrast, for noise, intelligibility decreases and annoyance increases with more coefficients. Based on these results, we selected 250 coefficients as a good compromise between annoyance and intelligibility.

5.2 Evaluation of the proposed optimization method

To validate our method, we evaluated its performance in different iterations to confirm that optimization improved the metrics as expected. We repeated the experiment with four masker sounds (Table1) to ensure consistency. Fig.5 shows the metric evolution for these sounds, with the origin on the x-axis representing 0 iterations (i.e., the raw masking signal as the baseline). For mixes 6, 8 and Noise, optimization decreased intelligibility (STOI and CSII), while mix 1 showed the opposite. However, annoyance decreased significantly for all cases, resulting in more agreeable maskers. This effect likely arises from the algorithm shaping the raw sound by retaining energy where speech is present and omitting regions without signal, producing a quieter and more tolerable masker. Interestingly, for three out of four sounds, the masking power diminished with optimization. We interpret this as the algorithm potentially failing to fully mask speech due to fixed window sizes or frequency-domain errors. If speech is present beyond the frame duration analyzed, it may remain un-

masked. This suggests a weaker than expected correlation between the masking curve in [17] and the actual intelligibility: Despite producing a theoretically better masker, the algorithm did not achieve lower intelligibility as anticipated.

5.3 Evaluation against the baseline

As a baseline, we measured intelligibility and annoyance metrics for a pink noise masker, used as the control signal for our optimization framework. To ensure a fair comparison, we block-processed the pink noise masker to adjust its energy according to the maskee's power, keeping the SNR constant. Fig. fig. 6 shows the metric evolution for different SNR values. To achieve a CSII of 0.5, we need an MSR of about -2.5 dB, yielding an Annoyance of around 56. The graphs also reveal that while CSII follows SNR monotonously, STOI shows discontinuities in the low-intelligibility range, suggesting saturation. For clearer comparison, Fig. 7 places the baseline and proposed method side-by-side, showing that our method consistently achieves lower annoyance for similar intelligibility at any SNR level. This confirms that our framework produces more efficient and less annoying maskers without compromising intelligibility, a highly successful outcome.

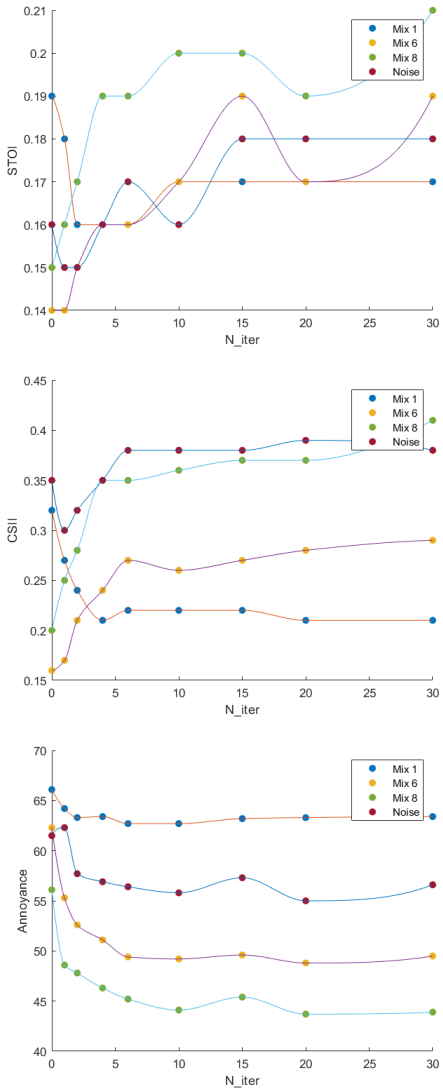

Figure 5: STOI, CSII and Annoyance metrics variation with the number of iterations, for masking sound 1

6. CONCLUSION

We have introduced a framework which optimizes the level of a masker sound at different frequency bins, in order to reduce the total energy of the masker by concentrating it only in frequency regions where it is needed. This is achieved by comparing the masking curve of the masker to the target speech maskee's spectrum, and finding a filter to shape the masker's spectrum so that the masking curve matches the maskee's spectrum. Using some intelligibility metrics as well as annoyance metrics from the literature (CSII, STOI, PA), our experimental results show that the masker signal produced by this framework exhibits lower annoyance at similar levels of intelligibility. Therefore this can find practical use in the design of masking systems for speech privacy, or at least guide the design of such systems, as used in office spaces or in cars for example.

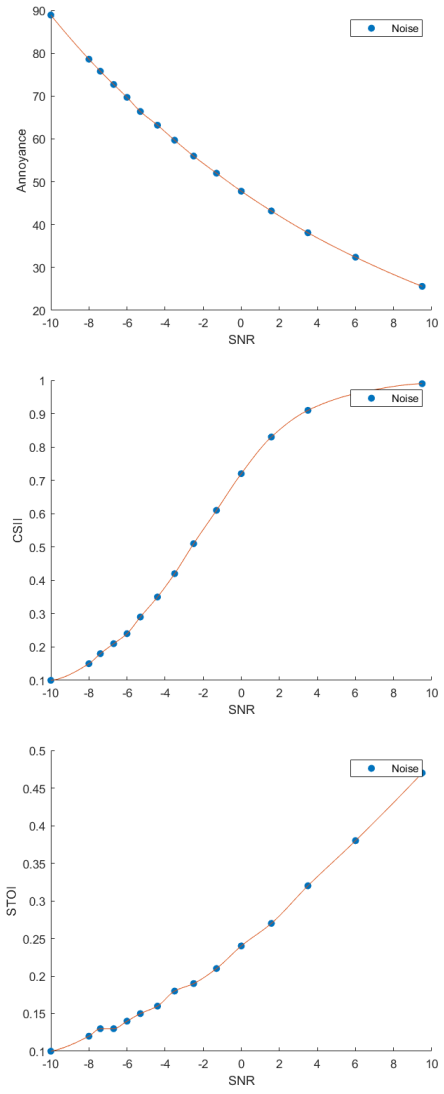

Figure 6: Evolution of STOI, CSII and Annoyance values for a pink noise masker vs. SNR.

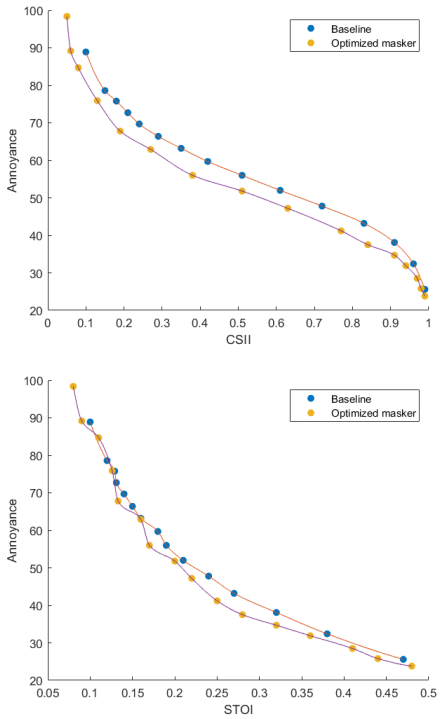

Figure 7: Comparison of baseline masker and optimized masker performance by looking at their corresponding Annoyance and SNR levels in function of CSII and STOI.

ABSTRACT

Outdoor noise outstanding at the boundaries of residential areas are perceived disagreeably and therefore managed strictly in accordance with the national or local noise ordinances. In many cases around high density urban areas, large scale solid noise barriers along residential boundaries are to intervene to lessen noise pollution downstream of road traffic, industrial facilities, or in particular, construction sites. Noise barriers are also required for power plants whose noise sources present across a broad site of plant facilities, even though they reside in suburban or low density remote areas. This study explored active noise control (ANC) against propagation of such environmental noise pollution and a way to shorten height and/or length of or even entirely replace desired physical noise barriers. A total of 4 arrays of anti-phase signal generating secondary sources in 6 test cases atop or around a 3-meter high temporary noise barrier were designed and investigated. Up to 12 secondary sources were engaged in those arrays. Noise reduction performance of their ANC schemes was evaluated at 8 locations along a distance of 20m. Multi-row arrays either on top of or lay on the barrier was found best among others. Their performance attained up to 5.6dB reduction on average.

1. INTRODUCTION

The outdoor noise mitigation measures typically applicable for environmental noise, which originates particularly in road traffic or construction sites, as well as for industrial noise call into question their effectiveness against noise propagation in the urban context. Such measures include noise barrier walls and temporary barrier panels. The noise barrier walls can be effective only on a massive solid scale. The temporary barrier panels that are commonly set up along the perimeter of a construction site in S. Korea are made of either galvanized iron within 1mm thick or recycled plastic. Two main purposes of those panels are 1) to reduce construction noise getting through; and 2) to screen the construction site from the view outside. However, the former is in fact not very practical due to their thin profile, causing lacking in sound insulation performance.

Noise barrier walls along the main roads and busy thoroughfares that are adjacent to a dense residential area are not unusual in S. Korea. Those barrier walls are employed profusely and erected higher than 10m oftentimes for high-rise residential buildings against roadway noise. If those barrier walls required to be higher than 10m, then their foundation structure shall be reinforced, increasing in construction cost. Such massive barrier walls whether transparent or not bring about many other issues: limited views and daylight at the lower floors of residential buildings; impeded air circulation across residential areas; and bird collisions. In some cases, tuned acoustic resonators are placed on top of the barrier walls to reduce diffraction of sound traveling around, escalating construction cost.

This study pioneered an active noise control (ANC) method to assist with such noise barrier walls or panels by attenuating sound waves traveling over and at the same time possibly weakening sound transmission passing through them. Eventually, it can be expected to scale down or replace a barrier structure entirely.

2. DEVELOPMENT OF ACTIVE WALL ARRAYS

Multi-row arrays of 8 to 12 anti-phase signal generating secondary sources (loudspeakers) were studied in close collaboration with the existing temporary barrier panels. Acoustic sample data acquisition and secondary path modeling were conducted to estimate the acoustic characteristics and behavior of outdoor sound propagation around the barrier panels. Based on this modeling, 4 arrays were designed atop or either side of the barrier panels and their active noise reduction performance was investigated.

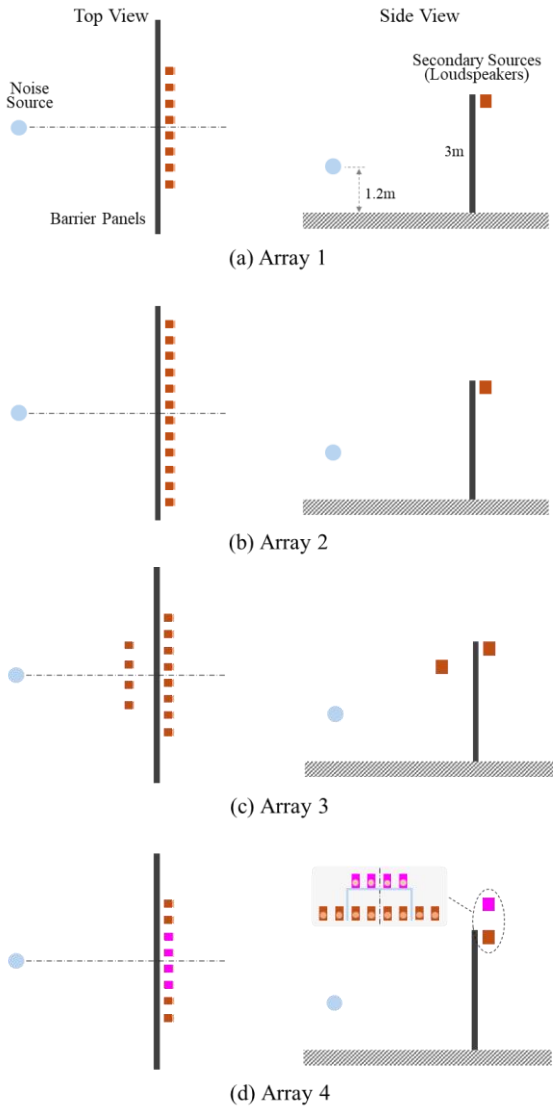

Figure 1. Active secondary source wall arrays.

Arrays 1 and 2 aligned the secondary sources along the other topside of the barrier panels against the noise source. While Array 1 accommodated 8 secondary sources, Array 2 did 12 ones. Array 3 aligned 8 secondary sources as same as Array 1 but with 4 other ones on the barrier panels facing the noise source. Array 4 employed 2 rows with 12 secondary sources on top of the barrier panels: 8 ones at the lower row and 4 ones at the upper row. See Fig. 1.

3. TEST SETTINGS AND PROCESS

3.1 Test site

The designed active secondary source wall arrays were tested at an inactive construction site, which has been no ground breaking, under free-field conditions. The site is surrounded at its boundary by 3-meter high temporary barrier panels that are made of recycled plastic. They are two-layer sandwich panels with an air cavity in a total thickness of 35mm. Each layer is 2mm thick and their sound transmission loss is unknown. See Fig. 2 and Fig.3..

3.2 Noise source

A dodecahedron omni-directional loudspeaker was used as a single point noise source. The test signal was white noise, which is a random continuous noise type that contains broadband spectrum. The noise source was set up at 1.2m high above ground and 3.5m from the barrier panels with a sound pressure level of 100dB as measured at 1m away.

3.3 Microphone settings

A number of microphones were employed for different purposes. They were assigned as reference microphones; error microphones; and observation microphones. Error microphones were designated as physical ones and virtual ones. In due course, the former remain for good with their original purpose, whereas the latter are to be removed upon tuning of a designed active noise control scheme.

A reference microphone (RM) was placed between the noise source and the secondary sources to pick up incoming signals from the noise source. Physical error microphones (PMs) were placed at the other side of the barrier panels to pick up the residual signals and increase their correlations with those at the virtual error microphones. On the other hand, virtual error microphones (VMs) were placed away in the designated active noise controlled zone or so-called quiet zone to fine-tune the perceived signals in line with those signals at the PMs. Plus, 8 observation microphones (OMs) were placed in a row at 1.6m intervals within the farthest distance of 20m for acoustic measurements.

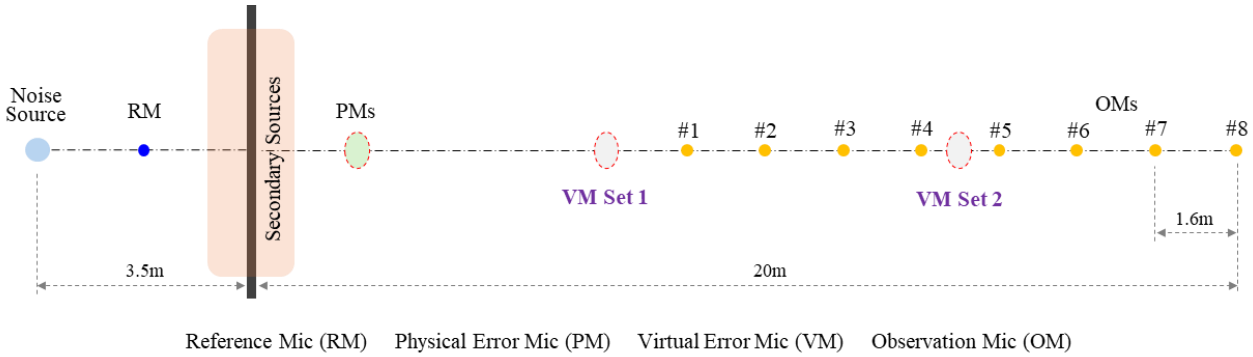

Figure 2. ANC test equipment setup plan (not to scale).

(a) At sound source side (b) At receiver side

Figure 3. ANC test setup example: Array 3.

3.4 Test method and process

A set of virtual error microphones (VMs) was placed either ahead or in the middle of the observation microphones (OMs). A total of 6 cases were tested and evaluated in combination with 4 designed active secondary source wall arrays and with those 2 locations of the VM set. Arrays 1 and 2 were evaluated only with the VM set located ahead and in the middle of the OMs respectively. Arrays 3 and 4 were done with the VM set at both locations.

Acoustic measurements of frequency-domain spectral responses up to 1kHz were carried out to evaluate noise reduction performance of the designed active secondary source wall arrays. Two measurement sets were taken for each array: one without and the other with an adaptive active noise control scheme up and running. In addition, a background noise measurement was taken for each array to review any eccentric acoustic events that might occur at the time of testing. Finally, noise reductions in dB were computed on the basis of the acoustic data obtained from the OMs.

4. TEST RESULTS

Spectral analyses were carried out across the frequency range of 30Hz through 500Hz where ANC filtering was applied. Noise reductions were computed from these analyses on the acoustic data obtained at each of the OMs and their performance by distance was examined within the designated active noise controlled zone. In addition, noise reductions of both all of 8 OMs and the last 3 OMs were tabulated on average and compared with each other. See Tab. 1.

Table 1. Summary of noise reductions on average.

Arrays	Test Cases	VM Locations		Average Reductions (dB)	
		Set 1	Set 2	Overall	End 3 OMs
1	1	●		3.0	1.6
2	2		●	4.8	5.1
3	3-1	●		4.2	3.0
	3-2		●	5.3	5.3
4	4-1	●		5.3	3.4
	4-2		●	5.6	4.6

Among the frequency range of interest, noise reduction performance was beginning to take effect from about 130Hz and it was effective up to 500Hz. Note that the designed ANC scheme performed ably between 200Hz and 450Hz but did not perform well at the lower frequencies than 130Hz. See Fig. 4. This noise reduction performance was observed broadly from most of the test cases coupled with those active secondary source wall arrays.

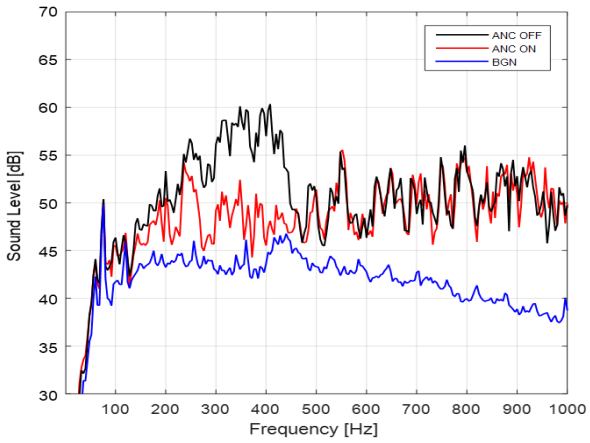

Figure 4. Spectral responses measured at the OM #6 from Test Case 3-2 with Array 3.

According to the test results of noise reduction by the active secondary source wall arrays, it is obvious that the more secondary sources are employed, the better noise reduction performance is achieved. The noise reductions of Arrays 2 through 4 which were with 12 secondary sources were 2 or 3dB higher than that of Array 1 which was with 8 ones. It appears that diffraction effect of sound decreases as the coverage by secondary sources widens either vertically or horizontally.

Next, it was found that the noise reduction performance improves as the virtual error microphones are set farther back in the active noise controlled zone. Among Arrays 3 and 4, Test Cases 3-2 and 4-2 that employed the VM Set 2 made 1 to 2dB or even more reductions than Test Cases 3-1 and 4-1 that employed the VM Set 1 except for the OMs at #1 and #2, which were the closest to VM Set 1. See Fig. 5

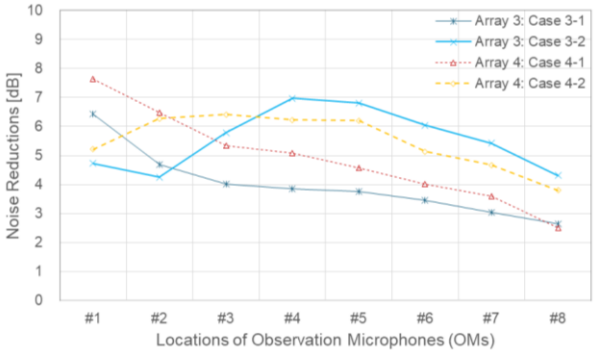

Figure 5. Noise reductions of Arrays 3 and 4 across the OMs by distance

Lastly, the noise reduction performance of Array 3 was comparable to that of either Array 2 or Array 4. Although the number of secondary sources was rather small, those residing at the sound source side of the barrier panels would come into play as the first line of active noise control directly on sound propagation from the noise source.

To summarize, for the cases of Arrays 2 through 4 tested with the VM Set 2, the overall noise reductions averaged from all of 8 OMs were 4.8, 5.3 and 5.6dB respectively and the noise reductions averaged from the last 3 OMs were 5.1, 5.3 and 4.6dB respectively.

5. CONCLUSION

The average noise reductions made by each of the active secondary source wall arrays, Arrays 2 through 4, that were equally with 12 secondary sources and tested with the VM Set 2 were shown comparable to each other in this study. Based on the overall noise reductions resulted from all of 8 measurement locations, the noise reduction performance of Array 4 appeared to be only marginally better than others. On the other hand, that of Array 3 was slightly higher if only the last 3 measurement locations were taken into account. However, it should not be suggested that Array 2 is to be considered least.

It is obvious that noise reduction performance becomes more effective as the virtual error microphones are placed as farther away from the noise source or the barrier panels back in the designated active noise controlled zone where the actual receivers reside to perceive the resulted sound. In addition, it should be noted that a set of the secondary sources accommodated near to the sound source can be of an initial role in noise reduction performance.

EMERGENCE OF INDOOR SOUNDSCAPE STUDIES FOCUSING ON NOISE MITIGATION: A BIBLIOMETRIC REVIEW

Zulfi Rachman[1*] **Francesco Aletta**[1] **Jian Kang**[1]
[1] UCL Institute for Environmental Design and Engineering, The Bartlett, University College London (UCL), Central House, 14 Upper Woburn Place, London WC1H 0NN, United Kingdom

ABSTRACT

Soundscape methodologies are increasingly recognised as effective approaches to address noise-related challenges. This study presents a bibliometric analysis of soundscape research focusing on the emerging domain of indoor soundscapes. Data were retrieved from the Scopus database using the keywords: "noise" AND ("noise barrier*" OR "noise control*" OR "noise reduction") AND "soundscape". After applying inclusion and exclusion criteria, 188 documents were selected for analysis, which included trend analysis, keyword co-occurrence mapping using VOSviewer (v1.16.19), and distribution analysis of indoor soundscape studies across different settings. Results show a notable growth in publication activity beginning in 2010. The highest number of studies was recorded in 2014 (n = 16), and citations peaked in 2016 (n = 518). Keyword analysis reveals that indoor soundscape remains an emerging topic, represented in only three papers (5.4%), mostly linked to terms such as "health" and "well-being" without a direct connection to "soundscape" as the central term. Further analysis identified 23 studies directly addressing indoor soundscapes, with open-plan offices being the most underrepresented setting, with only one study, followed by commercial spaces (e.g., retail shops, restaurants, cafes), with two studies.

Keywords: *Indoor soundscape, Indoor Acoustic Research, Noise control, Bibliometric analysis, soundscape research trends*

1. INTRODUCTION

Noise is considered one of the most widespread environmental pollutants, with the World Health Organization (WHO) and European Environment Agency (EEA) identifying it as a significant public health concern [1]. Exposure to community noise has been associated with hearing discomfort, cardiovascular issues, sleep disruption, reduced cognitive and work performance, and increased annoyance [2]. Traditional noise management in buildings has focused mainly on airborne and structural noise transmitted through building elements or generated by activities and operations within the building [3], with treatment approaches primarily aimed at reducing or isolating noise through physical interventions and active noise control systems.

Various standardised methods are available to evaluate noise reduction or isolation performance, such as sound absorption coefficient, transmission loss, sound transmission class, weighted sound reduction index, and weighted normalised impact sound pressure level [4], [5], [6], [7]. However, researchers have long questioned whether these objective parameters adequately reflect human perception of acoustic comfort [3]. This gap has prompted a shift towards more holistic, user-centred approaches to acoustic design, notably the soundscape approach.

Within this context, the present study is conducted as part of the INNOVA Doctoral Network, a collaborative research initiative that addresses noise challenges in encapsulated structures. This doctoral project, titled *"Noise Barriers with a Soundscape Approach,"* aims to extend the traditional concept of noise barriers by integrating soundscape principles with a focus on indoor applications. Rather than treating noise barriers solely as physical structures that block sound propagation, this project adopts a soundscape perspective to explore broader strategies that not only

reduce noise but also enhance how users perceive and experience the acoustic environment [8].

The soundscape concept bridges the divide between physical measurements and subjective experience by considering the perceptual and contextual dimensions of sound [9]. Defined by ISO 12913 as the *"acoustic environment as perceived or experienced and/or understood by a person or people, in context* [10]*,"* soundscape studies integrate both objective measurements and subjective evaluations [10], [11], [12]. This approach recognises that the impact of sound is not solely determined by its intensity but also by how listeners interpret and appraise it.

Over the past two decades, soundscape research has marked a significant shift in environmental acoustics, extending beyond traditional noise control engineering [13]. While early studies focused on urban and outdoor settings, recent years have seen growing interest in indoor soundscapes to address perceived acoustic quality in interior environments [3].

To explore the positioning of this emerging area, the present study conducts a bibliometric review of soundscape research applied to address noise-related challenges. The review includes a trend analysis to examine how the focus of publications has evolved over time, a keyword co-occurrence mapping to identify recurring concepts and relationships between research topics, and a distribution analysis to investigate how indoor soundscape studies are represented across different settings.

2. METHODS

This study employed a literature search to identify relevant publications for inclusion in the bibliometric review. All records were retrieved from the Scopus database using the following search query:

"noise" AND "noise barrier*" OR "noise control*" OR "noise reduction" AND "soundscape"

The search was conducted on January 28, 2025, resulting in an initial dataset of 264 documents. Subsequently, preliminary filtering was applied directly within Scopus by limiting the results based on subject area, document type, and language, which reduced the dataset to 199 documents. Further screening was performed by reviewing the titles and abstracts to assess their relevance, specifically focusing on studies addressing soundscape and noise control. After this screening process, 188 documents were identified and selected for inclusion in the bibliometric analysis. The document selection process is illustrated in Figure 1.

The dataset was manually analysed to identify trends and examine indoor soundscape studies across various settings. A keyword co-occurrence analysis was performed using VOSviewer (version 1.16.19) to visualise the network of authors' keywords. The full counting method was applied, where each keyword occurrence was counted equally. A minimum threshold of three keyword occurrences was set to refine the analysis and focus on the most significant terms. This approach produced a keywords network map highlighting the selected authors' keyword relationships and research clusters.

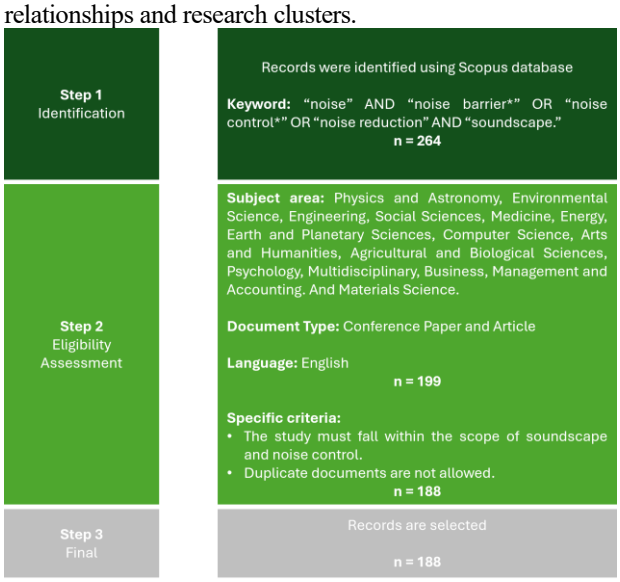

Figure 1. Study selection process

3. RESULTS AND DISCUSSIONS

This section presents and discusses the results of the bibliometric analysis, highlighting key trends, research clusters, and the distribution of indoor soundscape studies across various settings. These findings offer insights into the evolution and current state of research in the field.

3.1 Trends in Studies and Citations Over Time

The trend of soundscape research addressing noise issues shows a gradual increase in studies and citations over time, as illustrated in Figure 2. Early activity was limited, with only a few publications in the 1990s and early 2000s—for instance, just two studies appeared in 1993, and some years, such as 2001 and 2006, recorded only a single study.

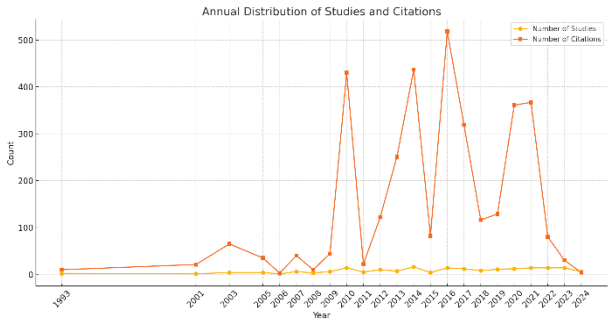

Figure 2. Annual distribution of studies and citations in soundscape and noise control research.

A noticeable rise began around 2010, when the number of studies reached 14, accompanied by 430 citations, marking a turning point in research interest. This upward trend continued, with 2014 standing out as the year with the highest number of studies (n=16) and 437 citations, indicating increased productivity and strong academic attention. The peak in citations occurred in 2016, with 518 citations across 14 studies, suggesting the presence of influential works that gained wide recognition.

The years 2017 to 2021 showed consistent research activity, with publication counts ranging from 12 to 14 studies per year and high citation levels, maintaining the visibility of the field. However, a decline is observed in the most recent data: while in 2023 sustained high output with 14 studies, citation counts dropped to 30, and in 2024, the number of studies decreased sharply to 6, with only four citations. This drop may reflect the limited time for newer publications to accumulate citations and the possibility that many 2024 studies have yet to be indexed or published.

3.2 Keyword Co-occurrence Analysis

This section presents a keyword co-occurrence analysis to explore the relationship between authors' keywords in soundscape research addressing noise issues. The analysis helps identify central themes, research clusters, and potential gaps in existing literature.

Figure 3 illustrates the network visualisation of each cluster, distinguished by colour coding. The colours used include red, green, blue, yellow, purple, light blue, orange, brown, and pink. In the keyword co-occurrence network, coloured circles represent individual keywords, with their node size corresponding to their frequency of occurrence. Keywords with higher frequencies appear with larger text and circles [14]. The bibliometric mapping of studies addressing noise challenges and innovative soundscape approaches yielded ten clusters, as shown in Table 1.

The central node, "soundscape", is the most frequently occurring term, underscoring its centrality in the analysed research. Closely related terms such as "noise", "environmental noise", "health", and "noise control" are prominently connected, reflecting their strong relevance to the field. Table 1 shows that the cluster with the fewest cluster occurrences is Cluster 9. However, its close proximity to the central node suggests that, despite its lower frequency, it holds significant conceptual relevance [15].

The next smallest is Cluster 7, whose relative distance "soundscape" highlights its position within an emerging subfield of soundscape research—distinct from outdoor or urban studies. This cluster centres on subjective evaluations, linking annoyance to perception and connecting health and well-being to environmental noise and control strategies. Notably, the keyword "indoor soundscape" is not directly linked to "soundscape" but instead connected through "health" and "well-being". This indirect pathway suggests a conceptual gap, indicating that indoor soundscape research has yet to be fully integrated into the broader soundscape discourse. Addressing this gap could help establish more holistic frameworks for designing health-supportive acoustic environments, particularly in indoor settings.

While limited in number, the three studies identified within the "indoor soundscape" theme provide valuable insights into how indoor soundscapes are perceived and evaluated. These works employ different methodological approaches—from experimental setups to qualitative inquiry and interventions using materials and active noise control—but share a common emphasis on subjective perception, acoustic comfort, and well-being.

- Lam, Bhan, et al. (2023) conducted an experimental study to assess the effectiveness of an anti-noise window using Active Noise Control (ANC) and biophilic maskers (birdsong and water sounds) in naturally ventilated urban dwellings. The findings revealed that ANC significantly reduced perceived loudness and annoyance, even with minimal objective sound level reduction. The addition of birdsong was more effective than water in further reducing annoyance, and perceptual metrics better predicted subjective comfort than by physical acoustic data alone [16].

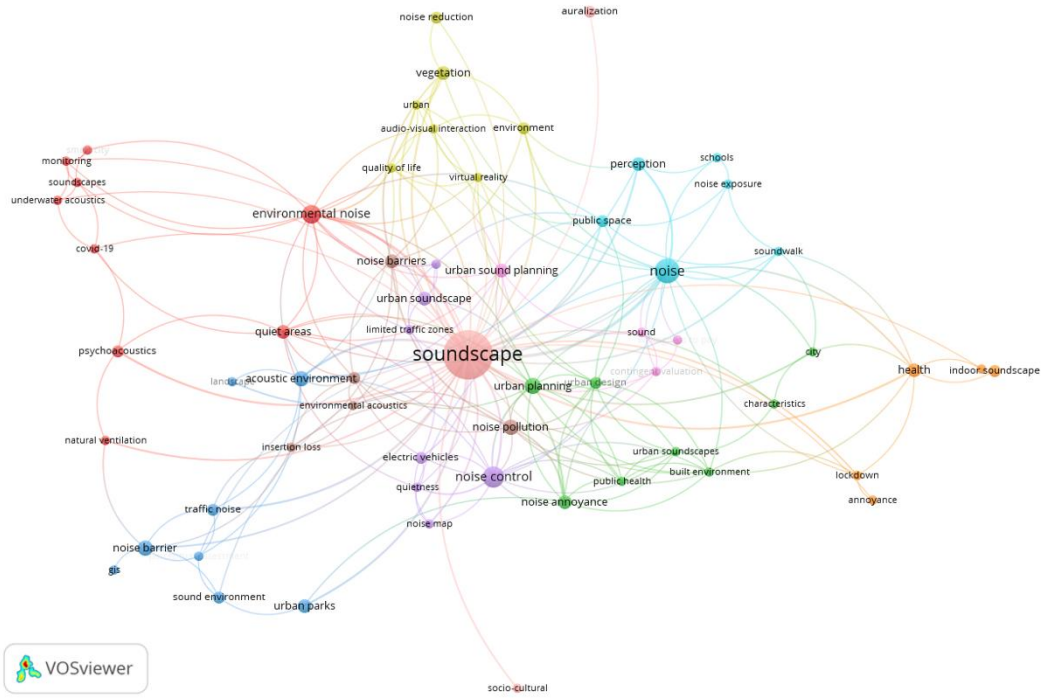

Figure 3. Keywords Network Visualisation

Table 1. Keyword Clusters Identified from Co-occurrence Analysis

Cluster	Keywords	Occurrence (%)
Cluster 1	covid-19, environmental noise, monitoring, natural ventilation, psychoacoustics, quiet areas, smart city, soundscapes, underwater acoustics	11.3%
Cluster 2	built environment, characteristics, city, noise annoyance, public health, urban design, urban planning, urban soundscapes	9.6%
Cluster 3	acoustic environment, GIS, landscape, noise barrier, perceptual assessment, sound environment, traffic noise, urban parks	10.4%
Cluster 4	audio-visual interaction, environment, noise reduction, quality of life, urban, vegetation, virtual reality	7.5%
Cluster 5	electric vehicles, limited traffic zones, noise control, noise map, noise perception, quietness, urban soundscape	10.4%
Cluster 6	noise, noise exposure, perception, public space, schools, soundwalk	10.8%
Cluster 7	annoyance, health, indoor soundscape, lockdown, well-being	5.4%
Cluster 8	environmental acoustics, insertion loss, noise barriers, noise pollution, soundscape design	6.7%
Cluster 9	contingent valuation, sound, urban sound planning, willingness to pay	4.2%
Cluster 10	auralization, socio-cultural, soundscape	23.8%

- Torresin, Simone, et al. (2020) employed a qualitative approach, using expert interviews to explore how user-centred acoustic design can enhance well-being in buildings. Their study identified perceptual dimensions of indoor soundscapes—spanning acoustic, visual, and thermal domains—and promoted the integration of soundscape-based methods into Post-Occupancy Evaluation (POE). They advocated a shift from noise elimination toward strategies that enhance positive sound experiences and increase user agency [17].
- Li, Feng, et al. (2022) presented a case study examining ceramic passive amplifiers as a design-based strategy for improving indoor soundscapes. Their results showed that these amplifiers enhanced pleasant sounds and contributed to multisensory comfort by combining visual and tactile elements. The study highlights that acoustic comfort improvements were influenced by sound level reduction, aesthetic coherence, and emotional resonance [18].

Collectively, these studies underscore the multidimensional nature of indoor soundscape research, demonstrating that soundscape quality is shaped not only by objective acoustic parameters but also by contextual, perceptual, and affective factors. This growing body of work supports the development of soundscape assessment frameworks that integrate both quantitative acoustic data and qualitative user experience—advancing more human-centred approaches to indoor acoustic design.

3.3 Distribution of Indoor Soundscape Studies Across Different Settings

A secondary screening was conducted from the 188 studies included in the main analysis to further understand the contextual scope of indoor soundscape research. This step involved selecting studies whose content directly addressed indoor soundscapes, resulting in 23 studies.

Figure 4 displays the distribution of these 23 studies across different indoor settings. The most commonly identified category was general indoor setting (n = 5), which includes studies that explored indoor soundscapes without specifying a particular type of space.

This is followed by residential, educational settings (e.g., schools, universities, libraries), and vehicle-related environments, each with four studies. The hospital category accounts for three studies, while commercial spaces (such as retail shops, restaurants, or cafés) are represented by two studies. Open-plan offices were the least represented, with only one study included. Further exploration of existing soundscape assessments and the factors involved has been conducted through a systematic review carried out by the authors [19].

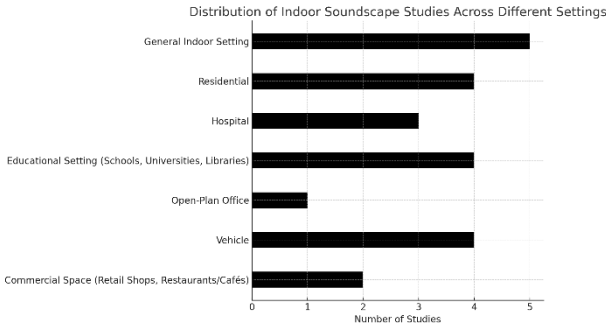

Figure 4. Distribution of Indoor Soundscape Studies Across Different Settings.

The distribution indicates that indoor soundscape research has been applied across various settings with varying degrees of attention. While some environments have received more focus, others—particularly office and commercial spaces—appear underexplored in the existing literature. This suggests potential directions for future research, especially in contexts where sound environments may significantly influence user experience and activity.

4. CONCLUSION

This bibliometric review examined indoor soundscape as an emerging topic in soundscape research, increasingly recognised for its potential to address noise-related issues. Research trends show a notable rise in interest beginning around 2010, marked by an increase in both publications and citations (n = 14 studies, 430 citations). Research productivity peaked in 2014 with 16 studies and 437 citations, while 2016 recorded the highest citation count, with 518 citations across 14 studies. From 2017 onward, research activity remained steady. However, a noticeable decline was observed in 2023, when citations dropped to 30 despite a consistent output of 14 studies. In 2024, the number of publications and citations further declined (n = 6 studies, 4 citations). This decrease may reflect the limited time for newer studies to gain recognition or delays in indexing.

Keyword occurrence analysis further confirms the status of indoor soundscape as an emerging area. The term appeared in Cluster 7 alongside annoyance, health, and well-being, with the second-lowest occurrence rate (5.4%). The “indoor soundscape” node was not directly linked to

the central "soundscape" node but connected through health and well-being. This suggests a conceptual gap and indicates that this area has yet to integrate into the broader soundscape discourse fully. Only three documents represented this node, emphasising the multidimensional nature of indoor soundscape research, which considers both acoustic parameters and contextual, perceptual, and affective factors.

Finally, the distribution of indoor soundscape studies across settings reveals limited exploration in open-plan offices and commercial spaces, represented by only one and two studies. This highlights a research gap and the need for further investigation in these underrepresented environments.

ABSTRACT

Environmental noise can harm people's health, leading to issues such as hearing loss, increased stress levels, and reduced overall well-being. This noise pollution is a growing concern in urban environments, where constant exposure to sounds from traffic, construction, and other sources can create an uncomfortable living situation. We can implement active sound control techniques to address these challenges, which offer a promising solution to reduce unwanted noise. This method uses loudspeakers to change the sound in an area and create a specific sound field. However, real-time active sound control is challenging. There are limitations based on where we place microphones and loudspeakers and how we select sound sources to create a comfortable environment for users. This paper presents a user-selective active sound seat that addresses these design challenges. This seating solution combines the principles of active sound control with advanced techniques derived from the Auditory Scene Analysis framework. These techniques help separate individual sound sources from a mix by analyzing the position and characteristics of different sounds in a room. As a result, users of the active sound seat can selectively mask unwanted sounds in their vicinity.

1. INTRODUCTION

Active Sound Control (ASC) is an acoustic technology that manipulates sound waves using secondary sources (loudspeakers) to shape the acoustic environment. A key application of ASC is Active Noise Control (ANC), where the system generates a sound field that destructively interferes with unwanted noise, effectively reducing it. Beyond noise reduction, ASC can also enhance auditory experiences, such as through spatial audio reproduction and zonal sound control [1, 2]. These capabilities allow ASC to suppress noise and selectively amplify or modify specific sound fields, improving sound quality in complex environments. In automotive applications, ASC technologies are increasingly used to reduce in-cabin noise and enrich the driving experience through powertrain sound enhancement or infotainment features [3].

A key enabler of such user-focused ASC systems is Auditory Scene Analysis (ASA), a perceptual process by which the human auditory system separates and identifies individual sound sources in a complex acoustic environment [4]. ASA helps us understand and focus on specific sounds even in noisy surroundings [5] but selectively listening to different sounds in an acoustic mixture remains a challenge in machine hearing [6]. Spatial cues, such as interaural time and level differences, play a crucial role in localizing sound sources—analogous to how microphone arrays can be used in machines to separate overlapping sources based on spatial filtering [7].

Spatial filtering techniques like beamforming are widely used for sound source separation. Traditional beamformers focus on sounds from a specific direction, but modern implementations must address more complex environments with reverberation and multiple sources. In

this broader context, beamformers are viewed as multiple-input single-output systems that combine spatially filtered microphone signals to enhance desired sources and suppress interference [8]. Recent advancements incorporate neural networks (NNs) to estimate beamforming parameters or directly predict filter coefficients [9–11]. Some architectures combine NNs with traditional spatial filters [12–14], followed by post-filtering stages for further enhancement [15, 16].

After separating sound sources using ASA-inspired techniques, ANC is applied to suppress unwanted noise and maintain an ambient acoustic environment around the listener. Among various ANC algorithms, the Filtered-X Least Mean Square (FxLMS) algorithm is favored for its simplicity and real-time adaptability [17–19]. Most real-time ANC systems use the FxLMS algorithm or its modifications [20–24] due to its proven effectiveness. In recent years, many researchers and engineers have chosen the Speedgoat platform to implement and test different acoustic models. Speedgoat supports machine-in-the-loop experiments, real-time simulation, and control validation under dynamic conditions [25, 26].

This work presents a real-time implementation of a user-selective Active Sound Control (ASC) seat that integrates Auditory Scene Analysis (ASA) principles. An NN-based spatial filtering system separates sound sources captured via a microphone array. After sound separation, a multi-channel FxLMS ANC system actively cancels unwanted noise around a selected user. The system is implemented and tested on the Speedgoat platform to validate performance under real-time conditions and ensure a targeted acoustic response around the seat.

2. METHODOLOGY

2.1 Multi-channel Active Noise Control System

The proposed system is based on a generic multi-channel Active Noise Control (ANC) framework consisting of I reference signals, J secondary sources, and K error sensors. The adaptive filtering approach used in this system follows the MultiChannel Filtered-X Least Mean Squares (MFXLMS) algorithm [27], which is detailed as follows.

The adaptive filter output at the j-th secondary source is expressed as:

$$\mathbf{y}_j(n) = \sum_{i=1}^{I} \mathbf{w}_{ji}^T(n)\mathbf{x}_i(n)\,. \tag{1}$$

The adaptive filter coefficient vector is given by:

$$\mathbf{w}_{ji}(n) = [w_{ji,0}(n), w_{ji,1}(n), \ldots, w_{ji,N-1}(n)]^T\,, \tag{2}$$

where N is the number of filter coefficients.

The input tap vector is defined as:

$$\mathbf{x}_i(n) = [\mathbf{x}_i(n), \mathbf{x}_i(n-1), \ldots, \mathbf{x}_i(n-N+1)]^T\,. \tag{3}$$

The update equation for the adaptive filter coefficients is given by:

$$\mathbf{w}_{ji}(n) = \mathbf{w}_{ji}(n-1) + \mu \sum_{k=1}^{N} e_k(n)(\hat{\mathbf{S}}_{kj}(n) * \mathbf{x}_i(n))\,. \tag{4}$$

Here, $\hat{\mathbf{S}}_{kj}(n)$ represents the estimated secondary path between the kth error sensor and the jth secondary source.

For example, a 2×2 MFXLMS system block diagram is shown in Figure 1. The proposed control system consists of two main modules: an **ASA Module** and an **ANC Module**. Both modules work together to create a personalized acoustic environment by suppressing unwanted noise while preserving desirable sounds such as music, alarms, and voice alerts.

The ANC module implements real-time noise cancellation using the MFXLMS algorithm. It operates on a sample-by-sample basis to minimize the error signal at the error microphones, thereby ensuring an ambient acoustic zone around the user.

2.2 Auditory Scene Analysis and Source Separation

The system must first isolate desired and undesired sound sources to enable user-selective noise cancellation. This separation is accomplished using a *Filter-and-Sum Beamformer* (FASB) [28], which enhances signals originating from a particular direction while suppressing others.

The FASB beamformer processes the signals captured by an array of microphones as follows:

- The beamformer individually filters each microphone signal.
- The filtered signals are then summed to generate a reference signal representing the selected noise source.

This reference signal is fed into the ANC system to cancel user-specified noises selectively.

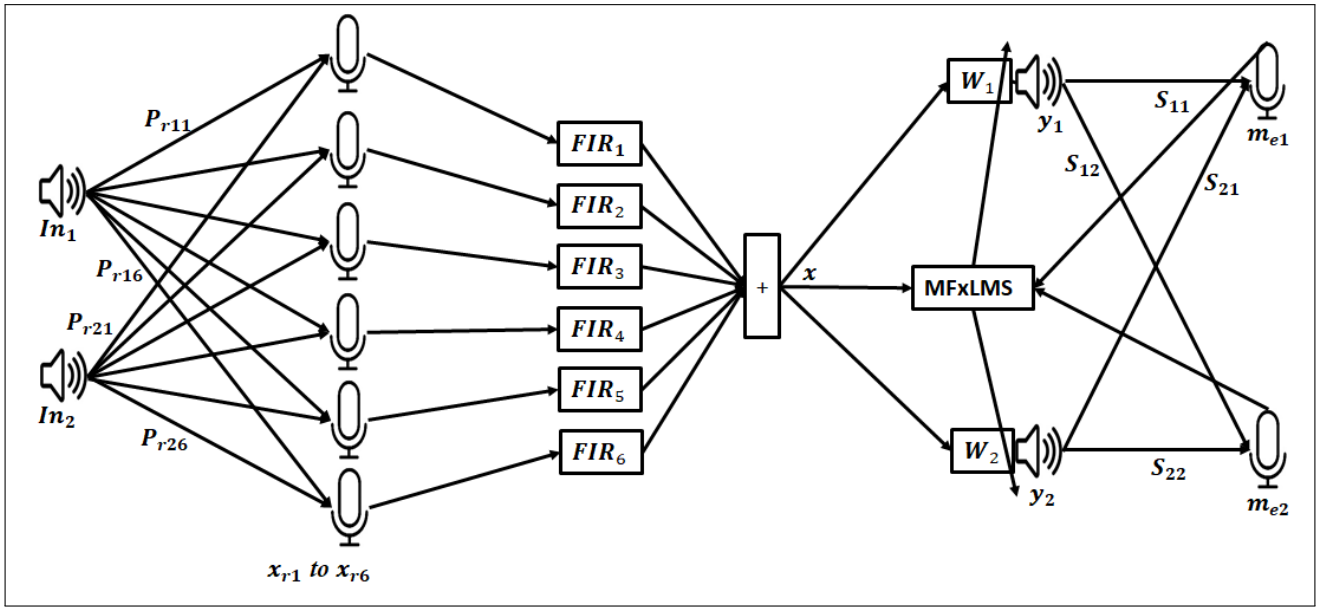

Figure 1. A block diagram illustrating an example of ASA with multichannel ANC system.

2.3 Neural Network-Based Beamformer Optimization

The beamformer filters are designed using an NN to optimize spatial filtering performance. The objective is to extract a single target sound source while suppressing others.

Consider an experimental setup with two independent sound sources located at different positions. The signals captured by the microphone array can be expressed as:

$$x_{rm}[n] = In_1[n] * \mathbf{P}_{r1m} + In_2[n] * \mathbf{P}_{r2m}\,, \quad (5)$$

where $\mathbf{P}_{rim}$ represents the acoustic path between the i-th source and the m-th microphone and $In_i[n]$ defines the primary signals at time instant n.

The signals from all microphones are linearly combined using a set of beamformer filters to extract the target source:

$$x[n] = \sum_{m=1}^{M} x_{rm}[n] * \mathbf{h}_m\,. \quad (6)$$

Here, $\mathbf{h}_m$ are the beamformer filter coefficients to be optimized.

The ideal objective is to recover only the target signal, i.e.,

$$x[n] = In_1[n]\,. \quad (7)$$

However, direct inversion of the acoustic propagation paths is highly complex. Instead, a relaxed objective is defined as:

$$x[n] = In_1[n] * \mathbf{P}_{r1m}\,. \quad (8)$$

This relaxed objective avoids the need for deconvolution while still achieving effective separation.

A neural network model is used to optimize the beamforming filters. The NN takes as input the raw signals from multiple microphones and processes them through a set of 1D convolutional layers. The outputs of these filters are summed to generate the beamformed signal.

The loss function used for training is the Mean Squared Error (MSE) between the network's output and the desired reference signal:

$$\mathcal{L} = \frac{1}{T}\sum_{n=1}^{T}\left(x[n] - In_1[n] * \mathbf{P}_{r1m}\right)^2\,. \quad (9)$$

The neural network learns optimal beamformer filter coefficients that maximize target source extraction by minimizing this loss function.

2.4 Real-Time Implementation on Speedgoat

The system, including the ASA-based source separation and MFXLMS-based ANC, is deployed in real time using

the Speedgoat rapid control prototyping platform. Speedgoat allows for hardware-in-the-loop testing and real-time validation of the proposed algorithm under practical conditions.

The real-time implementation involves:

- Estimating multi-microphone acoustic paths $\mathbf{P}_{rim}$ to perform the offline design of beamformers using the trained neural network.
- Extracting the selected noise source using the designed beamformers and feeding it into the ANC system.
- Applying the MFXLMS algorithm to generate anti-noise signals in real time.
- Continuously adapting the ANC system to changing acoustic conditions to ensure effective noise suppression.

3. EXPERIMENTAL RESULTS

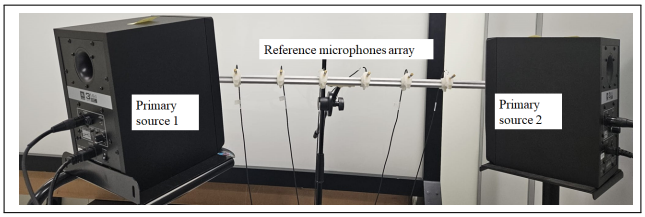

Figure 2. An array of six reference microphones for sound source separation.

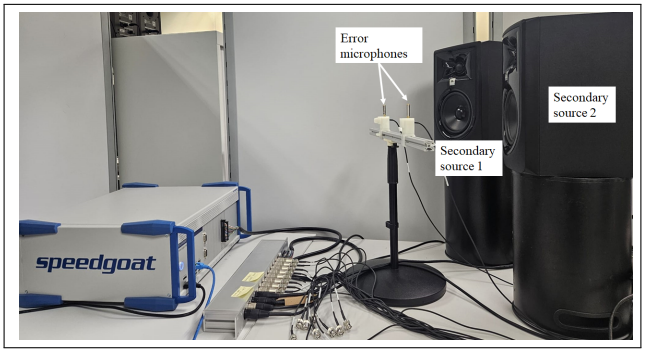

Figure 3. Control Area of the real time implementation.

This experiment utilized two primary sources to generate white noise and speech signals, where white noise was regarded as an undesired signal. An array of six microphones served as reference microphones (see Figure 2). The beamformers filtered the signals from these microphones to create a reference signal that represented the chosen noise source. In the control area, two secondary sources and two error microphones were employed to achieve user-selective Active Sound Control (ASC) at the car seat (see Figure 3).

The real-time experiments were conducted in three stages to assess the performance of the proposed ASA system, Only speech playing (Baseline Measurement): This scenario establishes a reference for clean speech signals without interference.

- Only speech playing (Baseline Measurement): This scenario establishes a reference for clean speech signals without interference.
- Speech and noise playing, ANC off: This represents a real-world noisy environment where the desired speech signal is masked by background noise.
- Speech and noise playing, ANC on: The ANC system is activated to suppress undesired noise while preserving the speech signal.

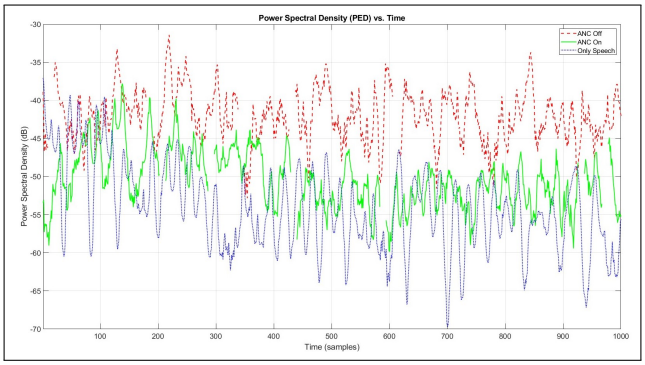

Figure 4. Power Spectral Density (PSD) of the signal at the error position with the ANC system Off, On, and with only a speech signal.

The measured signals from the error microphone in these scenarios are visualized in Figure 4. The dashed line represents when ANC is turned off, showing higher power spectral density due to noise. The dotted line corresponds to the clean speech signal without noise as a reference for ideal speech quality. The solid line represents the scenario with ANC enabled, illustrating the noise

reduction. In the ANC off condition, the noise significantly raises the power spectral density across the frequency spectrum, confirming that speech intelligibility is negatively impacted. When ANC is activated, there is a noticeable reduction in noise levels, as seen by the decrease in power spectral density (solid line curve compared to dash line). This demonstrates that the ANC system effectively reduces unwanted noise while preserving the desired speech signal.

4. CONCLUSION

The experimental results confirm that the proposed Active Sound Amplification (ASA) system significantly improves the acoustic environment by reducing unwanted noise while preserving desired sounds. The offline neural network processing used to obtain beamformer information simplifies the ASA, making it less computationally demanding for real-time implementation. This design makes ASA a promising solution for applications that require personalized sound zones, such as in-vehicle communication or selective noise control in shared spaces. However, some residual noise is still present even when active noise cancellation (ANC) is activated. This suggests that while the ASA-based sound separation performs well, further refinements in spatial filtering or active noise cancellation could enhance its effectiveness.

5. ACKNOWLEDGEMENTS

This project is supported by Horizon Europe Marie Skłodowska-Curie Actions (MSCA) Doctoral Net-work under the European Union's funding scheme. The project title is 'Active reduction of noise transmitted into and from enclosures through encapsulated structures' and is identified by project number 101073037.

ABSTRACT

Acoustic barriers are structures used to block or reduce noise propagation, improving people's quality of life. Barriers installed to mitigate traffic noise traditionally consist of continuously installed acoustic panels. In contrast, this work proposes the development of a directional barrier consisting of discrete cylindrical elements of stepped height distributed in the form of a sonic crystal. The barrier is designed to suppress transversely especially the frequency of 1000 Hz, the frequency at which the sound peak of rolling noise occurs. In order to test the sound effect of this barrier, numerical simulations of acoustic propagation are performed using FEM/BEM. The final objective aims to develop a sound barrier for application in urban environments that fulfils a dual application: mitigating noise pollution, but allowing a certain directivity of the noise from the transit of a vehicle to act as an acoustic warning element for pedestrians.

Keywords: *noise barrier, tyre road noise, sonic crystal, electric vehicle, traffic noise.*

1. INTRODUCTION

Noise emission generated by road traffic is one of the main sources of noise in urban and interurban environments. The noise emitted by a vehicle is generated by different sub-sources, commonly grouped into three categories: noise generated by the engine and traction system, noise produced by the interaction between tyre and road surface -tyre/road noise-, and aerodynamic noise. The gradual introduction of hybrid-electric and pure electric vehicles in road traffic can contribute to improving noise environments in cities by reducing engine noise, whereas tyre/road noise emission remains. However, the low detectability of the new generation of vehicles, mainly at low speeds - i.e. sound pressure levels below 56 dB at 10 km/h [1] - is of great concern for the most vulnerable groups [2] such as pedestrians, especially children and elderly people and people with blindness or low vision [3], cyclists or scooter users, as well as drivers of other vehicles [4]. Therefore, the coexistence of both types of vehicles (ICE vehicles and electric vehicles) will require technical solutions that allow adequate noise control in urban environments.

The use of acoustic barriers as a corrective measure for noise generated by road traffic has been used for decades [5-7]. Classical noise barriers, understood as continuous flat elements whose noise control mechanism is mainly based on reflection, have a series of drawbacks, some of which are caused precisely by the reflected sound [8,9]. This has led to the evolution of barrier designs through different solutions, either based on their material composition with the incorporation of absorbent materials, or based on their geometric definition with the inclusion of elements that disperse the reflected sound, for example through the use of sonic crystals [10,11].

Sonic crystals are materials formed by a regular distribution of repeated basic elements that allow the waves impinging on them with a certain frequency to suffer a destructive interference. Currently, the optimization of this type of materials is focused on different lines [12], such as the inclusion of resonances within their elements to analyze the interaction of both phenomena [13-15], the design of the geometry of the section of the discrete elements that form

the barrier [16-18], the configuration of the position of the elements within the barrier [19-21], the composition of the materials of the elements that form the barrier [22-25], or the height of the elements [26].

The diffraction of sound waves that occurs at the upper edge of the barriers is one of the main factors that reduce their performance, and one of the main lines of work in the optimization of classical barriers [8]. However, this aspect has also been considered in other barrier proposals, such as in [27] where the effect of diffraction at the edge of a sonic crystal-based barrier was analyzed, observing the possibility of varying its attenuation level by modifying the design of the upper edge of the barrier. In [28] the effect of diffraction was also considered, working with a barrier design based on sonic crystals made up of nested elements.

Therefore, this paper presents a preliminary study of a low height stepped directional acoustic barrier (SDAB) system. The purpose of the design of this barrier is to create an interference in the propagation of sound in the transverse direction, but at the same time to allow sound transmission at a certain angle in both the horizontal and vertical planes. Thus, the stepped directional acoustic barrier SDAB is based on a two-dimensional sonic crystal of circular elements of 0.125 m diameter arranged as a three-row square Bravais grid. Each of these rows has been assigned a different height: 0.4, 0.7 and 1 m. In this way, a three-dimensional barrier of staggered cylindrical elements has been achieved, where the elements with the lowest height are located on the emitter's side. The barrier is designed to mainly block the propagation of the 1000 Hz frequency in its transverse direction, the frequency at which the highest peak sound energy is produced in the tyre/road noise emission. Given that the rolling sound emission occurs at a very low height, hence the low height of the barrier elements. The grid parameter “a” has been set according to Bragg's law at 0.17 m, as half the wavelength of the interest frequency transmitted by the air.

The study has been based on the numerical modelling of a set composed by a point sound emitter, located at a distance of twice the parameter “a” from the axis of the first cylindrical dispersing element of the barrier. The objective of the work will be to study the ability of the SDAB barrier to reduce the sound propagation in the transverse direction, while at the same time allowing the sound transmission to reach a receiving area located towards the end of the barrier. Fig. 1 shows the source assembly in front of the SDAB, at the center of the barrier. The figure shows the area to be protected from sound transmission - the protected area - in a transverse direction to the barrier, as well as the area where it is desired that the barrier allows sound transmission - the receiving area-.

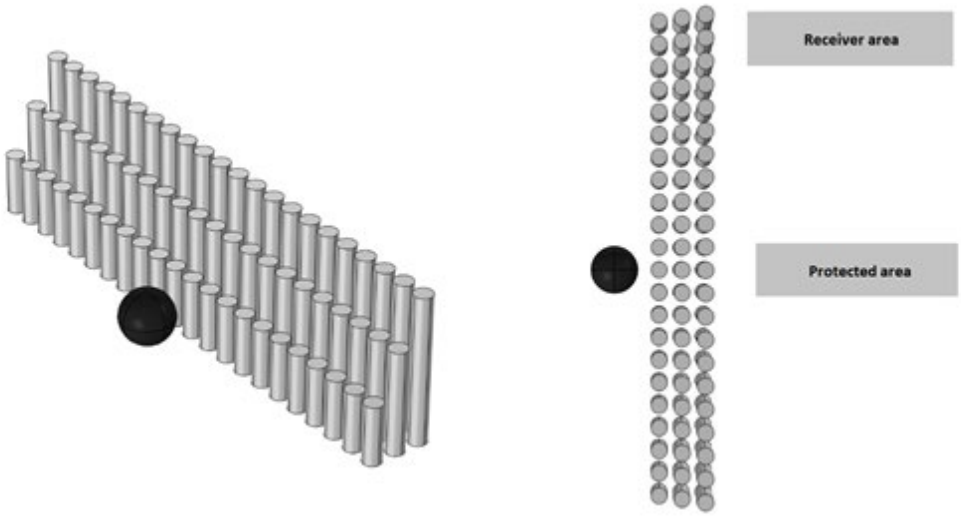

Figure 1. Noise source and SDAB barrier set. Left: isometric view. Right: plan view.

2. SIMULATION METHODOLOGY

The model developed to study the effect of the SDAB barrier on the acoustic propagation of an emitter, has been implemented in the COMSOL Multiphysics software. It is a BEM model where a sound source is placed in front of the acoustic barrier in an open field. Fig. 2 shows the geometry of the barrier as well as a detailed grid layout. The advantage of the BEM methodology is that it does not need to discretize the air volume, which is computationally advantageous for calculating sound propagation in open spaces. In this preliminary study, the emitter has been defined as a static omnidirectional sound source, located in front of the central area of the barrier. For this purpose, a point monopole has been placed at a height of 0.25 m, same height as the center of a commercial dodecahedral sound source, and separated by a distance of twice the parameter "a" from the axis of the first cylindrical dispersing element. To simulate the omnidirectional sound source, this monopole has been placed inside a 0.36 m diameter air sphere whose interior has been discretized by FEM. For the study, a barrier of 22 cylindrical elements for each of the rows has been used, giving a total barrier length of about 4 m. The surface of the sphere serves as a connection between the FEM environment and the BEM environment used for the study of acoustic propagation by imposing a continuity in the generated sound pressure field. The sides and top caps of the cylindrical elements of the barrier are established as fully reflective surfaces. In turn, the effect of the ground is modelled as a plane which is also considered as fully reflective.

3. RESULTS

The numerical model implemented in COMSOL Multiphysics has been run in a stationary analysis at the frequency of 1000 Hz with a sound source power of 5 W. Fig. 3.a) shows the effect of the directional SDAB barrier on the sound propagation of the acoustic field generated by the omnidirectional source. Additionally, the sound field produced by a conventional continuous flat barrier of rectangular geometry, 1 m high, placed at the same distance from the source as the highest row of cylindrical elements, see Fig. 3.b), has been simulated.

In the vertical plane of both simulations in Fig. 3 (lower images), it can be seen how the SDAB barrier is able to reduce, more effectively than the conventional barrier, the sound propagation from a distance of 1 m in the transverse direction of the barrier. In addition, the conventional barrier reflects, to a greater extent than the SDAB barrier, the sound field produced on the source side, instead of scattering it. In the horizontal plane (images above), there is also a different behavior between the two types of barriers. While the conventional barrier blocks the sound propagation similarly along its entire length, the SDAB barrier is more effective in the transverse direction, for which the distance between cylinders presents a destructive interference for the 1000 Hz wavelength. As the angle of incidence increases, the distance between elements increases, allowing more sound propagation.

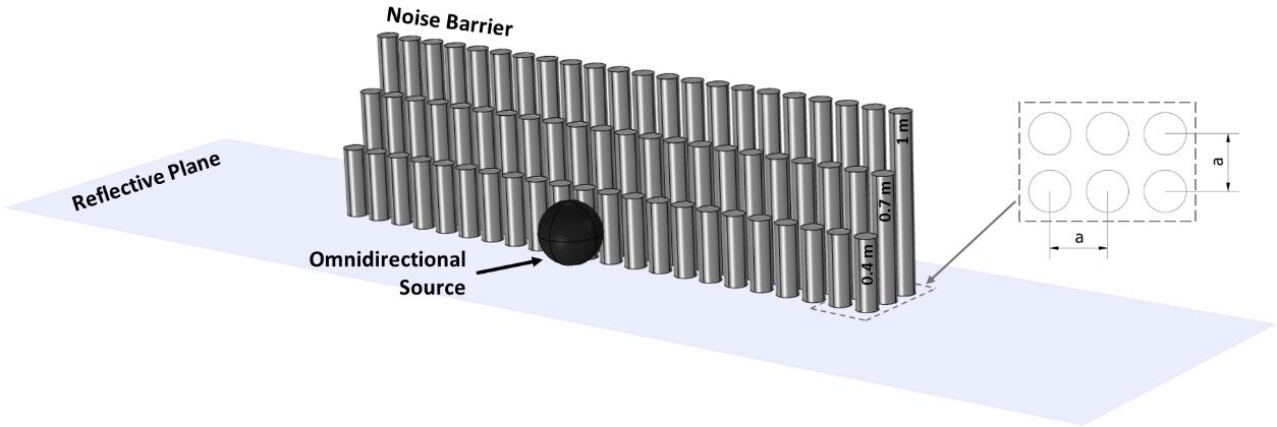

Figure 2. Geometric characteristics of the SDAB acoustic barrier and modelling in COMSOL Multiphysics.

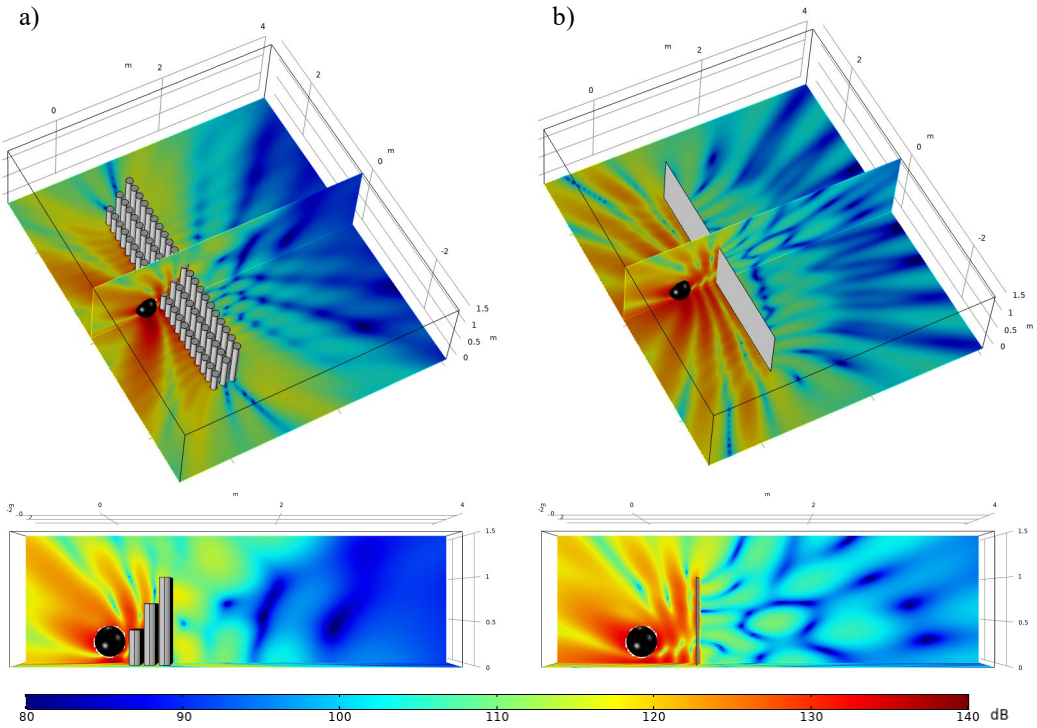

Figure 3. Sound Pressure Level of the simulated sound field at 1000 Hz: a). Directional barrier with cylindrical elements. b). Conventional rectangular barrier.

To better quantify the propagation in the horizontal plane, Fig. 4 shows a polar plot of the Sound Pressure Level, evaluated over a circumference of 4 m radius, centered on the source at 1.2 m height, thus lying above both barriers. In the transverse direction, at 0°, a receiver at a height of 1.2 m would perceive 90 dB for the SDAB barrier and 95 dB for the traditional barrier. The SDAB barrier is more effective than the rectangular barrier up to an angle of 50°, where it has a lobe of greater acoustic propagation. A difference of 5 dB can also be quantified at 180° due to the higher reflection of the traditional barrier towards the source itself.

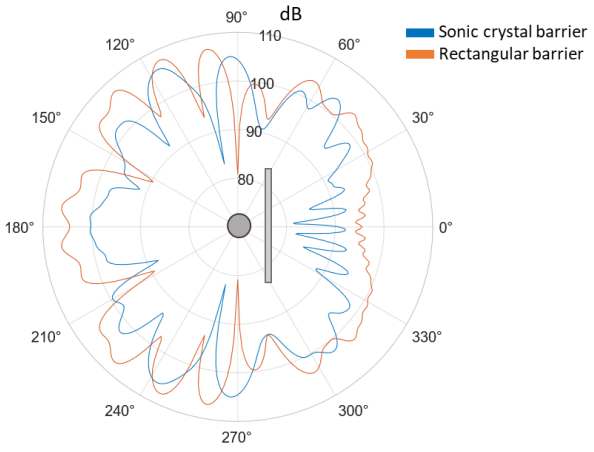

Figure 4. Polar plot of the Sound Pressure Level of the simulated sound field at 1000 Hz, at a height of 1.2 m and with an evaluation radius of 4 m.

4. CONCLUSIONS AND FURTHER WORK

The SDAB stepped acoustic barrier presented in this work has been designed in order to favor sound directivity at a frequency of 1000 Hz. In the horizontal plane, greater directivity has been achieved at an angle of 50º with respect to the transverse direction of the barrier, while it is reduced in the direction of 0º. In turn, in the vertical plane, the stepped barrier produces a more effective attenuation below the angle formed by its stepped elements. In this sense, the group is working on the experimental validation of a prototype SDAB stepped barrier, as shown in Fig. 5. This figure has been obtained using an acoustic camera that allows the sound field generated by the source, with an emission of 1000 Hz, and located at a distance of 4 m, to be seen graphically.

The behavior of the barrier at other frequencies is also being studied experimentally by obtaining the Insertion Loss in different positions in space. The final objective will be to achieve three-dimensional directivity by placing the barrier in the proximity of an urban traffic flow.

ABSTRACT

Achieving acoustic comfort inside the vehicle cabin typically requires a combination of Passive and Active Noise Control techniques, methods that have been effective at modifying the resulting sound field in a closed enclosure. [1] From a subjective point of view, not all noise sources are equally disturbing to passengers, and engine and road noise are often perceived as the most unpleasant noise sources, due to the presence of low-frequency components. This paper presents a subjective evaluation test designed to determine the most effective filter configuration that could improve the perception of engine noise inside a vehicle. Filtered engine noise samples are rated using the Bradley-Terry pairwise comparison method, allowing participants to express their preference between the original sound and three filtered versions of it. Recordings were captured under different operating conditions, including: driving state, gear shift and engine RPM configuration. Three perceptual attributes were chosen along with preference by default: pleasantness, power and naturality. This work aims to contribute to the development of Sound Quality Evaluation strategies that improve in-cabin acoustic comfort.

1. INTRODUCTION

Numerous efforts have been made to study and deal with the acoustic comfort and driving experience of users over time. Relevant publications in this field include [2], [3], [4], [5], [6], [7], [8]. Psychoacoustics in the automotive industry plays a crucial role in reflecting the audible preferences of drivers and passengers to ensure sound quality subjectively; this along objectively indices are the two ways noise experienced in the car can be assessed. [9] Through subjective evaluation methods, researchers can determine the level of comfort in the driving experience, having in mind a positive outcome for it. [10] In the beginning, the interior development of the vehicle was mainly focused on achieving objective indices and quantitative metrics given by airborne and structure-borne noise paths. [11] However, this idea has gradually evolved over time, as a result of different challenges faced by manufacturers due to trends such as lighter and more efficient automobiles, but also the integration of Electric Vehicles (EV). [12] Sound Quality Design (SQD) is introduced in this field when engineers on customized solutions, including comfort and power. Various approaches such as digital signal processing and adaptive algorithms have been explored, more recently through Deep Learning (DL). [13]

2. METHODS

The following section briefly describes how the audio recordings were obtained, selected, analysed, processed and presented.

2.1 Data acquisition

Data were acquired with a four-cylinder gasoline engine research vehicle on public roads of Neue Gautinger Strasse, Germering, Germany. Audios were provided by researchers at Müller-BBM Active Sound Technology GmbH. All windows were kept closed during the measurements. Eight microphones were strategically placed in the vehicle compartment at the following positions: microphones 1 to 4 were placed on the ceiling of the car in the front left (FL), front right (FR), rear left (RL), and rear right (RR) positions, while microphones 5 to 8 were placed on the inner side of the headrests at the same locations. The sampling frequency was set to 8192 Hz. Each individual operating point was set and measured for approximately 1 minute and 30 seconds.

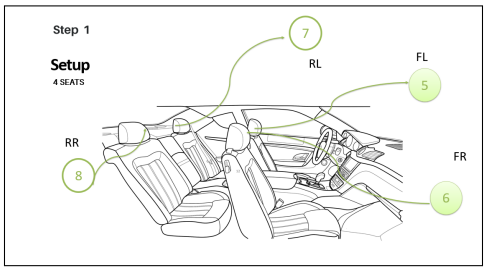

Figure 1. Setup Arrangement. M5-M6: Front seat microphones placed at the inner side of the headrests. M7-M8: Rear seat microphones.

2.2 Auditory Stimuli

From the original dataset, a total of 5 measurements were thoroughly selected for the test. Each driving operating mode was measured under different conditions: the first one reflects a smooth and constant ramp-down during the transition from 3rd to 4th gear. The second was recorded at constant speed while shifting from 3rd to 4th gear, starting at 1300 RPM (revolutions per minute). The third recording represents a smooth and continuous ramp-down in 5th gear. The fourth captures the initial ramp-up phase and, lastly, the fifth corresponds to a gradual ramp-down. All audio recordings were presented to participants in.wav format, through stereo reproduction and with normalized amplitude.

2.2.1 FIR Filters

Finite impulse response (FIR) filters are digital filters that are used to shape the frequency content of audio signals with high precision and stability. Due to their linear phase response, FIR filters keep the original shape of audio signals, which is ideal for applications such as equalization and noise reduction. Traditionally, are widely used in professional audio systems and digital audio workstations to ensure transparent sound processing without introducing phase distortion. FIR filters are also beneficial for loudspeaker correction and room compensation, where accurate control over both magnitude and phase is essential. Authors in [14] validate the effectiveness of FIR filters in modifying the frequency content of the noise signals. [15]

2.2.2 Frequency-based analysis

Power Spectral Density (PSD), also known as the power spectrum, describes how the power of a signal is distributed between different frequencies. It is widely used in signal processing applications because it helps identify dominant frequencies, noise levels, and other important signal characteristics. [16] The normalized cut-off frequency is determined based on the Nyquist theorem, which states that the maximum frequency that can be accurately represented is half the sampling rate. For the purpose of this study, 3 FIR filters were designed using the Hamming windowing method: a low-pass filter of order 800 and two high-pass filters of order 500.

2.3 Questionnaire

2.3.1 Evaluation Method

The pairwise comparison method was selected due to its effectiveness in facilitating listener evaluations by limiting judgments to two stimuli at a time, S1 and S2. This approach improves sensitivity to perceptual variations while minimizing cognitive load and individual bias, thereby increasing the reliability and consistency of the collected data. In contrast to rating scales or direct ranking procedures, pairwise comparisons are particularly well-suited for experiments aiming to establish a robust preference structure and to detect small differences in sound quality with more accuracy. [17] The order in which comparisons are presented has been manually configured based on a specific criterion: ensuring that the two most similar signals were not evaluated consecutively. This deliberate

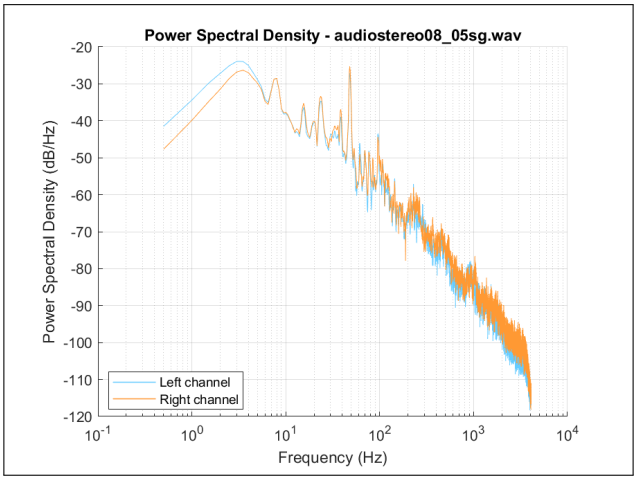

Figure 2. Power Spectral Density (PSD) of signal No. 08, measured at microphones 5 (Front Left) and 6 (Front Right). Driving operation condition: 5th gear, ramp-down. Length: 5 seconds. Sampling rate: 8192Hz.

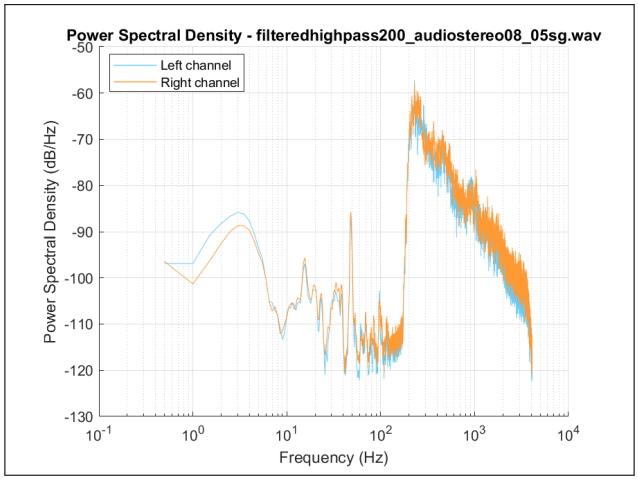

Figure 3. Powerspectral density (PSD) of signal No. 08, measured at microphones 5 (Front Left) and 6 (Front Right). Driving operation condition: 5th gear, ramp-down. Length: 5 seconds. Sampling rate: 8192Hz. Filter: High-pass, Cut-off frequency: 200Hz, Order: 500.

separation prevented potential listener bias and facilitated a more accurate and robust auditory assessment.

2.3.2 Perceptual attributes

According to [17], Pleasantness refers to the overall subjective acceptability or enjoyment of a sound, often influenced by tonal balance, loudness, and the absence of disturbing elements. Power is associated with the perceived strength or intensity of a sound, and is often linked to attributes such as loudness and spectral content that convey a sense of engine performance. Meanwhile, naturality refers to how realistic or lifelike a sound appears and whether it aligns with the listener's expectations based on prior experience with similar auditory events. These attributes were chosen based on the frequency components of the audio samples prepared. For instance, a filtered engine sound that is more pleasant may reduce listener fatigue during driving, while maintaining sufficient power ensures that the vehicle still provides a sense of performance. Additionally, preserving naturality is crucial, as overly artificial-sounding modifications can lead to user dissatisfaction, even if the sound is technically improved. Together, these attributes allow for a holistic evaluation of sound quality that balances subjective enjoyment with perceptual fidelity. [18]

2.4 Experiment

2.4.1 Tools

To avoid external and internal noise sources were perceived by listeners during the playback step, the experiment was carried out in the anechoic room of the GTAC Laboratory at UPV. Due to the low-frequency content of the noise signals, Senheiser HD600 headphones with a frequency response ranging from 12 to 40500 Hz were employed, as well as the M-Audio Track Quad sound card connected to an ASUS laptop.

2.4.2 Process

To ensure consistency, a total of 30 participants (25 Male and 5 Female) with normal hearing abilities were invited to participate in the test. Since 5 audios with different configuration were selected, 5 sets of stimuli were presented consecutively, one set of stimuli per driving mode. First, each jury was explained the step by step of the experiment and was given an example. The software application was then launched, and the subjects were asked to read the disclaimer that describes the task to be completed and their agreement to it. As the test started, volunteers were asked to listen to two signals and rate them according to their perceptual auditory preference. During every com-

parison, signals S1 and S2 are continuously played until the jurors tick the available checkboxes. The instruction provided to volunteers was: "Between signal one (S1) and signal two (S2), please select the one that you find to be most pleasant/powerful/natural, than the other based on the rating scale provided".

Figure 4. Jury inside the anechoic room, reading the agreement disclaimer prior to beginning the test.

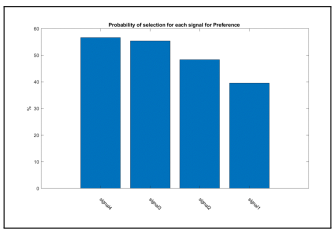

Figure 5. Probability of selection for each signal based on Preference attribute. Signal1 (original audio) was the least preferred, followed by Signal2 (low-pass filtered at 50 Hz). Signal3 and Signal4, processed with high-pass filters (200 Hz and 100 Hz respectively), received the highest preference scores.

3. RESULTS

3.1 Ratings

3.1.1 Preference ratings

The original audio signal, Signal1 received the lowest rating, indicating that it was the least preferred among the 4 available. Signal2, corresponding to the low-pass filtered signal (50 Hz, order 800), also received a negative rating, though less severe than the original, suggesting a slight improvement in perceived preference. Signal3 and Signal4, both processed with high-pass filters, demonstrated a significant increase in preference. Signal3 (high-pass filter at 200 Hz, order 500) achieved a positive rating, while signal4 (high-pass filter at 100 Hz, order 500) received the highest overall score. These results suggest that attenuating lower frequencies and preserving higher frequency content, particularly above 100 Hz, contribute positively to the subjective perception of the signal, making high-pass filtering a promising approach to improving sound quality in this context. Interestingly, this result has revealed that improved perceptual assessments can be obtained through FIR Filtering.

3.2 Acoustic EQ profile

Active Noise Control (ANC) and Active Noise Equalization (ANE) are similar schemes. While ANC focuses on reducing unwanted noise by generating anti-noise signals, ANE aims to shape the sound field to achieve a desired profile. ANE is based on ANC by not only canceling noise, but also enhancing sound quality through spectrum shaping. Relevant publications have focused on shaping the spectral content of engine noise in the vehicle interior cabin. At the same time, they highlight the importance of designing and choosing the suitable filters for the algorithms implemented in this systems. [19], [20], [21] The ultimate goal after obtaining the test results of this subjective test is to use the most pleasant filter as our Shaping filter: $C(z)$ inside the Adpative Noise Equalization algorithm.

SOUND ATTENUATION OF LOUVERED NOISE BARRIERS FOR INDUSTRIAL EQUIPMENT

Nikolay Kanev[1,2*] **Alexander Dolger**[2]
[1] Research Institute of Building Physics, Russia
[2] Moscow State University of Civil Engineering, Russia

ABSTRACT

An industrial equipment is often noise source in urban spaces and disturbs people everyday activities. The usual way to reduce noise level is application of barriers surrounding the equipment. On the other hand, any obstacles can interfere with the normal operation of the equipment, for example, they can block the air flow. Therefore, the barrier should provide both significant sound attenuation and sufficient ventilation. For this reason, the louvered noise barriers are used in practice to protect residential areas and other noise sensitive spaces. In the paper we study their sound attenuation performance in dependence on acoustic properties of the louvre blades. It is shown that the rigid blades are not so effective because sound energy penetrates through the barrier, whereas the dissipative louvre blades reduce sound more effective. In addition, we consider the other two boundary conditions for the louvers. It is found that the reactive impedance shows the highest performance at low frequencies.

Keywords: *simulation, impedance, diffraction, noise control*

1. INTRODUCTION

Technological and industrial equipment for various purposes continues to be one of the major sources of man-made noise in buildings and surrounding areas. Exposure to elevated noise levels reduces acoustic comfort and has a negative impact on human health, leading to physiological and psychological consequences. These factors highlight the need for effective noise reduction measures, making this an important area of focus in architectural and building acoustics.

One of the issues is shown in Fig. 1. Dry coolers are placed on the roof and emit noise around. To reduce noise radiated downwards the equipment is surrounded by a heavy brick barrier. The noise level on the lower floors and on the ground is appropriate, whereas on the upper floors the noise acts directly on the windows and terrasses and its level is still too high. It is impossible to cover the equipment with a solid roof, as this would prevent ventilation. Therefore, a ventilated barrier is required, and a louvered-type noise barrier can be used to achieve this.

The sound attenuation of louvered barriers has been studied [1-6], and this research continues these investigations. In this paper we focus on the acoustic properties of louvers. Using simulation, we study the attenuation of sound transmitted through the barrier depending on the acoustic impedance of the louvre surfaces.

Figure 1. Dry coolers on the roof.

2. LOUVERED NOISE BARRIERS

2.1 Sound diffraction by barriers

Sound attenuation by barriers is usually calculated using a classical diffraction theory [7]. The sound transmitted through the louvered barriers with a finite height can be divided into two components (Fig. 2). The first component T_1 is the sound that propagates around the upper edge of the barrier. The second component T_2 is the sound that penetrates through the barrier. By separating these two components, we can simplify the diffraction problem. The transmission coefficient T_1 can be found using the known results of diffraction by a rigid finite barrier. The calculation of the transmission coefficient T_2 can be fulfilled for the infinite louvered barrier. This approach allows us to focus on the second component of the transmitted sound and find the parameters of the barrier for maximum sound attenuation.

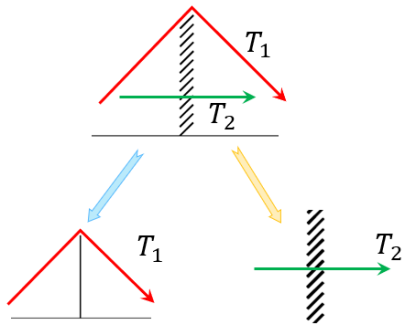

Figure 2. Simplification of the problem of sound diffraction by the louvered barrier.

In this paper, we examine the infinite louvered barrier and investigate the impact of its acoustic properties on sound attenuation.

2.2 Attenuation of sound transmission

The formulation of the sound diffraction problem by an infinite louvered barrier is illustrated in Fig. 3. The louvers are rectangular in shape with dimensions of h and L, with a spacing of H between the edges of the louvers. The inclination angle of the louvers is denoted by α. These four geometrical parameters completely define the barrier.

Acoustic properties of the louvers are described by the impedance Z normalized to ρc, where ρ is a density of the medium and c is a sound speed. All louver surfaces have the same acoustic impedance.

The incident sound is a harmonic plane wave with the wavenumber $k = \omega/c$, where ω is frequency. We are interested in the sound field behind the barrier.

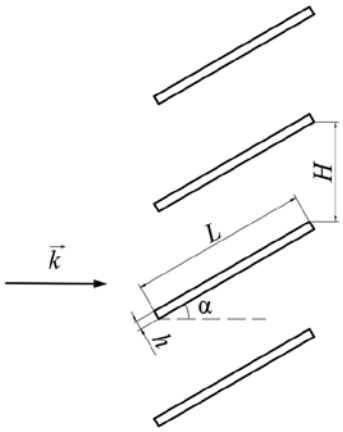

Figure 3. Formulation of the diffraction problem.

If the sound energy density of the incident wave is E_1 and the sound energy density behind the barrier is E_2, then the sound attenuation due to the barrier is determined as

$$T = 20\lg\frac{E_1}{E_2}. \quad (1)$$

We will use simulation to calculate the sound attenuation coefficient T.

3. SIMULATION

The scheme of the numerical experiment is shown in Fig. 4. We consider a two-dimensional case with a rectangular domain of dimensions 20 x 10 m. One side of the domain is a plane oscillating at frequency ω with a velocity normal to that side. All other sides of the domain have the impedance $Z_0 = 1$ and slightly reflect sound waves. Therefore, the oscillating side acts as a source for a plane wave.

A louvered barrier is placed in the middle of the domain. Each louver has dimensions $h = 0.05$ m and $L = 1$ m. The distance between the louvers edges is $H = 0.45$ m, resulting in a period of 0.5 m for the structure. The parameters h, H and L are fixed in this experiment, while the inclination angle α can take on different values. The impedance of the louver surfaces will be changed as well.

A probe domain is a rectangular area located behind the barrier. The sound energy density is calculated in the entire simulation domain without the barrier, and E_1 is the average of this value over the probe domain. To calculate the sound energy density E_2 with the barrier, the same process is followed, but with the addition of the barrier. The sound attenuation of the barrier is then found using Eqn. (1).

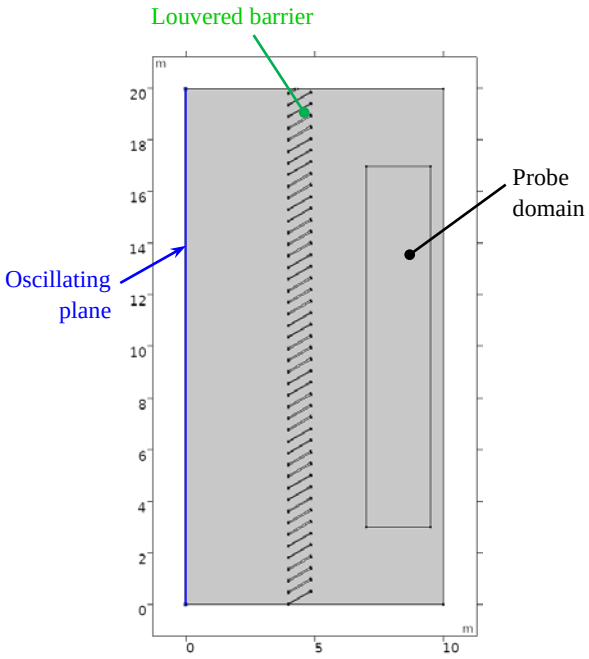

Figure 4. Scheme of the numerical experiment.

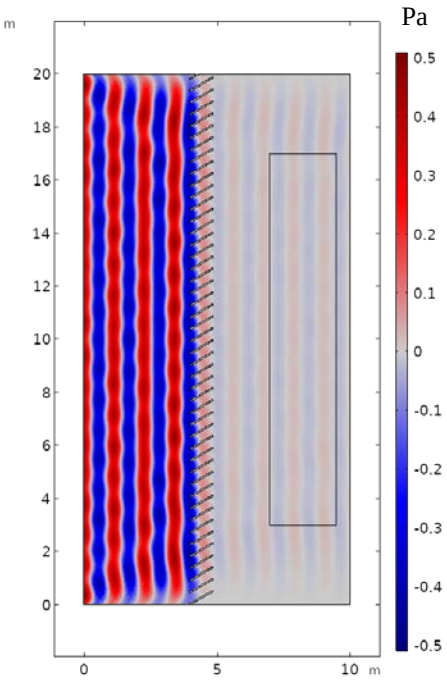

Figure 5. Sound pressure at 300 Hz with Z =1 and α = 30°.

Fig. 5 shows an example of calculating the sound pressure field at 300 Hz with the incilnation angle α = 30° and the surface impedance Z = 1. The sound field appears to be a set of the plane waves with slight distortions caused by reflections from the boundaries of the calculation domain. We can see that the transmitted wave has a smaller amplitude in comparison with the incident one. Therefore, the barrier effectively attenuates sound.
The following calculations of T are made in a similar way for different values of the louver impedance. We will use the frequency range 100-1000 Hz with a step size of 100 Hz.

3.1 Rigid surface

The first issue we consider is the louvers with the rigid surfaces. The standard boundary condition is $\partial p/\partial n = 0$, where p is the sound pressure, n is a normal to the surface. The sound attenuation defined by Eqn. (1) for the inclination angles α = 0, 30°, 60° is given in Fig. 6.

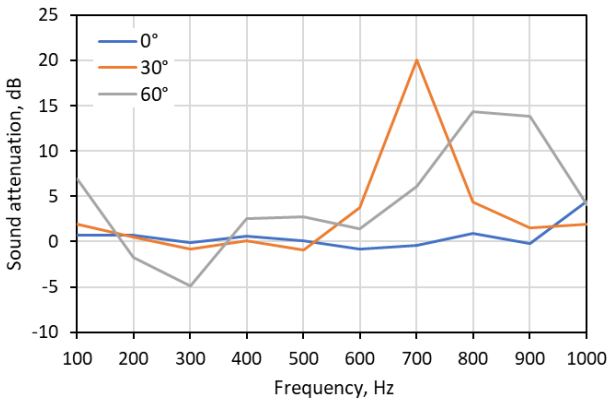

Figure 6. Sound attenuation for the rigid louvers.

If the louvers are parallel to the wavevector (α = 0) the sound attenuation is close to zero at all frequencies, whereas the inclined louvers reduce transmitted sound at certain frequencies. But their effect is narrowband, so the rigid louvers are not very effective.

3.2 Absorbing surface

Next type of the louvers is a sound absorber with the surface impedance Z_a = 1. This surface completely absorbs a normally incident sound wave. The calculated sound attenuation is shown in Fig. 7. The barrier reduces sound at all frequencies and the reduction increases with the increase of the angle α.

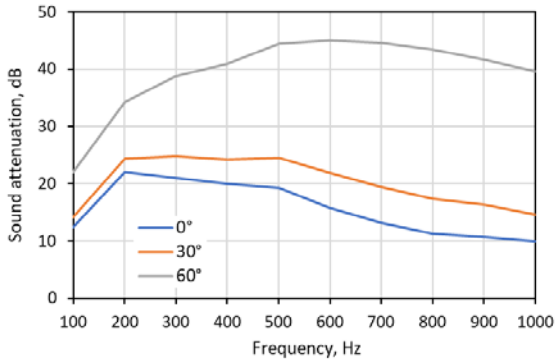

Figure 7. Sound attenuation for the absorptive louvers.

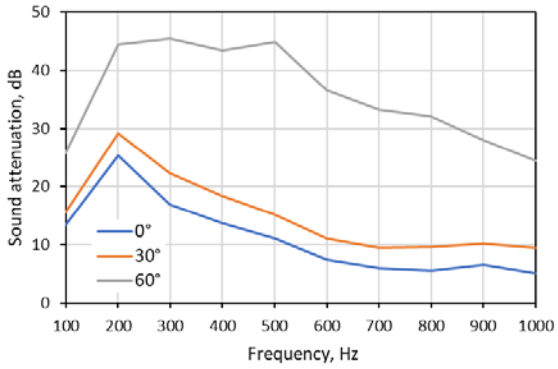

Figure 8. Sound attenuation for the louvers with the Creamer's impedance.

It is important to note that the distance between the louvers changes with the angle α, because the space period H is fixed. The distance is $H\cos\alpha$, it decreases with increase of α. So, the better attenuation for α > 0 is related to a smaller distance.

The non-inclined louvers have the performance of 10-20 dB in the entire frequency range. The maximum sound attenuation is at frequencies 200-500 Hz. The frequency characteristic resembles the performance of a plate muffler used for ducts [8].

3.3 Cremer's impedance

Sound propagation in a duct has a maximum attenuation coefficient if the duct surfaces have the Cremer's or optimal impedance [9,10]. Using the formula for the optimal impedance derived in [11] we can find it in dependance on the duct width d as follows

$$Z_c = kd(0.15 + 0.12i). \quad (2)$$

We can hope that the optimal sound decay in the duct between the louvers will provide a good performance of the sound attenuation by the barrier. At 500 Hz the optimal impedance as given by Eqn. (2) is Z_c = 0.61+0.49i. The simulation results for this impedance are presented in Fig. 8. The maximum attenuation for α = 0, 30° occurs at 200 Hz, rather than 500 Hz. It means that the short duct with the length L can not be considered as an infinite duct. Anyway, the found effect is comparable to that of the absorbing surfaces, but at high frequencies the sound attenuation is lower.

The large inclination angle as seen in Fig. 7 and 8 provides very high sound attenuation for both the absorptive louvers and the ones with the Cremer's impedance. At all frequencies the effect is greater than 20 dB.

3.4 Reactive impedance

The final type of impedance is a reactive impedance with Re Z = 0. The louvers do not dissipate sound energy, but at low frequencies, under certain conditions, all eigenmodes in the gap between the louvers are non-uniform. Above a certain frequency there are uniform modes and sound propagates through the gap. This physical principle allows us to hope that the barrier effectively isolates sound waves at low frequencies.

Fig. 9 shows the sound attenuation for the louvers with the impedance Z_r = –0.1i. For α = 0, 30° the barrier reduces the transmitted sound at frequencies below 500 Hz. At higher frequencies sound propagates between the louvers without attenuation. For α = 60° the effectiveness of the barrier is significant up to 1000 Hz.

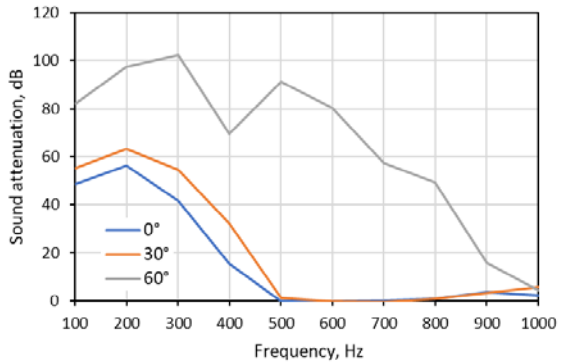

Figure 9. Sound attenuation for the louvers with the reactive impedance.

3.5 Comparison of different impedances

To compare the sound attenuation for different boundary conditions on the louver surfaces, we present the results for $\alpha = 0°$ and three types on the impedance are presented in Fig.10. We can see that the Cremer's impedance has the lowest performance, while the absorptive impedance provides significant attenuation over a wide frequency range. Louvers with reactive impedances have a very high reduction in transmitted wave at low frequencies, but their performance is negligible at higher frequencies.

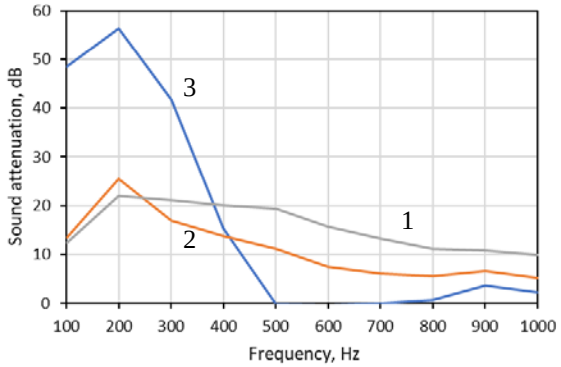

Figure 10. Sound attenuation for the louvers with different impedances for $\alpha = 0°$: $1 - Z_a$, $2 - Z_c$, $3 - Z_r$.

4. CONCLUSION

The findings of this study demonstrate the importance of selecting the acoustic properties of the louvers for designing ventilated barriers. Based on our findings, we can conclude that absorptive louvers can be used for wide-band sound attenuation. Industrial equipment typically emits low-frequency noise, so in this case, louvers with reactive impedance may be more suitable.

To generalize the findings, additional simulations and a theoretical study of infinite louvered barriers are required. The dependence of sound attenuation on the length, thickness of louvers, and the distance between them needs to be investigated in order to determine the optimal parameters for the barrier.

ACOUSTIC PROPERTIES OF A LOUVERED NOISE BARRIER WITH TIRE RUBBER GRANULATE INFILL

Edgaras Strazdas[1*] **Tomas Januševičius**[2]
[1] Department of Environmental Protection and Water Engineering, Vilnius Gediminas Technical University, Lithuania
[2] Research Institute of Environmental Protection, Vilnius Gediminas Technical University, Lithuania

ABSTRACT

To ensure comfortable working and living conditions, various systems such as heating, ventilation, heat pumps, and generators are employed, all of which require high air permeability for optimal performance. Consequently, conventional noise barriers are often unsuitable in these contexts. This study aims to design a louvered noise barrier with high air permeability by incorporating recycled tire rubber granulate as the sound-absorbing material. This approach supports the principles of the circular economy and sustainability by promoting the reuse of secondary materials. The barrier's acoustic performance was evaluated in a semi-anechoic noise reduction chamber. The influence of the number of louvers and their inclination angles on sound attenuation was investigated. Experimental measurements were used to determine the sound reduction index (R'), sound insertion loss (IL), and equivalent sound level loss (L_{Aeq}). The structure achieved a maximum weighted sound reduction index (R'_w) of 4.0 dB. The apparent sound reduction index reached up to 10.2 dB at high frequencies (4000 Hz). The highest recorded sound insertion loss was 12.63 dB at 2500 Hz, while the maximum equivalent sound level loss (L_{Aeq}) was 9.4 dB(A).

Keywords: *acoustic louvers, noise barrier, tire rubber granulate, anechoic chamber, insertion loss.*

1. INTRODUCTION

Noise is emitted by air-cooling equipment, water cooling units, fans, and diffusers due to the movement of exhaust and intake airflow, as well as the operation of condensers and compressors. Acoustic comfort issues can be addressed using conventional noise barriers. However, these enclosures are not suitable for ventilation equipment, which must exhaust or intake air to function properly. Increasingly strict noise regulations are prompting many manufacturing and commercial companies to seek effective solutions to avoid exceeding the prescribed noise levels in their environments.

Noise barriers are among the most effective and widely used methods for mitigating noise [1-4]. The selection of a specific type of barrier in each case is usually determined by the position of the noise source, the characteristics of the noise it emits, and the terrain of the site under consideration [5]. The effectiveness of an installed barrier depends on the materials used in its construction, the height of the barrier, surface geometry, shape, acoustic properties of additional elements installed on top of the barrier, as well as the surrounding terrain and meteorological conditions [6-8].

The operation of noise barriers is based on the principle that a sound wave loses its original energy and becomes attenuated when passing directly through an obstacle. A portion of the wave's energy is reflected upon impact, another portion is absorbed and converted into thermal energy, and the remainder is either transmitted through the material or diffracted. This residual energy can reach the receiver, either separately or as a combination of transmitted and diffracted waves [7].

One effective way to reduce noise is through sound absorption. Sound-absorbing materials are often used in combination with perforated plates made from materials such as steel, glass, plastic, and others. Many of these

materials are effective at reducing medium and high-frequency noise but are less effective at controlling low-frequency noise. To increase air permeability or provide adequate shading, scientists have proposed several types of noise barriers, such as sonic crystals or louvered structures. Researchers have found that sonic crystals can achieve noise attenuation levels between 16 and 25 dB(A) [9]. Louvered structures are often used as façade elements or structural components of buildings. They provide necessary light and air permeability while also offering sound attenuation properties [10]. Sound-attenuating louvers can be used to reduce noise from engineering equipment or road traffic [11]. One alternative for reducing noise from ventilation equipment is the use of sound-absorbing louvers made of perforated panels filled with absorbent material. The operating principle of a louvered noise barrier is based on the reflection, absorption, and refraction of incoming sound waves. Reflection occurs when a wave traveling through one medium encounters another medium and is partly scattered such as when a sound wave moves from a liquid to a gaseous medium, or from a solid to a liquid, and so on. Part of the wave passing through different media is reflected back into the original medium, while another part is absorbed and thus enters the new medium. Upon impact, the sound wave also undergoes refraction, changing its propagation trajectory in the new medium. This occurs due to the sudden change in the speed at which the sound wave travels. Sound absorption is directly related to the frequency of the sound waves and also depends on the angle at which the sound waves enter the material. Vilniškis et al. conducted a study examining three different louver configurations. The best noise-reduction performance was observed in louvers covered with glass wool panels, achieving sound insulation values ranging from 10.8 to 12.5 dB. Meanwhile, louvers covered with polystyrene foam panels achieved values between 5.4 and 8.4 dB [12]. Vilniškis also found that increasing the tilt angle of the panel structure increased the pressure near the structure from 45 Pa to 9 kPa, and the air velocity passing through the structure changed from 13 m/s to 70 m/s [13]. Astrauskas et al. found that the noise attenuation of the louvered barrier was greatest in the 2500 Hz and 3150 Hz octave frequency bands. Depending on the tilt angle of the louvers, sound attenuation in these bands reached up to 28 dB(A), and the equivalent sound pressure level was reduced by up to 17 dB(A) [11].

The aim of this paper is to design a louvered noise barrier with high air permeability, incorporating recycled tire rubber granulate as the sound-absorbing material. The paper is organized as follows: Section 2 describes the materials and methods; Section 3 presents the main results; and Section 4 provides the conclusions.

2. MATERIALS AND METHODS

The main research object of this study is a louvered barrier composed of a specific number of identical louvers filled with sound-absorbing recycled tire rubber granulate. The noise barrier consists of horizontal louvers inclined at a specified angle. The horizontal louvers are 30 mm thick and 860 mm long, and are made from bent metal sheets. The upper part of each louver is a solid metal plate, while the lower part is a perforated metal plate. Inside the louvers is the sound-absorbing material. The perforated plate is placed on the underside of the louver to protect the sound-absorbing material from environmental factors such as precipitation, dust, and icing. The structure of the louver is shown in Figure 1.

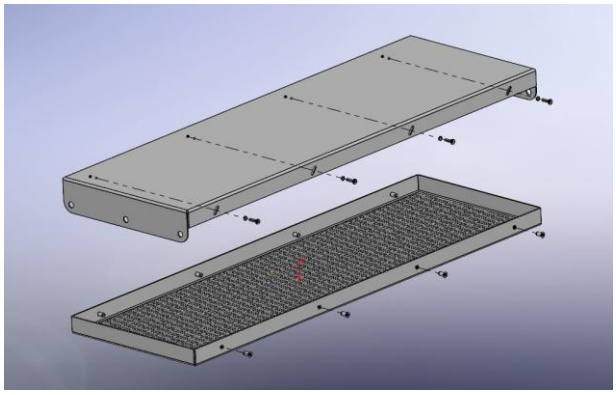

Figure 1. The structure of the louvers in the noise barrier.

The louvers are made from two 2 mm thick bent metal sheets. The upper sheet is a solid metal plate, while the lower one is a perforated metal plate. The parameters of the perforated sheet include 35% open area with round perforations, 5 mm in diameter, and 8 mm centre-to-centre spacing. After the louvers are filled, the metal sheets are joined together using rivets or bolts.

The louver infill consists of two layers of recycled tire rubber: a 10 mm thick rubber granulate plate for sound insulation and a 20 mm thick layer of rubber granules (granule size 2–5 mm) for sound absorption (Figure 2). The rubber granulate plate made from shredded tire rubber granules (1 mm in size), mixed with polyurethane glue in a 30/70% ratio. To prevent the granules from falling out

through the perforated sheet, a metal mesh with 1x1 mm openings is placed on top.

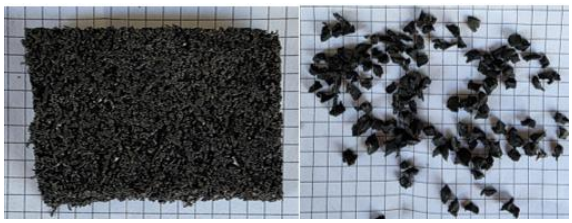

Figure 2. Louvers infill: 10 mm thick rubber granulate plate and 2–5 mm tire rubber granules.

The filled louvers are placed into a wooden frame measuring 900x970 mm and secured with screws from the sides. The frame with louvers is then placed into the window of a semi-anechoic chamber (Figure 4, Figure 5). A general view of the semi-anechoic chamber is shown in Figure 3.

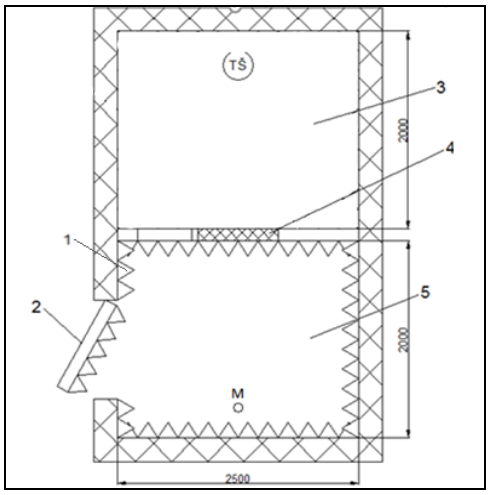

Figure 3. General view of the noise reduction chamber. 1 – walls covered with foam rubber, 2 – door, 3 – room for outgoing sound, 4 – location of structure, 5 – room for receiving sound, M – microphone position, TŠ – noise source.

Three different configurations of the louvered barrier were investigated: structures with 5, 6, and 7 louvers. Each configuration was tested with the louvers tilted at angles of 0, 15, 30, and 45 degrees. In total, 12 different louvered barrier configurations were tested.

The experimental studies were conducted using high-precision equipment from the manufacturer Brüel & Kjær: the sound source "Brüel & Kjær The Omni-Power Sound Source Type 4292-L," the amplifier "Brüel & Kjær Type 2734," and the sound level analyser "Brüel & Kjær 2270." The measuring device complies with standards IEC 61672, IEC 60651, and IEC 60804. During the tests, the sound level was measured using a one-third octave band filter.

Figure 4. Tested louvered noise barrier from room for outgoing sound.

Figure 5. Tested louvered noise barrier from sound receiving room.

The following parameters were determined during the experimental measurements:

- sound reduction index (R').
- sound insertion loss (IL).
- equivalent sound level loss (L_{Aeq}).

According to the [14], the sound insulation level of a louvered noise barrier was determined. This standard provides all the main measurement methods and procedures required to determine sound insulation under laboratory conditions. Sound pressure levels are measured in both the source and receiving rooms. The average sound pressure level is calculated in both rooms (applying background noise correction), and the sound reduction index the barrier is determined. The weighted sound reduction index (R'_w) is determined by fitting a standard reference curve to the measured sound reduction index values across various frequencies, as specified in [15].
Insertion loss was calculated as the difference between the sound pressure level without the louvers and the sound pressure level with the louvers. Insertion loss was calculated according to Eqn. (1) as described in [16].

$$IL = L_{p1} - L_{p2} \quad (1)$$

where L_{p1} is the sound pressure level without the louvers and L_{p2} is the sound pressure level with louvers.
Equivalent sound level loss (L_{Aeq}) is the difference in equivalent noise level between the sound emitted by the noise source, measured in the receiving room without the louvers, and the sound level measured after the louvers have been installed.

3. RESULTS

First, sound reduction measurements of the barrier were performed. Figure 6 presents the results of sound reduction measurements for constructions with 5, 6, and 7 louvers in 1/3 octave frequency bands, ranging from 100 to 5000 Hz. From the obtained results, it can be observed that in the low-frequency range to 500 Hz, the apparent sound reduction index is similar across the all barrier configurations. Additionally, the measured index is relatively high at low frequencies. However, these results may be affected by room or measurement effects. The chamber may have standing waves at low frequencies that "trap" energy, making the insulation performance appear better than it actually is. Moreover, since low frequencies have longer wavelengths, if the microphone is positioned at a node or null point, it may register lower sound levels, thereby artificially increasing the perceived sound insulation. In the mid-frequency range from 500 to 1600 Hz negative sound reduction index values are observed, which is caused by interference resulting from standing waves in the chamber. For these reasons, the most reliable results were obtained when analyzing the sound reduction at high frequencies, ranging from 2000 to 5000 Hz. When examining the barrier composed of 5 louvers, the apparent sound reduction index in these frequencies ranged from 0.1 dB with the louvers positioned at a 0-degree angle, to 5.1 dB when tilted at a 45-degree angle. The weighted sound reduction index (R'_w) ranged from 0.1 dB to 1.5 dB. The barrier with 6 louvers showed sound reduction of up to 8.2 dB at a frequency of 3150 Hz when the louvers were tilted at a 45-degree angle. The weighted sound reduction index (R'_w) ranged from 0.4 dB to 2.1 dB. The construction consisting of 7 louvers achieved the highest results, with the apparent sound reduction index reaching up to 10.2 dB at 4000 Hz when the louvers were tilted at a 45-degree angle. When the louvers were tilted at 30 degrees, the result at high frequencies reached up to 5.3 dB; at 15 degrees, up to 3.1 dB; and up to 2.4 dB at 0 degrees.

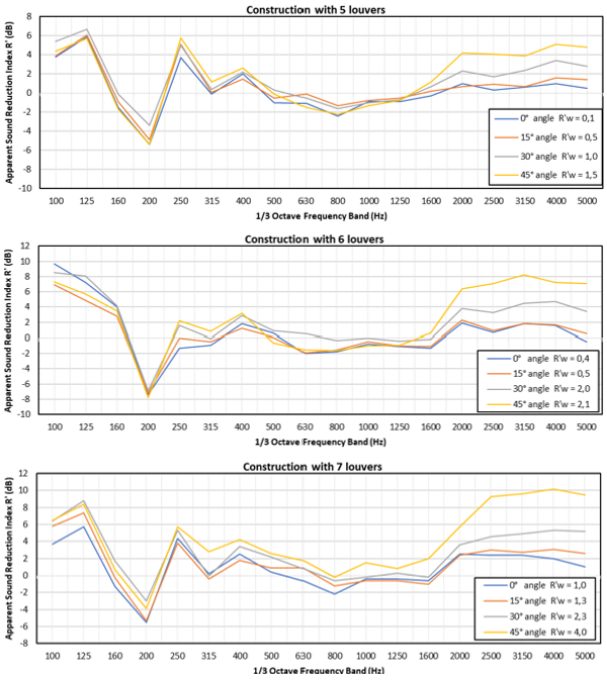

Figure 6. Louvered noise barrier sound reduction.

The weighted sound reduction index (R'_w) of construction with 7 louvers ranged from 1.0 dB to 4.0 dB at inclination angle from 0 to 45 degrees.

Another parameter examined was the sound insertion loss (IL). The insertion loss results for the louvered barrier are presented in Figure 7. For the barrier with 5 louvers, the results at low frequencies (100–500 Hz) reached up to 6.01 dB at 100 Hz when the louvers were tilted at a 15-degree angle. At 400 Hz, the highest IL was measured at 5.08 dB with the louvers tilted at 45 degrees. As with the previously analyzed parameter, results at low frequencies can be influenced by room or measurement effects. In the mid-frequency range (500–1600 Hz), the IL reached up to 6.26 dB at 1600 Hz. The highest IL was observed in the high-frequency range, reaching up to 8.35 dB near 5000 Hz with the louvers tilted at a 45-degree angle. At high frequencies, the influence of increasing the tilt angle on achieving higher insertion loss is clearly noticeable.

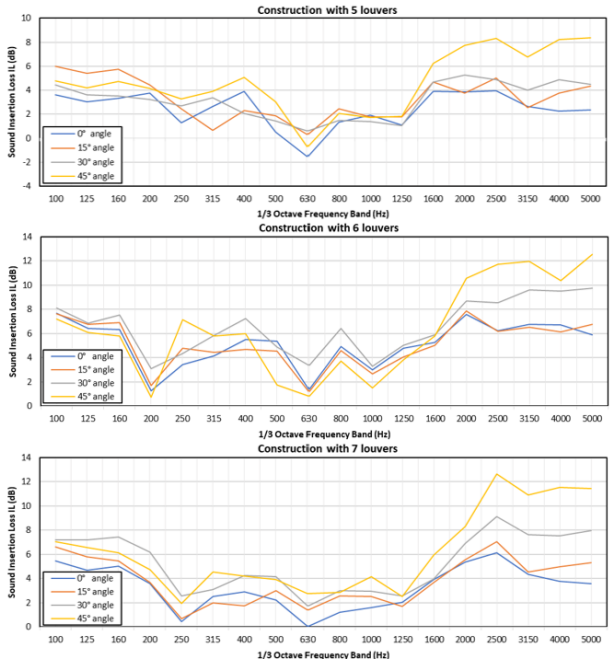

Figure 7. Louvered noise barrier sound insertion loss.

For the barrier with 6 louvers, the results of insertion loss at low frequencies (100–500 Hz) reached up to 7.52 dB at 160 Hz when the louvers were tilted at a 30-degree angle. In the mid-frequency range (500–1600 Hz), the IL reached up to 6.41 dB at 800 Hz with the louvers tilted at a 30-degree angle. The highest insertion loss (IL) was observed in the high-frequency range, reaching up to 12.55 dB at 5000 Hz with the louvers tilted at a 45-degree angle. The construction consisting of 7 louvers achieved the highest IL results overall up to 7.45 dB at low frequencies, 5.96 dB in the mid-frequency range, and up to 12.63 dB at 2500 Hz.

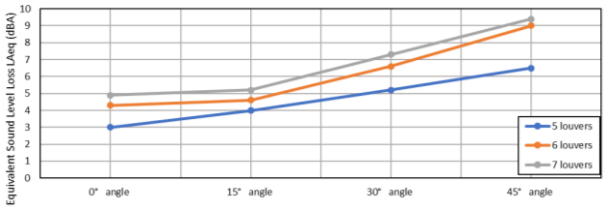

Figure 8. Equivalent sound level loss (L_{Aeq}) results.

Another parameter analyzed to evaluate the effectiveness of the louvered barrier was the Equivalent Sound Level Loss (L_{Aeq}). The results are presented in Figure 8. According to the data, when the number of louvers increased from 5 to 7 with a louver tilt angle of 0 degrees, the results changed from 3.0 dB(A) with 5 louvers to 4.3 dB(A) with 6 louvers, and 4.9 dB(A) with 7 louvers. When the louvers were tilted at a 15-degree angle, the results were 4.0, 4.6, and 5.2 dB(A), respectively. Increasing the tilt angle to 30 degrees, the equivalent sound level loss reached 5.2 dB(A) with 5 louvers, 6.6 dB(A) with 6 louvers, and 7.3 dB(A) with 7 louvers. The highest equivalent sound level loss in all cases was obtained when the louvers were tilted at a 45-degree angle, with results reaching 6.5 dB(A) for 5 louvers, 9.0 dB(A) for 6 louvers, and 9.4 dB(A) for 7 louvers.

In summary, it can be stated that the main parameter determining the effectiveness of the louvered barrier in all cases is the inclination angle of the louvers. The highest efficiency of louvered barrier is achieved when the louvers are tilted at a 45-degree angle and the structure consists of 7 louvers, as this increases the sound-absorbing surface area and reduces the gap between louvers. The louvered barrier is most effective at attenuating noise in the high-frequency range, from 1600 to 5000 Hz. Similar conclusions were reached by researchers who studied a similar type of louvered noise barrier with sound-absorbing materials applied to the louvers [11-12, 17].

4. CONCLUSIONS

This study evaluated the acoustic performance of a louvered noise barrier incorporating recycled tire rubber granulate as a sound-absorbing material. The experimental results demonstrated that both the number of louvers and their

inclination angle significantly affect the barrier's effectiveness in reducing noise. The most influential parameter across all configurations was the louver tilt angle, with the highest performance observed at 45 degrees. Increasing the number of louvers from 5 to 7 consistently improved sound attenuation results, due to the greater surface area of sound-absorbing material and reduced spacing between louvers. Among the tested configurations, the barrier with 7 louvers tilted at 45 degrees exhibited the best acoustic performance, achieving a maximum apparent sound reduction index of 10.2 dB at 4000 Hz, a sound insertion loss of 12.63 dB at 2500 Hz and an equivalent sound level loss (L_{Aeq}) of 9.4 dB(A). The barrier is most effective in the high-frequency range (1600–5000 Hz), aligning with the typical operational noise range of HVAC and similar equipment. These findings confirm the potential of louvered barriers using sustainable infill materials for application in ventilation-related noise control.

ABSTRACT

Human activities impact the environment, prompting science to help create policies for responsible use of natural resources. Environmental sustainability, biodiversity, and ecology are interconnected and crucial for healthy ecosystems. This means we need to study the ecosystems as a whole, not just as an integration of individual parts.

Sound is present in all environments and can help us understand the relationship between biodiversity and environmental conditions. Scientists usually study sounds in the air, focusing on how living organisms behave in different situations. However, the biosphere includes air, soil, and water, each requiring different methods based on available technology.

We investigated the potential of an instrumental set-up to simultaneously record sounds in air, soil, and water in two ecosystems: mangroves in Mozambique and a humid forest in Italy. Preliminary results allowed to identify common traits and differences between the different components, and suggest we should move beyond traditional methods that only analyze frequencies or acoustic indicators.

1. INTRODUCTION: WHY

Environmental sustainability, biodiversity, and ecology are interrelated foundations crucial for the well-being of ecosystems and the overall health of our planet. Safeguarding biodiversity, which refers to the variety of life on Earth, has received large attention as a key to contribute in the functioning of ecosystems. Every species has in fact a specific role in maintaining the equilibrium of the system, ranging from pollination to soil regeneration. Ecology, the study of interactions between organisms and their environments, helps us understand how ecosystems operate and how human activities impact on it. The integrity of ecosystems relies therefore on a rich tapestry of biodiversity [1] and the interrelationships between organisms and physical conditions [2-4]. Disrupting ecosystems through deforestation, habitat destruction, and the spread of invasive species endangers biodiversity and weakens ecological resilience. Protecting biodiversity is not just about saving individual species but preserving the intricate web of life that sustains ecosystems and the services they provide, such as air, water, soil, and food. In this context, it is essential to incorporate the monitoring of all the different components of biosphere to gain insights into the functioning of ecosystems. However, in many cases, these processes are technically complex, time-consuming, and challenging when needed for feeding models and simulations.

Since biological resources, natural events and human activities are pervading the acoustic field, we focused on monitoring the soundscape of the different components of the environment and look for emergent properties.

We investigated the potential of an instrumental set-up to simultaneously record sounds in air, soil, and water in two ecosystems: mangroves in Mozambique and a humid forest in Italy. Preliminary results allowed to identify common traits and differences between the different components, and suggest we should move beyond traditional methods that only analyze frequencies or acoustic indicators.

2. METHODOLOGY: WHERE, WHAT AND HOW

2.1 Locations

An instrumental set-up to monitor simultaneously the soundscapes in air, soil, and water has been developed and installed in Italy and in Mozambique.

One observing station was positioned in the Regional Park of Migliarino, San Rossore, Massaciuccoli, central Italy, 4 m above sea level (43°43'18.2"N, 10°17'4.8"E). The Park extends on a coastal alluvial plan, characterized by a coastal dune system [5]. In this environment, superficial aquifers are present, and the study area was selected within a coastal oak forest dominated by Quercus ilex L., typical of the Mediterranean forest ecotype of the Regional Park. The access to the Park is limited and very few cars can enter every day.
Data were acquired from March 2024 to July 2024.

Another station was installed in the island of Inhaca, in Mozambique, in two different locations (26°2'49.2"S, 32°54'3.6"E, and 26°3'8.22"S, 32°53'53.56"E). Both locations are characterized by the presence of mangroves and are included in a reserve area in Inhaca, where human activities are limited to few passages by foot, and they can be considered as pristine environments.
Data were acquired for two weeks during a summer school of the ManGrowth project held in October 2024 [6].

2.2 Instrumentation

A system consisting of four acoustic sensors were used and positioned accordingly to the geomorphology of the environments we selected for the observations.
The signals were amplified using the four channels of a Zoom P4 Podtrack, and the respective gains were adjusted to maintain the mean signals within the available dynamic range. Simultaneous recordings at 16 bit and 44100 Hz sampling frequency were saved as successive files of 3h 22m 53s duration each.
The overall system, excluding the sensors and the power supply, has a weight less than 1 Kg and dimensions of less than 20x20x20 cm3.

2.3 Positioning

One microphone (model Maono model PM 320), protected from atmospheric agents such as rain and wind, was positioned above the ground at approximately +60 cm in Italy, while hanging at approximately +120 cm on a mangrove branch in Mozambique.
Three other sensors (hydrophones Aquarian model H2a) were positioned.
In Italy, one hydrophone was at -15 cm depth from the ground level, and other two hydrophones, aligned vertically, at -15 cm and -80 cm respectively and both at a distance of approximately 13m from the first hydrophone. The hydrophone at -80 cm was immersed in the aquifer.
In Mozambique, one hydrophone was hanged on a mangrove's root, and at a height that allowed the sensor to be in air or in water accordingly to the tide cycle, another hydrophone was buried in the soil, that in our case was mainly in the mud, the last hydrophone was a few meters apart from the other two, ad always in the water. The first location was on a flat area, while the second close to a river.

In Fig. 1 and Fig. 2, the three different locations and positioning of the sensors are shown.
We will refer at signals from the four different positions of the sensors in the three locations as specified in Table 1.

Table 1. The four different positions of the sensors in the three locations. Colours refer to sensors in Fig.1.

REFERENCE NAMES	Location	Position
HUMFOR_AIR	Humid forest, IT	AIR
HUMFOR_SOIL1	Humid forest, IT	-15 cm
HUMFOR_SOIL_2	Humid forest, IT	-15 cm
HUMFOR_AQUIFER	Humid forest, IT	-80 cm
MANFLAT_AIR	Mangroves, MZ	AIR
MANFLAT_BRANCH	Mangroves, MZ	Branch
MANFLAT_SOIL	Mangroves, MZ	Mud
MANFLAT_WATER	Mangroves, MZ	Water
MANRIVER_AIR	Mangroves, MZ	AIR
MANRIVER_BRANCH	Mangroves, MZ	Branch
MANRIVER_SOIL	Mangroves, MZ	Mud
MANRIVER_WATER	Mangroves, MZ	Water

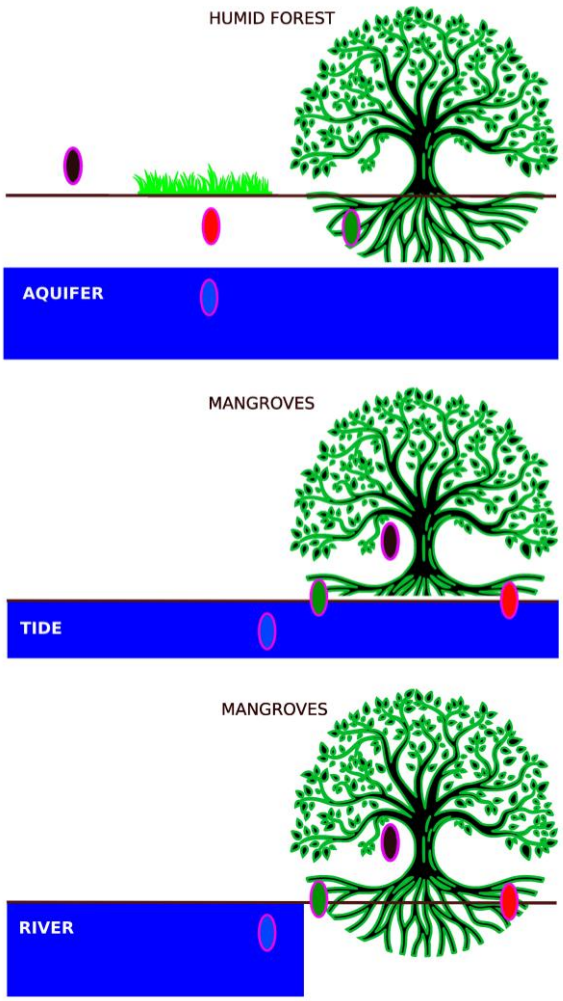

Figure 1. A schematic representation of the three locations (from upper to lower panels) and the four different positions of the sensors (colours refers to the positions described in Table 1).

2.4 Data analysis

Signals were analyzed via Fast Fourier Transform, using first the software *Audacity* for a preliminary check of frequencies and main traits. Timeseries, power spectra and further analysis were obtained with *IDL* software package. Additional elaboration of the signals to compute the acoustic indexes was performed using different software packages (soundecology [7-8], *warblerR* [9], *tunerR* [10] *seewave* [11]).

Figure 2. The observing stations in the three locations (from top to bottom, respectively: the humid forest in the Park of San Rossore, the first and second stations in Inhaca).

3. RESULTS

What immediately emerged from the analysis is that the dynamics of the soundscape in Inhaca MANRIVER is much richer than MANFLAT and richer than in the Park of San Rossore. Some samples are shown in Figures from 3 to 8.

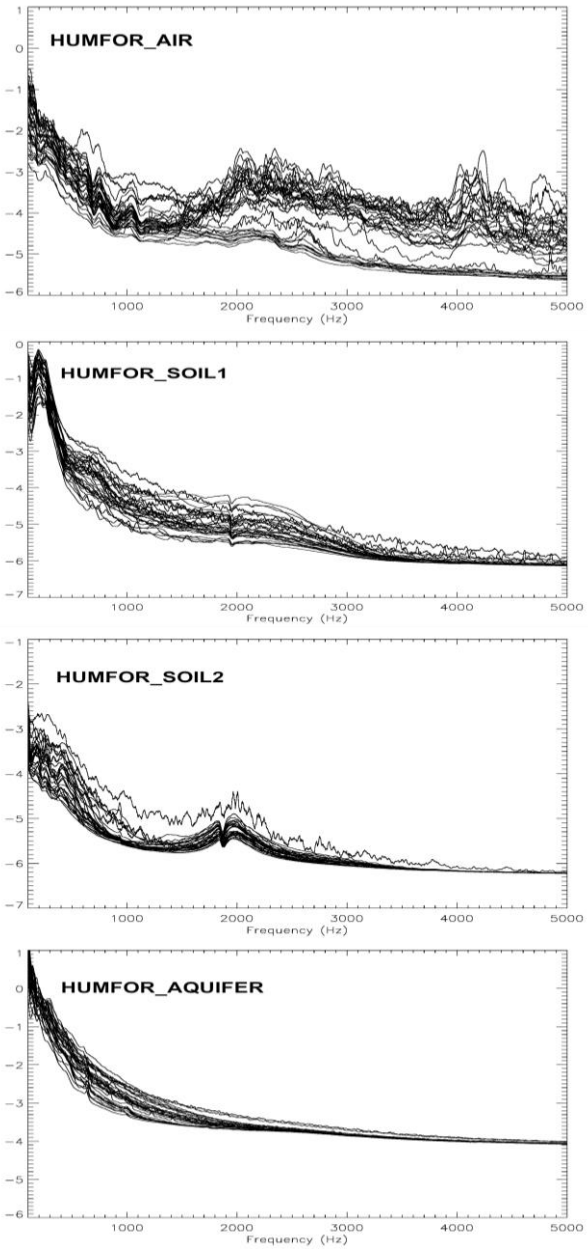

Figure 3. The log in base 10 of the power spectra (centred between 1 and 5 kHz to better show the details) of the signals from HUMFOR_AIR,HUMFOR_SOIL1,HUMFOR_SOIL 2,HUMFOR_AQUIFER (from top to bottom panels respectively). Each curve corresponds to a power spectrum of a set of 43 files of 3h 22m 23s duration, starting from 24 May 2024. On y-axis arbitrary units.

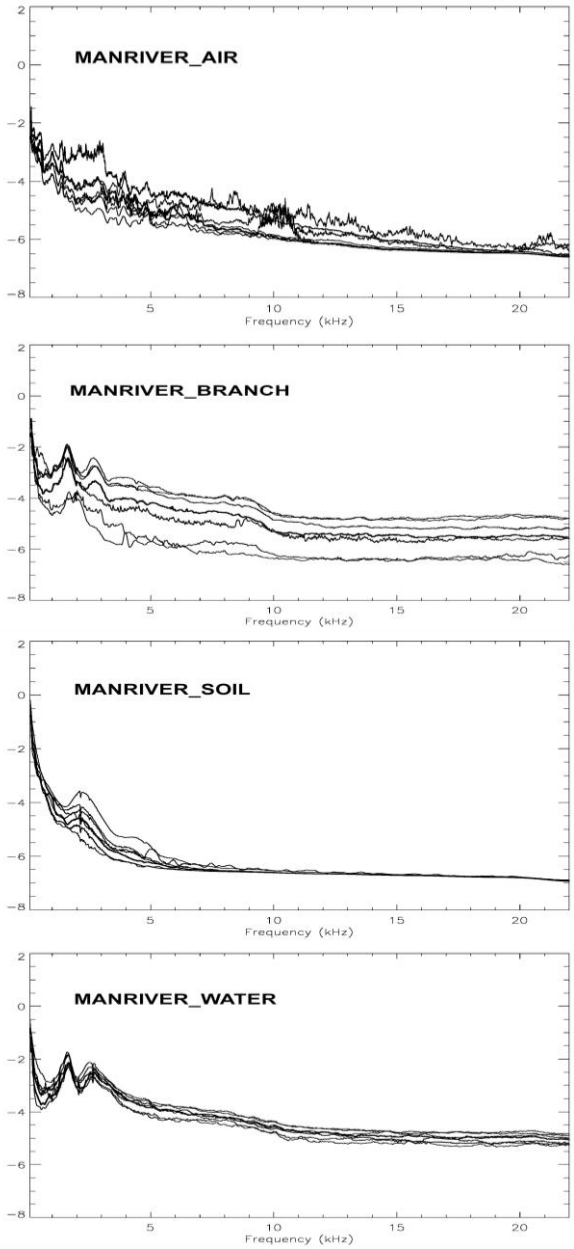

Figure 4. The log in base 10 of the power spectra (up to the Nyquist Frequency) of the signals from MANRIVER_AIR,MANRIVER_BRNCH,MANRIV ER_SOIL,MANRIVER_WATER (from top to bottom panels respectively). Each curve corresponds to a power spectrum of a set of 7 files of 3h22m23s duration, starting from 6 Oct 2024. On y-axis arbitrary units.

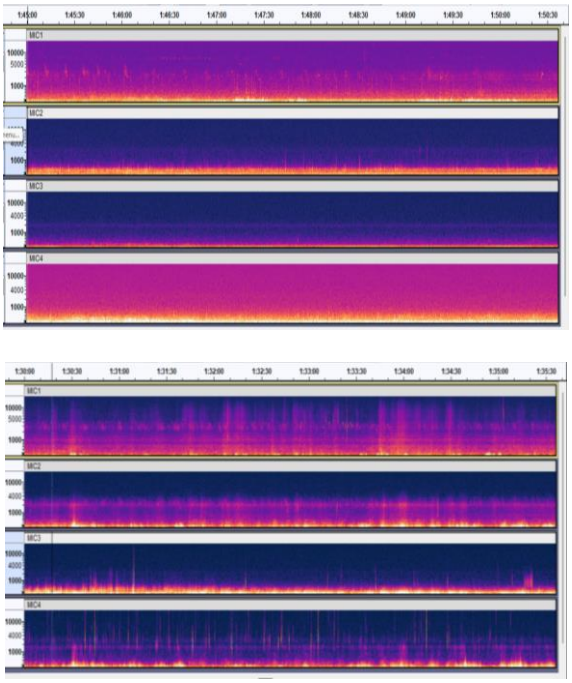

Figure 5. Examples of traits of power spectra for the 4 sensors in Park of San Rossore (upper panel) and in Inhaca (bottom panel). Panels show a 5-min zoom of the power spectra of a 3h22m23s run. On y-axis, frequencies in Hz. White and reddish colours refer to more powerful signals.

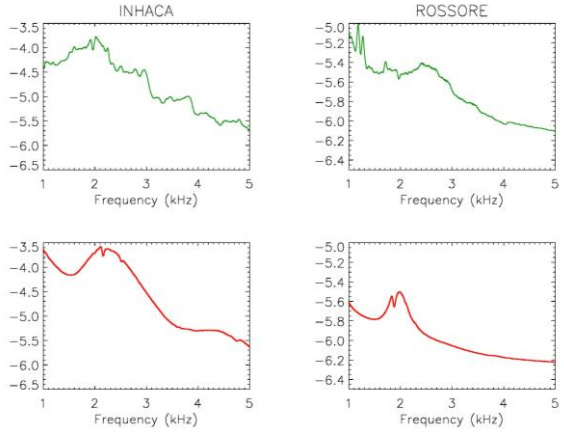

Figure 6. The log in base 10 of the power spectra (centred between 1 and 5 kHz) of the signals from MANRIVER_BRANCH and MANRIVER_SOIL (on the left, in green and red respectively), HUMFOR_SOIL1 and HUMFOR_SOIL2 (on the right, in green and red respectively), for a 3h22m23s temporal window. On y-axis arbitrary units.

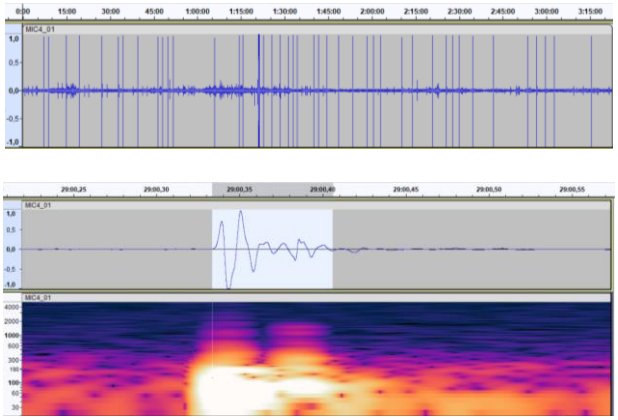

Figure 7. Examples of impulsive signals (i.e. spikes) detected in the aquifer in Park of San Rossore on 19th March 2024. Upper panel: a 3h22m23s run. Bottom panel: a zoom on one of the impulses with the associated power spectrum (on y-axis, frequencies in Hz). The impulses are not periodically occurring, show always the same signature, and last approximately 0.07s.

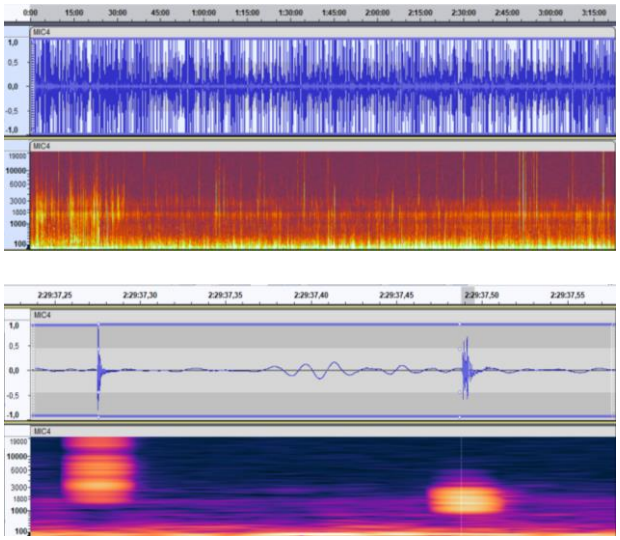

Figure 8. Examples of impulsive signals (i.e. spikes) detected in the river in Inhaca on 6th October 2024. Upper panel: a 3h22m23s run with the associated power spectrum (on y-axis, frequencies in Hz). Bottom panel: a zoom on a couple of successive impulses with the associated power spectrum (on y-axis, frequencies in Hz). The impulses are not periodically occurring, show different signatures with durations between 0.02 and 0.08s.

4. DISCUSSION AND CONCLUSIONS

Investigation of soundscapes in air relies on an historical large experience in the recognition of acoustic sources. Signatures of natural sources (e.g. rain, thunders, earthquakes), biological (mainly birds) and anthropogenic ones (e.g. cars, aircrafts) have been catalogued and many tools are available. It is not the aim of this paper to list the species that have been identified. As an example for one of our locations, some reports are available for the identification of birds In Inhaca [12].
Many acoustic indexes have been proposed for the extraction of information from the data, and their values have to be interpreted accordingly to the benefits and limitations that each of them can provide [13-14].

Despite of the large experience in acoustics in air, the identification of signals to the respective sources is a real challenge in soils and water.
In fact, when an acoustic signal is difficult to be clearly recognized in the spectrum, the experience as humans embedded in soundscapes in air facilitates the recognition via listening directly the sound. In soils and water this is very rare.
Acoustic studies in various terrains have traditionally focused on investigating movements within the Earth's mantle or rock layers. Beyond seismic applications, acoustic measurements served to monitor changes in soil characteristics, as well as capture sounds related to flowing water, cracks, and other indicators of physical conditions or habitats for flora and fauna. Generally, the methodologies to observe the biosphere within soils are not fully developed, and only a few examples have been documented. Our understanding of soil soundscapes at higher frequencies than those typically measured by geophones (20–20,000 Hz) remains limited, likely due to the increased attenuation of sound. In fact, soil structures strongly attenuate acoustic wave propagation above 2 kHz [15].
Few examples of acoustic studies of biodiversity in soils reported, mainly in forests [13,16]. Acoustic traits were associated with abiotic parameters and soil communities, Diurnal and seasonal trends were observed. Additional experiments in laboratory have been implemented to associate soundscapes and biotic sources in soils [17]. All the mentioned observations used sampling frequencies below 50kHz.
Some progress has been made in studying soundscapes within aquatic environments, particularly in marine ecosystems. The Wenz curves [18] still serve as the primary framework for understanding marine soundscapes, outlining the key characteristics of the spectral distribution of acoustic sources. However, most studies focus on the effects of maritime traffic at low frequencies, and many biological sources remain difficult to identify, with the exceptions of mammals' vocalism and fish chorus. Innovative approaches have been proposed for understanding the links between acoustic sources and processes that govern the equilibrium of the marine ecosystems [19-20].

For these reasons, when approaching the soundscape of ecosystems as a whole, we need to reflect on the limitations of the used instrumentation and the previous knowledge that can suggest any interpretation.

We installed acoustic observing stations in different ecosystems, and we took advantage of the high sensitivity of hydrophones installed in humid or aquatic media.
The system has already proven its potential to monitor the different components of the biosphere in a mangrove ecosystem in a remote island in Mozmbique [6].
Now we compared the data acquired also in a humid forest in a Reserve Area in Italy.
We focused on the main traits, commonalities and differences between the soundscapes, looking at clues for the identification of signatures of the ecosystems as a whole, that when signals are acquired simultaneously in air, soil and water.

Having in mind that is not the aim of this paper to describe in detail the identification of the signatures of the acoustic sources, we summarize the main results as follows.
Commonalities: the signals from the soil and vegetation show clear acoustic signatures at frequencies between 1 and 4 kHz. The power spectra show a characteristic "bell" shape with details that are slightly different between the stations, suggesting that they refer to a distribution of contributing acoustic sources (see Fig. 6).
Differences: the locations are very different in terms of ecosystems, with the African one characterized by a richness of biodiversity and the influence of tides. The aquifer in Italy is poor of living organisms, in contrast with the river in Africa. In terms of acoustic noise, the Italian ecosystem, despite embedded in a reserve area, is largely impacted at low frequencies by the aircraft passages that are detected in all the components, while the human impacts in Inhaca have not been detected and can therefore be considered a true pristine environment for acoustic monitoring.
Impulsive events in the aquatic media have been recorded in both locations: they are both aperiodic but their nature is very different.

Those in the aquifer shows a constant temporal profile, while those in the river not. We suggest that those in the aquifer are related to the relaxation of energy associated to the physical properties of the system, while those in the river are associated to the crustaceous and crabs.

In this context, we proceed to a comparison of the information extracted via acoustic indexes and other indicators produced by algorithms that were built ad-hoc to extract different information. Power spectra of 0.27s time intervals have been computed and, at different frequencies, powers above 10 standard deviations were selected and identified as events. The number of spikes has been averaged over a 5 min interval and named EVENTS.

We report the temporal behaviour of classical acoustic indexes and one indicator (EVENTS) in Fig. 9 and 10.

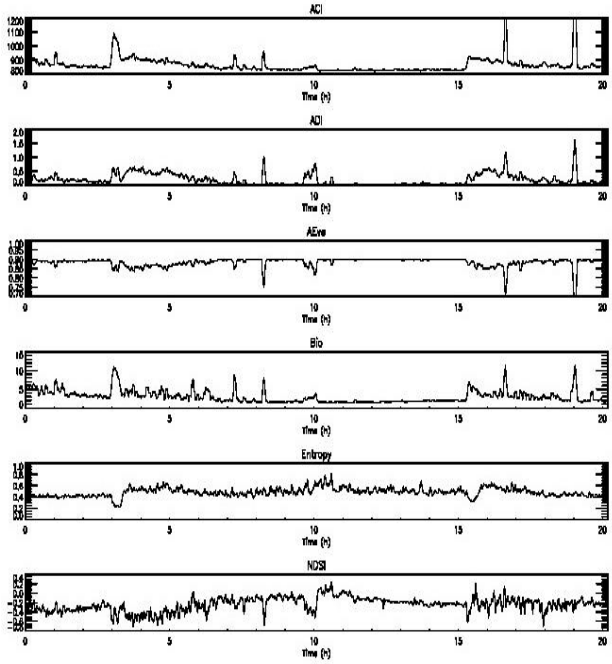

Figure 9. The values of different acoustic indexes (from top to bottom: ACI, ADI, AEve, Bio, Entropy and NDSI) computed for MANRIVER_WATER on 1st Oct 2024.

To conclude, we showed that the soundscape at frequencies between 1 and 4 kHz *in soils* from different ecosystems can be a useful tool to describe the characteristics of biotic sources and their health.

We also showed that the information on biodiversity usually extracted via acoustic indexes can be misleading, as already referred [21] when applied to soils and aquatic environments, suggesting to look at different data analysis for a better understanding of the interconnected components of the ecosystems.

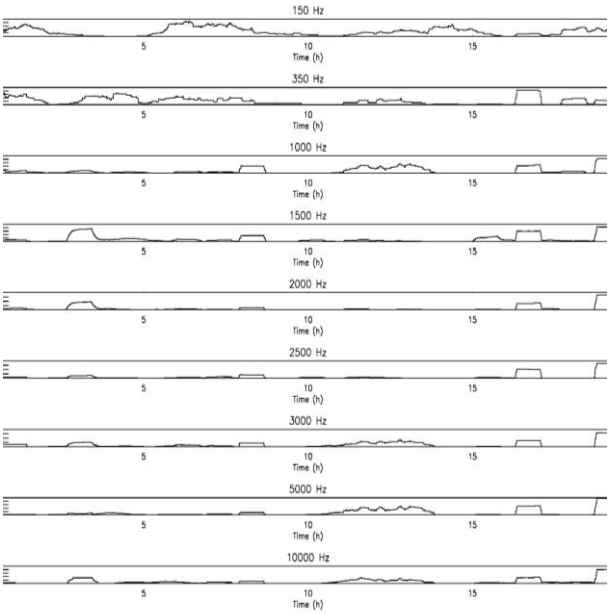

Figure 10. The values of the indicator named EVENTS (see text) at different frequencies (MANRIVER_WATER on 1st Oct 2024). Temporal coincidences at many different frequencies suggest impulsive events. Different time cycles are shown, preliminarily associated to biological sources and/or physical processes. On y-values are arbitrary units, aiming to show time cycles.

5. ACKNOWLEDGMENTS

This research was conducted within the framework of the ManGrowth Project (Preservation of Ecosystems for Sustainable Development – AID 012432/01/2), funded by the Italian Agency for Development Cooperation, and the project AFONIA, funded by the National Research Council of Italy.

We thank Paolo Ramoni for his valuable and outstanding support in Inhaca. We thank Augusto Nhampossa, Aura Rapino, Clotilde Nhancale, Lavinia Scepi, and Zaira Macheve for their help in the installation of the stations in Inhaca, and Damiano Biagini and Michele D'Ambrosio in the installation of the station in Park of San Rossore. We thank the Regional Park of San Rossore for their collaboration, the authorization to install the observing station and their valuable support in logistics and management of the activities.

ABSTRACT

Noise pollution is increasing in both scope and intensity due to the growth of the human population and urban development, significantly impacting terrestrial and aquatic habitats. Anthropogenic noise is pervasive in nature and has been shown to affect a wide range of animal taxa. Recent studies, however, reveal that noise and vibrations can also influence plants, altering their morphological, physiological, and genetic traits. This suggests that noise pollution may exert effects on ecosystems at more complex levels than previously understood. In this study, we investigated the effects of broadband noise (pink noise) on two plant species (one herbaceous and one tree species) to explore its potential impact on vegetation. Laboratory experiments were conducted under controlled conditions at the Department of Earth and Environmental Sciences, University of Milano-Bicocca, Italy. Seeds were planted in soil-filled pots and placed within two phytotrons -one designated as the treatment chamber, where pink noise was continuously emitted through a speaker, and the other as the control chamber, with no noise exposure. We assessed whether noise influenced germination rates, growth and survival of plants. Preliminary results show an effect on germination and development of the herbaceous species.

Keywords: *anthropogenic noise, laboratory experiment, plant, soil, microbiome.*

1. INTRODUCTION

The rapid expansion of urban areas has led to a significant increase in noise pollution, which now poses a serious threat to both terrestrial and aquatic ecosystems [1]. Among the various sources of anthropogenic noise, traffic and industrial activities are particularly disruptive to biodiversity [2–3]. While noise pollution is widely recognized as an environmental stressor, its impact extends beyond animals to affecting a broad range of organisms [4]. Previous research has extensively documented how noise interferes with animal communication, reproduction, and spatial behaviors [1–5–6].

More recent findings indicate that plants, too, can perceive and respond to sound stimuli [7–8]. Unlike animals, plants are immobile and must endure environmental stressors, relying on complex signaling networks and adaptive mechanisms to cope with fluctuating conditions [9]. Studies suggest that exposure to certain sound frequencies can alter seed germination, plant growth, oxidative stress levels, and the expression of stress-related genes [8]. Prolonged noise exposure has also been linked to reductions in photosynthetic and transpiration rates, ultimately affecting plant development and survival, particularly in urban environments [10–11].

Beyond physiological changes, noise pollution may also interfere with ecological interactions, such as plant-pollinator relationships. Excessive noise can disrupt pollinators' ability to detect floral cues, which may negatively impact pollination success and, consequently, plant reproduction [10].

Despite growing concern about noise pollution, most studies have focused on specific sound frequencies (e.g., 0.4kHz, 1kHz, 5kHz), limiting our understanding of the effects of broader noise exposure [12] as road traffic noise. Research on noise-induced changes in plant physiology is still scarce, with only one study examining how traffic noise affects urban vegetation [13]. Given the increasing presence of anthropogenic noise across landscapes, further research is needed to assess its potential effects on plants [14].

This study investigates the impact of broadband noise (pink noise) on an herbaceous and a tree species to evaluate how noise pollution may influence plant-microbe interactions and overall ecosystem dynamics.

2. MATERIAL AND METHODS

2.1 Species studied

This study focused on two species, one herbaceous, *Trifolium pratense L.* and one woody *Ulmus minor L.* The first one, commonly known as red clover, is a temperate perennial herb commonly growing wild in meadows throughout Europe and Asia. The second one is also widely planted in both countryside and urban areas, across almost all Europe. Both species are known for their tolerance to adverse environmental conditions and stress [15–16].

2.2 Experimental design

The study took place in 2023 at the University of Milan-Bicocca, Italy, in two phytotrons (growth chambers - Sanyo, 180Hx80Lx55W), maintaining a temperature of 25°C and a day/night cycle from 9 a.m. to 9 p.m. (light) and 9 p.m. to 9 a.m. (dark). The experiment was conducted using a speaker (JBL Control 1 Pro) placed on the top shelf X (Fig.1) emitting pink noise continuously for 24 hours (stimulus constructed using Audacity software). To mimic natural conditions, fluorescent lights alternated between 12-hour light/dark cycles. Seeds of *T. pratense* and *U. minor*, certified by research institutions, were sown in 24 soil-filled pots (12 per species, 50 seeds per pot). The pots were placed in shelfs Y and Z (Fig.1).

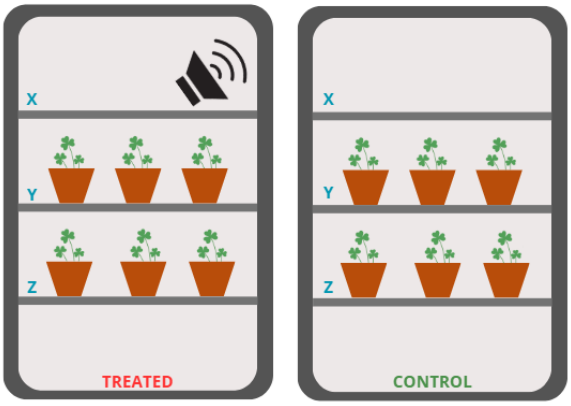

Figure 1. Treat phytotron (left) with a pink noise signal continuously emitted by a loudspeaker in shelf X, 24h a day and control phytotron (right) with no noise.

2.3 Acoustic data collection and analysis

Acoustic data collection was carried out using a Class 1 calibrated sound level meter (SLM -Larson Davis - 831C) equipped with a wired microphone, allowing precise placement inside the phytotron to record noise levels. To characterize the noise perceived by the plants both background and treatment noise levels were measured. The growth chamber was divided into four sections by three horizontal shelves: the speaker was placed on the first shelf (Figure 1), while the plants were positioned on the second and third shelves (three pots per species per shelf). Nine measurements were taken for each shelf (column A, B, C, row 1, 2, 3 - see Figure 2), following a regular grid in the treated and control conditions, with lights on/off, totaling 36 measurements per phytotron. Each recording lasted one minute, with a sampling rate of 48.000 Hz.
The acoustic data collected was extracted from the SLM and analyzed using its corresponding software, BZ5503 and Evaluator 7820. Data exported included LeqZ 1/3 octave bands . Sound pressure levels were measured at each points to characterize levels of noise arriving to the plants for both treatment and control phytotrones.

2.4 Acoustic data collection and analysis

The following plant morpho-functional traits were measured for both species: total and thorough time emergence (%), survival and growth (in terms of plant height, number and area of leaves).

2.5 Statistical analysis

We performed a linear mixed-effects model (LMM) using treatment, light condition and shelf as fixed factors and dB level as response variable. Data exploration followed the protocol described in [17]. We ran the models using packages “lme4” [18]. Visual analysis and figures were computed with R Studio (RStudio). Regarding biological parameters, univariate analyses (ANOVA and SNK tests) were conducted with GMAV software to analyze data regarding the morpho-functional traits considered for the two species and the bacterial abundances.

3. RESULTS

3.1 Acoustic characterization of the phytotrons

The Linear Mixed Model (LMM) analysis (Fig.2; Tab.1) revealed that background noise levels (dBZ) in treated phytotron were higher compared to control ($p < 0.001$).

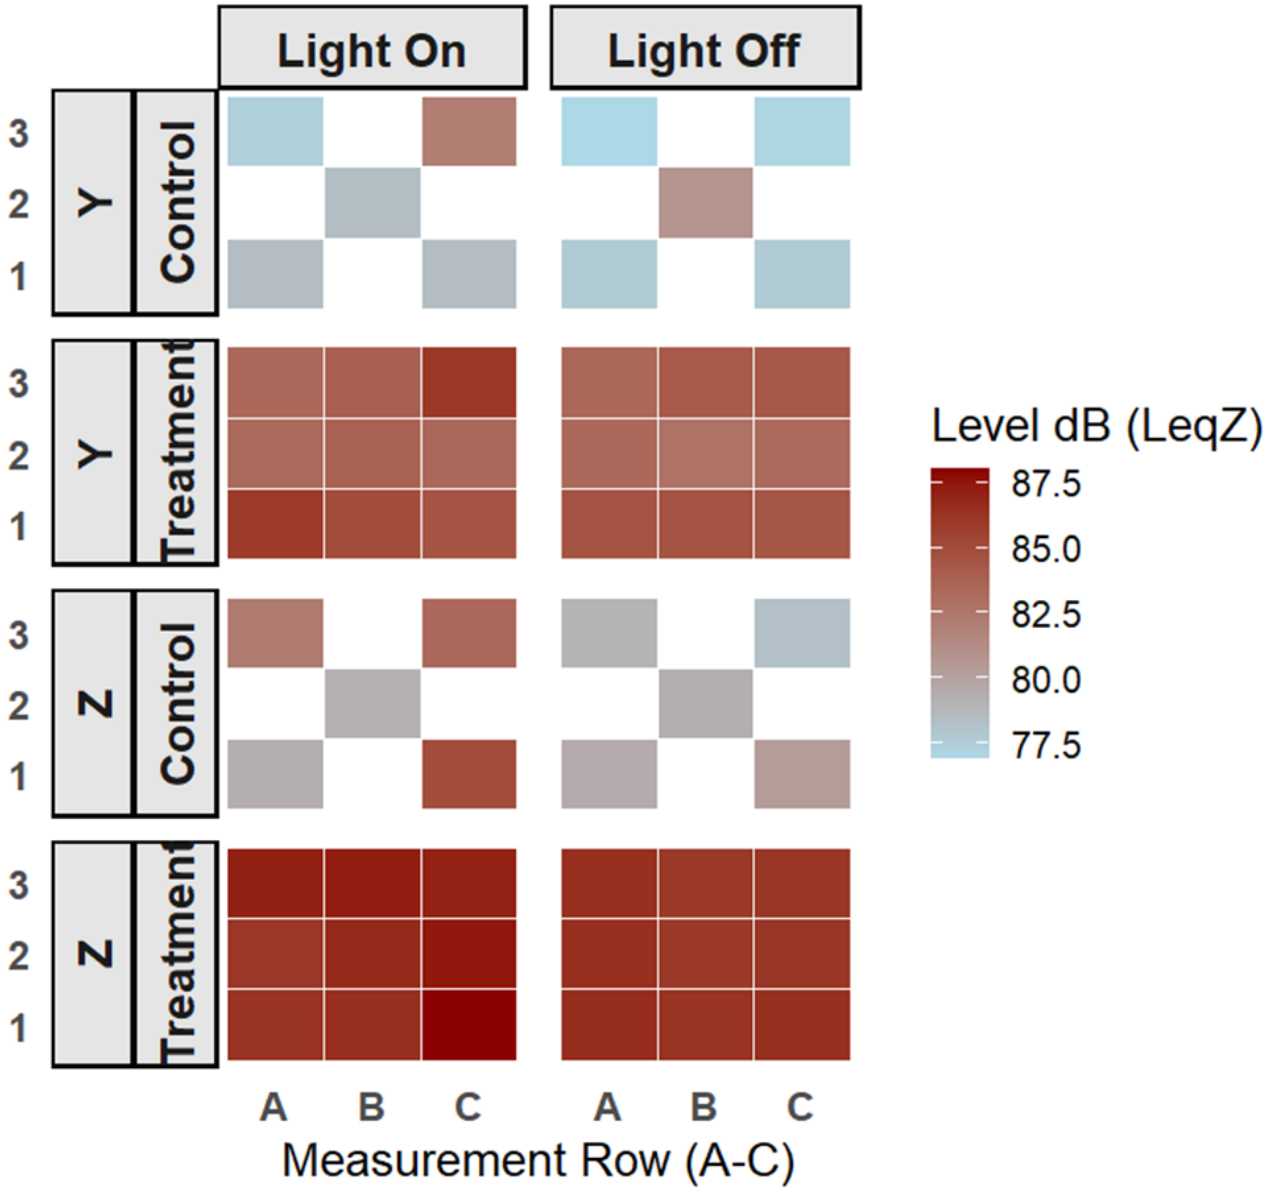

Figure 2. Heatmap of Noise Level dB (Z) by measurement site per shelf per treatment under light on/off condition.

Table 1. Summary of the Generalized Linear Mixed Model. Baseline reference: control, light off, shelf Y.

Factor	Estimate	SE	df	t-value	p-value
Intercept	78.9	0.55	28.45	143.90	<.0001
Treatment	5.37	0.636	44.4	8.453	<.0001
Light On /Off	-0.95	0.720	43.9	-1.313	0.196
Shelf (Y/Z)	2.83	0.720	43.9	3.934	<.0001
Treatment × Light	0.50	0.89	43.9	0.559	0.579
Treatment × Shelf	-0.23	0.89	43.9	-0.257	0.798
Light × Shelf	-1.59	1.018	43.9	-1.529	0.133
Treatment × Light × Shelf	1.36	1.27	43.9	1.077	0.288

Furthermore, the shelf position also influenced the level's noise with the higher levels in Z respect to Y ($p < 0.001$). On the contrary, the light condition, although a bit higher in the light condition, was not significantly different ($p = 0.196$). Regarding interactions, no significant two-way or three-way interactions were found (p-values > 0.05). This suggests that the effects of Treatment, Light, and Shelf Position were largely independent rather than influencing each other. These differences in noise distribution between shelves and treatments could influence plant physiological responses. For this reason, the pots were rotated within the phytotron throughout the experiment to ensure equal exposure to noise.

3.2 Effect of noise treatment on plant species

The effect of the treatment exposure on the target species showed that noise negatively affected the germination of *U. minor*, causing a significant delay and a reduction in the number of germinated seeds compared to the control. In contrast, *T. pratens*e showed no significant differences between the two conditions. At the end of the experiment, no significant differences in plant survival were observed between species and treatments, although *U. minor* showed slightly lower values under noise exposure. However, with regard to the growth, *U. minor* displayed significantly lower values for the height, the leaf number and area under noise exposure. In contrast, for *T. pratense* no significant variations between the noise exposure and the control treatment were observed.

4. DISCUSSION

The results from the acoustic characterization highlight key factors for improving experimental design when studying noise effects on plants. As expected, the treated phytotrons had significantly higher noise levels than the controls. However, the shelf position also influenced the noise distribution by having higher levels observed on the lower shelf. Meanwhile, light conditions showed no significant effect. The absence of significant interactions indicates that treatment and shelf position acted independently. These findings emphasize the need to account for spatial noise variability. Rotating pots, as done in this study, helps ensure equal exposure, reducing bias. Future experiments should integrate such controls to improve reproducibility and isolate noise effects more effectively.

Our results showed an effect of noise mainly on one of the considered plants, *Ulmus minor*, suggesting that species-specific responses to noise occur. This supports previous findings by [19], who observed varied plant reactions to different sound frequencies, with noise having both negative and, in some cases, positive effects on growth. Similar to other environmental factors like moisture, light, wind, and temperature, plant responses to noise appear to be primarily physiological and dependent on species-specific traits and functional groups [20].

5. CONCLUSION

Our results bring two important conclusions regarding both experimental design and noise impact on plants:

- Phytotrons represent a good environment for testing the effect of noise on plants, provided pot rotation is considered, as noise distribution is not homogeneous.
- Noise had an effect on plants, particularly on *Ulmus minor*, suggesting species-specific responses. These findings confirm previous studies and indicate that plant responses to noise, as well as to other environmental factors, depend on the species' physiological and functional traits.

ABSTRACT

In forest ecosystems, detecting birdcalls is hindered by high environmental noise and multiple sound sources, complicating species identification. Beamforming techniques can enhance signal-to-noise ratio (SNR) by focusing on specific directions but face challenges with numerous, unpredictably located sources. This study proposes a novel methodology integrating multidirectional beamforming with automated source selection to address these issues. Our approach sequentially scans multiple directions and employs BirdNET (a machine learning-based platform for bird recognition) confidence scores to identify optimal detection sectors, improving accuracy. Using a Multichannel Acoustic Autonomous Recording Unit (MAARU), experiments were conducted in a controlled virtual sound environment with simulated Eurasian Blue Tit calls under varying SNR conditions (+30dB to -30dB). Results demonstrate a significant enhancement in species detection accuracy compared to single-channel recordings, especially at low signal-to-noise ratio, with beamforming achieving up to 588% improvement in detection counts at -20 dB ($p < 0.0001$) and consistently higher confidence scores ($p < 0.05$). The findings highlight the potential of combining multidirectional beamforming with AI-based detection for biodiversity monitoring in challenging acoustic environments. Future work will extend these methods to field deployments to validate their effectiveness in real-world conditions.

1. INTRODUCTION

Passive Acoustic Monitoring (PAM) offers promising capabilities for biodiversity assessment through IoT sensors and AI analysis [1]. However, practical implementation faces challenges from overlapping sound sources and environmental noise [2, 3].

While autonomous recording units are increasingly used for monitoring bird occurrences in remote areas, multi-channel sensor devices remain uncommon due to data size constraints and their relative novelty in ecological applications [4]. Traditional single-channel systems struggle in low signal-to-noise ratio (SNR) environments, where target bird vocalisations are often obscured by background noise, making species identification difficult without spatial information [4, 5].

Multi-channel recording systems with beamforming techniques present an effective solution by enabling focused listening in specific directions. These techniques can be implemented through either dynamic steering, which continuously adjusts to sound source movements, or static steering, which maintains fixed directional focus points [6].

This research integrates multidirectional static steering beamforming with BirdNET, an AI-based detection system, aiming to enhance biodiversity monitoring accu-

racy in challenging acoustic environments with overlapping sound sources and significant background noise.

2. MATERIALS AND METHODS

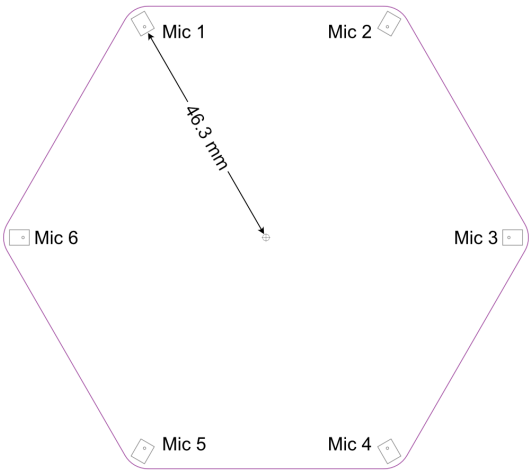

Figure 1. Circular microphone array configuration with six microphones (Mic 1-6) positioned at the vertices. Each microphone is positioned at an equal distance of 46.3 mm from the centre point of the array.

We used the Multichannel Acoustic Autonomous Recording Unit (MAARU) [4,7], which integrates a Raspberry Pi 3 Model B+ with a ReSpeaker 6-microphone circular array containing omnidirectional MEMS microphones (see Fig. 1) [8]. Complete instructions are available on GitHub [9]. The MAARU sampled audio at 16kHz during all experiments [10, 11].

Testing employed a Virtual Sound Environment (VSE) with third-order Ambisonics recordings reproduced through a 31-loudspeaker system [12]. Our experimental scenario combined an 8-minute background soundscape with Eurasian Blue Tit (EBT) calls (*Cyanistes caeruleus*) reproduced sequentially from 31 different positions at progressively decreasing sound pressure levels (70dB to 10dB in -10dB steps). The EBT call was selected for its frequency range (3-8kHz) which aligns with common bird vocalisations (see Fig. 2) [10].

For beamforming implementation, we measured 3D impulse responses using time-stretched pulse signals generated from 31 spatial positions at a fixed distance of 1.5 meters. These measurements incorporated azimuth angles

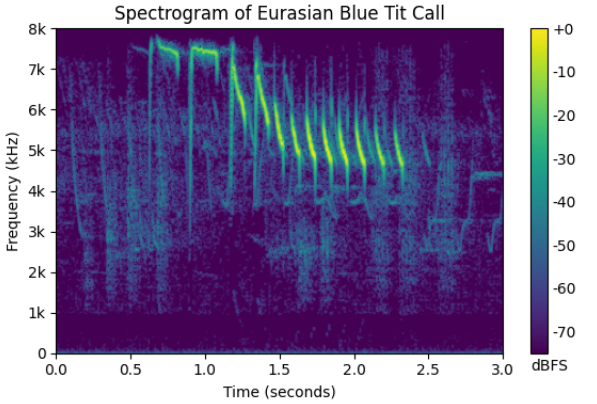

Figure 2. Spectrogram of a Eurasian Blue Tit (Cyanistes caeruleus, XC28208) call showing its distinctive frequency pattern. The characteristic high-frequency modulations (3-8kHz) are visible between 0.5-2.5 seconds.

from 0° to 360° (40° increments) and elevations of -45°, 0°, 45°, and 90°.

Our processing pipeline employed a Butterworth high-pass filter (500Hz cutoff) followed by an Impulse Response-based Filter-and-Sum beamformer, using measured impulse responses as steering vectors rather than analytical models. This data-driven approach captures complex acoustic environment characteristics including room reflections and array imperfections.

For automated source selection, we processed 3-second segments independently through beamforming, `birdnetlib` [13], and `BirdNET-Analyzer` model v2.4 [14]. For determining successful detections, we applied a confidence score threshold of 0.4, which represents a balance between detection sensitivity and false positive reduction as recommended in previous ecological monitoring studies [15, 16]. All detection events that exceeded this threshold were counted in our analysis of detection performance across varying SNR conditions. Our system automatically selects the direction yielding the highest BirdNET confidence score for each time segment, creating a comprehensive spatial acoustic map. For baseline comparison, we extracted single-channel audio from the same recordings and processed it directly with BirdNET without beamforming.

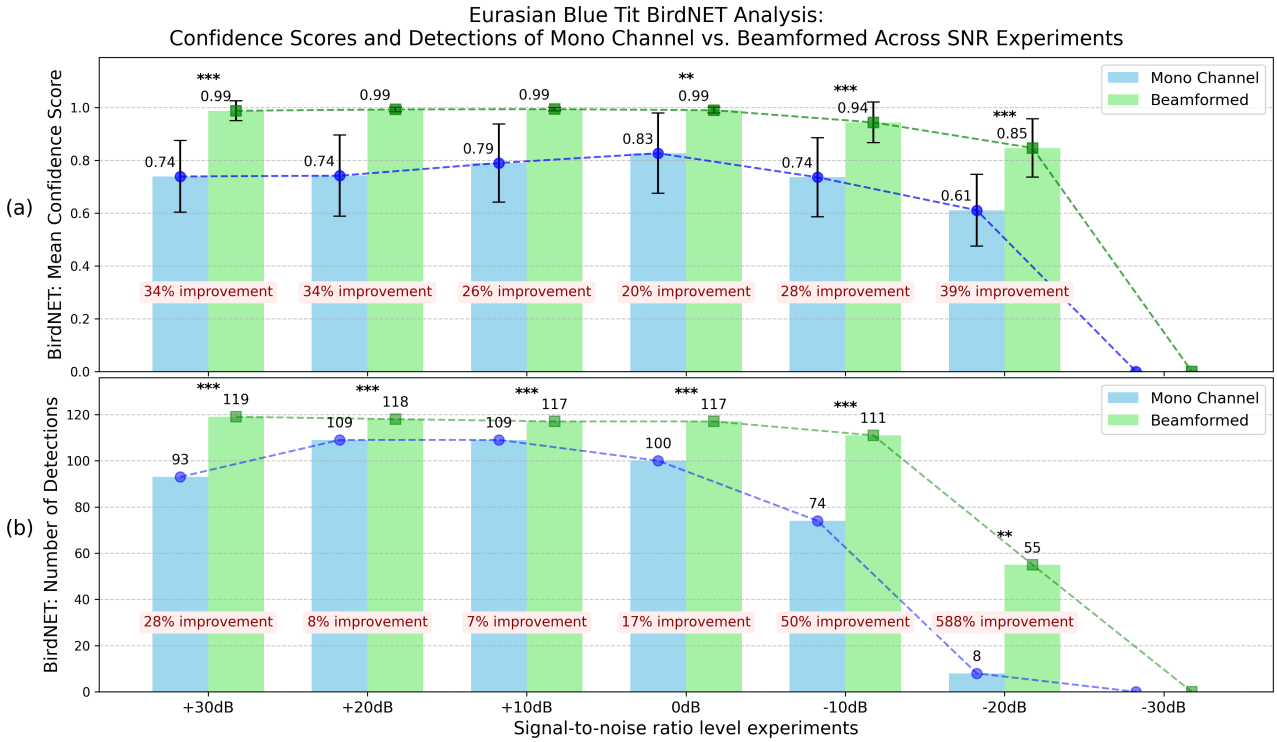

Figure 3. Performance comparison between mono channel recording and multidirectional beamforming for Eurasian Blue Tit detection across decreasing SNR levels. Panel (a) shows BirdNET confidence scores (0-1 scale), while panel (b) displays the number of successful detections (out of 124 possible events). Percentage values indicate the relative improvement of beamforming over mono channel recording. Error bars represent standard deviation.

3. RESULTS AND DISCUSSIONS

3.1 Detection Performance Comparison

Results demonstrate a clear superiority of multidirectional beamforming over conventional mono-channel recordings for birdcall detection. Higher BirdNET confidence scores were consistently achieved with the beamforming approach across various SNR levels (Fig. 3). Paired T-tests revealed significant differences in confidence scores at all SNR levels tested ($p < 0.05$), with Beamformed outperforming Mono Channel by 20-39% (Fig. 3). For instance, at +30dB, Beamformed achieved a mean confidence score of 0.9882 compared to 0.7392 for Mono Channel ($t = 17.0666$, $p < 0.0001$, ***; Fig. 3), with a large effect size (Cohen's $d = 2.6246$). This trend persisted even at lower SNRs, such as -20dB, where Beamformed maintained a confidence score of 0.8466 compared to 0.6107 for Mono Channel ($t = 4.3936$, $p = 0.0022$, **; Cohen's $d = 2.0474$). It is important to note that confidence scores are not direct probabilities and remain specific to the experimental setting and Eurasian Blue Tit species [16].

Both recording approaches showed declining confidence scores at extreme low SNR levels (-20dB and -30dB), with no detections recorded at -30dB where the birdcalls became virtually inaudible, aligning with our experimental design expectations.

3.2 Species Detection Accuracy at Varying SNR Levels

The experimental design incorporated 124 distinct birdcall events. At favourable SNR conditions (+30dB to -30dB), the beamforming approach detected up to 119 calls while mono-channel recordings detected a maximum of 109 calls (Fig. 3). Chi-square tests confirmed signifi-

cant differences in detection rates at several SNR levels. For example, at +30dB, Beamformed detected 119 calls compared to 93 by Mono Channel (χ^2 = 20.3092, p < 0.0001, ***; Cramer's V = 0.2862), indicating a moderate effect size.

A pronounced performance gap emerged at lower SNRs. At -10dB, mono-channel detection dropped to 74 calls while beamforming maintained 111 detections (χ^2 = 27.5768, p < 0.0001, ***; Cramer's V = 0.3335). This disparity widened dramatically at -20dB, with beamforming detecting 55 calls compared to only 8 with the mono-channel approach (χ^2 = 45.0251, p < 0.0001, ***; Cramer's V = 0.4261), corresponding to a 588% improvement in detection counts (Fig. 3). At -30dB, neither method detected any calls, causing statistical analysis infeasible at this level.

These findings, supported by significance stars in Fig. 3, demonstrate the beamforming technique's capacity to maintain reliable detection in challenging acoustic environments, simulating scenarios where birds are at considerable distances from recording equipment.

3.3 Key Performance Trends

Analysis of the performance data reveals several important patterns that highlight the practical advantages of beamforming:

Increasing advantage at lower SNR levels: The most striking trend is how the performance gap between beamforming and mono-channel recording widens dramatically as SNR decreases. While beamforming shows modest improvements (7-28%) at high SNR (+30dB to 0dB), where differences in detection counts were sometimes not statistically significant (e.g., at +20dB, χ^2 = 3.3296, p = 0.0680), this advantage increases exponentially at challenging SNR levels. At -10dB, beamforming achieved 50% improvement in detection counts, which surged to a remarkable 588% improvement at -20dB, supported by a highly significant Chi-square test (χ^2 = 45.0251, p < 0.0001, ***; Fig. 3).

Robustness across varying SNR conditions: Beamforming maintains consistently high performance (confidence scores >0.94 and detection counts >110) across the +30dB to -10dB range, while mono-channel performance fluctuates more dramatically even at favourable SNR levels. For instance,, at 0dB, Beamformed detected 117 calls compared to 100 by Mono Channel (χ^2 = 9.4378, p = 0.0021, **; Cramer's V = 0.1951), highlighting greater stability and reliability regardless of source distance.

Extended detection threshold: The beamforming approach extends the practical detection threshold by approximately 10dB, maintaining useful detection capabilities (55 detections) at -20dB where mono-channel recording nearly fails completely (8 detections). This effectively increases the functional detection range of the recording system, as evidenced by the significant difference at -20dB (p < 0.0001, ***).

These trends suggest beamforming's greatest value lies in extending reliable detection to challenging acoustic environments, effectively increasing monitoring range and providing more consistent data quality regardless of source distance in field deployments.

3.4 Limitations and Practical Considerations

The multidirectional beamforming approach faces three primary challenges:

Computational requirements: Processing an 8-minute recording required approximately 14 minutes (2 minutes for beamforming across 31 directions plus 12 minutes for BirdNET classification), potentially limiting large-scale deployments.

Storage demands: The process generates 31 WAV beamforming files (15MB each) plus a mono file (3MB) from a single 45MB FLAC file, necessitating substantial storage capacity for extensive field deployments.

Complex Impulse Response Characterisation Requirements: An additional significant limitation is the complexity involved in measuring impulse responses for multichannel devices. This process requires specialised equipment (such as precision turntables and calibrated loudspeaker arrays), anechoic or controlled acoustic environments, and considerable technical expertise. The full characterisation of 3D impulse responses across multiple azimuth and elevation angles is time-consuming and must be repeated for each new recording device configuration. This represents a substantial barrier to implementation compared to single-microphone deployments, which require no such calibration procedures.

4. CONCLUSION

This study demonstrates that integrating multidirectional beamforming with AI-based species detection significantly enhances birdcall identification in challenging acoustic environments. Statistical analysis confirmed that Beamformed outperformed Mono Channel across all SNR levels, with highly significant differences in both confidence scores (p < 0.05) and detection counts (p < 0.1

at significant levels), as indicated by significance stars in Fig. 3. Our approach maintained high detection accuracy at SNRs as low as -20dB, far outperforming traditional mono-channel recordings.

The methodology offers a promising framework for developing more sophisticated PAM systems capable of providing valuable behavioral and ecological insights across various species. While focused on birds, the approach could be adapted for other species with vocalisation frequencies below 8kHz.

This initial study demonstrates promising results, but several important areas require further investigation. Field testing in real-life environments with unknown sound source positions is essential to validate performance under natural reverberation conditions and diverse forest soundscapes. A more comprehensive analysis examining how beamforming affects other ecological metrics beyond simple detection is also needed. Additionally, deeper analysis of how detection performance varies with source location could provide valuable insights for optimizing array designs. Parallel to these ecological validations, optimising the computational efficiency of the BirdNET classification process would enhance the practical applicability of this method for large-scale monitoring. These extensions would strengthen the ecological applications of the multidirectional beamforming approach and better quantify its advantages over conventional recording methods across diverse monitoring scenarios.

5. ACKNOWLEDGMENTS

This work is funded by the Indonesia Endowment Fund for Education / Lembaga Pengelola Dana Pendidikan (LPDP), Indonesia (Scholarship Identification Number: 20230522097975).

We are grateful to Neel Patrick Le Penru for granting us permission to use his field recordings in our experiment to recreate the forest soundscape in a virtual sound environment.

ABSTRACT

Multichannel acoustic monitoring uses recorders with multiple microphones to capture the spatial distribution of sounds, potentially providing an enhanced understanding of ecosystems. However, due to practical barriers such as high power demands, large data needs, and ingress protection challenges, there have been few, long-term deployments of autonomous multichannel recorders (i.e., without manual intervention). Here, we describe new, 2 to 22 week long deployments of the Multichannel Acoustic Autonomous Recording Unit (MAARU) in temperate (UK) and tropical (Borneo) environments. MAARU is a custom six-microphone recorder that uses solar power and 4G data transmission for fully autonomous monitoring. We first outline updates to MAARU's weatherproofing and field installation, including a redesigned enclosure with improved robustness to insect ingress, and share lessons for future deployments. In particular, we found that the membranes that seal microphone holes in the recorder casing fail under heavy rain if not sheltered and that 3D-printed polymer parts with a low glass transition temperature may warp due to heat from the electronics. We also discuss MAARU's capacity to amplify sounds from target directions via beamforming, and consider its application to distinguishing bird communities in neighbouring areas of different land use. In all, we hope these insights advance the successful adoption of this powerful technology.

1. INTRODUCTION

Capturing natural soundscapes with multichannel recorders can unlock a range of information about the behaviour and distribution of animals. For instance, sounds' direction of arrival can be calculated, facilitating estimates of species abundance or tracking of individual movement [1, 2]. Beamforming can also be used to hone in on sounds from target directions, producing a higher signal-to-noise ratio (SNR) and allowing enhanced bird call classification and other analyses [2–5].

A growing number of commercial and custom multichannel field recorders have been developed (see an overview in [3]), including stereo units [6] and those with four or more microphones [3–5]. However, many remain costly and/or are not designed for fully autonomous deployments, with self-sufficient powering and data transmission alongside robustness to prolonged environmental exposure. Such features are necessary to obtain the large-scale insights of long-term continuous Passive Acoustic Monitoring (PAM) and/or for monitoring ecosystems and illegal activity in near real time (e.g., [7]).

MAARU was designed to fill this gap: it is open source, built from mostly off-the-shelf (OTS) components, and can employ solar powering and cellular data transmission [3]. Building on an existing fully autonomous, open source recorder [8], MAARU's core hardware consists of a Raspberry Pi (2B v1.2, 3B or 4B)

with a sound card and circular array of six omnidirectional MEMS microphones (full details in [3]). The existing MAARU design features two weatherproofing options: an affordable, modified OTS container and a custom 3D-printed enclosure for semi-autonomous deployment.

We present a new hybrid weatherproofing design, with modified OTS and 3D-printed parts for improved robustness and ease of use and manufacture. We deployed MAARUs with this updated weatherproofing for up to 5 months at temperate sites in the UK and in the tropical forests of Malaysian Borneo, to validate the revised design and further investigate the applications of beamforming in ecoacoustics. Here, we review how these deployments went, suggest further improvements to MAARU's design and deployment, and discuss forthcoming analyses.

2. MATERIALS AND METHODS

2.1 Weatherproofing Redesign

MAARU's original modified OTS weatherproofing was designed to be highly affordable and require no specialist tools to build. Early deployments revealed robustness challenges, though, in particular from animal interference, such as rodents chewing on power cables, and impacts, such as falling from height. The existing 3D-printed version addressed some of these issues with a sturdier enclosure. However, it was cumbersome to print (>15 hr on a *Prusa* MK3S) and required applying a coat of resin to fully seal against water, limiting accessibility for users without access to a well-equipped workshop. The water resistant ePTFE vents used to cover the microphone holes in both original designs were also found to be susceptible to insect ingress – specifically, termites chewing through the vents – during deployments in the Brazilian Amazon.

For the redesigned weatherproofing, we thus opted for a durable polycarbonate, water-resistant case (*Tactix* Water Proof Case (L), ∼10–15 USD depending on vendor) to house the core electronics (Raspberry Pi, sound card, microphone array, 4G dongle and a 12–5 V step-down converter). The case lid hinges for easy access to the internals. To prevent insect ingress, we used much smaller microphone holes and ePTFE vents, as the MEMS microphone ports are <0.5 mm in diameter. We also attached patches of fine stainless steel woven mesh (100 mesh, 0.15 mm hole size) over each microphone hole on the exterior of the case, using a water- and UV-resistant adhesive (Fig. 1A).

To accurately align the microphone ports with the corresponding holes in the case, we designed a 3D-printed mounting frame that sits near-flush against the base and sides of the case. The frame attaches to the case via velcro and the electronics mount to it without adhesives, allowing all parts to be removed with ease. The Raspberry Pi, sound card and microphone array form a sub-assembly, joined by screws and metal standoffs, that rests on springs glued into the mounting frame. A 3D-printed ring also sits around the microphones and flush with the top of the case. It contains a small hole for each microphone port and acts as an additional physical barrier to insect ingress. The springs prevent excessive force being placed on this sub-assembly when the case lid is closed.

A single power cable enters the case via a watertight cable gland. This can either be a USB cable connected to the Raspberry Pi, or, for solar powered deployments, a two-core power cable (AWG 17 was suitable for our powering setup), which connects to the step-down converter via bullet-style crimp connectors. Wherever possible, appropriately-specified crimp connectors were used instead of soldering to make electrical connections, as they can be easily dis/re-connected. The holes for the microphones and cable gland are all manually drilled and accurately located using 3D-printed jigs that can attach to the *Tactix* case. The electronics power cable's other end attaches to a 30 A solar charge controller which is housed with a lithium iron phosphate (LiFePO4) battery in a separate IP56-rated polypropylene box (supplier: *Solent Plastics*, product code: WBAT-S, ∼10 USD). Both the electronics power cable and a heavier duty power cable that runs to the solar panel (in our case, AWG 13 was suitable) enter this box via cable glands in manually-drilled holes. Where possible, we wrapped cables in a semi-rigid plastic cable tidy and nylon cable mesh to protect them from rodents and other animals. If costs permit, we recommend using armoured cable for long-term deployments.

2.2 UK and Borneo Deployments

MAARUs were deployed at four temperate sites at Imperial College's Silwood Park campus (Ascot, UK) for various periods of time (from 14 to 125 days) between February and July 2024. MAARUs and 60 W solar panels were mounted to custom-built metal frames fixed to the ground, with the battery box placed underneath (Fig. 1B). In September 2024, MAARUs were deployed at six tropical sites spanning a land-use gradient in and around the Danum Valley Conservation Area in Sabah, Malaysia. Two devices were deployed in each of: old-growth forest, logged forest, and smallholder oil palm plantations.

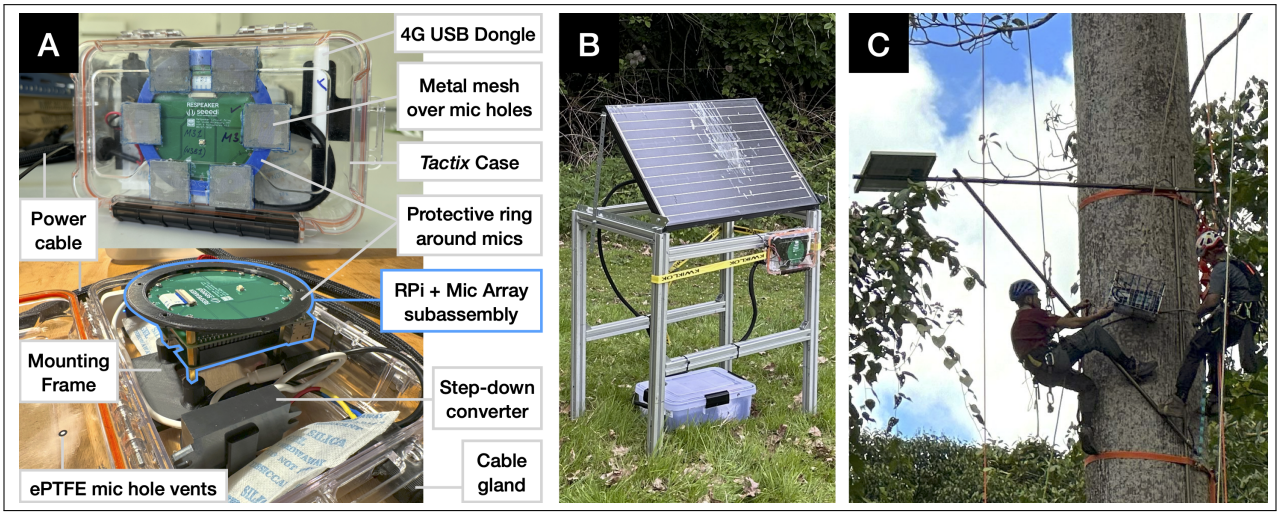

Figure 1. **A:** Redesigned MAARU weatherproofing enclosure. **B:** MAARU deployment in the UK. **C:** Professional tree climbers Jamiluddin Jami and Louis Makhluf mount a MAARU to a tree in Malaysian Borneo.

Data were collected between approx. two weeks and five months, depending on devices' survival time (see Section 3). For access to sunlight and protection from animals on the ground (e.g., elephants), the old growth and logged forest devices were mounted to trees by professional tree climbers. Solar panels (three 55 W and one 100 W) were attached to triangular structures assembled from aluminium poles (Fig. 1C). MAARUs and battery boxes were placed in a cage built from six steel grills (supplier: *DAISO*, ∼6 USD per cage), to protect them from animals in the trees (e.g., monkeys). The cages and pole structures were fixed to trees with heavy-duty ratchet straps. For the oil palm sites, the device cage and 100 W solar panels were mounted to slotted angle bars inserted in the ground.

Across all sites, MAARUs were deployed near the edges of different habitats or land-use types and/or within audible range of roads or other sources of anthropogenic noise from prevailing directions, so as to explore various applications of beamforming. All recordings were compressed to FLAC on-device and streamed over 4G to *Box* Cloud Storage via FTPS. For continuous 24/7 recording, this creates ∼8 GB/day of data (∼250 GB/month), so all devices had a minimum 300 GB/month cellular data plan.

3. RESULTS AND CONCLUSIONS

MAARU's redesigned weatherproofing improves robustness to previous failure modes while enabling better access to internals and easier manufacturing than the previous 3D-printed enclosure. However, new failure modes have been discovered. For the UK deployments, the 3D-printed parts were made from PLA, which is safe (minimal fumes) and straightforward to print, but has a fairly low glass transition temperature (T_g) of ∼57°C [9]. This was expected to be sufficient, however parts in three units warped due to heat from the electronics, damaging several microphones in these units (sometimes in just two weeks after deployment). The Raspberry Pi and 4G dongle can generate considerable heat, which was likely exacerbated by both being housed in a clear, sealed enclosure exposed to sunlight. For the Borneo deployments, these parts were printed from ABS, which has a T_g of ∼107°C [9], and did not warp. We thus recommend using ABS or other materials with a similar or higher T_g in future.

In Borneo, the old growth and logged forest units failed after ∼2-4 weeks. This appears to be due to water ingress from heavy rainfall piercing the ePTFE microphone vents (not all units have been retrieved yet). All old growth and logged forest units were deployed horizontally (i.e., with the ePTFE vents perpendicular to rainfall) to provide the freedom to beamform in any horizontal direction. MAARUs were deployed vertically in the UK and oil palm and did not face this issue. The oil palm devices were also sheltered by the solar panels. As such, we recommend either sheltering any units deployed horizontally (e.g., with the solar panel or some other cover [4]) or

deploying the MAARU units upside down, which should allow for equivalent beamforming and localisation capabilities. Finally, for all deployments, the 55 W and 60 W panels did not provide enough power for continuous 24/7 monitoring (perhaps due to lower insolation in the UK and some obstruction from trees and clouds in Borneo), whereas the 100 W panels in Borneo did, hence we recommend the latter for such monitoring efforts in future.

Despite device failures, sufficient data was gathered to investigate beamforming to distinguish neighbouring habitats/land-use types and to steer recordings away from reasonably directional unwanted noise (e.g., road traffic) towards directions of interest. For the UK deployments, there is also an opportunity to evaluate MAARU's beamforming capacity with fewer microphones undamaged by parts warping. Existing tests with MAARU showed improved confidence scores of avian call classifier BirdNET (which correlate with probability for many species) when beamforming in generic directions [3], likely owing to a higher SNR. Leveraging knowledge of habitat and site structure should allow for scaling these benefits to more ecologically relevant applications. Beamformed audio will also be analysed with acoustic indices and machine learning model embeddings as part of a representative ecoacoustic toolkit. While it is harder to define an improvement in these metrics without ground truth biodiversity data, we hypothesise that they should significantly differ for directions corresponding to different land-use. Should beamforming with MAARU successfully distinguish neighbouring habitats/land-use types, there is a notable opportunity for ecologists to monitor land-use gradients with fewer devices, and thus less cost and disturbance, than if single-channel, omnidirectional recorders are used (many of which cost a similar amount to MAARU). Overall, we hope these forthcoming analyses show that beamforming can segment soundscapes for more efficient and accurate ecosystem monitoring.

4. ACKNOWLEDGMENTS

We thank Jamiluddin Jami, Johnny Larenus, Ahmad Jelling, Yehezkiel Jahuri, and Louis Makhluf for invaluable assistance with the Borneo deployments. We are grateful to the Sabah Biodiversity Council for granting an access license and the Danum Valley Management Committee for providing a fieldwork permit. We also thank Dr. Henry Bernard, the South East Asia Rainforest Research Partnership, Silwood Park's field manager and technicians, and the Imperial AXD, ACE Workshop and IDEAS Lab teams for their support. N.P.L.P. was funded by NERC [NE/S007415/1] via the SSCP DTP and a UK Acoustics Network Plus Early Career Travel Grant.

ABSTRACT

Pollinators, like bees, use various cues to locate flowers with rewards such as nectar and pollen. While most research focuses on olfactory and optical signals, vibroacoustic and electrostatic cues may be more critical in pollination. Studies on honeybees, bumblebees, and hoverflies indicate that the electrical charges insects accumulate assist in navigating, identifying, and potentially communicating with flowers rich in nectar or pollen. Vibroacoustic signals and cues, such as buzzing, further enhance pollen extraction. However, the interplay between vibroacoustic and electrical signals in bees, including wild bees and eusocial Australian stingless bees, remains poorly understood. Additionally, the impact of insect morphology on their ability to acquire charge through triboelectric interactions with air and plants is unclear. This study examines vibroacoustic and electrostatic communication between plants and pollinators, with a focus on analysing existing literature. We hypothesise that Australian stingless bees have evolved a mechanism like honeybees for obtaining an electrical charge, though likely smaller due to their morphology. The review aims to facilitate the first experimental measurement of electrical charge in stingless bees.

1. INTRODUCTION

Navigation is essential for pollinators because it enables them to locate flowers efficiently, return to their nests, and ensure successful pollination, which is critical for ecosystem health and biodiversity [1]. Pollinators, including insects (bees, wasps, moths etc.), birds, and certain mammals, navigate between plants and the nest, enabling plant fertilisation through pollination between flowers. However, apart from navigation, recent research [2-5] shows that pollinators seem to communicate with the plants and make foraging decisions based on food availability and preference.

These navigation and communication mechanisms are highly diverse, encompassing a variety of sensory and cognitive strategies that allow them to find their way in complex environments. Some animals can orient themselves using the Earth's magnetic field, a process known as magnetoreception [6]. In addition to magnetoreception, animals rely on other advanced systems for navigation, such as infrasound, ultrasound, echolocation

[7] or biotremology (vibrational communication) [8]. Many insects rely heavily on their visual systems to navigate, locate food sources, and recognise landmarks [1]. Pollinators, particularly bees, see colours differently than humans. They can perceive ultraviolet (UV) light, which is invisible to the human eye. Many flowers have patterns in the UV spectrum that may enhance their attractiveness to pollinators [9].

We can classify the sensory mechanisms of communication and pollinator navigation into the following categories: olfactory, optics, vibroacoustic and electromagnetism [7]. The interaction of patterns, visual, vibrational, acoustic, and electromagnetic cues forms a complex communication network between plants and pollinators, greatly influencing the pollination process.

Communication cues are distinguishable based on their distance and timing [7] summarised in Table 1. Typically, long-distance communication occurs over a large time scale (lasting for hours), while medium- and short-distance signals are more likely to occur within minutes or seconds.

Table 1. Summary of observed common cues in the distance-time domain.

Cue Type	Distance range	Time of occurrence	Example
Olfactory	Long-range (m)	min to h	Floral scents and volatile production.
Optics	Medium-range (cm)	min	Bright colours, UV patterns.
Vibro-acoustic	Short-range (mm)	s	Buzz pollination, sugar increase to specific pollinator.
Electro-magnetism		ms	Pollen adhesion due to charge differences.

Apart from well-documented cues, researchers are investigating potential indications of an additional level of communication in plant-pollinator interactions. Recent evidence [10] indicates that the low-frequency motion of a flower (1 Hz to 2 Hz) serves as a distinct optical cue, independent of the object's shape. Experiments carried out by Desai et al. [11] suggest that foraging honeybees (*Apis mellifera*) can detect and identify both stationary and oscillating flowers, exhibiting a preference for the moving one. Further research is needed to determine whether a moving object can serve as an additional salience factor and whether pollinators use it in their decision-making.

While much research has focused on optical and olfactory cues in these interactions, the roles of vibroacoustic and electrical communication have garnered increasing interest in recent years [2-5, 12-15]. In the domain of electrical communication, publications predominantly focus on charge-measuring experiments involving honeybees [2, 16], bumblebees [17], hoverflies [5] and moths [18]. This current review aims to synthesise current knowledge regarding the significance of electrostatic fields in pollinator behaviour and plant-pollinator dynamics, as well as the potential coupling of this field with vibroacoustic cues to contribute to the field of plant-pollinator electro-acoustic (multimodal) communication.

2. ELECTROSTATIC FIELD AND CHARGE

2.1 Bee`s charge

Non-biological substances are known [19] to acquire an electric charge as they move through the atmosphere due to triboelectric charging. Experimentally observed raindrops [19] carry an electrical charge, typically ranging from 5 pico Coulombs (pC) to 100 pC, as they fall from the clouds during rainfall. With a diameter of approximately 4 mm, they are comparable in size to Australian native stingless bees, which are three to four times smaller than honeybees (Fig. 1). We assume that bees become highly triboelectrically positively charged while traveling through the atmosphere, in contrast to sessile and negatively charged flowers.

The first experiments providing some evidence of electrically charged insects were conducted in 1929 by Heuschmann [20], and bees specifically in 1975 by Erickson [21]. The last research shows that worker honeybees (*Apis mellifera*) possess a surface electrical charge when entering and leaving the hive, and the amount of the charge varies on their daily rhythm, peaking at midday or early afternoon. The experimental setup included two concentric conductive tubes with outer diameters of 12 mm and a length of 5 mm, separated by a 2 mm gap.

The calculated average charge shows that a bee returning from active flight had a charge of about 12 pC. However, due to the full contact between the bee and the tubes in this experiment and the inevitable transfer of charge while passing through the tube, the obtained results are likely lower compared to the actual value. A bee's surface can acquire and carry an electrical charge emanating a static electric field, similar to any physical object exposed to friction, pressure, or other external forces.

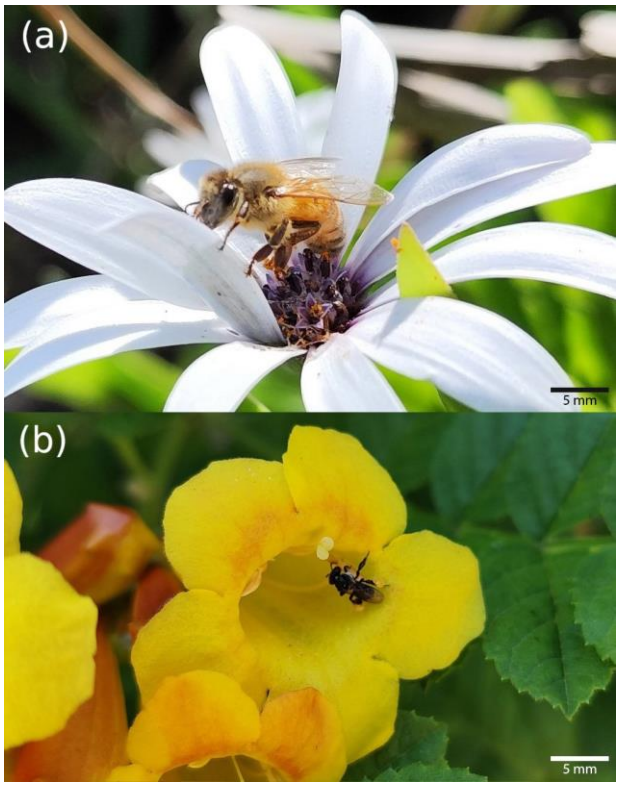

Figure 1. An equal-scale view of (a) the Western honeybee *Apis mellifera* and (b) the Australian stingless bee *Tetragonula carbonaria* foraging near local flowers in the northern region of Sydney, Australia (photo credit: Ivan Sili, November 2024)

As a result of this interaction, one entity gains additional electrons and becomes negatively charged, while the other becomes positively charged.

Over time, insects have learned to utilize the electrical charge they carry on their bodies. This charge varies based on the bee's activity, environmental conditions, and body size. There is evidence [21], that an inactive honeybee may carry a negative charge as well, typically ranging from −1.8 pC to +2.9 pC, inside the beehive at 70% humidity. An active bee, such as a dancing bee near the hive entrance, is usually positively charged up to 45 ± 4.3 pC, with a maximum charge reaching around 80 pC [21].

Colin et al. [16] measured the electrical potential of winter-clustered *Apis mellifera* and compared this to foraging bees in the spring, proposing a new technique with an induction ring. The same method and device were used in subsequent studies [17, 18]. The charge sensor consisted of two coaxial rings electrically insulated by a dielectric material. An electrometer connected to the inner ring measured the electrical current induced by the passage of a charged insect. It was observed that foraging bees typically possess smaller charges (mean = 29 ± 40 pC) than winter bees (mean = 153 ± 105 pC). Most bees carry a positive charge; however, 7% of measured bees were negatively charged, and less than 1% neutrally charged. These measurements align with findings published by Clarke et al. [22] for foraging bumblebees (mean = 32 ± 35 pC). Variations in body size among the measured bees did not significantly affect individual net charge variability, likely because fluctuations in bee size do not exceed 20%, except for the queen (whose net charge varies between +159.6 pC and +240.5 pC with a one-day delay measurement) [16]. However, the fact that the queen carries a higher amount of charge may correspond to a size-dependent charging effect, which has not been investigated yet.

Recent research by Montgomery et al. [23] suggests that the electric charge possessed by bumblebees stimulates volatile emissions. Findings indicate that *Petunia integrifolia* slightly increases the emission of behaviourally and physiologically active compounds in response to visits from positively charged bumblebees ~121 pC. Stronger emissions correlate with higher levels of electrical stimulation.

2.2 Humidity and the charge

Weather conditions, particularly relative air humidity, can significantly influence the charge carried by bees. Triboelectric charging, a primary factor in bees acquiring charge, is highly dependent on humidity levels. In [24] has shown that increasing humidity often corresponds to a decrease in bee charge, following an exponential decay relationship. The assumption is that water allows higher conductivity between two dielectric surfaces, thereby facilitating charge transfer. In conditions of high humidity, bees may have difficulty charging efficiently, which could result in reduced communication between plants and pollinators.

The only experimental study on the relationship between humidity and charging bees that we are aware of is that of Montgomery et al. [25]. The mathematical model derived as observed in the cited experiment can be represented as follows:

$$Q_{bee} = 0.26 + (5.73 - 0.022RH)\int Idt,\ [pC] \qquad (1)$$

where Q_{bee} – represents bee charge; RH – relative humidity; and I – induced electric current in the ring sensor.

Relative humidity also noticeably reduces a bee's charge retention time. An insect is likely to dissipate half of its charge within the first 30 seconds at humidity levels over 70%, while retaining 90% of its original charge when the relative humidity is below 70% [24]. Badger et al. reported [26], that a hummingbird's charge is also highly dependent on relative humidity, with net charge generally decreasing as humidity increases. Temperature, however, has no significant effect on the acquired charge. Previous research suggests that the variability of bee charges under different humidity levels should be considered when modelling future environmental experiments.

2.3 Foraging distance and the charge

One of the most common pollinators in the world, the western honeybee (*A. mellifera*), tends to visit only one type of flower while foraging in a specific direction and is highly flower-constant [27]. Bees can quickly learn all multimodal attributes of a specific plant and use this information while foraging. More than two thousand years ago, the Greek scientist Aristotle in his work "Historia Animalium" [28], remarked that a beekeeper could predict weather conditions based on the flight distance of bees. Bees can sense the approach of rain, as evidenced by their shorter flight distance. However, even under optimal weather conditions, their flight range is limited. In our current understanding, honeybee foraging range can reach up to 10 km from the hive, with a mean of 5.5 km. About 50% of bees foraged at distances more than 6 km, 25% more than 7.5 km, and only 10% more than 9.5 km [27].

Relevant work in this research line includes that of Es'kov and Sapozhnikov [29], which showed no evidence that foraging distance affects a honeybee's electric charge. Bees that flew 5 meters and 200 meters from the hive carried similar charges, varying between +0.98…+0.96 ± 0.13 pC. Controversially, in an experiment conducted by Montgomery [24], bumblebees had significantly higher charges when flying compared to walking, with positive charge increasing after more than 10 seconds of flight, assuming that flying activity impacts the positive charging of insects. This impact is expected to be logarithmic and can be approximated with:

$$Q_{bee} = 17.3 - 16.4e^{-0.17t}, \ [pC] \qquad (2)$$

where Q_{bee} - charge of the bee, and t – flight time.

Montgomery suggests [24] that a bee already carrying a positive charge is unlikely to gain additional charge during either short or long flights, emphasizing the limited electric charge saturation for an individual.

3. VIBROACOUSTICS COMMUNICATION

Vibroacoustic communication also is a crucial aspect of the interactions between pollinators, particularly bees, and flowering plants. This form of communication involves the use of vibrational and acoustic signals that can convey important information about foraging, mating, and environmental conditions.

Flight and non-flight vibrations produced by the rapid contraction of thoracic muscles in bees can be classified. To encourage bee visits, plants have evolved a mechanism to produce nectar rich in sugar and pollen, which bees collect and process to produce honey. However, certain plants, such as tomato, potato or snapdragon families, release pollen only under specific conditions, with precisely tuned vibrations being one of these requirements [12]. These vibrations are often produced by certain species of bees, known as "buzz-pollinators" [12]. This is an evolutionary adaptation that ensures more precise pollination, as only specific types of pollinators can access the pollen.

Buzz pollination is a documented yet not fully understood process employed by insects to efficiently extract pollen. The vibrations produced during buzz pollination are typically generated by the thoracic muscles through direct physical contact between the bee and the flower. During this process, a bee typically assumes a C-shaped position around the anthers and produces rapid, millisecond-long vibrations in the frequency range of 100 Hz to 400 Hz [30], often coinciding with the peak or dominant frequency, along with multiple harmonics of rapidly decreasing magnitude. This phenomenon is likely to occur in species within the families *Apidae* and *Melittidae*; meanwhile, only 6% of flowering plant species possess flowers with anthers that open in response to vibrations [31].

Bumblebees are known to transmit vibrations to flowers through various morphological structures, including the thorax, mandibles, and possibly legs [31]. Research [31] suggests that bee size is positively associated with vibration amplitude, but not necessarily with frequency. Morgan et al. [32] demonstrated that bees adjust the frequency, amplitude, and duration of their vibrations as they gain experience manipulating the same plant. Vallejo-Marín et al. [33] in their research conducted across North America, Europe, and Australia, found that the body size of bees, specifically thorax width, during non-flight defensive activity positively correlates with the acceleration amplitude of their buzzes, while it has no significant effect on buzz frequency. Non–flight (floral) vibrations exhibit also higher frequencies and greater amplitudes compared to the vibrations generated during flight. The frequency and amplitude of these vibrations play a crucial role in

determining the rate of pollen release. Observed in [34] was a positive correlation between vibration amplitude and the rate of pollen release, with a similar relationship found between higher vibration frequencies and increased pollen release and plant parts are likely grown with preferred resonance frequencies to accommodate a maximum of pollen release [35].

The most common eusocial Australian stingless bees, *T. carbonaria* and *A. australis*, have not been observed performing buzz pollination [36], likely due to their small body size. In contrast, some solitary bees, like blue-banded bees (*A. cingulata*) or carpenter bees (*Xylocopa* spp.), are recognized as native buzz pollinators in Australia [36].

While buzz-pollination is well studied, vibroacoustic signals (VAs) produced by pollinator`s wing beats could cause a potentially adaptive plant response, even before the contact between the plant and the insect. King [37] reported that after landing on a plant, the bee flaps its wings and rapidly contracts its flight muscles. The wingbeat frequency [30] of *Xylocopa* bees affects the amount of pollen removed from *Senna spectabilis*, maintaining constant values between 250 Hz and 500 Hz. In the range of 300 Hz to 400 Hz, an ejection of 0.02 to 0.10 mg of pollen was observed in flowers that received only one visit, with a tendency for less pollen to be ejected at frequencies greater than 500 Hz. The aforementioned study showed that different species of bees exhibit distinct buzzing patterns, which are related to their wingbeat frequency. Bees may modify their wingbeat frequency to approach the natural frequency of the plant they visit, optimizing the pollination process. Nerse et al. [38] studied the biomechanical properties of the snapdragon (*Antirrhinum litigiosum*) and showed how the features of flower organ material are flexible and respond to pollinator vibro-acoustic stimuli. While buzz-pollination behaviour is restricted to specific plant-insect interactions (such as those involving poricidal anthers), the responses gathered by Veits et al. [4] suggest that VA could serve as a signal potentially in all plant-insect interactions, hypothesised to be a basal plant mechanism for sensing and responding to vibrations.

4. DISCUSSION

From the analysis of the literature, we can conclude that recent research investigating the intricate communication between plants and pollinators has confirmed that electrostatic fields and vibroacoustic serve as additional cues in plant-pollinator communication.

Bees are known [39] to emanate both static and modulated electric fields. The static electric field is generated by the static charge possessed by the bee, while the modulated field is likely influenced by insect activity, with wing flapping being the most crucial factor. Although some studies have suggested this relationship [39, 40], there is no strong evidence supporting the idea that wing flapping alone modulates a bee's electric charge to a significant extent. While electrostatic interactions have been studied, the dynamic, real-time modulation of a bee's electric charge by its wing movements remains an underexplored area. Experimental research measuring both the acquired electric charge (e.g. emanating electric field) and wing flapping frequency simultaneously could provide a clearer understanding of this phenomenon.

An increase in wingbeat rate during a bee's foraging activity may enhance the positive charge it carries. Consequently, a higher charge could generate stronger electrostatic forces between the pollinator and pollen, enabling the insect to more efficiently analyse potential outcomes. Based on the measured electrical charge carried by the bees, we also aim to question whether flowers may have evolved to manipulate their electrical charges to ensure the loyalty of specific pollinators. If plants can manipulate their own electric charge in response to an approaching pollinator, this could open a new area of exploration. This trait may have evolved in a way similar to buzz pollination, but within the electrostatic realm, attracting specific pollinators to collect the pollen.

The morphology of bees determines its vibroacoustic properties. In cases where buzz-pollination is possible, the size of the thorax regulates the amplitude of the vibrations [33]. The frequency of these vibrations, however, is not influenced by body size but is instead determined by the wing flapping frequency. Additionally, bees can adjust the vibration frequency depending on the context, such as floral interaction or defensive behaviour. The potential influence of thorax size and musculature on the electrostatic charge acquired by bees, in a manner similar to their effect on vibrational properties, remains an open question. Future research is needed to investigate whether the amplitude of the electric signal, like that of vibroacoustic signals, is influenced by the size of the wing, wingspan or musculature of the thorax, clarifying the biomechanical interactions between body morphology and electrostatic charge.

A review of the literature reveals that the relationship between pollinators' morphology and their ability to acquire charge remains poorly understood. In [17] suggested that insect cuticle accumulates surface electric charge. While some evidence [14, 16] suggests that larger body size and wingspan correlate with increased charge, specific values vary among species. For instance, honeybees have been reported to possess an average charge of 29 pC [16],

bumblebees 32 pC [22], hoverflies 37 pC [5], butterflies 49 pC [18], and hummingbirds 66 pC [26]. Conversely, wasps have been reported to carry a smaller average charge of 8 pC [40], despite being larger in size compared to honeybees or bumblebees.

Why do wasps deviate from this trend? Could it be an evolutionary trait that wasps did not develop, as pollen and nectar collection are not their primary activities? Wasps have less triboelectric interaction with petals and sepals but still acquire some charge while flying through the air. Does physical contact with the flower play a more significant role in charge acquisition compared to airborne charging during flight? And what morphological features of wasps determine their small electric charge? One potential explanation is their smoother shape, with fewer body hair. In [41], researchers removed hair from the thorax of hoverflies, which reversed the polarity of the obtained charge or resulted in a neutral charge when hair from the propleuron was removed, concluded that the presence and distribution of hair on the thorax play a crucial role in determining both the amount and polarity of the induced charge. The idea that a larger surface area with longer hair could influence electric charge acquisition is also reasonable and should be further studied across different pollinator species.

But which species should be considered optimal for investigating the influence of morphological characteristics on charge acquisition? An Australian stingless bee *Tetragonula carbonaria* is a dominant candidate for such studies. These bees are approximately three to four times smaller than honeybees in terms of body size, have fewer hair on the thorax compared to honeybees or bumblebees, and possess a chitin-covered, smoother abdomen (Fig. 2a, b). We currently have no research on the average electric charge possessed by stingless bees, but considering their morphology, it could be of a lower magnitude than that of honeybees or bumblebees. The open question is whether this small charge could be sufficient for pollen adhesion via electrostatic forces. We also don't know whether stingless bees rely on vibroacoustic and electrostatic cues or both while foraging or if they prefer to use other sensory modalities or their combination. As this species deviates from *Apis* genus, they have evolved some important features to succeed in pollen and nectar collection: possession of corbiculae with hairy areas for attaching pollen grains (Fig. 2c), similar frequency of wing flapping, and, as a hypothesis, emit vibroacoustic and electrostatic stimuli to target flowers (Fig. 2d) to indicate their presence. Flowers are likely to respond to these stimuli by releasing pollen or increasing sugar concentration [4].

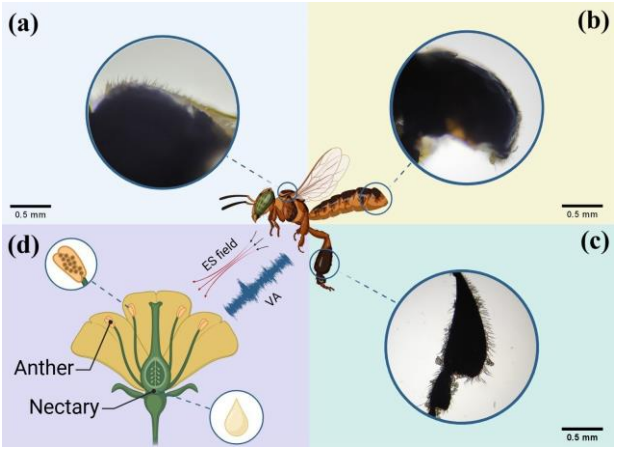

Figure 2. Morphological traits of the Australian stingless bee *Tetragonula carbonaria* and their potential impact on charge acquisition and vibroacoustic stimuli under a 40× magnification microscope view (photo credit: Ivan Sili, image created with BioRender.com). Circles indicate sampling positions on various parts of the bee's body, highlighting the detailed structure of the bee's anatomy. (a) Thorax sparsely covered with short hair. (b) Smooth hairless chitin abdomen. (c) Hairy corbicula with densely attached pollen. (d) The vibroacoustic (VA) and electrostatic (ES) stimuli emitted by a bee are hypothesized to trigger a plant's response, aiding in assessment outcomes and potentially leading to pollen release and an increase in nectar sugar concentration.

Airborne acoustic waves, thoracic vibrations, and electrostatic fields modulated by wing flapping may create a complex multimodal communication system between plants and pollinators. As a pollinator approaches a flower, it likely utilizes all available sensory modalities to evaluate the interaction and distinguish a rewarding flower. This leads to another hypothesis suggesting that a bee, upon landing a flower, may first sense the amount of pollen in the anther. Shortly after assessing the pollen, possibly through its electric charge, the "buzz bee" may either employ a vibroacoustic strategy—such as thoracic vibrations upon landing on the flower—which requires energy expenditure to obtain the reward, or choose to search for another flower that offers a more rewarding outcome without expending energy, while an increase in sugar concentration will help maintain the preferred pollinator's loyalty to the same flower.

CLASSIFICATION OF BIOLOGICAL SOUNDS USING SPATIAL DIRECTIVITY

Jurij Prezelj* **Luka Čurovič**[1] **Jure Murovec**[2] **Andrej Hvastja**[1]

ABSTRACT*

Bioacoustic methods for biodiversity monitoring face limitations, particularly when relying on single-channel recordings, that lack spatial context. To address this, we tested a novel approach that incorporates spatial directivity into biological sound classification using a network of microphone arrays. Each array, comprising of four microphones, estimates the Direction Of sound Arrival (DOA), attributing spatial features to sound events. By combining these spatial features with conventional acoustic features, in combination with unconventional use of K-means clustering, we developed a methodology for classifying biological sound events. Our approach employs iterative adjustment of the number of clusters to refine classification, filter out noise (e.g., traffic), and reveal tree-like class structures that separate between species and even individuals within same species. Experimental data from a multi-day field recording using synchronized 8-channel microphone systems demonstrates the method's ability to separate sound events and identify individual organisms. The results highlight the potential of spatially informed acoustic analysis to overcome some limitations of bioacousticaly based diversity assessment.

1. INTRODUCTION

In recent years, bioacoustic monitoring has emerged as an essential tool for assessing biodiversity, particularly in ecosystems where visual observation is limited or impractical. Acoustic signals generated by insects, amphibians, birds, and mammals provide rich information that can be used to estimate biodiversity, identify ecological changes, and support conservation efforts [1,2]. While the development of passive acoustic monitoring systems has enabled long-term, non-invasive data collection, the accurate classification of biological sound events remains a significant challenge. In many environments, the acoustic landscape is also heavily contaminated with anthropogenic noise sources such as traffic, aircraft, and industry noise [3]. These noise sources contaminate biologically relevant acoustic signals, reducing the effectiveness of automated classification. Traditional sound classification methods rely heavily on spectral features (e.g., energy levels at specific frequencies), temporal characteristics, and time-frequency representations such as spectrograms [4,5]. However, these approaches often fall short when biologically similar signals, such as calls from different individuals of the same species, exhibit overlapping frequency content. In such cases, additional information is required to improve classification accuracy. Promising and underexplored direction in acoustic monitoring is the use of spatial directivity. i.e. the direction from which sound event originates and how it changes over time. Direction Of sound Arrival (DOA), typically employed in microphone arrays, offers the ability to extract spatial features associated with sound sources [6,7]. This can be particularly useful in field conditions where multiple individuals of the same species are active simultaneously, or where moving sources produce time-varying spatial signatures.

In this study, we investigate the potential of combining conventional acoustic features with spatial directivity features for the classification of biological sound events, with a focus on insect species, specifically crickets. We hypothesize that spatial features such as mean direction, deviation of direction, and imaginary/real components of DOA vectors, when added to standard spectral features, can improve the separation between different individuals, even within the same species, under real environmental conditions. The proposed methodology is based on K-means algorithm with adaptive number of classes for unsupervised feature evaluation and classification. The aim is to develop a framework for distinguishing biologically relevant events from background noise, and for assessing biodiversity by estimating the number and identity of individual signal sources. By integrating spatial analysis into the bioacoustic feature space, this work contributes a novel perspective to acoustic biodiversity monitoring, particularly in complex and noisy environments. The results may have practical implications for automated species detection, behavioral studies, and long-term ecological assessments in increasingly urbanized and acoustically polluted habitats.

2. EXPERIMENTAL SETUP

2.1 Study Site and Recording Conditions

The selected study site is located in Zaplana, a rural area in Slovenia that offers stable infrastructure for long-term acoustic monitoring. This location was chosen primarily due to access to continuous electrical power, reliable on-site supervision, and controlled environmental conditions that minimize the risk of equipment damage or theft. The site provides a natural acoustic environment yet is close enough to human activity to also include anthropogenic noise, which is important for the development of separation techniques, as shown in Figure 1.

Figure 1: Data acquisition location with measurement systems

Eight Behringer ECM8000 measurement microphones, selected for their flat frequency response and omnidirectional pickup pattern, which are well suited for capturing complex environmental soundscapes. Four microphones, forming one system, were spatially distributed in a square array of 40mm, optimized for Direction Of Arrival (DOA) calculations in frequency range from 60 to 6000 Hz. Two systems, i.e. arrays, were used.
All eight microphones were connected to a MOTU Stage B 16-channel stage microphone preamplifier, with integrated AD converter and USB3 connection. Such a setup ensured phase-synchronized signal acquisition across all channels, a prerequisite for subsequent beamforming and directionality analysis. The AD converter was connected to a custom LabVIEW-based acquisition system that managed signal recording and real-time data processing. The software was developed in-house to enable robust control over file handling, signal normalization, and metadata logging.
The microphone array and hardware were housed in weather-protected enclosures and mounted at fixed positions throughout the measurement campaign to maintain geometric stability. The entire system operated autonomously over the 36-hour recording period, powered by the site's reliable local electricity supply, with occasional human supervision for maintenance and monitoring. Recordings were acquired in 30-second intervals, with a pause of 5 to 10 seconds between each segment due to WAV file saving time to disk. This led to the generation of 3880 multi-channel WAV files, each containing eight synchronized audio channels. Such temporal segmentation was a compromise between disk write speed and uninterrupted monitoring, and it ensured sufficient data quality for post-hoc feature extraction and classification analysis.

2.2 Signal Processing and Feature Extraction

A major challenge in biodiversity acoustics is the extraction of meaningful information from large volumes of long-term, multichannel audio recordings. The aim of this study was to identify and classify biological acoustic events using both spectral and spatial characteristics of sound. The following signal processing steps were implemented to transform raw waveform data into a structured set of acoustic features suitable for classification.

2.2.1 Data Preprocessing

The raw recordings consisted of 30-second-long multichannel WAV files. Due to constraints in disk writing speed, a gap of 5 to 10 seconds existed between consecutive files, resulting in discontinuous but time-stamped data. Each recording contained eight synchronously recorded channels, enabling spatial analysis. All recordings were

preprocessed using the custom LabVIEW-based software developed specifically for this application. Preprocessing included: Amplitude normalization of all signals to the same reference level, DC offset removal, Segmentation of the recordings into fixed intervals for time-aligned feature extraction, Filtering for optional band-limiting to biologically relevant frequency ranges.

2.2.2 Feature Extraction

Feature extraction was performed for each segment and on each channel independently unless otherwise specified. A total of over 100 acoustic features were computed, categorized into the following domains:

Spectral Features: including power spectral densities across third-octave bands, dominant frequency, spectral centroid, spectral roll-off, skewness and kurtosis of the normalized spectrum.

Cepstral Features: calculated from the real cepstrum of each segment, including the frequency and amplitude of the dominant peak, the cepstral centroid, and energy measures.

Time Domain Features: such as zero crossing rate, short-term signal energy, crest factor, skewness and kurtosis of the waveform, and amplitude envelope characteristics.

Autocorrelation Features: including number of zero crossings of the autocorrelation function, integral properties of its shape, and geometric descriptors (e.g., string length of normalized autocorrelation curve).

Spatial Features: derived from direction-of-arrival (DOA) estimation algorithms applied to the microphone array data. These included average and deviation of real and imaginary DOA components, and instantaneous DOA angle estimation using phase-difference methods.

Each feature was computed within a 125 ms time window with no overlapping, selected as a compromise between temporal resolution and stability of DOA and spectral statistics. Importantly, the spatial features were calculated from twelve DOA snapshots within each 125 ms frame, to account for the rapid directional fluctuations in low-SNR conditions.

2.2.3 2.3.3 Feature Selection and Dimensionality Reduction

Given the high dimensionality of the feature space, a series of statistical techniques were employed to reduce redundancy and highlight relevant dimensions for classification. These included:

- Principal Component Analysis (PCA) to identify dominant modes of variance,
- Singular Value Decomposition (SVD) to rank feature importance,
- Correlation analysis to remove colinear features,
- Expert-driven selection, particularly for features known to be relevant for distinguishing between insect species (e.g., 2576 Hz and 8000 Hz bands).

The final feature set used in classification experiments typically consisted of 4 to 6 features, balancing interpretability with classification accuracy. These included a mix of spectral bands, signal shape descriptors, and spatial DOA deviations. The extracted features formed the basis for further analyses, including unsupervised clustering (K-means) and biodiversity assessment discussed in the next section.

2.3 K-Means Classification

Unsupervised K-means classification algorithm was selected to assess the separability of different types of sound events and to support biodiversity monitoring. This method partitions the dataset into a specified number of clusters by minimizing the within-cluster variance and is widely used for its efficiency and interpretability of data [16].

In our study, a selected subset of features was used as input for clustering. These included both classical acoustic features such as signal energy levels at selected frequencies (e.g., 2576 Hz and 8000 Hz) and temporal characteristics (e.g., zero crossing rate), as well as spatial features related to the direction of arrival (DOA) and its variability.

The initial number of clusters was estimated using the Elbow method, which plots the within-cluster sum of squares (WCSS) against the number of clusters. A visible 'elbow' in the curve typically indicates the appropriate number of clusters. This method was implemented using MATLAB. In our data, the elbow typically occurred between 4 and 6 clusters. Initial results showed that traffic noise and biological signals often clustered separately, confirming that classical spectral features are sufficient to isolate low-frequency anthropogenic noise. Further subdivision of clusters revealed differences between different insect species calls.

An interesting aspect of the approach was the tree-like splitting of clusters when the number of clusters gradually increased. For instance, starting with three clusters often separated background, traffic, and biological signals. Increasing to five or six clusters revealed distinctions between insects. This exploratory method provided insights into both the structure of the dataset and the potential for unsupervised identification of acoustic diversity in the environment.

These findings highlight that unsupervised learning, when guided by expert's selected feature vector, can serve as a robust tool for separating meaningful acoustic events from environmental noise.

3. RESULTS

To better illustrate the challenges associated with classifying biological sounds in natural environments, Figure 2 presents a representative 10-second recording from two spatially separated microphone array systems, located 12 meters apart. Figure 2 shows the spectrograms for both systems (top and bottom panels) alongside the corresponding Direction of Arrival (DOA) estimates over time. DOA results are plotted between the two spectrograms, with red dots representing System 2 and blue dots representing System 1. DOA calculations were performed on filtered signals, using a band-pass filter (2000–4000 Hz) to isolate the frequency range of interest, the calling frequencies of cricket of species A. This filtering helps suppress environmental noise and focuses on the DOA of crickets. Accurate DOA tracking corresponds with cricket calls, while scattered DOA values appear during silent intervals.

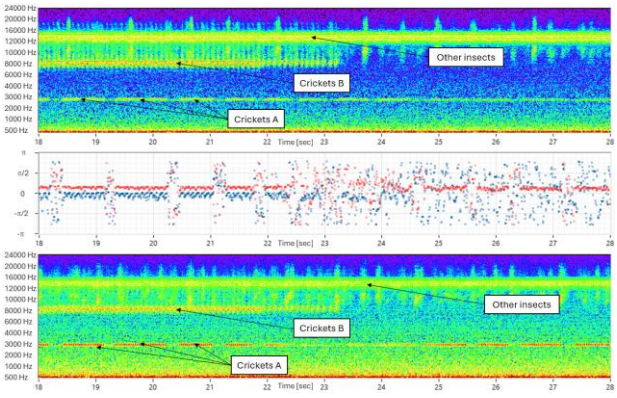

Figure 2: Example of a 10-second recording showing spectrograms of two synchronized microphone systems placed 12 meters apart. Red and blue dots represent DOA estimates from System 1 and System 2, respectively, in the 2000–4000 Hz range, specificly tuned to detect crickets of species A.

The visualization demonstrates that when a cricket is actively producing sound, the DOA algorithm accurately tracks its spatial position. However, during silent periods or low signal-to-noise conditions, the system yields scattered direction estimates with high deviation, suggesting that direction estimates are essentially random in the absence of a clear signal. This behavior underlines one of the key limitations of DOA based approaches in natural environments: direction estimation requires some minimal signal to noise ratio to be reliable.

An additional challenge is the temporal structure of cricket calls. Each call (approximately 1 second in duration) consists of a sequence of 12–30 short chirps, each lasting only a few milliseconds. These brief chirps are separated by short pauses. During these pauses, the DOA algorithm frequently registers spurious directions due to the lack of acoustic energy, which cannot be easily averaged due to the circular nature of angular data. This causes angular "jumps" or artifacts, making the differentiation between multiple crickets of the same species particularly challenging.

Despite these limitations, the system shows strong potential for spatially resolving biologically relevant sounds. This example sets the stage for the subsequent sections, which evaluate various feature extraction methods and classification strategies, including unsupervised learning.

3.1 PCA Analysis of the Whole Dataset

To assess the relative contribution of features in the dataset and to identify dominant patterns of variability, we performed principal component analysis (PCA) on the full dataset, comprising 108 features extracted from synchronized 8-channel acoustic recordings. Prior to the analysis, all features were normalized using min-max scaling to the [0,1] range.

This ensured that features of differing physical dimensions (e.g., signal amplitude, spectral centroid, direction deviation) contributed comparably to the analysis. PCA was then performed on the normalized dataset. The first principal component (PC1) alone explains approximately 30% of the total variance, while the first two components together account for more than 50%.

3.1.1 Feature Contributions to PC1

By examining the loadings of each feature on PC1, we can identify which features contribute most to this dominant source of variance. Among the most influential features were zero crossing rate, and its two derivatives (crossing at 0.125 and 0.25), high-frequency spectral components (e.g., 15608 Hz, 13664 Hz), and spectral centroid. Zero crosing of Autocorelation function and Cepstrum based features also proved to be important. Spatial features extracted during DOA calculation however showed only moderate influence.

The PCA results support our hypothesis that a combination of signal energy, zero-crossing, and spatial features collectively governs the variance in the overal acoustic dataset. Notably, individual frequency bands used for species classification (e.g., 2576 Hz and 8000 Hz) did not emerge as dominant contributors in PC1. This reinforces the need to integrate spatial directivity metrics when aiming to distinguish between acoustically similar species or individuals. These findings suggest that both spectral and

temporal discontinuity features are key discriminators in the data. However, the moderate loadings of spatial features also imply their relevance, particularly for distinguishing between individual sources of similar spectral character.

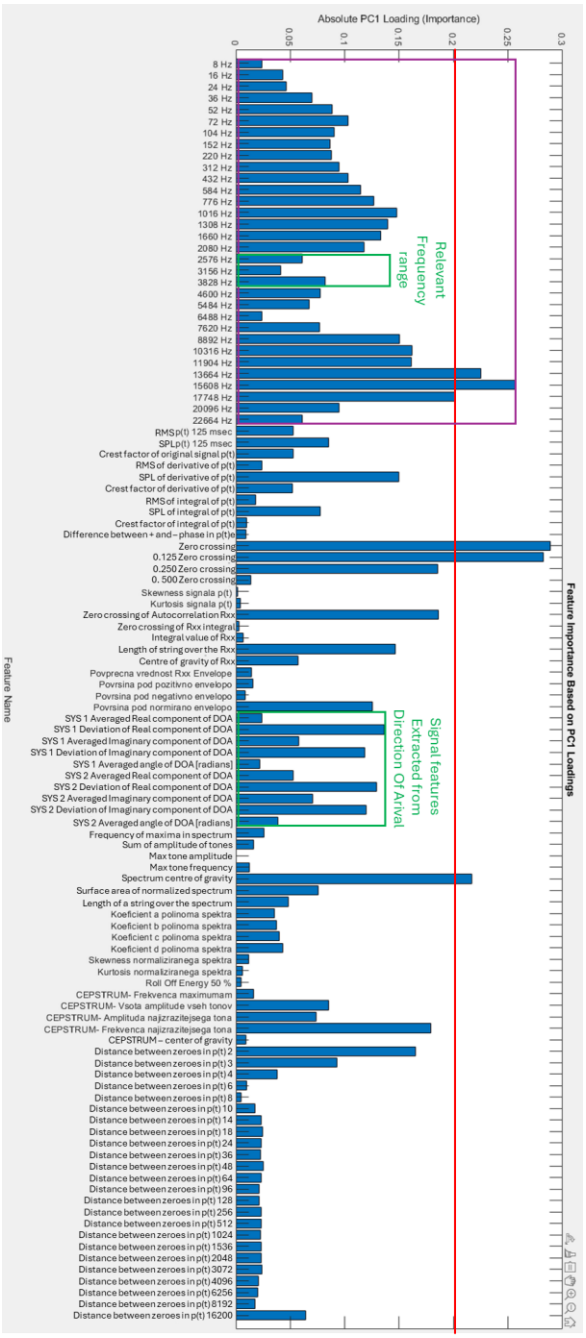

Figure 3: Bar chart of absolute PC1 loadings for all features

3.1.2 Subjective Feature Selection

Following the initial inspection of the recordings and DOA behavior, we performed a subjective selection of features for the unsupervised classification. Subjective approach was motivated by our experience, by the structural complexity of crickets calls, and the known limitations of automated feature selection methods in low signal-to-noise environments. To reduce data dimensionality while preserving relevant information, we selected a subset of features: from the complete dataset based on three criteria: (1) domain knowledge about cricket call characteristics, (2) visual correlation of features with known biological events (e.g., active chirping), and (3) interpretability and temporal stability of the feature across multiple recordings. The following eight features were chosen for initial analysis:
Level of signal derivative (captures abrupt energy changes in short-duration chirps)

1. Level at 2576 Hz
2. Level at 8000 Hz
3. Direction Of Arrival on System 1
4. Deviation of DOA on System 1
5. Direction Of Arrival on System 2
6. Deviation of DOA on System 2
7. Zero Crossing Rate (ZCR),

These features were selected not only for their statistical relevance but also for their interpretability. For example, signal derivative and zero-crossing features respond to the pulse-like nature of chirps, while DOA deviation provides a strong inverse indicator of consistent sound sources (i.e., crickets). Frequency-specific features were chosen to separate overlapping frequency bands used by different species. The subjective selection was further validated through data visualization and initial clustering tests. This manual step proved essential in capturing meaningful biological structure in a highly complex acoustic environmet.

3.2 K-Means Clustering

Several established methods exist to estimate the “optimal” number of clusters in K-means clustering, including the elbow method (which identifies a knee in the within-cluster sum of squares), silhouette analysis, and the gap statistic. More advanced criteria such as the Calinski-Harabasz, Davies-Bouldin, and Dunn indices, or model-based tools like Bayesian Information Criterion (BIC), are frequently employed in automatic model selection.
However, in the context of bioacoustic field recordings, these methods proved insufficient. They consistently suggested a relatively small number of clusters (typically fewer than six), which did not reflect the nuanced structure

of the biological acoustic environment. In our case, the goal was not to discover a fixed, singular classification scheme, but to explore the hierarchical relationships between sound events, and incrementally refine the detection and separation of biological signals from environmental noise.
To that end, we adopted a progressive and semi-supervised clustering approach. Starting with a subset of recordings that contained known biological activity (observed directly during data collection), we applied K-means repeatedly, increasing the number of clusters step by step. This revealed a tree-like evolution of classes, where larger clusters gradually split into finer subgroups as the number of clusters increased. Importantly, this process exposed meaningful patterns:

- A small number of clusters (e.g., k = 2–3), K-means already separates high-energy signals, such as traffic noise, from ambient biological sounds.
- As the number of clusters increased (k > 5), we began to see separation between different types of biological signals, including cricket chirps of different species, and eventually between individual crickets of the same species based on spatial and temporal features.

Figure 4 demonstrates how the separation between traffic noise and biological signals improves with an increasing number of classes, specifically in the context of filtering out peaks (e.g., traffic) while preserving fluctuating ambient sounds (e.g., insects). Based on this insight we structured our classification process into three stages as depicted in a series of figures from Figure 5 to 9.

1) Noise Filtering: Low-frequency traffic noise was excluded from the data based on spectral and temporal features. Consequently, higher-frequency traffic noise overlaping bioacoustic sound was removed as well.

2) Species Identification: By selecting key spectral features (SPL at 2576 Hz and 8000 Hz) we were able to distinguish between cricket of species A and B. Narrowband filtering alone was insufficient; classification relied on the overall feature vector and clustering behavior.

3) Individual Discrimination via DOA: By incorporating spatial features of direction of arrival (DOA) and deviation of DOA, K-means could distinguish signals from different individuals of the same species A, even when their spectral profiles were similar.

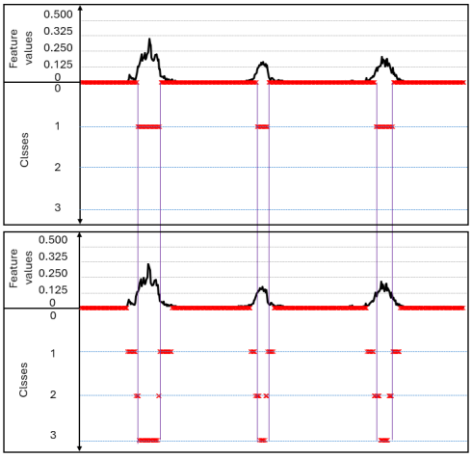

Figure 4: By increasing the number of classes in K-Means algorithm, the separation between background noise and signal is more effective. In our case we are interested into exclusion of pulses, representing traffic noise and to maintain background noise composed from biological sounds.

The presented approach effectively combines unsupervised clustering with subsequent supervised refinement, allowing us to separate traffic noise from biological signals and then further differentiate among species or members of species based on sound directivity data (DOA). The gradual increase in the number of clusters to form a tree-like structure is particularly insightful, as it provides a visual and quantitative means to identify the minimal number of classes required for effective discrimination. This multi-step process, first filtering out traffic noise, then distinguishing species based on spectral features, and finally resolving individual variation using spatial features, demonstrates a robust strategy for addressing the complexities inherent in bioacoustics data.

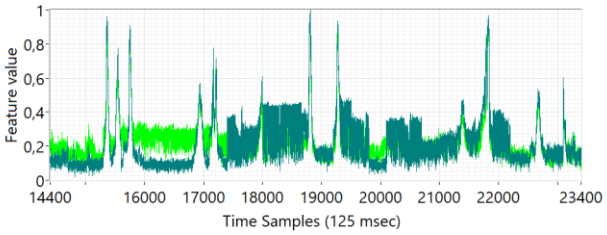

Figure 5: Recorded signal @ 2576 Hz and 8000 Hz, with pronounced spikes due to the traffic noise

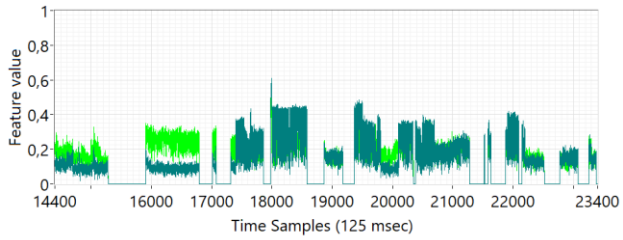

Figure 6: The first step: Exclusion of unappropriate samples, containing traffic noise 2576 Hz and 8000 Hz, that is in frequency range of cricket's calls.

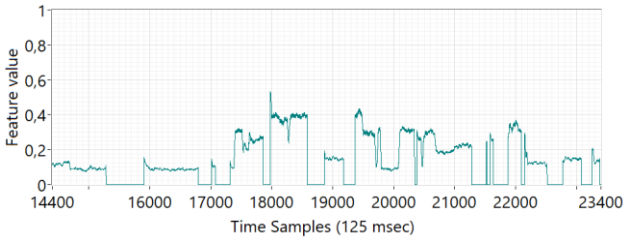

Figure 7: Second step was to smooth the data by moving average, while maintaining the exclusion of corrupted data by traffic noise

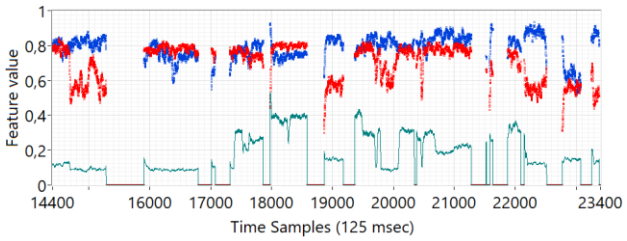

Figure 8: Third step was to implement the spatial directivity (DOA) from two systems into the classsification

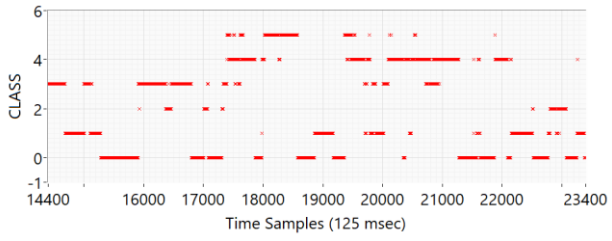

Figure 9: Results of Classification to 6 clases (evaluated by the elboww method) and using subjectivly selected features.. Classification includes DOA based features, hence classification of biological sounds using spatial directivity.

The use of K-means clustering in this study extended beyond traditional unsupervised classification. Through iterative refinement and adaptive manipulation of the number of clusters, we were able to explore the latent structure in the dataset and identify practical thresholds for signal separation. Notably, K-means classification was not only used as a final output but also as a tool for feature selection and filtering—enabling us to progressively refine the data by first removing traffic noise and later isolating biologically relevant events.

Despite promising results, some limitations were encountered. While spatial directivity (DOA) features significantly contributed to distinguishing individual sources, they were insufficient on their own for the complete classification of cricket species. Chirp structure and signal continuity played a crucial role in DOA reliability. The DOA subwindowing approach proved sensitive to brief signal gaps within cricket chirps, leading to erratic directional estimates during the pauses. This reduced the classification resolution and introduced variability into the spatial feature set.

A key insight from these challenges is the importance of synchronization between signal segmentation and DOA estimation. Future work should focus on optimizing the trade-off between subwindow duration and averaging period during feature extraction. For example, preliminary tests suggest that using a 25 ms subwindow and averaging over 250 ms may offer a better balance between time resolution and directional stability than the currently used 10 ms / 120 ms configuration. This will be crucial for capturing species-specific calling patterns while preserving spatial integrity.

Nonetheless, the integration of spatial features, particularly deviation metrics, demonstrated clear value in enhancing the separability of overlapping sound sources, especially for individuals within the same species. This directionally informed classification represents a novel addition to conventional bioacoustic methods, which often rely solely on spectral or temporal descriptors.

4. CONCLUSION

This study presents a novel approach to the classification of biological sounds by integrating spatial directivity information into the feature set. We demonstrated that alternative applications of unsupervised K-means classification algorithm, by iterative clustering with different number of classes can improve classification accuracy in complex outdoor acoustic environments.

We found that spatial features, particularly DOA and deviation of DOA within 125 msec, can successfully add information to traditional spectral features. While direct classification based solely on DOA remains challenging due to signal intermittency, combining directionality with

spectral features enables the identification of both species and individual callers in limited range.

This integrative methodology offers a promising framework for scalable, autonomous biodiversity monitoring, particularly in habitats affected by overlapping biological and anthropogenic sounds. The results not only highlight the potential of spatial information in bioacoustics but also lay the groundwork for future improvements in sensor design, feature synchronization, and hybrid supervised-unsupervised classification strategies.

With further development, such techniques may significantly advance acoustic biodiversity assessment, contributing to conservation science, species tracking, and real-time ecosystem monitoring.

"YOU TALKING TO ME!?": THE ROLE OF VISUAL-ACOUSTIC CUES IN ANEMONEFISH SOCIAL BEHAVIOUR

Lucia Yllan[1*], Theresa Rüeger[1]

[1]School of Natural and Environmental Sciences, Newcastle University, UK

ABSTRACT

Acoustic communication is integral to the social dynamics of many animal species, yet fish remain underrepresented in bioacoustics research despite their ecological diversity and environmental importance. This study investigates the vocalisations and associated behaviours of anemonefish, focusing on the orange clownfish (*Amphiprion percula*). Through in situ audio-video recordings of wild populations in Papua New Guinea, we documented a diverse repertoire of sounds and their behavioural contexts, highlighting their critical role in social hierarchy maintenance, group cohesion, and territorial interactions. To understand how anemonefish integrate sensory information, we conducted a visual-acoustic cue manipulation experiment, showing the reliance on multisensory cues for social behaviours. Our findings reveal the diversity and functional significance of fish vocalisations while highlighting potential vulnerabilities to underwater noise pollution. By combining behavioural ecology and experimental manipulation this work provides new perspectives on sensory ecology in marine systems and emphasizes the need for conservation strategies in increasingly noisy underwater environments.

1. INTRODUCTION

Despite fish representing 35% of the total chordate biomass and half of vertebrate species [1], knowledge about acoustic communication in fishes is limited compared to other taxa. The main reason for this bias is fishes' apparent limitation of acoustic signalling which is restricted to certain families and species [2]. Nevertheless, several fish taxa use acoustic signals for a variety of functions.

Anemonefishes (genus *Amphiprion*) are ideal to study acoustic communication in wild fish populations since. They display a complex array of behaviours both interacting with other species and within their social groups with strict size hierarchies and mutualistic relationship with their sea anemone host, which makes them extremely site attached [3]. Anemonefish groups are formed by unrelated individuals and have a strict size-based social hierarchy where individuals queue for the breeding position [4]. The largest anemonefish is the dominant female and the second largest is the sub-dominant male, the breeding pair, which can also have non-reproductive subordinates [5]. Acoustic cues may be key to maintain their strict hierarchical social structure within groups [6], by signalling dominance/submission and allowing group members to be differentiated.

Anemonefishes can hear sounds between 75 and 1800 Hz [7] and produce sounds using their jaw teeth and vibrations from their rib cage, which generates variation in their vocalisations related to their body size [8]. Consequently, these acoustic features may convey information on the social rank of the emitter within the group [9]. In addition, individuals might use their side vision or mechanosensors to assess conspecifics size through lateralisation or side-by-side swimming [11-12]. Thus, anemonefish can obtain information form visual and acoustic cues to assess a conspecifics' size and visual-

acoustic cues might be essential to maintain hierarchy stability within the group. However, the relative importance of these cues and their role in social interactions has not been studied.

This study examines the acoustic communication of orange clown anemonefish (*Amphiprion percula*) in natural reef habitats in Papua New Guinea, with the goal of advancing our understanding of acoustic communication in wild fish populations. The specific aims of this study are to: (1) characterize the vocal repertoire and associated behavioural contexts of *A. percula*; and (2) evaluate the integration of visual and acoustic cues in social interactions through sensory manipulation experiments.

2. METHODS

2.1 Baseline data collection

The study was conducted Kimbe Bay, Papua New Guinea. Anemonefish groups were recorded using GoPro Hero 9 action cameras and AudioMoths version 1.7.1 which were placed in front of groups on stationary tripods set close to the anemone to obtain video and audio data. A total of 142 vocalisation trains (594 individual vocalisations) were recorded *in situ* from *A. percula* groups. All individuals of the group were caught and measured underwater to obtain their standard length (SL) in mm.

2.2 Visual-acoustic cues experiment

For this experiment, three treatments (with three trials each, Tab. 1) manipulating different sensory cues were conducted: I) congruent visual-acoustic cues (A, E, I), II) constant visual cues (B, E, H) and III) constant acoustic cues (D, E, F). To simulate different size conspecifics (difference of less than 1cm, 25% larger, and 25% smaller) we used mirrors with different lenses and UW30 underwater speakers to playback sounds from different size individuals, previously recorded from the same population. The trials were recorded using GoPro cameras. For the experimental trials, only the subordinates (rank 3) of 18 groups were used. The dominant individuals, rank 1 and 2 were removed to remove effects of gender and social status as studies have shown that individual behaviour is influence by social rank [12].

Table 1. Table showing the combination of visual-acoustic cues used in the experiment.

		Visual cues		
		Smaller size	*Similar size*	*Larger size*
Auditory cues	*Smaller size*	A	B	
	Similar size	D	E	F
	Larger size		H	I

2.3 Behavioural and acoustic data

Video recordings from the baseline and experimental data were used to score individuals behaviour using BORIS (v. 7.12) (Tab. 2). Unwanted noise interferences present in the acoustic data were removed using a low-frequency filter in Audacity. Acoustic data in format *.wav* was cut in smaller clips and imported to Raven Pro v 1.6 to extract the acoustic parameters of all vocalisations, which were exported in selection tables. Vocalisations were labelled in relation to the behaviours that were displayed by the vocalising fish and the social rank of the fish.

Table 2. Ethogram used in the study showing the behavioural categories and descriptions of each behaviour.

Behaviour	**Description**
Aggression	Fish rapidly swims towards the mirror and bumps into it
	Fish rapidly darts and turns prior to or during aggressive contact.
Submission	Fish shakes body side to side in jolty fashion.
Social Interactions	Fish simultaneously approach, stay or follow each other within 1 body length
Territorial displays	Fish with stiffened body posture while vocalising
Lateralisation	Fish turns on their side within a body size of distance to the mirror
Time outside anemone	Fish swims outside the perimeter of the anemone
Out of sight	Fish cannot be seen because it enters anemone, moves under or behind anemone, or swims beyond the video frame.

2.4 Statistical analysis

All statistical analyses were performed in R v. 4.4.2 [13]. We used package *seewave* [14] to visualize the acoustic data, creating spectrograms and oscillograms. Using the packages *warbleR* and *Rraven* [15-16], we imported the selection tables created in Raven to analyse the parameters of the spectrograms. We used the *glmmTMB* package to fit generalised linear mixed models (GLMM) that accounted for zero-inflation in the data [17], using treatment, cues size and focal individual size as fixed effects. Individual ID as random effect to account for non-independence of individuals' behaviour. We used Akaike's Information Criterion (AIC) [18] for model selection. The *emmeans* package [19] was used to perform pairwise comparisons and the *performance* package was used to calculate the marginal R^2 (provides the variance of the model explained by the fixed effect) and conditional R^2 (provides the variance explained by both fixed and random effects) using Nakagawa's R^2 [20].

3. RESULTS

3.1 Vocalisations and behavioural context

We found that *A. percula* vocalisations are composed by pulses of sounds with a frequency range between 0.2 and 1.08 kHz and a duration between 0.007 and 0.361 ms. The pulses of sound could be produced individually or in a train of consecutive pulses that could range from 2 to 20 pulses, with an average of 0.036 ms of pause between pulses.

We identified five behaviours that were associated with vocalisations of *A. percula*: Interspecific aggression (aggressive displays to other fish species), intragroup aggression (aggressive displays to other fish within the social group), social interactions (non-agonistic interactions between members of the social group), submission (submissive displays to other members of the social group) and territorial displays, in which individuals would get close to the edge of the anemone and produce vocalisations without a direct interaction with another fish.

The pulse number analysis revealed several significant differences between behavioural categories. Submissive vocalisations were significantly different from aggressive (estimate = -1.899, $p < 0.01$, Fig. 1), competitive (estimate = -1.094, $p < 0.05$), territorial (estimate = 1.240, $p < 0.01$) and social vocalisations (estimate = -1.269, $p < 0.01$). However, no significant differences were found between vocalisations associated with other behaviours. These results suggest that the submissive sounds differed significantly from vocalisations associated with other behaviours.

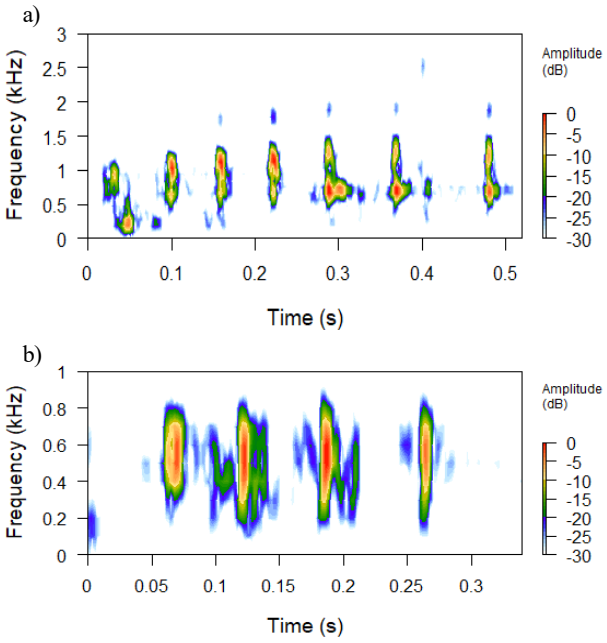

Figure 1. Spectrograms of *A. percula* vocalisation trains showing the frequency in kHz and the duration of the call in seconds (s). The spectrogram (a) correspondence with a submissive vocalisation while the spectrogram (b) corresponds with an aggressive vocalisation.

3.2 Visual-acoustic cues manipulation experiment

Focal fish exhibited different rates of display between behaviours and a higher interaction rate when visual-acoustic cues were congruent (Fig.2). There were significant differences in behavioural category (χ^2_3 = 60.355, $P < 0.001$) and experimental treatments (χ^2_2 = 6.407, $P < 0.01$). Aggressive, lateralisation, and territorial behaviours had positive estimates (Aggression: 0.498 ± 0.283 behaviour/min; Lateralisation: 1.083 ± 0.276 behaviour/min; Territorial: 0.509 ± 0.275 behaviour/min), while submission had a negative estimate (-0.414 ± 0.343 behaviour/min). Among treatments, the congruent cues experiment had the highest behavioural rate (0.498 ± 0.283 behaviour/min), compared to constant acoustic (0.126 ± 0.117 behaviour/min) and constant visual cues (-

0.184 ± 0.123 behaviour/min). There was no significant interaction between behavioural category and treatment. The fixed effects explained 30.1% of the variance (R^2m = 0.301, R^2c = 0.395).

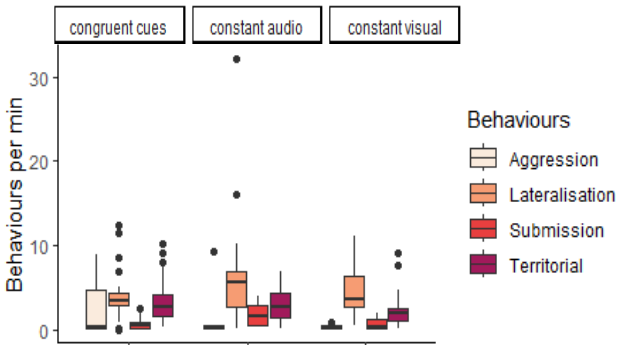

Figure 2. Distribution of behavioural rates (behaviours per minute) across treatments (congruent visual-acoustic cues, constant acoustic cues, and constant visual cues) for four behaviours: aggression, lateralization, submissions and territorial displays. Each box represents the interquartile range (IQR), with the median indicated by the horizontal line.

Lateralisation rates were significantly different between trials in the congruent (χ^2_2 = 10.774, P < 0.01, Fig. 3) and constant acoustic cues treatments (χ^2_2 = 15.126, P < 0.001). Individuals displayed higher lateralization rates when presented with similar-sized cues (congruent cues: 1.591 ± 0.609; constant acoustic cues: 2.535 ± 0.680), compared to cues from larger (congruent cues: -1.706 ± 0.625; constant acoustic cues: -2.126 ± 0.705) or smaller conspecifics (congruent cues: 0.634 ± 0.672; constant acoustic cues: 1.266 ± 0.692). This suggests that visual cues representing similar-sized conspecifics led to more pronounced lateralisation behaviours. In contrast, in the constant visual cues treatment, lateralization rates were the lowest when individuals were presented with similar-size cues, with the highest rates displayed when presented with small acoustic cues. However, these differences were not significant.

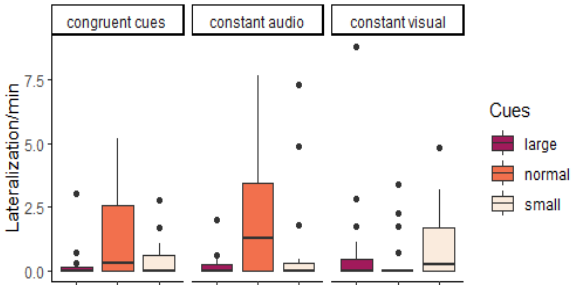

Figure 3. Lateralization events per minute across different cue sizes (larger cues, normal/similar size cues, and smaller cues) and treatments (congruent visual-acoustic cues, constant acoustic cues, and constant visual cues). Boxplots show the distribution of lateralization behaviour for each cue size within each treatment group. Each box represents the interquartile range with the median shown as a horizontal line; whiskers extend to 1.5× the IQR.

Territorial display rates were significantly influenced by focal individual standard length (Fig. 4). Territorial rates decreased with standard length increase in both the congruent treatment (χ^2_1 = 4.959, P < 0.05, -0.091 ± 0.040). This trend was also observed in the constant acoustic and constant visual treatments, however, there were not significant effect found.

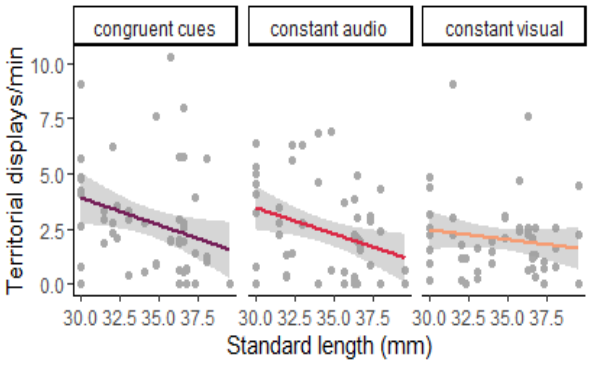

Figure 4. Relationship between standard length (mm) and frequency of territorial displays (displays per minute) across experimental treatments. Grey points indicate individual observations, while coloured lines represent linear regression with 95% confidence intervals.

Aggressive and submissive displays were primarily observed when individuals were presented with similar-size cues across all treatments. However, only the submission rate in the congruent cues treatment showed significant differences between trials ($\chi^2_2 = 10.774$, $P < 0.01$).

4. DISCUSSION

Our findings highlight the complexity of social communication in *A. percula*, emphasizing the critical role of multimodal signals—particularly the integration of visual and acoustic cues—in conspecific size assessment and social interactions. Across experimental treatments, individuals displayed distinct behavioural responses depending on the type and congruency of the sensory stimuli, with congruent visual-acoustic cues eliciting the strongest reactions. These included increased rates of interaction, heightened body shakes and lateralisation, and more time spent outside the anemone, suggesting that multimodal input enhances signal reliability and informs decision-making during social and agonistic encounters [22-23].

We demonstrated that vocalisations are used frequently in natural settings and across diverse social contexts—not only during aggression, but also in neutral interactions and interspecific encounters. These results expand upon previous research by showing that vocal signals are not limited to conflict scenarios but also serve broader social functions [24]. Notably, we observed vocalisations occurring independently of direct interaction, such as at the edge of the anemone or during interspecific interactions—an observation not previously reported in anemonefish bioacoustics literature. This broader range of social contexts highlights the limitations of laboratory settings, where social complexity is often reduced [25].

Lateralisation also emerged as a key behaviour, especially in response to similar-sized visual cues. This supports the hypothesis that lateralisation allows individuals to monitor conspecific size and evaluate their social status [10-11], potentially influencing their decision to engage in conflict [29]. This is consistent with findings in anurans, where vocal frequency is used to assess body size [30-31]. Interestingly, lateralisation was also increased in response to smaller acoustic cues under constant visual treatment, suggesting that individuals rely more on acoustic cues when visual differences are subtle.

Territorial display rates were inversely related to focal fish size, with smaller individuals showing higher rates, particularly in response to larger conspecific cues. This suggests that smaller individuals may use indirect strategies, such as territorial displays, to signal presence or dominance without engaging in direct conflict [32]. These displays may also serve as alert signals to other group members, though further research is needed to clarify their role in group-living contexts.

Behaviourally, body shakes and aggression were more frequent when individuals were exposed to similar-sized conspecific cues, particularly under congruent visual-acoustic treatments. While only body shakes showed statistically significant increases, this trend aligns with predictions that individuals engage in either aggressive or appeasing behaviours when size differences are minimal [26-27]. These behaviours may appear contradictory, but reflect strategic decisions based on social context and perceived dominance, as body size is a strong predictor of conflict outcomes [28].

Overall, our study reinforces the importance of multimodal sensory integration in social interactions and hierarchy maintenance among *A. percula*. Congruent visual-acoustic cues prompted stronger behavioural responses, supporting their role in enhancing recognition, reducing uncertainty, and guiding social decisions. While visual cues often dominated in conflict scenarios, acoustic cues provided critical size information when visual assessment was ambiguous. These findings contribute to a broader understanding of how sensory systems mediate social behaviour in complex group-living animals and underscore the need for future research that integrates ecological realism, individual variation, and dominance structure. Importantly, the reliance on acoustic signals in diverse social contexts highlights the potential vulnerability of these animals to anthropogenic noise, emphasizing the need to consider acoustic pollution as a disruptive force in reef fishes social dynamics.

5. ACKNOWLEDGEMENTS

We thank the Mahonia Na Dari Research and Conservation Centre (Kimbe Bay, Papua New Guinea)

for supporting the fieldwork for this study and the Tamare-Kilu communities which granted us access to work in their local coral reefs. This research was funded by the School of Natural and Environmental Sciences, at Newcastle University.

TOWARDS LARGE-SCALE ENVIRONMENTAL NOISE MAPPING IN EUROPE'S NATURAL AREAS

Rangaswamy Chandrashekar, Shreyas[1*] **Van Renterghem, Timothy**[1] **Botteldooren, Dick**[1]
[1] WAVES research group, Department of Information Technology, Ghent University, Belgium

ABSTRACT

Sound propagation outdoors involves complex physics, posing significant challenges for accurate computational modelling and environmental noise mapping in natural areas. This study uses the advanced Harmonoise point-to-point sound propagation model, which incorporates key features for natural environments, such as acoustically soft surfaces, terrain variations, meteorological effects, and their interactions. Considering the model requirements, the study leverages remotely sensed data featuring high spatial and temporal resolution. Relevant datasets such as elevation, land use and meteorological parameters are integrated into the modelling framework, allowing to produce detailed exposure level maps. Standard noise emission spectra for anthropogenic traffic sources such as roads, railways and aircrafts, together with wind turbine and mining activities, are of interest. By utilizing open input data only, the study ensures applicability over various countries to arrive at the challenging task of producing anthropogenic noise exposure maps in all of Europe's natural areas. In this paper, focus is on road traffic noise, where traffic parameters are based on road categorization, and an update of the progress is reported.

Keywords: *noise mapping, road traffic noise, analytical harmonoise point-to-point model, environmental noise*

1. INTRODUCTION

Environmental noise is increasingly recognized as a significant pollutant with adverse effects not only on human health but also on wildlife and biodiversity in natural areas. Following the Environmental Noise Directive (END) [1] and other European policies, there have been crucial efforts for human-centric large-scale noise mapping, consequently focusing on urban areas. However, natural regions-many of which fall under the Natura2000 network-remain underrepresented in these assessments.

Noise propagation in natural environments is influenced by factors such as undulated terrain, varying ground cover types, and dynamic meteorological conditions [2]. In remote areas, sources of noise, such as road traffic, wind turbines, railways or mining operations are often located at a distance from the natura2000 sites, i.e., away from the biodiverse habitat, necessitating models that accurately capture long-range sound propagation.

This study addresses these gaps by developing a methodology for large-scale environmental noise mapping across Europe's natural areas using exclusively open data sources. To simulate sound propagation with physical realism, the advanced analytical Harmonoise point-to-point model [2], [3] is employed. Unlike simpler methods, Harmonoise incorporates detailed ground characterization, impedance discontinuities, and terrain diffraction effects, which are critical for accurately estimating noise levels in complex natural environments, while keeping computing times within reason.

Ultimately, this work aims to contribute to the development of comprehensive, biodiversity-conscious noise mapping strategies that can inform environmental management and policy decisions across Europe.

2. DATA

This study uses open data sources, primarily derived from remote sensing. The key inputs to the model include ground cover, elevation (digital terrain model), meteorological datasets, and road traffic networks, each obtained from distinct sources.

For ground cover information, the study utilizes the Dynamic World land cover dataset. This dataset provides a spatial resolution of 10 meters across Europe, with a temporal resolution of 2 to 5 days, depending on the location [4]. The dataset delineates different types of ground cover class efficiently.

For large-scale environmental noise modeling across Europe, an essential input is accurate elevation data in the form of a digital terrain model (DTM), which represents the bare-earth surface without vegetation, buildings, or other surface features. While the EEA-10 dataset provided by the European Environment Agency [5] offers pan-European coverage at 10-meter resolution, it represents a digital surface model (DSM) rather than a true terrain model and is therefore less suitable for precise noise propagation modeling.

Ongoing research is exploring the derivation of DTMs from Sentinel-1 SAR data, which could potentially enable consistent terrain modeling across the continent. However, for the purpose of this study, a high-resolution regional DTM from the Flemish government (DHMV II) was used [6]. This dataset, based on LiDAR data, collected between 2013 and 2015, offers 1-meter spatial resolution and accurately captures ground elevation. While this limits the geographic scope of the current case study, it provides a robust testbed for assessing modeling methodologies with high-quality elevation inputs.

In this study the focus is on road traffic noise. The road network is obtained from the Open Street Map (OSM). OSM road data is categorized into different types to which appropriate traffic parameters were assigned. [7].

3. METHODOLOGY

The analytical Harmonoise point-to-point model (HP2P) was implemented in Python 3 [2]. Taking advantage of the available versatile geospatial manipulation libraries, such as the rasterio, osmnx, and shapely, the data processing and preparation were streamlined to serve as efficient inputs to the model. In this paper, as an example, a natura2000 site with coordinates 50.98° N 4.42° E in the Flemish province of Brabant, in Belgium, is chosen.

The study area is a relatively flat ground terrain with elevation varying between 9 m and 14 m above sea level. The site under observation is a mixture of ground cover, with dominant ground cover types forest floor, grass, shrub and scrub. Figure 1 and figure 2 shows ground cover and elevation maps in the study area, respectively.

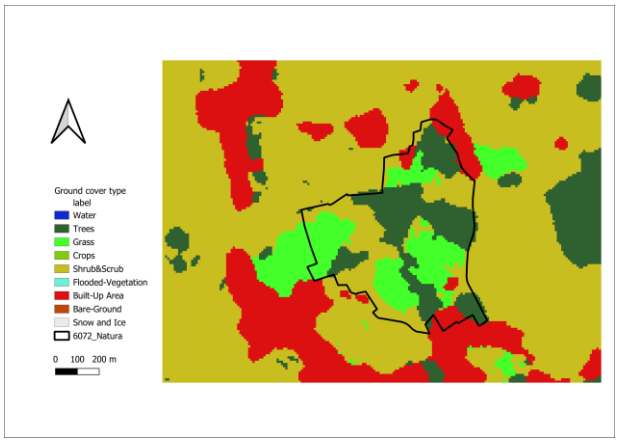

Figure 1. Ground cover map of the natura2000 site under study.

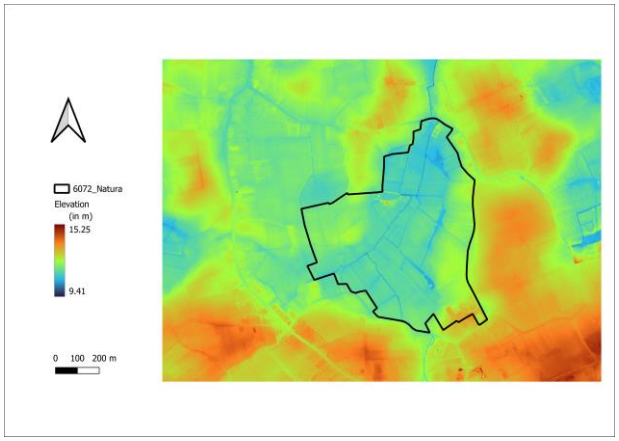

Figure 2. Elevation map of the natura2000 site under study.

3.1 Spatial ETL (Extract, Transform & Load) Pipeline

A buffer of 3.2 km is created around the Natura2000 site, i.e., the study area. Within this buffer, the existing road networks are downloaded. This network is then used to calculate the betweenness centrality [8] of each edge, assigning a corresponding value to each road segment.

Each road is then assigned a traffic intensity, vehicle speed and share of heavy vehicles based on the OSM category

(e.g., motorway, primary, secondary), as well as additional attributes such as the presence of tunnels, the number of lanes, and max speed. The constants linking road categories to traffic parameters are derived from observed traffic patterns in the Flanders region in Belgium. The betweenness values and assigned traffic intensity levels are combined to generate a final traffic-weighted road network.
Since we focus on Natura 2000 sites, we often don't find major road networks that pass through these areas. The following map (fig. 3) shows the road network. Most of the roads here belong to the tertiary or residential category.
Around the current Natura 2000 site, a grid of receiver points is generated at a resolution of 10 × 10 meters. The density of these points was decreased with increasing distance from the major road network (i.e., motorway, primary, secondary and tertiary) to optimize computational efficiency. Indeed, further away from the road, spatial variations in exposure levels become limited.
From each receiver point, cross-sections are drawn to the nearby road segments. The receiver points are divided into groups based on their distance to the road. For each group, a different discretisation of the roads segments in source points is applied. For example, as shown in the figure 3 below, the group of points closest to the major road have been assigned source separations along the road segments of 10 m, while the points furthest away 90 m. This approach strongly increases computational efficiency.

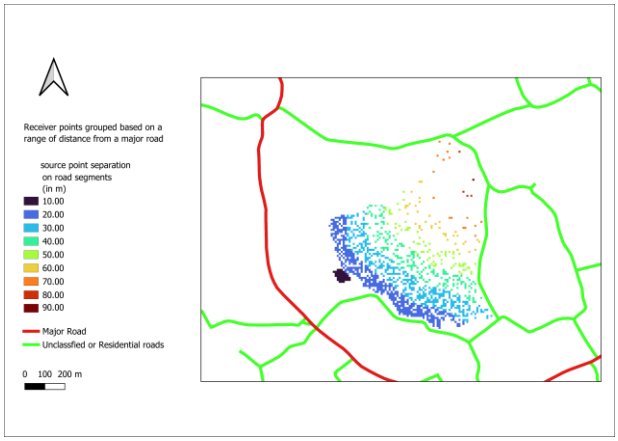

Figure 3. The solid black lines indicate the roads, the red region is the natura2000 site (study area) and the green dots are the receiver points, where the sound pressure levels are computed.

For a given receiver, only those road segments falling within four times the distance from the nearest line source are selected for generating the cross-sections.

The cross-sections are then used for sampling the elevation and ground cover values at a fine spatial resolution of 1 meter. Each of these cross-sections were then subject to the Douglas-Pecker algorithm for simplification to linear segments. With an allowed maximum deviation set at 0.1 m, the profiles preserve the topological features that are relevant for the sound propagation.
Therefore, the final simplified profile carries information on elevation, ground cover type, and the distance from the source. While preserving the topological structure of the profile, it is also essential to retain the exact positions where ground cover transitions occur. These points are explicitly included in the profile, along with the updated ground cover type. This ensures that the Harmonoise model correctly accounts for ground impedance discontinuities by assigning the appropriate acoustic parameters—such as porosity and flow resistivity—on a segment-wise basis. Including these transitions enables accurate Fresnel-zone-based weighting and avoids unrealistic attenuation estimates that could arise from assuming uniform ground conditions along the propagation path. The table 1 below summarizes different ground cover classes available in the ground cover dataset [4] and their associated effective porosity and flow resistivity values.

Table 1. Different types of ground cover and the associated effective flow resistivity and porosity values for using the Zwikker and Kosten ground impedance model [9]

Ground cover type	Flow resistivity ($kPas/m^2$)	Porosity
Water	10^7	10^{-7}
Forest-floor	20	0.5
Grass	300	0.75
Crops	200	0.9
Shrub & Scrub	100	0.45
Flooded Vegetation	10^7	10^{-7}
Built – Up Area	10^7	10^{-7}
Bare Ground	450	0.35

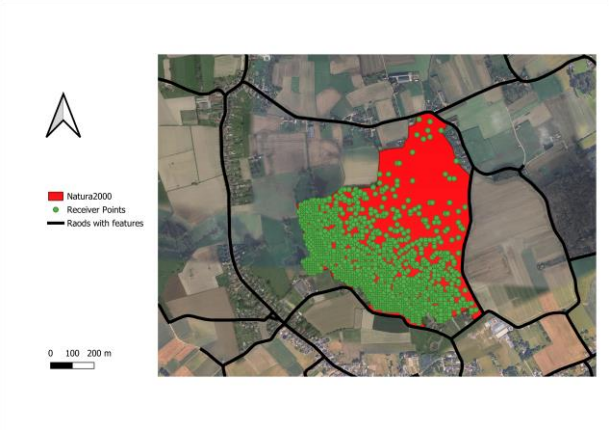

Figure 4. The solid black lines indicate the roads, the red region is the natura2000 site (study area) and the green dots are the receiver points, where the sound pressure levels are computed.

3.2 Computing Sound Pressure Levels at receiver points

The sound pressure levels (SPL) are computed for 1/3 octave bands with center frequencies ranging from 25 Hz till 10 kHz.

Table 2. Input parameters used to run the Harmonoise propagation model

Parameters	Values
Air temperature	15 ° C
Relative Humidity	70%
Atmospheric Pressure	101.325 kPa
Speed of Sound	340 (ms^{-1})
Turbulence scattering strength	5e-6
Source Height	0.03 (m)
Receiver Height	2 (m)

Following the Harmonoise/IMAGINE source power level model [3], [10], the sound pressure level at each receiver location is computed by first determining the source power level based on the traffic parameters (more precisely : traffic intensity, share of heavy and light vehicle, and vehicle speeds) for each road segment.

As the analytical model provides sound pressure levels relative to free field sound propagation, the geometrical spreading term is added afterwards to calculate the total attenuation towards a receiver. Additionally, an A-weighting correction is applied. Future research should explore alternative weighting schemes to better capture the effects on wildlife and biodiversity.

To look at the impacts of elevation and ground cover on the final sound pressure levels, the simulations were run with different simplifications. Test cases involve free field sound propagation only, neglecting terrain elevation by using a fixed elevation, and using a fixed ground cover. All other parameters remain the same as mentioned in Table 1. For simplicity, no refraction was considered in any noise map in this paper, although the Harmonoise analytical point-to-point model is able to model this accurately and efficiently.

4. RESULTS

The sound pressure levels are stored as a feature of the receiver points and are used in creating the noise maps. The outputs are stored as a separate vector files for each test case. The vector shape files are converted to raster pixels with a pixel size of 10 m in the georeferenced units, in our case it is EPSG:3035. The simulations for 4 different test cases are discussed below with fixed level axes. In a first step, interpolation is not applied and only the locations with actual calculations are shown (raw sound pressure level maps).

4.1 Case 1: Free field propagation

The simplest map, only accounting for free field propagation, is depicted in Fig. 5.

Figure 5. Sound pressure level map under free field propagation for the natura2000 site.

4.2 Case 2: Elevation and ground cover is kept constant

In this case, the elevation is kept at a constant value throughout the sampling locations. The ground cover is taken as forest floor, which was assigned a flow resistivity value of 20 kPas/m^2 and porosity value of 0.5 (From table 1).

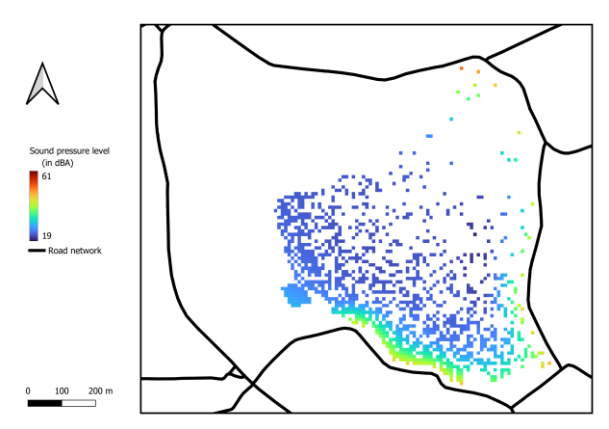

Figure 6. Sound pressure level map for flat forest floor ground

4.3 Case 3: Flat terrain with actual ground cover

Here, the actual ground cover from the dynamic world dataset [4] was used in case of flat terrain.

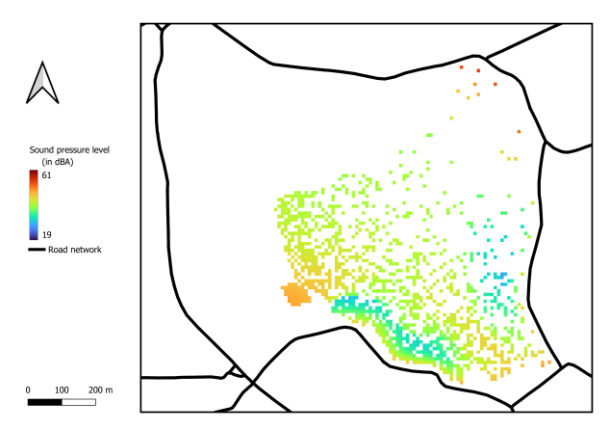

Figure 7. Sound pressure level map for constant elevation and actual ground cover values. The solid black lines indicate the roads

4.4 Case 4: Actual ground cover and actual elevation

In the final test case, actual elevation and ground cover are used, and represents the most accurate map.

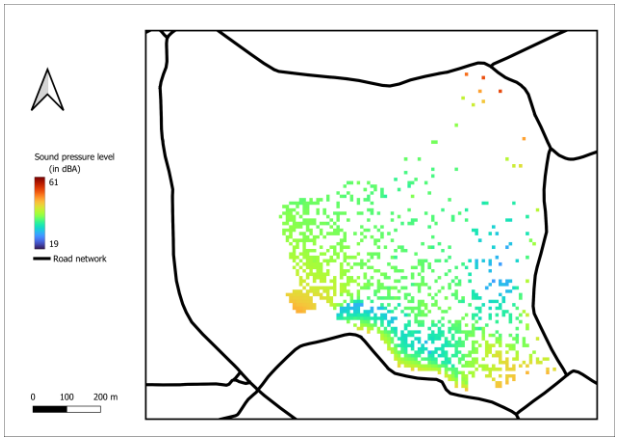

Figure 8. Sound pressure level map for actual ground cover and elevation values. The solid black lines indicate the roads.

4.5 Comparison map

Along with these 4 simulation cases, the difference map between the most simple free field propagation map and the most detailed one, including actual ground cover and elevation, is presented in fig. 9.

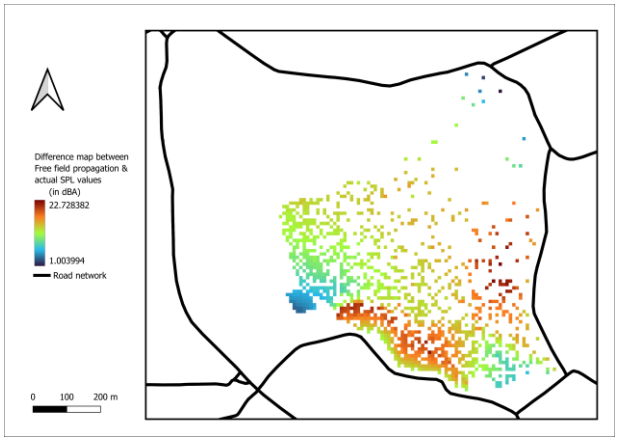

Figure 9. The difference map between the free field propagation and actual sound pressure level.

5. DISCUSSION

From the simulation test cases, it is found that both elevation and ground cover significantly affect the exposure levels. Table 3 summarizes the average differences and standard deviations in sound pressure levels.

Table 3. Average difference between the first three test cases and the final detailed exposure levels

Test case	Average difference (dBA)	Standard deviation (dBA)
Case 1: Free Field	13.5	3.5
Case 2: Flat terrain + forest-floor	10.8	5.4
Case 3: Flat terrain + actual ground cover	2.9	1.8

These variations highlight that ground-related excess attenuation is not merely an additive correction but a dominant propagation mechanism in vegetated and uneven terrain. Notably, the largest attenuation was seen in the final scenario, where both actual elevation and ground cover were used, suggesting synergistic attenuation effects between soft ground and terrain diffraction. Figure 9 illustrates that terrain and ground effects become increasingly important at greater distances, implying that simplified free-field approximations may severely overpredict noise exposure, thereby limiting the practical usefulness of noise mapping efforts. Free field maps, although they might seem attractive from a computational point of view, will not provide meaningful noise maps, with limited use in biodiversity studies.

The Harmonoise model's ability to account for ground attenuation and diffraction proves to be a critical advantage over simpler models like ISO 9613-2 or CNOSSOS - EU, which may underpredict attenuation in soft, vegetated environments [11].

6. FUTURE WORK

Future work will focus on reducing computational time through parallel processing, machine learning, and interpolation strategies. Parallel processing and machine learning methods can improve computational efficiency by optimizing noise modeling workflows, while interpolation techniques will help identify the minimum number of receiver points required to accurately estimate noise exposure across larger areas. These methods will be systematically tested by comparing their results against full calculations across a wider set of input parameters and scenarios, ultimately supporting more efficient large-scale environmental noise mapping for Europe's natural areas.

ACKNOWLEDGMENTS

This study is part of the PLAN-B project "The Path Towards Addressing Adverse Impacts of Light and Noise Pollution on Terrestrial Biodiversity and Ecosystems', funded by the European Union under the Horizon Europe program (project n°101135308).

ABSTRACT

Coastal marine ecosystems are increasingly exposed to sensory pollutants such as anthropogenic noise and artificial light at night. Within the AquaPLAN project framework, in summer 2024 we characterized the noise pollution levels within shallow *Posidonia oceanica* seagrass meadows. Sampling occurred at an urbanized light-polluted site (port) as well as at three naturally dark sites at different level of protection within marine protected areas (MPAs), along the Tuscan coastline (Italy). Acoustic data were recorded up to 192 kHz sampling frequency applying a 16% duty cycle (5 mins recording every 30 mins) by passive acoustic monitoring. Here, we present some preliminary results of a subset of data (96 files) from recordings of 3 days, considering 2 recordings each per 4 parts of the day (nighttime; dawn; daytime; dusk), per day (N=3), per site (N=4). These were processed focusing on the low-frequency continuous noise. Noise was louder and more frequent within the meadow situated close to the port of Capraia, while meadows within MPAs exhibited variable noise pollution levels. These findings provide critical baselines for long-term initiatives assessing noise pollution exposure along with quantitatively measured light pollution levels and then developing mitigation strategies for key-habitats.

Keywords: *Mediterranean Sea, Posidonia oceanica, Noise pollution*

1. INTRODUCTION

Coastal zones are densely populated and largely exposed to human-induced global and local stressors [1]. With the fast pace at which coastal urbanization goes, some novel human-related stressors have become more common, including sensory pollutants like anthropogenic noise and artificial light at night [2,3,4].
The Horizon Europe project AquaPLAN (Aquatic Pollution from Light and Anthropogenic Noise: Management of Impacts on Biodiversity) aims to characterize, both spatially and temporally, anthropogenic noise and artificial light at night and their effects in aquatic habitats. The interest of the Italian project partners, University of Pisa and Stazione Zoologica Anton Dohrn, focus on the impacts of the before-mentioned pollutants on subtidal coastal ecosystems, such as those sustained by the seagrass *Posidonia oceanica*, forming extensive meadows which provide several ecosystem services. This species, endemic to the Mediterranean Sea, is protected together

with its peculiar habitat type (Habitat 1120) [5] and, to date, only a few studies have directly investigated the anthropogenic noise levels to which this is exposed [6].
Here, we present preliminary data collected in summer 2024 at four sites, selected by an *a-priori* qualitative assessment of potential differences in noise pollution levels, as related to recreational boating and the proximity to a marina where light pollution also occurred.
Following the Marine Strategy Framework Directive (MSFD; 2008/56/EC), our goal was to describe the anthropogenic low-frequency continuous noise levels present in these sites and to assess the possible threatened status of the investigated meadows. The MSFD is one of the few legislations directly mentioning noise as the 11th descriptor for a good environmental status (GES) and it defines it as '*anthropogenic sound that has potential to cause negative impacts on the marine environment, including component biota but not necessarily the whole environment*' [7]. Anthropogenic noise sources in water can be distinguished into impulsive and non-impulsive (continuous), with the latter being mainly associated with noise pollution (NP) produced by shipping, sonar and recreational boats often continuously emitting at low frequencies <1-kHz [8]. Regarding this, the 11.2.1 indicator defined the average level centered at 63- and 125-Hz of the 1/3 octave frequency bands (TOLs) as representative of the non-impulsive low-frequency noise ('shipping bands' *sensu* [9]).

2. MATERIAL AND METHODS

2.1 Study area

Field monitoring activities were conducted between July and September 2024, where *Posidonia oceanica* is at its maximum growth [10]. Among the selected sites, three were located around Capraia Island (Capraia Port - CP, Cala del Moreto - CM, and Peraiola – PER - this latter being part of a no-take zone), and one offshore the Leghorn port, on a shallow bank called 'Secche della Meloria - MEL – within a Marine Protected Area (MPA) (Fig.1).

2.2 Data acquisition and processing

Acoustic recordings were collected via Passive Acoustic Monitoring technique (PAM) using an autonomous recorder (Hydromic384K, DODOTRONIC) with sensibility of -156.1 dB re. 1 V/µPa. Acoustic data were acquired up to a sampling frequency of 192 kHz and 16-bit dynamic range, with a 16% duty cycle (5 mins of recording every 30 mins). This was selected to balance battery time-consumption and data storage limitation. The recorders were mounted and tidily assured on a seabed station and deployed at around 10 m depth for 14 days at Capraia Port (672 files), 19 days at Peraiola (912 files), 20 days at Cala del Moreto (960 files) and 21 days at Secche della Meloria (5040 files). Sea state conditions were similar among sites (<3 Beaufort scale) and wave height field (2-3 Douglas scale). The temperature at the three sites at Capraia island was 26.67±1.30°C, while at the Secche della Meloria site was 23.88±1.89°C. Salinity was constant at around 37-38 ppm.

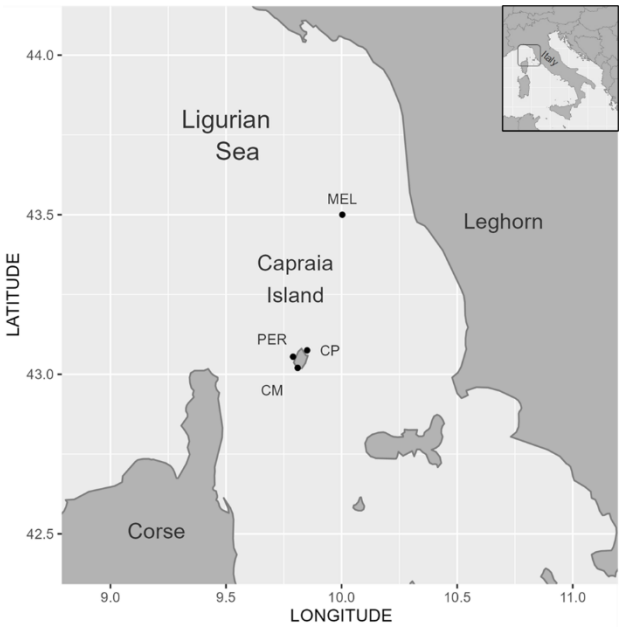

Figure 1. Map of the study area located in the Ligurian Sea (Italy), on the northwestern Mediterranean Sea: MEL - Secche della Meloria; CP – Capraia Port; CM – Cala del Moreto; PER – Peraiola. Map obtained in R Studio version 4.3.3 [11-14].

To this preliminary study, we extracted one subsampled dataset following a procedural scheme: two 5-min recordings per hour per four slots per day from three randomly chosen days per site. The three days included at least one weekend-day (N=6) and the whole subset consisted of 40 minutes a day for a total of 480 minutes. The four slots were the following: 'night'– from midnight to 1am; 'dawn' – from 6 to 7am; 'day' – from noon to 1pm;

'dusk' – from 6 to 7pm. Data were collected as .wav files and no pre-amplification or filtering was applied. Firstly, the audio files were aurally and visually inspected using the free software Raven Lite (from the Cornell Laboratory; www.birds.cornell.edu/home/). The Sound Pressure Level (SPL dB re: 1µPa-rms) was calculated for seventeen 1/3 octave bands (TOLs - frequency range 25 Hz – 1 kHz) using a toolbox in MATLAB [15], with Hann window type with 1 second window length, 50% window overlap and 300 second time-average data (one value for each single file). Special attention was given to the two 1/3 octave bands highlighted by the MSFD and centered at 63-Hz and 125-Hz. Statistical analyses and plots were run in RStudio v.4.3.3 [11,14]. Data was processed with generalized additive mixed effect models (GAMMs) through the 'mgcv' package [16] for the two bands separately. The additive mixed model was chosen to address the non-linear relationship between time of the day and SPL (rms) per site, with the former as the smooth part and days as the random intercept. Due to the limited set of data here processed, we set a flexibility of 4 knots to avoid overfitting.

3. RESULTS

The variations of the SPLs centered at the two shipping bands of the 1/3 octave bands per site are shown in Figure 2. Overall, the 125-Hz band was louder than the 63-Hz at all sites and time slots. Both shipping bands' values showed a similar diel trend, except for the Capraia Port site, where at noon and at dusk higher values were recorded at both bands (Fig. 2). The diel trend of the root-mean-square sound pressure levels at both 63- and 125-Hz bands showed non-linear patterns with variation over time at Capraia Port and Cala del Moreto, while at Peraiola the trend was linear and no temporal pattern was observed (GAMM, $p<0.05$). Meloria site showed a significantly different temporal trend at 63-Hz, but not at the 125-Hz band. The Capraia Port site was the loudest with peak values recorded at dusk for the 63-Hz and at noon in the 125-Hz band. Following the Capraia Port site, Cala del Moreto was the second loudest with the highest peak recorded at noon at both bands, being three- and two-fold lower than the Capraia Port value at 63-Hz and 125-Hz, respectively. The models explained 68.7% and 81.3% of the diel variance for the 63-Hz and 125-Hz bands. As for the random terms, days resulted significantly different at Capraia Port at both bands, and at Meloria when considering the 63-Hz band. For both TOLs, the difference in the medians of the loudest and quietest sites was around 18-22 dB and about 34 dB at 63- and 125-Hz, respectively.

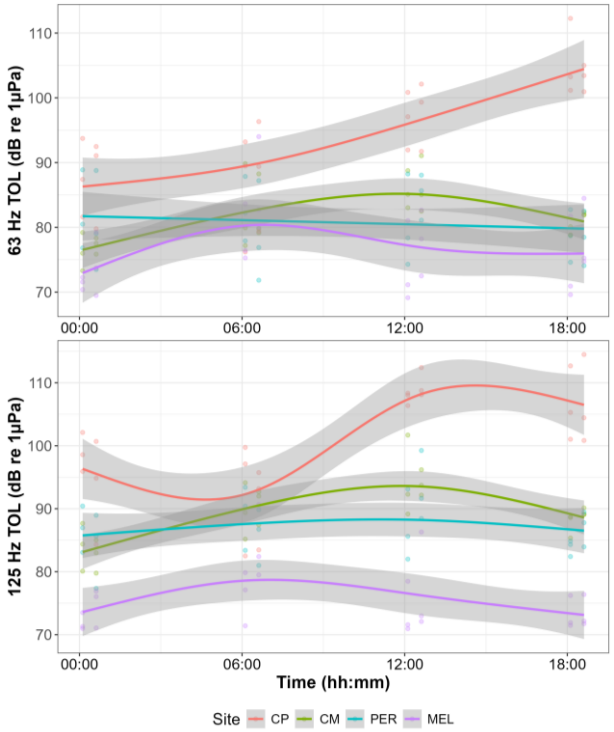

Figure 2. Temporal trend of the two shipping bands TOLs centered at 63- and 125-Hz (dB re: 1µPa). Coloured points and lines represent the SPL (rms) values per site, recorded at a six-hour interval per three days per site (N=2 per time slot). Shaded lines represent upper and lower 95% confidence intervals.

4. DISCUSSION

The preliminary data here shown are, to date, the first related to the anthropogenic noise exposure level of the *P. oceanica* meadows of the Tuscan coast (north-western Mediterranean Sea, Italy) and expressed in terms of TOLs sound pressure levels [17]. Here, our interest was addressed to the diel variation of the two shipping bands, the 63-Hz and 125-Hz, at four different sites, including two MPAs. Not surprisingly, the Capraia Port site was the loudest with the highest median values recorded at noon (92.73 dB re 1µPa and 105.89 dB 1µPa) and at dusk (92.02 dB 1µPa and 103.15 dB 1µPa) at 63- and 125-Hz bands, respectively, when most human activities happen. Moreover, our values were comparable to those obtained in other noisy coastal areas within the Mediterranean Sea (e.g., Gulf of Naples, Civitavecchia port, and the North Adriatic Sea) characterized by intensive human presence [18,19,20,21].

Cala del Moreto, the site on the western coast of Capraia island, was significantly different from Capraia Port and showed significant non-linear temporal trends, possibly due to its site location facing several naval routes as well as small vessels traffic [22]. The highest value at Cala del Moreto was recorded at noon for both bands with 81.03 and 88.40 dB 1µPa at 63- and 125-Hz, respectively. Interestingly, the two MPAs, Peraiola and Secche della Meloria, had two different temporal trends. The former was constant along the diel cycle spanning from 73.40 and 79.11dB 1µPa, and 82.81 and 87.63 dB 1µPa at 63- and 125-Hz, while the latter had a significantly different temporal behavior at 63-Hz, and no differences were recorded at 125-Hz. The lowest rms SPLs at the 125-Hz band were also recorded at Meloria, spanning from 71.34 dB 1µPa at dawn to 71.74 dB 1µPa at noon, respectively (median values). The overall louder 125-Hz band could be due to the combination of shallow sites, high number of recreational boats and less favorable propagation conditions for low frequencies, affecting the contribution from distant shipping as suggested by Garrett et al (2016) [23].

5. FUTURE REMARKS AND CONCLUSION

Drawing conclusions regarding the anthropogenic noise pollution of these sites require further investigation integrating PAM data with automatic identification system (AIS) data [17,19,20]. Follow-ups will consist in processing the remaining recordings, which span a period of ~2-3 weeks and expanding the analyses to natural biological sounds (biophony). This will contribute to widening soundscape information related to the Mediterranean Sea and, more in particular to *Posidonia oceanica* meadows. Furthermore, soundscape analysis, considering both anthropony and biophony, combined to naval traffic information may allow us to detect possible effects of noise pollution on species associated to the meadows. Urbanized sites such as the Capraia Port are also affected by several other threats such as artificial light at night, so that investigating the two factors in multiple stimuli research will provide further insights towards a more comprehensive characterization of sensory pollutants exposure levels [24]. Finally, because the amelioration of sensory polluted sites can be immediate by limiting the naval traffic in certain areas and switching off/to light emission at certain wavelengths, knowledge of their combined effects can help to quickly act and mitigate their impacts within the purpose of the here-presented AquaPLAN project.

ANTHROPOGENIC NOISE AND ARTIFICIAL LIGHT AT NIGHT: ADDITIVE AND INTERACTIVE EFFECTS ON ACTIVITY LEVEL AND SPATIAL BEHAVIOUR

Hans Slabbekoorn[1*] Christina May[1,2] Lisa Dörner[1]
Danielle Crowley[1] Kees te Velde[1] Christian Tudorache[1]

ABSTRACT

Visual and auditory sensory capacities play an important role in the animal kingdom in communication and orientation. For most animals, sound and light are most prominent in relatively long-range signaling and in gathering information about their local and more distant environments. Natural conditions for each modality have therefore continuous impact on general activity level and on spatial decisions to get closer, go further away, or stay put. Insight into these fundamental processes is critical to understand the potential effects of pollution from anthropogenic noise throughout the day and artificial light at night. The impact of sound and light on animal responsiveness roughly follows the same principles and the effects may add up or show interactive effects. We will address fundamental and applied insights into the potential effects of noise and light pollution, by themselves and in concert, and we present an early case study on Lake Victoria cichlids with experimental exposure to elevated intensity levels of both sound and light. We conclude with addressing the specific conditions of migratory fish, and we argue that it is critical to study them for potentially negative consequences of short- and long-term effects of anthropogenic noise and artificial light at night.

1. INTRODUCTION

Sound and light play an important role in the life of animals. Natural sound and light background intensities and spectra determine general activity levels and affect circadian or seasonal rhythms. Specific sound and light sources can also influence spatial decisions: drawing animals closer (attraction) or driving them away (deterrence). This is also referred to as positive and negative phonotaxis and phototaxis [1,2]. For many species, sound and light are the principal modalities used to communicate with conspecifics and to extract information from their environment. Sounds are generated in a variety of ways, propagate through the environment, dependent on habitat- and condition specific scattering and absorption, after which they have communicative potential within the audible range of conspecifics. Behavioural displays and colouration only become visible in the presence of light and when reflected light meets the eye. Objects in the habitat and context will also play a role in detection probability, next to visual attention. Auditory and visual stimuli are often used in concert for communication, and also typically co-occur as environmental cues. Their perceptual prominence varies as with communicative signals with the environmental conditions, behavioural context, and focus (hearing is continuous and omnidirectional, watching is restricted to a particular angular focus and field of vision. In the Anthropocene, both light and noise pollution have altered the world and thereby also the

multi-modal perception of communicative signals and environmental cues.

1.1 Sounds of sexual selection and survival

Natural soundscapes include all that is audible in the environment for an individual animal in a particular habitat at a specific time of day [3,4]. The onset of vocalizations of conspecifics or heterospecifics in the morning may wake up animals and stimulate them to do the same or start other activities, such as foraging or nest-building (Figure 1). Also gradual fluctuations over the day in audible presence of local animal communities may affect vocal and other activity levels. Vocal activities are fluctuating seasonally, driven by hormonal variation over the year, likely stimulated by day length and temperature. The acute effect of natural soundscapes per day may therefore also contribute to longer-term, stimulating effects on physiological and behavioural cycles related to seasonal migration and reproduction. The ability to respond and participate in vocal interactions can for example be critical for reproductive development and mate choice in birds and thereby affect breeding success. Natural soundscapes may also suppress activities when they indicate potential danger by the presence or arrival of a predator. Responsiveness in slowing down activity can then directly translate into survival. Conversely, the resurgence of natural level and composition of local soundscapes may signal the apparent release of danger and trigger revival of halted activities. Abiotic sounds of rain or wind can also affect vocal or other activity levels, likely related to the masking effect on their own vocalizations or on audibility of predator risk, or through learned association with rain or wind, which may be unfavourable to many activities.

1.2 Ambient light by day and night

Light intensity as perceived by animals depends on their visual abilities and the species-specific sensitivity for parts of the light spectrum. The response to light intensity in terms of general activity level is determined by their nocturnal, crepuscular, or diurnal life style (Figure 1), which varies among and within species [5,6]. The length of daylight varies by season and latitude and tunes the biological clock of animals in such a way that their activity levels are optimally timed to ecological opportunities related to feeding and breeding, and to risks of predation and disease. This means that light conditions not only have acute effects, but also influence longer-term physiological and behavioural cycles, such as migratory and reproductive seasons. Acute effects of natural daylight could be regarded as stimulating when triggering activity of diurnal animals, but also as suppressing when making nocturnal animals seek shelter. Twilight and moonlight have a different spectrum and intensity and may also be stimulating or suppressing, depending on species and context. Nocturnal and crepuscular animals typically have special visual adaptations to see at low light intensities (scotopic vision), usually correlated to declines in colour vision or shifts in spectral sensitivities towards colour ranges that are relevant at the dim hours of the day.

1.3 Anthropogenic noise and artificial light at night

Noisy conditions due to human activities [7,8] and artificially lit up nights [9,10] typically disturb or distract animals, generally leading to lower activity levels of whatever they would have done at the time and place (Figure 1). Anthropogenic noise is typically louder, more repetitive, and lower in frequency, than natural sounds. Any time of day, such noisy conditions may elicit fear, stress, or anxiety, making animals to reduce activities that would be risky under the acoustic conditions of perceived threat. Noisy conditions may also just distract, as animals of various taxa have been shown to be unable to avoid processing audible sound, and they thereby lower activity levels of behaviours that require attention for appropriate performance. Finally, masking may yield decreased activity levels through lower stimulating effects of natural soundscapes or reduced opportunities for auditory predator scanning. Lower vocal activity levels may also be the result of lowered auditory feedback from hearing less of their own sounds or of vocal responses from conspecifics. Interestingly, there are also birds and frogs that are vocally triggered by anthropogenic sound events and many species that elevate their vocal intensity and sound production rate in response to more continuously elevated noise levels due to human activities.

Artificial light at night takes away the safety of dim and dark conditions that allow many prey animals to room around with lowered predation rates. Despite intensity typically being much less than natural day time light levels, direct light from lamps, and even indirect light reflected from clouds and air of high humidity (skyglow), usually outcompetes by far any natural light at night from moon or stars. Even though not all diurnal predators become active at night at lit up places, many nocturnal prey species may be less active under artificially elevated conditions and spend less time on critical activities such as foraging, exploring, socializing, and courting. Interestingly, artificial light at night may

also trigger or stimulate activity levels. Birdsong is known to be starting earlier and to end later during the day at territories lit up by artificial light. Predatory fish and birds like herons or grebes may go hunting for fish at times of day that would naturally be too dark to see their prey.

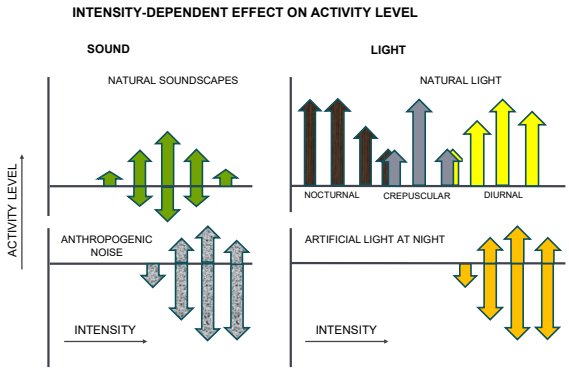

Figure 1: Sound and light conditions can affect general activity level. Soundscapes of conspecific and heterospecific sounds indicating safe conditions for foraging or social activities may elevate activity level in a parabolic way from modest to familiar to extreme sound levels. Natural light levels may stimulate activity depending on whether species are nocturnal, crepuscular, or diurnal. Anthropogenic noise and artificial light at night can also trigger or stimulate activity of animals that are usually not or less active at night, but more often suppress activity of nocturnal and crepuscular species with increasing intensity.

2. CICHLID CASE STUDY

A study with Lake Victoria cichlids (*Pundamilia nyererei*) at Leiden University in August and September 2009, provides a nice example of suppressing effects of sound and light on activity level [11]. Christina May exposed solitary males to noisy or ambient quiet conditions, in bright or dark conditions, and scored their swimming activity and style. After that, she added a female and quantified the courtship behaviour and male calls per pair under the four combinations of sound and light exposure treatments. Earlier studies in this species had shown that both noisy conditions [12] and light intensity and spectrum [13] affect swimming patterns and spatial preferences respectively, likely through familiarity, stress, or anxiety related tendencies to engage in explorative activity. Furthermore, both male sound production [14] and male colouration during behavioural displays [15] have been shown to play a role in communication among male cichlids and in female mate choice.

2.1 Cichlid methodology

We used 40 unique pairs of cichlids from our Leiden stock at the time. These fish were three-year-old, lab-raised individuals [c.f. 14]. All recordings and behavioural observations were made in the same experimental tank (300 x 100 x 100 cm, water level at 90 cm, swimming area restricted to 200 cm, away from both ends). Housing conditions and all experimental procedures were in accordance with guidelines of the Association for the Study of Animal Behaviour and licensed by approval from the ethical committee on animal experimentation of Leiden University (licence number: UDEC 08055). Male and female cichlids within a test pair always came from different stock tanks and were unfamiliar to each other. Relatively large or small males were paired with relatively large or small females respectively, and randomly assigned to sound and light conditions. At the end of the test, fish were transferred back to the stock tank, where they resumed normal activities, and were kept alive as breeding stock.

During the experimental exposure, cichlids experience ambient sound levels at 116 dB re 1 uPa, from the ambient building conditions in the aquarium facilities at the Gorlaeus building of Leiden University. We used an ING 32mV amplifier with an MR23333-000 waterproof speaker (Knowles Electronics, Itasca, IL), in the center of the tank, 10 cm below the water surface, connected to a desktop computer for playing back sound underwater. The speaker was in the water and turned on, but not playing back any sound for the ambient sound treatment. During elevated noise conditions, we played back white noise between 500 and 2000 Hz to generate sound levels of 119 re 1 uPa, which reflects possible conditions for nearby human machinery or boat presence in natural waters. Cichlid calls center around 500 Hz, and they readily respond to playback of calls and white noise of the same frequency range and temporal pattern [14,16]. This made it likely that they would also hear the artificially elevated noise levels in the current set-up, while we would not miss any courtship calls due to masking. Bright and dark light levels in the aquarium were adjusted to 19,800 and 770 Lux, respectively (measured with a light meter and nAmp converted to Lux). The measurements and light levels corresponded with samples taken at Lake Victoria close to the surface and at 6 meters depth (~21,000 and 325 Lux) respectively (Frans Witte, unpublished data).

For the experiment, male and female were introduced in the 200 cm tank arena, on either side of an opaque divider, with a sandy bottom and a three-rock shelter on the male side. After an hour of acclimatization, the male swimming behaviour was observed and scored for 15 min, using JWatcher V6.1. After another two hours, the opaque divider between male and female was removed and we observed courtship interactions for 15 min and recorded any male calls, using an HTI 96-min hydrophone (High-Tech, Inc, Gulfport, MS), with a 20-dB amplifier, and a digital recorder (Marantz PMD 660, WAV-format, 44.1-kHz sampling rate). We analyzed our data with JMP (version 8.0) and R (version 2.10.1) statistical software. Shapiro-Wilk tests revealed that our data were not normally distributed and we applied general linear models, using a Gaussian distribution and identity link for continuous response variables (swimming and window swimming) and a Poisson distribution and log identity for count data (courtship quivers and calls). Male size caused variability, but did not affect treatment dependent patterns.

2.2 Cichlid results

General swimming behaviour of solitary males appeared to go down but was not significantly affected by sound treatment ($F = 0.09$, $p = 0.77$). In contrast, during the dark conditions the male cichlids were significantly more away from their rock shelter and swam significantly more than during the bright conditions ($F = 23.39$, $p < 0.0001$, see Figure 2). In the time swimming, they also exhibited a stereotypical window-swimming behaviour, with their noses against the glass, going up and down and left and right, usually regarded as an indication of discomfort. Of the time swimming, they swam significantly more in this mode of window swimming in noisy compared to ambient quiet conditions ($F = 4.30$, $p < 0.05$), which was not affected by light treatment ($F = 0.02$, $p = 0.88$).

Courtship behaviour of the pairs of cichlids was affect by both sound and light treatments (Figure 2). The noisy treatment yielded significantly less lateral quiver displays than the quiet treatment ($F = 5.02$, $p < 0.05$) and the bright significantly less than the dark treatment ($F = 5.20$, $p < 0.05$). As, two out of the ten pairs for the quiet and dark condition were highly active, with only modest activity for the 30 pairs in the other conditions, there also was a significant interaction ($F = 6.38$, $p < 0.02$). Vocal activity of the males was especially low for the bright conditions, and not very different for the sound treatments in the dark conditions, which yielded a non-significant effect of sound on call rate ($F = 1.66$, $p = 0.20$) and a significant impact of light on call rate ($F = 17.10$, $p < 0.0001$), and no interaction effect.

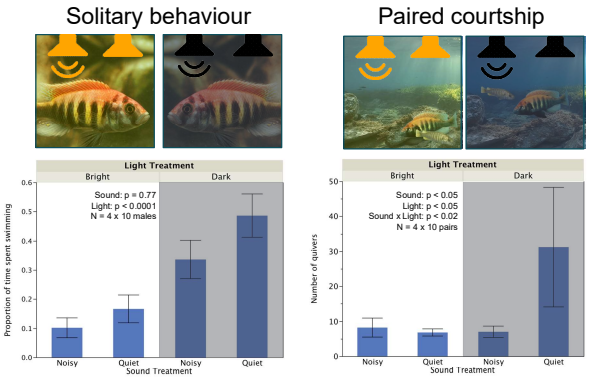

Figure 2: Multi-modal exposure experiment with *Pundamilia nyererei* cichlids. Male cichlids were exposed to playback-induced noisy conditions or ambient control conditions (2 x 2 design) and to bright or dark light conditions. Both sound and light reduced activity levels in a way: cichlids swam significantly less under bright light than dark conditions (left graph), and were involved more in window swimming under noisy than quiet conditions. When a female was introduced, modest levels of courtship where observed, except for two out of the ten pairs in the dark and quiet conditions, which were very active with quivers, and hence the significant effect of both light and sound and a significant interaction (right graph). Courtship call rate was also significantly reduced by light, not by sound.

3. EFFECTS ON SPATIAL DECISIONS

3.1 Looming and luring sound conditions

Besides the effects on activity level, anthropogenic noise and artificial light at night can also affect spatial decisions. Many studies investigated the potentially negative effects of anthropogenic noise on aquatic animals and deterrence is probably one of the most reported effects. Noise exposure level is often varying in amplitude, as vessels are for example moving, and approaching vessels may acoustically suggest a looming threat. Driving away in fear is also the focus in acoustic deterrent studies, in which responsiveness to human-made sounds is investigated as application for herding marine mammals away from fishing nets [17] or guiding fishes away from harmful pumping stations [18]. Variation in acoustic features may determine effect sizes, but typically deterrent capacity is assumed to be positively related to sound intensity (Figure 3).

However, anthropogenic sounds can also be audible and not drive animals away and even attract them out of curiosity or after experience with positive rewards when human activity underwater yields feeding opportunities. Although even loud deterrent devices like pingers have been shown to be successful in their targets at first and become a dinner bell after dolphins find out that they are associated with full nets of fish, amplitude levels of attractive sounds are likely to be relatively low amplitude (Figure 3).

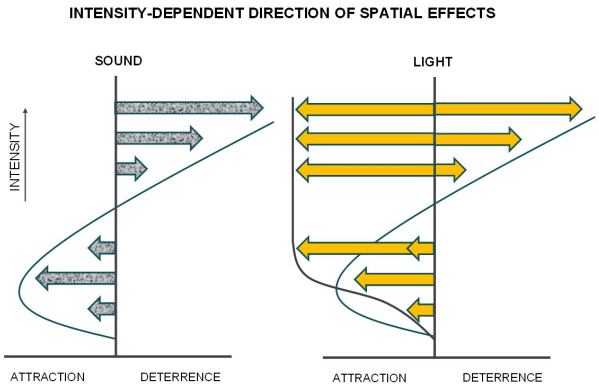

Figure 3: Generalized and schematic illustration of spatial responsiveness to sound and light relative to intensity. At low intensity, animals may just detect sound or light and become interested and be drawn towards the source. At higher intensities, this phonotactic or phototactic behaviour may get stronger, up to an optimum level at which the attractive power starts to decline again. Sound and light may also become deterrent and get stronger towards more extreme intensities. For some animal groups, intense light seems not to become aversive and phototaxis can even become stronger, persistent, maladaptive, and often fatal.

3.2 Fatal attraction: blinded by the light

The spatial effects of artificial light at night can have a similar pattern as anthropogenic noise (Figure 3). Animals with nocturnal habits or living in dark habitats typically avoid bright areas and move away from light sources. The higher the light intensity, the higher the probability of spatial deterrence. However, also at lower intensities of light, animals may be drawn towards the source out of curiosity and the explorative nature of the species or caused by positive experience with food-associated light sources. Actually, there are many examples, in contrast to sound in which the attractive effect of light does not fade with intensity. Moths and many nocturnal insects are attracted to bright lamps at night. Also migratory birds are known to be attracted to brightly lit oil platforms at sea [19] or exceptional beacons of light, such as the Tribute in light, an annual art installation at the Twin tower memorial site. The insects and birds seem to blinded by the light or at least loose the capacity to escape the light source site as long as the light is on. Another fatal attraction is found in marine turtles, where juvenile animals, just out of the egg, crawl on the beach into the wrong direction: towards lamps of coastal roads or buildings, away from the ocean which they used to find by going for the bright side with most open sky [20].

3.3 Multimodality

Given that most animals have perceptual abilities for both sound and light, they are likely to be affected by both all the time [21]. Responsiveness to playback of conspecific song may yield a different response strength depending on amplitude and other acoustic features, but may also vary between bright and dark conditions. Similarly, the response strength to a visual display of a fish during particular light conditions may be modified by ambient sound levels from nearby conspecific or heterospecific vocalizations or by the rustling of leaves in the wind. Consequently, also the effects of noisy conditions and artificial light at night will depend on multimodality. Noise and light pollution may co-occur at night, such as with passing cars or brightly lit highways or industrial areas, but each may also occur independently of each other. Noise and light pollution may have unimodal, cross-modal, and multimodal effects [21]. Multimodal effects may be in the same or opposite direction [22], with respect to stimulation or suppression of activity level and with respect to attraction or deterrence (Figure 4).

3.4 Additive and interactive effects

The co-occurrence of both anthropogenic noise and artificial light at night may yield additive effects, where the combined effect is equal to the sum of each separately (Figure 4). If the effect is in the same direction, they add up, if they are in opposite direction, they get subtracted. The effect of sound and light exposure on swimming activity in the cichlid case study suggested such an additive effect in the suppression of activity. The effect of courtship quivers seemed to be more dramatic and either of the stressors seemed to have a similar suppressive impact as the two together, although this may also be due to a bottom effect. The pattern yielded a significant interaction, as the absence

of noisy conditions was only yielding high activity levels in dark and not in bright conditions. More interactions are possible, for which there are no or limited examples available at the moment, where there may be antagonism and synergism [22], leading to variable patterns for effects in the same and different direction (Figure 4).

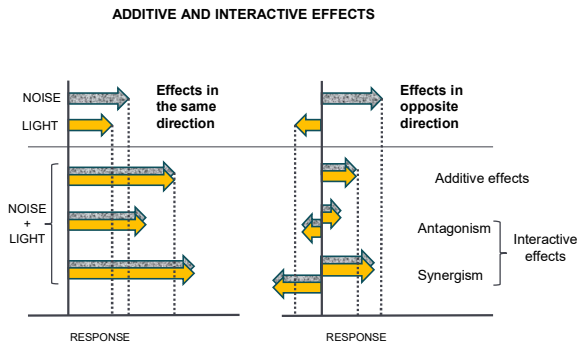

Figure 4: Spatial responsiveness to light and sound can involve attraction and deterrence, depending on the intensity (figure 2), and co-occurrence of both modalities can thus result in responsiveness into the same (left panel) or opposite direction (right panel). The combined effects of both can be additive and yield the sum or subtraction of both of the directional responsiveness. Sound and light can also interact and yield antagonistic or synergistic effects that are more complex (after [22]).

3.5 Particle motion of sound and polarized light

Sound and light can be characterized by intensity and spectrum, but there are additional features with similar aspects and consequences for animal species that can perceive these. For most aquatic invertebrates and fish, sound is perceived through the particle motion aspect of sound [23,24], which makes sound pressure level measurements less reliable in terms of exposure conditions, especially when close to boundaries with air, rock, or bottom. The sensitivity to particle motion can be extended with pressure sensitivity in case there is a gas-filled cavity such as a swim bladder. In both cases, the animals perceive directionality through the particle motion. Relative particle motion levels of a sound from a source at a particular distance and angle are dependent on ambient noise from just the same direction. Signal-to-noise ratios are therefore favorable compared to sound pressure of an unidirectionally arriving signal and omnidirectionally accumulated ambient noise. There is also a special role for polarized light for some species groups: the oscillation of the electric field vector of light can be detected by many invertebrates. Insects can for example use the polarization of light to detect water, improve visual contrast, undermine camouflage, navigate through landscapes, and even to signal during mating [25]. Many animals that also exploit the direction of light polarization as a source of information may be detrimentally affected by light that has been polarized through interaction with human-made objects, such as reflective windows at large office buildings, car window screens, or specific parts of wasted bottles [26].

4. THE CASE FOR MIGRATORY FISHES

In this final section, we would like to draw attention to migratory fish. Migratory fish provide an interesting case for studying the effect of both sounds and light in terms of activity level and spatial decisions, as done in the context of the EU Horizon-project AquaPLAN. We lack fundamental insights into the role of natural soundscapes and natural light during day and night. Furthermore, the expansion of noise and light pollution in and around aquatic habitats is spreading worldwide and may warrant the label acoustic climate change [7]. Freshwater ecosystems are among the most vulnerable in the world and the protection of especially migratory fish is a major challenge, because their decline is often caused by multiple stressors. These stressors include blockage of migratory routes, overfishing of populations, water quality changes and habitat deterioration [27].

4.1 Noisy conditions on migration

On top of the many recognized stressors, both noise and light pollution may add significant problems. The habitat of migratory fishes has been increasingly affected by anthropogenic noise worldwide, especially due to an increase in the number and size of shipping vessels [28]. Natural soundscapes are increasingly recognized as an important ecological feature of critical importance to animals [3,29]. Sounds audible to freshwater fish may include sounds of mammals, fish, frogs, and aquatic invertebrates, gas bubbles produced by aquatic plants and decomposing bacteria, but also physical disturbance of the substrate or water surface by animal or water currents and wind [28]. However, high levels of shipping and recreational activity may render the acoustic cues about the river environment inaudible and this may also be true when rivers flow through noisy urban areas. Migratory fish are therefore constantly challenged acoustically, as spatial details, temporal dynamics, and directionality of natural auditory cues can be masked and become inaccessible.

4.2 Light on short- and long-term effects

Also light pollution along rivers and coastal areas has spread worldwide. Natural light cycles are increasingly disrupted by artificial light pollution [30]. Currently, ~80% of the global population resides under light-polluted skies, and artificial sky brightness continues to rise. Artificial light at night impacts freshwater ecosystems both directly, via illuminated infrastructure like bridges and vessels, and indirectly through skyglow caused by atmospheric light scattering [31], and might disrupt specifically light-dependent biological processes such as migration. In species such as Atlantic salmon (*Salmo salar*) and European eel (*Anguilla anguilla*), artificial light at night has already been linked to various detrimental short-term and long-term effects, such as increased predation, disorientation, and delayed migration timing [32]. The alignment with the biological clock is likely to be especially vital during migration, but more studies are needed to shed a better light on problems and potential solutions.

5. CONCLUSIONS

Sound and light play an important role in the live of all animals and especially migratory fish. Sound and light conditions affect general activity levels and may influence spatial decisions. Noise and light pollution can detrimentally affect these natural processes and undermine adaptive responsiveness to the natural environment. More studies are required to gain insight into the fundamental nature of positive and negative phono- and phototaxis, both to natural and artificial conditions. Studies in captivity such as in the cichlid case study may be suitable to explore additive and interactive effects and migratory fish may provide a suitable and important model system to investigate responsiveness to experimental exposure to anthropogenic noise and artificial light at night in their natural habitat.

ABSTRACT

In epidemiological research on the effects of noise on terrestrial animals (primarily birds and mammals), A-weighted sound levels are often used for convenience. However, A-weighting is based on human loudness perception and is not well-suited for this purpose. The plan-B project explored alternatives, as assessing perceived loudness across multiple species is impractical. Two alternatives used in humans are hearing level weighting and communication interference weighting. These could also be applied for terrestrial animals. The former is a conservative approach covering all sound uses, while the latter can be easily extracted from the vast database of recorded animal communications. Different weightings were applied to two-week recordings at 40 suburban and urban locations, where traffic is the dominant noise source. The Spearman correlation between 15-minute equivalent levels with different weightings was very high. Thus, for a Europe-wide assessment, the specific weighting applied may not be critical. However, for specific locations, sources, or particular (endangered) species, the chosen weighting may affect conclusions.

1. INTRODUCTION

The effects of noise on terrestrial biodiversity have become a critical area of ecological research. Anthropogenic noise, stemming from urbanization, industrial activities, and transportation, poses a significant threat to the persistence of many species [1] [2]. Studies have shown that noise pollution can influence physiology [3], increase costs of communication, and disrupt various biological functions, leading to changes in species interactions and altering community structures [4] [5].

Sound plays vital roles in the lives of many organisms, similar to its functions in humans. It serves as a tool for passive monitoring, enabling situational awareness by detecting danger, confirming safety, and identifying opportunities for food and water. Additionally, sound facilitates active communication, essential for mate finding, establishing territorial boundaries, and sharing experiences. However, task-irrelevant sounds can interfere with these primary functions, causing masking effects or making auditory scene analysis more challenging.

To measure the interference caused by noise, various strategies have been developed. One approach focuses on what can be heard being disturbing, while another emphasizes the impact on active communication. In humans, the former approach led to the adoption of A-weighting, a method that adjusts sound measurements to reflect the relative loudness perceived by the human ear [6]. Historically, speech interference weighting has also been used to assess how background noise affects speech communication.

This study investigates the potential to calculate com-

munication interference weights for terrestrial animals using analysis of recordings in 1/3 octave band spectra. By clustering these spectra, we can decrease the diversity of variants and simultaneously exclude recordings contaminated by extraneous sounds. In Section 3, the derived weighting curves are utilized on a variety of noise recordings from suburban and urban areas, while Section 4 provides a discussion of our key results.

2. DERIVING SOUND COMMUNICATION INTERFERENCE WEIGHTING

For deriving communication interference a representative amount of bird sounds had to be collected. For this, we used one of the primary sources for bird song recordings, Xeno-canto, a collaborative website dedicated to sharing wildlife sounds from around the world. For deriving a weighting curve, only the spectral content of the song is relevant. Hence, 1/3 octave band spectra are calculated for each recording and normalized to obtain an rms-value of one for the highest 1/3 octave band while ignoring temporal structure.

However, several bird species produce songs with comparable spectra. This similarity can be explored to reduce the number of weighting curves that one could obtain. Hence, the spectra in the frequency range 160 Hz to 10000 Hz were mapped to two dimensions using UMAP (Uniform Manifold Approximation and Projection) [7] and subsequently clustering based on DBSCAN(Density-Based Spatial Clustering of Applications with Noise) [8] was applied. This procedure also allows to identify outlier spectra that could be caused by noisy recordings. the resulting mapping to two dimensions is shown in Figure 1. In this figure, different symbols refer to automatically identified clusters while colors are related to species. The prevalence of species in each cluster is further analyzed in Figure 3.

Figure 2 illustrates the mean spectral data grouped by bird clusters, revealing three prominent classifications: the extensively populated cluster 5 along with its numerous variants, cluster 4, and cluster 0. As depicted in Figure 3, cluster 5 and its variants encompass recordings of songbirds, cluster 0 is characterized by doves and pigeons, while cluster 4 includes species such as the mallard, grey heron, Eurasian jay, Eurasian coot, and common buzzard. The birds in this last group utilize vocalizations not for marking territories but for interactions such as mutual communication, signaling danger, or expressing aggression. Notably, the coot is recognized for its high-pitched

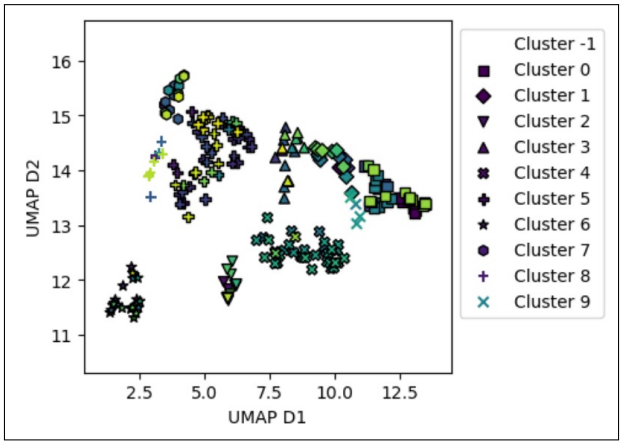

Figure 1. Clusters of bird song spectra based on 250 recordings from 25 bird species, mapped in 2 dimensions.

vocalizations at elevated pressure levels. A shared feature within this group may be their body size, which influences the ability to produce sound at lower frequencies [9]

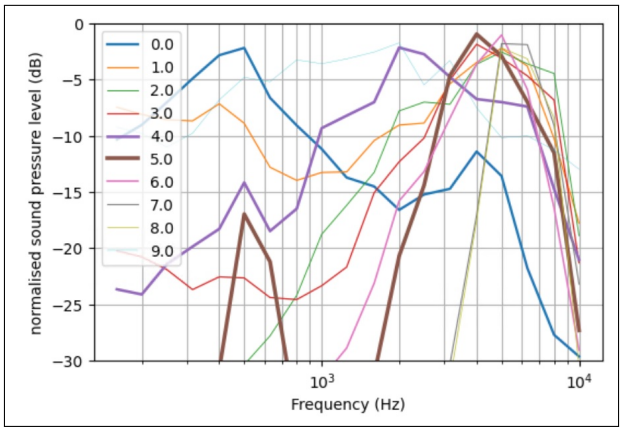

Figure 2. Song spectra averaged over each cluster; line width is proportional to the number of exemplars in the cluster thus thinner lines may refer to clusters of noisy or poor quality measurements.

Based on the communication spectra, three different weighting curves are proposed: CI1, CI2, CI3 (Figure 4). They are described by analytical functions similar to the ones used for describing A, B, and C-weighting. These functions correspond to filters with sets of complex conjugate poles and zeros, and can thus be implemented easily

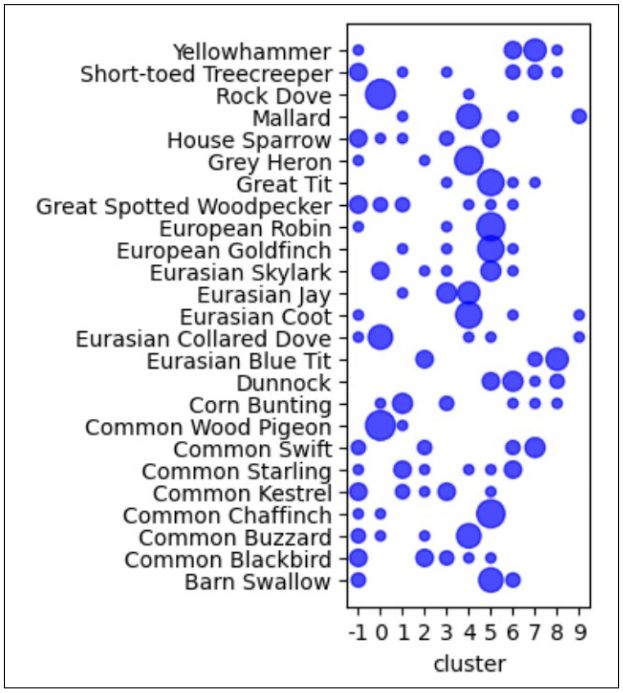

Figure 3. Distribution of the species over the clusters; the size of the circle is proportional to the number of recordings of that species in that cluster; cluster -1 refers to recordings that do not fall in one cluster

in measurement equipment.

3. INTERFERENCE WEIGHTED NOISE LEVELS

3.1 Effect of weighting on biodiversity surveys

To investigate how the selection of weighting curves could influence large-scale biodiversity studies, this research compares 15-minute equivalent noise levels using both A-weighting and CI-weighting. Approximately two weeks of data were gathered from 40 sites within the broader Ghent (Belgium) area. Each measurement was taken at the facade of a building, with environments varying from suburban to urban.

In Figure 5, a scatter plot is depicted illustrating the comparison between A-weighted and CI1-weighted levels (for songbirds) and A-weighted and CI2-weighted levels (for doves). To assess the monotonic relationship within these data points, we have determined Spearman's correlation coefficients: 0.898 for A-weighted vs. CI1-

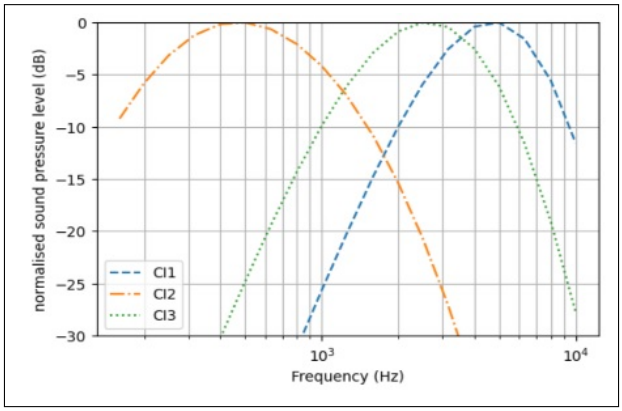

Figure 4. Communication Interference weighting curves proposed for three groups of bird species.

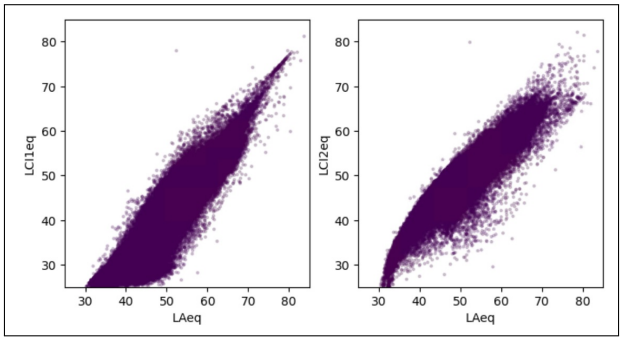

Figure 5. Scatter plot of 15-minute CI1 and CI2 weighted Leq versus A-weighted Leq; each dot represents a single observation at any time during the day at any of the 40 locations.

weighted, 0.928 for CI2-weighted, and 0.965 for CI3-weighted. The substantial correlation values suggest that on a broad scale, such as biodiversity surveys across an entire continent, using existing A-weighted noise maps could be an acceptable approach, particularly given the prevalence of anthropocentric noise mapping. With traffic being a primary contributor to anthropogenic sounds, especially in the suburban and urban areas examined here, either weighting scheme would indeed effectively highlight these human-induced auditory disturbances.

3.2 Temporal patterns

When examining specific situations, communication interference weighting can highlight differences between

recording sites. Figure 6 illustrates the effect of weighting by comparing measurements at two suburban gardens. At the first measurement location (until day 115), the CI1-weighted levels exhibit a pattern over the day that is clearly influenced by the light/dark cycle. On certain days (depending on the weather), the CI1-weighted level shows a distinct increase in the early morning, linked to the morning bird chorus, which is the primary communication interference for songbirds. This pattern is not as evident in the A-weighted level plot (left part of the figure). At the second location (after day 115), a clear diurnal anthropogenic noise pattern is visible in A-weighted levels, including typical daily and weekly variations. The CI1-weighted level shows a more uniform pattern throughout the day. Interestingly, the highest CI1-weighted levels at this second location are lower than the levels observed during the morning chorus at the first location.

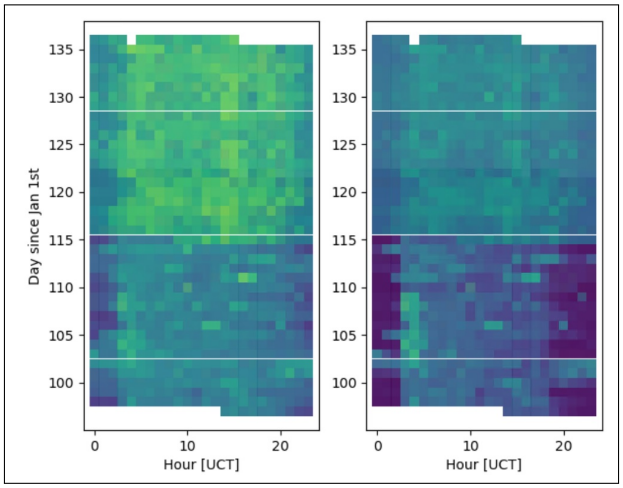

Figure 6. Heat map of noise levels at two suburban gardens (location change on day 115); left: A-weighted, right: CI1-weighted.

4. DISCUSSION

Communication interference weighting curves extracted in this publication are extracted from recordings of the communication of several bird species. These species were selected based on their estimated abundance in Belgium, hence the resulting weighting curves might not be applicable in different climatological zones and different continents. The database used for collecting the sounds was Xeno-canto. This sound collection contains contributions from lay persons and is not carefully checked for origin of the data nor the recording conditions are carefully checked. It can be expected that most recordings originate from suburban neighborhoods and thus song bird frequencies may already have been shifted to higher frequencies because of the presence of anthropogenic sounds [5].

The importance of appropriate frequency weighting is explored based on measurements in the Ghent area, Belgium. Belgium is situated at the crossroads of Europe, with two major roads, E40 and E17, intersecting near Ghent. Several air corridors pass over the measurement area, and although the nearest airport is 60 km away, aircraft noise is often clearly audible in the more tranquil areas. Within this context, and considering measurements at different hours of the day, a monotonous relationship was observed between A-weighted levels and CI-weighted levels. Thus, at times and locations with significant noise, whether anthropogenic or natural, a high noise level will be obtained regardless of the weighting. From this, one could conclude that for identifying zones with high disturbance, A-weighting might still be an acceptable alternative for assessing effects of noise on wildlife and biodiversity, even though it lacks a logical foundation. Although we would not advise doing so, it could be a cost-effective alternative for lengthy calculations when A-weighted noise maps are available.

More detailed analysis of the diurnal pattern of CI1-weighted noise level reveals the relative importance of other bird sounds compared to anthropogenic noise. Indeed, not only anthropogenic environmental noise has to be considered as a source of disturbance but also natural soundscapes can be noisy because of wind, waves, or other species, e.g. such as frogs [10]. Animals have adapted to noisy environments by selecting a specific window of opportunity for singing. This can include optimal meteorological conditions for acoustic transfer [11], diurnal pattern of other bio-phonic sounds, or waiting for a specific short time window [12]. Based on the above, one could expect that some birds have the ability to select optimal singing strategies to avoid anthropogenic noise as well as bio-phonic sound. Literature on birds adapting their singing behavior to urban sound environment [3] has gained a lot of attention, also in lay literature. Some experimental work is not so univocal [13] and point at the role of overlapping spectra. Observed pitch changes might not be the adaptive strategy but rather a side effect of singing louder in noisier environment [14], comparable to the Lombard effect in humans.

As a general conclusion, both theoretical considera-

tions and measurement examples show that using a specific weighting curve for assessing communication interference in animals could be beneficial. This could allow for a more targeted impact assessment of new initiatives and interventions, in particular if the species of interest are known. This could also lead for more efficient noise mapping as the frequency range that needs to be modeled is usually less extended than for human-related A-weighting. Hence, for new biodiversity-related noise mapping the use of CI-weighting should be preferred.

5. ACKNOWLEDGMENTS

This study is part of the PLAN-B project "The Path Towards Addressing Adverse Impacts of Light and Noise Pollution on Terrestrial Biodiversity and Ecosystems', funded by the European Union under the Horizon Europe program (project n°101135308). TOWARDS A SIMPLIFIED PERIODIC TESTING OF TAPPING MACHINES

Volker Wittstock [1*] **Sylvia Stange-Kölling** [1] **Kevin Picker** [1]
Heinrich Bietz [1]
[1] Physikalisch-Technische Bundesanstalt, 38116 Braunschweig, Germany

ABSTRACT

ISO-tapping machines are used as a standardised excitation when measuring impact noise. It is required that 5 hammers with a mass of 500 g each impact the floor at a velocity of 886 mm/s at time intervals of 0.1 s. There are several other requirements like the distance between the hammers, the hammer diameter and the radius of the impact surface of the hammer. These requirements are today defined in different international standards but there is an activity ongoing to develop a new standard ISO/PWI 21791 "Acoustics – Sound sources for building acoustics" which shall also cover the testing of tapping machines.
The current standards prescribe that some of the parameters have to be measured only once like the distance between the hammers whereas other parameters shall be checked regularly like the velocity at impact and time between impacts.
The contribution introduces an alternative periodic test of ISO tapping machines which is based on a simultaneous measurement of the acting force at each of the five hammer positions. Results of test measurements are presented and conclusions with respect to the applicability of such a method are derived.

1. INTRODUCTION

It has been agreed that a new standard ISO/PWI 21791 "Acoustics – Sound sources for building acoustics" is developed. This standard shall contain all information for different types of sound sources used for measurements in building acoustics which are currently described in the different standards. Possible extensions to the currently standardised situation are also discussed. One of these possible extensions is a simplified method for a periodic testing of tapping machines. The motivation for this is that the verification of the current requirements for tapping machines is laborious, which may be one of the reasons why periodic testing of tapping machines is avoided quite often.

2. FORCE EXERTED BY TAPPING MACHINES

A straightforward way of testing tapping machines is to measure their force directly and to compare this to a required force. This leads directly to the question how large the force of a tapping machine should be.
Starting point to answer this question is the blocked force level $L_{F,\mathrm{b}}$ of a tapping machine. It could be shown in [2] that this can be described by a sum of two terms

$$L_{F,\mathrm{b}} = L_{F,\mathrm{b},1} + \Delta L_{F,\mathrm{b}} \tag{1}$$

Here $L_{F,\mathrm{b},1}$ is the level of the blocked force when each hammer impacts the receiver only once in each cycle. It is calculated from

$$L_{F,\mathrm{b},1} = 20\,\mathrm{lg}\left[\frac{m\,v_{\max}\,(1+k)}{F_0}\sqrt{\frac{2\,(10^{1/20}-10^{-1/20})\,f}{T}}\right]\mathrm{dB} \tag{2}$$

with the hammer mass m, the velocity at impact $v_{\max}$, the restitution coefficient k, the reference force $F_0 = 10^{-6}$ N, the centre frequency of the one-third octave band f and the time between impacts T. The second summand $\Delta L_{F,\mathrm{b}}$

in eq. (1) is the increase of the force level due to double or triple impacts. It is

$$\Delta L_{F,\mathrm{b}} = \begin{cases} 10\,\mathrm{lg}\,[1+k^2+k^4]\,\mathrm{dB} & \text{for } k<k_1 \\ 10\,\mathrm{lg}\,[1+k^2]\,\mathrm{dB} & \text{for } k_1<k<k_2 \\ 0\,\mathrm{dB} & \text{for } k>k_2 \end{cases} \quad (3)$$

with

$$k_1 = -0{,}5 + \sqrt{0{,}25 + \frac{t_{\mathrm{lift}}\, g}{2\sqrt{2\, g\, h}}} \quad (4)$$

and

$$k_2 = \frac{t_{\mathrm{lift}}\, g}{2\sqrt{2\, g\, h}} \quad (5)$$

In eqs. (4) and (5), g is the gravitational acceleration, h is the hammer falling height and t_{lift} is the time between impact and lift of the hammer. The standard [1] requires that t_{lift} is smaller than 80 ms. This ensures that $\Delta L_{F,\mathrm{b}}$ is smaller than 0.8 dB [2].

For a mobility mismatch situation, i.e. the hammer mobility is sufficiently large compared to the receiver mobility, the exerted force is equal to the blocked force of a tapping machine. Then equations (1) to (5) clearly show that the force exerted by tapping machines depends on the required quantities of the current standard [1] (hammer mass, hammer impact velocity, time between impacts) but also on additional quantities, namely the restitution coefficient and the occurence of double or triple impacts. These additional quantities are not known and can not be predicted easily [2].

3. TEST MEASUREMENTS

To test a direct measurement of the force of tapping machines, a brass plate with five force sensors [2] is used. The hammers of the tapping machine hit directly on the force sensors. Six different tapping machines are used. Prior to the measurements, their properties (impact velocity, time between impacts) had been tested. Five tapping machines were within the specifications from [1], one tapping machine revealed an impact velocity which was too small. For the force sensors, the sensitivity provided by the manufacturer is used.

Fig. 1 shows the difference between the measured force level and the calculated blocked force level for five hammers of one tapping machine. The measurement has been performed three times. Between the measurements, the tapping machine was dismounted and remounted, in some cases several days were between the measurements. The result of the second measurement is shifted by -1 dB and the results of the third measurement by -2 dB for a better graphical representation. For the comparison, the restitution coefficient is set to 0.65 and $\Delta L_{F,\mathrm{b}}$ to 0. The impact velocity, the time between hammer impacts and the hammer mass are set to the default values from the standard. This input for the calculation of the blocked force level is the same for all tapping machines. The measured force levels are close to the calculated blocked force level for all five hammers between 20 Hz and 1 kHz. At higher frequencies, the measured force levels become smaller than the calculated blocked force level due to the mobility ratio [2]. In all three measurements, a certain pattern is observed. Hammer 3 always exhibits the largest force, hammer 1 always the smallest.

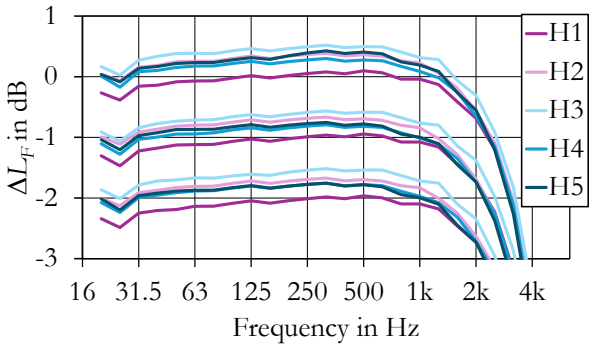

Figure 1. Difference between the measured force level and the calculated blocked force level for five Hammers of a tapping machine; Measurements were repeated three times and the results shifted by -1 dB (second measurement) and -2 dB (third measurement) for better visibility.

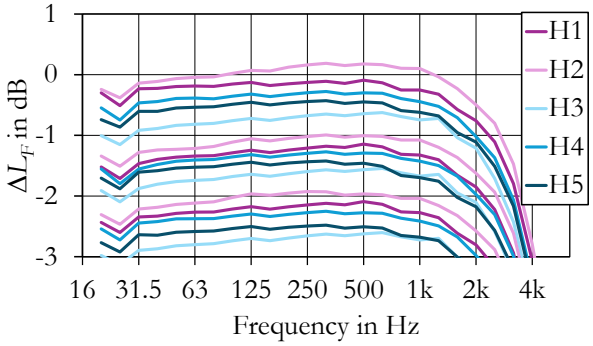

Figure 2. Same as Fig. 1 but different tapping machine.

The observed pattern may suggest that the sensitivity of the force sensors may show some systematic deviation. Fig. 2 proves that this is not the case since the pattern is very

different for another tapping machine. The reason is probably that the restitution coefficient is not identical for different tapping machines. In [2], a standard deviation of the restitution coefficient of about 10 % had been observed when different tapping machines act on the same position of the same receiver.
It is now interesting to see which force is measured for the tapping machine where the impact velocity was too small. This result is displayed in Fig. 3. Hammer 1 clearly shows a much smaller force than the other hammers.

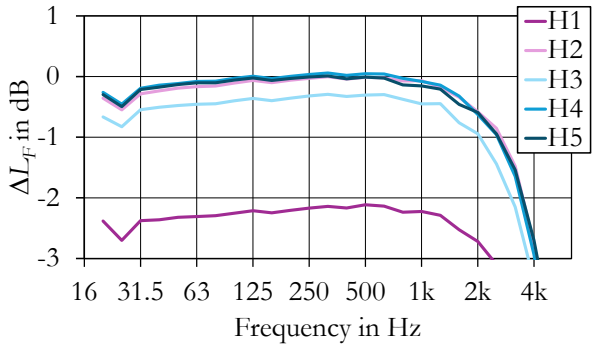

Figure 3. Same as Fig. 1 and Fig. 2 but tapping machine not complying to the specifications from [1] and no repeated measurement shown.

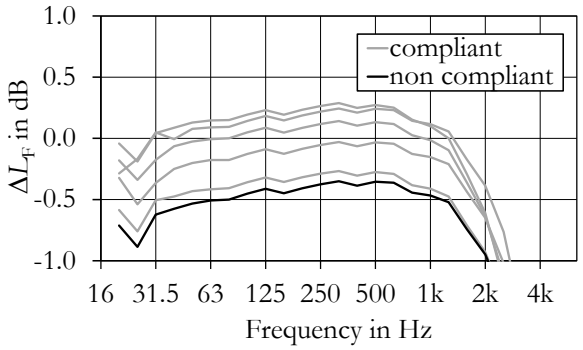

Figure 4. Deviation between the measured force level and the calculated blocked force level averaged over all five hammers for the six tapping machines tested.

Finally, the differences of the measured force levels to the calculated blocked force levels were averaged for the five hammers of one tapping machine. This result is shown in Fig 4. At frequencies from 50 Hz to 1 kHz, this difference is between -0.5 dB and 0.3 dB for the tapping machines complying to the standard requirements. For the tapping machine not complying to the standard requirements, this difference is only slightly larger. The reason is that only one out of five hammers has a much smaller force level which is largely compensated by the averaging over 5 hammers.

4. CONCLUSIONS

A periodic testing of tapping machines by measuring their force levels seems to be possible. An application of a criterion for each single hammer and for the average of all five hammers seems to be appropriate. It is essential for the method that the occurring restitution coefficients are determined, possibly by a set of tapping machines which are known to meet the requirements from [1]. Before such a method can be standardised, further investigations need to be performed, e.g. on the reproducibility of the results and on the uncertainty of the measured force levels compared to the uncertainty of the calculated blocked force level.

TESTING THE HEAVY SOFT IMPACT SOURCE AT PTB: SETUP, CALIBRATION AND UNCERTAINTY

Kevin Picker [1*] **Volker Wittstock** [1] **Michael Kobusch** [1]
[1] Physikalisch-Technische Bundesanstalt (PTB), Bundesallee 100, D-38116 Braunschweig, Germany

ABSTRACT

The heavy soft impact source is a rubber ball with a mass of 2.5 kg which is used as a standard device to excite floor constructions. This device is dropped from a height of 1 m in the source room, and the maximum sound pressure level is measured inside the receiving room either in one-third octave bands from 50 Hz to 630 Hz or in octave bands between 63 Hz and 500 Hz. The A-weighted sum of these values together with some corrections for reverberation time and room volume is finally used to assess the acoustic insulation against impact noise.
From a metrological point of view, the rubber ball is an absolute standard. Its properties are defined mainly by the force exerted on a hard receiver in octave bands between 31.5 Hz and 500 Hz. At PTB, a new facility for testing rubber balls was set up to measure this force. In the contribution, the setup is described, the calibration of the force sensor by a calibrated impact hammer is explained and a first estimate of the measurement uncertainty is derived.

Keywords: *heavy soft impact source, ball impact, dynamic force measurement, in-situ calibration, uncertainty estimation.*

1. INTRODUCTION

There are two standards, [1] and [2], which describe the measurement of sound insulation in buildings or laboratories. In both standards there are proposals for at least two impact sources and the characteristics or requirements of those. One is the tapping machine, which is the more commonly used device for measurements according to the named standards in Europe. However, the heavy soft impact source is gaining attention more and more. It is discussed whether this source can simulate certain everyday situations, such as jumping children and dropping objects, better than the tapping machine.
At PTB, a test setup for tapping machines already exists, but due to increasing interest a test setup for the heavy soft impact source is also required.

2. MEASUREMENT SETUP

The measurement setup at PTB consists of a force sensor mounted on a heavy base mass, and both are placed on a concrete floor (Figure 1). The force sensor is attached to the base mass via an adapter plate, and an aluminium impact plate measuring 100 mm in diameter is mounted at the top using a second adaptor.

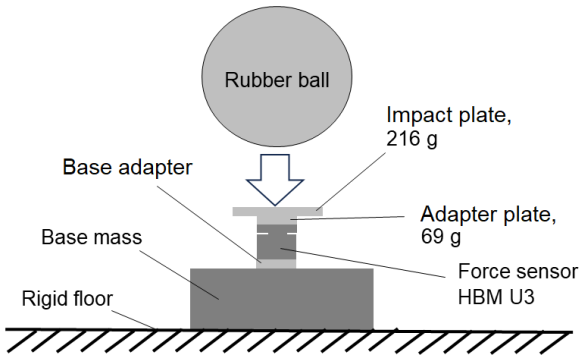

Figure 1. Measurement setup for impact forces.

Thanks to a wall-mounted spacer (not shown in Figure 1), the ball to be tested can be dropped onto the centre of the impact plate from a height of 1 m with good repeatability.

The strain gauge force sensor is connected to a bridge amplifier before the input signal is fed into a measurement unit for further analysis.

3. CALIBRATION OF THE SETUP

The force measurement setup was calibrated in-situ by applying several hammer strokes (approx. 25) with a traceably calibrated impact hammer of a head mass of 500 g. The method of the in-situ dynamic force calibration by means of an impact hammer (see Figure 2) is described in [3].

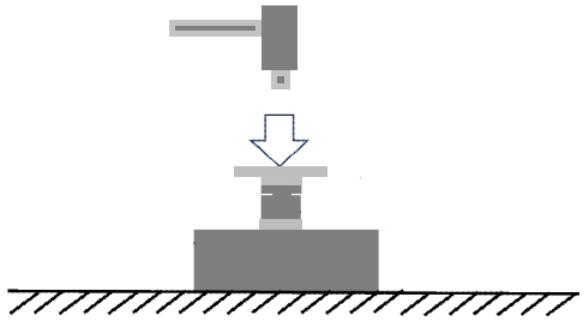

Figure 2. Calibration of the measurement setup with an impact hammer.

The measurements were made with three hammer tips of different stiffness (soft, medium, hard), and the force spectra for the hammer and force sensor were analyzed in octave bands from 31.5 Hz to 500 Hz. The calibrated sensitivity of the considered hammer tip configuration was also determined in the frequency domain. Therefore, the respective sensitivity S_{cal} of the force measurement setup could be calculated.
In Figure 3, the deviation ΔL_{S} from the nominal sensitivity S_{nom} is visualized. The average of the frequency-dependent sensitivity was used to scale the measured time signals. However, it became clear that it makes a difference which hammer tip is used.

$$\Delta L_{\mathrm{S}} = 20\,\mathrm{lg}\frac{S_{\mathrm{cal}}}{S_{\mathrm{nom}}}\ \mathrm{dB} \tag{1}$$

For better estimation, the difference between the individual values and the nominal sensitivity was determined in dB according to Equation (1). The nominal sensitivity for the measuring chain of force sensor and bridge amplifier is 0.1 mV/N. For the octave bands up to 250 Hz, the sensitivity differences between different hammer tips are below ± 0.2 dB and show a smooth shape. This changes at 250 Hz, as the differences with all the tips become larger. Hirakawa et al. made a similar discovery in their work [4] (Page 5, Figure 7). They were using only a hard hammer tip to calibrate their setup, but the difference is also getting larger with increasing frequencies. At 500 Hz the difference is about 1 dB in [4]. It is assumed that the impulse generated by the hammer no longer produces a force that is sufficiently large compared to the noise at these frequencies. This applies more to softer tips than to harder ones.

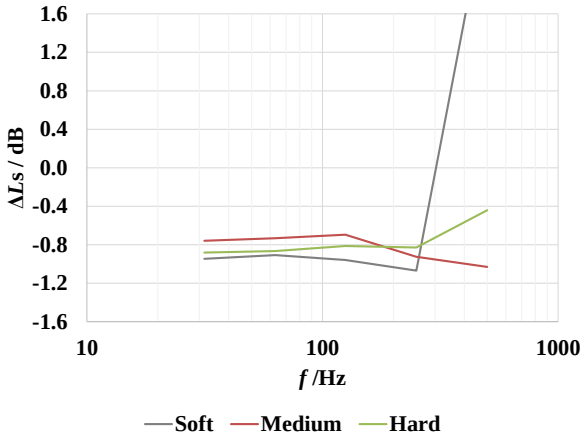

Figure 3. Calibrated sensor sensitivity for different hammer tips in octave bands.

$$u_{\mathrm{cal}} = 20\,\mathrm{lg}\left(1+\frac{\sigma}{S_{\mathrm{cal}}}\right)\ \mathrm{dB} \tag{2}$$

Finally, the uncertainty for the sensitivity of the force measurement setup was estimated according to formula (2) from the experimental standard deviation σ of repeated hammer impacts (Figure 4), which is 0.2 dB at the lower octave bands and increases towards higher octave bands for the medium and soft hammer tips. The variations in sensitivity due to different hammer tips shown in Figure 3 are well covered by this estimated uncertainty.

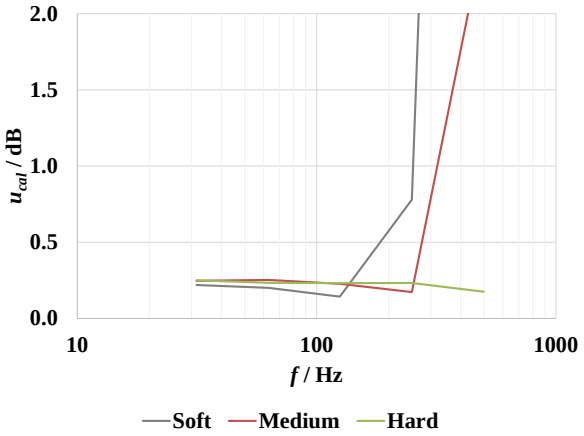

Figure 4. Estimated uncertainty of the sensitivity of the force measuring setup.

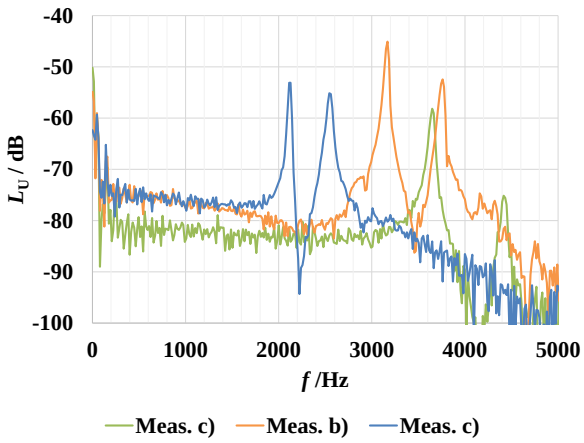

Figure 5. Sensor response for different mass loads.

4. TEST MEASUREMENTS

4.1 Sensor response

The aluminium impact plate and adapter mounted on the force sensor are required to enable impact measurements with the dropping ball. However, these components provide additional mass that acts on the sensor element and changes its dynamic response. This effect was investigated by measuring the pulse response of the force sensor using different mass loads. A narrowband spectrum was measured for the following mechanical configurations:

a) Force sensor without mass load
b) Force sensor with upper adapter plate (69 g)
c) Force sensor with adapter and impact plate (mass 285 g)

The results can be seen in Figure 5. All three narrowband spectra exhibit two resonances, which are shifted towards lower frequencies with increasing mass. However, these resonances should not have any significant influence on the octave band analysis, as these are well below 2 kHz.

4.2 Time signals of ball drops

A series of test drops with three rubber balls was performed (Table 1). Ball 3 is a prototype that is about 30 years old, while the two other balls are newer types that can be purchased today. Also, ball 3 is slightly heavier than the other two balls. Each ball was dropped ten times onto the force measuring setup and the time signals were recorded (Figures 6 to 8).

Table 1. Mass values of the rubber balls under test.

	Ball 1	Ball 2	Ball 3
m / kg	2.448	2.364	2.589

The time signals of balls 1 and 2 have more in common than those of ball 3: their pulse shape is similar, the force reaches a peak value of around 1.6 kN, and the pulse duration is around 20 ms for both balls. Ball 3 generates impacts with a considerably larger peak force, more than 3.5 kN, and the duration here is approximately 10 ms.

Another aspect can be seen in all time signals. The force pulses exhibit a superposed wavy disturbance, especially on the rising slope. To estimate the frequency of this ripple, the time interval between two maxima or minima was determined. The values show that we deal with the resonances of the system previously presented in Figure 5c), which occur in the range from 2 kHz to 3 kHz. The same effect can actually be observed in the pulse curves shown in the standards [1] and [2], or in similar studies with other force sensors [4].

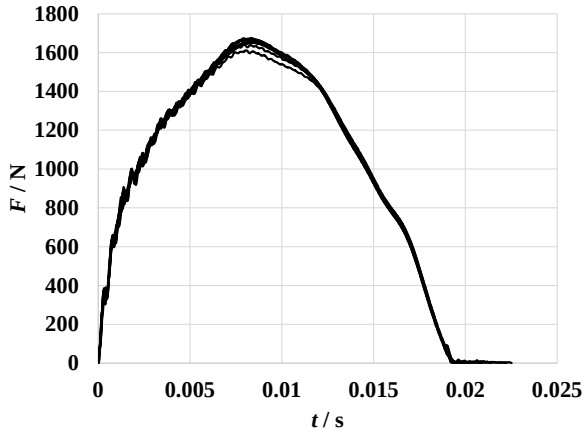

Figure 6. 10 force pulses obtained with ball 1.

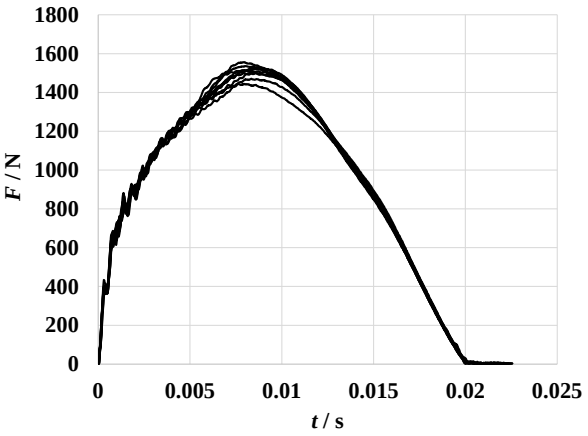

Figure 7. 10 force pulses obtained ball 2.

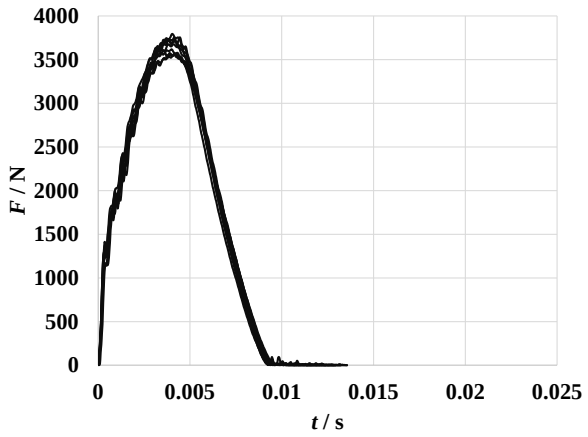

Figure 8. 10 force pulses of obtained with ball 3.

4.3 Integration time for octave band measurement

The ball impacts have a duration of up to 20 ms. However, the main criterium for the validation of a heavy soft impact source is the impact force exposure level measured in octave bands. Depending on the filter centre frequency f, the filters require a settling time depending on $1 / B$ with a bandwidth of $B = f / \sqrt{2}$. It is therefore necessary to investigate which integration time is appropriate.

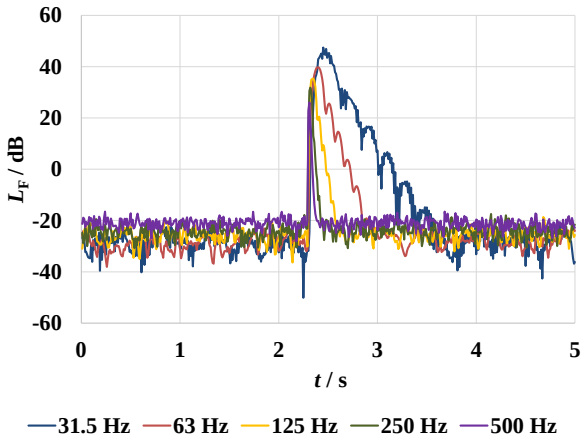

Figure 9. Force levels over the measurement time for different octave bands.

For one ball drop, the time history of the octave bands was measured for a duration of 5 s. Figure 9 shows the time history of the filter output for five octave bands. With increasing frequency, the filters need less time to process the impact. While the lower bands require more time, this will be a disadvantage for the higher bands, as the amount of noise increases. This is illustrated in Figure 10. Here, the impact force exposure level $L_{F,E}$, according to Equation (3), is shown as a function of the integration time T_{av} for each octave band. The data in Figure 9 has been split so that the pre-impact part of the measurement is included in the analysis as background noise (dashed, shorter curves). An integration time of less than 50 ms results in distorted impact force exposure levels for the lowest frequency bands; for all octave bands above 63 Hz, the levels reach a constant value more quickly. Again, the noise curves show that the influence of noise increases with integration time. For example, for the highest octave specified in the standard at 500 Hz, the SNR is approx. 24 dB.

$$L_{\mathrm{F,E}} = L_{\mathrm{F}} + 10\,\mathrm{lg}\left(\frac{T_{\mathrm{av}}}{T_{\mathrm{ref}}}\right)\ \mathrm{dB} \tag{3}$$

To make a decision on the required integration time, the difference between each force exposure level and the level at the longest integration time of 2.7 s was determined for each octave band. Figure 11 shows that for all octaves of the standard (31.5 Hz to 500 Hz) the deviations after 1 s are very small. Such an integration time also has the advantage that the reference value of Equation (3) is 1 s, so the measured impact force level is equal to the desired impact force exposure level.

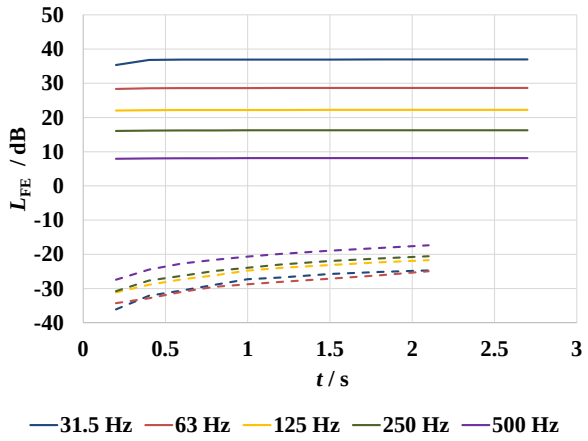

Figure 10. Impact force exposure level and noise level in dependance of integration time.

4.4 Results of octave band measurements

With the knowledge presented in the previous section, the triggered measurement was set to 1 s integration time and the results of 10 ball drops were analyzed in octave bands. Figure 12 shows the difference between the average of the measured octave band levels and the required level of the standards [1] and [2] for each ball. The results for ball 1 and ball 2 are between the limits, with a small deviation at 500 Hz for ball 1. The impact force exposure levels of ball 3 are outside the limits in every octave band.

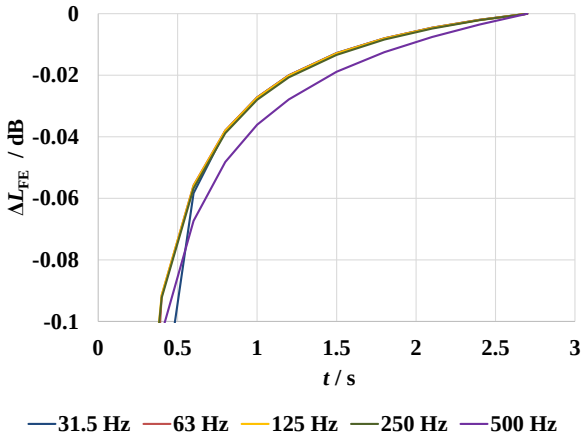

Figure 11. Dependence of the impact force exposure level on integration time for each octave band, plotted as deviation ΔL from the longest integration time of 2.7 s.

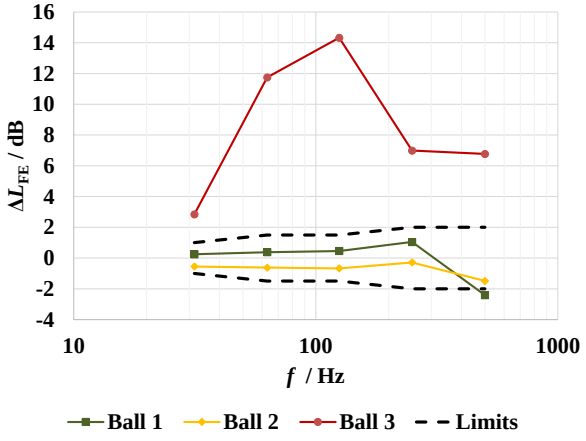

Figure 12. Impact force exposure level of the three balls in comparison with the limits.

The standard deviations of the impact force exposure levels from the 10 ball drops were also calculated. The values are between 0.1 dB and 0.5 dB (Figure 13). For the two balls complying with the standard requirements, they are below 0.3 dB.

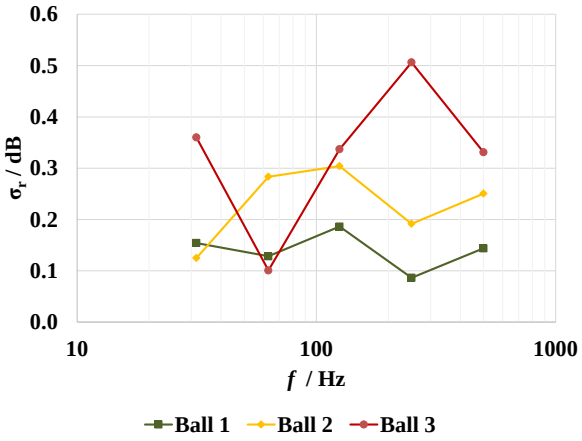

Figure 13. Standard deviation of the impact force level determined from ten repeated ball drops.

5. UNCERTAINTY ESTIMATE

To estimate the uncertainty of the measured force exposure level, the mean value from the 10 ball drops is used as the measurand. A first uncertainty estimate for this measurand is determined by using the uncertainty estimate of the calibration u_{cal}, the standard deviation of repeatability σ_{r} and the influence of the noise due to the averaging. The latter is estimated from Figure 11 to be $u_{\mathrm{N}} = 0.05$ dB.

$$u(L_{\mathrm{F,E}}) = \sqrt{u_{\mathrm{cal}}^2 + \frac{\sigma_{\mathrm{r}}^2}{n} + u_{\mathrm{N}}^2} \tag{4}$$

The resulting uncertainty is about 0.3 dB for the calibration with the hardest hammer tip (Figure 14). For the soft hammer tip, the uncertainty is much larger at 250 Hz and 500 Hz, and the medium hammer tip is between these two cases. In view of the standard's tolerance range for the impact force exposure level of ±1.0 dB to ±2.0 dB, this uncertainty is comparatively large and must be investigated further.

6. SUMMARY

A new setup for measuring the impact force exposure levels of heavy soft impact sources has been installed at PTB. It consists of a strain gauge sensor with a bridge amplifier and an octave band analyzer. This device was calibrated by an impact hammer which had been traceably calibrated at PTB. The uncertainty of the measured force exposure level of heavy impact sources was estimated to be about 0.3 dB. This very first uncertainty estimate indicates that the uncertainty is not negligible when comparing measured force exposure levels to the requirements from the standard. Further investigations are necessary before a test service can be established at PTB.

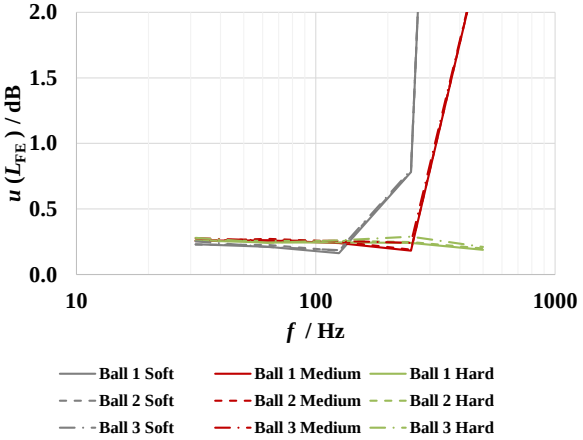

Figure 14. Uncertainty estimates for the measured force exposure level.

IMPACT NOISE FROM ONE STOREY TO THE NEXT STOREY – FROM SLAB ON THE GROUND AND SLAB BETWEEN FLOORS

Bernt Mikal Larsen[1*]
[1] Multiconsult Norway, Fjellgata 6, 4612 KRISTIANSAND S, NORWAY

ABSTRACT

There are few studies or little information in the literature about impact noise from one storey to the next storey above. The issue is important when designing shopping centres or other facilities below apartments, when deciding the flooring to be used above the concrete slab. Measurement from apartment building in Kristiansand in Norway shows $L'_{n,w}$ 26 dB to the floor above (from one storey to the next storey above) when a 150 mm thick slab is used on the ground with gap to walls and columns. When slab on ground is in contact with concrete wall (no gap), $L'_{n,w}$ of 51-54 dB is measured to the floor above from a 90 mm slab on ground. Between floors with a main construction of 250-260 mm concrete, $L'_{n,w}$ of 61-65 dB is measured to the floor above. The measured impact level is higher from slab between floors than from ground, and no contact between wall and slab reduces the impact level significantly.

Keywords: *impact noise between floors, impact noise to floor above, impact noise from slab to above*

1. INTRODUCTION

Few or no studies have been made in field on impact noise from one storey to the next floor above [1]. This paper shows impact noise levels from slab on ground to the floor above, and from slab between floors to the next storey above. The issue is important when designing apartments or offices above shopping centres and other facilities. All measurements and analyses are from finished buildings in field with construction as summarized below.

2. MEASUREMENT METHOD

The impact noise levels were measured with tapping machine Norsonic 211 in finished buildings. The results are given for bare concrete slab, corrected for damping effect of floor coating or floating floor and to receiving room volume of 100 m^3. Above the concrete slab, there were different flooring for all the measurements as summarized in each chapter. The frequency spectrum is also given in figures for all measurements.

3. SLAB ON GROUND, IMPACT NOISE TO FLOOR ABOVE

3.1 Slab with airgap to surrounding walls and columns

One measurement was done in a building with parking basement on the ground and apartments in the floor above. For this situation the measurement was done directly on the bare concrete floor in the parking basement. The concrete floor was with gap to surrounding walls and all columns in the parking basement. The construction of the floor in the basement was:

- 150 mm thick concrete slab on 2 layers of plastic and gravel
- Gap to surrounding walls and columns

The receiving room volume was 100 m^3, and the measured $L'_{n,w}$ 26 dB. In general the impact levels are low, and in the lowest frequencies close to 30 dB. In figure 1 the measurement curve is given. The impact levels in the floor above are supposed to be due to movements in polystyrene and/or ground transferred up through walls and columns.

This construction is transferring the highest levels in the low-frequency range.

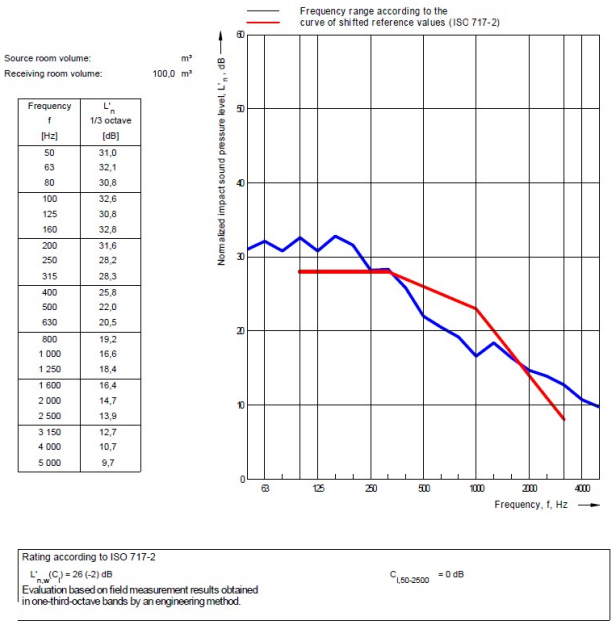

Figure 1. Impact noise from slab on ground to floor above. 150 mm concrete slab on 2 layers of plastic and gravel with gap to surrounding walls and columns.

3.2 Slab in contact with concrete wall

Other measurement for ground slab was done when the slab had contact with a concrete wall. Such a measurement was done in building with apartments on the ground floor and the floor above. The basement construction was as follows:

- Hard oak parquet
- 2 mm Selit pro parquet flooring
- 90 mm concrete slab
- 300 mm polystyrene

The measured L'$_{n,w}$ was 34 dB to receiving room volume of 100 m^3. The damping effect of the floor coating consisting of oak parquet and 2 mm parquet flooring is 17-20 dB [2] according to experiences in Norway. The impact noise level to the floor above is then L'$_{n,w}$ 51-54 dB for bare concrete slab in contact with concrete wall. In figure 2 it can be seen a much steeper curve from highest to lowest frequencies than in figure 1, and almost similar levels as in figure 1 for the highest frequencies. The effect of splitting a concrete slab against walls and columns is 25-28 dB for the L'$_{n,w}$-value. In the lowest frequencies the levels are 10-20 higher with contact between slab and wall than for the situation with no contact between ground slab and surrounding walls and columns.

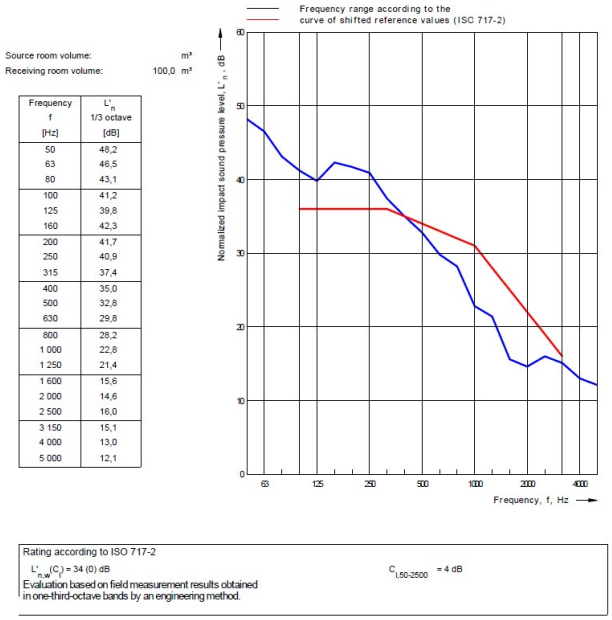

Figure 2. Impact noise from slab on ground to floor above, when the ground slab has contact with concrete wall. Measurement done on oak parquet.

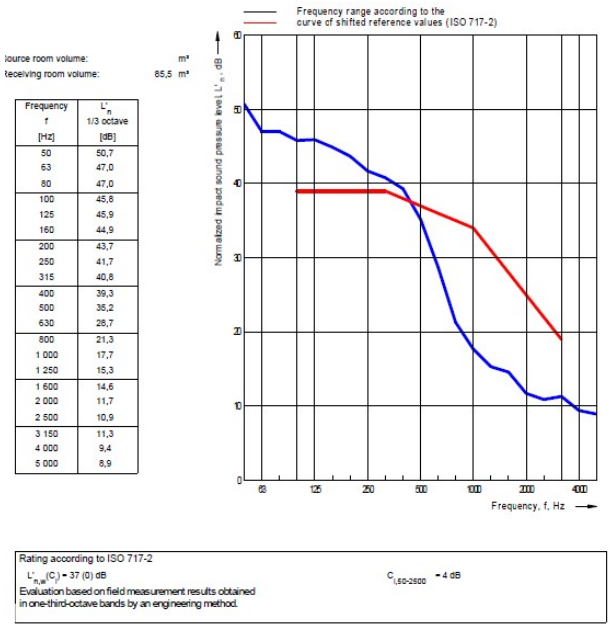
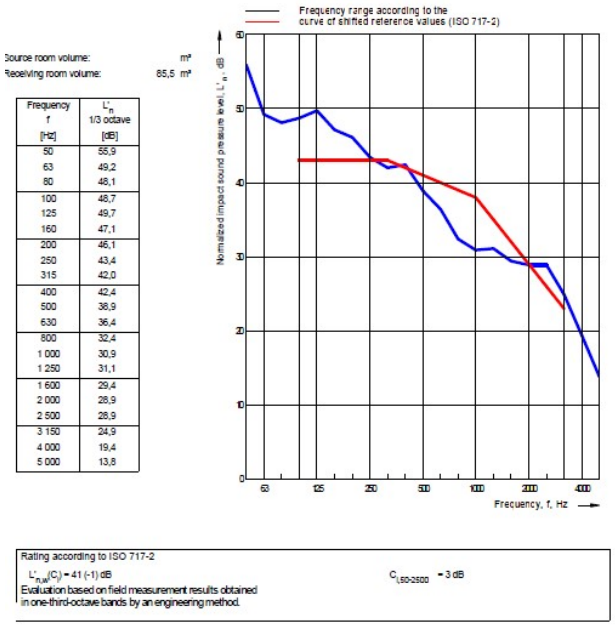


3.3 Slab on ground – lightweight walls

In a building with lightweight walls between apartments, two different measurements of impact noise to living room in the floor above were done. The lightweight walls were in contact with the concrete slab, and mounted directly to the concrete slab. Construction was as follows:

- laminate
- wool cardboard
- 100 concrete slab
- 100 mm polystyrene
- plastic film due to radon gas
- 150 mm polystyrene

The measured L'$_{n,w}$ was 37 dB and given in figure 3. The damping effect of the floor coating consisting of laminate on wool cardboard is 13-15 dB [2] according to experiences in Norway. The impact noise level to the floor above is then



L'$_{n,w}$ 51-53 dB for bare concrete slab in contact to the floor above in building with lightweight walls.

Frequency f [Hz]	L'n 1/3 octave [dB]
50	50,7
63	47,0

2 000	11,7
2 500	10,9
3 150	11,3
4 000	9,4
5 000	8,9

Figure 3. Impact noise from slab on ground to floor above, in building with leightweight walls. Measurement done on laminate floor .

Similar result in the same building is from bathroom to living room, where the flooring was with vinyl coating. The measured L'$_{n,w}$ was 41 dB and given in figure 4. The damping effect of the floor coating consisting of vinyl coating is 7-10 dB [2] according to experiences in Norway. The impact noise level to the floor above is then L'$_{n,w}$ 49-52 dB for bare concrete slab in contact to the floor above in building with lightweight walls.

Frequency f [Hz]	L'n 1/3 octave [dB]
50	55,9
63	49,2
80	48,1
100	46,7

2 500	28,9
3 150	24,9
4 000	19,4
5 000	13,8

Figure 4. Impact noise from slab on ground to floor above, in building with lightweight walls. Measurement done on vinyl coating.

By comparing figure 3 and 4 with figure 1, it may be observed that the levels in the lowest frequencies (100-160 Hz) transferred through walls and columns in contact with a slab, are much higher than what is transmitted through movements in polystyrene or ground (figure 1).

4. SLAB BETWEEN FLOORS – IMPACT NOISE TO FLOOR ABOVE

4.1 Slab with no apartment (free space) below

Measurement was done for a slab between 3rd and 4th floor in apartment building, In this case, there was free space below the apartment in 3rd floor. The situation is shown in figure 5. The situation will affect the stiffness of the construction and the levels in the lowest frequencies. The floor construction was as follows:

- 15 mm parquet
- 35 mm putty compound
- 25 mm polystyrene

- 260 mm concrete slab
- 115-145 mm airgap with mineralwool
- 12 mm gypsum

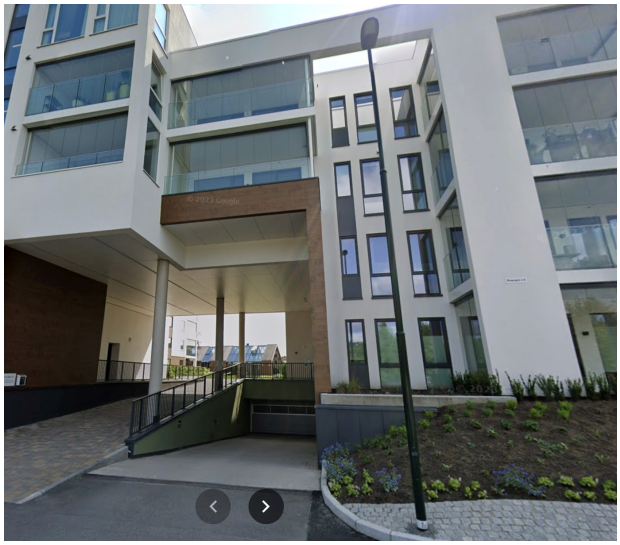

Figure 5. Picture of apartment with free space below where impact measurement was done to floor above.

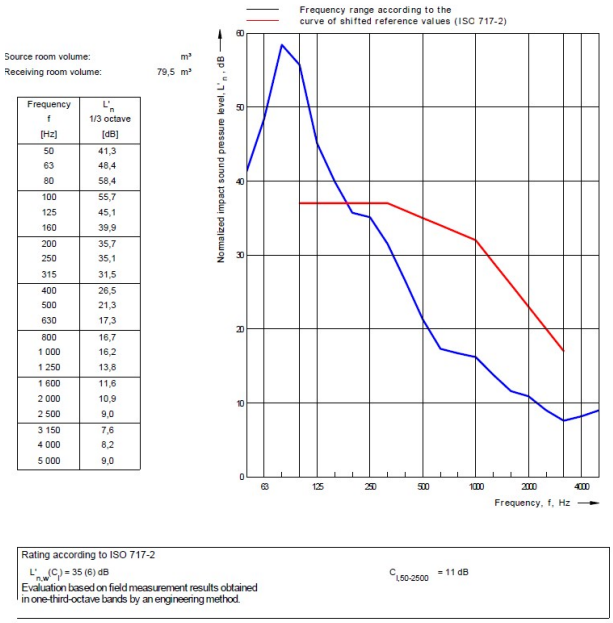

Figure 6. Measurement result to floor above with free space below.

The measurement was done to a room with receiving room volume of 80 m^3. The damping effect of the floor coating consisting of parquet, putty compound and polystyrene is 25-28 dB [2] according to experiences in Norway. The impact noise level to the floor above is then $L'_{n,w}$ 61-64 dB for bare concrete slab of thickness 260 mm and with receiving volume of 100 m^3. This shows that there in general is a need for a coating or floating floor, to satisfy the demands for impact noise values to the floor above in Norway. The impact levels to the floor above are quite high in 80 and 100 Hz compared to surrounding frequencies. Comparison of figure 6 with figure 1 and 2 verifies that there will be much more annoyance due to low frequency noise from a general slab between different floors than from a slab on ground.

4.2 Slab between floors – stiff fastened to concrete walls

Impact noise for a situation with concrete slab between floors of thickness 250 mm was measured. In this case there were concrete walls in the building with the concrete slab stiff fastened to these concrete walls. The construction was as follows:

- parquet
- 35 mm putty compound
- 25 mm polystyrene
- 250 mm concrete slab

The damping effect of the floor coating consisting of parquet, putty compound and polystyrene is 25-28 dB [2]. The impact noise level to the floor above is then $L'_{n,w}$ 62-65 dB for bare concrete slab of 250 mm and corrected to receiving room volume of 100 m^3. The result is shown in figure 7 below. Even with a floating floor (with no contact to walls) on slab between floors, there is still significant level of low-frequency noise transferred to the floor above.

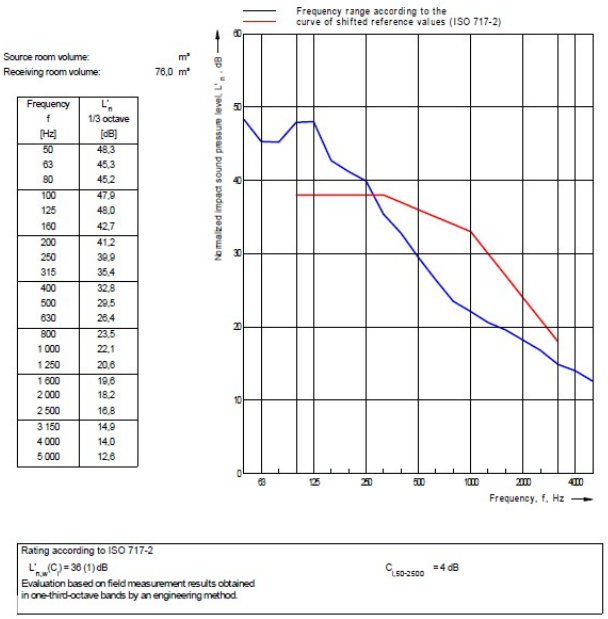

Figure 7. Measurement result to floor above from 250 mm slab between floors, stiff fastened to concrete walls in the building

4.3 Hollow core slab between floors – lightweight walls in building

Impact noise for a situation with hollow core slab between floors of thickness 200 mm was measured, between 1st and 2nd floor. In this case there were lightweight walls in the building between apartments. The construction was as follows:

- parquet
- 40 mm putty compound
- 30 mm impact reducing plate
- 280 mm polystyrene
- 200 mm hollow core slab

The damping effect of the floor coating consisting of parquet, putty compound and polystyrene is 30 dB [2]. The impact noise level to the floor above is then $L'_{n,w}$ 64 dB for bare hollow concrete slab of 200 mm and corrected to receiving room volume of 100 m^3. The result is shown in figure 8 below.

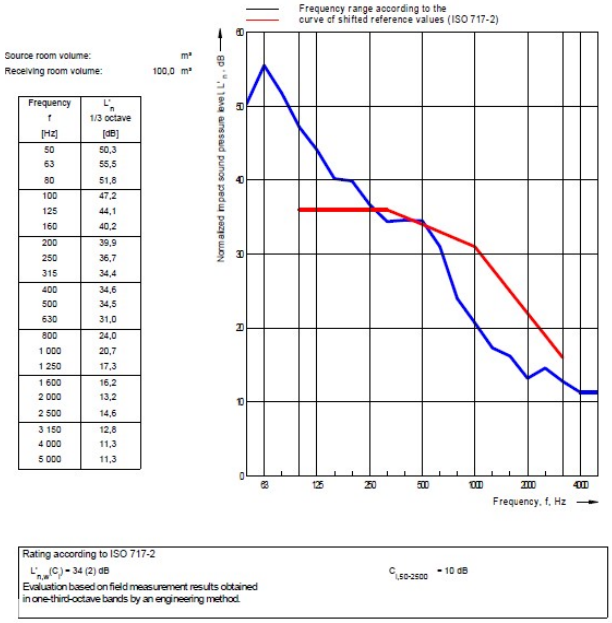

Figure 8. Measurement result to floor above from 200 mm hollow core slab between floors, lightweight walls in the building. The levels below 100 Hz is due to stiffness of the construction.

5. CONCLUSIONS

5.1 Slab on ground to floor above

Measurement shows $L'_{n,w}$ of 26 dB when slab on ground is with airgap to surrounding walls and columns, and with low levels of low frequency noise. When the concrete slab is in contact with concrete wall, columns or lightweight walls, the $L'_{n,w}$ for bare concrete slab to the floor above increases to 51-54 dB. The difference is 25-28 dB with connections to walls and colums, compared with the situation with airgap. To fulfill demands in Norwegian standard from shopping centre or parking basement to apartment ($L'_{n,w} \leq 48$ dB), there is a need for thick enough slab or a flooring reducing impact noise with 6 dB or more, when the slab is in contact with surrounding walls and columns.

5.2 Slab between floors

From slab between floors of concrete and thickness 250-260 mm to the floor above, impact noise from bare slab is

$L'_{n,w}$ 61-65 dB. There will then be a need for impact noise reduction of 13-17 dB to fulfill the requirement of $L'_{n,w} \leq 48$ dB from shopping centre to apartments above.

The measurements show approximately 10 dB higher $L'_{n,w}$ from a slab between floors to the floor above than from a slab on ground to floor above. The reason for this difference is thought to be due to different stiffness. By comparison of the levels from slab on ground with slab between floors, the main difference is related to the levels in the frequency range from 100-160 Hz. It can be seen that a slab between floors stiff fastened to concrete walls gives lower levels to floor above than other situations and is closer to impact noise from slab on ground. By comparison of concrete slab in buildings stiff fastened to concrete walls with concrete slab in buildings with lighweight walls, it can be seen much higher levels in the lowest frequencies for building with lightweight walls.

5.3 Consequences for solutions in buidlings

The measurements summarized from buildings show a need for a good enough solution with both slab on ground and slab between floors, to satisfy $L'_{n,w} \leq 48$ dB from shopping centre or parking basement to apartments in floor above for combined buildings.

6. SUMMARIZING POEM

Impact noise to storey above is studied by few
That's why this paper passed conference review
A splitted concrete slab on the ground
Is really the best for low impact sound
Connection with walls transfers frequency low
That is what this presentation should show
What damping you need on the slab below
Is after all this something you will know

7. ACKNOWLEDGMENTS

May I give my biggest acknowledgements to the companies Mur I Sør and Aamodt Bygg for data from measurements in their projects. In the future it would be interesting with more results and experiences from finished buildings. This could increase the knowledge and improve the necessary solutions in different buildings.

ON THE INFLUENCE OF SAMPLING SIZE IN THE ASSESSMENT OF UNCERTAINTY AND REPEATABILITY OF FIELD MEASUREMENTS OF IMPACT SOUND INSULATION IN VARIOUS FLOOR SCENARIOS

San Millán-Castillo, Roberto[1*] **Trujillo, Jose Alberto**[2] **Romero-Fernández, Amelia**[3]

ABSTRACT

One of the most widely used standards for field measurements of impact sound insulation is ISO 16283-2: 2020. The assessment of the standard deviation of repeatability must comply with ISO 12999-1, as repeatability is a crucial factor in ensuring reliable test performance. However, in some cases, the frequency band results do not comply with the maximum standard deviation limits for repeatability. These deviations raise concerns about the adequacy of the current repeatability limits and the testing procedures outlined in the ISO standard. This study compares the maximum standard deviation of repeatability between impact sound insulation tests conducted with four and six sound source positions, as well as the limits specified in ISO 12999-1, regarding the one-third octave bands of interest in various typical floor scenarios in Spain. Furthermore, these tests study the effect of increasing the number of tapping machine positions on global uncertainty.

Keywords: *impact sound insulation, field testing, uncertainty, repeatability).*

1. INTRODUCTION

ISO 16283-2 is a widely used standard for field measurement of impact sound insulation [1]. This standard aims at assessing impact sound insulation by measuring sound pressure level in a receiving room employing an impact source [1]. Generally, building acoustics standards require uncertainty by ISO 12999-1 [2].

The measurement uncertainty limits can be determined through reproducibility rates [2]. Moreover, ISO 12999-1 recommends repeatability for verifying the quality of laboratory's testing procedures, on their own. In repeatability conditions, results must remain under the maximum values of the typical deviation of repeatability (σ_r) versus frequency in one third-octaves resolution, from 50 Hz to 5 kHz; higher tolerances in the low-frequency range up to 400 Hz, and in higher frequencies, it remains constant. This limit is the same for airborne sound insulation, façade sound insulation, and impact sound insulation. This differs from previous standards such as EN 20140-2 [3], and even *Case C* of ISO 12999-1: 2020, for inter-laboratory repeatability assessment. An extensive survey in [4, 5] reports significant deviations in impact sound insulation testing for different tapping machine positions, correlated with some types of floor, structure and finish. However, no systematic differences were found in global ratings. The study in [6] on gypsum concrete floors and concrete floors shows that repeatability tests exceed σr limits in ISO 12999-1 at some bands. The structure of wood floors may lead to increases on impact sound pressure level in low frequencies, reaching out from 4 dB to 7 dB, depending on tapping machine location, according to [5]. A previous work by the authors [7], presented some examples for a range of typical Spanish floors and four source positions, in which σ_r exceeded the recommended repeatability limits.

This is an open-access article distributed under the terms of the Creative Commons Attribution 3.0 Unported License, which permits unrestricted use, distribution, and reproduction in any medium, provided the original author and source are credited.*

This study provides additional data to this issue by performing tests with a reasonable increase on source positions and related insights about uncertainty.
Current literature suggests that impact source location and building technology may influence testing and requires further research to decrease measurement uncertainty. This work aims at 1) assessing σ_r of four typical Spanish floor scenarios in horizontal and vertical set-up, including four and six impact source locations within the same test; 2) comparing σ_r to the limits of ISO 12999-1 and the impact on measurement uncertainty.
The remainder of this paper is organized as follows. Section 2 describes the measurement procedure and scenarios. After that, Section 3 includes the results and discussion of the testing. Section 4 provides conclusions.

2. MATERIALS AND METHODS

2.1 Measurement procedure and equipment description

Impact sound insulation measurements were performed following ISO 16283-2 [1] in 4 different scenarios (see Section 2.2). In each of them, the measurements were repeated 5 times, under conditions of repeatability, that is, with the same measurement procedure, the same measuring system and the same operators, over a short time; but modifying the source and microphone positions for each repeated measurement and selecting them again more or less randomly.
The magnitude measured was the 'standardised impact sound pressure level' (L'_{nT}), defined in Eqn. (1), in the frequency range from 50 Hz to 5000 Hz in the one-third octave bands. The default procedure ($V > 25$ m^3) and fixed microphone positions were used. A tapping machine was used as an impact source.

$$L'_{nT} = L_i - 10 \cdot \lg \frac{T}{T_0} \quad \text{[dB]} \qquad (1)$$

where L_i is the energy-average impact sound pressure level in the receiving room corrected by background noise; T is the reverberation time in the receiving room [8]; T_0 is the reference reverberation time, in s (for dwellings, $T_0 = 0{,}5$ s).
Six and four different positions of the tapping machine were used, randomly distributed on the floor under test. Likewise, four or six different microphone positions were used, measuring impact noise levels in two of these positions for each source position. The averaging time for the level measurements was 15 s. The location of the tapping machine and microphone positions met the specifications of the reference standard regarding the distances between them, the source positions and room boundaries.

For each tapping machine position, the standardised impact sound pressure level is calculated, and an averaged final value is obtained, according to equation Eqn. (2):

$$L'_{nT} = 10 \cdot \lg \frac{1}{m} \sum_{j=1}^{m} 10^{L'_{nT,j}/10} \quad \text{[dB]} \qquad (2)$$

where m is the number of tapping machine positions; $L'_{nT,j}$ is the standardised impact sound pressure level for tapping machine position j.
For each scenario and each test, two L'_{nT} index results were obtained. The first was derived from the combination of all six tapping machine positions with their associated microphone positions, while the second was obtained by combining only four tapping machine positions with their corresponding microphone positions.
The airborne sound contribution from the tapping machine was also evaluated to determine whether it should be considered negligible or if it might influence the results in some way.
The suitable Class 1 equipment, according to reference standards, for measurements and the tools used for data post-processing are defined in [7].

2.2 Scenarios description

The four measurement scenarios correspond to existing dwellings with a typical separating floor configuration in Spain. This configuration consists of a concrete beam and block floor, likely with some layers of mortar and sand (total thickness ≈ 300 mm). The only difference between them lies in the floor finish: non-floating wood flooring (ID1) and non-floating ceramic tile flooring (ID2, ID3, ID4).
Regarding the relative positioning of the test rooms, ID1 and ID2 are horizontally adjacent, while ID3 and ID4 are vertically adjacent.

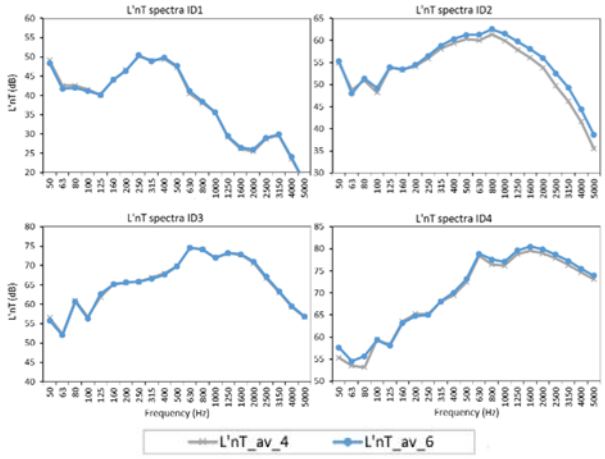
3. RESULTS AND DISCUSSION

The following sections present the measurement results for the four scenarios. For each measurement set, compliance with the repeatability requirements of ISO 12999-1 was evaluated.
First, the L'_{nT} spectra for the four measurement scenarios are presented, considering both six and four tapping machine positions during testing (Fig. 1).
Next, the received noise levels in the receiving room are analyzed for each source position in the emitting room and its two corresponding measurement points in the receiving room (Fig. 2).
Finally, the standard deviation of repeatability (σ_r) and the expanded uncertainty (U) are analyzed for the different

scenarios, assessing the differences caused by using six or four tapping machine positions (Fig. 3 and 4).
The airborne sound contribution from the tapping machine and its influence was found to be negligible in most cases. This contribution is usually much more controlled when the rooms are vertically adjacent. In this case, some transmission was found from 630 Hz onwards in scenario ID1, where the rooms are horizontally adjacent.

3.1 Spectra of the 5 repeated measurements of L'$_{nT}$

Fig. 1 shows the L'_{nT} spectra corresponding to the average of the five repetitions in each set-up, comparing results obtained using four and six tapping machine positions.



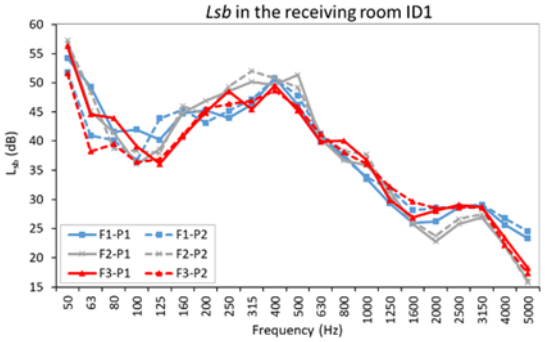


Figure 1. Spectra of the 5 repeated measurements of L'_{nT}.

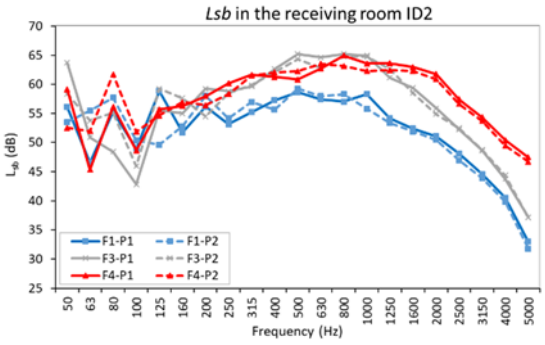
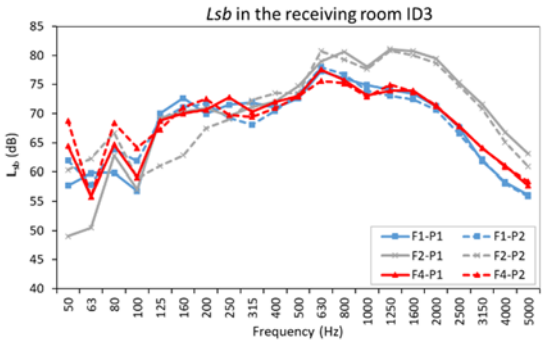
The L'_{nT} spectra for each scenario remain practically overlapping when using four and six tapping machine positions. This suggests that increasing the sampling size by adding more tapping machine positions has minimal influence on the final result. However, compared to performing the test five times under repeatability conditions, some variations may still be observed, as discussed in section 3.3.

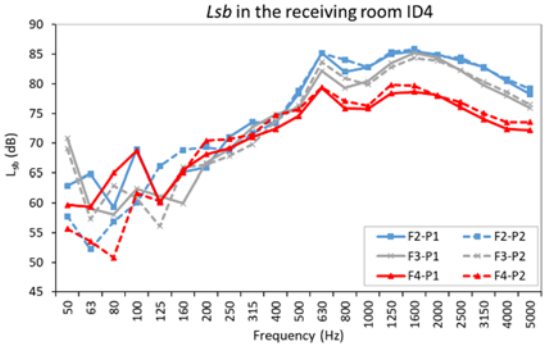


3.2 Analysis of signal and background noise levels (L_{sb}) in the receiving room

The following graphs represent the spectra of the combined signal and background noise level (L_{sb}) measured in the receiving room for the four test scenarios The data correspond to one of the repetitions and represent the combinations of source positions (F_i) and their corresponding microphone positions (P1 and P2).



Although four and six tapping machine positions were used for the tests, the graphs only show measurement combinations for three source positions to simplify the representation.



(a)

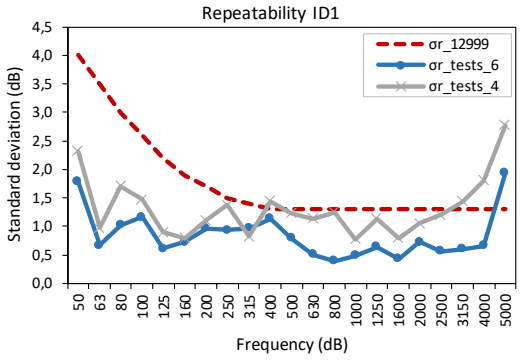
(b)

(c)

(d)

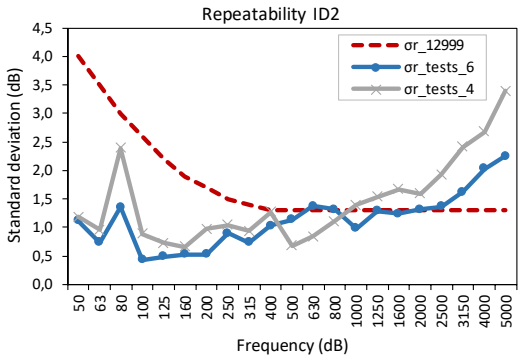
Figure 2. Combined signal and background noise level (L_{sb}) in the receiving room. Combinations of source position and measurement points for one of the repetitions. (a) ID1, (b) ID2, (c) ID3, (d) ID4.

The data in Fig. 2 can be roughly grouped into pairs, mostly from mid frequencies onwards. Each pair of microphone positions with a similar response in the receiving room corresponds to the same source position. This suggests that the tapping machine positions influence the results of this test and introduce variability in repeatability. The same findings were reported in [7].



In scenario ID1 (Fig. 2a), the microphone positions can also be roughly paired, but the grouping is less clear compared to the other scenarios. In this case, the floor was more homogeneous, which theoretically allows for a more uniform response of the transmitted impact noise. The separating floor is finished with a non-floating wooden flooring, which might contribute to providing a homogeneous surface for hammer impacts. As a result, the variability between measurement points is lower than in other cases, though small deviations can still be observed at higher frequencies.

The dependence of impact sound levels on the source position is very clear in scenarios ID2, ID3, and ID4 (Fig. 2b, 2c, and 2d), where the curves for P1 and P2 are almost completely overlapped from 1 kHz onwards. This indicates a strong consistency between the measurement points when the same source position is used. However, these scenarios exhibit greater variability, particularly at lower frequencies. In these cases, the separating floor is finished with a non-floating ceramic tile flooring, which might increase the variability of the transmitted noise levels. The differences observed between measurement points could be influenced by the location of the hammer strikes and possible variations in the attachment quality of the tiles. Similar results have been reported in previous studies for both wood and ceramic flooring [5-7].



These results reinforce the idea that the positioning of the tapping machine can affect measurement repeatability.

3.3 Analysis of repeatability results (Standard deviation)

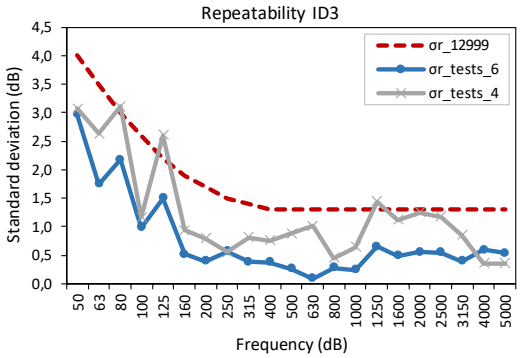


Fig. 3 presents the standard deviation of repeatability (σ_r) for each test scenario, comparing the results obtained using four and six tapping machine positions with the limits given in Table 1 of ISO 12999-1 [2]. When values from measurements are higher than those indicated in the reference standard, they are non-compliant with repeatability requirements.

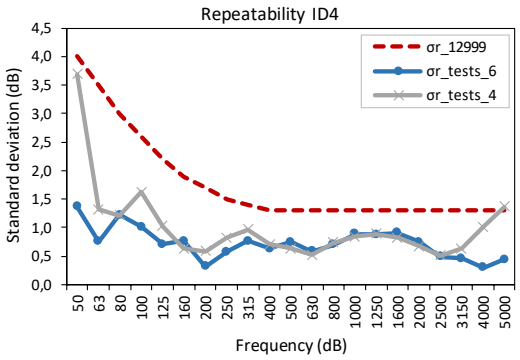


(a)

(b)

(c)

(d)

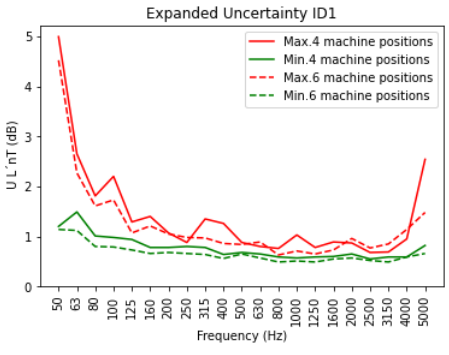
Figure 3. Standard deviation: ISO 12999-1 vs measurements. (a) ID1, (b) ID2, (c) ID3, (d) ID4.

Overall, a significant improvement in repeatability values is observed when increasing from four to six tapping machine positions. Although this improvement is noticeable across all scenarios, each scenario presents particular nuances depending on the frequency range considered.

Scenarios ID1 (Fig. 3a) and ID2 (Fig. 3b) generally comply with the repeatability requirements up to the highest frequencies. However, at high frequencies, improvements in repeatability can still be observed when increasing from four to six positions. The non-compliance shifts from 2.5 kHz to 4 kHz in ID1 and from 800 Hz to 2 kHz in ID2, indicating a beneficial effect of using more tapping machine positions. In ID2, a peak in the value of σ_r exceeding the limit curve repeatability appears at 80 Hz, which, although still within the standard limits, improves significantly when increasing positions.

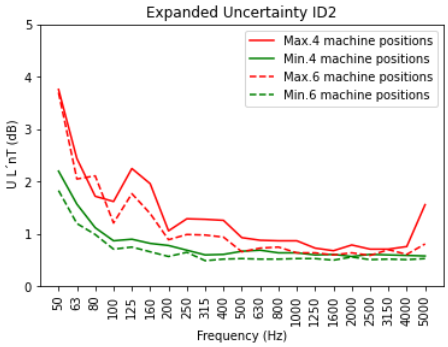
Scenario ID3 (Fig. 3c) exhibits the worst repeatability issues at low frequencies (80 Hz, 125 Hz) when using four positions, exceeding the ISO limit. There is also a minor non-compliance with σ_r at 1.25 kHz. Increasing positions significantly reduces these deviations, bringing them below the ISO threshold. At mid and high frequencies (from 500 Hz onwards), repeatability remains stable when using six source positions, with no exceedances of the ISO 12999-1 limit.

Scenario ID4 (Fig. 3d) shows relatively stable repeatability values across the entire frequency range. At 50 Hz, repeatability is quite high with four source positions, nearly exceeding the limit, but this value improves significantly with six positions. A notable improvement is also observed at 5 kHz.



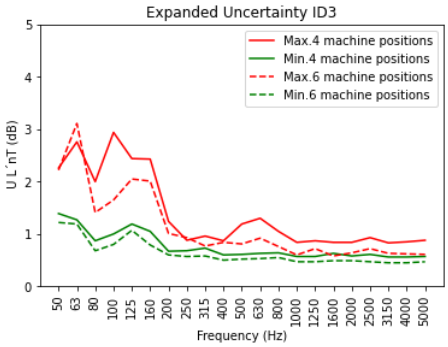
As a summary, it has been observed that compliance with ISO 12999-1 and repeatability values generally improves when increasing from four to six source positions, although issues in ID1 and ID2 remain problematic, exceeding the ISO 12999-1 limit in both cases even with six positions.

The most notable improvement occurs at 50 Hz in scenario ID4, where the repeatability value is significantly reduced when using six positions. Peak repeatability values at 80 Hz and 125 Hz in ID3 and at 80 Hz in ID2 are also significantly reduced.

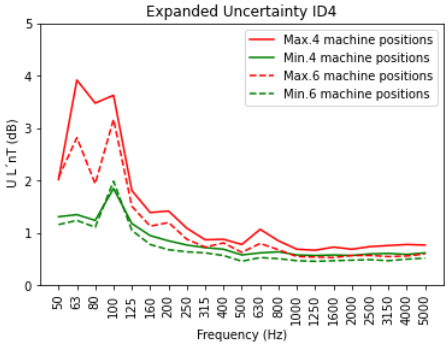


These results confirm that increasing the number of tapping machine positions improves repeatability in most situations. However, remaining high-frequency deviations require further research to determine whether other factors may be influencing the variability.

3.4 Uncertainty



Generally, in building acoustics, expanded uncertainty provides insights of the testing quality and robustness. Fig. 4 presents the expanded uncertainty range vs. frequency for all the scenarios, using four and six source positions, of five test under conditions of repeatability.



(a)

(b)

(c)

(d)

Figure 4. Expanded uncertainty range for four and six source positions: (a) ID1, (b) ID2, (c) ID3, (d) ID4.

The uncertainty analysis highlights the impact of increasing the number of tapping machine positions. The comparison of expanded uncertainty allows us to evaluate the effect of this increase results in a reduction of both minimum and maximum uncertainty values.

This effect is particularly noticeable in low frequencies, where uncertainty tends to be higher, mainly in the vertical scenarios ID3, Fig. 4(c), and ID4, Fig. 4 (d). In higher frequency the deviations are less prominent.

In the horizontal scenarios ID1, Fig. 4(a), and ID2, Fig. 4 (b), the difference is less relevant than in vertical set-ups. Although the uncertainty improvement is evident, it is not generally substantial.

4. CONCLUSIONS

The results confirm that increasing the number of tapping machine positions from four to six does not introduce significant changes in the averaged L'_{nT} spectra. Therefore, reducing the number of source positions could be considered without significantly affecting the final values of the results in L'_{nT}. However, there is a significant affectation in repeatability values.

A clear dependence of the received noise levels on the tapping machine position was observed. This finding reinforces the idea that increasing the number of microphone positions alone would not contribute to better repeatability. Instead, the key factor in measurement variability appears to be the location of the tapping machine. Given this, future research should explore whether reducing the number of microphone positions to one per source position while maintaining six source positions could still ensure reliable results while optimizing test procedures. Additionally, expanding the dataset with more samples would allow for broader conclusions.

Despite the lack of significant spectral differences, increasing the number of source positions led to a notable reduction in standard deviation in all scenarios, improving repeatability. This confirms that a higher sampling density contributes to more stable and consistent measurements. However, some high-frequency deviations remained, particularly in scenarios ID1 and ID2, indicating that further research is needed to understand whether other factors could be influencing the observed variability.

The results confirm that increasing the number of source positions enhances measurement reliability by reducing the uncertainty range. This is particularly beneficial in cases where uncertainty is initially higher, such as in low-frequency regions. However, at high frequencies, while some improvements are observed, they are less pronounced. When comparing the uncertainty results associated with the tests using four source positions to those obtained using six, it can be observed that, at mid and high frequencies, there is no significant difference between the uncertainties in both cases. However, this trend is not reflected in the repeatability

curves, where the use of six source positions instead of four does show a clear improvement in the levels of repeatability achieved.

The increase of tapping machine positions does not significantly change the final L'_{nT} values, but it plays a relevant role in reducing measurement uncertainty and improving repeatability. This suggests that an optimized balance between source positions and uncertainty reduction should be considered.

ABSTRACT

In Andalusia, the second-largest autonomous community in Spain, energy production through biomass combustion is emerging as one of the most promising alternatives to fossil fuels. This biomass can be incorporated into construction materials. Analyzing the acoustic properties of these new, more sustainable materials is essential. It could contribute to the search for quieter spaces, as noise reduction is key to enhancing comfort in buildings. A wide range of thermal insulating materials, such as rock wool boards, cellulose boards, and wood fibers, are commonly used for acoustic insulation in walls, floors, doors, ceilings, ducts, enclosures, and building installations. Currently, conventional insulating materials dominate the market, while innovative natural and recycled insulating materials are either minimally marketed or not yet commercially available. However, materials like rock wool and glass wool, derived from natural processes, are highly energy-intensive to produce. Additionally, porous materials made from synthetic petrochemicals are widely used as acoustic insulation but pose potential risks to human health and the environment. As a result, there is an increasing demand for environmentally friendly insulation materials to meet noise reduction needs. This study focuses on analyzing the potential of innovative construction materials to enhance sound quality and acoustic insulation.

Keywords: *biomass bottom ash, lightweight concrete, self-compacting concrete, acoustic insulation*

1. INTRODUCTION

Nowadays, there is an increasing demand for quieter spaces in workplaces and residential areas. Reducing noise levels helps improve people's quality of life and comfort [1]. The WHO published a guideline on noise exposure in Europe. This guideline reviews studies that provide evidence on noise exposure, particularly night noise exposure, and its consequences for human health. For night noise exposure caused by road traffic, 45 dB is set as the reference level to avoid health effects. However, noise levels in Europe are well above this value. The health consequences of this night noise exposure range from cardiovascular disorders to menta health problems [2]. For these reasons, soundproofing in construction materiales is increasing being considered. A wide variety of thermal insulating materials, such as rock wool boards, cellulose boards, and wood fibers, are also used for acoustic insulation in walls, floors, doors, ceilings, duct, enclosures, and building installations. Today, insulating materials (e.g. rock wool, polystyrene) are commercially available and more commonly used compared to innovative natural and recicled insulating materials (e.g., rice, cotton, palm oil fiber, glass foam, plastics, recycled textile fibers), which are either barely marketed or not yet available [3]. However, rock and glass wool, derived from natural processes, are energy-intensive building insulation materials during manufacturing. Although porous materials derived from synthetic petrochemicals (e.g., rock wool, glass wool, polyurethane, polyester) are used as acoustic insulationmaterials, they can cause adverse effects on human health and the environment. Consequently, there is a growing demand for environmentally friendly insulation materials [4]

for noise reduction. It is important to distinguish between sound absorption and sound insulation. The firth refers to a material's ability to absorb sound anergy, thereby preventing echoes and improving indoor quality. In contrast, sound insulation or soundproofing materials pevent sound waves from entering or leaving a space, acting as a barrier to sound. This study will analyze the potential of new construction materials to improve sound quality and acoustic insulation.

2. MATERIALS AND METHODS

The conventional raw materials used were:
Portland cement from Cementos Portland Valderrivas S.A, Alcalá de Guadaíra, Seville, Spain: type I of medium-high strength 42.5 MPa at 28 days with high initial strength R (CEM I 42.5-R). This type of cement is recommended for the production of normal high-performance concrete, very suitable for the industrial manufacture of prefabricated structural elements requiring maximum strength.
For this study a by-product was used as an alternative material replacing natural sand and expanded clay in each type of manufactured concrete. Biomass bottom ash (BBA) is composed of unburned coarse particles produced in the primary combustion chamber during the biomass energy production process [5,6]. In this study the BBA used comes from the biomass power plant located in Linares of the company Sacyr Industrial. The biomass used as fuel supply for electricity generation is composed of 60% wood from pruning almond and olive trees, and 40% olive cake. A pre-processing of the BBA was carried out in the laboratory to obtain different materials for making concrete:
- BBA-D: Oven-dried at 60ºC to constant mass.
- BBA-C: Oven-dried at 60ºC to constant mass and crushed and sieved to obtain a grain size between 0 and 4 mm.

A study was carried out in two separate series. The first series, called SCC, produced self-compacting concrete with partial substitution of sand and limestone filler; the second series, called LC, produced lightweight concrete with partial substitution of sand and expanded clay.
It is essential to evaluate the properties of density, absorption and porosity in order to select the type of concrete for a specific use, as these characteristics affect the long-term performance and durability of the structures. Table 1 shows the results obtained for all the mixes studied.

Table 1. Density, absortion and open porosity of hardened concrete.

	Density (kg/dm3)	Absorption(%)	Open porosity (%)
SCC-CR	2.37	3.16%	7.48%
SCC-15NS	2.33	4.77%	9.68%
SCC-30NS	2.30	5.25%	11.23%
SCC-15NS/30LF	2.32	4.98%	10.66%
SCC-30NS/60LF	2.29	5.80%	12.15%
LC-CR	1.88	6.96%	14.26%
LC/BBA-25NS	1.65	7.45%	15.12%
LC/BBA-50NS	1.52	9.21%	16.15%
LC/BBA-25EC/25NS	1.89	7.16%	8.92%
LC/BBA-50EC/50NS	1.73	9.84%	8.05%

All tests were carried out in a reverberation chamber, following the guidelines of the UNE-EN ISO 10140-2:2022 standard, which establishes a laboratory method for measuring airborne sound insulation in construction materials.
The measurement equipment used complies with the specifications set forth in ISO 10140-5:2022. This includes class 1 sound level meters, as per the IEC 61672-1 standard, and an acoustic calibrator meeting class 1 requirements in accordance with the IEC 60942:2017 standard.
The sound generated in the emitting room must remain stable. In line with standard recommendations, white noise was used during testing, produced by a standardized white noise generator.
According to ISO 10140-4:2022, when performing measurements with fixed-position microphones and a single sound source, at least five microphone positions must be used in each room (both emitting and receiving) for every speaker placement. Additionally, the sound source must be positioned in at least two different locations within the emitting room.
Sound quality refers to how a listener perceives and evaluates a sound. Unlike objective properties such as loudness or frequency, sound quality is inherently subjective and shaped by human perception.
Loudness, a fundamental component of sound perception, describes the perceived intensity or strength of a sound.
To assess sound quality, a Mikado Gfai acoustic camera was used, equipped with 96 MEMS microphones operating within a frequency range of 10 Hz to 24 kHz.

3. RESULTS

Analysing the attenuation efficiency of the concrete plates by frequency, Table 2 shows the acoustic attenuation produced by each concrete plate during the tests.

Table 2. Acoustic attenuation for each concrete plate.

	L_{Aeq} 125Hz	L_{Aeq} 250Hz	L_{Aeq} 500Hz	L_{Aeq} 1000Hz	L_{Aeq} 2000Hz	L_{Aeq} 4000Hz	L_{Aeq} 8000Hz
SCC-CR	36.5	40.0	42.9	40.2	39.3	43.9	44.1
SCC-30NS	38.0	40.8	46.1	47.5	47.5	49.6	51.7
SCC-30NS/60LF	37.8	40.7	45.6	46.1	47.0	46.3	49.2
LC-CR	38.1	40.4	47.7	47.0	49.5	53.4	58.2
LC/BBA-25EC/25NS	38.3	40.6	47.5	47.4	50.3	53.4	57.7
LC/BBA-50EC/50NS	38.2	40.5	47.1	48.5	51.7	54.0	58.0

As can be seen, the main insulation efficiency occurs at high frequencies, 4000Hz and 8000Hz, with LC/BBA-50EC/50NS being more effective and SCC-CR less effective.

Obtaining the average values for each mix concrete, the attenuation values achieved are collected in Table 2.

In Figure 1, it can be seen that the highest loudness corresponds to the concrete (SCC-CR). It is observed that the LC compounds have lower loudness than the SCCs. This may be due to the fact that the LCs have greater absorption and open porosity compared to the SCCs. Open porosity is the ratio of the total volume of open pores to the total volume of the material. High open porosity values correspond to high efficiency in dissipating acoustic energy due to the viscous and thermal effects occurring in the interconnected pores. Additionally, the presence of different scales of porosity enhances sound absorption [7].

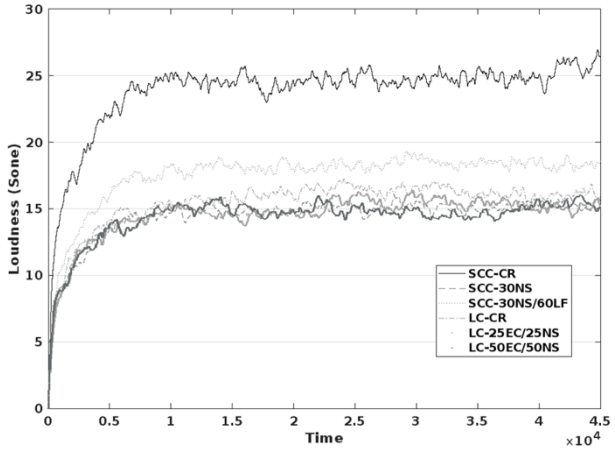

Figure 1. Loudness results.

4. CONCLUSIONS

The conclusions drawn from this study are shown below:

- The level of acoustic insulation of the tested concrete has been determined through comparative analysis. The concrete with the highest acoustic insulation capacity was the one corresponding to LC/BBA-50EC/50NS, and the one with the least acoustic insulation capacity was LCC-CR, which shows that lightweight concrete with a high BBA application rate leads to improved acoustic insulation. The greatest insulation effect occurs at high frequencies (4000Hz and 8000Hz).
- The sound quality of the noise transmitted by the concrete specimens was also studied. The highest level of loudness corresponds to SCC-CR concrete.

ABSTRACT

The main objective of the CarAc'Terre project is to remove regulatory and normative obstacles to raw earth construction techniques relative to acoustics. A multi-scale methodology for characterizing the acoustic performance of raw earth construction systems is proposed using both a performance-based and a perceptual approach. A state-of-the-art review on earth-based walls and floors has been conducted as a means of proposing a large experimental design in response to the identified gaps. Measurements are planned at the material, wall as well as building scale, such that contributions from materials formulation, walls composition, system type, and the construction implementation can be investigated.
This paper describes the general outline of the CarAc'Terre project and discusses the preliminary sound insulation results obtained on different types of walls. Measurements to determine material characteristics are described; these material characteristics are subsequently used as input data to numerical models. Comparison between predicted and measured acoustic performance, in terms of sound insulation, is also examined.

Keywords: *acoustic performance, raw earth, building acoustics, measurement, prediction.*

1. INTRODUCTION

1.1 The CarAc'Terre project

The main objectives of the CarAc'Terre project are to characterize the acoustic performance of raw earth constructions from a physical and sensory perspective, distinguishing the contributions from material formulation, wall composition, and their implementation.
The project, running for 3 years (2024-2027), is carried out with the support of the French Earth National Project [1] which aims to enable a new, large-scale deployment of raw earth constructions by removing cultural, socio-economic, technical, insurance, and regulatory barriers, particularly by involving craftsmen in the earth industry.

1.2 Raw earth in buildings

Environmental regulations strongly influence material choices by imposing strict standards on energy performance and carbon emissions. Raw earth, as a low-carbon material, is a response to these requirements, promoting sustainable construction that respects natural resources. Such a strategic material, naturally abundant and renewable, also offers interesting thermal properties to improve summer comfort, thus impacting the energy efficiency and comfort of buildings.
However, the critical lack of acoustic data on raw earth is a major obstacle to its widespread specification and use. Without this information, architects, acousticians, designers, and construction professionals in general are still hesitant to adopt this material, despite its numerous environmental benefits.

1.3 Acoustic issues and challenges of raw earth

Mastering the acoustic properties of raw earth-based materials and construction systems in buildings necessarily requires a better understanding of the physical phenomena governing acoustic properties at the material, wall, and in situ scales.
This work has been initiated for certain materials for which results are already available. This is the case, for example, of lightweight earth mixtures [2]. These initial studies have raised numerous questions, such as the effect of the earth and plant fillers used, the elastic characteristics of various materials, and the assumptions of isotropy or multi-scale porosity. Beyond understanding performance levels, it is important to be able to model acoustic behavior and extrapolate them to various formulations or implementation configurations. An initial benchmark of available acoustic modeling tools was carried out on various raw earth systems (earth brick walls, lightweight earth walls, partitions with earth plates) [3].

2. PROJECT METHODOLOGY

The main objective of the project is to remove regulatory and normative barriers for all raw earth construction techniques regarding acoustics. The proposed approach is based on the following tasks:

- State of the art and fabrication
- Laboratory measurements
- In situ measurements and surveys
- Modeling at element and building scales
- Knowledge dissemination

The first task aimed to gather all existing data on the subject through a state-of-the-art review in order to define the most appropriate experimental investigation (earth and construction systems choice).
The experimental approach is implemented in two ways: the laboratory level at the material and wall scales under controlled conditions, and the in situ level, with the aim of completing the characterizations while collecting user feedback on their perceptions of the acoustic comfort associated with the raw earth material.
The modeling task will allow the measurement results to be extended to various configurations (formulations, thicknesses, frame types, junctions, etc.) or construction systems.
Finally, the dissemination task intends to communicate the main results in an understandable manner to the raw earth stakeholders in the construction sector. Databases, charts, test reports and standard construction solutions will be widely shared and usable to promote raw earth for different types of buildings, including collective housing.

3. MATERIAL SCALE

3.1 Material types

Raw earth is implemented using numerous and very different techniques. Furthermore, the raw earth material itself can be very diverse, partly due to the nature of the earth in question and partly due to the elements associated with it (plant fillers, wooden frames, etc.).
The following materials are mainly distinguished [4]:

- Lightweight earth: obtained by combining a large proportion of fibers (hemp, straw, flax, etc.) to earth, with a density around 150 to 1000 kg/m^3, implemented through shuttering or projecting, or precast bricks;
- Cob: mixture of clay earth and fibers (usually straw) around secondary frames, with a density from 600 to 1800 kg/m^3;
- Bauge: earth-fiber mixture with density from 1400 to 1800 kg/m^3, applied in a plastic state by lifting directly onto a wall, with or without formwork;
- Rammed earth: earth and gravel (no fibers) mounted by compaction with formwork, with density from 1700 to 2200 kg/m^3;
- Adobes: earth bricks eventually including fibers shaped manually using molds, with density from 1200 to 1800 kg/m^3;
- Earth bricks: generally obtained without fibers through compression or extrusion, with density from 1400 to 2200 kg/m^3;
- Raw earth boards: fiber-reinforced earth boards (similar use as plaster boards) with density ranges from 700 to 2000 kg/m^3;
- Coatings: earth renderings (with or without fibers) are used in addition to all the previously listed materials as a finishing layer to homogenize the appearance of a wall and to protect it, with density from 1500 to 1800 kg/m^3;
- Loose earth for floor: adding weight to wood-based floor systems.

It is desired to be able to use all kind of earths regardless of their origin (quarries, spoil, reuse-deconstruction, etc.). Therefore, the tested samples will be representative of a very wide variability of origins, allowing to generalize the obtained acoustic performance results as much as possible.

3.2 Approach implemented

The material-scale approach is based on measuring the acoustic performance (absorption coefficient, transmission loss) in a Kundt tube on the different selected materials, and simultaneously characterizing the porous (porosity, airflow resistance, tortuosity, etc.) and elastic (Young's modulus, structural damping) parameters.
Once these properties and characteristics have been determined, an initial modeling step is carried out at this scale to identify the most appropriate material model for each case. In this context, acoustic models account for three modes of dissipation: viscous and thermal dissipations linked to the porous nature of the material, but also mechanical dissipations linked to the elastic skeleton [5]. The parameters required for these models can be relatively numerous depending on the complexity of the material, but a satisfactory description is generally possible by retaining only the most significant ones. MATELYS's AlphaCell© software based on the transfer matrix method (TMM) will be used primarily to predict the acoustic performance at the material scale.
In addition to these parameters, there are mechanical parameters, whose effect at the wall/component level can be very significant. The longitudinal dynamic modulus of elasticity is determined according to standard EN 14146. This measurement is primarily used to characterize the elastic properties of "solid" materials such as concrete (standard, lightweight, polymer, etc.), terracotta, various renders, etc. The method is based on measuring the fundamental resonant frequency of a "bar" or "cylinder" specimen subjected to longitudinal vibration (compression mode). The damping factor is obtained based on the width of the resonance peak. The flexural elastic modulus of the boards (plaster based or earth based) is also determined using the standard ISO 16940 (sample sizes being in the order of 600 mm long and 60 mm wide).

4. BUILDING ELEMENT SCALE

Building elements are made from the materials previously studied to form the construction systems for walls, floors, and their coatings. The acoustic challenges for these components and raw earth construction systems are numerous. One of them is to understand their acoustic properties in terms of direct transmission, lateral transmission, and absorption under controlled laboratory conditions, and to successfully maintain these performances once they are installed in situ.
Others are to include the complexity of ensuring peripheral sealing of walls due to shrinkage and settlement as the material dries, the management of wall junctions, the behavior of the systems, and the inhomogeneities of the material that can cause localized weaknesses.
The acoustic and mechanical properties of diffuse-field systems presented below are measured according to building acoustic standards in the CSTB laboratories.

4.1 Mechanical properties

The structural reverberation time Ts (in s) is evaluated according to the EN ISO 10848-1 standard on each supporting wall without finish. The total loss factor, including internal losses, coupling losses, and radiation losses, can then be deduced and used in simulations.
The mechanical mobility Y_{ij} (in m/(Ns)) is the ratio of the velocity response at point i to an excitation force applied at point j, according to the ISO 7626-1 standard. An impact hammer (instrumented for evaluating the injected force) is used to excite the wall (transient excitation), and several measurement points on the wall are considered, along with several excitation positions.

4.2 Acoustic properties

The acoustic behavior of a system (wall, floor, etc.) is characterized in a laboratory from a direct sound insulation perspective by measuring the sound reduction index R, evaluated according to standard NF EN ISO 10140-2 and from a lateral transmission perspective by measuring the standardized lateral sound insulation $D_{n,f}$, according to standard NF EN ISO 10848-1. Sound absorption behavior represents the ability of a material or system to absorb the energy of sound waves, thus reducing sound reflection and limiting phenomena such as acoustic reverberation. It is characterized by the sound absorption coefficient α_s, measured according to the NF EN ISO 354 standard.

4.3 Radiation homogeneity

For non-homogeneous structures of certain raw earth construction systems, such as cob or rammed earth, transmission through the walls has been analyzed using supplementary sound intensity measurements. Areas of greater radiation can be observed locally within the studied walls due to certain cracks, clusters of fibers or aggregates (see Figure 1).

4.4 Boundaries treatment

The shrinkage and settling of the earth during drying can create voids around the edges of the walls, ranging from one to several centimeters (see Figure 2), which must be filled to obtain satisfactory acoustic measurement.

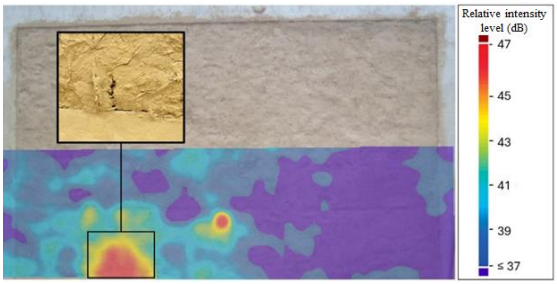

Figure 1. Intensity measurement on the cob wall showing effect of local crack (400 Hz).

Figure 2. Peripheral shrinkage of an earth wall due to drying.

4.5 Modelling

CSTB's AcouSYS software will be used primarily to predict the acoustic performance of multi-layer systems. Calculations are based on the transfer matrix method (TMM) combined with spatial windowing to account for the finite dimensions of the systems. Materials are available: isotropic or orthotropic solid, fluid, porous, perforated, and viscoelastic. Partition assemblies use a frame transmission model with a SEA (Statistical Energy Analysis) approach integrating the distance between studs, the screw pitch, and point contact stiffnesses for frames.
All physical parameters of the materials must be defined.

5. BUILDING SCALE

The difficulty in transposing and maintaining performance at the building scale lies in controlling the direct and flanking transmissions.

5.1 Junctions

Junction characterizations are planned to be conducted on a prototype built from earth bricks and a timber frame specifically, as well as in situ when the configurations encountered allow it. Measurements will be based on the EN ISO 10848 series of standards for the frequency range covering one-third octave frequencies from 50 to 5000 Hz.

5.2 In situ acoustic measurements

Sites containing raw earth construction systems are being identified to conduct in situ acoustic measurements in order to link building elements acoustic performances to the building acoustic performance. The adequacy of the in situ acoustic performance with respect to regulatory criteria and comfort will be verified.

5.3 Perceptive survey

A significant built heritage of raw earth is present in France and around the world [6-7]. Despite a Ph.D thesis on the perception of raw earth including the acoustic aspect [8], the absence of quantitative and qualitative data on projects built with raw earth (heritage or recent projects) is quite notable [9]. Therefore, as part of the CarAc'Terre project, it is intended to collect users perception of acoustic comfort and, more broadly, interior comfort based on a survey methodology to be established. The subjective data collected will be compared with acoustic measurements at the building scale in order to observe the influences and relationships between material-related parameters, implementation parameters and user-related parameters (physical, physiological and psychosocial).

6. PRELIMINARY RESULTS

6.1 Material scale

6.1.1 Acoustic based characterization

For each material, an experimental campaign is first carried out to obtain as many mechanical and acoustic parameters as possible, which are essential for subsequent modelling.
An example of material-scale modelling is proposed for the coating on adobe wall. The material behavior can be considered as purely elastic, porous-rigid, or poro-elastic. In the case of a purely elastic material, considered here as isotropic, only the mechanical contributions come into play. These are described in terms of density ρ, Young's modulus E, Poisson's ratio ν, and damping factor η. The porous-rigid hypothesis, which considers only the porous phase of the material, is based on acoustic dissipation resulting solely from visco-inertial and thermal effects. Finally, poro-elastic behavior combines the three dissipative effects. The porous character modeling proposed here is based on the Boutin-Geindreau granular model [10], requiring only two parameters Φ, the porosity, and R_p, the radius of earth aggregate considered to be spherical, from which all the other acoustic parameters are deduced.
Five cylindrical samples of coating, with an average

thickness of 41 mm and an average diameter of 96 mm, were tested. Considering the elastic parameters given in Table 1, a Poisson's ratio ν = 0.2 [11], and the acoustic parameters obtained, i.e. Φ=40% and R_p=2.1 10^{-5} mm, the absorption coefficient α (-) and the transmission loss TL (dB) of the coating are calculated and compared to the average experimental response measured in a Kundt's tube as shown in Figure 3. Results analysis reveals that the hypothesis of purely porous behavior fails to predict TL, while the one of purely elastic behavior fails to predict α. The poro-elastic behavior hypothesis therefore seems to be the most interesting approaches for TL and α prediction; however, the approach could be refined to improve accuracy.

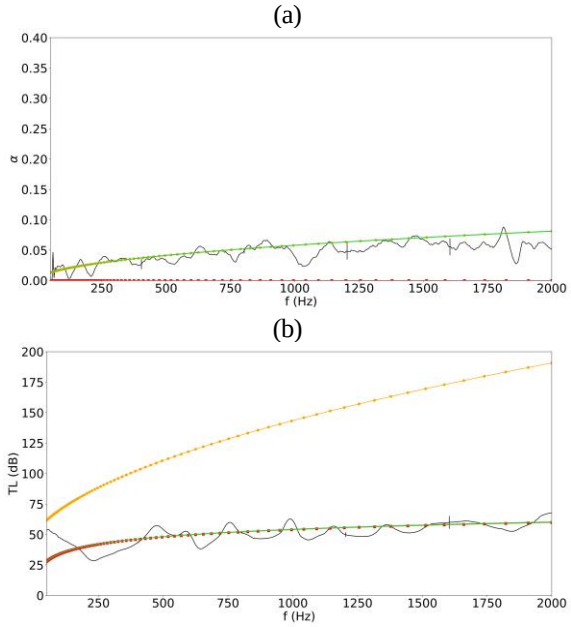

Figure 3. Coating material scale behavior for (a) absorption coefficient α (-) and (b) transmission loss TL (dB); experimental measurement (–), simulation of elastic (■), porous-rigid (●), and poro-elastic (–) approaches.

Concerning the acoustic measurement at the material scale for the adobe samples, difficulties were encountered. On the one hand, it was impossible to machine the adobe bricks with the various tools available (hole saw, diamond core bit) to the desired dimensions. The porosity was however measured on brick fragments and found to be around 36%. On the other hand, the materials proved to be too resistive to characterize directly the resistivity. The order of magnitude for this parameter is 10^7 N.m^{-4}s, and this value allowed to determine the absorption behavior and the correct orders of magnitude for transmission performance during modeling at the material scale. Evaluation of other parameters (tortuosity and characteristic lengths) were also not possible due to this impermeable nature.
Therefore, these different materials will be modelled as elastic materials at the building component scale when transmission loss is concerned.

6.1.2 Structure based characterization

Samples in the form of bars of 210 mm in length and a square cross section of 50 mm x 50 mm, were produced using the same mix as the adobe bricks. They are used to determine the first compressional mode for longitudinal vibration propagation. Similar measurements were carried out for the coating applied to adobe wall as well as the coating on the earth-based boards mounted on the lining. The elastic modulus of the boards (plaster based or earth based) was determined on beam samples. Table 1 presents the determined characteristics.

Table 1. Characteristics determined for the different configurations of the adobe wall.

Material	ρ (kg/m^3)	E (MPa)	η (%)
Adobe	1835	3270	2.3
Coating on adobe	1605	4195	4.2
Plaster board	725	2200	2.0
Earth based board	1480	664	3.9
Coating on earth based board	1738	4360	2.3

6.2 Building component scale

Following the state-of-the-art phase, a first group of laboratory measurements has been conducted on different wall systems. Sound reduction index R was obtained for

- Bauge wall
- Two rammed earth walls: 30 and 40 cm in thickness
- Adobe wall considering the effect of a layer of earth slip, earth coating, and plasterboard or raw earth-based board linings

Absorption coefficient α was obtained for several coatings made of clay and earth-hemp mix. Sound reduction index R and airborne flanking transmission $D_{n,f}$ was obtained for a partition wall made of raw earth boards mounted on a

metallic frame. Figure 4 illustrates some of the laboratory tested systems.

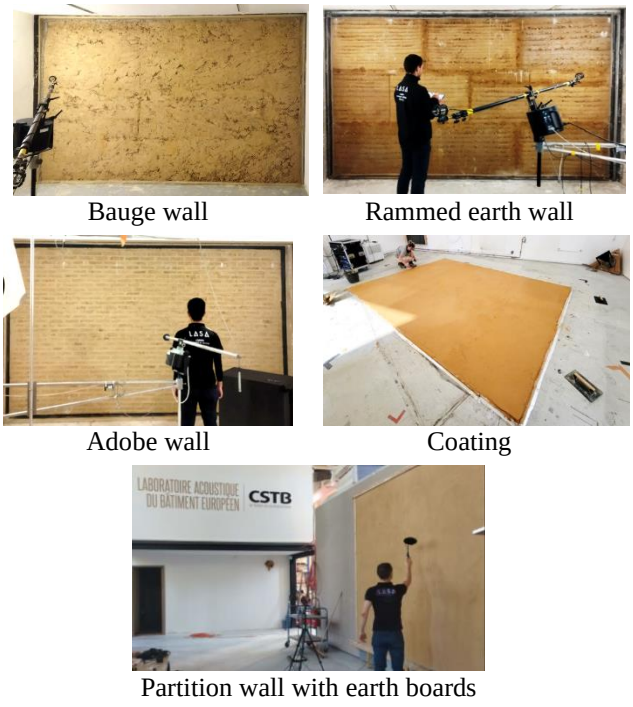

Figure 4. Illustration of the systems tested in laboratory.

These measurement results along preliminary prediction results are presented below in details for the adode wall.

6.2.1 Adobe wall – Laboratory acoustic measurements

The masonry type adobe wall is 110 mm thick, and made of 110 mm x 50 mm x 220 mm bricks composed of clay, with a mass per unit area of 184 kg/m². The adobe wall is 2.5 m in height and 4.2 m in width and the first measurements were performed 56 days after manufacturing. Then, on the emission side, a thin layer (≈2 mm) of earth slip was first put on the wall, and afterwards a complementary layer of earth coating of 22 mm in thickness was applied.
On the receiving side, two types of lining on standard metallic frame independent from the adobe wall, are considered: the first one is a standard plasterboards lining (45 mm of mineral wool and a double layer of 12.5 mm thick plasterboards); the second one uses earth based boards (earth with coco fibers) 22 mm in thickness instead of the plaster boards, and a earth based coating 10 mm in thickness. The first lining corresponds to a surface mass of about 18 kg/m² while the second one to about 49.5 kg/m². Figure 5 presents the sound reduction index measurement results for the different configurations considered.

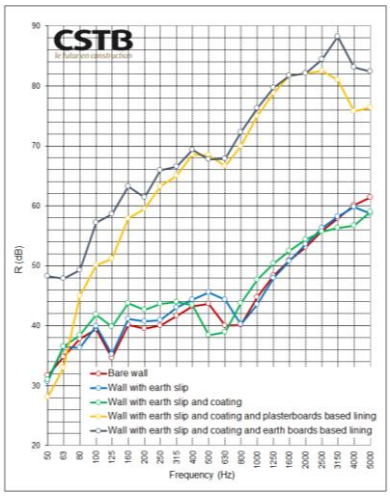

Figure 5. Sound reduction index R for the different configurations of the adobe wall.

It can be observed that the application of the earth slip layer has limited influence of the sound reduction index, meaning that the wall has a low porosity. Adding the earth coating layer increases the mass per unit area of the wall thus modifying the apparent critical frequency and improving the sound reduction index below this critical frequency.
Applying a lining on the other side of the wall greatly improves the acoustic performance. The lining using earth based boards with an earth coating finish being heavier than the standard plaster boards is associated to the better performance especially in the low frequency range. In the high frequency range, a flanking pass (probably related to the concrete frame used to mount the wall system) limits the acoustic performance of the linings.

6.2.2 Adobe wall – Mechanical measurements

Mobility depends on frequency and has peaks corresponding to the resonance frequencies of the structure considered in the low frequency range. In the high frequency limit, the input mobility Y_{ii} is essentially real and determined by the mass per unit area and the bending stiffness. Figure 6 presents the measured input mobility of the bare adobe wall obtained at 5 different positions on the wall, along with the one predicted using AcouSYS software with an elastic modulus of 2.2 GPa and 3.3 GPa. Since the wall is not a thin plate, the predicted input mobility is not independent of frequency.

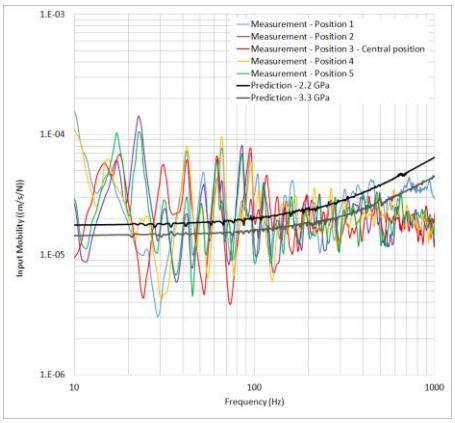

Figure 6. Input mobility for the adobe wall (bare configuration).

6.2.3 Adobe wall – Comparison between measurement and prediction

The comparison between the measured and predicted sound reduction index for the different configurations of the adobe wall is presented in Figures 7 to 10. The corresponding single number quantities are given in Table 2.
It can be observed that the predicted performances are in line with those measured except for the lower frequency range in the case of the bare wall and the wall with coating on one side (Figures 7 and 8). The elastic modulus of the adobe wall is taken to be 2.2 GPa in order to match the critical frequency between measurement and prediction.

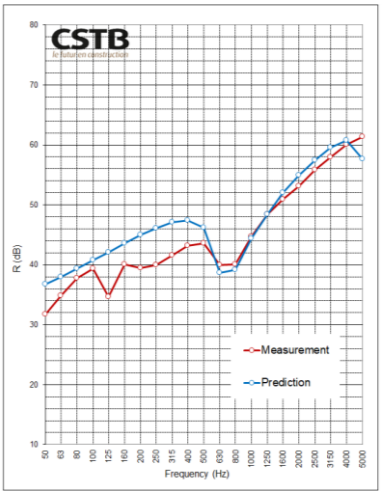

Figure 7. Sound reduction index for the bare adobe wall.

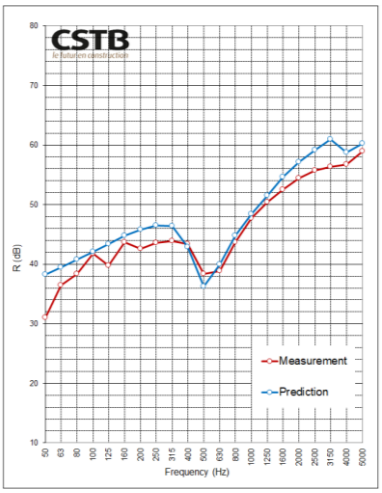

Figure 8. Sound reduction index for the adobe wall with earth coating on one side.

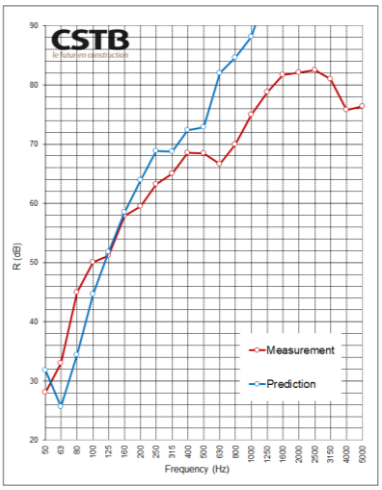

Figure 9. Sound reduction index for the adobe wall with earth coating on one side and with standard plaster board lining on the other side.

The presence of a lining improves greatly the acoustic performance; however, the prediction overestimates the acoustic performance (Figures 9 and 10). This is probably due to a flanking transmission associated to the concrete frame holding the wall and the lining. This is under investigation and will be taken into account in the future prediction. However, the SNQ in the case of the standard lining obtained from the measurement and the prediction is close; this is not the case for the other type of lining tested.

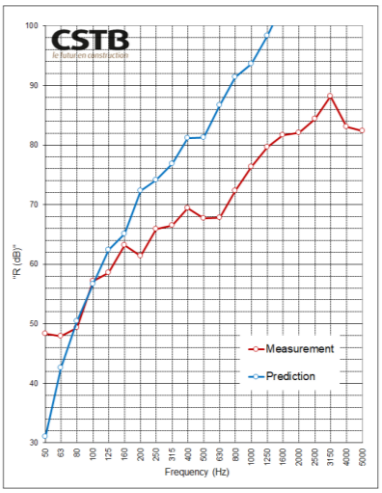

Figure 10. Sound reduction index for the adobe wall with earth coating on one side and with earth based board lining on the other side.

Table 2. SNQ for the different configurations of the adobe wall – Measurement and prediction.

Configuration	R_w+C (dB) Measured / Predicted
Bare wall	45 / 45
Wall with earth slip and coating	46 / 46
Wall with earth slip and coating and plasterboards based lining	70 / 71
Wall with earth slip and coating and earth boards based lining	73 / 81

7. CONCLUSIONS

This paper describes the general outline of the CarAc'Terre project and discusses the preliminary sound insulation results obtained on different types of walls. Measurements to determine material characteristics are described; these material characteristics are subsequently used as input data to numerical models.

Preliminary comparison between predicted and measured acoustic performance, in terms of sound insulation, has been examined for the adobe wall. Similar methodology is applied to the other walls already tested.

More measurements both in laboratory and in situ are planned in 2025, as well as the first occupants survey.

EURONOISE 2025

ACOUSTIC PERFORMANCE OF THE JUNCTION BETWEEN FAÇADES WITH ETICS AND THE JOINERY

Lieven De Geetere[1*]
[1] Buildwise, Kleine Kloosterstraat 23, 1932 Zaventem, Belgium

ABSTRACT

Due to the use of lightweight and often rigid insulation materials in External Thermal Insulation Composite Systems (ETICS), the risk of sound leaks at the junction with the external joinery is real. However, detailed knowledge of the acoustic performance of common connection methods is lacking. Therefore, an acoustic measurement campaign was set up in the acoustic laboratory of Buildwise in Belgium to measure the acoustic insulation performance of the junction $R_{s,Atr}$ $(= R_{s,w} + C_{tr})$ (standardized in ISO 10140-1) for a large number of common connection methods. From this dataset, interesting trends are observed and guidelines for the applicability of the different junction types with respect to the required façade sound insulation are deduced.

Keywords: *ETICS, façades, sound leaks, joinery, junction*

1. INTRODUCTION

External Thermal Insulation Composite Systems (ETICS) are frequently used to improve the energy efficiency and sustainability of buildings, both new and existing. They basically comprise an insulating layer and an external rendering. The insulating layer consists of panels that can be glued or mechanically fixed to the structural façade. These are either made up of fibrous materials (like mineral wool, wood fibers,…) or are foam-based (like EPS, XPS, PU, …). They usually increase the direct façade sound insulation R_{Atr}, but can also lower it, especially when relatively thin and stiff insulation layers are combined with lightweight renderings (see EN ISO 12354-1 [1], Annex D.2.3 for design values of ΔR_{Atr}).

Further, due to their light and stiff character, they are prone to cause sound leaks at the junction with the external joinery. Whether these sound leaks will determine the overall in-situ sound insulation of a composed façade pane, will depend on the (opaque) façade composition, the window composition, the way of mounting the window to the façade, the way of connecting the ETICS to the window and the finishing of the internal reveal. The acoustic performance of the junction can be quantified by the so-called sound reduction index of joints or slits R_s, which is defined in EN ISO 12354-3 [2] and which will be called junction sound reduction index throughout this paper. It represents the sound reduction index that would be measured for a perfectly insulating panel with area of 1 m² in which a joint with a length of 1 m is applied. For façades, the spectral adaptation term C_{tr} (defined in ISO 717-1 [3]) is usually applied to obtain a single number rating representative for urban traffic noise $R_{s,Atr}$ $(= R_{s,w} + C_{tr})$.
Since experimental data on this important junction sound reduction index is hard to find, a laboratory measurement campaign was set up to study a large number of common connection methods used in Belgium.

2. MEASUREMENT SETUP

The measurement method to measure the sound reduction index of joints or slits is standardized in ISO 10140-1 [4], Annex J. Since this method is mainly intended for simple joints filled with fillers or seals, it is not directly applicable to more complicated junctions of ETICS façades with the external joinery. Therefore, a dedicated measurement setup was built, however keeping the same measurement methodology.

In a standard 10 m² laboratory measurement opening, first a façade wall with an ETICS is constructed. This wall is made up of 19 cm thick massive concrete blocks, plastered on the indoor side. On the outdoor side, the insulating layer is made up of 20 cm thick EPS insulation panels that are glued to the base wall. For practical reasons, the exterior rendering is represented by a 9.5 mm gypsum board lining glued to the insulation panels. The sound reduction index of this ETICS wall is called R_{wall}. By comparing the measured spectra of the wall with and without the ETICS, the mass-spring-mass resonance frequency of the ETICS is estimated to be in the 250 Hz third-octave band.
Secondly, a highly insulating dummy window is assembled. It is made up of a 7 cm thick heavy timber peripheral frame, completely filled with mineral wool. On both sides, it is closed by a composite layer of two 2 mm thick steel plates glued together with a 3 mm thick bituminous layer in between (see Fig. 1). The sound reduction index of this dummy window is measured in the laboratory in a standardized small-sized test opening and called R_{dummy}.

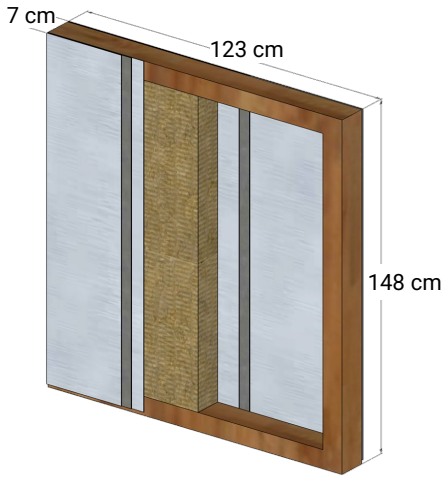

Figure 1. Dummy window.

Finally, an opening is made in the façade wall to host a concrete precast frame to which the dummy window can be mounted using the connection methods to be investigated. Four concrete frames with different opening dimensions make it possible to control the mounting gap width between concrete frame and dummy window very precisely to respectively 0, 2, 4 and 8 cm (see Fig. 2 and Fig. 4, nr. 6). The measured sound reduction index of this composed wall is called R_{tot}.

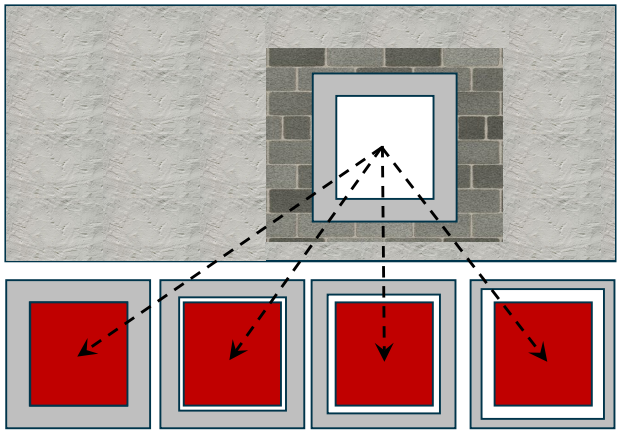

Figure 2. Principle to ensure controlled gap widths of 0, 2, 4 and 8 cm between window and façade wall by using precast concrete frames to mount the dummy window (red).

This total sound reduction index can be calculated by Eqn. (1):

$$R_{tot} = -10log\left\{\frac{1}{S_{tot}}\left[\begin{array}{c} S_{wall}\cdot 10^{\left(\frac{-R_{wall}}{10}\right)}\ldots \\ +S_{dummy}\cdot 10^{\left(\frac{-R_{dummy}}{10}\right)}\ldots \\ +1\cdot l_S 10^{\left(\frac{-R_S}{10}\right)}\end{array}\right]\right\} \quad (1)$$

in which S_{tot} is the area of the laboratory measurement opening, S_{wall} is the area of the façade wall excluding the window opening, S_{dummy} is the area of the dummy window, l_s is the perimeter of the window opening. Here it is supposed that the junction type is the same for all 4 sides of the window panel.
From that equation and the previously measured spectra for R_{wall} and R_{dummy}, the junction sound reduction index can be estimated by Eqn. (2):

$$R_s = -10log\left\{\frac{1}{l_s}\left[\begin{array}{c} S_{tot}\cdot 10^{\left(\frac{-R_{tot}}{10}\right)}\ldots \\ -S_{wall}\cdot 10^{\left(\frac{-R_{wall}}{10}\right)}\ldots \\ -S_{dummy}\cdot 10^{\left(\frac{-R_{dummy}}{10}\right)}\end{array}\right]\right\} \quad (2)$$

In the ideal case where there is no sound leakage across the window junctions, the maximum total sound reduction index can be calculated by omitting the green term in Eqn. (1). It can be seen from Fig. 3 that this ideal sound reduction index is determined by the performance of the façade wall at low

frequencies and by the performance of the dummy window at high frequencies.

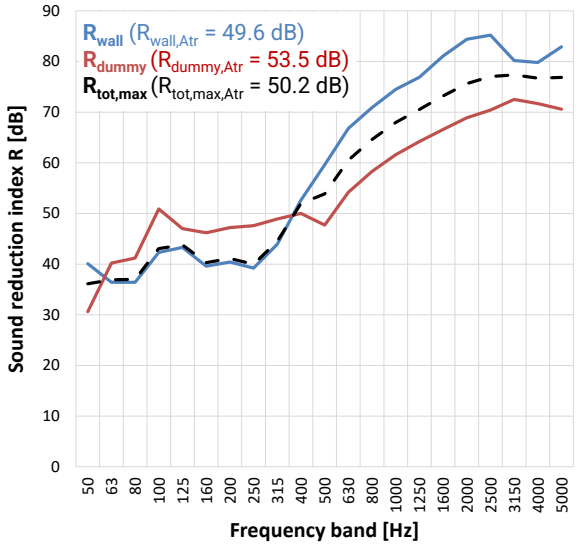

Figure 3. Measured sound reduction index for the façade wall and the dummy window and calculated maximum total sound reduction index.

3. TESTED CONFIGURATIONS

In the Buildwise acoustic lab in Limelette, Belgium, a large number of variants of typical mountings of exterior joinery in an ETICS wall were tested (Fig. 4), both in flush (a) and eccentric (b-f) mounting. Anchoring methods using dowels or angle brackets (a-c), positioning frames (i.e. first attached to the structural wall) (d-e) and installation frames (i.e. first attached to the window) (e-f) were combined with interior finishes made of plasterboard, either fixed directly in the reveal (c) or via mounting blocks where the remaining space between the reveal and the plasterboards is completely filled with standard PU spray foam (a, b, f), or glued on XPS reveal boards (d-e).

4. STUDIED EFFECTS

4.1 General remarks

In the following graphs, a selection of the measured junction sound reduction index spectra R_s are presented. The single number values mentioned in the graphs are $R_{s,Atr}$ values. When some curves are lacking data, it means that the values in these frequency bands could not be calculated by Eqn. (2) because in these bands the measured R_{tot} was higher than the $R_{tot,max}$.

Since the single number value $R_{s,Atr}$ is in most cases largely determined by the value of R_s around the mass-spring-mass resonance frequency of the ETICS, mounting alternatives that give large variations in the 250 Hz band will also reflect large variations in the single number value. Inversely, mounting variations that cause variations only at higher frequencies can show uncorrelated changes in the single number value due to usual statistical variations within the expected measurement uncertainty at 250 Hz.

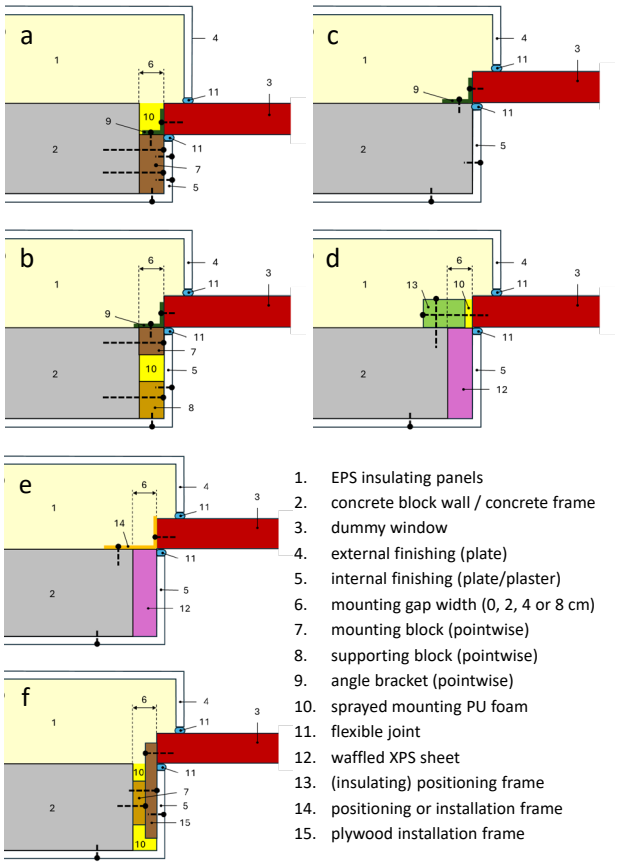

Figure 4. Examples of tested mounting variations.

4.2 Mounting gap width

The mounting gap width (see Fig. 4, nr. 6) is an important parameter, especially when the window is mounted pointwise by dowels or angle brackets, which is illustrated in Fig. 5 and Fig. 6. A mountain gap width of 4 cm or 8 cm

lowers the $R_{s,Atr}$ value by 4 respectively 9 dB compared to the case where no mounting gap was present.

Figure 5. Example of a (partial) mounting using angle brackets on mounting blocks with a mounting gap of 8 cm (exterior side).

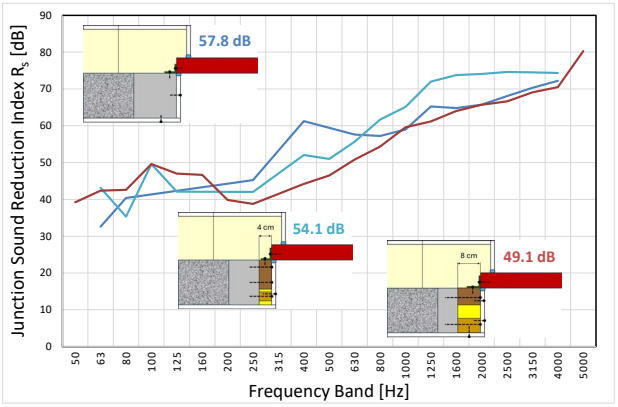

Figure 6. Influence of the mounting gap width.

4.3 Interior finishing

For the cases with spray foamed interior reveals in combination with a pointwise connection of the window panel (Fig. 8), adding an extra gypsum board at the interior side, gives an average gain in $R_{s,Atr}$ of about 1 dB.
However, when in these cases, the sprayed PU foam on the interior reveal is replaced by rigid XPS insulating panels, a large wideband drop of about 9 dB is observed (Fig. 7). This was found to be due to remaining thin air gaps between these insulating panels and the reveal and between the insulating panels themselves.

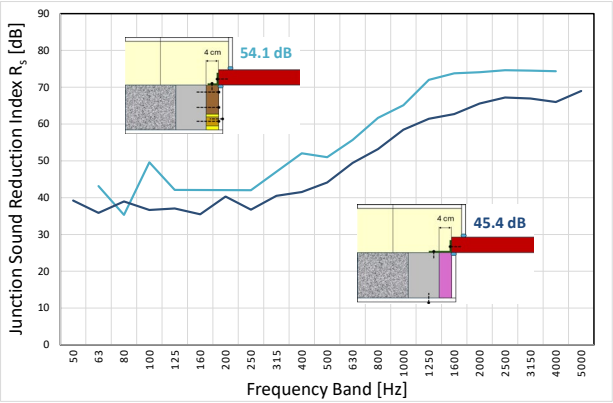

Figure 7. Influence of replacing the PU spray foam at the interior side by rigid XPS insulating panels (case with pointwise mounted windows).

Figure 8. Example of a (partial) mounting using angle brackets on mounting blocks with a mounting gap of 8 cm and spray foamed interior reveals (interior side).

4.4 Flush versus eccentric mounting

When switching from a flush to an eccentric mounting in the case of pointwise mounted windows, the $R_{s,Atr}$ value drops about 2.5 dB and 1 dB in the case of respectively a 4 cm and 8 cm mounting gap. This drop is mainly due to the behaviour in the 250 Hz band and since both curves remain similar in

each case, this difference is more likely to be determined by the measurement uncertainty in this band (Fig. 9).

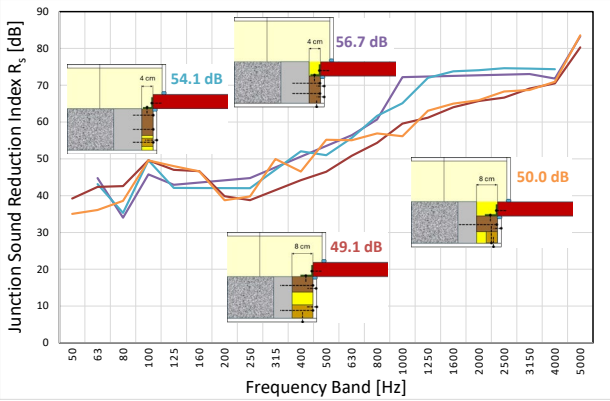

Figure 9. Influence of the mounting depth of the window: flush mounting versus eccentric mounting.

4.5 Installation frame type

Installation frames are commonly used in eccentric mountings to laterally extend the window chassis to enable fixing it to the structural façade while completely covering the mounting gap. They can be made of different materials. However, comparing 60x60 mm² heavy timber battens with L-shaped frames made of a 8 mm thick PES fiberglass composite (Fig. 4e) did not show significant performance differences.

4.6 Plywood installation frame

Another common technique in Belgium to install windows while ensuring airtightness is to apply a plywood installation frame to the window before it is being installed. This installation frame is mounted pointwise on the structural façade wall using mounting blocks. The remaining space between the installation frame and the reveal is then filled with sprayed PU foam (Fig. 4f). No considerable changes in performance are observed compared to pointwise connection methods without installation frame (Fig. 4b), as long as the mounting gap width is comparable.

4.7 Positioning frame density

The insulating positioning frames in Fig. 4d are made of compacted EPS battens with nominal densities of 100, 200 and 400 kg/m³. They have been tested for a mounting gap width of 4 cm and show no remarkable change in performance between these 3 densities.

4.8 Positioning frame filler type

The levelling clearance between the compacted EPS positioning frames and the window panel was filled either by a self-expanding foam tape or by a sprayed PU foam. In all cases, the PU foam performed considerably better (an improvement of about 3 dB in $R_{s,Atr}$) and is additionally more practical to apply (Fig. 10).

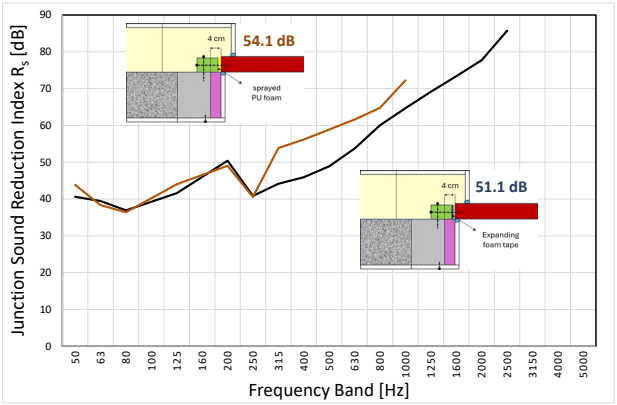

Figure 10. Influence of the filler type for the levelling clearance between positioning frame and window.

4.9 Sealing joints

Sealing joints between the interior and exterior finishings and the window are important to achieve a good air- and rain tightness. They also play an acoustic role at higher frequencies as can be seen in Fig. 11. The influence on the $R_{s,Atr}$ value however remains rather small (1 to 2 dB per joint), since the behavior around the mass-spring-mass resonance frequency of the ETICS remains unaffected.

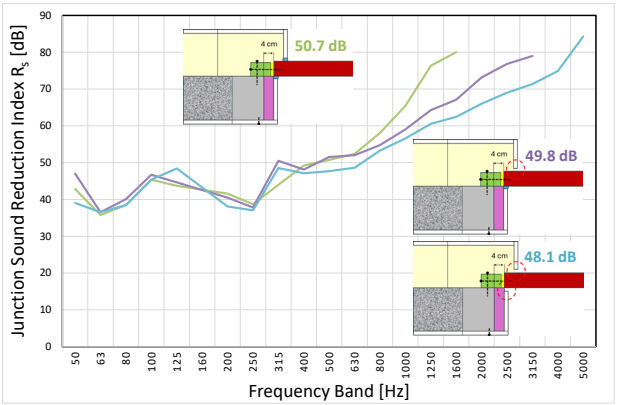

Figure 11. Influence of the sealing joints.

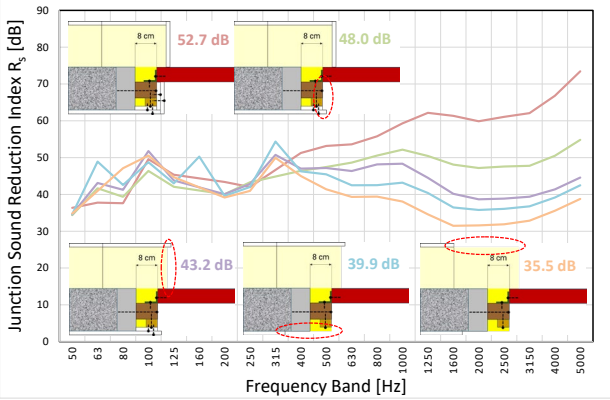
4.10 Exterior and interior finishing

For practical reasons, the external rendering and interior reveal finishing used in-situ were replaced during the laboratory measurements by acoustically equivalent plasterboards. Although not reflecting good practices but interesting from a scientific point of view, the effect of locally removing these lining plates was additionally studied (Fig. 12). Gradually removing these lining boards lowered the junction sound reduction index systematically in the frequency region above the mass-spring-mass resonance frequency of the ETICS. However, no systematic changes were observed around and below this resonance frequency. Since the $R_{s,Atr}$ value becomes more and more dominated by the spectral values at higher frequencies, a gradual decrease of 3 to 5 dB with each step was measured.



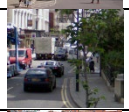


Figure 12. Effect of gradually removing exterior and interior lining boards.

5. APPLICABILITY OF THE TESTED JUNCTIONS IN DIFFERENT OUTDOOR NOISE CLASSES

5.1 Façade insulation requirements

The façade sound insulation requirements in Belgium are specified in the building acoustical standards series NBN S 01-400-x. Four outdoor noise classes are defined, going from a quiet rural environment or quiet residential area (Class 1) to very busy urban traffic (Class 4). For each class, a reference outdoor sound pressure level L_{Aref} is set. For dwellings, most strict requirements are for bedrooms during night. If there are no structural frequent loud passages of vehicles during night along bedrooms, the requirements, expressed in D_{Atr} (= $D_{2m,nT}$ + C_{tr}) for façade panes, are summarized in Table 1.

Table 1. Belgian façade sound insulation requirements.

Outdoor noise class		Day spaces		Night spaces	
		$L_{Aref,day}$	D_{Atr}	$L_{Aref,night}$	D_{Atr}
1		60 dB	≥ 28 dB	55 dB	≥ 28 dB
2		65 dB	≥ 31 dB	60 dB	≥ 32 dB
3		70 dB	≥ 36 dB	65 dB	≥ 37 dB
4		≥ 77 dB	≥ 43 dB	≥ 72 dB	≥ 44 dB

5.2 Use case

To verify what mounting methods can be used in each of the outdoor noise classes, an acoustically rather unfavourable situation of a small bedroom with a large total junction length between the ETICS wall and the joinery is considered (Fig. 13). We assume that the ETICS wall has an $R_{Atr,wall}$ of at least 48 dB. The in-situ façade sound insulation can be calculated according to [2]:

$$D_{Atr,tot} \cong R_{Atr,tot} + 10lg\left(\frac{V}{3S_{tot}}\right), \qquad (3)$$

in which $R_{Atr,tot}$ is the traffic-noise related single number value of the sound reduction index of the composed façade pane, that can be calculated using Eqn. (1) in which R_{dummy} is replaced by R_{window}.

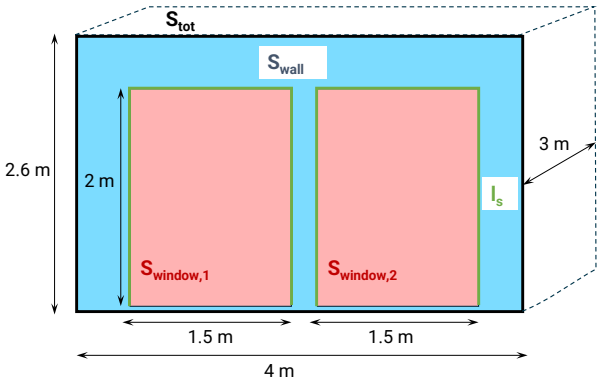

Figure 13. Use case of a small bedroom with S_{tot} = 10.4 m², S_{wall} = 4.4 m², S_{window} = 6 m² and l_s = 11 m.

Since the composed façade sound reduction index $R_{Atr,tot}$ will be largely determined by the sound transmitted through the windows and the junction, the choice of an appropriate window type is quite important. We first need to make a deliberate choice of the glazing, appropriate for the different outdoor noise classes. Then we make the necessary corrections described in EN 14351-1 [5] to estimate the chosen $R_{Atr,window}$ (Table 2).

Table 2. Choice of appropriate windows for the outdoor noise classes 2-4 for the selected use case.

Outdoor noise class	$R_{Atr,\ glazing}$	Area correction [5]	Frame correction [5]	$R_{Atr,\ window}$
2	30 dB	-1 dB	+1 dB	30 dB
3	40 dB	-1 dB	-3 dB	36 dB
4	47 dB	-1 dB	-3 dB	43 dB

5.3 Junction sound reduction index requirements

With these choices for $R_{Atr,wall}$ and $R_{Atr,window}$, the minimum required values for the junction sound reduction index $R_{s,Atr}$ to fulfill the D_{Atr} requirements for the bedroom in Table 1 can be calculated by combining Eqn. (3) and Eqn. (2) in which R_{dummy} is replaced by R_{window}. For classes 2, 3 and 4 this results in minimum $R_{s,Atr}$ values of 42.9, 43.3 and 53.6 dB respectively. Important to note is that in these cases, the fraction of sound energy passing through the windows is quite substantial: 90%, 72% and 72% respectively, while the fraction passing through the junction remains small: 9%, 25% and 11% respectively. This shows that the choice of an appropriate window is of prime importance.

5.4 Eligible junction solutions

From this simple use case, it follows that for the outdoor noise classes 1-3, all studied connecting methods are possible since all measured $R_{s,Atr}$ values were larger than 45 dB. In class 4 however, only the following junction types are eligible:

- connection methods where there is no mounting gap between the chassis and the reveal opening;
- installation methods with positioning frames: the clearance between the positioning frame and chassis must be limited to 1 cm and must be filled with spray foam (swelling strips are not recommended from both a practical and acoustic point of view);
- plywood installation frames in combination with a maximum of 2 cm wide spray foam;
- angle brackets or dowels in combination with a plasterboard interior lining and a max. 4 cm wide spray foam.

6. ACKNOWLEDGMENTS

Buildwise wants to thank all companies that made this research possible by supplying components to build the laboratory setups, in particular Knauf, Buildtechnics and Staduco.

ABSTRACT

In some countries, it is necessary to measure sound insulation with large receiving rooms that are currently outside the scope of ISO 16283-3. Façade sound insulation needs to be measured in schools, universities and offices, which often have room volumes greater than 250 m^3. In this paper, grid measurements of the sound pressure level are made in a receiving room of about 470 m^3 with a non-uniform absorption distribution. This allows an assessment of the spatial variation of sound pressure level when measuring the façade sound insulation, where the façade includes windows with relatively low sound insulation. The results show high sound pressure levels near the windows. This results in standard deviations for the spatial variation in the mid and high-frequency range that are higher than would be expected due to the direct field from these windows.

Keywords: *large volumes, façade sound insulation, spatial variation*

1. INTRODUCTION

The current version of ISO 16283 all parts is intended for room volumes from 10 m^3 to 250 m^3 in the frequency range from 50 Hz to 5000 Hz. This is a change with respect to the previous version of the ISO 140 relative to the on-site measurements. In fact, the series ISO 140 did not include limits for the volumes of the receiving rooms. In the present version, therefore, it is out of the scope of the standard the measurements of room volumes exceeding 250 m^3. In particular, this can be an issue for façade sound insulation that must be measured in some countries, such as schools or open-plan offices. The main issue in small room volumes, such as in dwellings, is the large variation in the sound pressure level at low frequencies [1]. Although low-frequency issues are potentially less problematic in large rooms, an assessment is needed to check whether there are any issues for façade sound insulation when the receiving room volume exceeds 250 m^3. As a first step, this paper assesses the spatial variation of the sound field inside a large room of about 470 m^3 using grid measurements of the sound pressure level.

The spatial variation of the sound field is often assessed with the sound source inside the room [2, 3]. In the present study, which is focused on façade sound insulation, the sound source is outside the room. The diffuse field theory predicts a uniform sound field in the centre of a room. On the basis that the onset of reflected sound cannot occur prior to the arrival of the direct sound, Barron and Lee [4] developed a revised theory for large-volume concert halls that predicts the average behaviour of sound levels more accurately.

This paper compares the measured standard deviation from the grid of microphone positions with different theories. For a diffuse sound field where the direct field is negligible, Schroeder's theory [5] is used along with the Lubman-Craik approach [6, 7, 8] for low-frequencies where there is a modal sound field. The Gaussian Orthogonal Ensemble GOE approach from Langley and Cotoni [9] is combined with Lubman's theory [6] for the direct field in a source room, as described by Davy [10].

2. MEASUREMENT SET-UP

The measurements were performed in a historical university lecture room of about 470 m^3 volume. The room has 15 rows (see Fig. 1) of continuous school desks and folding chairs with a Class D absorptive ceiling. The floor surface of the room is approx. 141 m^2, and the dimensions are approximately 17 m in length, 8.3 m in depth and 3.5 m high. The two facades of the room are made of 0.7 m plastered double walls with 0.4 m full bricks, an internal air gap, and 0,14 m hollow bricks. Include two wood frame single pane windows 2 m long and 2.7 m high that were not sealed and, therefore, not airtight.

Sound pressure level measurements were made in a three-dimensional grid when the outside sound source pointed towards the windows on the longest façade. The grid points are indicated in Fig. 2. For each point of the grid, four different heights were measured to give a total of 648 grid points.

Figure 1. View from the front of the lecture room with the longest façade wall on the right-hand side.

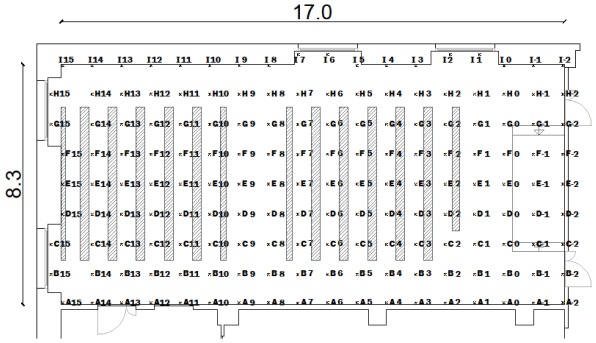

Figure 2. Sketch of the lecture room with grid points.

3. RESULTS

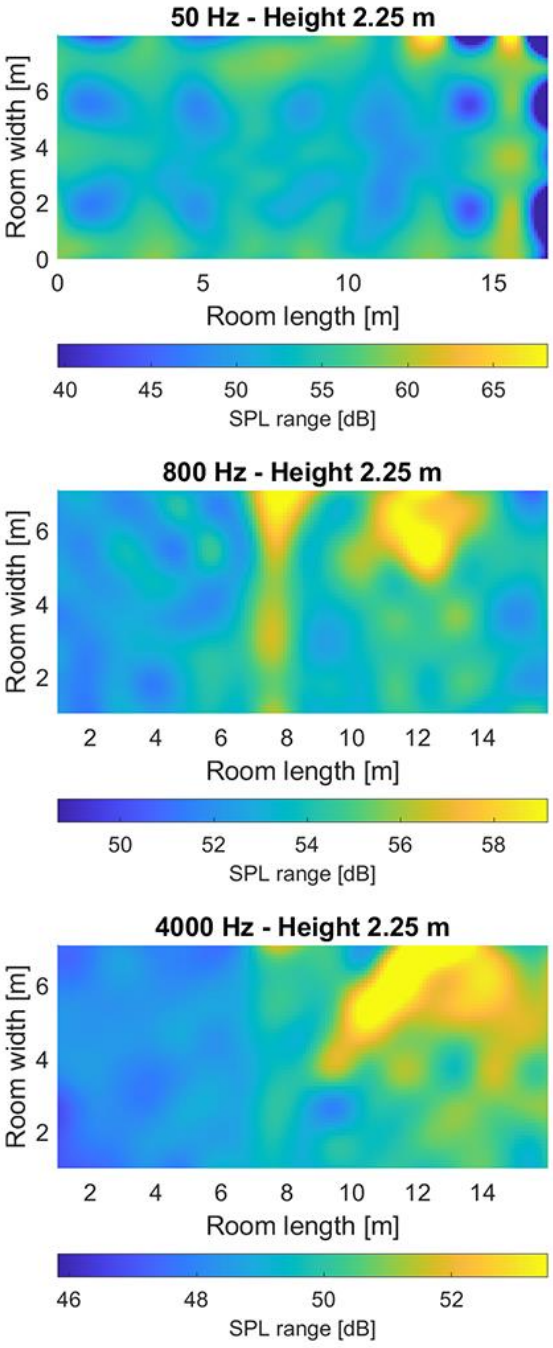

Figure 3. Contour plots of the sound pressure level at a height of 2.25 m. The SPL range shown at the bottom of each plot is a function of the frequency of the surface plot range.

Figure 3 shows contour plots of the sound pressure level at a height of 2.25 m at 50 Hz, 800 Hz and 4 kHz, with the exception of points located on the room's edges. At 50 Hz, there is evidence of modal behaviour. At 800 Hz, there is evidence of strong sound radiation from both windows, with sound transmitted across the room that is reflected across the desks. At 4 kHz there is strong radiation from the right-side window that is expected to be caused by the absence of seals around the window frame and a closing mechanism that causes a gap near the top of the window.

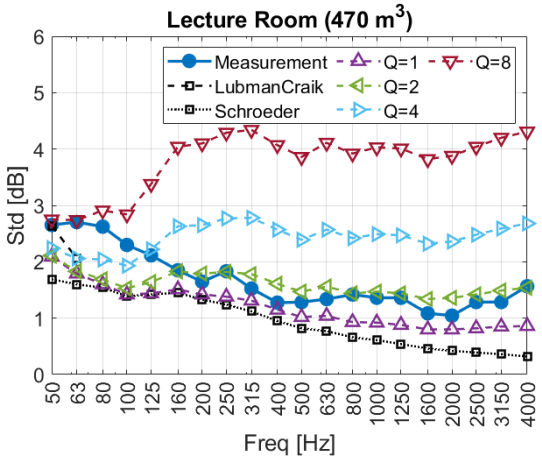

Figure 4. Standard deviations from measurements and theory.

Figure 4 shows the measured standard deviation of the sound pressure levels from the grid, excluding grid points next to the walls, floor and ceiling. At 50 Hz, where there are approximately seven modes, the theory from Lubman-Craik shows the closest agreement with measurements as this theory accounts for low modal density. The Schroeder theory underestimates the standard deviation across the entire frequency range because no account of the direct field from the high levels of transmitted sound from the windows is taken. Ideally, the directivity, Q, needs to be related to a physically meaningfully description for the source. For Q=1 the source would be omnidirectional; hence this would not be appropriate. For Q=2 the source would be sited on a plane and this is a reasonable approximation, but Q=4 might represent a source situated along an edge to represent a leak from the top edge of the window. However, the actual situation is more complex because there is a deep niche of approx. 0.4 m and there could be a two-dimensional reverberant field within the niche above 1 kHz. Comparison of the measured standard deviation with Q=1, 2, 4 and 8 indicates that Q=2 is a reasonable value that the deep niche might justify.

4. CONCLUSIONS

Extending ISO 16283-3 to larger room volumes requires an assessment of the standard deviation for the spatial variation of sound pressure levels. Schroeder theory (or other theories) that only considers the reverberant field underestimate the standard deviation across the entire frequency range because no account is taken of the direct field. The large room considered in this paper had windows with relatively low airborne sound insulation, which led to significant levels of mid- and high-frequency sound radiating from the windows across the room. Therefore, it was necessary to consider the direct field when calculating the standard deviation.

PROPOSAL FOR A METHODOLOGY AND CALCULATION TO APPLY IN THE SOUND INSULATION MEASUREMENT OF CORNER FAÇADES USING ISO 16283-3 STANDARD

Trujillo Gallego, Jose Alberto[1*] **Romero Fernández, Amelia**[2]
[1] Laboratorio de Ensayos Acústicos (Labenac) - Universidad Politécnica de Madrid, Spain
[2] Instituto de la Construcción Eduardo Torroja (CSIC), Madrid, Spain.

ABSTRACT

The measurement methodology described in ISO 16283-3:2015 for façade sound insulation allows the use of a loudspeaker as a substitute for real noise sources (road, railway, or aircraft traffic). Using this source, the sound insulation tests of multi-wall façades are conducted wall by wall. The method requires positioning the loudspeaker at an angle of sound incidence of 45°, which, for ground-floor façades necessitates placing the sound source off-center, toward one of the two lateral edges of the wall under test. This situation becomes particularly critical for corner façades with two walls, where the side to which the sound source is shifted may lead to significantly different results due to potential indirect noise transmission into the interior space via the opposite wall. Furthermore, the mathematical approach used to calculate the final sound insulation value does not accurately reflect a real situation.

This study proposes a more appropriate positioning and calculation method to achieve repeatable and representative results under realistic conditions, demonstrated through an example in a real scenario.

Keywords: *ISO 16283-3; façade sound insulation, corner façade, field measurements, repeatability.*

1. INTRODUCTION

The current standard for façade sound insulation, ISO 16283-3 [1], defines a field measurement and calculation method to determine the acoustic insulation of whole façades (global methods). The specified test method is general, meaning that in specific cases, it may lack precision or fail to provide representative results.

This paper studies the specific case of a corner façade with two walls exposed to outdoor noise and how standard testing procedures can yield different results depending on their application. Additionally, it evaluates how the current calculation method may not accurately reflect real conditions in this scenario of a corner façade.

2. SCENARIO

Figure 1 illustrates a typical scenario of a corner façade with two walls on the ground floor.

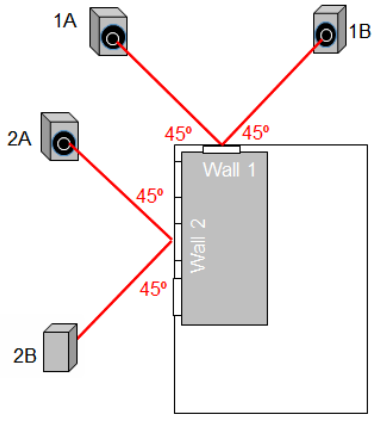

Figure 1. Possible sound source positions per wall.

[*] ***Corresponding author***: jtrujillo@labenac.es.

According to the measurement standard, when using the global loudspeaker method, each façade wall must be tested separately. To ensure an angle of sound incidence equal to 45°±5° on the wall, the noise source must be laterally displaced from the façade centre. The standard allows for two possible loudspeaker positions: either towards the corner or in the opposite direction (Fig. 1).

2.1 Insulation procedure for Wall 1

For measuring the sound insulation of Wall 1, two noise source positions are possible: 1A, with the source shifted towards the corner (Fig. 2a), and 1B, shifted in the opposite direction (Fig. 2b).

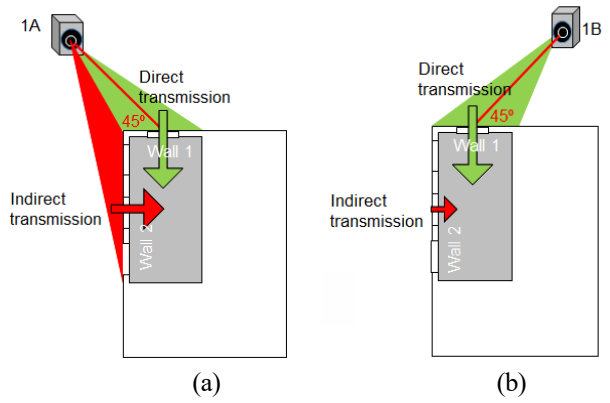

Figure 2. (a) Noise transmission for 1A sound source position. (b) Noise transmission for 1B sound source position.

For source position 1A, due to the small length of Wall 1, the noise source has a direct line of sight to both tested walls. As a result, although the source is directed at Wall 1 (direct transmission), part of the sound beam directly reaches Wall 2. This means that the indoor noise level (L_2) consists of contributions from both the tested wall ($L_{2,W1}$) and the adjacent wall ($L_{2,W2}$), making it impossible to isolate the contribution of Wall 2 in the overall measured levels, without any other additional and specific studies.

$$L_2 = 10Log(10^{(0,1*L_{2,W1})} + 10^{(0,1*L_{2,W2})}) \quad (1)$$

Consequently, the partial insulation of Wall 1 ($D_{nT,W1}$) may be underestimated. However, using source position 1B ensures that most of the loudspeaker's sound beam is transmitted through Wall 1, with significantly lower and negligible indirect transmission through Wall 2. Thus, in this configuration, $L_{2,W1} >> L_{2,W2}$, and consequently, $L_2 \approx L_{2,W1}$.

In conclusion, selecting source position 1B provides a result closer to the real sound insulation of the wall.

2.2 Insulation procedure for Wall 2

As in the previous case, two source positions can be used to characterize the sound insulation of Wall 2: 2A, with the source shifted towards the corner (Fig. 3a), and 2B, shifted in the opposite direction (Fig. 3b).

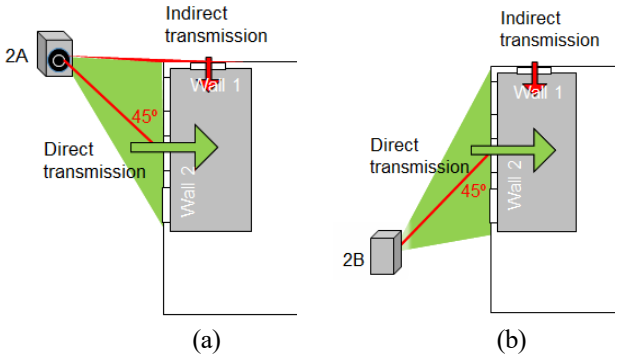

Figure 3. (a) Noise transmission for 2A sound source position. (b) Noise transmission for 2B sound source position.

Due to the greater length of Wall 2, in the least favorable position (2A, near the corner), there is hardly any direct view of Wall 1. Therefore, regardless of whether 2A or 2B is chosen, the direct transmission through Wall 2 will be significantly higher than the indirect transmission through Wall 1 ($L_{2,W2} >> L_{2,W1}$). This means that, in this case, the source position is less critical, and the partial insulation result of Wall 2 ($D_{nT,W2}$) is expected to be similar for both source positions.

2.3 Conclusions on sound source position

Since the measurement procedure in ISO 16283-3 standard [1] requires that façades with multiple walls be tested independently (wall by wall), it is essential to ensure that the measured insulation corresponds exclusively to the tested wall, avoiding noise transmission into the room through the adjacent corner wall. Source positions shifted towards the façade corner may lead to lower-than-actual partial insulation values due to indirect noise transmission, with deviations that cannot be precisely quantified. These deviations depend on factors such as source position, coverage beam, and wall dimensions.

Therefore, to minimize this situation, the best approach is to locate the source away from the façade centre, as far as possible, always in the direction opposite to the corner.
Other authors [2] have also studied the influence of the source position on the final results of the façade insulation of corner rooms, additionally considering the acoustic attenuation due to corner diffraction.

3. ON THE CALCULATION METODOLOGY

ISO 16283-3 [1] allows the use of road traffic (see Fig. 4), railway traffic, and even aircraft noise as sound sources. Conducting tests with these sources provides insulation values that reflect real façade performance under actual noise exposure. However, using traffic noise requires very specific conditions, making the global loudspeaker method the preferred option due to its simplicity and independence from external sources.
The standard's calculation method evaluates each façade wall separately, determining a partial insulation index ($D_{2m,i}$) for each. The final insulation value is then obtained by averaging the individual results, as expressed in Eqn. (2):

$$D_{2m} = -10Log(\frac{1}{n}\sum_{i=1}^{n}(10^{(0,1*D_{2m,i})})) \qquad (2)$$

3.1 Comparison of road traffic and loudspeaker global methods

Next, a theoretical case of a corner façade is evaluated using both global methods: road traffic noise and the loudspeaker.

3.1.1 Theoretical considerations

For the development of this example, the following considerations will be taken into account:

- To simplify the analysis, the examples will use global values rather than one-third octave band frequency spectra.
- The two walls forming the façade are identical in both dimensions and construction characteristics. Each wall provides a sound insulation level of D = 35 dB.
- In both the road traffic noise method and the loudspeaker method, the external measurement point receives the same noise level in all cases: $L_{1,2m}$ = 85 dB.

3.1.2 Test 1. Sound insulation measurement using loudspeaker global method

As mentioned in the previous section, the loudspeaker positions farthest from the corner are selected to avoid indirect transmissions that could affect the results (Fig. 4).

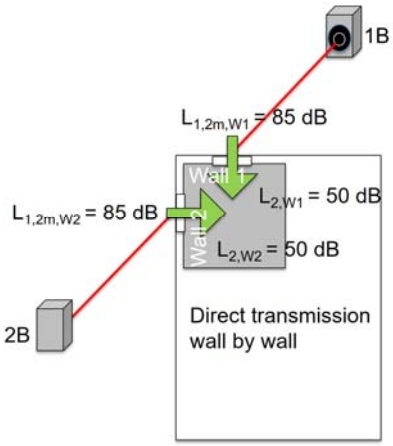

Figure 4. Façade sound insulation calculation using a loudspeaker as a sound source.

As specified by the standard's procedure, each wall is tested separately. For Wall 1, with an outdoor noise level $L_{1,2m}$ = 85 dB and a sound insulation value D = 35 dB, the indoor noise level will be 50 dB ($L_{2,W1}$). Since indirect transmission is negligible, it follows that $L_2 \approx L_{2,W1}$ = 50 dB.
Given that both walls have identical properties, their partial insulation values are:

$$D_{ls,2m,W1} = D_{ls,2m,W2} = 85\ \text{dB} - 50\ \text{dB} = 35\ \text{dB} \qquad (3)$$

Finally, applying Eqn. (2), the overall insulation is $\mathbf{D_{ls,2m}}$ = **35 dB**.

3.1.3 Test 1. Sound insulation measurement using road traffic global method

As previously mentioned, the insulation test must be performed separately for each wall. However, in this case, it is important to consider that outdoor noise enters the indoor space simultaneously through both façade walls.
Since both walls are identical and exposed to the same outdoor noise levels, the insulation calculation for Wall 1 ($D_{tr,2m,W1}$) is also valid for Wall 2 ($D_{tr,2m,W2}$), giving the same result.

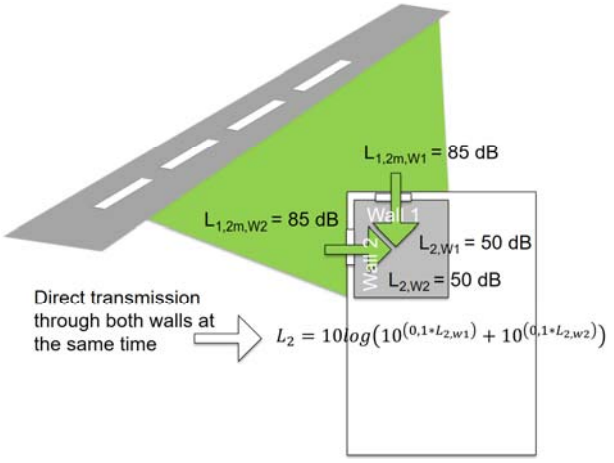

Figure 5. Façade sound insulation calculation using road traffic noise.

For Wall 1, with an outdoor noise level of $L_{2m,W1}$ = 85 dB and a known insulation value $D_{tr,2m}$ = 35 dB, the noise reaching the interior through this wall is 50 dB. However, as the traffic noise excites both walls equally, an additional 50 dB also enters through Wall 2. Therefore, the total indoor noise level (L_2) can be calculated as:

$$L_2 = 10Log(10^{(0,1*L_2,W_1)} + 10^{(0,1*L_2,W_2)}) \quad (4)$$

Resulting in L_2 = 53 dB (Fig. 5).
Thus, the partial insulation values for both walls are:

$$D_{tr,2m,W1} = D_{tr,2m,W2} = 85\ \text{dB} - 53\ \text{dB} = 32\ \text{dB} \quad (5)$$

Finally, applying Eqn. (2), the overall insulation value is **$D_{tr,2m}$ = 32 dB**.

3.2 Conclusions on the calculation method

Therefore, as reflected in the previous theoretical discussion, for the same façade and identical outdoor noise conditions, there is a 3 dB deviation between the traffic noise insulation procedure and the loudspeaker method, despite using the same testing methodology and calculation approach.
The key difference lies in the fact that, during traffic noise insulation measurements, outdoor noise enters through both façade walls simultaneously, regardless of which wall is being tested at a given moment. This results in a higher interior noise level and, consequently, a lower insulation value compared to the loudspeaker method.
Considering that traffic noise insulation measurement better represents real-world conditions and should therefore be used as a reference, two alternative adaptations of the loudspeaker method are proposed to achieve similar results:

Option 1: Modification of the testing method: This approach requires using two identical loudspeakers, each directed towards the centre of one wall, positioned to minimize indirect transmission (Fig. 6), away from the corner. The testing procedure follows the standard method, assessing the partial insulation of each wall. The only difference is that, during the test of each wall, both loudspeakers (sound sources S_1 and S_2) will emit the same noise simultaneously at the same intensity.

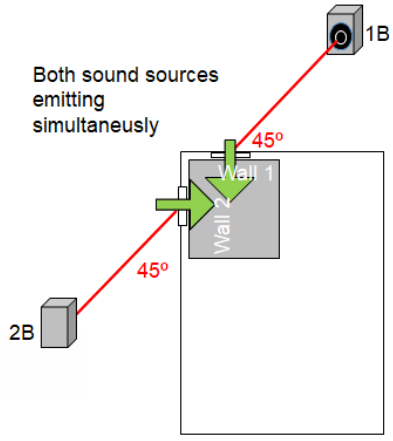

Figure 4. Façade sound insulation measurement using two loudspeakers simultaneously as sound sources.

Option 2. Modification of the Calculation Method: In this case, the standard procedure remains unchanged: each wall is tested separately using a single noise source, positioned sequentially; first for Wall 1 to calculate its partial insulation, then for Wall 2.
To determine the overall insulation, the standard Eqn. (2) is replaced with a new equation that sums the partial insulation values instead of averaging them:

$$D_{2m} = -10Log(\sum_{i=1}^{n}(10^{(0,1*D_{2m,i})})) \quad (6)$$

4. PRACTICAL CASE

To validate the previous findings, a sound insulation test was conducted on a corner façade. Two identical loudspeakers were positioned to excite both façade walls, with their locations shifted away from the corner to reduce indirect transmissions.

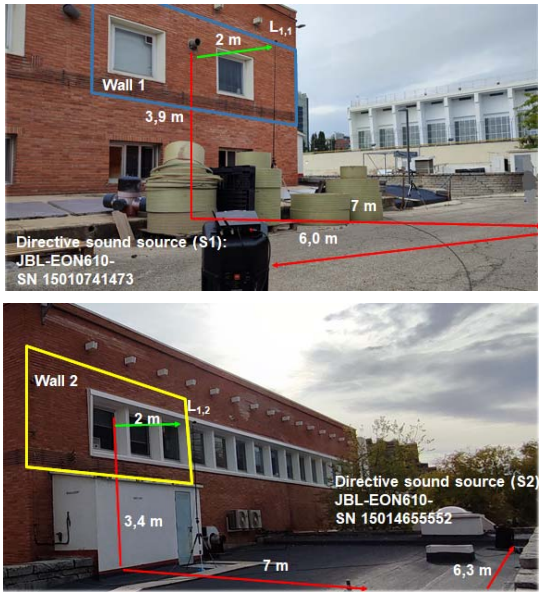

Figure 5. Measurement scenario. Outdoor microphone and sound source positions per wall.

4.1 Measurements

The following tests were performed according to ISO 16283-3 [1]:

- Test 1: "Real-World Scenario". Both noise sources emitted simultaneously during the testing of each wall.
- Test 2: Standard Procedure. Sound insulation measured separately per wall.
- Control Tests: Outdoor measurements taken 2m from Wall 1 while testing Wall 2, and vice versa, to check for indirect transmission.

4.2 Instrumentation

The following equipment was used for the tests:

- Brüel & Kjaer model 2270 dual-channel sound level meter and one-third octave band analyzer.
- Brüel & Kjaer model 2260 dual-channel sound level meter and one-third octave band analyzer.
- Brüel&Kjaer model 4231acoustic calibrator.
- Two JBL model EON610 directive sound sources.
- AKG dual-channel RF transmitter.

5. RESULTS AND DISCUSSION

5.1 Outdoor noise level results

Next, the outdoor results are presented according to

- $L_{1,W1\ (S1\&S2)}$: Outdoor noise level 2m in front of wall 1. Sound sources S1 and S2 emitting simultaneously.
- $L_{1,W1\ (S1)}$: Outdoor noise level 2m in front of wall 1. Only emitting sound source S1.
- $L_{1,W2\ (S1\&S2)}$: Outdoor noise level 2m in front of wall 2. Sound sources S1 and S2 emitting simultaneously.
- $L_{1,W2\ (S2)}$: Outdoor noise level 2m in front of wall 2. Only emitting sound source S2.
- $L_{1,W1\ (S2)}$: Outdoor noise level 2m in front of wall 1. Only emitting sound source S2 (control measurement).
- $L_{1,W2\ (S1)}$: Outdoor noise level 2m in front of wall 2. Only emitting sound source S1 (control measurement).

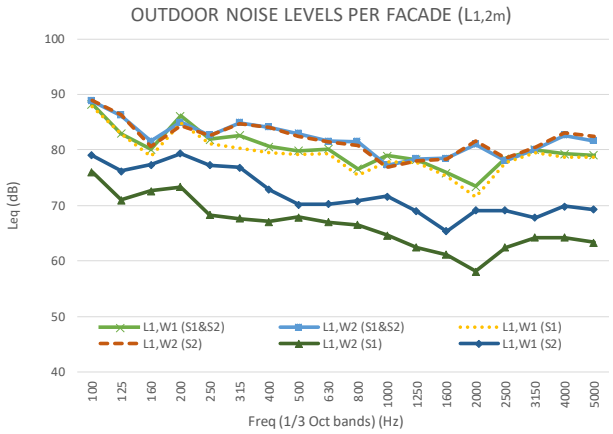

Figure 6. Outdoor levels.

For each wall, the noise spectrum measured at 2m remains similar, whether both sources operate simultaneously or only the one exciting the measured wall is active. This confirms that, with the selected source positioning, the influence of the secondary source on the measured wall is negligible. This effect is particularly evident for Wall 2, where the measured spectra closely align in both test conditions, reinforcing the validity of the experimental setup.

5.2 Indoor noise levels results

The following results were obtained indoors:

- $L_{sb(S1\&S2)}$: Indoor noise level when S1 and S2 emitting simultaneously.
- $L_{sb\ (S1)}$: Indoor noise level when S1 emitting.
- $L_{sb\ (S2)}$: Indoor noise level when S2 emitting.
- L_b: Indoor background noise level.

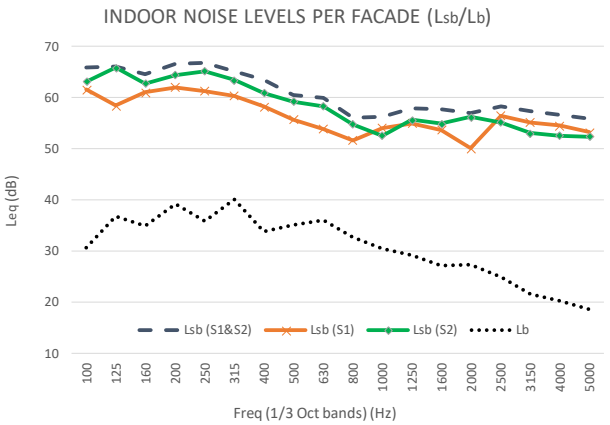

Figure 7. Indoor levels.

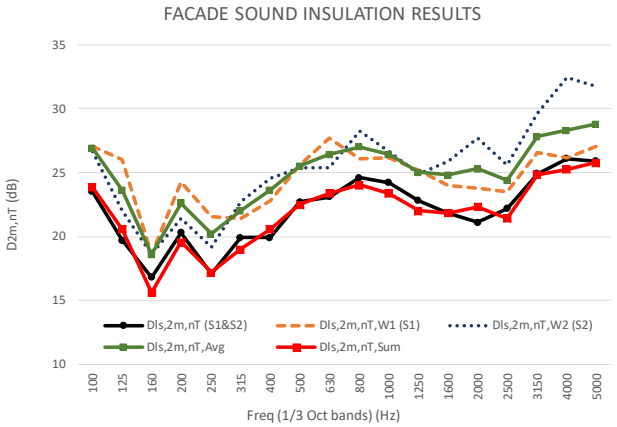

Figure 8. Standardized level difference.

The results confirm no significant background noise influence. As expected, indoor noise levels are higher when both façade walls are excited simultaneously, replicating real-world conditions.

5.3 Standardized level difference ($D_{ls,2m,nT}$)

Graph in Fig. 10 presents the results:

- $D_{ls,2m,nT\ (S1\&S2)}$: Final standardized level difference calculated using Eqn. (2), for sound insulation descriptor $D_{ls,2m,nT}$. when both sound sources are emitting simultaneously.
- $D_{ls,2m,nT,W1\ (S1)}$: Partial standardized level difference for Wall 1 (with only sound source 1 emitting).
- $D_{ls,2m,nT,W2\ (S2)}$: Partial standardized level difference for Wall 2 (with only sound source 2 emitting).
- $D_{ls,2m,nT,Avg}$: Final standardized level difference level calculated using Eqn. (2) based on the partial results $D_{ls,2m,nT,W1\ (S1)}$ and $D_{ls,2m,nT,W2\ (S2)}$.
- $D_{ls,2m,nT,Sum}$: Final standardized level difference calculated using Eqn. (6), summing the partial results $D_{ls,2m,nT,W1\ (S1)}$ and $D_{ls,2m,nT,W2\ (S2)}$.

Considering that the sound insulation curve $D_{ls,2m,nT\ (S1\&S2)}$ represents a real-life scenario (e.g., road traffic noise exciting both walls simultaneously), it can be observed that this curve closely matches the $D_{ls,2m,nT,Sum}$ curve, obtained by summing the partial insulation values using Eqn. (6). This differs from Eqn. (2), currently in the standard, which averages these partial insulation values.

Thus, applying Eqn. (2) to calculate the final insulation from partial insulation values ($D_{ls,2m,nT,Avg}$) results in higher insulation levels across all frequency bands than those observed in a real scenario.

All findings are validated when applying the calculation method for obtaining weighted values according to ISO 717-1 [3], as shown in Table 1.

Table 1. Weighted standardized level difference.

Freq. range (Hz)	$D_{ls,2m,nT,w}$ (C; C_{tr}) (dB)		
	S_1&S_2 simultaneously	Eqn. (2)	Eqn. (6)
Weighted	23	26	23
100-3150	(-1;-1)	(-1;-1)	(-1;-1)
100-5000	(0;-1)	(0;-1)	(0;-1)
50-3150	(-1;-2)	(-1;-2)	(-1;-2)
50-5000	(0;-2)	(0;-2)	(0;-2)

6. CONCLUSIONS

Based on the findings presented in this study, it is concluded that testing façades with two corner walls is a complex process influenced by multiple factors. Additionally, the mathematical approach currently applied in the standard to compute the final insulation from partial insulation values

may not be adequate or representative of real conditions. Therefore, the following recommendations are proposed:

- When using the loudspeaker method, the noise source should be positioned in a way that minimizes indirect transmissions through the adjacent wall while measuring the insulation of the tested wall.
- Whenever possible, the sound source should be placed away from the façade's centre, in the opposite direction of the corner. In some cases, achieving this may require increasing the source-to-façade distance.
- Positioning the source too close to the corner can lead to an underestimated insulation value for the tested wall. Moreover, in such cases, it becomes difficult to quantify the impact of indirect transmissions, as they depend on uncontrollable factors such as façade length, direct visibility of the other wall, and placement of façade elements on the untested wall.

Furthermore, the study confirms that the calculation equation currently used in the standard, Eqn. (2) does not accurately reflect real-world conditions and often leads to an overestimation of façade insulation. Instead, a more appropriate approach is to sum the partial insulation values rather than averaging them, as proposed in Eqn. (6). If indirect transmissions are properly controlled, this equation yields results that are representative of real conditions.

This approach aligns with the calculation methodology of ISO 12354, Part 3 [4], which states that the apparent sound reduction index of a façade is obtained by summing the acoustic power transmitted through each of its components.

Indirectly, similar considerations are already reflected in some European national regulations, such as the Belgian standard NBN S 01-400-1 [5], which establishes sound insulation requirements for residential buildings. In cases of corner façades with elements on both walls, this standard increases the sound insulation requirement by 3 dB.

ADVANCED MONITORING FOR HERITAGE CONSERVATION: TECHNOLOGICAL INNOVATION IN PREVENTIVE MAINTENANCE OF HISTORIC BUILDINGS

Alberto Izquierdo[1*] **Juan José Villacorta**[1] **Lara del Val**[1]
Javier Retortillo[2] **Antolin Lorenzana**[2]
[1] Department of Signal Theory and Communications and Telematics Engineering, University of Valladolid, Spain
[2] ITAP (Institute of Advanced Production Technologies), Universidad de Valladolid, Spain,

ABSTRACT

Preventive maintenance of historical buildings through continuous structural monitoring is essential for the preservation of cultural heritage. It enables efficient management of the physical interaction between tourism and architecture and supports early detection of structural anomalies, facilitating data-driven decision-making.
The University of Valladolid has established a multidisciplinary research team composed of architects, mechanical engineers, and telecommunication engineers. This team has developed an innovative, reconfigurable, scalable, and low-cost technological platform based on MEMS (Micro Electro Mechanical Systems) sensors. These sensors allow real-time and synchronous monitoring of vibrations, mechanical stresses, inclinations, temperature, humidity, and crack evolution in structural elements.
The system integrates local and cloud-based data processing and storage using open-source technologies. Advanced signal processing, statistical analysis, and artificial intelligence techniques—including modal analysis and machine learning algorithms—enable the early identification of potential structural issues, reducing the need for costly corrective interventions and ensuring the longevity of historic structures.
A case study of the 45-meter-high tower of the Monastery of San Jerónimo in Granada is presented to demonstrate the effectiveness of the proposed monitoring solution in a real-world heritage setting.

Keywords: *Structural Health Monitoring, MEMS sensors, cultural heritage conservation, preventive maintenance, machine learning.*

1. INTRODUCTION

Preventive maintenance through continuous monitoring of historic buildings is a key factor in the conservation of cultural heritage, as it allows for efficient management of the physical interaction between tourism and architecture. Early detection of structural anomalies facilitates data-driven decision-making, minimizing the risk of severe damage and optimizing the resources allocated to conservation [1-3].
At the University of Valladolid, a multidisciplinary group has been established. It is composed of researchers from the Wood Structures and Technology Group, the Array Processing Group and the Structural Dynamics Group.
This interdisciplinary team combines the knowledge of architects in the field of heritage wooden structures and the expertise of mechanical engineers in vibration analysis and modal characterization of structures. It also leverages the skills of a team of telecommunications engineers who are capable of hardware design and development, as well as algorithm programming and the creation of open-access libraries for data acquisition, processing, and analysis.

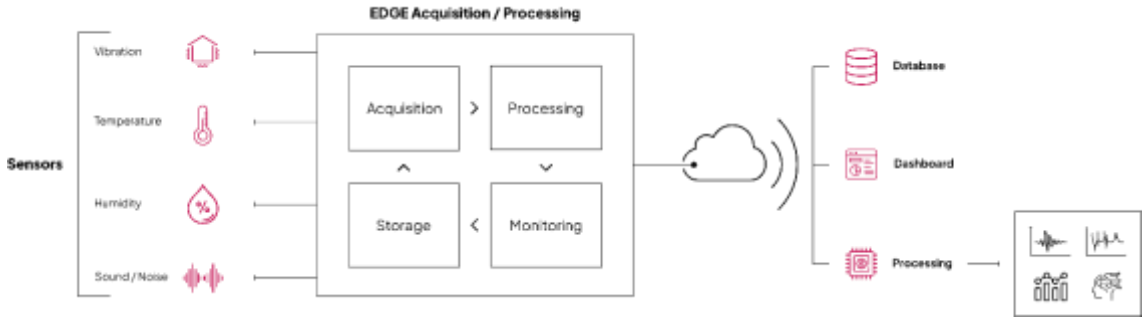

Figure 1. Smart Monitoring System for Architectural Heritage

This team has recently developed an innovative, reconfigurable, scalable, and low-cost technological architecture based on MEMS (Micro-Electro-Mechanical Systems) sensors. These sensors allow precise monitoring of vibrations, mechanical stresses, inclinations, temperature, humidity, and the progression of cracks in the structures. Integrating these data into a synchronous acquisition system provides a detailed and continuous view of the structural condition of the buildings [4-5].

In addition, a platform for processing and analyzing these data has been implemented using open-source technologies. This platform enables the logging, statistical analysis, and remote monitoring of key structural parameters. Thanks to its ability to identify anomalies before they become critical problems, it emerges as an efficient and cost-effective solution for managing preventive maintenance in historic buildings, reducing the need for costly and potentially disruptive corrective interventions.

This paper presents the technical characteristics of the monitoring system and its potential applications in the conservation of architectural heritage. A case study is also discussed: the monitoring of the 45 m tall tower of the Monastery of San Jerónimo in Granada, where the system's capabilities have been evaluated in a real heritage environment.

2. SYSTEM DESCRIPTION

As illustrated in the figure (Fig. 1), the structural monitoring platform is composed of three main components:

1. A set of sensors capable of detecting vibrations, temperature, humidity, and acoustic sources such as ambient noise and sound.
2. A hardware system with embedded software, responsible for four core tasks: data acquisition, local
3. A visualization and storage platform, where data are stored in a database and graphically displayed through a dashboard.

The resulting technological architecture is reconfigurable, scalable, and low-cost, making it suitable for the continuous structural monitoring of heritage buildings.

2.1 Sensors

The system uses MEMS (Micro Electro Mechanical Systems) technology, which integrates both the sensor and the associated electronics on a single chip. These devices capture signals, amplify them, and convert them to a digital format. The multisensor captures variations in mechanical stress, inclination, temperature, humidity, crack development, and even acoustic pressure.

2.2 Data Acquisition

During acquisition, data are collected synchronously (all sensors sample at the same time) and in real time. Preliminary local processing reduces the volume of data to be transmitted, optimizing computational and storage resources.

Several system implementations have been developed, some of which include over 40 triaxial acceleration sensors, operating at sampling rates close to 500 Hz. The large volumes of data generated are processed locally to extract key statistical parameters, which are then uploaded to the cloud for storage and visualization. When required, raw data can be transferred for advanced offline analysis.

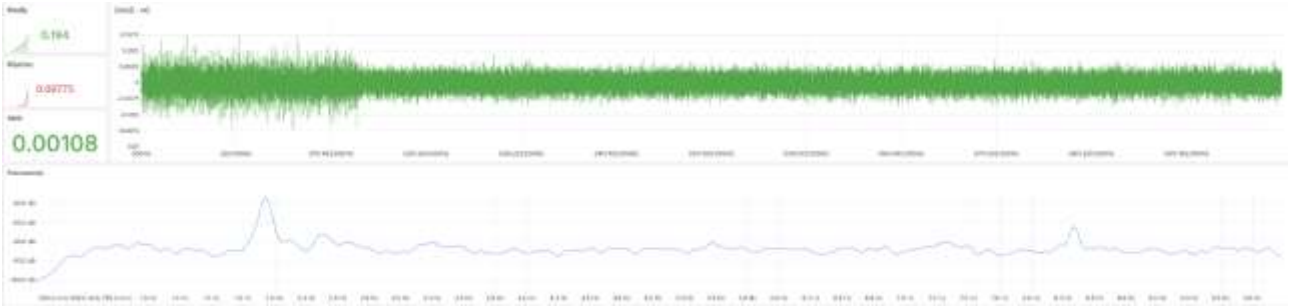

Figure 2. Vibration evolution recorded

2.3 Post-Processing

The system integrates technologies and algorithms across four main areas:

1. Signal processing algorithms that filter data within the desired bandwidth and remove bias.
2. A set of libraries that compute statistical metrics such as mean, variance, maximum, and minimum values.
3. Advanced algorithms including Experimental Modal Analysis (EMA) and Operational Modal Analysis (OMA).
4. AI-based techniques, including machine learning and deep learning classifiers, to support health status assessment and decision-making in heritage conservation.

All sensor data are uploaded to the cloud, where dedicated time-series databases and result visualization dashboards are deployed. Figure 2 shows an example of sensor-recorded vibrations evolution in a monitored building.

3. CASE STUDY

Since May 2024, in collaboration with the School of Civil Engineering at the University of Granada, a structural monitoring project has been carried out on the tower of the Monastery of San Jerónimo, located in the city of Granada (Fig. 3).

A set of five sensors has been installed, measuring triaxial acceleration, temperature, and humidity, along with two additional sensors monitoring the width of two major cracks located between the main nave and the tower. The tower comprises five levels, with the bell chamber located on the penultimate floor. Figure 4 highlights the placement of the five accelerometers within the interior slabs.

The primary objective of this project is to analyze the tower's modal behavior and to correlate crack width evolution with environmental variables (temperature and humidity) as well as the vibrational response of the structure.

Sensor installation was completed in record time, ensuring proper placement on each level. Data acquisition is carried out using a system based on National Instruments' myRIO platform, equipped with 5G cellular communication capabilities. This technology enables real-time data transmission, facilitating the remote structural health monitoring of the tower.

4. CONCLUSIONS

This work presents an innovative technological architecture for the structural monitoring of architectural heritage, characterized by its reconfigurability, scalability, and low cost. The system has demonstrated its capacity to provide continuous and detailed insight into the structural health of historic buildings, enabling early detection of anomalies before they evolve into critical damage.

The developed system integrates advanced MEMS sensors capable of recording vibrations, mechanical stresses, inclinations, temperature, humidity, and crack evolution in heritage structures. Leveraging open-source technologies, collected data are processed in real time and stored in accessible platforms for remote analysis and visualization.

Furthermore, advanced artificial intelligence techniques, including machine learning and deep learning models, have been incorporated to enhance the system's predictive capabilities, optimizing preventive maintenance strategies and supporting informed decision-making in heritage conservation.

DOUBLE-LEAF SYSTEM SOUND INSULATION IMPROVEMENT THROUGH EMBEDDING RESONANT ELEMENTS IN THE STEEL STUDS

Julia Idczak[1*] **Klara Chojnacka**[1]

Faculty of Mechanical Engineering and Robotics
al. Adama Mickiewicza 30, Cracow

ABSTRACT

Lightweight partitions, consisting of two parallel plates connected by steel studs, are commonly used in buildings. While these structures offer clear advantages over heavyweight alternatives, as extensively documented in the literature, they also have drawbacks, notably the reduced sound transmission loss in high frequency range due to the steel studs acting as sound bridges between the two layers. Various solutions have been proposed in the literature to reduce sound transmission through the studs, such as optimizing their shape. This study introduces an innovative approach to achieve high sound insulation in multilayer structures by incorporating resonant elements into the steel junctions. Thorough numerical analysis was performed in COMSOL Multiphysics software. The results highlight the differences in vibroacoustic parameters, especially focus on transmission loss, between structures with standard junctions and those with resonant elements, underscoring the significant potential of new, proposed in this work structures.

1. INTRODUCTION

Double-leaf partitions (DL), commonly analyzed in theoretical models as two parallel plates separated by an air cavity or porous material, are often associated with high transmission loss (TL), especially in the high frequency range. However, in practical applications, such constructions require structural supports to ensure stability and stiffness. These supports, known as studs, are typically made of steel and spaced at 60 cm intervals. Although the presence of studs enhances the mechanical stability of the partition, it also facilitates the transmission of impact sound, leading to a reduction in TL due to the introduction of an additional transmission path.

Sharp was one of the first researchers to introduce a comprehensive approach to predict TL [1]. His model presents the decoupled approach, where airborne and structure-borne sound transmission paths are treated as separate, additive contributions. The total transmission coefficient τ is defined as a sum of ratio of power radiated due to the airborne excitation W_a to power inserted to the structure W_i and ratio of power radiated by the sample due to structure-borne excitation W_s to power W_i according to the equation $\tau = \frac{W_a}{W_i} + \frac{W_s}{W_i} = \tau_a \left(1 + \frac{W_s}{W_a}\right)$.

Craik studied double-leaf structures using statistical energy analysis (SEA), separately examining airborne and structure-borne transmission [2, 3]. The TL values for a representative double-leaf structure, analyzed for both transmission paths separately, are shown in Figure 1. Following extended analytical and numerical investigations, one of the first researchers to experimentally examine the influence of studs on TL was J. Poblet-Puig [4], who an-

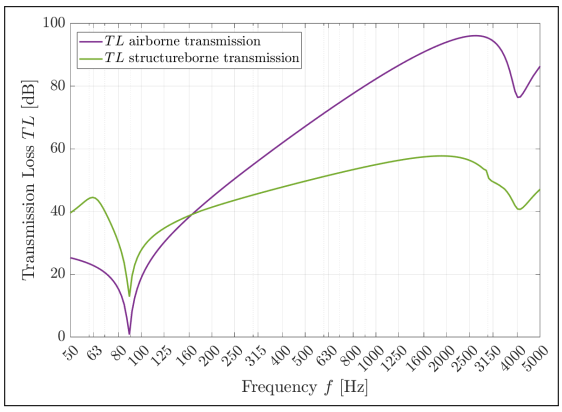

Figure 1. Transmission Loss obtained for DL structure with pure airborne transmission, and pure structureborne transmission.

alyzed the effect of the size and distribution of the stud. Since then, numerous studies have explored various aspects of the vibroacoustic behavior of studs [5] and optimized stud geometry to improve the sound insulation performance of partitions [6]. In this study, a novel approach is proposed in which locally resonant elements are embedded within the studs to enhance sound insulation. By introducing these resonant components, impact sound transmission can be mitigated, leading to improved acoustic performance of the partition.

Metamaterials are artificially engineered geometric structures that, when properly designed and manufactured, can be used to mitigate vibrations and noise across various frequency ranges. One type of metamaterial commonly used for vibration and noise reduction is the locally resonant metamaterial (LRS). These materials consist of small resonant elements which, when attached to a base structure (e.g., a plate), create a stopband for flexural waves propagating through the structure. Within this stopband frequency range, the propagation of flexural waves is significantly suppressed due to the interaction between the base plate and the resonant elements [7].

In the basic configuration, the resonant elements are manufactured separately and attached to the base plate at sub-wavelength distances to induce the stopband effect. However, alternative approaches propose integrating the resonant elements directly into the base structure itself to attenuate the propagation of flexural waves more efficiently. In [8] a matryoshka design of LRS was proposed as a solution for a multi-resonant broadband vibration mitigation solution. Then the same idea was used in [9] in thermoformed plate for noise suppresion in resonance driven environments.

This study examines a double-leaf partition composed of plasterboard plates separated by a layer of porous material and connected by steel studs. To enhance its sound insulation properties, the research explores the carving resonant elements within the studs to reduce the structureborne sound transmission. The results indicate an increase in transmission loss when resonant elements are incorporated into the structure. Numerical simulations of eigenmodes and transmission loss were performed using COMSOL Multiphysics.

2. NUMERICAL ANALYSIS

Numerical analysis of the system was performed using COMSOL Multiphysics with Solid Mechanics and Pressure Acoustics Module. A 3D model is presented in Figure 2. Three configurations were tested in the simulations:

- double-leaf construction with no mechanical connection between two plates and porous material filling an air cavity,
- double-leaf construction with steel studs and porous material,
- double-leaf with steel studs with one and two resonant elements.

The basic structure consisted of two plasterboard plates ($\rho = 1150[\frac{\text{kg}}{\text{m}^3}]$, $E = 3(1 + 0.01i)$ [GPa], $\nu = 0.3$ [-]), each with a thickness of 0.0125 m, separated by a 0.05 m layer of porous material with an air flow resistivity of 11400 $\frac{\text{Pa} \cdot \text{s}}{\text{m}^2}$.

The geometry and dimensions of the stud with resonant elements are illustrated in Figure 3. Two steel studs ($\rho = 7850[\frac{\text{kg}}{\text{m}^3}]$, $E = 205$ [GPa], $\nu = 0.33$ [-]), of height $h_1 = 0.05$ [m], thickness $t_s = 0.002$ [m], and unit cell width of $l_1 = 0.06$ [m], were placed at both boundaries of the sample as shown in Figure 2. Resonant elements were placed at the boundary of the stud that was not attached to the plasterboard. There were two configurations of resonant elements tested: the first with only one resonant element with radius $r_1 = 0.019$ [m], and the second with two resonators of radius r_1 and $r_2 = 0.0126$ [m].

The analysis was performed in COMSOL Multiphysics, focusing on frequency domain analysis within the 100–3150 Hz range, using a step size of 1 Hz. The structure was excited using a boundary load of 1 Pa on

the first plasterboard. Each side boundary of the sample was considered free. The radiating side of the structure was connected to the air domain terminated with Perfecly Matched Layer.

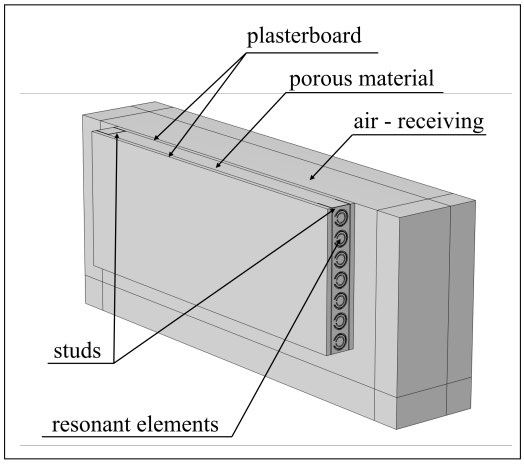

Figure 2. 3D model of the structure with resonant elements embedded in the studs made in COMSOL.

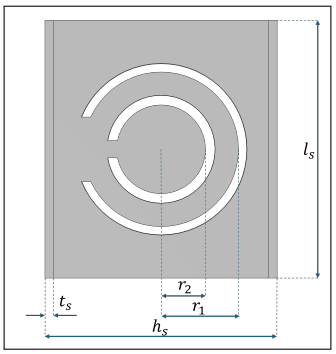

Figure 3. Dimensioning of the stud and resonant elements.

Firstly, eigenfrequencies were calculated for a stud element modeled as one resonant element using periodic conditions and considering the element infinite in one dimension (stud length). In addition, to preserve the mass applied to the stud by the plates, a boundary condition of the added mass was attached. The eigenfrequency analysis was crucial to predict the resonant frequencies of the element and its influence on the TL characteristics of the whole partition. Knowing the eigenfrequencies of the resonant element, a frequency domain analysis was performed. The key parameter most commonly studied in the case of DL structures is Transmission Loss, calculated according to equation $TL = 10\log_{10}(\frac{p_{in}}{p_{out}})$, where p_{in} is the input pressure, defined as the boundary load equal to 1 Pa, and p_{out} is the average value of the acoustic pressure on the radiating side of the sample, calculated from the total area of the plate.

3. RESULTS

The results shown in Figure 4 present eigenfrequencies and modes for the first four natural frequencies of the resonant elements embedded in the studs, within the analyzed frequency range. Analyzing the TL values presented in Figure 5, a significant increase in the parameter is observed at the resonant frequencies of the embedded elements, particularly around 740 Hz and 1375 Hz, therefore, overlapping with the first two natural frequencies of the resonant elements. In both cases, the TL improvement reaches approximately 15 dB for the first stopband around 740 dB, and 20 dB - for stopband around 1375 Hz. These results highlight the crucial role of integrated resonant elements in steel studs, demonstrating their effectiveness in locally enhancing TL values in double-leaf structures.

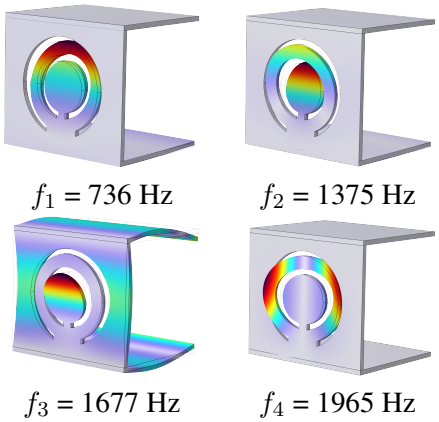

Figure 4. First modes of resonant elements on the steel studs

4. CONCLUSIONS

This paper presents a numerical analysis of double-leaf structures with steel studs. The study compares the Transmission Loss results for a traditional sample with a standard C-shaped steel stud and for studs that incorporate resonant elements. These resonant elements were designed

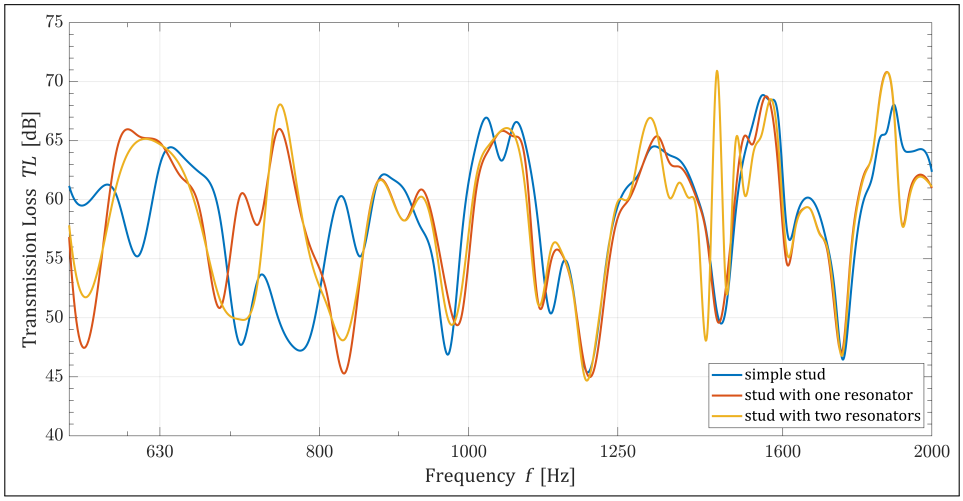

Figure 5. Transmission Loss obtained for DL structure with traditional stud (blue curve), resonator consisted of one ring (red curve), and resonator consisted of two rings (yellow curve).

with frequencies tuned to the frequencies corresponding to the lowest TL values observed in the spectra obtained for the traditional stud. The increase in TL at these specific frequencies is 15 dB, which is a significant improvement. This substantial increase demonstrates the potential for further investigation and practical implementation to improve sound insulation in stud-based partition systems. The follow-up to this study will focus on optimizing the shape of the resonant elements to improve the overall transmission loss characteristics of double-leaf structures, for a significant local enhancement. In addition, an experimental investigation will be conducted to validate the proposed solution in real-world applications.

ACOUSTIC DESIGN OF TWO FILM SOUND STAGES NEAR A TRAIN LINE

Javier Sanz Soriano[1*] **Malcolm Dunn**[1]
[1] Marshall Day Acoustics, Auckland, New Zealand

ABSTRACT

The Auckland Film Studios (New Zealand) site has recently expanded its facilities with the construction of the Te Pūtahi building. This includes two large sound stages (2,000m^2 each) which provide a word class facility for film production. The project location, situated in an industrial area and near a train line, required careful acoustic consideration of the constructions to ensure a low background noise. While precast concrete walls typically used in soundstages would provide the required sound insulation performance to control airborne noise ingress, reradiated noise from the vibration generated by train pass bys was identified to exceed the design specification with this construction. A simple and robust alternative design, with a double layer construction, was developed to reduce reradiated noise, but still provide adequate airborne sound insulation and reduce the risk of construction errors. Furthermore, an auralisation demonstration of train pass bys was also prepared during the design process to assist the design team and client to understand the effects of building materials in the audibility of trains in the studios. This paper outlines the design process and technical solutions developed to achieve the required design specification.

Keywords: *sound stages, train, reradiated noise, auralisation.*

1. INTRODUCTION

Sound stages are an essential part of the filming production process. These provide a controlled and versatile environment for filmmakers to explore and make their ideas reality. Sound stages are typically large empty rooms with high ceilings, structural grids to support lighting, curtains and other equipment or props used during filming and building sets.

A low background sound and a controlled internal environment are essential in a soundstage. With sound stages often located in industrial areas or main transport areas, the acoustic design is a key element of the success of the sound stages.

Auckland Film Studios in New Zealand, has recently expanded their facilities with the Te Pūtahi sound stages. The Te Pūtahi building, which includes two sound stages (2,000 m^2 each) in one building, is located in a moderately high noise environment, within an industrially zoned area and approximately 25m from a train line. The project was developed by Tātaki Auckland Unlimited and was co-funded by Government and Auckland Council.

Thanks to active client engagement and a detailed and well-coordinated design, an excellent outcome was achieved - a high-performance facility was delivered which readily met the client's expectations.

In this paper the authors describe the design challenges and decisions undertaken during the design of Te Pūtahi sound stages.

2. SITE LOCATION AND EXISTING NOISE ENVIRONMENT

2.1 Site location

The Auckland Film Studios site is located in an industrial zone with the rail corridor approximately 25m from one of the Te Pūtahi sound stages (see Figure 1 and Figure 2).

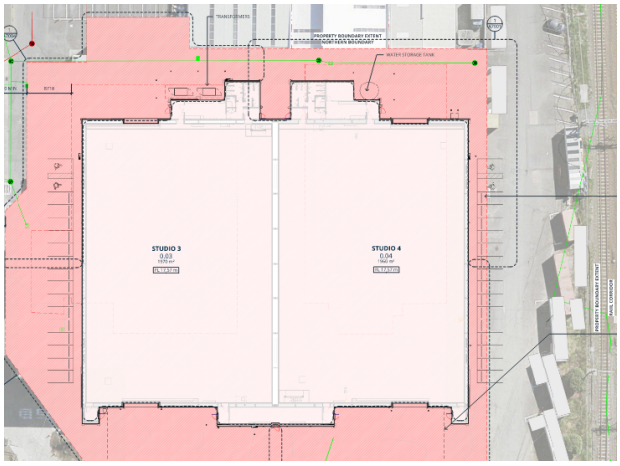

Figure 1. Location of Te Pūtahi sound stages[1]

Figure 2. Te Pūtahi building during construction[2]

2.2 Existing noise and vibration environment

2.2.1 Noise environment

According to the noise regulations, adjacent sites can generate noise levels of up to 65 dB L_{Aeq} at the site boundary of Auckland Film Studios.
The sound stages are exposed to noise from other sites, but also noise from adjacent roads and train pass bys.
A noise logger was installed at the proposed location of the building for one week. A detailed analysis of a representative day was undertaken and the noise sources and design level discussed with the client. An incident level of 72 dBA was decided as the design level - this would cover the noise from passenger trains as well as other ambient sources. The design level is shown in Figure 3 with a horizontal red dashed line. Noise from some film related activities within the site exceeded this level for short durations of time, but we were informed these could be managed and should not be considered. Nevertheless, based on the noise data measured, the ambient noise levels would only exceed 72 dBA approximately 2 minutes per day.

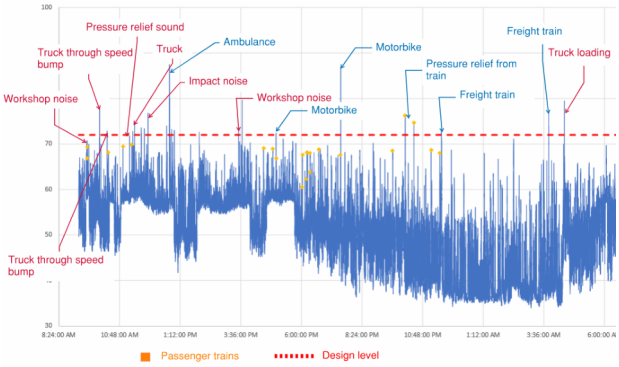

Figure 3. Analysis of noise levels measured

2.2.2 Vibration from trains

There was an existing building in the same location as the proposed soundstages. Vibration levels were measured during one week at this location. Trains pass bys were the main vibration source, and while the vibration was moderately low and subjectively barely perceptible, reradiated noise from train vibration had an important influence on the building construction.

3. DESIGN CRITERIA

3.1 Background noise criteria

When filming, sound stages require a low background noise to ensure the sound recordings are not affected. A noise criterion on NC 25 during filming was specified as part of the brief. The design brief also indicated that internal noise sources within the site or non-frequent sources (freight trains, ambulance, etc.) would not need to be considered as part of the design.
The Noise Criteria descriptor (NC) is typically used to set a background noise criterion of room from relatively constant noise sources (e.g. mechanical services noise). However, it appears that this descriptor is commonly used in the design of sound stages. In accordance with the measurement standard, ANSI/ASA S12.2-2019 [1], noise is 'averaged' over the room during a measurement period of not less than 20 seconds.
Noise from train pass-bys can be of a short duration and if an average level descriptor, like NC, was to be used, the design criterion could be achieved but noise ingress might not meet the client's expectation. Discussions on the meaning and intent of the NC design criterion specified in the brief and the perception of short duration noise levels were important aspects to ensuring the design would meet the client's expectations. The use of percentile descriptors to communicate the transient nature of the noise sources was investigated, but these can be complicated to understand for non-acousticians. An auralisation of the predicted noise from train pass bys as well as typical background noise levels in the sound stage was undertaken in Marshall Day Acoustics' Listening Room [2]. This process, which is discussed later in this document, played an important in explaining the potential impact of train noise intrusion, enabled the client to fully participate in the decision-making process and gave them assurance about the outcome of the project.

3.2 Vibration criteria

Vibration from HVAC plant and trains also needs to be considered. While not part of the brief, the ASHRAE human comfort criteria was used and a design criteria of 0.14 mm/s was used for 'typical' trains with some minor exceedance of 0.2 mm/s allowed for 'worst-case' trains.
A vibration level of 0.1 mm/s is the limit of perception when placing hands on the floor and are concentrating in a quiet environment, this is 'operating theatre' level. A criterion of 'night-time residential' 0.14 mm/s would mean that vibration would generally not be perceivable during general activities.

4. BUILDING DESIGN

Sound stages' buildings require constructions that provide high levels of sound insulation. The use of precast concrete walls is very frequent in sound stages due to structural durability and sound insulation performance.
Concrete is effective at stopping airborne noise but is unfortunately efficient at radiating ground borne vibration. With building located near the train line, the use of concrete walls would have resulted in a large area of efficiently radiating concrete exposed within the studio. Based on the vibration levels measured, averaged noise levels of NC 23-29 were predicted from reradiated noise. This meant that investigating the use of alternative materials that are less efficient at reradiating ground borne vibration was required.
The design and construction program were only 22 months. This meant that an early contractor involvement was an important aspect in the design. While the design concept was developed early in the design, the exact construction materials were adjusted in close collaboration between all design team members and selected contractor to ensure all requirements were achieved: acoustic performance, procurement times, cost, etc. The design process and solutions proposed are described in the next sections.

4.1 Building constructions to control noise ingress and reradiated noise

4.1.1 External walls

High levels of sound insulation can be provided by either very heavy masonry constructions or from multiple skins of lighter weight materials. As regenerated noise from train vibration with concrete walls was identified early in the design, a double skin facade system spaced by a large cavity and isolated between layers was proposed.
Materials like Korok and Durra panels (see Figure 4) are less efficient at reradiating ground borne vibration and are commonly used in large buildings in New Zealand due to its long spans and quick installation. Durra panels are made of compressed wheat straw, which is a natural and renewable resource. Korok panels are made of a galvanised steel shell with an aerated concrete infill.

Figure 4. Image of Durra panel (left) Korok (right)

The construction below was recommended (see the architectural detail in Figure 5).

- Steel profile cladding on a 45mm ventilated cavity with battens at 1200mm centres
- 78 mm Korok panels
- 500mm cavity with a lightweight fibreglass/polyester blanket (90 mm thick and minimum density of 10 kg/m^3)
- Durra panel to the studios side

To maintain the sound insulation performance of the system it was important to maintain the isolation between the inner and outer layers. A robust and consistent solution, isolating the connection of the Korok panels to the main structure with neoprene pads, was designed between the authors and the architects to ensure this isolation was achieved throughout the building and reduce the risk of construction errors on site.

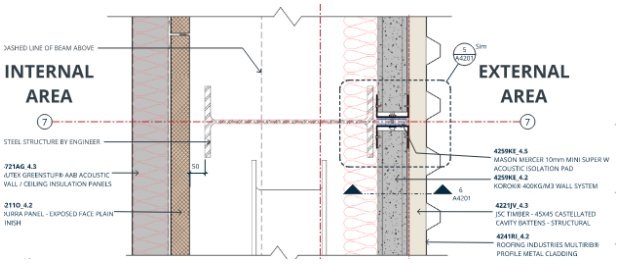

Figure 5. Image of external wall construction[3]

Figure 6 shows a comparison of the predicted sound insulation performance of the system proposed compared to a 200mm thick concrete wall.

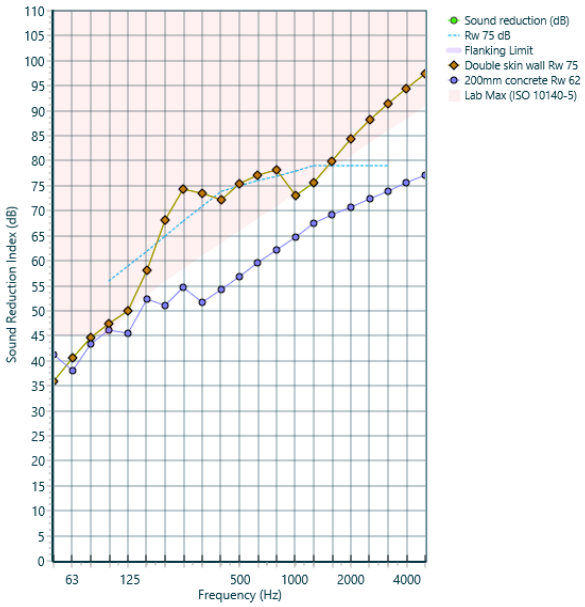

Figure 6. Comparison of sound insulation of concrete wall with double skin system in INSUL

As it can be seen in Figure 1, in one of the external walls, the Korok panel and external cladding had to be replaced with a concrete panel for fire reasons due to the close proximity of a building from another site to the sound stages.

4.1.2 Roof/ceiling

The roof/ceiling represents a very large area, and therefore the sound insulation performance was important too. Furthermore, rainfall is frequent all year round in Auckland with sporadic heavy falls. The client informed that rain noise is a limitation in other sound stages.
With the tight construction period and the roof construction planned for the winter period, the contractor's input in the roof systems to ensure building was weather tight as soon as possible was important. The design team worked collaboratively with the contractor to design a system based on this and met the acoustic performance required. The roof/ceiling system in Figure 7 was proposed, which addresses both noise ingress and controls rain noise.

[3] Architecural detail from Ignite Architects

- Steel warm roof system with a solid mass layer and stone wool core
- 400mm cavity with a lightweight fibreglass/polyester blanket (min 90mm thick and min density of 10 kg/m^3)
- Korok (600 kg/m^3) connected to the roof at no closer than 1200 mm centres

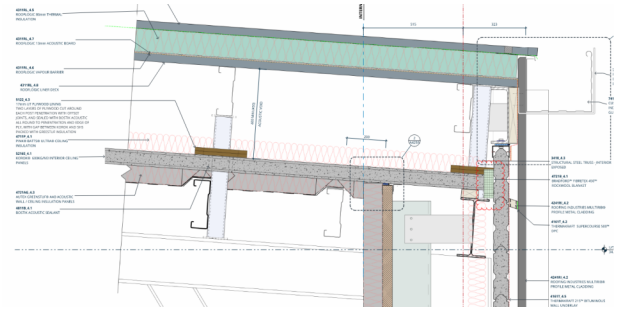

Figure 7. Roof/ceiling construction[3]

4.1.3 Scenery doors

Large scenery / elephant doors (7m x 7m) are required in sound stages for loading and unloading purposes. Doors are typically the weakest point in the sound insulation of a building, but their performance was key to achieving the design criteria.

Two sets of medium performance doors were initially discussed as the most robust solution. However, a single high performance scenery door (STC/R_w 55 and NIIC/D_w 58) was finally selected for cost reasons. Each studio has two of these doors.

The operational mechanism of the doors was an important aspect in the design. Sprinklers are typically not desired in sound stages because a false trigger could destroy the sets, which would have a significant cost implication. Large smoke extract fans connected to the AHU ductwork were used as the fire protection and smoke extract design. This meant that the doors need to be capable of opening quickly to provide enough make up air.

4.1.4 Slab

With the slab on grade, noise reradiated from train vibration through the slab and masonry upstand was predicted to range between NC $_{1sec}$ 23-28 during short periods of time but meet the design criterion of NC 25 when averaged according to the relevant measuring standards (ANSI/ASA S12.2-2019) in the studio closer to the train line.

An example of the noise levels predicted within the studio from the train vibration during a train pass-by with the slab on grade is shown in Figure 8. The approximated duration of the train pass by is 30 seconds. The graph shows the noise levels predicted for each second (NC_{1sec}) in blue, and the averaged noise level when measured/assessed according to ANSI/ASA S12.2-2019 is shown in red. While the averaged noise level for 20 seconds (minimum measurement length) would be NC 20-25, noise from trains would be higher than NC 25 during short periods of time, in this example 8 seconds.

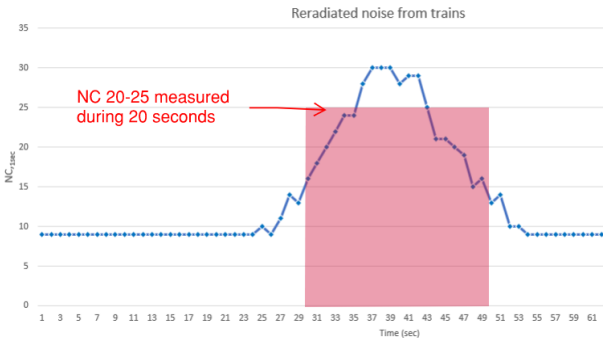

Figure 8. Noise from train pass by in sound stage closer to the train line with slab on grade

Up to approximately 12 trains per hour cross near the sound stages at times. Even though the design was predicted to meet the design criteria without further treatment, additional mitigation measures were explored to reduce the possible disruption from train pass bys: isolating the train tracks (this was not possible for practical reasons), trench along site (the trench to be effective this would need to be very deep, and it was found out this the trench was not possible because of the high water table on site) and isolating the slab of the sound stage.

Due to the elevated cost of isolating the slab, it was important for the client to understand the effects of the noise from the trains in the sound stages. An auralisation of the noise from train pass bys with and without the isolation was demonstrated in Marshall Day Acoustics' Listening Room. The demonstration was presented to representatives of the client. During the demonstration, sound engineers, who would be working in the studios, simultaneously recorded the background noise to verify if this would be disruptive in their recordings. The demonstration included a VR 3D model of the sound stage and sound was reproduced via a calibrated array of speakers providing an immersive as well as accurate experience (see Figure 9).

Figure 9. MDA's Listening Room

Following the demonstration the client decided that the isolation of the slab was required to achieve sufficient protection from train pass-bys.
The slab was isolated using a 50mm Sylomer mat (SR-11) below the entire slab (see Figure 10), which has a natural frequency of 21 Hz. Measurements showed that most of the vibration energy from passenger trains was around 125 Hz. With this design the noise from the trains was predicted to meet the design criteria and be well below NC_{1sec} 25. A minor increase in vibration was predicted at some low frequencies but this was predicted to still be generally imperceptible, only just noticed when lying down still and quietly.

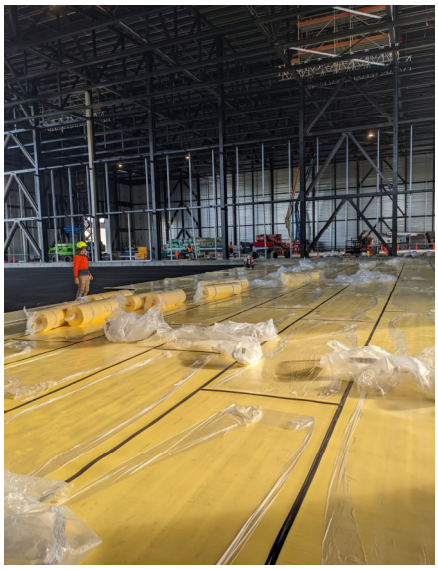

Figure 10. Sylomer mat during construction

4.2 Other design considerations

4.2.1 Sound insulation between studios

The Te Pūtahi building has two sound stages. Each sound stage could be used by a different client and therefore the sound insulation between sound stages needed to be considered.
A concrete wall, similar to other sound stages, was not appropriate due to the reradiated noise from trains. With the use of Durra panels to the internal walls of the building envelope, it seemed logical to use Durra panels for the internal wall. A double Durra panel wall including fibrecement layer with a large cavity and independent structures was proposed (see Figure 11).

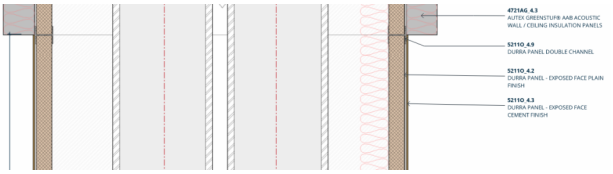

Figure 11. Wall construction between studios[4]

4.2.2 HVAC noise

The design team was informed that the low background noise from mechanical services is only required during critical recording and the mechanical systems would typically be turned off during filming. Nevertheless, the following design criteria for mechanical services noise was agreed for the different uses:

Table 1. Background noise criteria for different uses

Activity	**Background noise criteria (NC)**
Filming preparation with an occupied set and speech communication required	30-35
Scenery construction	35-40
Warehouse/workshop	40-45

Mechanical equipment is typically located in an outdoor plantroom and sections of internally lined ductwork and long attenuators are required to control noise from the HVAC equipment and noise ingress.

[4] Architecural detail from Ignite Architects

4.2.3 Rain noise and noise ingress via the ductwork

With the mechanical equipment located on an external plant platform, rainfall on the external ducts and external noise break-in into the ductwork after the attenuators can compromise the design, particularly in a high rainfall location like Auckland.
Acoustically it would be preferable to locate the attenuators at the penetration of the building envelope, but this was not practicable due to the space constrains. To mitigate the risk of rainfall and noise ingress, a flexible connection in the ductwork and a rain shroud, isolated and spaced away from the ductwork, between the attenuators and building penetrations was built (see Figure 12).

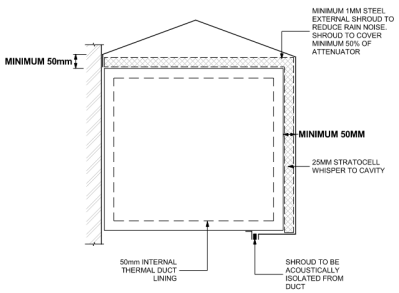

Figure 12. Rain shroud[4]

4.2.4 Absorptive treatment

It is important that sound stages are acoustically 'dead' spaces, and all available surfaces (ceiling and walls) are to be covered with absorptive materials. The lower section of the walls (<2m) is typically not covered with an absorptive material as a robust layer is desirable. This area will be normally obscured by sets during filming, treatment over this section of the wall is not normally required.
A black 100mm high density polyester blanket (density of 48 kg/m^3) was used on the walls and ceiling (see Figure 13).

Figure 13. Internal view of Te Pūtahi sound stages[5]

[5] Photo from Mark Scowen

5. COMMISSIONING RESULTS

Commissioning measurements were undertaken to confirm compliance with the design brief. These included measurements of the background noise from noise ingress and mechanical services at different operation modes, and the sound insulation performance of the doors. Overall, both sound stages perform very well and readily meet the design criteria.

5.1 Noise ingress

Background noise measurements from noise ingress were undertaken with a low noise microphone to ensure the floor noise of the microphone/sound level meter did not limit the measured performance. All HVAC systems were turned off during the measurements. Measurements were undertaken at a time with high train pass-bys to ensure a representative sample of noise sources was captured.
Studio 3 is the sound stage located at a further distance from the railway. The slab in this studio was not isolated as the rail line is located further away and the studio is shielded by studio 4 and other buildings. In this studio noise from trains was the most audible source. Averaged noise levels of NC 12-17 were measured from train pass bys with noise levels typically below $NC_{1,sec}$ 17, with the exception of an event where two trains (one each line) pass by during the measurements and noise levels raised of up to $NC_{1,sec}$ 22 (see Figure 14).

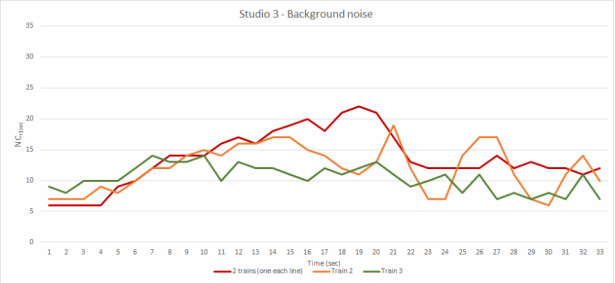

Figure 14. Background noise in sound stage non isolated (further away from train line)

In Studio 4, the isolated soundstage located near the rail line, train noise was barely audible above the background. An averaged noise levels of NC 15 was measured during train pass bys. As shown in Figure 15 (coloured solid lines), noise levels just barely exceeded $NC_{1,sec}$ 15 during some events. Noise from other noise sources (e.g. ambulance or loud motorbikes) were also below NC 20.

While studio 3 is the sound stage located at a further distance from the rail line, measurements show that noise from trains was higher in studio 4. This shows the importance of the reradiated sound from train vibration and effectiveness of the slab isolation.

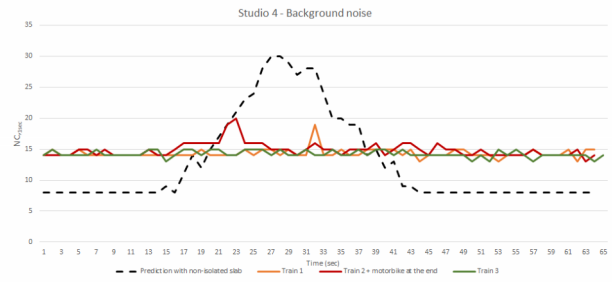

Figure 15. Background noise in sound stage with slab isolated compared with non-isolated prediction

Figure 15 shows a comparison of the noise levels measured in studio 4 (sound stage near the railway) and the predicted noise level from the reradiated noise without the slab isolated (dashed line in Figure 15).

5.2 Mechanical services noise

Noise from mechanical services noise was also measured for the different modes: air conditioning mode (mode with the AHU and fan set to maintain the temperature in the room) and boost mode (mode to cool/heat the sound stages).
The results of the measurements are shown in Table 2. These readily met the design performance recommended.

Table 2. HVAC background noise

Mode	Noise level (NC)
Air conditioning	20
Boost mode	25-26

6. ACKNOWLEDGMENTS

The authors would like to thank Auckland Tātaki Unlimited and Ignite Architects for their support on this paper and facilitating the architectural details shown. The authors would also like to acknowledge the teamwork and collaboration from the design team and contractors (Ignite Architects, eCubed, BGT Structures, Hayden + Rollet, Crossfire/Jensen Hughes, Precon and others) in a challenging but enjoyable project which has resulted in a very successful outcome.

ABSTRACT

The elastic properties of ethylene tetrafluoroethylene (ETFE) membranes are of importance for the features of their distinct drum-like acoustic response when subjected to rainfall, which in turn can affect acoustic comfort, speech intelligibility, and cognitive task performance. The spectrum and loudness of the sound caused by rain impact is dependent on the elastic parameters of the membrane, on the membrane tension, and on the geometry. This study addresses the elastic behavior of single-layer ETFE membranes and multi-layer ETFE cushions, using shaker-excited, scanning laser Doppler vibrometry (LDV)-detected guided wave measurements. The dispersion relation of bending waves running along ETFE membranes was determined, enabling the extraction of the applied tension. The findings contribute to a deeper understanding of the acoustic behavior of ETFE systems during rainfall and their implications for architectural design.

Keywords: *ETFE, Rain noise, Tension, Stress, LDV*

1. INTRODUCTION

Ethylene tetrafluoroethylene (ETFE) membranes are widely used in contemporary architecture due to their lightweight properties, durability, and optical transparency. They are commonly implemented in large-span roofs, façades, and stadium enclosures, where their mechanical and acoustic behavior plays a crucial role in overall performance. One of the significant acoustic challenges associated with ETFE structures is the sound generated by impacting raindrops [1,2]. Depending on factors such as membrane tension, material stiffness, and structural configuration, rain-induced noise can range from subtle background sound to disruptive levels that affect acoustic comfort in enclosed spaces. Accurately predicting this noise requires a precise understanding of ETFE's mechanical properties, particularly the in-plane tension, bending stiffness, and Young's modulus.

The in-plane tension of an ETFE membrane directly influences the propagation of bending waves, which in turn affects how vibrations and sound waves are generated upon raindrop impact. However, the exact tension in mounted ETFE membranes is not always well known, leading to uncertainties in acoustic modeling. A more accurate estimation of these mechanical properties allows for better predictions of rain-induced noise and improved numerical simulations of droplet impacts.

To address this, this study investigates the mechanical properties of single-layer ETFE membranes and multi-layer ETFE cushions through wave propagation analysis. The findings will contribute to improving the modeling of the

acoustic response of ETFE membranes under raindrop impact, enhancing the accuracy of predictions for architectural applications.

2. METHODOLOGY

The measurement of ETFE membranes' vibrational properties was achieved through Laser Doppler Vibrometry (LDV), by recording the vibrational response of the membranes under excitation. This setup allows for a detailed analysis of the material's dynamic behavior at various frequencies and distances from the shaker. Figure 1 presents an image of the experimental setup. The measurements were conducted in a semi-anechoic chamber. The sample was placed on a damping material to minimize the transmission of vibrations from the sample through floor to the laser measurement device.

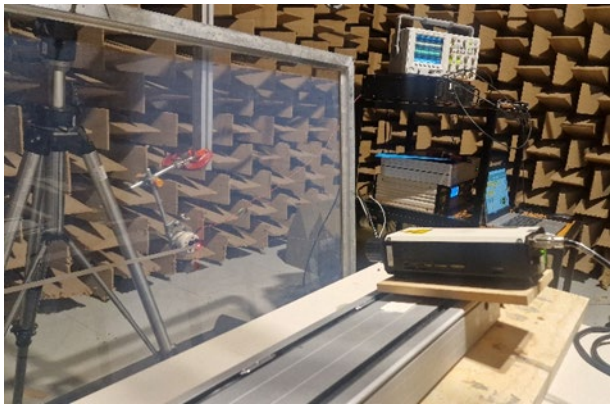

Figure 1. Picture of the measurement setup

A schematic representation of the measurement setup is provided in Figure 2.
The key steps were as follows:

- A swept-frequency signal is generated by a computer and transmitted to the shaker via a sound card, with amplification applied during transmission. The shaker's cylindrical moving element made gentle contact with the membrane, with its circular end (approximately 2 mm in diameter) touching the surface. The sweep covers a frequency range from 10 Hz to 10 kHz. To prevent overloading at low frequencies, the amplitude was fading in from low to high values till 1000 Hz and constant above. The total sweep duration was 20 seconds, which is more than twice of measured structural reverberation time of the sample. Figures 3 and 4 show the waveform and spectrogram of the sweep, respectively.

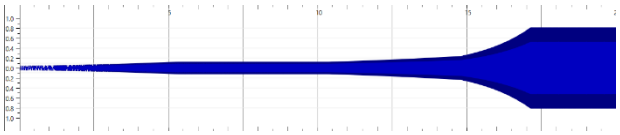

Figure 3. Waveform of the 20 second sweep

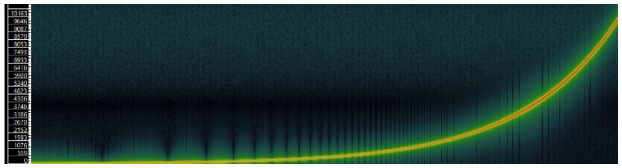

Figure 4. Spectrogram of the sweep

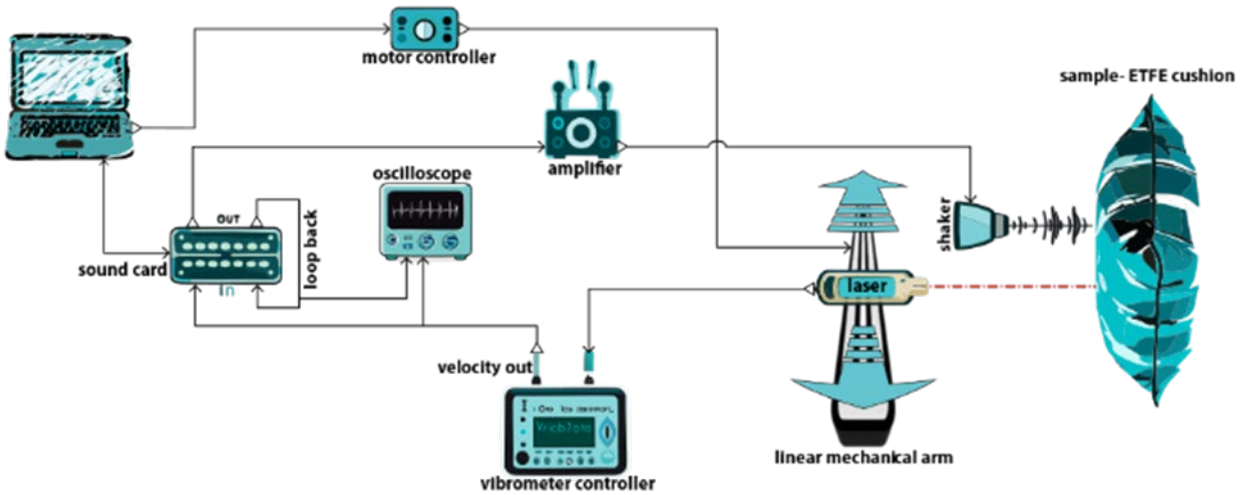

Figure 2. Schematic representation of the Laser Doppler Vibrometry (LDV) setup.

- The vibrational response was recorded with a sampling rate of 44.1kHz . In addition to the normal displacement component of the vibration response with a Laser Doppler Vibrometer (LDV), also the sent signal was looped back to a second recording channel, to serve as reference.
- The vibrations were recorded at different distances from the shaker contact point along a line starting from the excitation point using a linear mechanical arm. For each sample, over 600 recordings were taken along a distance exceeding 60 cm, with a spatial step size of 1 mm, thus obtaining the spatiotemporal dependence of the normal vibration velocities $v_z(r,t)$. The overall measurement range was sufficient to capture the longest wavelengths, while the spatial step size was fine enough to resolve the shortest wavelengths. Table 1 provides detailed specifications of the equipment used in this measurement setup.
- From the sweep recordings, for each detection distance, the spectrum $v_z(r,f)$ was determined. By making use of the sent spectrum, the transfer spectrum was determined and Fourier transformed to get the impulse response for each distance r.
- The impulse responses were windowed in order to select only the direct wave arrivals, and then Fourier transformed back to frequency domain. Finally, the direct signals $v_{z,direct}(f,r)$ were spatially Fourier transformed to obtain the waveumber-frequency dispersion relation $v_{z,direct}(f,k_b)$.
- From the maximum amplitudes in wavenumber-frequency domain, the velocity dispersion was determined.

$$c(f) = \frac{\omega}{k} \tag{1}$$

Table 1. Equipment details

Equipment	Model/Specification	Details
Sound Card	Roland Quad-Capture	24-bit, 192 kHz
Amplifier	EHQ Power VPA2350MB	
Shaker	LDS V100 series	Diameter of moving circular end: 2mm
Velocity Controller(LDV Decoder)	Polytec OFV 3001 Vibrometer Controller	Velocity Range: 1000 mm/s/V
Retroreflective Tape		Thickness: 0.5 mm

Two types of samples were measured: a membrane and a cushion. Both consisted of similar membranes, as shown in Table 1, but differed in structure. The first sample was a single-layer membrane, while the second was a three-layer cushion with an air pressure of approximately 250 Pa in both cavities. The outer layers had a thickness of 250 µm, while the inner layer's thickness is uncertain but is estimated to be between 80 and 120 µm based on the company's production specifications.

3. THEORETICAL MODEL

3.1 Wave propagation in uniaxially stressed membrane

The material properties, specifically Young's modulus and tension, were determined by fitting the obtained c(f) to a theoretical model for Lamb wave propagation in a membrane under stress: for uniaxial stress, the governing dispersion relation for wave propagation is given by [3]:

$$\omega = \sqrt{\frac{\frac{B}{h} * k_b^2 + \sigma_{xx}}{\rho}}\, k_b \qquad (\text{rad.s}^{-1}) \tag{2}$$

where ω is angular frequency(rad/s), h is the membrane thickness (m), k_b is the wavenumber (1/m), σ_{xx} is in-plane tension(Pa), ρ is the material density(Kg/m^3), and B is the bending stiffness(N·m), given by:

$$B = \frac{Eh^3}{12(1-\nu^2)} \qquad (\text{N.m}) \tag{3}$$

E is Young's modulus (Pa) and ν is Poisson's ratio (dimensionless).

Eq. (2) can be rewritten to determine the phase velocity of the propagating bending wave:

$$c_b = \pm\sqrt{\frac{\sigma_{xx} \pm \sqrt{{\sigma_{xx}}^2 + 4\omega^2 \rho B/h}}{2\rho}} \qquad (\text{m.s}^{-1}) \tag{4}$$

where c_b represents the phase velocity. Equation (4) shows that the bending wave velocity is dependent on the in-plane tension of the material, as demonstrated in Figure 5 for an ETFE membrane-the sample used in this experiment, for literature values for the material properties listed in Table 2 and varying values of the tension.

Table 2. Known physical properties of the ETFE sample

Abbreviation	Name	Value	Unit
E	Young's modulus	0.52×10^{9}	Pa
H	Thickness	250×10^{-6}	m
μ	Poisson's Ratio	0.45	-
ρ	Density	1750	kg/m3
η	Loss Factor	0	-

4. RESULTS

4.1 Impulse response(time vs distance plot)

The impulse responses from all measurement positions were combined into a spectrogram, where the color represents the amplitude of the impulse response. The recordings were normalized to ensure that the impulse responses from further positions could be adequately visualized without excessive amplitude variation. Additionally, to mitigate the effects of high-frequency noise and improve signal clarity, low-pass filter was applied to the recordings.

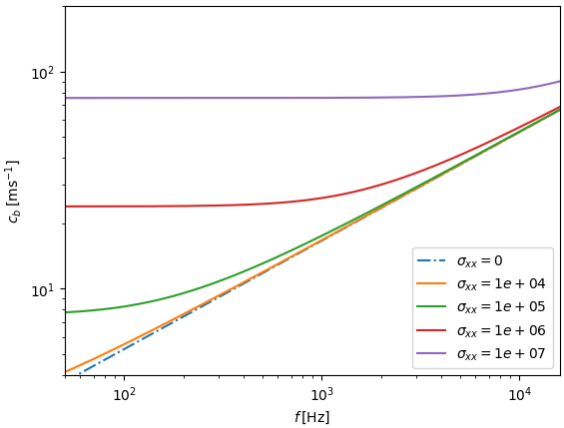

Figure 5. Theoretical relation between bending wave velocity and frequency for different values of the in-plane tension of an ETFE membrane.

The results are plotted as a function of position and time in Figure 6 (single-layer membrane) and Figure 7 (cushion). The signal magnitude is color-coded. The slope of the bright color regions corresponds to the bending wave velocity, with steeper slopes indicating a higher wave velocity. Also reflected waves, particularly in the cushion sample, can be observed, with the 722 mm position marking the edge of the sample.

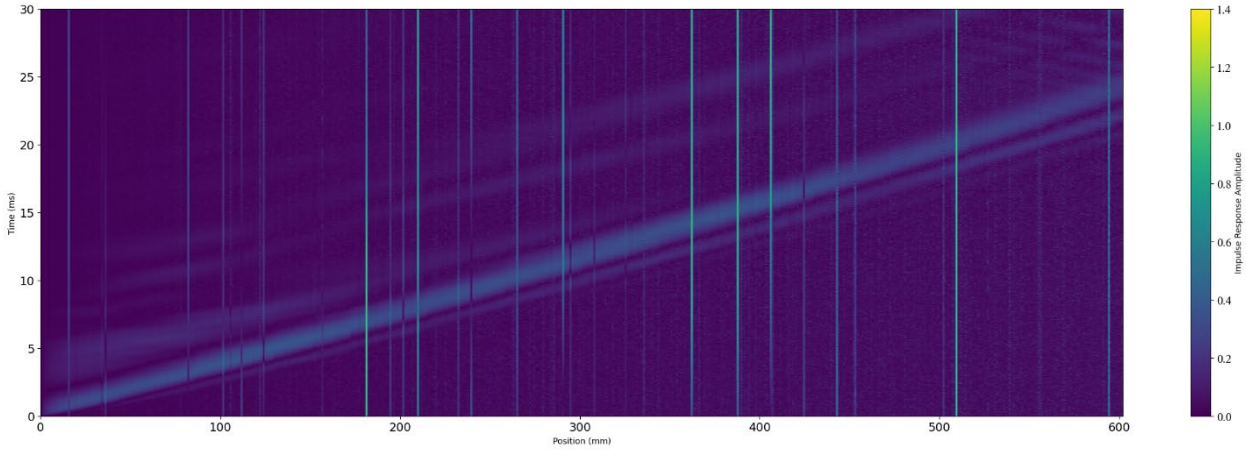

Figure 6. Time-distance plot of the arriving waves of the single-layer membrane.

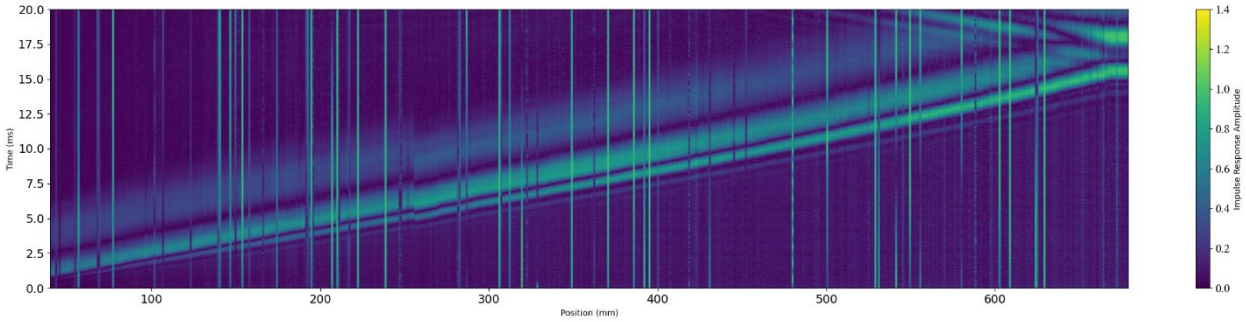

Figure 7. Time-distance plot of the arriving wave of the 3 layers cushion.

4.2 Wavenumber–frequency dispersion curve

After windowing the direct sound from the impulse responses, a 2D Fourier transform was applied, resulting in the wavenumber-frequency spectrum $S(k_b,f)$ in Figures 8 and 9, for the membrane and the cushion, respectively.

4.3 Tension estimation

Eq. (2), the relationship between wavenumber and frequency was used to fit the experimental k-f plot, enabling the estimation of the corresponding in-plane tension. The value of Young's modulus and Poisson' ratio were taken from literature (Table 1). The tension was found to be 1.95±0.03 MPa in the single membrane and 3.30±0.02MPa in the cushion.

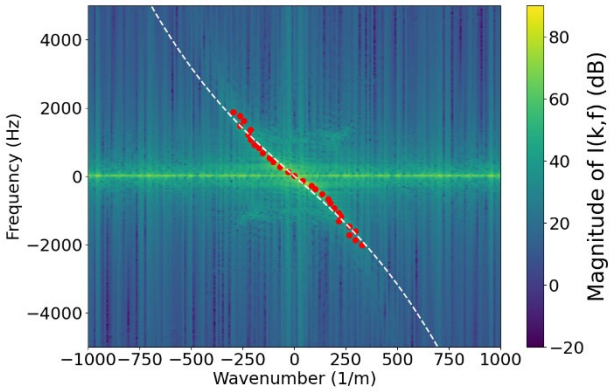

Figure 8. Fitted frequency-velocity plot of the bending wave along the membrane. The white dashed line represents the theoretical dispersion curve fitted using a tension value of 1.95 MPa.

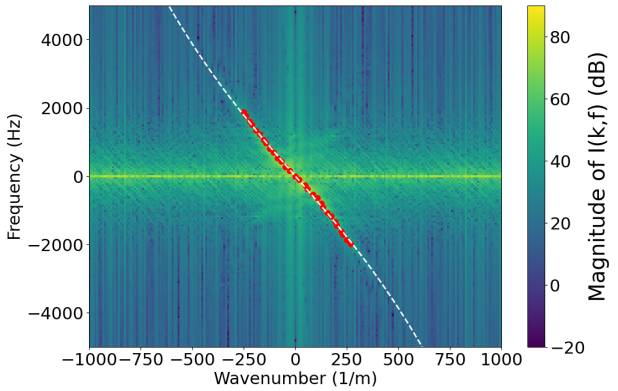

Figure 9. Fitted frequency-velocity plot of the bending wave along the 3 layer-cushion. The white dashed line represents the theoretical dispersion curve fitted using a tension value of 3.30 MPa.

5. CONCLUSION

This study has demonstrated the effectiveness of using shaker-excited Laser Doppler Vibrometry (LDV) to characterize the dynamic behavior and estimate the in-plane tension of ETFE membranes and cushions. We characterized a single-layer membrane with a thickness of 250 microns and a multi-layer cushion, which had an outer layer thickness of 250 microns, with an estimated internal air pressure of approximately 250 Pa. The results reveal a clear and significant difference in mechanical tension between the single-layer membrane (1.95±0.03 MPa) and the multi-layer cushion (3.30±0.02 MPa). These large tension values

strongly affect the dispersion and therefore also the acoustic impedance[4] and radiation efficiency when rain drop impact generated bending waves are running along the surface.

This indicates that the applied tension can be used as a parameter to control or mitigate the loudness and spectral features of rain noise, which can be exploited in architectural design of membrane and cushion based building structures.

THE EFFECTIVENESS OF PLENUMS IN ROOM ACOUSTIC CONDITIONING

Espinel Valdivieso, Ana Esther[1*] **Arenaz Gombau, Angel**[1] **Riesco García, Jose Ignacio**[1]
Mena Moreno, Andrea[1] **Gonzalez Nieto, Jairo**[1] **Cambor Iglesias, Pablo**[1]

ABSTRACT

The same absorbent material behaves differently depending on whether it is installed directly on a surface or if there is a plenum - an air chamber - between the supporting surface and the material.

This fact is particularly relevant in cases where these materials are used with or without a plenum in the acoustic conditioning of rooms, as the acoustic quality of a room can vary considerably depending on this factor.

AUDIOTEC has developed a study in which, in a first phase, was characterized in a reverberation chamber the variation of the sound absorption coefficient of different materials as a function of the plenum used in the tests.

Based on this information, simulations were carried out using ODEON Room Acoustic Software to calculate various room acoustic quality parameters (reverberation time, definition, clarity, STI) as a function of the plenum used.

This study concludes that in the project phase of room acoustic conditioning, the correct definition of the plenum to be used is fundamental, as depending on it, the acoustic quality of these rooms can be significantly improved.

1. INTRODUCTION

The purpose of this study is to evaluate, by means of acoustic modelling, the improvement obtained by the use of plenums in the acoustic conditioning of rooms.
For this purpose, test results of the acoustic absorption of materials with and without plenums, obtained in standardised test chambers, are used, as well as the room acoustic simulation software Odeon © room acoustics simulation software.

2. SOUND ABSORPTION TESTS

As a starting point for carrying out the study, we have used the results of sound absorption tests on materials with and without a plenum, carried out in Audiotec's standardised reverberation chamber at its facilities in the Boecillo Technological Park in Valladolid. These tests were carried out in accordance with the ISO 354 standard.

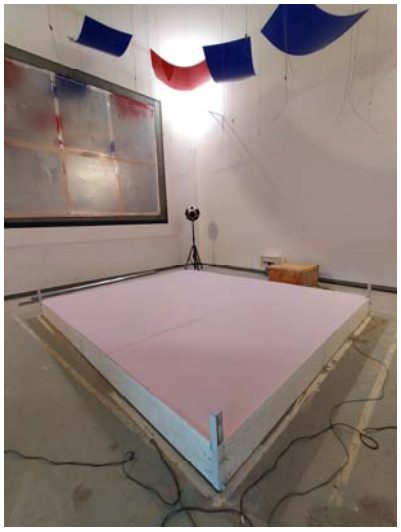

Figure 1. Plenum in reverberation chamber

2.1 TEST RESULTS USED IN THE STUDY

This study used the results of the absorption coefficient of different sound absorbing materials, including PET panels and mineral wool panels.
Firstly, the behaviour of sound-absorbing PET panels was analysed by varying the plenum.
The results obtained for the same material using different plenums

Frec Hz	α 0 mm plenum	α 50 mm plenum	α 200 mm plenum	α 400 mm plenum
125	0,05	0,15	0,35	0,40
250	0,05	0,40	0,65	0,75
500	0,25	0,85	0,85	0,80
1000	0,55	0,80	0,80	0,80
2000	0,85	0,95	0,85	0,85
4000	0,95	0,90	0,85	0,90

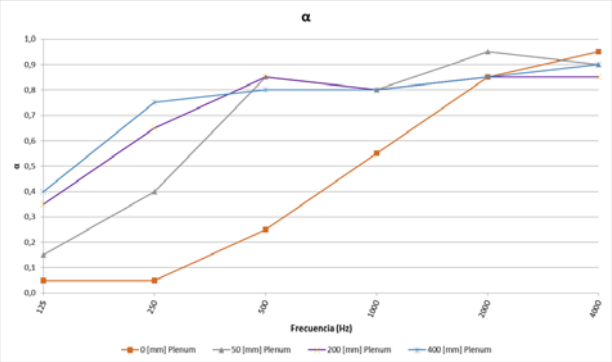

Figure 2. Sound Absorption Coefficient

3. ACOUSTIC CONDITIONING SIMULATION

3.1 The enclosure

In order to carry out the simulations, a multi-purpose enclosure was considered, with the following dimensions Floor area: 56 m2; height: 3 m; volume: 168 m3.

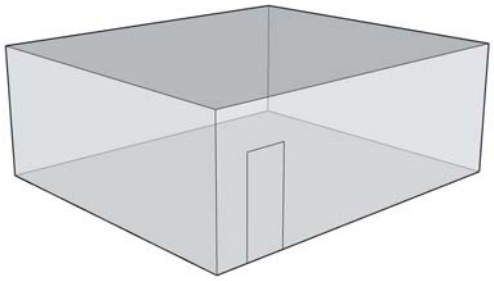

Figure 3. 3D Room Model.

The surfaces of the room are highly reflective: Ceramic tiled floor, smooth concrete walls and ceiling with plaster finish and a wooden door.
For the purposes of the simulation, only the ceiling is modified, leaving the other surfaces unchanged

3.2 Acoustic parameter recommended

Taking into account the intended use of our theoretical The recommended values to be obtained, taking into account the intended use of our theoretical enclosure as a multiple room, are as follows:

Parameter	Value
T20	0,80[s] – 1[s]
STI	≥ 0,65

3.3 Acoustic simulation

The simulations were carried out using the Odeon © acoustic prediction software. This software can be used to characterise various acoustic parameters, the results of which will vary according to the different materials present on the surfaces of the room.

The following parameters were analysed for this study:

- Reveberation timeT20 [s]
- Speech intelligibility STI

3.4 Initial acoustic characterization of the enclosure

As a starting point, we took the 3D model that had been generated to carry out a study of the most important acoustic parameters.

3.4.1 Reverberation time

The average reverberation time obtained (500 Hz, 1000 Hz and 2000 Hz) is 5.48 s, although there are reverberation times of the order of 10 s at low frequencies.
At medium frequencies, the reverberation times are also high, in the order of 6 s, which has a direct impact on speech intelligibility.
Finally, the high frequencies show values in the order of 3 and 4 s.

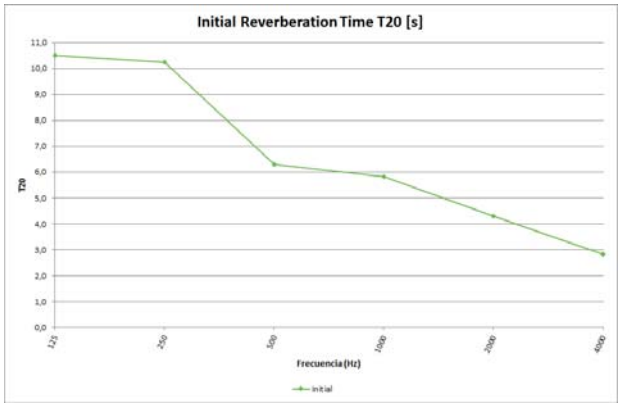

Figure 4. Initial reverberation time.

3.4.2 Speech intelligibility

Another parameter calculated is the speech intelligibility STI, which evaluates the quality of the perception of the spoken word, the initial value obtained is poor, which is consistent with what was observed in the reverberation time:

Parameter	Value
STI	0.30

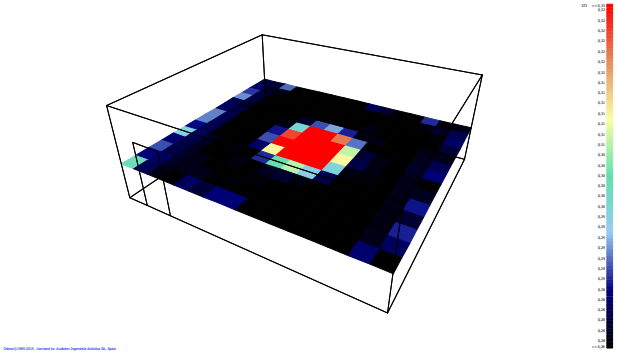

Figure 5. Initial speech intelligibility.

3.5 Acoustic characterisation of the enclosure with the sound-absorbing material installed without a plenum

3.5.1 Reverberation time

The simple application of the material to the ceiling reduces the reverberation time at low frequencies by almost half, with values around 5 [s].
At medium frequencies, the reverberation time is reduced to values around 1.6 [s].
The reverberation time at high frequencies shows a significant reduction with values around 1 second.

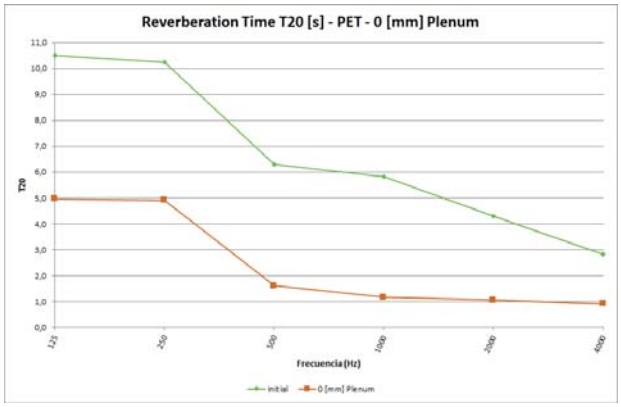

Figure 6. Reverberation time – 0 [mm] plenum

The application of the sound-absorbing material in the enclosure is effective at medium and high frequencies, although its behaviour is not so effective at low frequencies, since the reverberation time, although reduced, is still high for this type of enclosure.

Parameter	Value
T20 mid	1,17 s
T20 125 Hz	5 s
T20 250 Hz	5 s

3.5.2 Speech intelligibility

The impact of installing a non-plenum sound-absorbing material in the enclosure is positive, and speech intelligibility values have improved significantly, although they are still not good.

Parameter	Value
STI	0.55

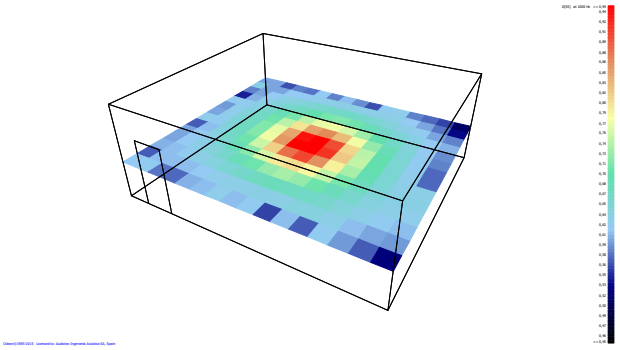

Figure 7. Speech intelligibility STI – 0 [mm] plenum.

3.6 Acoustic characterization of the enclosure with the material installed with 50 mm, 200 mm and 400 mm plenums

In this section we analyse the effectiveness and the improvement offered by the plenum in the acoustic conditioning of the enclosure.

For this purpose, a new simulation was carried out using plenums of 50 mm. 200 mm. and 400 mm. with the same material.

3.6.1 Reverberation time

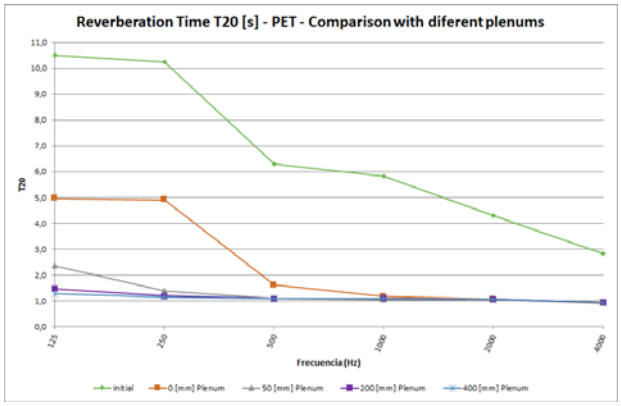

Figure 8. Reverberation time - Comparison according to the use of plenums.

As can be seen, the introduction of plenums with an air chamber improves the reduction of the reverberation time in the low frequency bands. This improvement is progressive as the air space (plenum) behind the material is increased, although there is hardly any difference between the 200 mm and 400 mm plenum.

The mid-frequencies also show a significant improvement with the introduction of an air gap. However, the improvement becomes less noticeable as the air gap increases.

Finally, it is observed that the high frequency is hardly affected by the introduction of the air gap. In other words, the improvement in this range is determined by the surface properties of the material.

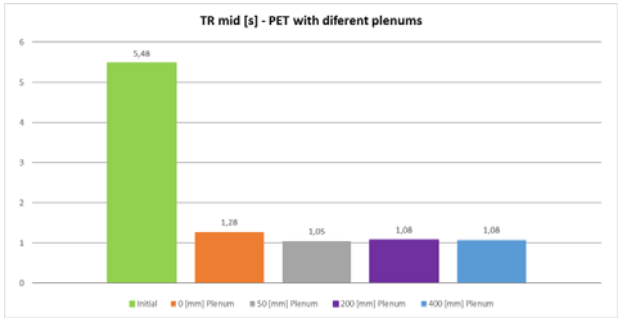

Figure 9. TRmid comparison

When the sound absorbing material is placed in the room without the air chamber, the average reverberation time shows a noticeable improvement.

It should be noted that the TR mid only considers the 500, 1000 and 2000 Hz bands.

mm, we have a decrease in the average reverberation time with respect to the material installed directly, but when the chamber is increased to 200 mm, we have a slight increase and a stagnation for the 400 mm chamber, proving that when the air chamber is increased, the medium and high frequencies are hardly affected, in this case, although an improvement is observed in the low frequencies.

3.6.2 Speech intelligibility STI

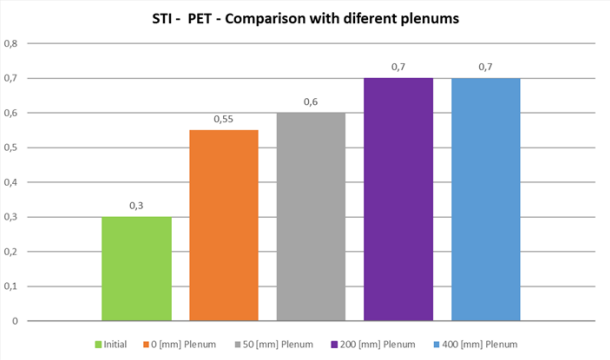

Figure 10. Speech intelligibility STI comparison

Speech intelligibility shows a significant improvement when the material is placed directly without an air chamber, going from a "very poor" value of 0.30 to a "fair" value of 0.55, meaning that the material alone has a positive effect on speech intelligibility.

With the addition of a 50 mm air chamber, the improvement is notable, with values classified as "good" of 0.65, indicating that this configuration provides better control of sound energy in the speech frequency range.

With 200 mm and 400 mm plenums, the values are 0.7 and are considered "very good".

Increasing the size of the air chamber shows little significant improvement, keeping the speech intelligibility values in the "very good" range.

4. COMPLEMENTARY STUDY

4.1 Test results used in the complementary study

A complementary study was conducted with a different material type (mineral wool) to verify the influence of material type on plenum performance.

The absorption coefficient of the material tested with different configurations is as follows:

F Hz	α 0 mm plenum	α 400 mm plenum
125	0,15	0,40
250	0,60	0,70
500	1,00	0,80
1000	0,95	0,90
2000	0,90	0,90
4000	0,90	0,90

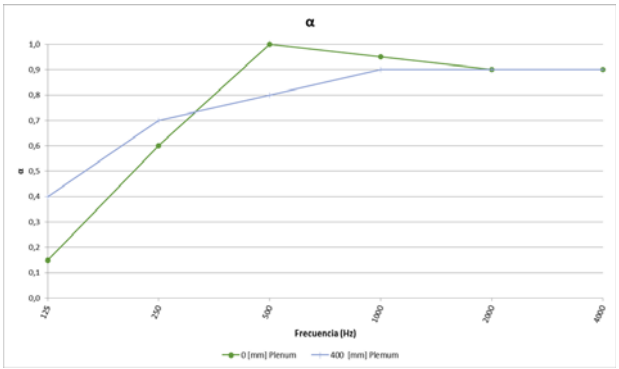

Figure 11. Sound Absorption Coefficient.

4.2 Acoustic characterisation of the enclosure with the sound-absorbing material 2 installed without a plenum

4.2.1 Reverberation time

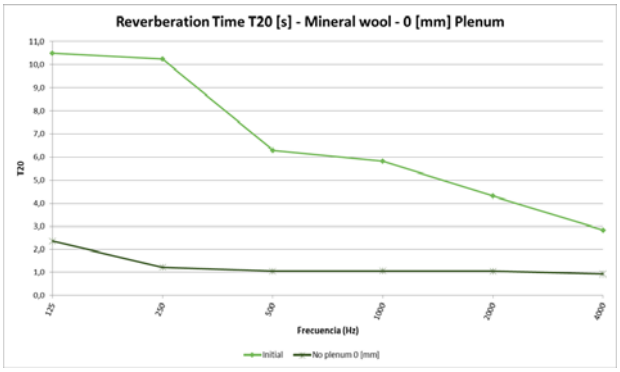

Figure 12. Reverberation time – 0 [mm] plenum.

The effect of using Material 2 in the enclosure without a plenum shows a reverberation curve with adequate values at medium and high frequencies.

The performance of material 2 at low frequencies without enclosure is better than that of material 1, reducing the reverberation time from around 10 [s] to values of 2.3 [s] for 125 Hz and 1.2 [s] for 250 Hz, reaching values of around 1.2 seconds, although still high.

At medium and high frequencies, the improvement in relation to material 1 is not so significant.

The average reverberation time obtained is slightly longer than recommended for this type of enclosure, although this difference is hardly noticeable at practical levels.

Parameter	Value
T20 mid	1,06 s
T20 125 Hz	2,3 s
T20 250 Hz	1,2 s

4.2.2 Speech intelligibility

The average speech intelligibility is rated "good". This indicates that the material has good control of the sound energy in the voice range.

Parameter	Value
STI	0.65

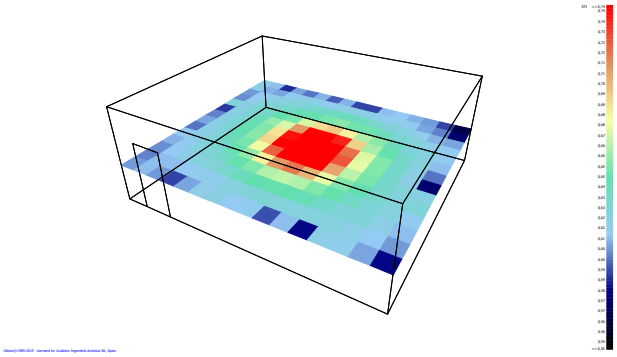

Figure 13. Speech intelligibility STI – 0 [mm] plenum.

4.3 Caracterización acústica del recinto con el material 2 instalado con plenum de 400 mm

4.3.1 Reverberation time

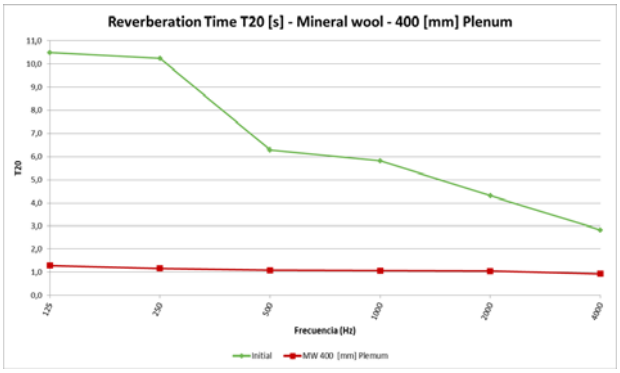

Figure 14. Reverberation time – 400 [mm] plenum.

As in the case of material 1, the reverberation time curve with a 400 mm air chamber stabilises at values close to 1 s over the whole frequency range studied, although a significant improvement can be observed in the 125 Hz band for this material.

4.3.2 Inteligibilidad de la palabra

In terms of speech intelligibility, the results are "very good".

Parameter	Value
STI	0.70

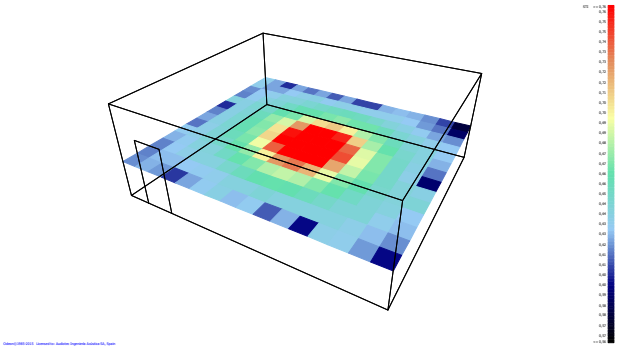

Figure 15. Speech intelligibility STI – 400 [mm] plenum.

5. COMPARATIVE ANALYSIS

5.1 Reverberation time

5.1.1 Materials installed without a plenum

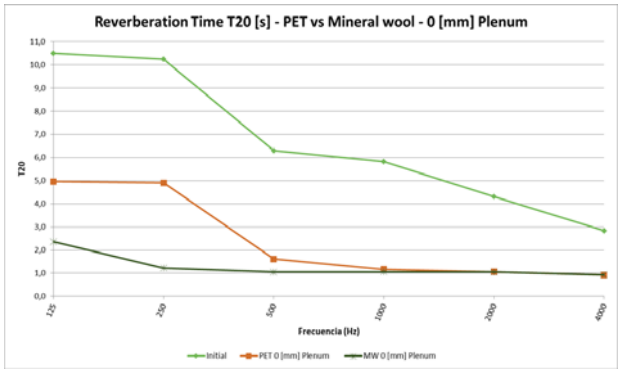

Figure 26. Reverberation time – 0 [mm] plenum comparison.

Material 2 has a better performance in the low frequency range compared to material 1 and controls the low frequency range more efficiently.

There is a slight increase in reverberation time in the 500 Hz band for material 1 at mid frequencies,

Both materials show similar behavior at high frequency, with material 2 being slightly better.

5.1.2 Materials installed with 400 mm plenum

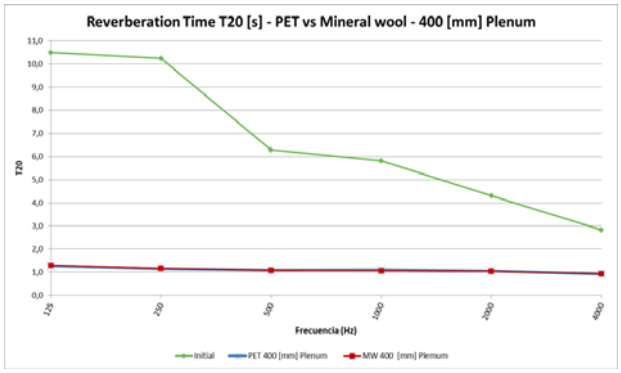

Figure 37. Reverberation time – 400 [mm] plenum comparison

The performance of the two materials with a 400 mm chamber is very similar, and in both cases the control of the low frequencies is significantly improved, while the performance in the mid and high frequencies remains stable.

5.1.3 TR mid comparison

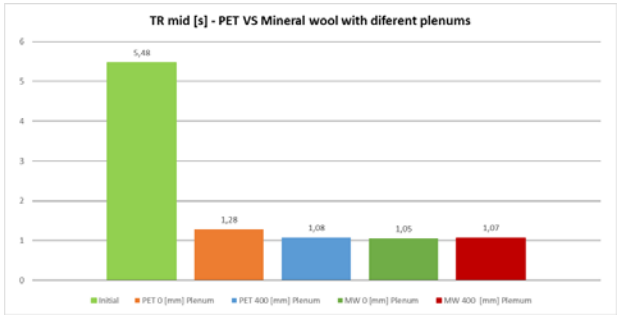

Figure 48. Trmid comparison.

As far as the average reverberation time is concerned, the placement of any sound-absorbing material improves the conditions, with material 2 showing the best performance

without an air chamber, with the most significant improvement at 125 and 250 Hz.

The reverberation time values obtained with a 400mm air chamber show hardly any perceptible differences between the different materials under consideration.

5.2 Speech intelligibility comparison

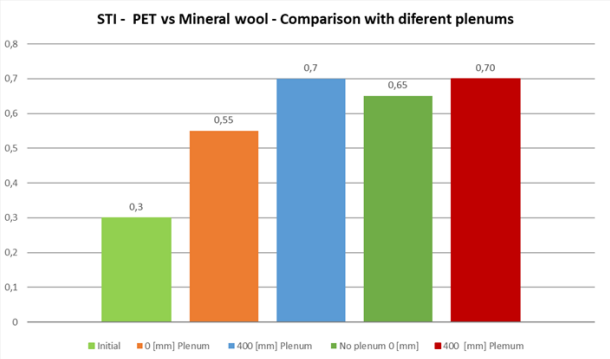

Figure 19. Speech intelligibility STI comparison

In terms of speech intelligibility, when placing the materials without air chamber, we have an improvement but insufficient with material 1.

Under the same conditions, material 2 without air chamber performs better than material 1.

The performance of both materials with 400 mm air chamber is similar, obtaining a "very good" performance.

6. CONCLUSIONS

The air chamber (plenum) is very effective in reducing low frequency reverberation (125Hz and 250Hz) for both materials, although its effect is less at medium and high frequencies than not using a plenum.

Material 2 without plenum shows a better performance at low frequencies than material 1, although this fact does not significantly affect the TRmid value, since it is calculated considering the 500 Hz, 1000 Hz and 2000 Hz bands.

The improvement in speech intelligibility without plenum is more significant with material 2, which has higher absorption results, especially at low frequencies, although the installation of a 400 mm air chamber tends to compensate for the improvement in room intelligibility.

The fact of inserting a plenum improves the speech intelligibility compared to not inserting it, although this improvement is hardly noticeable between the use of a 200 mm plenum and a 400 mm plenum.

INVESTIGATING POSITIONAL EFFECTS OF THE PERIMETER FRAME IN SOUND ABSORPTION MEASUREMENTS

Gjermund V. Holøyen[1*]
[1] SINTEF Community, Børrestuveien 3, 0373 Oslo, Norway

ABSTRACT

When measuring the sound absorption coefficient according to ISO 354:2003, the standard commonly requires the use of a reflective frame around the perimeter of the test specimen, to keep the edges from absorbing sound. Logically, this is most important at high and medium frequencies, but previous studies have shown a significant impact also at lower frequencies. At this end of the spectrum, the frame seems to have a positive effect on the measurement results – an effect that persists even when the test specimen is only partially covered by a frame. To get closer to the cause of this phenomenon, reverberation room measurements have been carried out on a partially framed test specimen. Several different configurations of a partial frame have been tested, with a view to observe whether the position of the partial frame relative to the test specimen is of any importance to the measurement results. The results from these measurements are presented and discussed in this paper.

Keywords: *sound absorption measurements, reverberation room, measurement setup, edge effects*

1. INTRODUCTION

In annex B in the standard for measuring the sound absorption coefficient in a reverberation room, ISO 354:2003, rules and guidelines for mounting of different types of sound absorbers are given [1]. Most commonly, sound absorbers are placed directly on the floor during testing, for which the standard normally requires a reflective frame to be built around the perimeter of the test specimen to keep the edges from absorbing sound. However, previous studies have shown that the presence of a frame has a significant positive impact on the measured sound absorption coefficient at the lowest frequencies [2], an impact that seems to be dependent on the placement of the test specimen and its perimeter frame in the reverberation room [3]. To look deeper into this phenomenon, further reverberation room measurements have been carried out – this time with a focus on what happens when a test specimen is only partially covered by a frame.

2. METHODOLOGY

A test specimen of 200 mm melamine foam was used in the measurements. 15 pieces of 0.6 x 1.2 m was assembled into a test object of 3 x 3.6 m. This test specimen size fully complies with the requirements for test specimen size and shape given in ISO 354 when fully framed, however, the absorptive area is larger than 12 m^2 for most of the partially framed measurements.

For the frame, 48 x 195 mm spruce wood was used. Weights were used to keep the frame in place, avoiding air spaces between the frame and the test specimen, and the frame was sealed to the floor with tape. The frame is 5 mm lower than the test specimen, but this is not expected to affect the measurement results at lower frequencies. The test specimen was placed in the room as shown in Fig. 1, and the four parts of the frame named North, South, East and West (abbreviated N, S, E and W). In total, 16 tests were carried out, covering all possible frame combinations, see Tab. 1.

The reverberation room is 8 x 6.65 x 3.76 m, which gives a volume of exactly 200 m^3. It is equipped with 14 diffusers with a total area of 42 m^2. All tests were carried out with the interrupted noise method in accordance

with ISO 354:2003, with three source positions, four microphone positions per source position and three measurements per microphone position. Ensemble averaging was used to evaluate the reverberation times with T_{20} used as evaluation range.

Finally, the results have been subject to a limited analysis in an attempt to discover any emerging patterns in the data. However, due to time and funding constraints, a deeper analysis is left for future work.

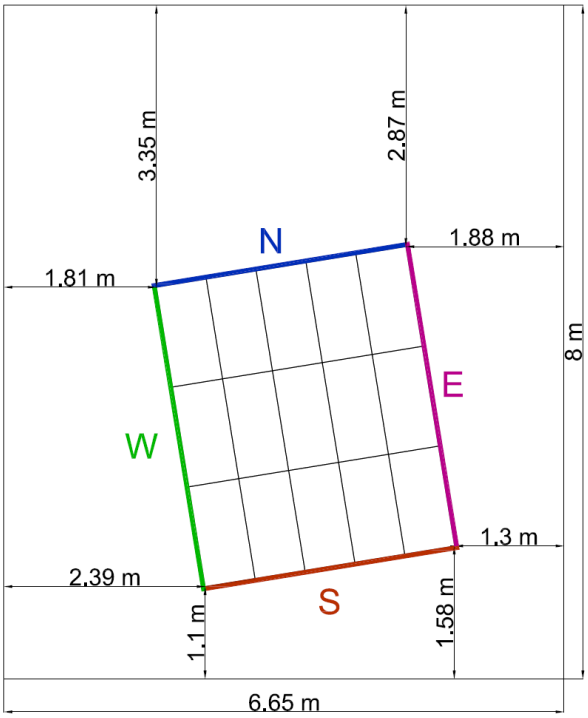

Figure 1. A horizontal view of the reverberation room, the placement of the test specimen and the names of the four parts of the frame.

3. RESULTS

All measurement results are presented, somewhat chaotically, in Fig. 2. The figure shows that between 100 and 160 Hz, the measurements with no frame and full frame act as outliers, with every other measurement inbetween the two. The standard deviation of all 16 measurements is plotted in Fig. 3. Because the low frequencies are the ones at interest, the remaining figures will be limited to the frequency range of 100–315 Hz for the sake of both author and readers.

Table 1. A list of the 16 tests, with frame configurations and exposed absorptive area.

Frame configuration	Exposed absorptive area
No frame	13.44 m^2
N	12.84 m^2
S	12.84 m^2
E	12.72 m^2
W	12.72 m^2
S+W	12.12 m^2
S+E	12.12 m^2
N+W	12.12 m^2
N+E	12.12 m^2
N+S	12.24 m^2
E+W	12.00 m^2
N+E+W	11.40 m^2
S+E+W	11.40 m^2
N+W+S	11.52 m^2
N+E+S	11.52 m^2
Full frame	10.80 m^2

In Fig. 4 the average of the measurement series with one piece of frame, two pieces of frame and three pieces of frame are plotted together with the measurements without frame and with a full frame. Then Fig. 5–Fig. 7 are showing the measurements with one piece of frame, two pieces of frame and three pieces of frame separately.

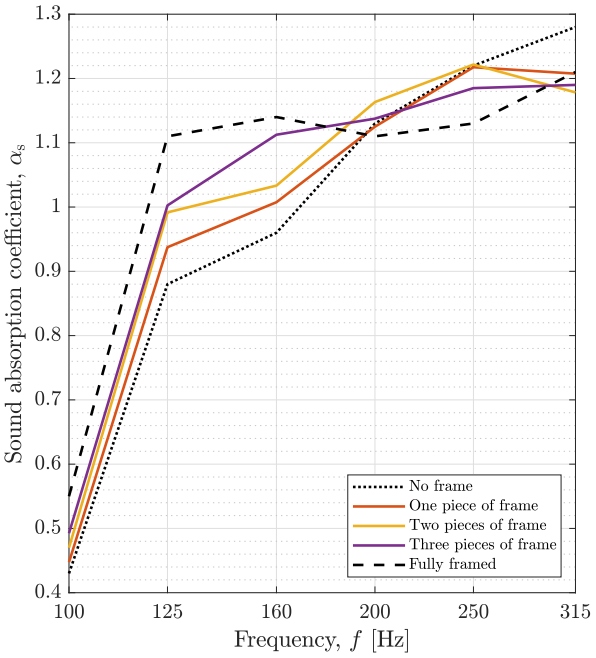

Figure 4. The average of the measurements with one, two and three pieces of frame

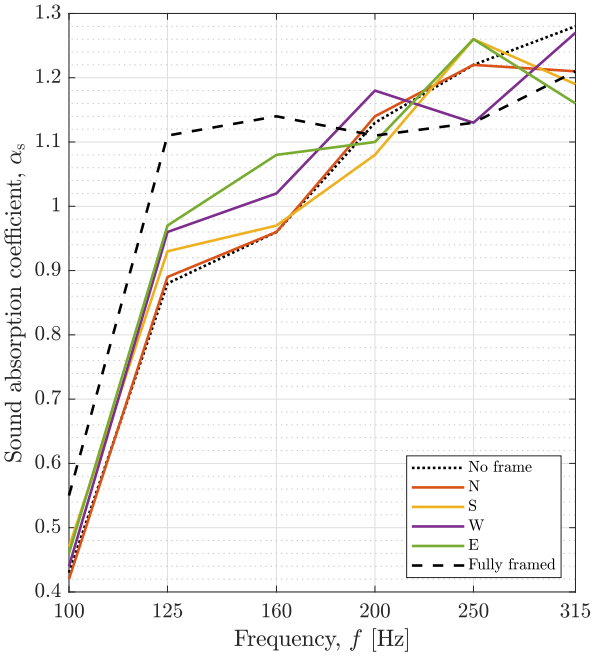

Figure 5. Measurement results with one piece of frame.

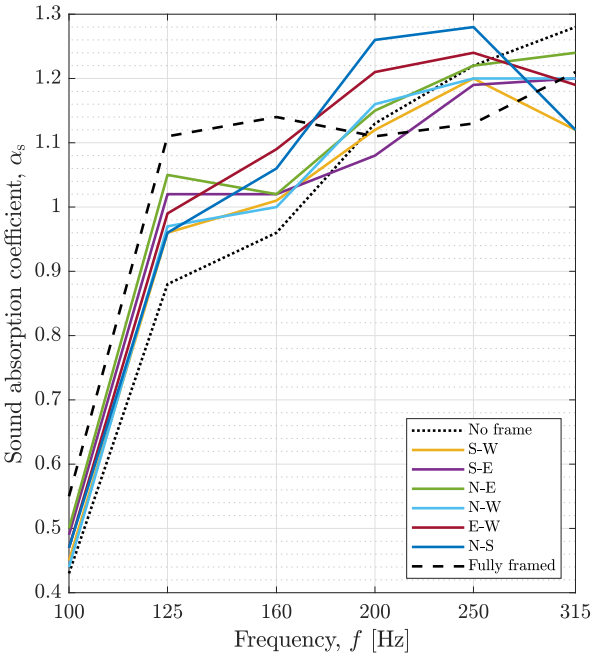

Figure 6. Measurement results with two pieces of frame.

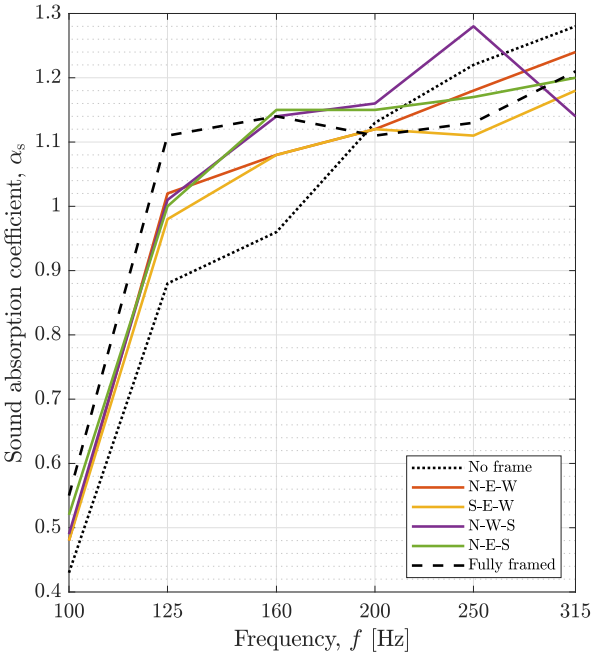

Figure 7. Measurement results with three pieces of frame.

4. DISCUSSION

The results clearly show that the frame has a positive impact on the results at lower frequencies, as seen in previous work. As shown in Fig. 4, when adding an additional piece of frame, the measured sound absorption coefficient increased at 100, 125 and 160 Hz. The difference between the measurements without a frame and with a full frame at these frequency bands were 0.12, 0.22 and 0.18 respectively, which correspond to increases of 28, 26 and 19 % from the worst to best result. At 200 Hz, the curves intersect. This is somewhat lower than in previous experiments [2, 3].

At frequencies above 160 Hz, there are also significant differences between the measurement series, but those differences are seemingly more chaotic, and the clear relationship between levels of framing and the measured sound absorption coefficient that is observed at the lowest frequencies is not observed here. In terms of positional effects, no simple relationship between the position of the frame and which frequencies are affected by its presence has been found. However, the Eastern frame seems to have a generally strong impact on the 125 Hz band, and it was present in all but one measurement series where the 125 Hz band was measured at or above 1. Similarly, it was present in all but one measurement series where the 160 Hz band was measured at or above 1.05. This will be subject to future investigation.

The far and away best result at 125 Hz was obtained with a fully framed test specimen. Similar results were seen at 100 Hz, but less dramatic, seeing as the sound absorption coefficient there were lower to begin with. At 160 Hz, however, the three pieced frame performed strongly, and two of those measurement series were on par with the fully framed one. At 200 and 250 Hz, several partial frame configurations performed better than the fully framed one.

A fascinating observation was that when averaging the results in every third octave band across a measurement series, all measurement series had an average sound absorption coefficient between 1.05 and 1.085. The standard deviation of this average was much lower than in any single third octave band. This points in the direction of randomness playing a significant part in the deviations seen above 160 Hz.

5. FURTHER WORK

The measurement data will lay the foundations for deeper investigations. There are many intriguing tendencies in the dataset, which will be interesting to look at in further detail.

6. CONCLUSION

Reverberation room measurements of sound absorption have been carried out in order to further investigate the positional effects of the frame around a test specimen. The measurement results have shown a clear positive impact from the frame at the lowest frequencies – an impact that at the three lowest third octave bands can be observed to an increasing degree as the test specimen goes from unframed via partially framed to fully framed. The highest standard deviations were found at 125 and 160 Hz, but when accounting for the lower sound absorption coefficient, the 100 Hz band is also significantly affected.

No simple relationship between frame configuration and what frequency bands are affected has been found at the time of writing, and a deeper analysis of the measurement data will be carried out in future work.

7. ACKNOWLEDGMENTS

The measurements covered in this paper has largely been carried out outside of the author's working hours. The work with the paper itself has been funded by the Construction Technology group at SINTEF Community, led by Monica Strøm Nodland. I would like to thank Monica for her support.

ABSTRACT

In most environments, the Local Plane Wave (LPW) method estimates the amplitude and phase of the incident and reflects sound waves without making assumptions regarding the global sound field. This study compares the results of standardized ISO tests and LPW tests in some practical cases of airborne sound insulation and acoustic absorption.

The first step in the validation consisted of performing laboratory measurements for all target applications in reverberant or anechoic rooms according to the corresponding ISO standards. Subsequently, the same samples were tested using the LPW method in regular non-laboratory rooms. The results of the LPW method showed reasonable agreement with the ISO results, despite the simplified test environments.

Keywords: *Local Plane Wave, Acoustic measurement, Airborne sound insulation, Sound absorption*

1. INTRODUCTION

In situ measurements of acoustic parameters are crucial for various applications, including the automotive industry and architecture. Traditionally, the determination of acoustic absorption, transmission loss, and sound power has been performed according to ISO standards in controlled laboratory environments. However, these conditions do not always accurately reflect the behavior of materials in real-world applications. Therefore, in recent years, methods have been developed to assess these parameters without prior assumptions about the global sound field.

In this context, the University of Twente and the company Soundinsight (Demcon group) have developed new techniques and devices (Sonocat) to measure the incident sound energy and, separately, the reflected sound energy in any sound field. In doing so, the Local Plane Wave (LPW) method allows the in situ absorption and emission coefficients as well as the transmission loss and radiated power to be estimated. There is no need for a predefined sound field or restrictions on the configuration of the environment [1] [2].

This study compares in situ measurements made with the LPW probe against traditional methods based on ISO standards, intending to validate the accuracy and reliability of the LPW method as an effective alternative for acoustic characterization in practical and in situ applications, which shows good correlation with laboratory-controlled and standardized tests.

2. THEORETICAL BACKGROUND

The LPW method is a novel approach for measuring sound absorption, transmission loss, and sound power in situ, without relying on the assumptions of the global

sound field. This method is particularly useful in practical applications where the sound field is complex and cannot be easily replicated in laboratory settings. The LPW method is based on the assumption that the sound field can be approximated as a combination of incoming and reflected plane waves, that is, the pressure and particle velocity in the normal direction to the surfaces of interest (absorber/partition). By measuring the sound pressure, P, and the normal particle velocity to the absorbing surface, U_n, the complex amplitudes of the incoming wave, A, and the reflected wave, B, can be determined using Eqn. (1) and Eqn. (2). [3]:

$$A = \frac{1}{2}(P + \rho_0 c_0 \overrightarrow{U} \cdot \overrightarrow{n}), \tag{1}$$

$$B = \frac{1}{2}(P - \rho_0 c_0 \overrightarrow{U} \cdot \overrightarrow{n}), \tag{2}$$

where ρ_0 is the density of the medium, c_0 is the speed of sound, and $\overrightarrow{n}$ is the normal vector, with direction pointing into the absorbing surface.

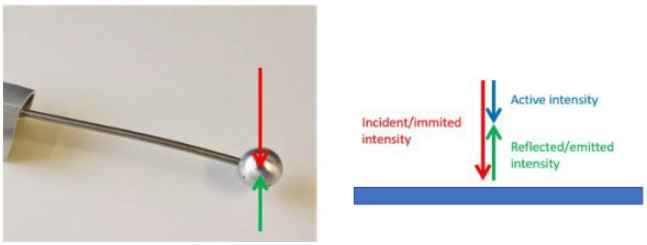

Figure 1. Diagram illustrating the incident, active, and reflected/emitted intensities in the LPW method.

The incident sound intensity I_{in} can then be calculated as in Eqn. (3):

$$I_{in} = \frac{A \cdot \overline{A}}{2 \cdot \rho_0 c_0}, \tag{3}$$

Both, the active and incident power are obtained by spatial integration of the active and incident intensity, respectively. Note that this is an essential part of the LPW method; similar to the active intensity, the incident intensity is now a local quantitative measurement in situ, where $\overline{A}$ denotes the complex conjugate of A. The absorption coefficient α is defined as the ratio of the active power P_{ac} (net acoustic power) to the incident power P_{in}, as shown in Eqn. (4):

$$\alpha = \frac{P_{ac}}{P_{in}}, \tag{4}$$

As illustrated in Figure 1, the LPW method distinguishes between an incident, active and reflected/emitted intensities, which are crucial to accurately determine the absorption coefficient and transmission loss. This distinction allows for more precise measurement of sound energy interactions with surfaces under real-world conditions.

The LPW method can also be applied to measure in situ sound transmission loss. Transmission loss (TL) is defined as the reduction in sound power when a sound passes through a partition, as in Eqn. (5):

$$TL = -10 \log_{10}(\frac{P_{tr}}{P_{in}}), \tag{5}$$

where P_{tr} is the transmitted power and P_{in} is the incident power. Using the LPW method, the incident and transmitted powers can be measured by scanning the pressure and particle velocity on both sides of the partition. This allows for the determination of transmission loss under real conditions, even when the sound field is not diffuse or anechoic [4].

Figure 2. Measurement of incident sound power, scanning the surface approximately at 3 cm of partitions, using Sonocat probe.

3. EXPERIMENTAL PROCEDURES FOR THE ACOUSTIC CHARACTERIZATION

3.1 Evaluation of airborne sound Insulation

3.1.1 Experimental setup

Airborne sound insulation was measured on a separating wall between two dwellings in a building block, following the methodology established in ISO 16283-1 [5]. A pink noise source, dodecahedron (IAG DD5), was used for the test. For data acquisition and processing following the ISO standard procedure, a 01 dB SONO 1/3 octave band analyzer and DB BATI software were used. For the alternative LPW method, the Sonocat probe was used.

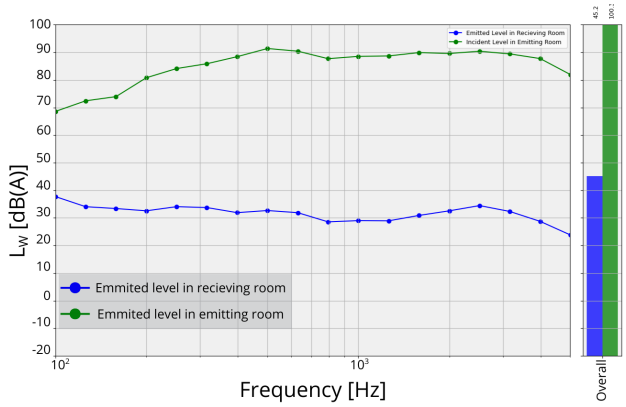

Figure 3. Incident and radiated sound power levels for the partition measured as shown in Figure 2.

3.1.2 Measurement procedure

Measurement of incident sound power. In the emitting room, a diffuse sound field was generated using a pink noise source. The incident sound power on the separation wall was measured by scanning the surface approximately 3 cm from the separating wall (partition) using a Sonocat probe.

Measurement of emitted sound power. In the receiving room, the sound power emitted by the separating partition was measured by scanning the surface again at 3 cm using a Sonocat probe.

Measurement of background noise. The background noise level was recorded by scanning the partition noise radiation in the receiving room once more, but the noise source was turned off to evaluate its influence on the measurements.

Figure 2 shows the scanning of the separating wall using a Sonocat probe. Figure 3 shows the values of the incident (sound power in the emitting room) and radiated (sound power in the receiving room) levels captured by Sonocat. Remarkably, background noise measurements were not performed using the Sonocat probe.

3.1.3 Calculation of acoustic parameters

Calculation of R' (apparent sound reduction index) The apparent sound reduction index R' was calculated in the frequency domain for all frequencies in the 1/3-octave band test range (100 Hz–5 KHz), according to ISO 16283-1, we applied Eqn. (6):

$$R' = L_1 - L_2 + 10log_{10}\left(\frac{S}{A}\right), \qquad (6)$$

where S is the area of the wall and A is the equivalent absorption area of the receiving room.

3.1.4 Comparison with the ISO 16283-1 Standard

The spectrum value of the transmission loss (*TL*) obtained experimentally using the LPW method was compared with the spectrum values obtained following the ISO 16283-1 standard. Deviations were analyzed, and potential sources of variation were discussed.

3.2 Determination of the sound absorption coefficient

3.2.1 Sample selection

The absorption coefficient, measured using the LPW method, was evaluated for various material samples. The method was compared with the absorption coefficients, as characterized by the manufacturer. These samples included several materials that are representative of applications in building acoustics. In addition, the behavior of the absorption coefficient was studied under various conditions, including different sample sizes, different sound incident angles over the sample, and different placement locations.

3.2.2 Experimental setup

An omnidirectional sound source consisting of a dodecahedral loudspeaker (IAG DD5) powered by a pink noise

amplifier (IAG DD400A) was used to measure the absorption coefficient. The experimental setup was designed not only to validate the LPW method using the Sonocat probe against manufacturer-provided data, but also to analyze the influence of sample size and placement location on the measured absorption coefficient.

3.2.3 Measurement procedure

Sample Size Variation. To study the effect of sample size on the absorption coefficient, measurements were taken using four different surface areas of the same material.

Placement configuration variation. The absorption coefficient was measured under three different conditions to analyze the influence of the placement configuration. The sample was placed directly on the floor, placed on a table, and surrounded with another absorbent material. Figure 4 shows the setup for the 45º incidence sound test.

Figure 4. Setup for the measurement of the absorption coefficient with 45º incidence sound.

Measurement with Sonocat probe. Multiple measurements were taken using a Sonocat probe, and the surface of the sample was systematically scanned to capture the necessary levels to calculate the absorption coefficient. Figure 5 shows the in situ absorption measurements for Ecophon Akusto One and Ecophon Master Eg.

Data recording. The absorption coefficient values were recorded in one-third octave frequency bands ranging from 100 Hz to 5 KHz.

Figure 5. Example of measurement setup of the sound absorption using Sonocat.

4. ANALYSIS OF RESULTS

4.1 Airborne sound insulation

4.1.1 Comparison of experimental and reference data

In Figure 6 shows the experimental direct transmission loss of the separating partition (TL), using Sonocat, compared with the in situ R' measurement (according to ISO 16283-1 standard).

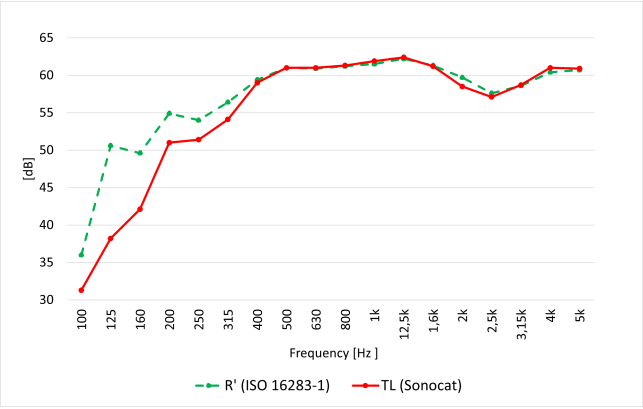

Figure 6. Comparison of TL Values using Sonocat and R' ISO 16283-1.

4.1.2 *Discussion of results*

Low Frequencies (100 Hz - 250 Hz). Deviations were observed between the experimental and reference values. These deviations can be attributed to the difficulties in generating a true or ideal diffuse sound field at low frequencies and the influence of uncontrolled flanking paths (sound transmission through adjacent structures in the wall or receiving room).

Mid and High Frequencies (250 Hz - 5000 Hz). The values calculated using the LPW method were in excellent agreement with reference values. This confirms the accuracy of the LPW method using the Sonocat probe in this frequency range.

4.1.3 *Validation of the Method*

Despite the deviations observed at low frequencies, the experimental results showed a good correlation with the theoretical values in the mid- and high-frequency ranges. This validates the methodology and confirms the usefulness of the LPW method, helping to separately analyze the radiation for different room partitions (floor, walls, and roof) to evaluate the sound insulation in practical applications.

4.1.4 *Recommendations for future studies*

To improve the accuracy of ISO measurements, it is recommended to ensure a completely diffuse sound field, especially at low frequencies. The LPW method does not rely on the diffusivity of the sound field because it directly measures the incoming sound intensity. Hence, it can also be used in non-diffused sound fields. For optimal test accuracy according to the ISO method, a perfectly diffuse sound field was required in both rooms. However, this condition is not necessary when the Sonocat method is used. Consequently, diffuse field conditions are not properly achieved in various scenarios, and variability in the sound pressure levels may occur, particularly at low frequencies. This may lead to higher values than the actual performance when the ISO standard is followed. The LPW method can also be used to evaluate the influence of flaking paths on the sound transmission. Additional measurements must be conducted at lower frequencies to better understand the reasons for these deviations.

4.2 Sound absorption coefficient

4.2.1 *Experimental validation and analysis of measurement conditions*

Behavior of the absorption coefficient in various situations:

Sample size. The area of the sample significantly influenced the measured absorption coefficient, particularly at low frequencies. The results for the different sample sizes are presented in Figure 7. We measured samples of different sizes (e.g. 2400 mm × 1200 mm and 2400 mm × 1800 mm). Analyzing the results, it is observed that if the sample is larger, the effect of the sample size decreases and converges to a value that is also measured by the laboratory ISO 354 absorption test.

Placement configuration. The placement of the samples also affected the measurements. The results for the different placement configurations (table, floor, and surrounded by another absorbent material) are summarized in Figure 8. Samples placed directly on the floor exhibited higher absorption coefficients at low frequencies than those placed on a table, likely because of the interaction with the floor surface and resonances of the table. The similarity between the sample placed on the ground and that surrounded by absorbent material proved that the Sonocat method measures the absorption coefficient of the scanned material regardless of its surroundings.

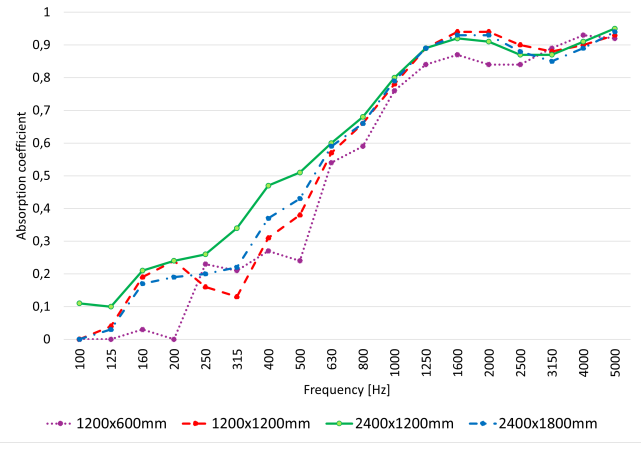

Figure 7. Values obtained by measuring a sample of Geopannel PYL of different dimensions.

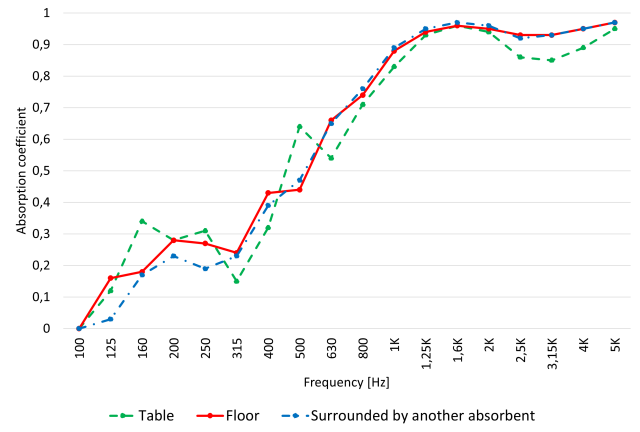

Figure 8. Values obtained by measuring a sample of Basotec G+ of different placement configuration.

Comparison with Manufacturer-Provided Data: The sound absorption coefficient (α) was measured using the Sonocat probe (LPW method) for the same material (Basotec G+) in different configurations. It was concluded that the best way to measure α, such that the LPW method closely resembles the ISO method, is to place a sufficiently large sample (in the experiments, a surface of 1200 mm x 1200 mm was used) on a surface that ensures a fixed position, such as the floor. The results were compared with the α values provided by the manufacturer, which were measured using a reverberation chamber and impedance tube according to the ISO 354 and ISO 10534-2 standards [6] [7].

4.2.2 Discussion of results

Low frequencies (100 Hz - 200 Hz). In this range, the values obtained with the Sonocat method were higher than those obtained with the impedance tube and close to those obtained with the reverberation chamber.

Mid frequencies (200 Hz - 1 KHz). In this frequency range, the values obtained were between those provided by the reverberation chamber and those obtained using an impedance tube.

High frequencies (1 KHz - 5 KHz). In this range, the Sonocat method demonstrated excellent reliability, with absorption coefficients very close to those of both the reverberation chamber and impedance tube.

4.2.3 Validation of LPW method

Currently, there are two standardized test methods for measuring the sound absorption coefficient: the reverberation chamber method and the impedance tube method. Both methods are based on different sound field assumptions (diffuse and normal incident, respectively), different calculation criteria, different sample sizes, and different test environments, the absorption coefficients are different for both methods.

As shown in Figure 9, we compared the spectrum absorption coefficients of the three methods. Sonocat led to intermediate values with respect to the values obtained in the impedance tube and those obtained in the reverberation chamber.

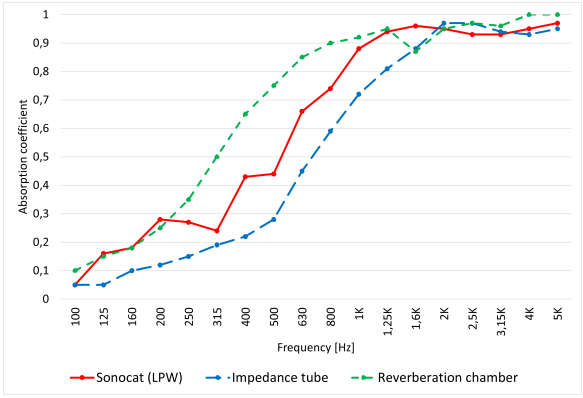

Figure 9. Comparison of α values using Sonocat (LPW method), impedance tube and reverberation chamber.

4.2.4 Recommendations for future studies

To obtain good results, it is recommended that a sample surface of at least 1200 mm x 1200 mm. Measurements should be conducted in a solid basement without radiated sounds.

To obtain results similar to those of the standard methods, future tests should consider the perpendicular incidence of sound waves. A Previous experiment, as shown in Figure 10, showed results that were closer to those in Figure 9, performed with an incidence of 45º. Therefore, it is suggested that a perpendicular sound field impinges on the surface of the sample to compare the standard's

results with those obtained using the LPW method,

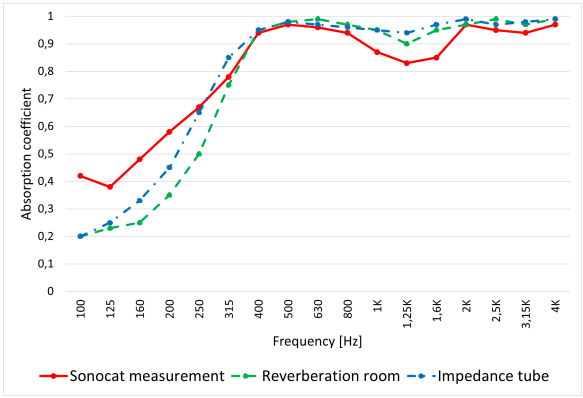

Figure 10. Comparison of α values using Sonocat (LPW method) with normal incident sound field, impedance tube and reverberation chamber.

This type of scenario occurs only when we want to evaluate the manufacturer's samples. However, this fact is not relevant when we perform in situ measurement tests; for example, when we measure complete construction solution areas, such as ceilings, walls, or floors, each covered with different absorption materials, allowing the absorption coefficient of each surface to be measured with this LPW method.

Additional applications can focus on the in situ measurement of the absorption coefficient inside a moving vehicle, where the noise source is the noise generated by the vehicle itself.

5. CONCLUSIONS

In conclusion, it is important to highlight the difference between the in situ method and the ISO method. ISO standards rely heavily on a true diffuse field; however, the reality is different, and the results depend on the diffusivity of the sound field, which we never obtain in real measurements. Therefore, we can conclude that by using the LPW method, we will obtain in situ insulation and absorption values with reliable results that can never be obtained with currently standardized methods. The LPW method is an ideal representative method for determining the acoustic behavior of materials at locations where they are installed.

6. ACKNOWLEDGMENTS

The authors express their gratitude to Juan Negreira from Ecophon (Saint Gobain Group) and Sandra Yaniz from Geopannel for their support in providing the necessary samples and information required for the various experiments conducted in this study. Their kind contributions, including material and technical insights, were relevant to the successful completion of this study.

ABSTRACT

The integration of electrical energy storage in buildings is a transformative solution for enhancing the efficiency and reliability of the power grid. By installing battery systems, households can store excess energy generated from renewable sources, such as solar panels, during periods of low demand. This stored energy can then be utilized during peak hours, reducing the strain on the grid and mitigating the risk of outages. Energy storage also promotes better utilization of renewable resources by addressing their intermittent nature, ensuring a more stable supply of green energy. A wall equipped with energy storage systems is proposed, to be installed in the external envelope; beyond structural and thermal properties analyses, not described in this research, the acoustic properties of the solution are evaluated, in comparison with an equivalent traditional light-weight wall. In more detail, the airborne sound insulation of these walls has been measured in coupled reverberating rooms, showing a certain improvement respect to light-weight walls, especially at low frequencies. A large space for improvement emerges also as one of the main results.

1. INTRODUCTION

Building walls serve structural, insulating, and protective functions, with solutions ranging from traditional masonry to prefabricated panels, dry construction systems, wood, and aerated concrete. Traditional masonry, known for its robustness and durability, is complemented by faster and more sustainable technologies such as wood, valued for its energy efficiency and sustainability. A comparison between masonry and wood highlights the ecological and seismic advantages of wood, despite higher costs and maintenance requirements. The choice fell on wooden construction due to its adaptability to various dimensions and ease of customization for integrating electrical storage.

Prefabricated wooden walls can utilize X-Lam or frame systems as load-bearing elements. The X-Lam system, made of cross-laminated solid wood panels, offers high structural strength. The frame system, lightweight yet strong, consists of wooden studs and insulation materials. Due to its configuration, the frame structure proves more suitable for integrating electrical storage modules.

Energy storage systems are essential for balancing energy production and demand, promoting the use of renewable sources, and supporting electric mobility. Commercially available devices rely on lead-acid or, more recently,

lithium-ion batteries. Lithium batteries offer advantages such as high energy density, long lifespan, and integrated management systems, but they come with higher costs and disposal challenges. A rapidly developing technology is supercapacitors, based on electrochemical double-layer principles, which provide benefits in charge/discharge cycles and versatility, though currently limited by high costs and lower specific energy.

The supercapacitor production and application sector has been expanding rapidly in recent years, particularly due to technological advancements driven by the automotive industry's interest. This has led to significant technological improvements, and increased commercialization is expected to drive down costs.

The prefabricated wall analyzed in this research has been designed using a load-bearing frame structure, with an internal stratigraphy based on the most common commercial configurations (Figure 1) to ensure broad market representation. The wooden studs are spaced at 62.5 cm intervals to accommodate the developing supercapacitor modules.

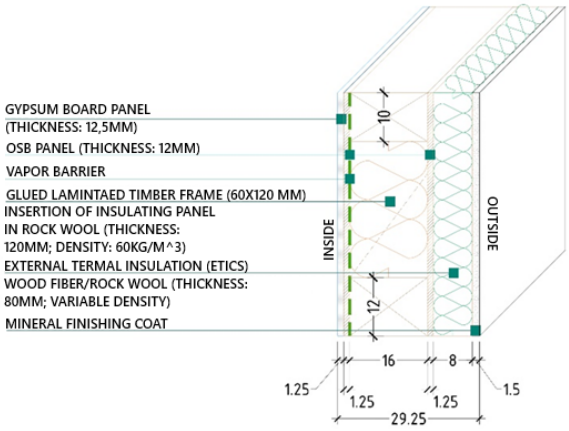

Figure 1. Typical stratigraphy of the prefabricated wooden wall.

The integration of the prefabricated wall's characteristics with the need for a modular supercapacitor system led to the development of an interlocking and lamellar system, featuring high-potential modules.

The proposed solution employs 48V supercapacitor modules with a capacity of 1050 Wh each (Figure 2). These modules are stackable up to 15 units, enabling quick and easy installation of the storage system (Figure 3). The technical specifications are listed in Table 1. Additionally, thanks to the modularity of the final design, the system can cover a wide range of applications and energy needs.

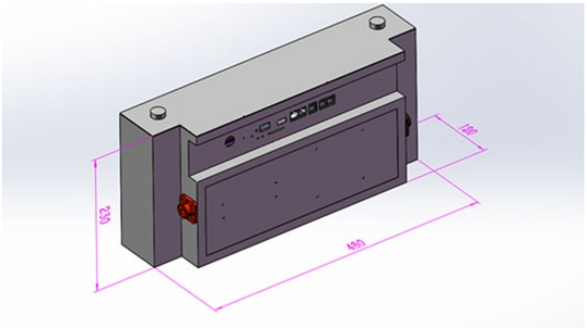

Figure 2. Draw of the storage systems.

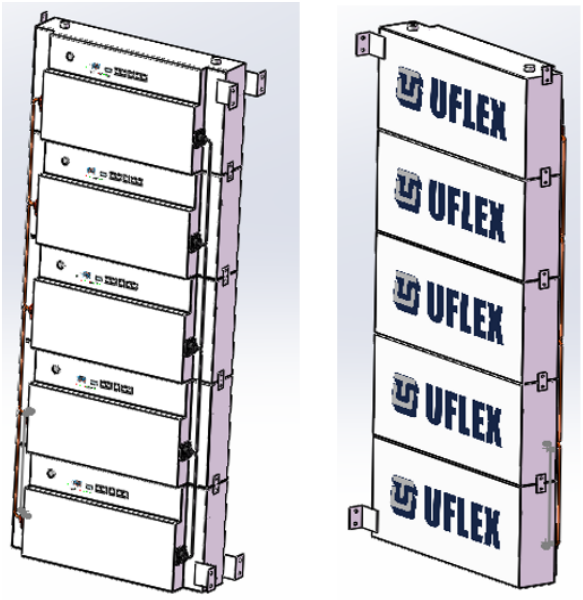

Figure 3. Storage system modules.

Characteristic	Parameter
Nominal Energy	1050 Wh (@10A)
Max Charging Voltage	58.8 VDC
Min Charging Voltage	42 VDC
Charging Current	Standard: 10A, Max: 20A
Discharging Current	Standard: 10A, Max: 20A
Operating Temperature	Charge: 0 °C ~ +60 °C Discharge: -20 °C ~ +55 °C
Life Cycles	20,000 cycles (@10A)
Storage Temperature	-20 °C ~ +45 °C
Parallel Connection	Up to 15 units
Dimensions (W x D x H)	48 x 12 x 23 cm
Weight	12 kg
IP Rating	IP30

Table 1. Supercapacitor module specifications.

The wiring system is designed to avoid occupying additional space within the wall, with the module's shape allowing cables to pass along the edges without exceeding the module's maximum footprint (Figure 4).

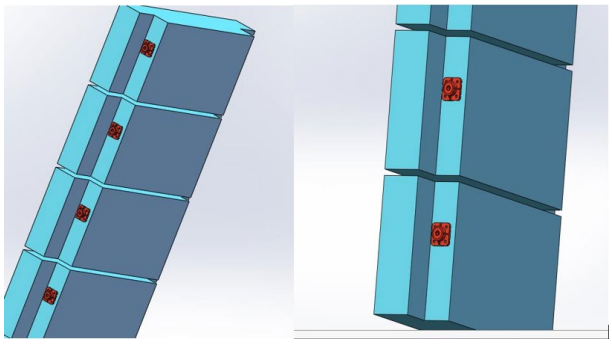

Figure 4. Electrical connection details.

2. DESCRIPTION OF THE REVERBATING ROOMS AND SAMPLE HOUSING PARTITION

The reverberating rooms of Perugia University are characterized by a test opening of the partition between the chambers, with a surface area of 10.5 m^2. Since samples of these dimensions were not available, the opening had to be adapted, reducing the sample area and trying to get as close as possible to the real assembly conditions. For this reason, it was decided to install a masonry wall, which. in the central part, was equipped with a hole where the sample being tested was installed.

It should be emphasized that the partition for housing the samples must have soundproofing properties sufficiently higher than those of the tested sample; for this reason, high mass materials were chosen.

The partition wall between the reverberation chambers was built with 2 rows of Lecablocco Fonoisolante ® elements measuring 20 cm x 20 cm x 25 cm, laid so that the length corresponds to the longest dimension, for a total thickness of 40 cm. The wall was plastered on both sides.

A value of the sound insulation index R_w equal to approximately 60 dB was estimated for this wall, significantly higher than that presumed for the samples under examination.

3. MEASUREMENTS RESULTS

Figure 5 shows the stratigraphy of the walls used for the comparison with the wall equipped with the storage system.

Figure 5. Stratigraphy of the tested walls.

Beyond an external thick coating of wood wall and cement, there is a space that hosts wood wool (or storage devices), to end with a thin inner layer of wood wall, closed with a final layer of plaster.

In figure 6, the traditional wall filled of wood wool is shown during the installation in the reverberating rooms.

Figure 6. View of the traditional sample with rock wool, before internal finishing.

Figure 7 shows the wall with the storage systems, again during the installation in the reverberating rooms.

Figure 7. View of the sample with storage devices, before internal finishing.

Figures 8 and 9 display the traditional sample during the tests both in the emitting and receiving room.

Figure 8. Sample from the emitting room.

Figure 9. Sample from the receiving room.

In figure 10, the trend of the sound insulation power with frequency is reported for both the traditional sample and the sample with the storage system.

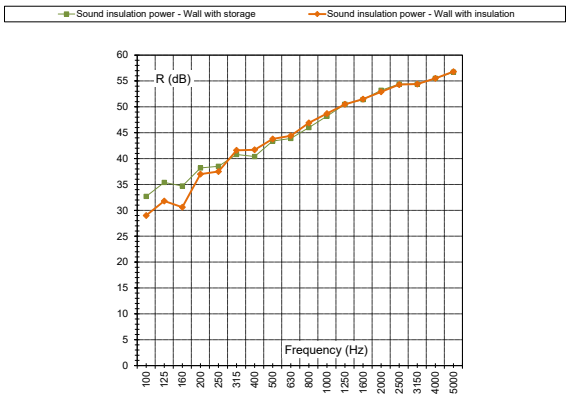

Figure 10. Comparison of the trend of the Sound insulation power R in one-third octave bands between 100 and 5000 Hz for the sample with storage systems and the traditional sample.

It is evident how the addition of mass generates an improvement in the acoustic insulation performance, especially at low frequencies, although the single-number index for airborne sound insulation R_w shows a rather limited growth, moving from 47 to 48 dB.
This circumstance is probably due to the presence of acoustic bridges that interrupt the continuity of the modules of the storage systems.
A more accurate design of the stratigraphy could lead to a more significant improvement in the sound insulation characteristics of the wall with storage systems.

4. ACKNOWLEDGMENTS

This research was funded in the Program Agreement between the Italian National Agency for New Technologies, Energy and Sustainable Economic Development (ENEA) and the Ministry of Environment and Energy Safety (MASE) for the Electric System Research, in the framework of its Implementation Plan for 2022–2024, Project 1.5 “High-efficiency buildings for the energy transition” (CUP I53C22003050001), Work Package 3 “Innovative technologies and components for increasing the energy performance of buildings”. THE LEGISLATIVE LEAP FORWARD TOWARDS REGULATING THE ACOUSTICS IN BUILDINGS IN CROATIA

Marko Horvat[1*] **Zoran Veršić**[2] **Kristian Jambrošić**[1]
[1] University of Zagreb Faculty of Electrical Engineering and Computing, Croatia
[2] University of Zagreb Faculty of Architecture, Croatia

ABSTRACT

For a long time, acoustics in buildings in Croatia has been poorly regulated in terms of appropriate legislative documents. The future of this field has been brightened by the recent development and completion of a comprehensive technical regulation on the subject matter. This document addresses the aspects of acoustics in buildings that concern room acoustics, building acoustics, and noise, providing a set of requirements for the architects and other involved experts to adhere to, thus facilitating better building design in terms of acoustics in buildings. The aim of this paper is to present the key provisions of this document that will help achieve this goal. Details will be given on the stipulated requirements on sound insulation and permitted noise levels in buildings that are considered acoustically sensitive, such as residential buildings, office buildings, buildings used for accommodation, buildings used for activities on all levels of education, and healthcare buildings. The requirements on the design for optimal room acoustics will be given for rooms used for music, speech, education, and sports, as well as requirements on room acoustics in noise-sensitive spaces focused on reducing excessive reverberance and excessive noise that stems from it.

Keywords: *technical regulation, acoustics in buildings, room acoustics, building acoustics, noise.*

1. INTRODUCTION

Acoustics in buildings is a field that has not been properly addressed during the entire existence of Croatia as a sovereign state, despite several prior attempts that have been made to improve this status quo. The latest efforts to rectify the situation have been encouraged by the European Union, stating that the Croatian regulations in this field are outdated and in need of updating. After 18 months of work, the new Technical Regulation on Acoustics in Buildings has been created. The document has passed scrutinization on all levels and is now ready to be published in the Official Gazette of the Republic of Croatia.

In [1,2] details have been given on the history of the field of acoustics in buildings in Croatia in the past 40 years, explaining the urgent need for creating a comprehensive regulation that has been lacking all these years. A description of the workflow that resulted in the creation of this document has also been given, as well as the description of its scope, and a general overview of its content.

This paper focuses on the technical requirements stipulated by the Regulation in terms of airborne and impact sound insulation, maximum permissible noise levels inside buildings, and the requirements on room acoustics (where applicable). In terms of sound insulation and noise, a detailed overview of these criteria is given for buildings that contain spaces that are deemed as noise-sensitive and must, therefore, be protected from noise. The spaces to be protected are housing units in strictly residential and mixed residential-commercial buildings, office spaces in commercial buildings, commerce spaces in shopping malls, accommodation units in hotels, dormitories, etc., spaces used for activities at all levels of education, spaces in healthcare facilities, and preschool spaces. In terms of room acoustics, the Regulation addresses spaces used for music, speech, education, and sports, for which optimal acoustics

needs to be achieved. In addition, mandatory acoustic treatment is stipulated for certain spaces that are expected to benefit from reduction of excessive reverberance and consequent noise reduction inside those spaces.

2. KEY PROVISIONS IN THE REGULATION

This Regulation is to be applied in design and construction of new buildings, reconstruction of the existing ones, and construction of simple buildings that do not require a building permit, so that the fundamental requirement that concerns the protection from noise is met in every aspect.
The technical requirements in terms of acoustics in buildings are stipulated as:

- $R'_{w,min}$ or $D_{nT,w,min}$ or $R_{w,min}$ as the minimum required value for airborne sound insulation of a building element (door, window, glass wall) or between two spaces in a building
- $L'_{n,w,max}$ as the maximum permissible value for impact sound insulation between two spaces
- $L_{R,Aeq}$ as the maximum permissible noise rating level in dwelling rooms for living and rest, work rooms, and special-purpose rooms
- $L_{AF,max,nT}$ as the maximum permissible level of service equipment noise
- T_{Soll} as the required reverberation time for spaces that require optimal room acoustic conditions
- A/V as the minimum required ratio of the equivalent absorption area and room volume for spaces that require reduction of reverberance

The airborne sound insulation of the outer shell of a building is to be designed to meet the requirements on the maximum permissible noise rating level $L_{R,Aeq}$ in the protected spaces inside the building, taking into account the most exposed spaces and the least favourable conditions during the day, evening or night. The outdoor noise level is to be obtained from (in the given order of priority) noise measurements, calculation estimates, or taken as maximum permissible outdoor noise level in the particular noise zone.
Rooms inside a building that contain service and other equipment or host activities connected with commercial exploitation are divided into three noisiness groups according to the expected, designed, or measured noise rating level $L_{R,Aeq}$:

- N1 – the noise rating level is below 70 dBA
- N2 – the noise rating level is between 70 and 80 dBA
- N3 – the noise rating level exceeds 80 dBA

These designations shall be used in the remainder of the article. In new buildings, no direct contact between N3-rated spaces and critically protected spaces is allowed, in terms of sharing a common party wall or floor.

To prove that the requirements will be met, this Regulation stipulates the use of the EN 12354 series of standards [3-7] in the design process but also allows the use of calculation methods or models (e.g. ray-tracing methods in room acoustics) that are based on verified technical solutions and/or new advancements and solutions in the fields of noise protection and room acoustics. Laboratory reports on sound insulation and sound absorption of materials and constructions may/should be used as input data for the design process.

The proof of meeting the set requirements in the design and construction process shall be obtained through measurements according to relevant standards [8-18]. The "simple acceptance" rule shall be applied. In exceptional cases, the required proof may be obtained through reports provided by all parties that partake in the building process.

3. SOUND INSULATION REQUIREMENTS

The requirements on airborne and impact sound insulation in critical types of buildings are presented in detail in Tables 1 to 7. In specific cases, $D_{nT,w}$ or R_w are used instead of R'_w.

Table 1. Sound insulation requirements for residential and residential-commercial buildings

Residential and residential-commercial use	$R'_{w,min}$ (dB)	$L'_{n,w,max}$ (dB)
Party wall between any two rooms in two housing units (within a multi storey building or in two adjacent buildings in direct contact)	52	
Party wall between dwelling rooms of a housing unit and a technical/commercial space* – N1; N2; N3***	57 62 67	
Party wall between other rooms in a housing unit and a technical/commercial space* – N1; N2; N3	52 57 62	
Party wall between a housing unit and storage rooms, entrance spaces, stairwells	52	
Party wall between a housing unit and garbage rooms, fitness, wellness, other common spaces for residents only	57	
Entrance door to the housing unit (R_w)** - with buffer space with a second door	30	
Entrance door to the housing unit (R_w)** - without buffer space	37	

Party wall with a door between a housing unit and common hallway or stairway ($D_{nT,w,min}$)	42	
Party wall between dwelling rooms of a housing unit and a single garage	55	
Party wall between dwelling rooms of a housing unit and a common garage, common garage entrance or exit	57	
Party floor between all rooms of two housing units	52	55
Party ceiling of a housing unit towards a terrace or a loggia of another housing unit		53
Party ceiling of a housing unit towards a common terrace		50
Party floor of a housing unit towards technical or commercial spaces* – N1; N2; N3***	57 62 67	58
Party ceiling of a housing unit towards technical or commercial spaces* – N1; N2; N2 fitness and sports; N3***	57 62 62 67	48 48 46 46
Party floor of a housing unit towards storage rooms, entrance spaces, stairwells	52	58
Party floor of a housing unit towards garbage rooms, fitness, wellness, other common spaces for residents only	57	58
Party ceiling of a housing unit towards storage rooms, entrance spaces, stairwells	52	48
Party ceiling of a housing unit towards garbage rooms, fitness, wellness, other common spaces for residents only	57	48
Party floor of a housing unit towards a single garage	55	58
Party floor of a housing unit towards a common garage, common garage entrance or exit	57	58
Party floor or floor on the ground of a housing unit towards another housing unit		55
Stairwells, balconies, common hallways, gallery hallways		58
Party floor or floor on the ground of commercial spaces or N2 and N3*** rooms towards a housing unit		48
Party floor or floor on the ground of an N3 room, towards housing unit (no direct contact is allowed!)		42
Outdoor entrance door to a housing unit (R_w)**	30	
Windows and balcony doors (R_w)**	30	

Notes:

*N3 rooms are not allowed in strictly residential buildings

*N3 rooms are allowed in residential-commercial buildings, but they must not be in direct contact with dwellings in the building

**R_w of a door, window, or a glass wall must be 2 dB higher than stipulated by this Regulation

***Not allowed in new buildings; allowed when reconstructing an existing N3 room in an old building, or when such room has already been designed and partially constructed

Table 2. Sound insulation requirements for office-commercial buildings

Office-commercial use	$R'_{w,min}$ **(dB)**	$L'_{n,w,max}$ **(dB)**
Party wall between two different users	52	
Wall between rooms for intellectual work within offices of a single user	44	
Wall between demanding workrooms or between a conference room and other spaces of the same user	47	
Wall between a room for intellectual work and other rooms – N1; N2 and garages; N3	47 52 57	
Wall between a room for intellectual work and communication spaces of a single user	44	
Door between a room for intellectual work and a hallway or other rooms (R_w)*	30	
Door between a demanding workroom or a conference room and a hallway or other rooms (R_w)*	32	
Glass wall between rooms for intellectual work of the same user (R_w)*	30	
Party floor/ceiling between all rooms for intellectual work and rooms of different users	52	58
Party floor of a room for intellectual work towards other rooms – N1; N2; N3	47 52 57	58
Party ceiling of a room for intellectual work towards other rooms – N1; N2; N3	47 52 57	55
Party floor or floor on the ground of service equipment rooms or N2 and N3 rooms towards dwelling rooms		48

Notes:

*R_w of a door, window, or a glass wall must be 2 dB higher than stipulated by this Regulation

Table 3. Sound insulation requirements for shopping malls

Shopping malls	$R'_{w,min}$ **(dB)**	$L'_{n,w,max}$ **(dB)**
Party wall between commerce rooms of two different users*	44	
Wall between a commerce room of a single user and other rooms – N1; N2 and garages; N3	44 47 52	
Party floor/ceiling	44	

Notes:

*The requirement is not set for commerce rooms that are open towards common areas of the shopping mall

Table 4. Sound insulation requirements for hotels, motels, dormitories and other accommodation buildings

Hotels and other types of accommodation	$R'_{w,min}$ (dB)	$L'_{n,w,max}$ (dB)
Party wall between accommodation units (four-star and five-star category)	52	
Party wall between accommodation units (other categories)	47	
Party wall with a door between connected accommodation units (four-star and five-star category) ($D_{nT,w,min}$)	52	
Party wall with a door between connected accommodation units (other categories) ($D_{nT,w,min}$)	47	
Wall between an accommodation unit and a hallway (four-star and five-star category)	52	
Wall between an accommodation unit and a hallway (other categories)	47	
Wall between an accommodation unit and other rooms – N1; N2 and garages	52 57	
Party floor/ceiling between accommodation units	52	58
Party floor of an accommodation unit towards other rooms – N1; N2 and garages	52 57	58
Party ceiling of an accommodation unit towards other rooms – N1; N2 and garages	52 57	48
Party floor or floor on the ground of service equipment rooms towards dwelling rooms		48
Entrance door to the accommodation unit (four-star and five-star category) (R_w)*	35	
Entrance door to the accommodation unit (other categories) (R_w)*	27	

Notes:

*R_w of a door, window, or a glass wall must be 2 dB higher than stipulated by this Regulation

Table 5. Sound insulation requirements for healthcare facilities

Healthcare use	$R'_{w,min}$ (dB)	$L'_{n,w,max}$ (dB)
Wall between hospital rooms	47	
Wall between hospital suites	52	
Wall between a hospital room and other rooms – N1; N2 and garages	52 57	
Wall between a hospital room and a hallway	47	
Wall between a hospital suite and a hallway	52	
Wall between an operating room and other rooms – N1; N2 and garages	52 57	
Wall between operating rooms	42	
Party floor/ceiling between accommodation units	52	58
Party floor of an accommodation unit towards other rooms – N1; N2 and garages	52 57	58
Party ceiling of an accommodation unit towards other rooms – N1; N2 and garages	52 57	48
Party floor or floor on the ground of service equipment rooms towards dwelling rooms		48
Entrance door to the accommodation unit (four-star and five-star category) (R_w)*	35	
Entrance door to the accommodation unit (other categories) (R_w)*	27	

Notes:

N3 rooms must not be in direct contact with hospital rooms/suites

*R_w of a door, window, or a glass wall must be 2 dB higher than stipulated by this Regulation

Table 6. Sound insulation requirements for educational facilities (elementary, middle and higher education; other education)

Educational use	$R'_{w,min}$ (dB)	$L'_{n,w,max}$ (dB)
Wall between classrooms and/or teachers' cabinets	52	
Wall between classrooms, teachers' cabinets or libraries and (class)rooms for physical, technical, or musical education	60	
Wall between classrooms or teacher's cabinets and communication spaces (hallways, stairwells, galleries, etc.) in schools	52 49	
Wall between classrooms or teacher's cabinets and communication spaces (hallways, stairwells, galleries, etc.) in higher education institutions	52	
Wall between a library and communication spaces (hallways, stairwells, galleries, etc.)	52	
Wall between classrooms, teachers' cabinets or libraries and other rooms – N1; N2 and garages, multipurpose spaces, mess halls, sports or multipurpose halls	52 60	
Party floor of classrooms, teachers' cabinets, libraries and communication spaces above – N1 and classrooms and teachers' cabinets; N2 and garages, sports or multipurpose halls, mess halls, and (class)rooms for physical, technical and musical education	52 60	48 58
Party ceiling of classrooms, teachers' cabinets, libraries and communication spaces above – N1 and classrooms and teachers' cabinets; N2 and garages, sports or multipurpose halls, mess halls, and (class)rooms for physical, technical and musical education	52 60	48 46
Party floor or floor on the ground of service equipment rooms, towards dwelling room		48
Other party floors/ceilings towards dwelling rooms	52	48
Door between a classroom and a teacher's cabinet (R_w)*	32	
Door and/or a transom between classrooms, teachers' cabinets or libraries and hallways or other	37	

rooms (R_w)*	
Door to a sports or multipurpose hall (R_w)*	35
Door to a technical room or a service equipment room (R_w)*	37
Wall with a door of a sports or multipurpose hall ($D_{nT,w,min}$)	45
Wall with a door of a technical room or a service equipment room ($D_{nT,w,min}$)	45

Notes:
N3 rooms must not be in direct contact with dwelling rooms
*R_w of a door, window, or a glass wall must be 2 dB higher than stipulated by this Regulation

Table 7. Sound insulation requirements for preschool facilities

Preschool use	$R'_{w,min}$ **(dB)**	$L'_{n,w,max}$ **(dB)**
Wall between rooms for daily dwelling of children and communication spaces or other units	52	
Wall between rooms for daily dwelling of children and other rooms – N1; N2 and garages; N3***	52 60 65	
Party floor of rooms for daily dwelling of children, offices, dwelling rooms, and communication spaces above – N1, rooms for daily dwelling of children or offices; N2, garages, sports or multipurpose halls, and mess halls; N3***	52 60 65	48
Party ceiling of rooms for daily dwelling of children, offices, dwelling rooms, and communication spaces below – N1, rooms for daily dwelling of children or offices; N2, garages, sports or multipurpose halls, and mess halls; N3***	52 60 65	48 46 46
Party floor or floor on the ground of service equipment rooms, towards dwelling room		48
Other party floors/ceilings towards dwelling rooms	52	48
Door to a sports or multipurpose hall (R_w)*	35	
Door to a technical room or a service equipment room (R_w)*	37	
Wall with a door of a sports or multipurpose hall ($D_{nT,w,min}$)	45	
Wall with a door of a technical room or a service equipment room ($D_{nT,w,min}$)	45	

Notes:
N3 rooms must not be in direct contact with dwelling rooms
*R_w of a door, window, or a glass wall must be 2 dB higher than stipulated by this Regulation
***Not allowed in new buildings; allowed when reconstructing an existing N3 room in an old building, or when such room has already been designed and partially constructed

Specific additional provisions stipulate that no requirement is set on the impact sound insulation for the fire escape stairwell if a non-residential building has an elevator. Furthermore, common garages are classified as N2 spaces. Rooms used by the hospitality industry or craftsmen, as well as rooms used for games and fun (movie theatres, game rooms, etc.) are classified as N3 spaces by default, regardless of the predicted or measured A-weighted noise rating level $L_{R,Aeq}$. Engine rooms, technical rooms, and service equipment rooms are also classified as N3 by default, regardless of the predicted or measured A-weighted noise rating level $L_{R,Aeq}$. Finally, the requirements set for impact sound insulation as $L'_{n,w,max}$ are valid for all possible directions of sound propagation.

4. NOISE REQUIREMENTS

The requirements regarding the maximum permissible noise levels in critically protected spaces are given in detail in Tables 8 to 11.

Table 8. Maximum permissible noise rating levels in dwelling spaces used for rest and living

Room type	$L_{R,Aeq,max}$ **(dBA)**		
	day	***evening***	***night***
Dwelling rooms in a housing unit	35	35	30
Dwelling rooms in accommodation units in community housing buildings	35	35	30
Dwelling rooms in accommodation units in buildings used for accommodation or in other buildings	35	35	30
Hospital rooms in healthcare facilities (not including the noise of medical equipment)	30	30	30

Table 9. Maximum permissible noise rating levels in workplace spaces

Room type	$L_{R,Aeq,max}$ **(dBA)**
Doctor's offices, infirmaries, operation rooms, etc.	35
Classrooms, lecture rooms, teachers' and study cabinets, libraries, reading rooms, offices for focused intellectual work, laboratory facilities, etc.	35
Dwelling rooms for children in kindergartens and nurseries, multipurpose halls and mess halls, sports halls in schools and kindergartens	40
Offices, meeting rooms, conference rooms	40

Table 10. Maximum permissible noise rating levels in special-purpose spaces

Room type	$L_{R,Aeq,max}$ (dBA)
Concert halls, theatres, etc.	25
Movie theatres, reading rooms, exhibition rooms	35

Note: The requirement is valid with the electroacoustic equipment switched on, but not reproducing sound.

Table 11. Maximum permissible levels of service equipment noise or noise originating in other spaces, in dwelling spaces

Room type	$L_{AF,max,nT}$ (dBA)	
	Stationary or intermittent noise	Short-term or fluctuating noise
Dwelling rooms in housing units	30	35
Dwelling rooms in accommodation units in buildings used for accommodation or in other buildings	30	35
Dwelling rooms in accommodation units in community housing buildings	30	35
Hospital rooms in healthcare facilities (not including the noise of medical equipment)	30	35
Doctor's offices, infirmaries, operation rooms, etc.	35	40
Classrooms, lecture rooms, teachers' and study cabinets, libraries, reading rooms, offices for focused intellectual work, laboratory facilities, etc.	35	40
Dwelling rooms for children in kindergartens and nurseries,	35	40
Offices, meeting rooms, conference rooms, multipurpose halls and mess halls, sports halls in schools and kindergartens	40	45

Additional provisions stipulate that sound insulation of building parts must be designed to ensure that the requirements given in Tables 8 to 11 are met. The noise rating levels given in these tables are set for fully furnished rooms. The levels of noise in dwelling rooms, coming from service equipment or from other rooms, must not exceed maximum permissible noise levels set in Table 11. Maximum permissible noise levels $L_{AF,max,nT}$ are normalized taking into account the actual reverberation time in the room.

5. ROOM ACOUSTICS REQUIREMENTS

The room acoustics requirements stipulated in this Regulation are based on the HRN DIN 18041:2024 standard [19]. As opposed to sound insulation and noise requirements which are given directly as fixed values, the room acoustics requirements are given implicitly, and the required values need to be calculated based on the size and the type of the room for which they are to be defined. All spaces for which the room acoustics requirements are set in this Regulation are divided into type A and type B.

Type A is further divided into five categories, named and marked as "Music" (A1) "Speech / lecture" (A2), "Education / communication" and "Speech / lecture (inclusive)" (A3), "Education / communication" (inclusive)" (A4), and "Sports" (A5). The technical requirement set on type A rooms is the required reverberation time T_{Soll}, calculated from the room volume V according to the category of the given room. The Regulation provides a general description of each category, and the actual categorization is to be made using the HRN DIN 18041 standard. Figure 1 shows a graphic display of the required reverberation time T_{Soll} depending on the category and the size of type A rooms.

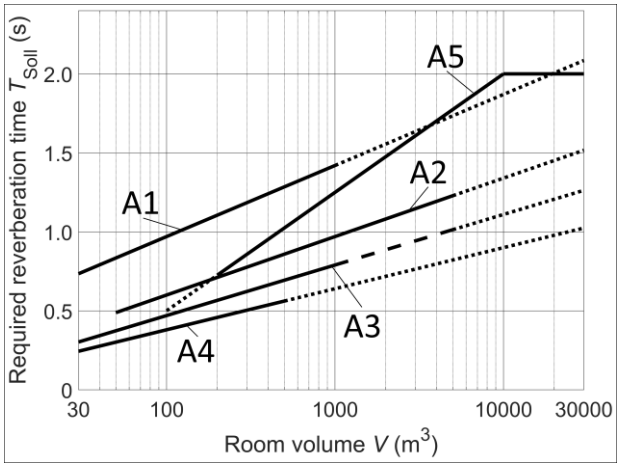

Figure 1. The required reverberation time T_{Soll} for type A rooms, depending on size (room volume) and the category (A1 to A5) of the room.

The obtained value of T_{Soll} is the one the architect/engineer should strive to obtain by designing appropriate acoustic treatment of a room. The tolerances within which the reverberation time T obtained by design should fall are

shown in Figure 2 as values normalized to the required reverberation time T_{Soll}.

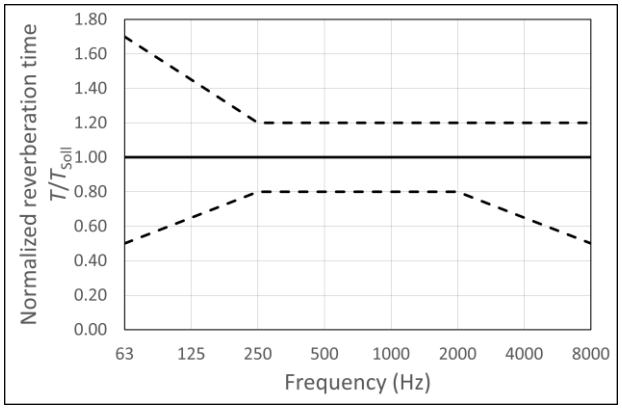

Figure 2. The tolerances of the required reverberation time T_{Soll} in type A rooms.

Type B spaces are defined as the ones that require some sort of acoustic treatment to prevent excessive reverberance. Although the HRN DIN 18041 standard lists the requirements for this type of spaces purely as recommendations, this Regulation stipulates them as mandatory for the following spaces: common rooms in kindergartens and nurseries, teaching cabinets; multipurpose spaces in kindergartens, nurseries, elementary and middle schools; teacher lounges; sports halls in schools; libraries; hallways in front of classrooms and lecture rooms; common hospital rooms; hospital hallways and waiting rooms; open-plan offices and call centres; administrative spaces in which multiple clients are handled simultaneously; entrance halls in public and other buildings (schools, hotels, train stations, airports, etc.). The spaces are categorized into categories B1 to B5 according to the HRN DIN 18041 standard. The technical requirement set on type B rooms is the minimal required ratio *A/V* of the equivalent absorption area *A* and room volume *V*, according to the category of the given room and the ceiling height *h* of the room. No requirement is set for category B1. The illustration of the requirements set for categories B2 to B5 is shown in Figure 3. The minimal required values of the *A/V* ratio are fixed for each category for ceiling heights up to 2.5 metres, and they continuously decrease with the ceiling height increasing above that threshold value.

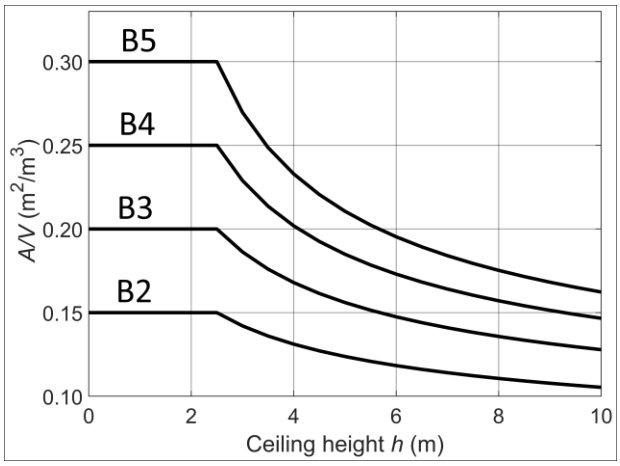

Figure 3. The minimum required value of the ratio *A/V* of the equivalent absorption area *A* and room volume *V* for type B spaces (categories B2 to B5), depending on ceiling height *h* and the category of the room.

6. CONCLUSION

The new Technical Regulation on Acoustics in Buildings that is now awaiting official publication represents a big legislative leap forward towards regulating this particular field in Croatia, after decades of neglect. Prior publications have given an overview of this document, its scope and content, the historical and technical reasons for its creation, and a description of the efforts and the employed workflow that was required to achieve this goal. This technical regulation contains comprehensive information for all who participate in the building process, in terms of the set requirements that need to be met, the methods to be used in the design process for the purpose of meeting the set requirements, and the methods of checking and verifying that the design values have indeed been achieved. For the first time, all the key factors of acoustics in buildings have been addressed in a single document.

This paper has provided key provisions of this Regulation that will facilitate correct building design in terms of acoustic comfort. A detailed overview of the technical requirements stipulated in this document has been given as well, in terms of airborne and impact sound insulation between rooms in critically sensitive buildings, permitted noise levels, and optimal room acoustics conditions depending on the use of a room/space.

The authors hope that the application of this Regulation will improve acoustic design of buildings in Croatia.

7. ACKNOWLEDGMENTS

The authors wish to thank the members of the expert committee engaged in creating this Technical Regulation, as follows: Dunja Magaš, Damir Borović, Slavica Radić-Vuković, Lejla Ahmetašević, and Jelena Svibovec of the Ministry of Physical Planning, Construction and State Assets; Bojan Milovanović of the Faculty of Civil Engineering in Zagreb; Mateo Biluš of the Croatian Chamber of Architects; Hrvoje Damić of the Croatian Chamber of Civil Engineers; Miljenko Henich of the Croatian Standards Institute; and Neno Torić of the Faculty of Civil Engineering, Architecture and Geodesy in Split.

FORUM ACUSTICUM EURONOISE 2025

REVISING A NATIONAL STANDARD ON RESIDENTIAL ACOUSTIC DESIGN: SCIENCE, EMBEDDED PRACTICES, HEARTS AND MINDS

Benjamin Fenech[1*] **Jack Harvie-Clark**[2]
[1] Noise and Public Health, Radiation Chemical Climate and Environmental Hazards, UK Health Security Agency (UKHSA), London, UK
[2] Apex Acoustics, Gateshead, UK

ABSTRACT

In 2024, Harvie-Clark and Fenech published a set of proposals for updating a British Standard widely used for its residential acoustic design guidance. The proposals suggested a shift from the current approach targeting fixed averaged internal sound levels, irrespective of the sound source. The proposals put stronger emphasis on external sound levels, by assigning facades into sound exposure categories (SEC), informed by the synthesis of epidemiological evidence gathered over the past two decades. The building envelope is then designed with equivalent levels of sound insulation corresponding to equivalent adverse effects from noise, and a holistic consideration of indoor environmental quality. The proposals were accompanied by an extensive programme of dissemination events in the UK. This paper gives an overview of the feedback gathered from these events - with a particular focus on the aspects that were least and most contentious. Some of the areas covered include: differences between the WHO 1999 vs 2018 Guidelines, the relevance of external sound levels to population health, the additional value and underpinning evidence associated with criteria for noise events, specifying a facade acoustic performance vs internal levels, and setting criteria for noise sources other than transport.

Keywords: residential acoustic design, national standards, acoustic regulations.

1. INTRODUCTION

The British Standard BS 8233 "Guidance on sound insulation and noise reduction for buildings," [1] provides guidance for the control of noise in and around buildings. It is applicable to the design of new buildings, or refurbished buildings undergoing a change of use within the UK. In this paper we are focusing on the requirements relevant to the acoustic design of new residential development. The standard was last updated in 2014 and is currently undergoing a revision. In 2024, Harvie-Clark and Fenech [2] published proposals that aimed to align the acoustic criteria for residential development with the body of evidence that has been published in the last two decades, including the 2018 WHO Environmental Noise Guidelines for the European region [3]. In brief, the proposals:

a) Introduced the concept of noise source-specific "Sound Exposure Categories", defined by the external sound levels corresponding to specific health outcomes (i.e. percentage of population highly annoyed or highly sleep disturbed);
b) Specified target internal conditions in terms of a facade sound insulation performance, with an equivalent performance requirement for equivalent source-dependent health burden; and
c) Suggested guidance whether opening windows can be used to mitigate overheating, depending on the corresponding Sound Exposure Category.

The rationale for point (a) is the strengthening epidemiological evidence showing that the adverse health risk increases with external sound level, and the availability of exposure response relationships allows the increased risk above a certain threshold to be quantified. The rationale for point (b) is that for a given long-term averaged sound level, aircraft and railway noise are more annoying and sleep disturbing than road traffic noise - this could be partly

explained by the higher instantaneous sound levels during aircraft flyovers and train pass-bys for typical exposure situations. The rationale for point (c) is to emphasize the need for a holistic design of a healthy indoor environment that takes into account safe temperatures, noting the increased risk of overheating from a changing climate[1].

To encourage debate on these proposals, Harvie-Clark and Fenech participated in an extensive programme of dissemination events between September 2024 and March 2025, both in-person and online, targeting members of relevant professional and trade bodies in the UK (Institute of Acoustics (IOA), the Association of Noise Consultants (ANC) and the Chartered Institute of Environmental Health (CIEH)). These events sparked strong interest[2] and a very active debate, with practitioners expressing a broad range of views. In general, there was good agreement with the underpinning principles of the proposed changes during these events (see Annex A). However the discourse outside the events was largely shaped by those that had strong opposing views, which even led to requests for stopping the proposals from going out for a public consultation. In this paper, we present some of the salient points from the debate that has taken place to date.

2. RELEVANCE OF OUTDOOR VS INDOOR SOUND LEVELS TO PUBLIC HEALTH

A letter to the editor [5] published in a bimonthly magazine of the Institute of Acoustics, signed by 33 experienced acousticians, raised important questions about the proposed approach to include external noise levels as key design criteria. Their concern can be summarised by the following extract from the letter [5]:

"To align with public health research the proposal is to assess and control noise exposure via the external sound levels, under the mistaken assumption that this alignment with the evidence base justifies a departure from controlling internal levels.

I don't think anyone has ever actually suggested that the community health impacts from environmental sound on residents in buildings is predicated more on the noise levels outside the buildings in which they are exposed than those they experience internally. It is just much more difficult to do large scale studies on actual internal levels in comparison with the convenience of large-scale noise mapping. Hence all the recent studies refer to external levels as a proxy.

By definition, a proxy is not the parameter we are trying to control to the benefit of residents to deliver suitable internal living conditions. It's like trying to drive a car looking only at the sat-nav screen! This lack of precision – the failure to target the parameter itself rather than the more convenient proxy is uniquely problematic in relation to exposure of individuals to environmental sound."

Similar arguments were made in a position statement published on the website of the Chartered Institute of Environmental Health [6], where it was argued that:

"If we are interested in the design of new homes to provide good or reasonable living conditions indoors then we need to identify the best evidence that relates to internal noise conditions."

Harvie-Clark and Fenech published a response to these points [7]. The response drew on three fundamental concepts that have defined noise and health theory for many decades:

i. Noise is a psychosocial stressor, i.e. '*an environmental factor interacting with social and cultural factors to influence the mind and behaviour*' [8]. Within this framework, noise exposure 'at home' is not limited to the sound levels inside the physical space enclosed within a building envelope. It also covers any outdoor spaces that residents consider part of their home. This is also consistent with how the international standard for measuring noise annoyance [9] defines the wording 'at home' to capture inside the home or outdoors at home, including balconies, gardens, etc.

ii. The mechanistic evidence on the relationship between chronic noise exposure and chronic health outcomes supports a direct pathway and an indirect pathway [3,10]. The indirect (psychological) pathway is mediated by cognitive and emotional responses to the personal experience of the noise, which is not limited to the sound levels experienced when inside the home.

[1] For example, a report by the Climate Change Committee [4] notes that "*Increases in temperature have been linked with an increase in the death rate (particularly amongst older people) across the UK, including in recent heatwaves in every year from 2018 to 2021. Recent estimates suggest that around a fifth of homes in the UK are already overheating in summers today*" and "*Climate projections suggest that a 'hot' summer such as 2018 will become the average summer by 2050, even with deep cuts in global greenhouse gas emissions. The combination of increasing hot weather, and an ageing population, means that heat-related deaths may treble without further adaptation actions.*"

[2] One lunchtime webinar organized specifically for introducing the proposals hit the participants limit of the IOA's Zoom account (500) and was one of the most attended IOA event in its history.

iii. A dwelling is not just a physical structure – it represents a place where people call home [11]. The places where people live have a significant impact on their mental and physical health [12]. When residents feel a deep connection to their place of residence, they are more likely to be satisfied with their living conditions. This relationship is influenced by various factors, including the quality of the physical environment, social interactions and the availability of amenities. Noise has been shown to interact with some of these factors [13, 14]. Socio-acoustic studies from Norway found that the noise levels in the immediate neighbourhood of a home can affect residential noise annoyance, with a similar effect on both outdoor and indoor noise annoyance [15].

To support these theoretical concepts, Fenech and Harvie-Clark drew on evidence from two studies in Sweden [16, 17] that investigated the influence of the external sound environment on disturbances inside the dwelling. For example, in [17], for the same internal averaged noise levels, disturbances to communication, listening to TV/radio, concentration and relaxation were consistently higher with high external levels (windows closed) than with a quieter external environment (windows open). Similar observations were made for sleep disturbance. Other studies on noise annoyance investigated differences between outdoor and indoor annoyance (see for example [18]) and indoor annoyance with windows open and closed (see for example [19]). These studies show that both outdoor annoyance, and indoor annoyance with windows open are important contributors to the overall annoyance reactions and therefore support the relevance of both the external and internal sound exposure at home.

3. RELEVANCE OF WHO ENVIRONMENTAL NOISE GUIDELINES (2018) FOR RESIDENTIAL ACOUSTIC DESIGN

The CIEH statement included the following arguments [6]:
"*The recommendations made in the WHO Community Noise Guidelines were derived using evidence relevant to internal noise conditions, including interference with communication and sleep disturbance effects. It was recognised that the maximum noise level was best correlated with effects on sleep and that is the reason why the recommendations for the protection of sleep inside dwellings included the 45 dB L_{Amax} criterion. In 2018 the WHO reviewed the available scientific evidence and published the Environmental Noise Guidelines European Region 2018* [ENG2018]. *It concluded that:*
"The current environmental noise guidelines for the European Region supersede the CNG [1999 WHO guidelines for community noise] from 1999. Nevertheless, the GDG [Guideline Development Group] recommends that all 1999 CNG ***indoor guideline values*** *and any values not covered by the current guidelines (such as industrial noise and shopping areas)* ***should remain valid****." (Our emphasis)."*
The CIEH statement went on to suggest that the proposals by Harvie-Clark and Fenech departed from WHO recommendations. The statement did not mention that the ENG2018 explicitly state that "*The* [2018] *guidelines are source specific and not environment specific. They therefore cover all settings where people spend a significant portion of their time, such as residences …*". The CIEH statement also did not mention that the 1999 CNG [20] guideline values for residential settings were expressed as both external and internal levels.
In response, Fenech and Stansfeld [21] published an article to clarify the relationship between the WHO 1999 CNG and ENG2018. In summary, Fenech and Stansfeld argue:
"When referring to WHO guidelines to set criteria for residential settings (dwellings) exposed to transport noise, the main reference should be to the WHO Environmental Noise Guidelines for the European Region (ENG2018), because they are the most up-to-date guidelines. Additional consideration can be given to the indoor guideline values in the Guidelines for Community Noise [CNG (1999)], but only if this is done in conjunction with the external guidelines in the ENG2018 and taking into account the source-specific characteristics of the sound (e.g. intermittency, low frequency content, etc). In writing the ENG2018 it was clear that the indoor guidelines from the CNG (1999) could not and should not be quoted or used in isolation."

4. CAN HIGH FAÇADE SOUND INSULATION PERFORMANCE LEAD TO "COMPROMISED LIVING CONDITIONS"?

The letter to the editor by Clarke and Fiumicelli [5] appeared to suggest that up to a certain level, transport noise ingress in buildings with windows closed can have beneficial health effects:
"*If, for example, rather than achieving internal conditions at night of 30dB $L_{Aeq,8hr}$ with L_{max} levels in the low 40s in two apartment buildings, we get one building with 20 $L_{Aeq,8hr}$ (L_{max} in the low 30s) and one building at 40 $L_{Aeq,8hr}$*

(L_{max} in the low 50s) then BOTH sets of residents have dramatically compromised living conditions, due to annoyance and sleep disturbance in the under-attenuated case and high levels of neighbour noise disturbance in the over-attenuated building."

The CIEH statement [6] also included the following statement:

"The proposed revisions to BS8233 place too much emphasis on façade insulation and overheating. This appears to be fundamentally at odds with the guidance contained in the ProPG[3]".

To our knowledge, there is no robust scientific evidence demonstrating that lower internal sound levels due to higher façade sound insulation leads to 'dramatically compromised living conditions' or increased neighbour noise disturbance. While anecdotal reports of increased sensitivity to neighbour noise in quieter environments exist, these have not been substantiated by systematic studies. It is not clear how noise from discrete car/train pass-bys or aircraft flyovers that averages to an internal level of 30dB $L_{Aeq,8hr}$ can be effective at reducing disturbance from an unpredictable and intermittent source such as neighbour noise. External anthropogenic noise ingress with windows closed should not be relied on as a sound source contributing to a positive internal soundscape in homes, because it is completely out of the control of the building occupant. Research by Torresin et al [22] demonstrated the importance of control over one's environment to achieve an ideal indoor soundscape for work and relaxation. We argue that neighbour noise disturbance should be managed by appropriate levels of sound insulation between dwellings and, if acoustic masking is necessary, this should be achieved by sources of sound that are under the full control of the building occupants.

5. THE ROLE OF MAXIMUM SOUND LEVELS IN RESIDENTIAL ACOUSTIC DESIGN

A common argument that came up at several engagement events and was noted in the CIEH statement [6], was the lack of L_{max} criteria in our original proposals, and the perceived lack of protection for sleep disturbance because of this omission.

There is clear evidence that L_{max} correlates better with short-term noise-induced physiological sleep disturbances than long-term averaged noise metrics [24]. However the relationship between single-event noise indicators and long-term health outcomes at the population level remains tentative [3]. Simplistic criteria, such as indoor sound pressure levels not to exceed approximately 45 dB L_{Amax} more than 10–15 times per night, are based on studies from the 1970s-80s [20], and such criteria can be expressed in terms of an energy equivalent level such as $L_{Aeq,8hr}$ [20]. Basner et al. [23] proposed a physiological noise effects criterion for the protection against adverse effects of nocturnal aircraft noise. Applying this criterion requires detailed knowledge of all the noise events and their respective L_{max} throughout the night. Such an approach would be feasible and appropriate to inform decisions on changes around transport hubs such as airports (e.g. new runway, airspace changes or changes to night flights), given that aircraft noise modelling software can predict L_{max} data. However, applying this approach to new residential acoustic design would require comprehensive new guidance on how to obtain representative internal L_{max} distributions throughout the entire night period[4]. Instead, our proposals [2] were derived from source-specific self-reported sleep disturbance evidence, in accordance with the WHO 2018 recommendations [3]. Self-reported sleep disturbance responses take into account additional dimensions of sleep disturbance, such as problems falling asleep at the beginning of the night and falling back to sleep after a conscious awakening [24].

5.1 Practitioners' views on maximum levels

In a questionnaire ran at some of the outreach events (see Annex A), participants were asked to state to what extent they agreed with these five statements (shown from left to right in Fig. 1):

i. I am comfortable specifying and/or complying with L_{max} criteria.
ii. There is good quality evidence linking L_{max} criteria to long term health outcomes.
iii. Including additional L_{max} criteria in BS 8233 will add value to residential acoustic design.
iv. BS 8233 should include L_{max} criteria for all situations.
v. BS 8233 should include L_{max} criteria only for specific situations.

Statements *ii*,*iv* and *v* invited additional free text comments.

Referring to Fig. 1, practitioners were generally comfortable specifying and/or complying with L_{max}

[3] The Professional Practice Guidance on Planning and Noise (ProPG) was published in 2017 to provide practitioners with guidance on a recommended approach to the management of noise within the planning system in England. It was co-produced by the CIEH, IOA and ANC.

[4] In the UK, current national noise modelling tools for road and conventional railway noise do not output L_{max} data.

criteria, despite responses to the second question being mostly neutral or disagreeing that "There is good quality evidence linking L_{max} criteria to long term health outcomes". Most respondents strongly agreed, agreed or were neutral in response to the statement that "*Including additional L_{max} criteria in BS 8233 will add value to residential acoustic design"*. Most respondents were neutral, however, in response to the final two statements suggesting that BS 8233 should include L_{max} criteria for all situations / only for specific situations.

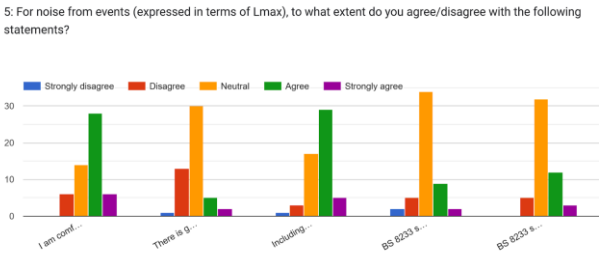

Figure 1 Survey question on noise events - see text for the complete text of the five options.

The following sections summarize the free text responses, categorized under six themes.

5.1.1 Practical Utility Despite Evidential Limitations

A prominent theme in the responses was the suggestion of the practical utility of L_{max} in real-world applications, despite acknowledged limitations in its evidential basis. Many respondents consider L_{max} "well understood" and effective for "giving a resident an appropriate environment", despite the lack of evidence linking this metric with long term health outcomes.
Several comments suggested that L_{max} provides valuable contextual information that benefits "all stakeholders". Respondents highlighted specific applications where L_{max} is particularly useful, such as "nighttime economy in urban areas" and "where residential is located above or adjacent to a significant sound source".

5.1.2 Concern About Evidence Gap vs. Practical Need

Responses acknowledged the tension between the lack of robust evidence linking L_{max} to health outcomes and their perception of its practical importance. Several comments acknowledge the evidence gap we had presented: "You've presented the case that there is insufficient health evidence". However, this was frequently countered with caution: "Lack of evidence of correlation isn't evidence of a lack of correlation". Some respondents remained hesitant about abandoning L_{max}: "not convinced yet that we should be disregarding L_{max} levels altogether".

5.1.3 Source-Specific Applications

Some comments suggested that L_{max} may be more relevant for certain noise sources than others. Specific mentions of "ambulance and police alarm", "lift noise, plant noise," and "wind farms", for example. Several respondents suggested that while our approach for "road, rail, air traffic sources" may be appropriate, guidance is still needed "for other sources". Entertainment venues, "intermittent disturbing noise sources running through the night," and impulsive sounds were highlighted as requiring specific consideration. We acknowledge these arguments, and changes were made to the BS8233 proposals to state that an assessment of noise from events may be appropriate in certain situations.

5.1.4 Pragmatic Regulatory Concerns

Some respondents raised concerns about the practical implications of removing L_{max} criteria in regulatory contexts: "removing L_{max} altogether from BS 8233 might open the door to more unscrupulous developers/ contractors". There were concerns that without L_{max}, some stakeholders "won't pay for a more detailed approach/ or attempt to understand the health effects". There were some suggestions that L_{max} serves as a simple, understood metric that facilitates compliance checks.

5.1.5 International Context and Alternative Approaches

A few responses alluded to international perspectives and alternative approaches. Reference was made to criteria in "some other countries (primarily Australia and particularly Spain/Barcelona)", for example. There were suggestions that further research into L_{max} "ahead of the revision" would have been beneficial, and indications that a comparative analysis of different regulatory approaches might be valuable.

5.1.6 Assessment Challenges

Several comments acknowledged the practical difficulties in using L_{max} as an assessment tool. There was recognition that "L_{max} assessment is fraught with assumptions and uncertainty", and implicit acknowledgment of methodological challenges in applying L_{max} criteria consistently.

5.2 Comparing L_{max} criteria with real-world data

This thematic analysis suggests that while there is acknowledgment of the limited evidence base for L_{max}

criteria in relation to long-term health outcomes, there remains significant attachment to the metric for specific applications and contexts. The responses suggest a desire for better guidance rather than its complete removal.

We carried out simulations based on actual measurements of road traffic noise to test how our proposed internal criterion (façade sound insulation ≥ L_{den} – 32dB) compares with two L_{max} based criteria:

- less than 10 events with L_{AFmax} > 45dB (referred to as "10th highest $L_{AF,max}$ meeting 45dB") [20]; and
- less than one additional awakening per night (referred to as "1AW") [23].

The measurements consisted of 187 24hr sound level profiles, typically made at distances of up to 10m from the kerbside[5]. From each data set, we extracted the following information: L_{den}, $L_{Aeq,16hr}$, $L_{Aeq,8hr}$, and for the night time period: highest $L_{AF,max,8hr}$, 10th highest $L_{AF,max,2\ min}$ and the complete set of $L_{AS,max,2min}$ (i.e. 240 values for each night). We then calculated the façade reduction required to achieve the relevant criterion. The reduction required was calculated as a facade level difference, based on the A-weighted values for the indicators, and assuming a standardised road traffic spectrum[6]. The method used to determine the facade level difference to achieve the 1AW criterion internally is described in [25], using dose response functions from [24].

Figures 2 and 3 show how our original proposals (orange line: equivalent to a Class D classification in ISO/TS 19488:2021) compares to the two different L_{max}-based criteria. Individual markers represent each 24hr dataset. If a marker is above the orange line, the façade insulation requirement to meet the relevant L_{max} criterion is higher than our proposed target, and vice-versa.

Fig. 2 shows that in the majority of cases, a higher level of facade sound insulation is required to achieve less than ten events with $L_{AF,max}$ > 45 dB than to meet an internal level of 35 dB L_{den}. Fig. 3 shows that meeting 35 dB L_{den} achieves the 1AW criterion on average, and in more than 80% of cases. The mean difference between the requirement to meet the 45 dB $L_{AF,max}$ criterion and the 1AW criterion was 4.0 (± 3.2) dB, with a range from + 13 to -5 dB.

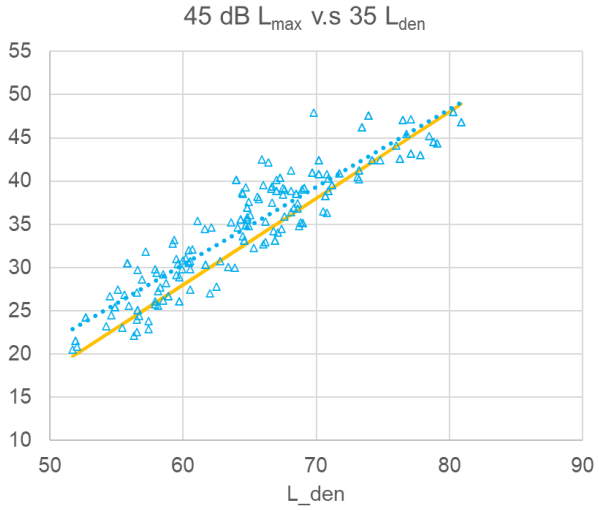

Figure 2 Facade level difference required to ensure the "10th highest $L_{AF,max,inside}$ < 45dB" criterion is met, plotted as a function of external L_{den} level. Each blue marker represents a 24hr measurement. The orange line represents the criterion in our original proposals [2].

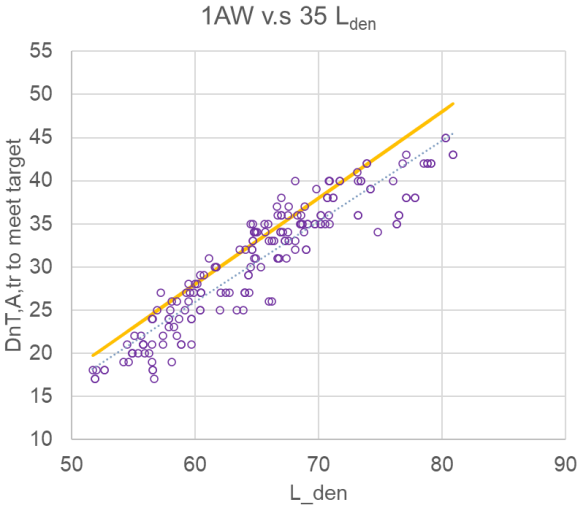

Figure 3 Facade level difference required to ensure the "1 additional awakening per night" criterion is met, plotted as a function of external L_{den} level. Each purple marker represents a 24hr measurement. The orange line represents the criterion in our original proposals [2].

[5] Further details of the measurements can be found in [26].

[6] This is a simplification, as a real facade provides different levels of A-weighted attenuation depending on the frequency content of the incoming sound field. This is particularly relevant for assessing noise from events, for which the frequency content can vary widely.

6. CHANGING THE STATUS QUO – HEARTS AND MINDS

Both the letter to the editor by Clarke and Fiumicelli and the CIEH statement argued in favour of maintaining the status quo. The former argued [5]:

The UK has a reputation for practical delivery against internal criteria. It's what we do really well. As with the delivery of sound insulation between dwellings via pre-completion testing and Robust Details, acousticians in other jurisdictions look on with envy at the UK's track record for effective delivery against measured in-situ performance.

The suggestion that we dispense with this process to align with the proxy parameter used for convenience in the broader-brush epidemiological studies is a reductive and retrograde proposition.

The CIEH statement argued [6]:

"Although the proposed revisions to the standard are based on what the authors consider to be sound scientific studies, the internal and external noise levels have been used for decades without apparent problems or challenges."

Whilst both narratives suggest that current methods work '*without apparent problems*', no evidence was provided in either instance to support these claims. However, there is evidence that current approaches are leading to problems. For example, a Quieter Road-Map published by Sustainable Aviation noted [26]:

"*The development of land near and within areas of high aircraft noise areas around airports for noise-sensitive uses, including residential development continues to be, a major challenge that many UK airports are facing. Many of the measures in the ICAO Balanced Approach are in place at UK airports and are incorporated in airport Noise Action Plans. However, the effectiveness of airport and airline noise control measures can be compromised by competing demands on the planning system to deliver residential development in noise sensitive areas, Some Local Planning Authorities have been forced to prioritise housing targets over exposure to aircraft noise. This has resulted in residential development encroaching in areas around airports that are subject to higher levels of aircraft noise."*

The CIEH statement also argued against any potential conflicts with existing guidance (ProPG), published in 2017, because "*Discrepancies between the ProPG and BS8233 could lead to confusion and hinder the promotion of design outcomes that support good health and quality of life.*" During the engagement events it was noted that there was currently no appetite within the ANC or the CIEH to revise ProPG.

Another criticism of the proposals that came up at some of the events was on the use of the L_{den} metric. Whilst we acknowledge that the L_{den} metric does not fully capture the complex relationships between sound and health, the same can be said of the other metrics in the current standard ($L_{Aeq,16hr}$ and $L_{Aeq,8hr}$). Our original proposals were expressed in terms of L_{den} to align with the large body of epidemiological evidence on sound and health. Whilst conversions between metrics are possible, these introduce additional, and in our view, unnecessary uncertainties.

7. ACKNOWLEDGMENTS

We are grateful for the extensive engagement of the UK acoustics community during the outreach events that took place since September 2024, which has led to further refinement of the proposals. We also acknowledge the constructive "check and challenge" by the BS8233 drafting panel, led by Dr. David Hiller. Special thanks to Weigang Wei, AtkinsRealis for extracting the sound data used in the L_{max} analysis. The views expressed in this article are those of the authors and are not necessarily those of UKHSA or the Department of Health and Social Care.

9. ANNEX A – ENGAGEMENT EVENTS

The development process of British Standards of UK origin is broadly similar to that for international and European standards, although there are no voting stages. The relevant committee overseeing a standard revision is asked to give approval at two stages (for the draft to go to public consultation and for the final version to be published). Public consultation on a 'draft for public comment' is considered an essential part of the process and the responses arising from it are reviewed in the same manner as for international and European projects [28].

The engagement and dissemination events were intended to inform relevant audiences of the main proposed changes to BS 8233 in advance of the public consultation, and to provide more detailed information on the rationale and supporting evidence that informed the proposals.

During four of the events taking place between January and March 2025, we gathered feedback using two separate questionnaires. We obtained 56 and 70 responses to these questionnaires, out of an estimated 150-200 delegates. 50 – 60% of respondents were from the private sector. The majority of the non-private sector responses were from environmental health practitioners working in the public sector, who take a regulating role within the planning system in the UK.

Respondents to the questionnaire were generally supportive of our guiding principles:

- 59% agreed that current knowledge on noise and health warrants more emphasis on external sound levels, reflecting the latest WHO evidence base.
- 89% of respondents supported accounting for how different transportation sources affect health to different extents.
- 75% of respondents viewed Sound Exposure Categories as useful markers for navigating noise impacts in planning.

Concerns were raised about specifying a sound insulation performance instead of internal sound levels, and about the challenges associated with practical implementation. Further details on the survey responses can be found in [29].

ACOUSTIC COMFORT IN BUILDINGS, SAINT-GOBAIN BAROMETER 2024. TOOLS FOR DESIGNING ACOUSTIC COMFORT IN BUILDINGS.

Penélope González de la Peña[1*] **Paula Belenguer Rubio**[2]
[1] Saint-Gobain España, Spain
[2] Saint-Gobain España, Spain

ABSTRACT

Does the current Technical Building Code (DB HR) provide the acoustic comfort required by users? In 2024, the 2nd Saint-Gobain Housing Barometer was carried out to answer the many questions that arise about the situation of main residences in Spain and the immediate future expectations of those who live in them. More than 1,000 people between the ages of 18 and 70 were interviewed in five major urban centers and smaller towns, with the help of CAWI methodology, which guarantees a 95.5% confidence interval.

Among the concerns of the users, acoustic insulation concerns half of the respondents and it's linked with the sustainability of the building.

In this paper, we will discuss the survey carried out, the current requirements of the DB HR and its future planned modification, and the Acoustic Classification of Buildings standard, as well as the Saint-Gobain Acustic software, which helps to select construction solutions that meet user requirements, both for renovation and new construction.

Keywords: *CTE DB HR, acoustic comfort, survey, software, Saint-Gobain Acustic.*

1. INTRODUCTION

In 2021, the first Home Barometer was carried out, analyzing the situation of the main residence in Spain and the main concerns of its users. The aim of this Barometer was to answer the many questions that have arisen about the situation of main residences in Spain and the immediate future expectations of those who live in them. The study focused on the main residence buildings, gathering the opinions and evaluations of the household members, who are the current or potential decision-makers, regarding the main residence, such as buying, renting, renovating...

This Barometer was marked by the impact of the pandemic and the post-confinement period, a time when new needs were activated in our homes.

In 2023, the Barometer has been repeated and includes, in addition to the aspects covered in 2021, sustainability and the impact of teleworking on the perception of housing.

2. INSULATION AND ACOUSTIC COMFORT. RESULTS IN THE 2024 BAROMETER

One of the main housing concerns in the Barometer is acoustic insulation, at 48%. When broken down by age, we see that younger generations are most concerned about this aspect of their current home.

Principales preocupaciones sobre la vivienda	Total	18-29 Generación Z	30-44 Millennials	45-59 Generación X	60-70 Boomers
Aislamiento acústico	48 %	51,5 %	53,3 %	47,9 %	35,0 %

Figure 1. Concern about acoustic insulation in the usual residence by age.

When broken down by type of family, the percentage varies according to whether people live alone, with children or with a family member.

Principales preocupaciones sobre la vivienda	Total	tipo de hogar				
		Sólo	En pareja sin hijos	En pareja con hijos	Con mis padres	Con algún familiar
Aislamiento acústico	48 %	54,0 %	44,9 %	53,2 %	40,0 %	33,7 %

Figure 2. Concern about acoustic insulation by family type.

Similarly, the importance of soundproofing changes depending on whether the dwelling user teleworks or not: 55% of teleworkers consider soundproofing to be very important, while this figure falls to 45% for users who do not telework. Teleworking increases the need to improve acoustic insulation, brightness, space and views.

But not only does teleworking increase the amount of time we spend at home, more than 44.8% of respondents say that they spend more time at home since the pandemic, so the need for acoustic comfort in the usual home is also important in this case.

In terms of concern about acoustic insulation by geographical area, the percentages are as follows:

Principales preocupaciones sobre la vivienda	Total	Madrid	Barcelona	Bilbao	Sevilla	Valencia	Resto de España
Aislamiento acústico	48 %	45,9 %	48,6 %	56,1 %	60,0 %	53,1 %	45,9 %

Figure 3. Sound insulation concerns by geographical area.

In the south of Spain, the importance of good acoustic comfort is 15% higher than in other regions.

When it comes to buying a new home, acoustic insulation becomes even more important, with 87.8% of respondents considering soundproofing to be an important aspect when choosing a home.

When asked about renovating their current home, 26.5% of people who have carried out renovations in their home have done so with the motivation of improving its acoustic insulation, and this percentage rises to 31.3% in the case of teleworkers. If we analyze these renovations according to the year of construction of the building, we see that they are the same in houses built before 1979 (before any acoustic regulations) and in houses built after 2007, with the Technical Acoustic Code already in force, so the perception of low acoustic comfort in current houses remains even to be built with acoustic parameters.

Motivos reforma vivienda	año de construcción			
	Total	<1979	1980-2006	2007>
El aislamiento acústico (minimizar/eliminar ruidos)	26,5 %	29,4 %	22,4 %	29,4 %

Figure 4. Percentage of acoustic insulation renovations by year of construction.

As a conclusion of the 2024 Barometer on insulation and acoustic comfort, we can see that the concern for acoustics in the home is not diminishing and is even increasing for those users who telework and need a suitable acoustic environment to concentrate.

3. REGULATIONS APPLICABLE TO HOUSING

3.1 Current regulations. DB HR and UNE 74201

In October 2007, as part of the Technical Building Code, the Basic Document on Noise Protection (DB HR) was published, which became mandatory in 2008, six months after its publication.

In the survey, the year of construction of the buildings was as follows:

Año de construcción vivienda actual	Total
De 1979 o anterior	26,3 %
Entre 1980 y 2006	39,1 %
Entre 2007 y 2012	14,6 %
Entre 2013 y 2019	5,8 %
A partir de 2019	3,1 %
No lo sé, lo desconozco	11,1 %
Nueva	23,5 %
Base	1025

Figure 5. Year of construction of the current home.

Therefore, when we talk about concern for acoustic insulation, we can see that 34.6% of respondents already live in homes built to DB HR and therefore have acoustic insulation built into their construction solutions.

Nevertheless, acoustic insulation is an important issue that stands out despite the fact that they have homes built to DB HR specifications.

Reflecting this concern for acoustic comfort in homes, the UNE 74201 standard was published in September 2021. "Acoustics. Acoustic classification scheme for buildings", which establishes a classification scheme that makes it possible to characterise the level of acoustic comfort in newly constructed buildings and to evaluate the acoustic conditions in existing buildings, offering the possibility of improving them in future renovations. A building that complies with the Technical Building Code in DB HR is generally classified in Class D according to the UNE 74201 standard; this classification is based on sampling carried out in the most unfavourable rooms of the building, taking into account the performance of airborne noise insulation, impact noise, facades and installations.

As noted in the survey, this Class D rating is below what almost half of respondents consider to be acoustic comfort, so there is still room for improvement in new buildings and refurbishment of existing buildings.

3.2 Possible modification of DB HR

The Administration is currently considering changing some aspects of the basic noise protection document.

Table 1. Current insulation limits and possible changes

Constructive element. Protected space	Current requirement	Possible modification
$D_{nT,A}$ room with different unit of use	50 dBA	52 dBA
$D_{nT,A}$ room with installations or activities	55 dBA	57 dBA
$L'_{nT,w}$ room with different unit of use	65 dB	60 dB
$L'_{nT,w}$ room with installations or activities	60 dB	55 dB

With the increase in the requirements for protected spaces, the acoustic classification of the building would move from class D to class C or B. Therefore, the possible modification of DB HR is an advance compared to the current requirements, but it still has room for improvement, as it falls short of the acoustic classification of the building of class A, which would provide optimal acoustic comfort to the users.

In parallel with this modification of the requirements in terms of insulation limit values, the tables of the simplified option for checking DB HR should be modified in the part that concerns plasterboard systems, which are excessively increased in the current standard. In this case, the modification concerns the systems used for internal partitions, where the minimum insulation requirement and the minimum mass must been adapted to the current systems and to the tests made by UNE 102045 test standard "Procedure for monitoring and characterizing the assembly of gypsum plasterboard systems for airborne sound insulation tests in the laboratory".

The change in requirements for partition walls in self-supporting frame systems may change the tables associated with these systems in the simplified option to adapt them.

Table 2. Modification of simplified option tables for self-supporting frame elements

	Current requirement	Possible modification
Internal partitions	33 dBA	39 dBA

3.3 Need to adapt support documents to DB HR changes.

This regulatory change in DB HR must also be reflected in the various support documents and programmes, so that the solutions proposed in them are in line with the current situation of the systems and also with the new insulation values.

3.3.1 DB HR Application Guide.

This guide, which contains interpretation criteria, comments and application examples to assist technicians, develops the DB HR principles and regulatory texts so that they must be adapted to global requirements and to the new Simplified Option tables.

3.3.2 Catalog of Construction Elements (CEC)

The CEC provides users with a database of information on the hygrothermal and acoustic performance of generic building components. This catalogue was created in conjunction with the introduction of DB HR to assist designers in incorporating systems into acoustic studies for which acoustic tests were not available.

Since the publication of the CEC, there has been an update in the testing of different construction systems, with the development of the above-mentioned UNE 102045 standard, which avoids the dispersion of acoustic test results in plasterboard systems and reduces uncertainty between laboratories.

Therefore, the CEC should also be modified and adapted to the new values of the tests carried out with the new protocol, in order to provide more reliable results to acoustic technicians.

4. ACOUSTIC CALCULATION SOFTWARE. SAINT-GOBAIN ACUSTIC

There are several softwares on the market that perform the calculation of the acoustic insulation in buildings using the General Option of DB HR, taking into account all the spaces, construction solutions, types of joints... These programs offer a complete acoustic study of the building, which allows an in-depth analysis, but requires modelling the building in all its spaces and construction solutions, which requires in-depth knowledge of it and also a certain technical knowledge, in addition to being time consuming. Therefore, this calculation using the General Option is more common when dealing with buildings of a certain size or relevance.

Most residential buildings, such as those covered by the Saint-Gobain Barometer, are calculated using the Simplified Option, which offers a simpler calculation model based on tables depending on the construction configuration used and allows the building to be modelled more quickly without requiring extensive acoustic knowledge.

In 2022, the Saint-Gobain Acustic software will be launched as an add-on to the Ce3X building energy certification programme, with the idea of making it easier for technicians to choose different acoustic solutions in the building, checking compliance with the DB HR using the Simplified Option and also performing a pre-classification of the building using the UNE 74201 system, so that in addition to compliance with the regulations, the technician can have an idea of what class of acoustic comfort will be achieved in the building.

4.1 Introduction of Acoustic data of the building in Saint-Gobain Acustic.

The Saint-Gobain Acustic add-on is integrated into the Ce3X software and allows the user to carry out both the energy certification of the building and the verification of compliance with CTE DB HE and DB HR without having to model the building in different software.

Within the add-on, different tabs are opened where the technician must fill in the conditions and construction solutions of the building:

- Acoustic description of the building
- Vertical indoor systems
- Horizontal indoor systems
- Envelope (facades, roofs and external floors)
- Reverberation and facilities

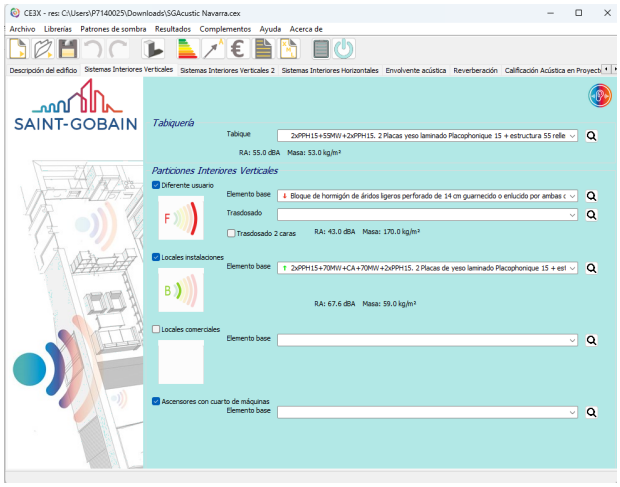

Figure 6. System introduction screen.

The software has a database of acoustically characterized construction solutions, including the CEC and Saint-Gobain acoustic solutions. In addition, the user can introduce their systems with tests or perform the calculation of their own systems.

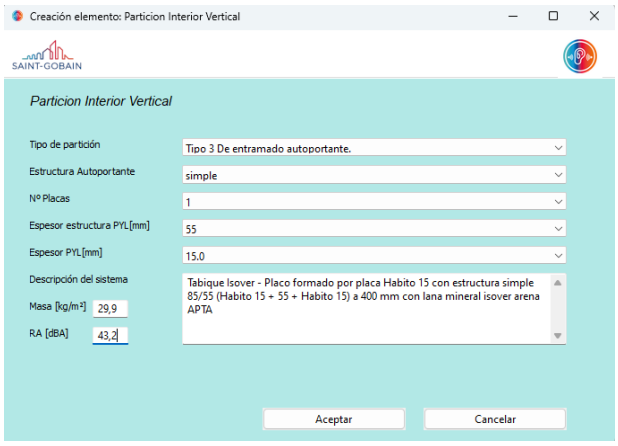

Figure 7. Introduction of new systems with values known to the technician screen.

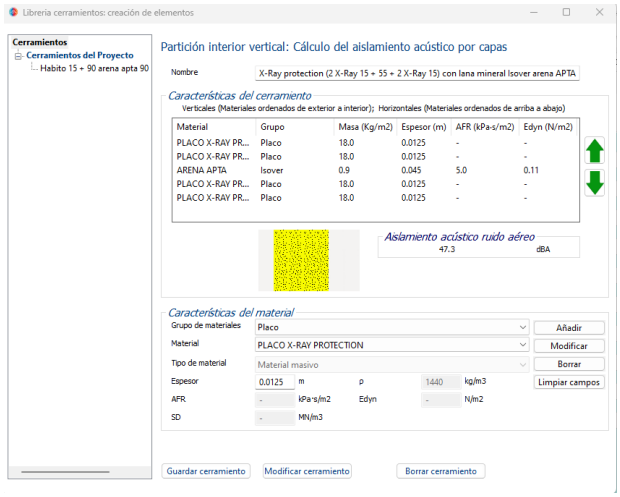

Figure 8. Acoustic calculation construction system screen.

4.2 Checks and reports.

Saint-Gobain Acustic carries out the verification of the CTE DB HR using the simplified option, using the tables and conditions defined in the basic document. In the case of different construction systems for the same use, the least favourable (with lower acoustic performance) must always be introduced in the software to ensure compliance with DB HR.

With regard to the acoustic classification of buildings, Saint-Gobain Acustic carries out an estimated pre-classification based on laboratory tests of the construction elements installed in the building, in accordance with option B of the standard for classification using "in situ" measurements for subsequent classification.

The reports generated by the tool are as follows:

- Acoustic report. With the data of the property, the construction solutions used in the building, and different checklists for the solutions with important points to be checked in the construction site from an acoustic point of view, both construction systems and the facilities.
- Justification Simplified Option DB HR with the format of the Basic Document.
- Acoustic pre-classification according to UNE 74201. Partial and global.
- Building Acoustic label. Similar in format to the energy certification, this label allows, at a glance, to know the acoustic classification of the building, partial and total.

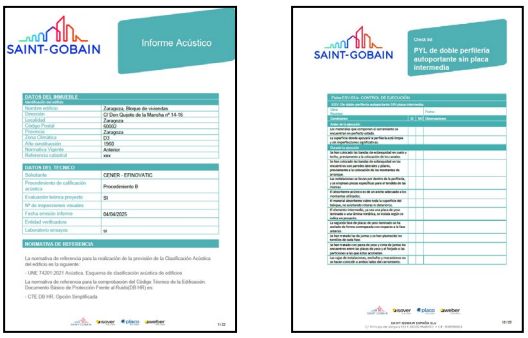

Figure 9. Acoustic report.

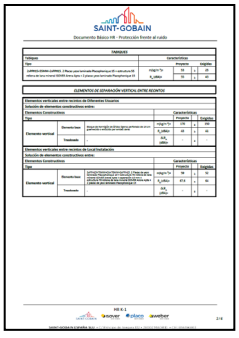

Figure 10. Justification DB HR.

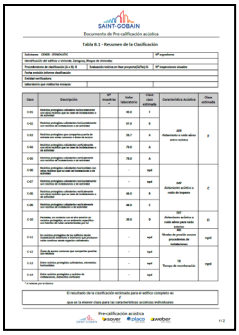

Figure 11. Acoustic pre-classification.

Figure 12. Acoustic label.

5. CONCLUSIONS.

There is a demand from users to achieve adequate acoustic comfort in their buildings, to increase the current requirements for acoustic insulation for both airborne and impact noise and for installations in current dwellings.

The future modification of the CTE DB HR goes in this direction by increasing the requirements to achieve a C or B classification in the Acoustic Classification of Buildings. These new values, although still far from an A classification, will allow greater comfort.

These changes must also be reflected in all the supporting documents of the CTE (Application Guide and Catalogue of Construction Elements), so that technicians have tools to design buildings from an acoustic point of view, both in the design phase and in the execution phase.

In addition, manufacturers of building materials must develop their systems to offer solutions adapted to the new acoustic requirements.

The use of simple calculation tools, such as Saint-Gobain Acustic, allows the democratization of acoustics, making it more accessible to technicians involved in projects and construction.

SUGGESTIONS FOR THE POTENTIAL REVISION OF THE BASIC DOCUMENT ON PROTECTION AGAINST NOISE OF SPANISH BUILDING CODE

Romero-Fernández, Amelia[1*] **Casla-Herguedas, Belén**[1] **Carrascal, Teresa**[1]
[1] Instituto de la Construcción Eduardo Torroja (CSIC), Madrid, Spain.

ABSTRACT

In Spain, the Basic Document DB HR Protection Against Noise, part of the Building Code (CTE), regulates the acoustic conditions in buildings. This regulation, in force since 2009, has accumulated 16 years of implementation and experience, during which maintenance tasks and continuous studies have been conducted to explore potential improvements.

As a result, steps are being taken towards a possible new version of the document, which may address the deficiencies identified over the years and expand its content to include aspects previously not considered.

This paper presents some of the proposals currently under study. For instance, updates to the requirements are being considered, including a slight increase in the performance levels for airborne and impact sound insulation, as well as a review of the sound insulation descriptors currently in use. Additionally, new content is being evaluated, such as criteria for applying the DB HR to existing buildings, construction solutions for wooden buildings, noise from building services, and mandatory field acoustic measurements to verify compliance with the requirements.

Keywords: *DB HR, building acoustics regulations, sound insulation requirements, field measurements, noise from building services*.

1. INTRODUCTION

The Basic Document DB HR on Protection Against Noise, part of the Spanish Building Code (CTE) [1,2], establishes the acoustic requirements for buildings, as well as the rules and procedures to ensure compliance. Published in 2009, it represented a significant change from the previous regulation (NBE-CA-88) [3], as it introduced higher sound insulation requirements and adopted a performance-based approach, using in situ acoustic descriptors instead of laboratory test values. This allowed a final performance of the building to be verified.

Acoustic comfort is a key factor in building quality, with a direct impact on the well-being, health, and productivity of occupants. Noise pollution is recognized as a major environmental issue, with proven effects on stress, sleep quality, and cognitive performance [4]. In residential buildings, inadequate sound insulation can affect privacy and lead to conflicts between neighbours, while in work and educational environments, poor acoustic conditions can impair concentration and learning. In addition to airborne and impact noise insulation, controlling noise from building installations, such as elevators, HVAC systems, and plumbing, is essential to ensuring occupant comfort.

Since its implementation, DB HR has accumulated 16 years of application and experience, during which continuous studies and in situ tests have been conducted to assess its effectiveness. These efforts, carried out in collaboration with the building sector and within the regulatory maintenance activities for the Ministry of Housing, have helped verify

[*] ***Corresponding author***: aromero@ietcc.csic.es.

This is an open-access article distributed under the terms of the Creative Commons Attribution 3.0 Unported License, which permits unrestricted use, distribution, and reproduction in any medium, provided the original author and source are credited.*

compliance with acoustic requirements, identify challenges in the application of the regulations, and gain experience in using testing standards such as ISO 16283 [5].

Over the years, the evolution of the construction sector and data analysis have revealed certain limitations and areas for improvement within DB HR. Advances in construction techniques, the introduction of new materials, and changing user expectations make it necessary to adapt the regulatory framework to ensure its effectiveness. Additionally, in situ testing has identified implementation difficulties, variations in execution quality, and specific cases where current requirements may be insufficient.

In this context, Spain is currently reviewing its building acoustics standard, exploring possible modifications to optimize their application and enhance acoustic quality in buildings. This paper provides an overview of the ongoing changes under consideration and the new approaches that could be incorporated into the future revision of the regulations.

2. CURRENT STATE OF DB HR: ANALYSIS OF IDENTIFIED AREAS FOR IMPROVEMENT

The current DB HR is structured into different sections that address each of the regulated aspects: sound insulation (airborne, impact, and exterior noise in facades), reverberation time and sound absorption, and noise and vibration from building services. Among these, sound insulation is the most extensively developed, whereas protection against noise from building services is addressed more generally and with less detail.

Scope of application

Currently, DB HR applies exclusively to new buildings and major restorations, without considering other types of interventions in existing buildings. To facilitate the progressive adaptation of the building stock to current quality standards, it would be advisable to define specific criteria based on the type of intervention, distinguishing between major restorations, partial refurbishments, extensions, and changes of use, among others. Additionally, introducing flexibility conditions in the application of these criteria could be beneficial, considering the context of the intervention and the characteristics of the building.

Sound insulation requirements and descriptors

A critical aspect of DB HR is the selection of sound insulation indices and the corresponding regulatory requirements. Across Europe, building codes show significant disparities in the descriptors used to assess airborne and impact sound insulation between dwellings, as well as in the required performance levels [6, 7].

Acoustic descriptors in building regulations are defined in ISO standards [5, 8]. In Spain, the descriptor used to assess in-situ airborne sound insulation is the Standardized level difference, weighted A ($D_{nT,A}$), over a frequency range of 100 Hz to 5000 Hz, which approximately corresponds to $D_{nT,w} + C_{100\text{-}5000}$, where C represents the Spectrum adaptation term for pink noise.

Given the European context, it may be advisable to align these indices with those more commonly used in other countries, such as $D_{nT,w}$ and R'_w (with or without the spectrum adaptation term C) for indoor sound insulation, and $D_{2m,nT,w} + C_{tr}$ for facades, within the 100 Hz to 3150 Hz frequency range.

Regarding fundamental acoustic requirements between adjacent dwellings, the values established in DB HR for airborne sound insulation ($D_{nT,A} \approx D_{nT,w} + C_{100\text{-}5000} \geq 50$ dBA) and impact sound insulation ($L'_{nT,w} \leq 65$ dB) are at the lower end compared to most European countries. Other nations generally impose stricter requirements, often exceeding 53-55 dB for airborne sound insulation and setting impact sound limits below 60 dB. The Spanish regulatory values thus reflect a lower level of acoustic protection.

These requirements have remained unchanged since the publication of DB HR in 2009. However, practical experience suggests that most buildings constructed under this regulation comply with the acoustic requirements [9]. In the case of impact sound insulation, measured values often significantly exceed the minimum requirements. This demonstrates that it is possible to achieve higher acoustic quality levels, suggesting that it may be an appropriate time to consider increasing the regulatory requirements for sound insulation.

Design and dimensioning using the simplified method

DB HR provides two methods for designing acoustic solutions: the simplified and the detailed method, both based on the prediction models outlined in ISO 12354 [10]. While the detailed method requires precise calculations of sound insulation, the simplified method offers predefined construction solutions for building elements, ensuring compliance through their combination.

After several years of application, the simplified method could benefit from review and optimization to enhance its accessibility and efficiency. Although Tables 3.2 and 3.3 in DB HR [1] appear to provide a wide range of solutions, in practice, when translating these laboratory-measured insulation values and surface mass densities into commercially available construction systems, the number of viable solutions is relatively limited.

Moreover, the use of the simplified method is complicated by the requirement to comply with numerous additional conditions to control flanking transmissions. While these constraints ensure the validity of the proposed solutions, they also render the application of the method cumbersome and unintuitive.
Finally, the simplified method does not include solutions for lightweight timber structures, such as CLT (cross-laminated timber), light timber frames, or hybrid timber-concrete structures. Timber construction has experienced significant growth in recent years, including multi-story buildings, yet the lack of predefined solutions in DB HR forces reliance on the detailed method or specific testing for compliance. It would be beneficial for DB HR to incorporate acoustic compliance options for such constructions within the simplified method framework.

Noise from Building Services

As previously mentioned, DB HR addresses building service noise in a very general manner, without establishing specific requirements. Instead, it provides guidelines that can be considered best practices for noise and vibration control. However, acoustic requirements for building services are not explicitly defined within DB HR but are instead referenced in Royal Decree 1367/2007 [11], a regulatory development of Law 37/2003 on Noise [12], which remains pending revision and update [13]. This decree establishes noise limit values to transmit to adjacent rooms caused by building services, as well as the corresponding testing and assessment procedures.
However, these procedures are identical to those applied for commercial and industrial noise, leading to interpretation issues regarding whether building services are indeed covered under this regulation. Moreover, applying the same measurement and assessment methodology to building services may be inappropriate, as it fails to consider key aspects such as: the specific characteristics of each type of installation, operating modes and work cycles, and the nature of the noise generated.
It is therefore necessary for DB HR to provide a more detailed and tailored regulatory framework for building service noise, ensuring clearer guidelines adapted to their specific characteristics, in the context of the building.

Finished Building Control: In-Situ Testing

DB HR does not mandate acoustic testing upon completion of construction. However, if tests are conducted, it specifies the technical standards under which they should be performed [5, 14], along with the acceptable tolerances for verifying compliance with acoustic requirements. The following tolerances are permitted for in-situ measurements: 3dBA for airborne sound insulation, 3dB for impact sound insulation, and 0.1s for reverberation time.
Although acoustic control upon completion is not mandatory at the national level, several autonomous communities and municipalities require in-situ testing as a prerequisite to obtain the first occupation license. These controls include verifying sound insulation in walls, floors, and facades, as well as measuring sound pressure levels generated by building services.
Regions such as Andalucía, Castilla y León, and País Vasco, along with cities such as Barcelona, Murcia, Valencia, and Valladolid, have developed specific regulations governing these tests. In some cases, beyond requiring the tests, they also establish sampling procedures and specific evaluation criteria. Details on how these regulations make this control acoustic testing can be found in [15].
The heterogeneity of these regulations highlights the need for greater standardization in the obligation and methodology of finished building acoustic testing, ensuring a uniform and reliable verification of compliance with acoustic requirements across the country.

3. PROPOSALS CURRENTLY UNDER STUDY FOR THE REVISION OF DB HR

In light of the issues discussed above, this section presents some of the proposals currently under study to address areas identified for improvement. Work is underway on a revised version aimed at refining certain aspects and expanding on topics that have not yet been covered in these regulations.

3.1 Document restructuring

The DB HR document is being restructured into new sections, grouped according to the acoustical characteristics it regulates: Section HR1 for airborne and impact sound insulation, Section HR2 for sound absorption and reverberation time, and Section HR3 for service equipment noise.
This restructuring aims to provide a more systematic and specific approach, ensuring that each section includes its own requirements, scope of application, and specific criteria. Additionally, the original content will be reviewed and adapted accordingly.

3.2 Criteria for application to existing buildings

This section summarizes some of the criteria under study for applying DB HR to interventions in existing buildings, depending on the degree of intervention:

- Full intervention (major restorations): The entire building must comply with the acoustic requirements of DB HR.
- Extension: Any newly added part of an existing building must meet DB HR requirements, and the new separating walls and floors with the existing spaces must ensure compliance.
- Change of use: When the change of use affects the entire building, it must be fully adapted to the requirements. But, when the change of use is partial, affecting only a part of the building, only that part must meet the corresponding requirements. For instance, in a conversion to residential use (a dwelling), the newly created living spaces must comply with DB HR regulations.
- Partial renovation or localized intervention in building elements and installations: The applicable criteria must be defined in greater detail. Depending on whether the intervention significantly affects multiple construction elements, involves simultaneous work in several dwellings, or is more localized, flexibility criteria may be applied to approach DB HR requirements as closely as possible, even if full compliance is not achievable.

In all cases, the non-degradation principle shall prevail, ensuring that the intervention does not reduce the existing acoustic performance before the works.

3.3 Update of requirements and standardization of sound insulation descriptors

In alignment with European regulations, it is proposed to replace $D_{nT,A}$ with $D_{nT,w} + C$ for indoor airborne sound insulation and $D_{2m,nT,Atr}$ with $D_{2m,nT,w} + C_{tr}$ for façades, both within the frequency range of 100 Hz to 3150 Hz.

Additionally, an update to the regulatory requirements is being considered, including a 2 dB increase in airborne sound insulation and a 5 dB reduction in impact noise levels. Table 1 presents the sound insulation requirements currently under study for protected spaces such as living rooms and bedrooms in residential buildings.

Table 1. Sound insulation requirements for protected spaces in dwellings.

Sound insulation	Type of spaces	Current reqs.	New reqs. proposal
Airborne	Between protected spaces and other spaces outside the living unit [1]	$D_{nT,A}$ ≥ 50 dBA	$D_{nT,w} + C$ ≥ 52 dB
	Between protected spaces and noisy areas, such as equipment rooms or activity rooms	$D_{nT,A}$ ≥ 55 dBA	$D_{nT,w} + C$ ≥ 57 dB
Impact	Between protected spaces and other spaces outside the living unit [1]	L'_{nTw} ≤ 65 dB	L'_{nTw} ≤ 60 dB
	Between protected spaces and noisy areas, such as equipment rooms or activity rooms	L'_{nTw} ≤ 60 dB	L'_{nTw} ≤ 55 dB
Façade [2] (Same values)	Bedrooms	$D_{2m,nT,Atr}$ ≥ 30-47 dBA	$D_{2m,nT,w} + C_{tr}$ ≥ 30-47 dB
	Living rooms	$D_{2m,nT,Atr}$ ≥ 30-42dBA	$D_{2m,nT,w} + C_{tr}$ ≥ 30 – 42 dB

[1] A living unit refers to a section of a building designated for a specific function, whose occupants share a functional connection (e.g., dwellings, hospital rooms, hotel rooms, classrooms, etc.). In this case, a living unit is considered a dwelling.

[2] The sound insulation requirements for façades depend on the day noise level (L_{day}) of the area where the building is located.

3.4 Review of the simplified option for sound insulation

The simplified option in DB HR presents several areas for improvement. While its main advantage is ease of application, it also has limitations that need to be addressed in the upcoming revision of DB HR. First, the construction solutions for separating walls and floors (Tables 3.2 and 3.3 in DB HR [1]) must be recalculated to meet the new sound insulation requirements under consideration. Additionally, this simplified option should be reviewed and optimized to make it more accessible and practical, simplifying the adaptation of laboratory sound insulation values to construction elements available on the market. It is also necessary to reduce the complexity of additional conditions for controlling flanking transmissions, aiming for greater flexibility without compromising the technical validity of the proposed solutions. This would facilitate the practical application of viable acoustic solutions in real projects.

Furthermore, the simplified option could incorporate solutions for lightweight timber buildings, such as those built

with CLT, timber frame, or hybrid timber-concrete structures. These should be basic or fundamental solutions, covering the most common cases while ensuring compliance with acoustic requirements. The goal is to integrate these solutions into the regulation without unnecessarily complicating the design and application process, avoiding the need to resort to the general option or conduct specific acoustic tests.

Finally, it is important to clarify that the simplified option is merely a guideline providing examples of possible solutions. Other alternatives exist beyond those explicitly included in DB HR. In its current wording, the simplified option may be mistakenly interpreted as a mandatory requirement, which needs to be addressed.

3.5 Service equipment noise

Currently, DB HR regulates service equipment noise in buildings by referencing Law 37/2003 on Noise [12] and Royal Decree 1367/2007 [11], which sets maximum permissible noise levels in adjacent spaces. However, since building service equipment is an integral part of the building itself, it is necessary to regulate this aspect more specifically within DB HR, adopting a more architectural approach rather than treating it similarly to commercial or industrial activities, as is currently the case.

The objective is to define specific noise requirements for building service equipment by establishing appropriate noise indices, their corresponding limit values, and a measurement method adapted to the characteristics and operating cycles of each type of installation. The testing procedure could be based on ISO 16032 [16], which includes the measurement of both the equivalent continuous sound pressure level (L_{eq}) and the maximum sound pressure level (L_{max}) for different types of installations.

At the same time, maintaining a degree of compatibility with the methodology of RD 1367/2007 is desirable, while incorporating some improvements, such as:

- Averaging measurement points instead of using only the most unfavorable measurement.
- Defining a sampling methodology based on the operating cycles and working modes of each system, instead of the current minimum measurement duration of 5 seconds.
- Applying the corrections for impulsive, tonal, and low-frequency components only when they exceed the hearing threshold [17].
- Normalizing measurement results relative to the reverberation time of the spaces.

A key step is the correct classification of service equipment according to their characteristics and operating conditions, as these factors determine the generated sound pressure levels, the appropriate measurement procedure, and the noise index to be used ($L_{A,max}$, $L_{A,eq,Ti}$, $L_{Aeq,cycle}$, etc.). While some systems operate continuously (e.g., HVAC), others operate intermittently or by events (e.g., plumbing, elevators), making it essential to define specific criteria for their evaluation. In particular, an index based on maximum noise levels is proposed for systems with intermittent operation, as well as those with start-up phases or changing working modes that generate noise peaks.

Finally, while most European countries establish a single noise limit for service equipment (whether in terms of $L_{Aeq,T}$, $L_{A,max}$, or both), Spain differentiates limit values depending on the period (day, evening, night). Aligning this approach with international practice should be considered.

3.6 On-site testing for final compliance verification

It is proposed to establish mandatory in-situ testing at the national level to verify compliance with sound insulation, reverberation time, and service equipment noise level requirements. Currently, some regional governments already require these tests before granting the first occupancy license. Implementing this requirement nationwide would help standardize quality control in building construction.

To ensure proper implementation, a minimum sampling procedure must be defined to guarantee compliance with the DB HR of the CTE without interfering with regional competencies. This minimum approach will allow regions that have already developed their own testing systems to maintain them without regulatory conflicts. Additionally, clear criteria for compliance declarations must be established, studying aspects such as measurement uncertainty and the application of tolerances to limit values.

In this regard, it is proposed to reduce the tolerance in sound insulation compliance measurements from 3dB to 2dB. This proposal is based on an analysis of European regulations [7], where 21 out of 28 countries do not establish any tolerance or uncertainty, requiring strict compliance with the regulatory values. Among the countries that do consider tolerances, Denmark sets a 1 dB tolerance, Austria, Belgium, and Sweden apply 2 dB, while Spain, France, and Portugal allow a 3 dB tolerance.

4. CONCLUSIONS

The analysis of the Basic Document DB HR Noise Protection, part of the Spanish Building Code (CTE), highlights the progress made in the acoustic regulation of buildings since its publication in 2009. However, it also reveals areas that require improvement and updates to meet

current industry demands and align with international practices. In this regard, a series of enhancements have been identified and proposed, starting with the reorganization of the document to facilitate its application.

Regarding the current sound insulation requirements, they are among the lowest in Europe, making it advisable to revise and raise the standards to improve acoustic quality in buildings. Additionally, it is necessary to optimize the simplified option to enhance its applicability and incorporate timber construction solutions, and develop more specific regulations for building service noise, ensuring they are appropriately tailored to the characteristics of each type of project.

Furthermore, it is essential to establish specific criteria for applying DB HR to existing buildings, considering different levels of intervention. It must be ensured that interventions do not degrade the initial acoustic conditions and, when full compliance with the requirements is not feasible, promote improvements that bring the building as close as possible to the established standards.

Finally, the implementation of mandatory field acoustic testing at the national level is proposed to verify compliance with the requirements. This would ensure more uniform and rigorous quality control across the country.

Overall, these proposed revisions to the Basic Document DB HR represent a key opportunity to enhance the acoustic quality of buildings in Spain and ensure greater comfort for users.

5. ACKNOWLEDGEMENTS

This work has been carried out within the framework of the development of building regulations at the national level, specifically the Technical Building Code, with the support of the Ministry of Transport, Mobility, and Urban Agenda (MITMA), which is gratefully acknowledged.

FORUM ACUSTICUM EURONOISE 2025

TECHNICAL SPECIFICATION FOR STANDARDIZED GRAPHICAL PRESENTATION OF ACOUSTIC REQUIREMENTS IN SWEDEN

Bo Gärdhagen[*1]
Niklas Jakobsson[2]
[1] Akustikverkstan Konsult AB, Göteborg, Sweden
[2] Akustikkonsulten i Sverige AB, Stockholm, Sweden

ABSTRACT

Ten Swedish acoustic consultant companies sent their experts to standardize the graphical presentation of acoustical requirements for buildings, now published as SIS/TS 25261.
The need for a standardized method became quite urgent when the latest Swedish sound classification scheme for healthcare, educational and business premises were published in 2023, which introduced a new approach to defining sound requirements. In the new SS 25268:2023 the requirements are based on the needs of noise control and speech intelligibility that come from the intended usage of the rooms, instead of the designation of the room. To furthermore express requirements based on the need for noise control, the values of sound reduction are presented in a matrix with level differences, $D_{nT,w}$, not reduction indexes, R'_w.
SIS/TS 25261 specifies a working order from acoustical needs analysis, via measurable quantities, to acoustical specifications for building elements. It presents colours, line types and symbols to use, and layout for tables. This unified approach will simplify for architects, property developers, contractors and consultants, and eliminates the need for each acoustic consultant to use their own individual method, leading to misunderstandings and ad hoc solutions.

Keywords: requirements, classification, graphic, needs, colours.

1. BACKGROUND

1.1 SS 25268:2023 – Acoustic Requirements Based on Functional Room Use

Contemporary Swedish office buildings rarely consist of a corridor flanked by a row of cellular offices, which formed the basis for the airborne sound insulation criteria in earlier editions of the Swedish acoustic classification standard for non-residential premises. Historically, the standard included separate requirements for room-to-room and room-to-corridor transmission.
Today, office layouts more commonly include various forms of open-plan areas combined with meeting rooms, small rooms for phone calls or focused work, and a limited number of individual offices for specific purposes. Some staff categories are accommodated in shared multi-occupancy rooms. Informal break areas are often located in open zones between enclosed rooms. The same is true for schools in Sweden, where corridors often have been replaced by big open spaces for where students both study and relax.
In the previous version of the standard, it was unclear how to classify a meeting room that adjoins an open-plan office. Some interpreted the requirements as applying to a wall facing a corridor, which resulted in under-specified insulation. Others treated it as a wall between two enclosed rooms, leading to overly stringent requirements, as open-plan offices inherently contribute to sound attenuation.
The adopted solution was to shift the requirement from sound reduction index (R'_w) to weighted standardized level

difference ($D_{nT,w}$), and to define room types based on their functional acoustic needs. This conceptual shift has also been applied to all other acoustic parameters covered by requirements, with an emphasis on the intended acoustic function of each space.

1.2 Variation in Acoustic Requirement Documentation

Acoustic descriptions and noise control specifications previously produced for Swedish construction projects have varied significantly, primarily due to the absence of a unified framework for presenting such requirements. Each consultant has adopted their own approach—even within the same firm—resulting in documentation that is often difficult to interpret consistently.
When previous requirements were expressed as R'_w in 4 dB intervals, many consultants illustrated airborne sound insulation requirements using coloured lines on wall layouts. As most manufacturers specified the expected sound insulation performance of their products under ideal conditions (e.g., "Sound Class R'_w = 44 dB"), this practice appeared convenient—an orange line might then imply both that the partition must meet R'_w = 44 dB and that the corresponding wall product should be selected accordingly.
However, this approach becomes problematic in cases such as partitions incorporating doors, or when cross-laminated timber (CLT) floor slabs are used, which may introduce significant flanking transmission at higher performance levels. Furthermore, when the chosen colours are too similar in hue, it increases the risk of misinterpreting the actual requirement.

1.3 The Solution

Members of the SIS Technical Committee for Building Acoustics, who developed the new standard for non-residential premises, invited numerous acoustics firms across Sweden to participate in a collaborative effort. The objective was to establish a coherent and transparent approach to presenting the new acoustic requirements.
Consensus was reached on a process that begins with end-user needs as defined in a functional room programme, continues through the specification of measurable performance targets, and concludes with the detailed representation of requirements for individual building elements.
A smaller group developed proposals for graphical symbols and colour schemes. These proposals were then reviewed by the broader group, and the result was published as a Technical Specification—a format that allows for faster implementation than a full standard, while maintaining consistency and clarity.

1.4 Room Function vs Spatial Function

A *room* is defined as a volume enclosed on all sides by floor, walls, and ceiling. A *space*, by contrast, refers to either an entire room or a part of a room that serves a specific function.
Since the presence or absence of separating constructions between different areas—i.e., whether they are distinct rooms—has significant implications for acoustic performance, SS 25268:2023 [1] specifies that the stated requirements apply to *spaces*. For this reason, the term *spatial function* is used in place of *room function* throughout the standard.

2. METHOD

2.1 General

The method follows the typical design process used in Swedish construction projects, which is structured in three stages: programme design, system design, and construction documentation.
In many projects, the design is put out to tender for what is known as a design-and-build contract (*totalentreprenad*) at some point during or between the system design and construction documentation phases. In a strictly defined design-and-build contract, the client is responsible for providing layout plans and performance requirements. However, in practice, the level of prescription can be quite extensive—sometimes approaching the level of a detailed construction document. Consequently, the tender documentation for design-and-build contracts often becomes the central legal reference for determining whether a building satisfies the performance requirements at the final inspection.

2.2 Acoustic Spatial Function

During the programme design phase, the organisation intended to occupy the premises specifies its needs for the different room functions the building is required to support. To achieve an appropriate acoustic environment, these acoustic needs must be clearly defined.
In the acoustic standard SS 25268:2023, airborne sound insulation requirements are presented in matrix form, with rows representing the expected noise levels within the space, and columns indicating the space's sensitivity to acoustic disturbances. The acoustic spatial function is expressed in everyday language, such as "normal speech noise level" or "need for speech privacy," combined with the space's sensitivity level—low, normal, elevated, or high.

5.4.2.2 Basic requirements

Table 2 – Minimum weighted standardised level difference, $D_{nT,w}$ [dB] for healthcare premises

Spatial Function	For the receiving space: Need for disturbance protection			
From the source space: Category of airborne noise source	Low	Normal	Elevated	High
2a need for confidentiality of speech	52 I, II	52 I	52 I	52 I
2b need for speech privacy	44 III	44	48	52

I The conditions for requirements to and from other activities are specified in section 5.3.3.2.

II A minimum $D_{nT,w}$ = 40 dB is permitted for separating constructions with a door or glazed partition towards a corridor, passageway, or other space intended for transit only. This deviation may only be accepted where the risk of overhearing or breach of confidentiality is low.

III A minimum $D_{nT,w}$ = 36 dB is permitted for separating constructions with a door or glazed partition towards a corridor, passageway, or other space intended for transit only.

Figure 1. Excerpt from table presenting acoustic spatial function for sound level difference in healthcare premises, as presented in SS 25268:2023, translated into English.

Examples of typical room types associated with each acoustic function are listed in a supporting table. For instance, a meeting room is typically described as having a normal sensitivity to disturbances and a need for speech privacy. A distinction is made between confidentiality—which refers to preventing the intelligibility of speech outside the room even at raised voice levels and under quiet background conditions—and speech privacy, which means that, under normal conditions, conversations inside the room should not be heard outside.

In SIS/TS 25261 [2], the acoustic spatial function may be represented either in tabular form or graphically using a designated symbol (see Graphical Representation below).

2.3 Verifiable Acoustic Requirements

It is essential that the acoustic requirements to be fulfilled at the final inspection of a building are both unambiguous and clearly defined, so that those performing measurements and other forms of verification can readily determine whether the measurement results meet the stipulated criteria.

During the development of SIS/TS 25261, it was concluded that verifiable airborne sound insulation is often more clearly represented not as the tabulated $D_{nT,w}$ value, but rather as the performance required of the separating element, expressed in terms of R'_w. Several reasons support this approach:

- **Standardised procedure:** According to EN ISO 16283-1, measurements should be conducted from the larger room to the smaller one. If the governing requirement for the partition is defined in the opposite direction, this deviates from the standard, and measurement conditions may become suboptimal—especially if the source and receiver positions are forced too close due to limited space.
- **Measurement direction:** R'_w is independent on the direction of measurement. In contrast, $D_{nT,w}$ tends to be higher when measured from a small room into a larger one. If the operator, for practical reasons, chooses the wrong direction, the result may be misleading.
- **Clarity in comparison:** With R'_w, it is clear which target value the measured result should be compared against. For example, from an open-plan office with normal speech activity into a small room for private phone calls, the required $D_{nT,w}$ is 36 dB. In the reverse direction—where speech privacy is needed—the requirement is $D_{nT,w}$ = 44 dB. Although the lower value (36 dB) implies a stricter requirement for the separating structure, it is easy to mistakenly compare the measurement with the higher threshold.

That said, in certain cases it may still be preferable to specify and measure $D_{nT,w}$ directly—particularly when the boundaries of the separating structure are unclear. For instance, when a corridor intersects with a larger room and a corner room has a robust wall facing the open space but a door leading to the corridor, it is the latter that weakens the overall insulation. Measuring $D_{nT,w}$ from the larger space into the corner room provides a clear and unambiguous assessment.

SIS/TS 25261 permits verifiable acoustic requirements to be stated either as R'_w or $D_{nT,w}$. However, when specifying $D_{nT,w}$, it must be in the direction that places the highest demand on the separating construction. In the section Graphical Representation below, corresponding symbols are presented. In addition to airborne sound insulation, there are also standardised symbols for impact sound level, reverberation time, noise from building services, and environmental noise (e.g., from traffic or external sources).

2.4 Requirements for Building Elements

The final step in the design process is to specify the building elements required to meet the defined acoustic performance criteria. If this has not been addressed earlier, it must be done during the preparation of construction documentation. However, in some cases, it may be desirable to establish these requirements earlier in the process—for budgeting purposes or to influence the execution of the design.

Until roughly a decade ago, it was common practice in Sweden to specify the expected in-situ sound insulation (R'_w) for glazed partitions, doors, and windows. This is now less frequent, as it often led to errors: procurement staff from contractors and sales representatives from suppliers frequently overlooked the prime symbol, resulting in products being delivered based on laboratory-tested R_w values instead. This mismatch commonly led to failed field measurements.

As mentioned in the Background section, it has also been standard practice in Sweden for suppliers of gypsum board

partitions to report their products' in-situ performance as R'_w. However, for the reasons discussed above, this practice is increasingly being reconsidered. The recommended approach is now a general transition towards specifying products and systems based on their laboratory-measured values.

SIS/TS 25261 provides clear graphical symbols indicating performance requirements of building products directly on construction drawings. These values must be based on laboratory measurements—or equivalent calculated data. It is the responsibility of the acoustic consultant to ensure that an appropriate safety margin is applied between laboratory data and the expected in-situ sound insulation performance.

3. GRAPHICAL REPRESENTATION

3.1 General

The development of a graphical system for representing acoustic requirements—covering spatial acoustic function, verifiable acoustic parameters, and requirements for building elements—began with an unconventional approach: a designer with expertise in graphic communication, but without prior experience in acoustics or construction drawings, was invited to create an initial concept.

This method was chosen to promote a fresh perspective, unencumbered by established habits or conventions. The initial design was subsequently reviewed and refined by experienced acousticians to ensure its practical applicability in real project environments.

3.2 Toolbox

To facilitate the implementation of standardised symbols and visual conventions, a custom toolbox has been developed for the PDF markup software Bluebeam Revu. This platform offers robust functionality for the purpose and is already widely used by Swedish acoustics consultants. In most cases, consultants add acoustic requirements directly onto architectural PDF drawings.

The graphical symbols have also been designed to be compatible with Revit, and future development plans include dedicated toolboxes for that platform as well.

3.3 Tabular Format

In some cases, it is more efficient to present the acoustic spatial function in tabular form—for example, when the layout has not yet been finalised, or when the number of room types is limited. SIS/TS 25261 provides design guidelines for such tables to enhance legibility and ensure consistency across different consultants.

Table 1. Summary of acoustical spatial functions for large meeting rooms

MEETING ROOMS ≥ 50 M²	SPATIAL FUNCTION	COMMENT
Requirement level	Basic requirements	
Sound level difference	20b Need for speech privacy	
Impact sound level	23b Moderate impact sound load	
Disturbance protection	Elevated need	
Room acoustics	26b Speech communication	Digital meetings[1]
Noise from installations, traffic, etc.	27a, 28a Special requirements for disturbance protection	

[1] Requires $T_{125} \leq 0{,}7$ s and wall absorbers covering ≥ 8 % of wall surface area

Figure 2. Example of table presenting acoustical spatial functions in tabular form, following SIS/TS 25261.

3.4 Colour Scale

SIS/TS 25261 prescribes a colour scale designed to maximise the visual distinction between categories by using primary digital colours from the RGB and CMY colour models:

Magenta – special conditions or requirements and is always accompanied by explanatory text
Blue – exceptionally high-performance requirements
Red – high requirements
Yellow – elevated requirements
Green – standard requirements
Cyan – low requirements
Grey – very low requirements

The intention is to improve readability for individuals with colour vision deficiencies and to support digital readability. With consistent application, this unified colour scale contributes to improved clarity and familiarity over time.

3.5 Symbols for Acoustic Spatial Function

When representing acoustic spatial function on drawings, a specific symbol is used: four or five circles arranged within a rectangle, supplemented by one or two triangles. The circles represent individual acoustic characteristics, while the triangles indicate the space's sensitivity to disturbances regarding sound insulation.

Typically, four circles are used, since requirements for noise from building services and from external sources (e.g., traffic) are often aligned. Similarly, a single triangle is generally sufficient, as sensitivity to airborne and impact sound tends to be coordinated.

Each circle contains a code referring to the corresponding row in SS 25268. For instance, "5b" denotes "Moderate impact sound load" in healthcare premises. The characteristics are listed in the same order as in SS 25268: airborne sound insulation, impact sound insulation, room acoustics, noise from installations, and environmental noise from traffic or other external sources.

3.6 Symbols for Verifiable Acoustic Requirements

A set of graphical symbols—comprising arrows, triangles, 45°-rotated squares, and pentagons—combined with colours and numerical values, is used to represent measurable acoustic requirements on drawings.

The symbols are functionally motivated: a double-headed arrow represents R'_w, which is a reciprocal value, while a single-headed arrow indicates $D_{nT,w}$, which applies in one direction only. There is also a combined symbol for environmental noise from installations, traffic, and other external sources, used when the A-weighted equivalent sound level requirement is the same for all. A perpendicular line is added to sound insulation symbols to indicate extended frequency range down to 50 Hz.

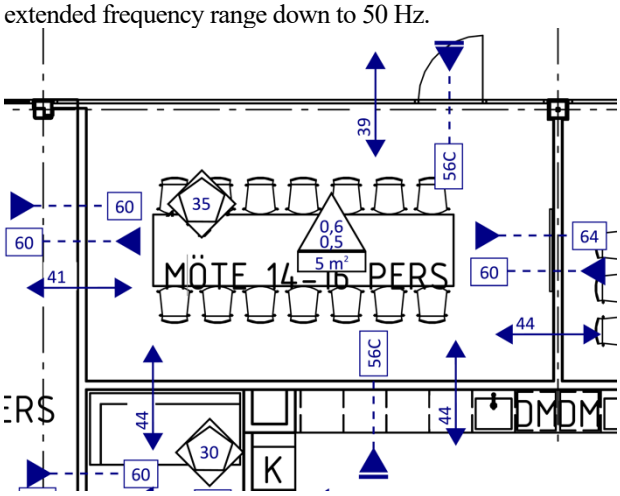

Figure 3. Example of verifiable acoustic requirements in meeting room, following SIS/TS 25261.

3.7 Symbols for Building Element Requirements

Requirements for building elements may be indicated using coloured lines on the corresponding partition, text within a rectangle, or a combination of both. For façade windows, requirements can be represented using coloured areas on the façade drawings or as special coloured lines on plan drawings.

The text inside the rectangle consists of one or two letters indicating the type of building element, followed by two digits representing the minimum laboratory-measured sound reduction index.

The letter codes are as follows:

- V for walls (vägg in Swedish)
- D for doors
- G for glass
- ÖD for transfer air devices (överluftsdon in Swedish).

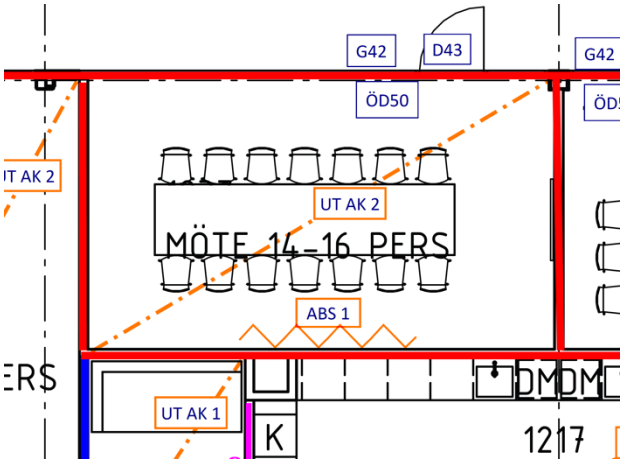

Figure 4. Example of acoustical requirements for building parts for meeting room, following SIS/TS 25261.

3.8 Application in Residential Buildings

Although the symbols for verifiable acoustic requirements also are applicable to residential buildings following SS 25267 [3], it is primarily the symbols representing acoustic requirements for building elements that are relevant for use in residential housing projects.

4. SUMMARY

The introduction of SS 25268:2023 and the associated technical specification SIS/TS 25261:2024 marks a fundamental shift in how acoustic requirements are defined and communicated in Swedish building projects. Instead of focusing on room labels or construction types, the requirements are now derived from functional acoustic needs—expressed in terms of spatial usage and verifiable performance metrics.

SIS/TS 25261 establishes a structured workflow from needs analysis to construction documentation and offers a comprehensive graphical system for representing acoustic requirements. This includes standardised symbols, colour codes, and table formats for acoustic spatial functions, verifiable sound parameters, and building elements. The approach improves clarity, facilitates communication across disciplines, and supports consistent documentation—especially important in large or complex projects.

While developed with non-residential buildings in mind, some of the graphical tools can also be applied in residential contexts following SS 25267. The proposed standard is expected to streamline acoustic coordination in Swedish

construction and serves as a model for harmonisation in future European guidelines.

A LOOK INTO THE LOW FREQUENCY DEFICIENCIES OF ISO 717-2

Gjermund V. Holøyen[1*]
[1] SINTEF Community, Børrestuveien 3, 0373 Oslo, Norway

ABSTRACT

As the world of building acoustics is moving towards a stronger emphasis on low frequency sounds, certain standards are lagging behind. In particular, the lack of low frequency spectra for the calculation of the weighted improvement of impact sound insulation, ΔL_{w}, in ISO 717-2 might soon prove to be a significant issue as countries are moving in the direction of including the low frequency spectrum adaption term $C_{\mathrm{I},50-2500}$ in their building legislation. However, it is no straightforward task to find a functional solution to this problem, and a simple extension of the spectra given in the standard today, may not alone be enough. In the work leading to this paper, potential solutions for the heavyweight reference floor have been investigated and assessed. The results are presented and discussed in this paper.

Keywords: *improvement of impact sound reduction, floating floor, low frequencies, spectrum adaption terms*

1. INTRODUCTION

In recent years, the focus on low frequency sound insulation has increased. In Norway, the standard NS 8175 was revised in 2019, where a significant change from the previous version was the inclusion of low frequency spectrum adaption terms in class C for dwellings [1]. Class C in NS 8175 is referred to in the Norwegian building code (TEK), and by ensuring compliance with class C in NS 8175, one is also ensuring compliance with TEK [2]. At the time of writing, the 2019-version of the standard is yet to be adopted into TEK, but signals from the authorities are suggesting that an adoption may be on the cards within 2026 or at the latest when TEK is fully revised.

When this eventually happens, low frequency spectrum adaption terms must be considered for both airborne and impact sound, which from a construction technology point of view is likely going to be relatively undramatic [3]. However, one critical issue is the single number quantity ΔL_{w}, which is defined in ISO 717-2 [4]. The calculation procedure for ΔL_{w} relies on reference spectra given in ISO 717-2, which are limited downwards to 100 Hz. That means ΔL_{w} cannot be calculated including frequencies below 100 Hz, and no corresponding low frequency spectrum adaption terms can be calculated either. This could in theory be solved by simply extending the existing spectra down to 50 Hz, but previous studies have shown that it's not quite so straightforward [7]. This paper looks at other options for calculating low frequency spectrum terms to go along with ΔL_{w} for the heavyweight reference floor.

2. METHODOLOGY

Two paths have been considered, both based on $C_{\mathrm{I},50-80}$ as an alternative to $C_{\mathrm{I},50-2500}$. For both, extensions of the current spectrum in ISO 717-2 are essential. For this paper, four possible extensions have been suggested. The extensions, denoted as α, β, γ and δ and presented in Fig. 1, are simple extensions of the current heavyweight reference floor spectrum in ISO 717-2. α represents a linear extension of the current spectrum (a reduction of 0.5 dB per third octave), and the other three extensions with reductions of 2, 3 and 4 dB per octave respectively. For both paths, measurement results from five measurements performed at SINTEF have been used, see Fig. 2. The five floors are all floating floor constructions with a concrete screed. An average of measured impact sound levels from the 140 mm bare concrete reference floor at SINTEF is also shown in Fig. 1.

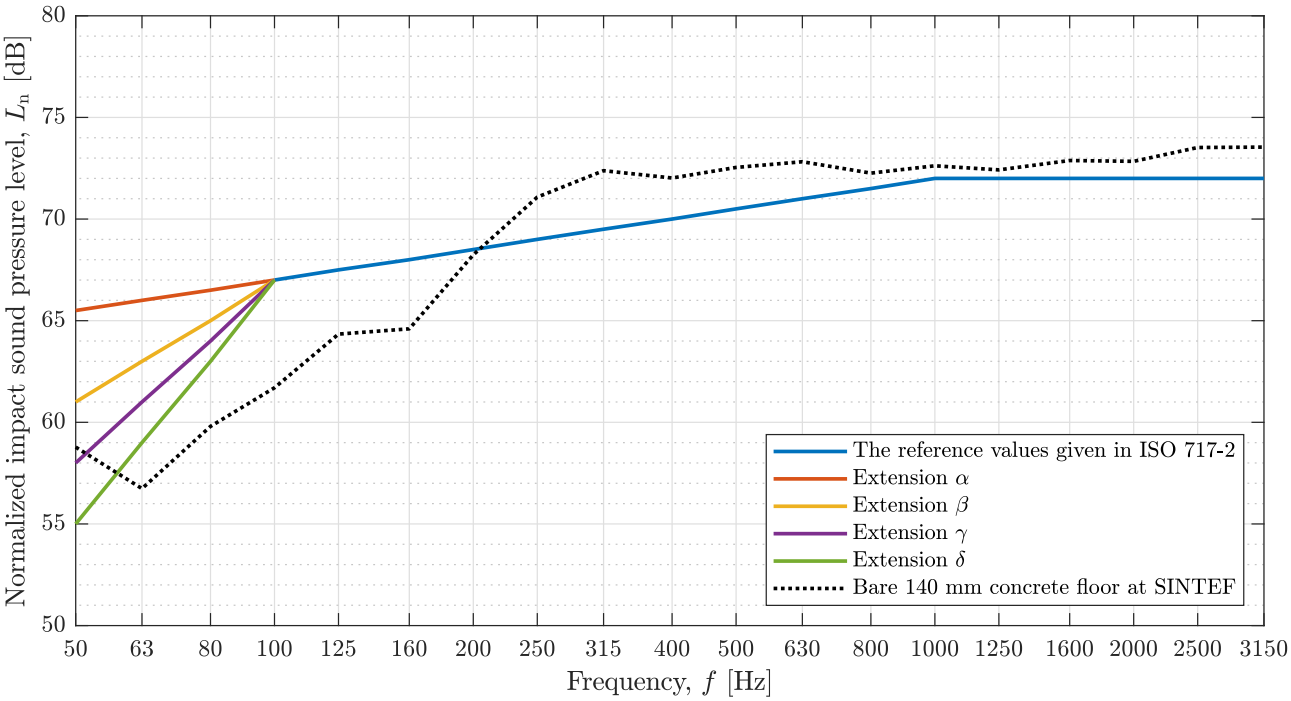

Figure 1. A graphical representation of the suggested extensions of the reference values in ISO 717-2, as well as an average of measured impact sound levels for SINTEF's bare 140 mm concrete floor

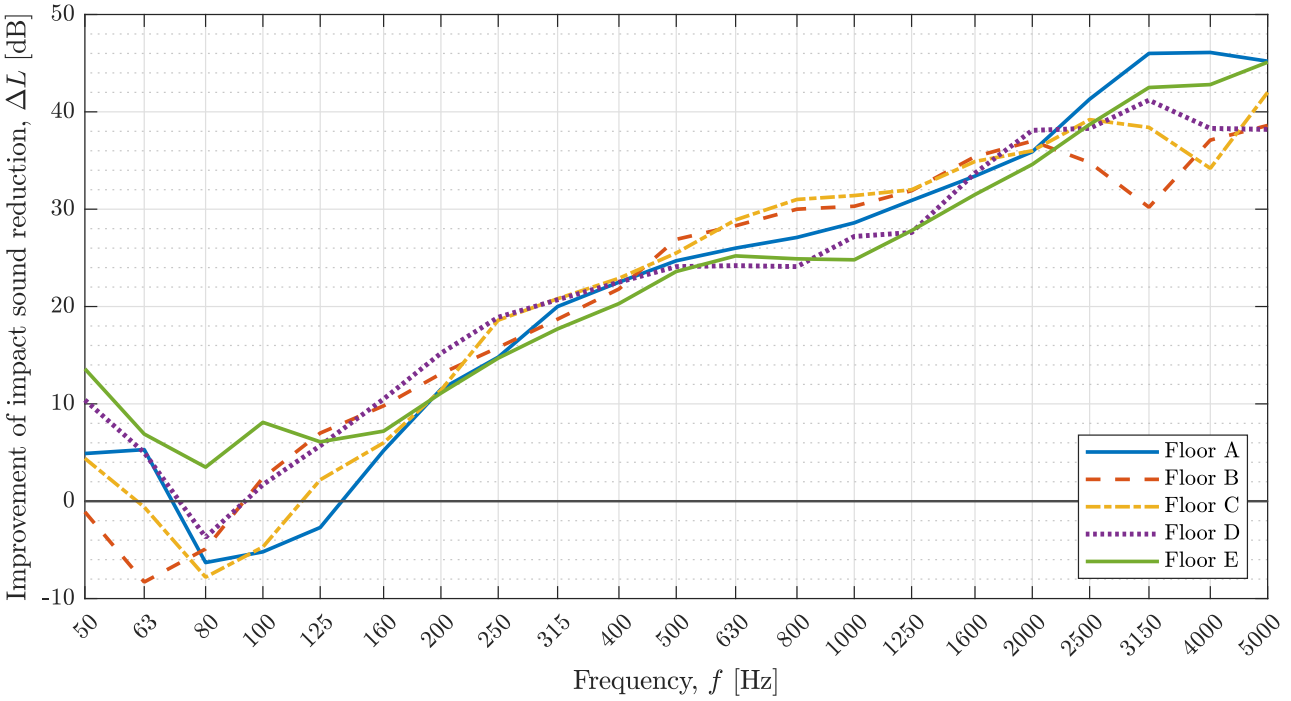

Figure 2. ΔL as a function of frequency for the five floors used in this study.

The first path considers $C_{\mathrm{I},50-80}$ as a direct alternative to $C_{\mathrm{I},50-2500}$. The other path considers calculating $C_{\mathrm{I,r},50-80}$ as a low frequency spectrum adaption term that is tied to ΔL_{w}, without affecting the use of $C_{\mathrm{I},50-2500}$. In essence, for the second path, ΔL_{w} describes 100–3150 Hz while $C_{\mathrm{I,r},50-80}$ works as a tool for an extended frequency range, describing only 50–80 Hz.

The goal is for the measured $L_{\mathrm{n,w}} + C_{50-80/2500}$ for the entire floor to align with the measured $L_{\mathrm{n,0,w}}$ for the bare reference floor minus ΔL_{w} for the floating floor plus the suggested low frequency spectrum adaption term, ideally on the conservative side. Additionally, ΔL_{w} and $C_{\mathrm{I},50-2500}$ are generally favouring floating floors with a low resonance frequency, which is good for the lowest frequencies in the traditional 100–3150 Hz range, but significantly less so for the extended part of the frequency range. A low frequency spectrum adaption term to accompany ΔL_{w} should therefore ideally also reflect how well the floor in question handles the lowest frequencies.

It the follwing, it is important to be aware that $C_{\mathrm{I},50-80}$ or $C_{\mathrm{I},50-2500}$ refers to the spectrum adaption term calculated from the measured $L_{\mathrm{n,w}}$ of a complete floor, while $C_{\mathrm{I,}\mathbf{r}\mathrm{,}50-80}$ or $C_{\mathrm{I,}\mathbf{r}\mathrm{,}50-2500}$ refers to the spectrum adaption term calculated to go alongside ΔL_{w}. The calculation procedures are described in ISO 717-2, and are also briefly explained in chapter 3 below.

3. CALCULATION PROCEDURE

When measuring the weighted improvement of impact sound reduction, ΔL_{w}, according to ISO 10140-1 [5] and ISO 10140-3 [6], a reference measurement is performed on a bare reference floor, and then the measurement is repeated on the test floor. The first set of measurement values are denoted as $L_{\mathrm{n,0}}$ and the latter as L_{n}. The frequency dependent reduction of impact sound pressure level, ΔL, may then be calculated as follows:

$$\Delta L = L_{\mathrm{n,0}} - L_{\mathrm{n}}. \tag{1}$$

Following from this, one can calculate ΔL_{w} with the help of the reference spectra that are defined between 100 and 3150 Hz in ISO 717-2. For the heavyweight reference floor the spectrum is denoted as $L_{\mathrm{n,r,0}}$. This calculation is performed in two steps, with the first being

$$L_{\mathrm{n,r}} = L_{\mathrm{n,r,0}} - \Delta L. \tag{2}$$

At this point, $L_{\mathrm{n,r,w}}$ is calculated from $L_{\mathrm{n,r}}$ using the regular procedure for calculating the normalized weighted impact sound level given in ISO 717-2. Then, the second step is

$$\Delta L_{\mathrm{w}} = L_{\mathrm{n,r,0,w}} - L_{\mathrm{n,r,w}}, \tag{3}$$

where $L_{\mathrm{n,r,0,w}}$ equals 78 dB for heavyweight floors.

As for spectrum adaption terms, they are calculated with the following formula, normally for the frequency range 100–2500 Hz or 50–2500 Hz:

$$C_{\mathrm{I}} = L_{\mathrm{n,sum}} - 15 - L_{\mathrm{n,w}}, \tag{4}$$

where

$$L_{\mathrm{n,sum}} = 10\mathrm{lg} \sum_{i=1}^{k} 10^{L_i/10}. \tag{5}$$

The same calculation can be carried out for $L_{\mathrm{n,r}}$ and $L_{\mathrm{n,r,w}}$, then denoted as $C_{\mathrm{I,r}}$. It is not explicitly stated in the standard that Eqn. (4) may be used for other frequency ranges, but any calculations of $C_{\mathrm{I},50-80}$ and $C_{\mathrm{I,r},50-80}$ in this paper have been performed using this equation.

4. RESULTS AND DISCUSSION

4.1 Measurement and calculation data

Measurement data for the five floors are given in Tab. 1 and Tab. 2. Calculated $C_{\mathrm{I,r},50-80}$ for the five floating floors and four extensions of the reference spectra are shown in Tab. 3.

Table 1. $L_{\mathrm{n,w}}$ and ΔL_{w} for the five floors.

Floor	A	B	C	D	E
$L_{\mathrm{n,w}}$	53 dB	51 dB	53 dB	49 dB	50 dB
ΔL_{w}	22 dB	26 dB	23 dB	28 dB	28 dB

Table 2. $C_{\mathrm{I},50-5000}$ and $C_{\mathrm{I},50-80}$ for the five floors.

Floor	A	B	C	D	E
$C_{\mathrm{I},50-2500}$	4 dB	4 dB	4 dB	3 dB	1 dB
$C_{\mathrm{I},50-80}$	-2 dB	3 dB	0 dB	0 dB	-8 dB

Table 3. Calculated $C_{\mathrm{I,r},50-80}$ for the five floors and four extended spectra.

Floor	A	B	C	D	E
$C_{\mathrm{I,r},50-80,\alpha}$	2 dB	10 dB	5 dB	6 dB	-1 dB
$C_{\mathrm{I,r},50-80,\beta}$	1 dB	7 dB	3 dB	4 dB	-3 dB
$C_{\mathrm{I,r},50-80,\gamma}$	0 dB	5 dB	2 dB	3 dB	-5 dB
$C_{\mathrm{I,r},50-80,\delta}$	-2 dB	4 dB	1 dB	2 dB	-6 dB

4.2 Path one

As Tab. 2 shows, $C_{\mathrm{I},50-80}$ is 0 or lower for four of the floors. which suggests that it's poorly suited as a low frequency spectrum adaption term. Even for Floor B, which is by far the worst performing floors at these frequencies, $C_{\mathrm{I},50-80}$ is lower than the presently used $C_{\mathrm{I},50-2500}$.

However, Tab. 2 also highlights a major weakness in $C_{\mathrm{I},50-2500}$, which is the same for floors A, B and C despite Floor B being very different to the other two. In fact, ΔL for Floor B is negative in all three third octave bands below 100 Hz due to the floor's low resonance frequency, which has a strong positive impact on ΔL_{w}, and a less strong, but nonetheless positive, impact on $C_{\mathrm{I},50-2500}$.

One could, however, consider using a different constant than 15 in Eqn. (4) for the calculation of $C_{\mathrm{I},50-80}$, see Fig. 3.

As the figure shows, it is difficult to obtain values for $C_{\mathrm{I},50-80}$ that show particular likeness with $C_{\mathrm{I},50-2500}$ using this calculation method. Other frequency ranges, like 50–100 Hz or 50–125 Hz could also be considered, but as Fig. 4 shows, $C_{\mathrm{I},50-x}$ moves quickly towards $C_{\mathrm{I},50-2500}$ as x goes above 80 Hz. It is difficult to find good arguments for why any of these alternative spectrum adaption terms are any better than $C_{\mathrm{I},50-2500}$, and therefore it seems sensible to avoid this path.

4.3 Path two

$C_{\mathrm{I},50-80}$ may be a poor choice for a spectrum adaption term to go along with $L_{\mathrm{n,w}}$, but when calculated as a spectrum adaption term to go alongside ΔL_{w}, the numbers in Tab. 3 are showing more promise. An issue with using $C_{\mathrm{I,r},50-2500}$ are the relatively high reference values at 100–160 Hz, which normally lead to very conservative values for $C_{\mathrm{I,r},50-2500}$ no matter how steeply the curve for the reference floor is dropping below 100 Hz [7].

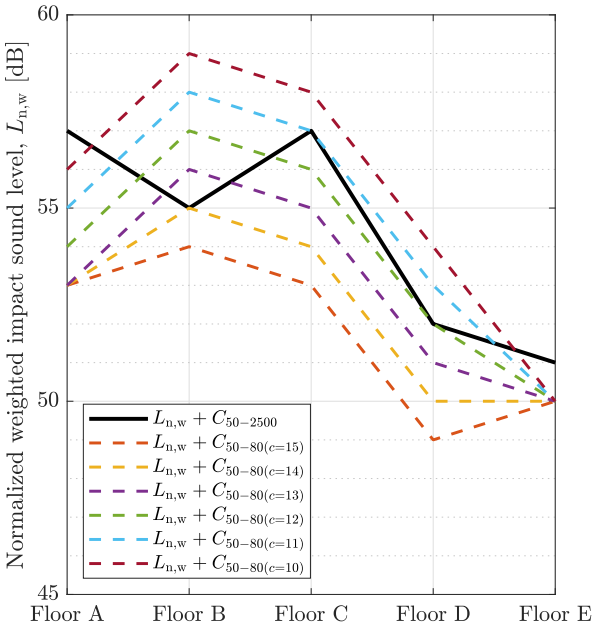

Figure 3. Alternatives for calculating $C_{\mathrm{I},50-80}$.

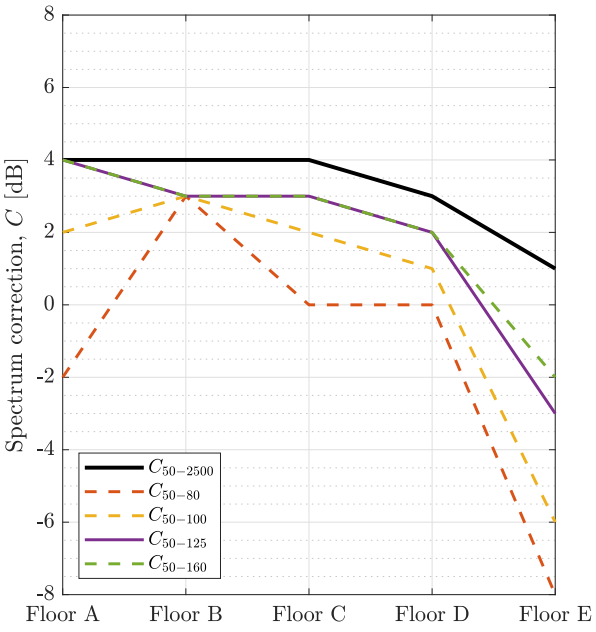

Figure 4. A graphical representation of how different evaluation ranges affect the calculated spectrum adaption terms.

By adding up $L_{\mathrm{n,0,w}}$ for the 140 mm concrete floor, which is 79 dB, ΔL_{w} from Tab. 1 and $C_{\mathrm{I,r,50-80}}$ from Tab. 3 and comparing the numbers with the measured $L_{\mathrm{n,w}} + C_{\mathrm{I,50-2500}}$, relatively similar results are achieved for the more aggressive approaches to the extension of the reference spectrum. This is assuming negative values are not to be counted, which at least is the case in Norway [1]. This is visualised graphically in Fig. 5.

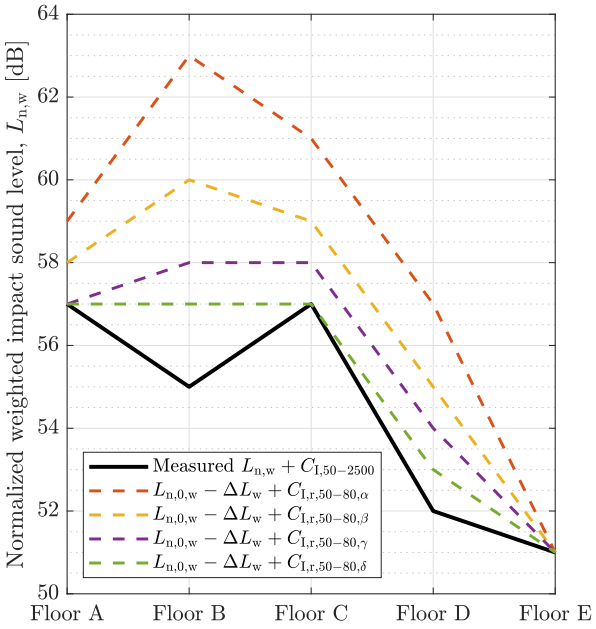

Figure 5. A graphical representation of how the calculated spectrum adaption terms in Tab. 3 align with measured results.

As the figure shows, the results for the δ-spectrum are very close to the measured results, with the exception of Floor B. However, given Floor B's poor low frequency characteristics it can be argued that this is a good thing. In this format, $C_{\mathrm{I,r,50-80}}$ acts as a number that can be added to ΔL_{w} to obtain a relatively good approximation of $L_{\mathrm{n,w}} + C_{\mathrm{I,50-2500}}$, but it can also be used as a comparison tool for the five floating floors. Floor B has the worst low frequency characteristics of the five, and therefore also the highest $C_{\mathrm{I,r,50-80}}$. Floor E, on the other hand, has excellent low frequency characteristics, and $C_{\mathrm{I,r,50-80}}$ for that floor is correspondingly low.

Thus, the values in Tab. 3 can be used as a simple way to rank the low frequency characteristics of a number of floors. The relative low frequency strength of the five floors seems to be generally well represented in Tab. 3, perhaps with the exception of Floor D. However, any low frequency spectrum adaption term is calculated in context of the $L_{\mathrm{n,w}}$ of the floor, meaning that although Floor D's low frequency characteristics in isolation are the second best of the five, they are relatively poor in context of the floor's measured $L_{\mathrm{n,w}}$.

The negative values for Floors A and E can perhaps be used as an argument against this method, but when using the data to calculate the expected $L_{\mathrm{n,w}} + C_{\mathrm{I,50-2500}}$, any negative values will be set to 0. As a tool to compare the different floors, large variations can be positive. It should also be noted that the spectrum adaption terms for floors A and E effectively are 0 for both the δ and γ spectra. This is a cause for concern, but Floor E has $C_{\mathrm{I,50-2500}}$ of 1, so the difference here is small. The difference is significantly larger for Floor A, but Floor A is also somewhat of an outlier, with the largest difference between $L_{\mathrm{n,w}}$ and $L_{\mathrm{n,0,w}} - \Delta L_{\mathrm{w}}$, see Fig. 6.

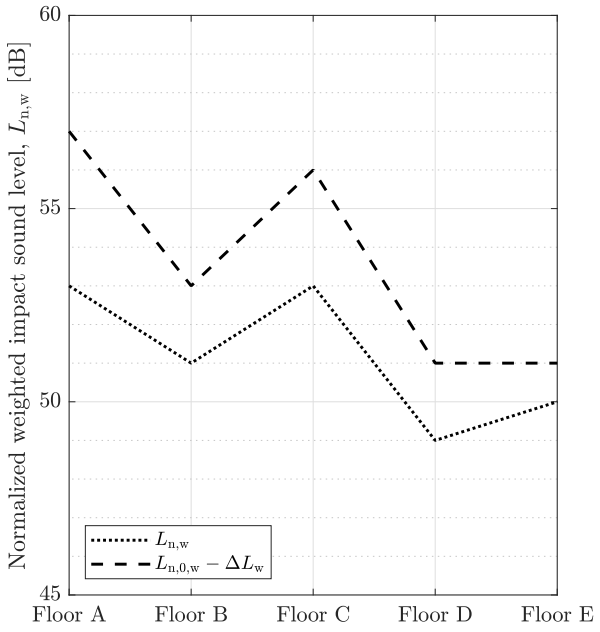

Figure 6. The difference between $L_{\mathrm{n,w}}$ and $L_{\mathrm{n,0,w}} - \Delta L_{\mathrm{w}}$.

4.4 Summary

It has been difficult to find a way to calculate a low frequency spectrum adaption term for ΔL_{w} that is directly comparable to $C_{\mathrm{I,50-2500}}$. Using $C_{\mathrm{I,r,50-2500}}$ is not a

good option because it leads to very conservative results. $C_{\mathrm{I,r},50-80}$ does however give sensible results for some of the suggested extensions of the reference spectra in ISO 717-2, but it isn't directly comparable to $C_{\mathrm{I},50-2500}$, and replacing $C_{\mathrm{I},50-2500}$ with $C_{\mathrm{I},50-80}$ or similar variations does not seem to be a good idea.

As a possible solution, it is suggested to use $C_{\mathrm{I,r},50-80}$ as a term that is strictly connected to ΔL_{w}. For the γ and δ spectrum extensions suggested in this paper, $C_{\mathrm{I,r},50-80}$ provides good differentiation between the different floors. This makes $C_{\mathrm{I,r},50-80}$ suitable as a tool to rank the low frequency performance of different floors as well as to calculate the expected $L_{\mathrm{n,w}} + C_{\mathrm{I},50-2500}$ for a floor construction based on $L_{\mathrm{n,w}}$ for the bare floor, and ΔL_{w} and $C_{\mathrm{I,r},50-80}$ for the floating floor.

5. FURTHER WORK

The findings above suggest that $C_{\mathrm{I,r},50-80}$ may be an option for how frequencies lower than 100 Hz can be tied to ΔL_{w} via a low frequency spectrum adaption term. However, the findings are based on a small sample size from one lab, and to obtain a better basis for decision, deeper studies with more data from several labs are needed.

6. CONCLUSION

When $C_{\mathrm{I},50-2500}$ gets introduced in building legislation, there is a need to update ISO 717-2 to facilitate calculations of a low frequency spectrum adaption term for the weighted improvement of impact sound reduction, ΔL_{w}. To be able to perform such a calculation, an extension of the reference spectra in ISO 717-2 down to 50 Hz is necessary.

In this paper, some alternative extensions for the heavyweight reference floor are suggested, and the low frequency spectrum adaption term $C_{\mathrm{I,r},50-80}$ is assessed as a possibility. The findings show that $C_{\mathrm{I,r},50-80}$ in combination with one or more of the suggested spectra may well be a viable solution. However, since this paper is based on a small sample size from one lab, further and more comprehensive studies are needed.

FORUM ACUSTICUM EURONOISE 2025

THE CONSTRUCTION OF A STANDARDIZED ACOUSTIC TESTING ROOM FOSTERS INNOVATIVE SOLUTIONS MEETING FUTURE MARKET TECHNICAL DEMANDS.

Alvaro Martínez de Marcos
Head of Acoustics. Product Manager
Danosa Group S.A., Polígono Industrial Sector, 9, 19290 Fontanar, Guadalajara, Spain

ABSTRACT

The construction of a standardized acoustic testing room is a key development in fostering innovative solutions that meet the current technical demands of the market. This presentation details the design and construction process of a specialized facility that provides controlled conditions for the precise evaluation of acoustic technologies. The room enables the research and enhancement of materials and technologies that improve acoustic comfort and soundproofing, contributing to the advancement of acoustic engineering in key sectors such as construction. Additionally, the presentation highlights how this infrastructure serves as a crucial tool for complying with technical standards and addressing the growing market demands. It also emphasizes the important role manufacturers play in promoting initiatives from technical committees, working closely with governments to ensure that acoustic solutions improve the quality of life for the population. Through this approach, the collaboration between industry and authorities is key to creating healthier and more comfortable living conditions, contributing to the continuous improvement of urban and residential environments.

1. INTRODUCTION

This article presents the development of specialised acoustic rooms for the evaluation of construction solutions. The creation of these facilities responds to the growing need to investigate new alternatives within the field of lightweight and industrialised construction, understanding 'lightweight' as one in which the structural elements are mainly composed of wood, sheet metal or other low-mass materials. Furthermore, this initiative is linked to the future update of the Spanish Technical Building Code (Código Técnico de la Edificación), scheduled for 2026, which drives the need to adapt construction solutions to the new regulatory requirements.

2. DRIVING ACOUSTIC INNOVATION BY DANOSA GROUP S.A.

The new acoustic rooms are being constructed in Fontanar, a small village in the province of Guadalajara (Spain) , with a population of just over a hundred inhabitants, where the facilities of Danosa Group S.A. are located, the company behind this project. Founded over 60 years ago, Danosa Group S.A. has been a pioneer in the development of acoustic insulation since the 1980s, specialising in the manufacture of elastic materials such as polyethylene foams and anti-resonant elements like acoustic membranes and multi-layer products.

Throughout its history, Danosa Group S.A. has played a key role in the development of various national technical standards, contributing to the advancement of the industry and the establishment of benchmarks in the sector. Furthermore, the company has introduced innovative solutions to the market by creating integrated acoustic systems that combine different materials to improve both airborne and impact sound insulation in construction. Its approach has always been to provide value-added

proposals, adapting to the growing needs of the sector and contributing to the improvement of acoustic quality in built environments.

3. DEVELOPMETN CONTEXT

3.1 New construction systems

The increasing adoption of new lightweight construction solutions, such as thin sheet metal (1 mm to 1.5 mm thickness), laminated wood panels (CLT), sandwich panels with rigid insulation cores, and traditional timber beam systems, presents significant challenges in accurately modelling their acoustic performance using specialised software. These novel construction methods necessitate substantial research and development efforts from acoustic insulation manufacturers to ensure effective soundproofing. This situation mirrors the developments of the 1980s, when the industry pioneered decoupling solutions for compression layers on floors and structural elements to mitigate impact noise, or replaced lead sheets with bituminous membranes for improved airborne noise insulation. Today, manufacturers are once again called upon to innovate and design new solutions to address the acoustic complexities associated with these lightweight construction systems. This ongoing demand for technological advancements continues to drive the evolution of acoustic insulation products and methodologies.

3.2 Regulatory change

The second factor driving the creation of this project is the knowledge of an imminent significant change in Spanish acoustic regulations[1], which involves an increase of approximately 2 dB in airborne sound levels (DnTa 52 dBA) and a reduction of 5 dB in impact noise (Lntw 60 dB) in protected rooms, along with new restrictions on tolerances in measurements. This change is accompanied by a renewed focus from the National Technical Committees, emphasizing the importance of manufacturers actively collaborating in the development of new acoustically justified solutions. The goal is to create "standard" solution catalogs that can serve as references for designing future constructions, ensuring compliance with the new regulatory requirements.

3.3 Improving quality of life

The involvement of construction manufacturers in technical committees, associations, forums, and various markets, alongside architects and building designers, provides a realistic representation of the impact on people's quality of life. In this context, without delving into purely commercial matters, manufacturers position themselves as innovative entities with the financial capacity to allocate resources towards the development of testing and measurement elements for future systems. Furthermore, they possess extensive knowledge of diverse products and solutions used worldwide, which allows them to contribute to society by providing solutions that enhance quality of life. These solutions are also closely aligned with environmental sustainability, as they often incorporate new materials that reduce the ecological footprint of the products.

3.4 Participants in project development

The following paragraph describes the participants who have directly contributed their expertise to the design and construction of the testing rooms.

3.4.1 Danosa Group S.A.

As the promoting and contracting entity, is represented by Álvaro Martínez, a member of the Technical Standardization Committee CTN-74 and Head of Acoustics at the company. Advocates for the construction of an acoustic measurement facility where new solutions for the market can be developed.

3.4.2 Tecnalia

As one of the leading companies in innovation at the national level and one of the main institutes, it has Marta Fuente as the head of acoustics.

3.4.3 Gikesa

As an acoustic measurement laboratory and a benchmark in technical support for the construction sector.

3.4.4 Maribel Castro (Architect)

Architect in charge of the projects and construction management of the buildings and constructions at Danosa Group S.A.

4. TESTIGN ROOM DESIGN

4.1 Regulation

The design of the testing chambers is based, as expected, on the ISO 10140 standards, both with regard to the requirements for installations and equipment [UNE-EN ISO

[1] Incomming regulation January 2026. New CTE DB-HR

10140-5] and the measurement methodology itself [UNE-EN ISO 10140-2 and 4], enabling the comparison of results with those obtained by other laboratories.
Although the aforementioned standards do not specifically address the design of acoustic transmission chambers, they do specify, either quantitatively or qualitatively, a set of requirements that significantly influence the design, such as:

- Minimum dimensions and volumes.
- Controlled reverberation time in both chambers.
- The need for the acoustic field inside the chambers to be diffuse.
- Minimisation of indirect transmissions between chambers.
- Background noise as low as possible in the receiving chamber.
- Energy dissipation (loss factor) for heavy samples.

4.2 Sizing

Regarding the dimensions and volumes, a separator element measuring 3.4 x 4.6 meters has been chosen, which closely resembles the standard surface area of a residential space. The volume difference between the chambers is maintained within 10%, in compliance with the requirements set out by the standard.

4.2.1 Minimisation of Indirect Sound Transmission

One of the key aspects in the design of an acoustic laboratory is the minimisation of indirect sound transmission between chambers. Unlike real-world construction, where sound is transmitted between spaces through multiple transmission paths, the goal in a laboratory setting is to ensure that the sound only travels through the test sample, thereby characterising the material or construction solution. The joints between elements of the different chambers are specifically designed to achieve this by using structural decoupling components with very low dynamic stiffness. This approach effectively isolates the chambers, ensuring that the measurements accurately reflect the acoustic properties of the sample under test.

4.2.2 Energy Dissipation (Loss Factor)

Another important parameter is the loss factor (energy dissipation) of the sample once placed between the transmission chambers. While this aspect is primarily relevant for heavy samples, it has also been considered in the design to ensure the accuracy and reliability of the test results.

4.2.3 Reverberation Time

The reverberation time is carefully controlled in both chambers, set between 1 and 2 seconds, achieved through the strategic placement of absorbent materials in both the emitter and receiver rooms. The acoustic field within each chamber is diffuse, meaning that a large number of reflected waves, originating from all directions, combine in such a way that, at any given point and in any instantaneous direction of the sound wave, the average density of acoustic energy is equally probable. This is first achieved through appropriate chamber sizing, which accounts for the potential for standing waves or dominant modes, particularly at low frequencies. Additionally, once the laboratory is constructed, this diffuse field is further ensured by the placement of curved reflective elements, whose positioning and orientation are determined through a statistical testing process.

As part of the design development, a model of the potential indirect transmissions has been created, which integrates the defined construction solution. Based on this model, the maximum acoustic parameters R'w and L'nTw have been estimated, yielding a value of 94 dB for R'w and 23 dB for L'nTw.
It is important to highlight that these values represent the measurement limit due to flanking transmissions, but they are subject to the influence of background noise in the receiving room. This factor is controlled through the configuration of the room envelope, as well as by the influence of external noise generated outside.

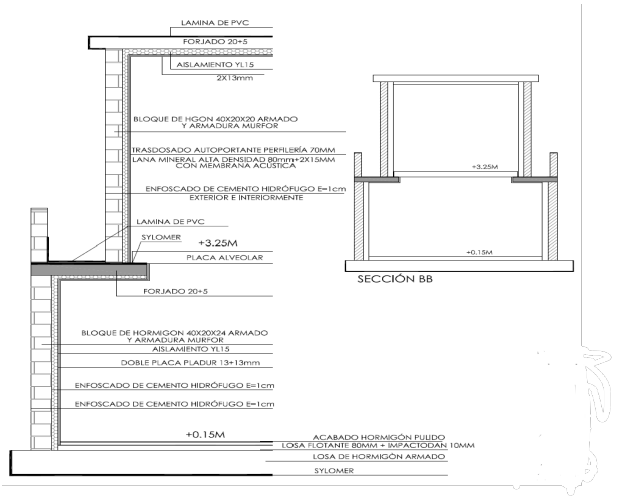

Figure 1. Construction section of the testing rooms (1)

4.2.4 Isolation of the chambers

Finally, yet equally important, the isolation of the chambers from external noise sources ensures the lowest possible background noise in the receiving chamber. This allows for the accurate measurement of high levels of sound insulation without any interference, ensuring the reliability of the test results.

Once the testing room is designed, constructed, and calibrated, the measurement procedure and the equipment to be used will be established. Following this, the results of the insulation tests will be validated. To achieve this, tests will be conducted on various items with known insulation properties, ensuring that the measurements align with the expected values.

Figure 2. Construction interior of the testing rooms (2)

5. SOLUTIONS TO BE TESTED

5.1 Light or industrialised construction

Lightweight construction solutions are increasingly in demand within the sector. The rapid construction time, coupled with the reduced cost of buildings due to the use of fewer materials, has driven the adoption of new building systems. However, the limited acoustic insulation offered by these structures, combined with the rigidity of their connections, necessitates the integration of additional elements with insulating properties. Within the category of "lightweight" systems, the following can be considered.

5.1.1 CLT (Cross-Laminated Timber)

Innovative and sustainable building material that has gained popularity in modern architecture. CLT is manufactured by bonding layers of wood (typically pine, spruce, or other types of wood) arranged in alternating directions (crosswise), which provides greater strength and dimensional stability compared to traditional wood.

5.1.2 Wood beam structure

Construction system primarily used in buildings and other infrastructures to support loads and distribute them efficiently. Beams are horizontal or inclined components responsible for transferring the loads from the structure to the ground or other supporting elements, such as columns or walls. In a wood beam structure, wood is the primary material used due to its mechanical properties, aesthetics, and sustainability.

5.1.3 Deck-type sheet structure

Construction system that uses steel panels (or, in some cases, other metallic materials) to form a strong and continuous surface that serves both to support loads and as part of the structural element of a building, typically in floor or roof slabs. This system is commonly used in the construction of industrial, commercial, residential buildings, and certain infrastructure applications due to its efficiency, speed of execution, and structural performance.

5.1.4 Prefabricated panel structure

A construction system that uses panels manufactured off-site (in a prefabrication plant) which are then

transported and assembled at the construction site. These panels can be made from various materials, such as concrete, wood, steel, or composite materials, and are designed to serve structural, aesthetic, or both functions. Prefabricated panels are modular elements produced in series under controlled conditions, ensuring their quality and dimensional accuracy.

The rigid elements to be used as separation layers and/or supports include OSB boards and fibre cement boards.

The acoustic components employed will consist of cross-linked polyethylene, acoustic membranes, rubber mats, multi-layer panels, anti-resonant elements, and other sound-absorbing materials. These can be placed in structural gaps or used as spring elements between masses. Additionally, vibration isolation systems will be integrated into certain solutions where low-frequency performance is required.

SPATIAL VARIATION OF THE SOUND PRESSURE LEVELS DUE TO HVAC SYSTEMS AND THE ASSESSMENT OF NOISE

Teresa Carrascal[1*] **Amelia Romero-Fernández** [1] **Belén Casla-Herguedas**[1]
[1] Eduardo Torroja Institute for Construction Sciences. IETcc- CSIC. Madrid, Spain

ABSTRACT

Regulations in many countries establish limits on noise produced by building services and equipment and refer to international standards such as ISO 16032 and ISO 10052 or to national procedures for the verification of such requirements.
This study analyses the distribution of sound produced by HVAC equipment in an office building. For that purpose, systematic measurements were conducted at multiple locations within a room to determine spatial variations in sound pressure levels produced by internal units. Factors influencing noise assessments such as room geometry, spatial sampling, HVAC equipment settings and the presence of background noise are also examined. The ultimate aim of this work is to study how variations of sound pressure levels affect the assessment of L_{Aeq} and to propose practical recommendations to assess noise from building services to fulfil regulatory requirements.

Keywords: *noise from building services, noise limit, requirements, ISO 16032, HVAC noise, spatial variation.*

1. INTRODUCTION

This communication aims to study the distribution of sound produced by HVAC (Heating, ventilation, and Air Conditioning) systems in a training room located at the Eduardo Torroja Institute for Construction Sciences, which is part of the Spanish National Research Council (CSIC) in Madrid.

Regulations in many countries establish limits on noise produced by building services and equipment and refer to international standards such as ISO 16032[1] and ISO 10052[2] or to national procedures for the verification of such requirements.
Although weighted descriptors used in regulations such as L_{Aeq}, $L_{Aeq,nT}$, $L_{AFmax,}$ etc. provide a general sense of acoustic performance, they often fail to capture the spatial non-uniformities of the sound field, in particular in the low frequency range.
This paper studies the spatial variations of sound pressure levels due to service and equipment in a training room in an office building, and its impact on weighted values.

2. SCENARIO DESCRIPTION

The Eduardo Torroja Institute for Construction Sciences is an entity that conducts scientific research and technological development in the field of construction, its materials, and the performance associated with the pursued approaches. It is housed in a distinctive building inaugurated in 1953, originally serving as the new headquarters for the Technical Institute of Construction and Cement, now known as the Eduardo Torroja Institute for Construction Sciences.
A room belonging to the Eduardo Torroja Institute for Construction Sciences was studied, as described below.
The room was originally the archive of the former library of the Institute. This archive was relocated to the basement of the building, creating a space that began to be used as a training room. An absorbent ceiling was installed, along with a movable partition to divide the room into two sections[3]. The absorbent ceiling improves user comfort and ensures compliance with the acoustic conditioning requirements outlined in the current regulations, specifically the Basic Document DB HR Protection Against Noise of the Spanish Technical Building Code[4]. The current layout

of the training room is rectangular, with a floor area of 69.8 m² and a height of 2.75 m. See Figure 1.

a) b)

Figure 1. a) Photograph of the training room. b) Detail of one of the three indoor units the room is equipped with.

3. MEASUREMENTS PERFORMED

Equivalent sound level (L_{eq}) measurements were conducted over 15-second intervals at 30 points within the room (Figure 2), at two different heights: 1.20 m and 1.50 m, resulting in a total of 60 measurements. These two heights were chosen because they represent typical positions of the occupants in the room, 1.20 m is the ear height used in standards for acoustic measurements[5]. The height of 1.50 m above floor level below the noise source is specified in ISO 16032 procedure [1].

Additionally, sound levels were taken at three room corners, (separated 50 cm from the walls and the floor) and nine background noise measurements were taken in different positions. These measurements were repeated for the V3 and V5 ventilation modes.

The training room is equipped with three ceiling-mounted variable refrigerant flow (VRF) indoor units positioned at the distances marked in Figure 2. These units consisted on four-way ceiling cassettes that operate simultaneously and have three modes of operation: heating, cooling, and ventilation. Each of these modes has five ventilation speed settings.

For this study, measurements were carried out with the "ventilation" mode at two speeds: the highest (V5) and the medium (V3), while the lowest speed was excluded due to its noise levels being close to the background noise. The ventilation mode was selected because it provides a constant fan speed during operation, in contrast to the heating and cooling modes, where the system automatically regulates fan speed and refrigerant flow to maintain the desired room temperature.

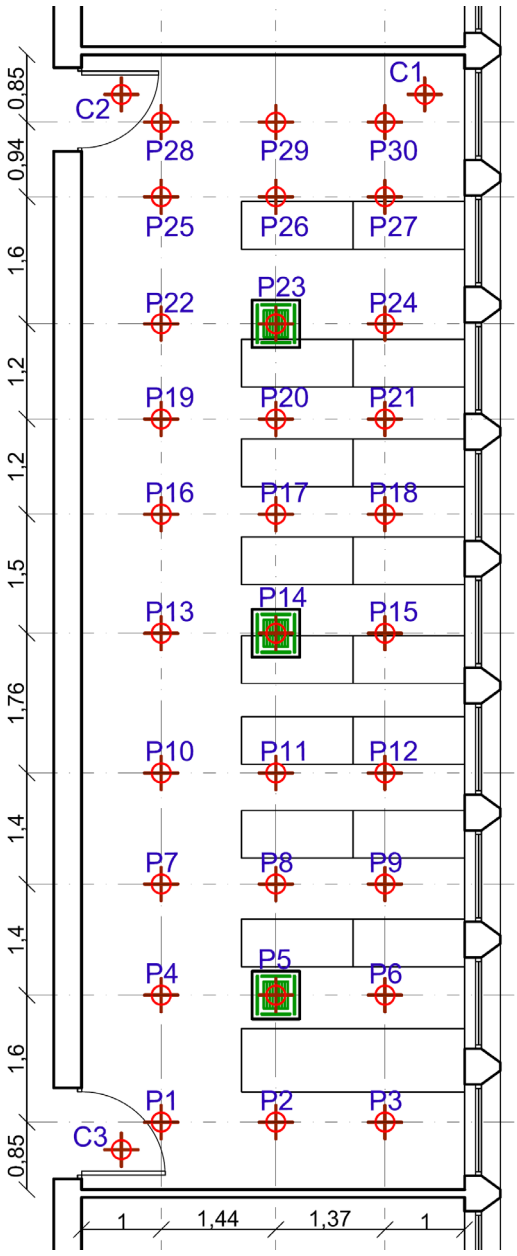

Figure 2. Plan of the room indicating the measurement positions and the location of the VRF cassettes.

The measurements were conducted with two people present in the room, which was furnished with chairs and tables (see test scenario description in Section 2.2). A floor plan of the room with the distribution of the source and microphone positions for the measurements is shown in Figure 2.

The equipment used for the measurements was as follows:

- Environmental sound level meter, Class 1, model CR:171B, by Cirrus Research plc;
- Calibrator model CB006, by Cesva.

Using an acoustic calibrator, sound level checks of the measurement chain were performed before and after the tests, with satisfactory results.

Data processing was carried out using the NoiseTools v1.8.9 software for data downloading, analysis, and reporting, along with Microsoft Excel and MATLAB R2024b update 3.

4. RESULTS

The primary noise sources during the measurements were the fans and the airflow passing through filters, coils and louvers. Refrigerant-related noise was negligible since the compressor was not active, which is why the ventilation mode was chosen for this study.

The sound source remained steady and did not show significant fluctuations over time as the equivalent continuous sound pressure levels (L_{eq}) remained stable throughout the measurement periods.

Table 1 shows the average A-weighted and C-weighted equivalent continuous sound pressure levels obtained for the 30 measurement points, as well as the maximum values and the minimum values of L_{Aeq} and L_{Ceq}, along with the corresponding ranges, for the two fan speed settings and the two measurement heights.

Table 1. L_{Aeq} and L_{Ceq} for the two fan speed settings and the two measurement heights.

Velocity setting		**Velocity 3**		**Velocity 5**	
Height (cm)		**h=120**	**h=150**	**h=120**	**h=150**
$L_{A,eq}$ (dB)	Average	40.1	40.0	44.7	44.8
	Max	41.3	41.9	45.9	47.2
	Min	38.8	38.3	43.5	43.1
	Range	2.4	3.6	2.4	4.1
$L_{C,eq}$ (dB)	Average	52.3	53.4	53.9	54.6
	Max	56.3	59.0	55.4	60.5
	Min	49.4	49.9	52.7	52.3
	Range	6.9	9.1	2.7	8.2

Table 2 shows the values of the equivalent continuous sound pressure level measured at the 3 corner positions. The average background noise levels L_{Aeq} measured at the nine positions were 32.0 dB and 31.4 dB. Two sets of background noise level measurements were obtained, as the measurements for each fan speed setting were conducted different days.

Table 2. L_{Aeq} and L_{Ceq} measured at the 3 corner positions.

Velocity setting	**Velocity 3**			**Velocity 5**		
Corner	C1	C2	C3	C1	C2	C3
$L_{A,eq}$ (dB)	39.4	38.2	38.1	43.9	44.9	43.2
$L_{C,eq}$ (dB)	57.1	53.6	56.7	56.2	56.5	57.2

4.1 Spatial distribution of sound

Figure 3 shows the L_{Aeq} at each measurement position, including the corner positions, for each velocity setting and measurement height. The highest values corresponded to the positions located directly beneath the internal VRF units (P5, P14 and P26). The values of corner positions are represented by crosses.

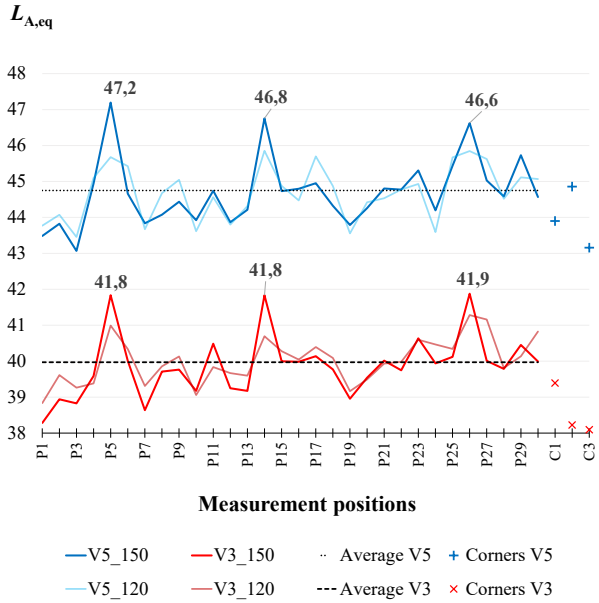

Figure 3. L_{Aeq} at each measurement position.

As seen in Figure 3 and Table 1, the average difference between the measurements performed at 120 cm and 150

cm is 0.4 dB in average. In contrast, the average difference between the measurements performed with V5 and V3 fan speeds is significantly higher 4.7 dB, likely due to the increased air volume and turbulence at V5.

Figure 4 shows the spatial variations of the L_{Aeq} in the room for the fan speed V5 and height 120 cm. It is clearly seen the positions with the highest L_{Aeq}, which are beneath the internal units.

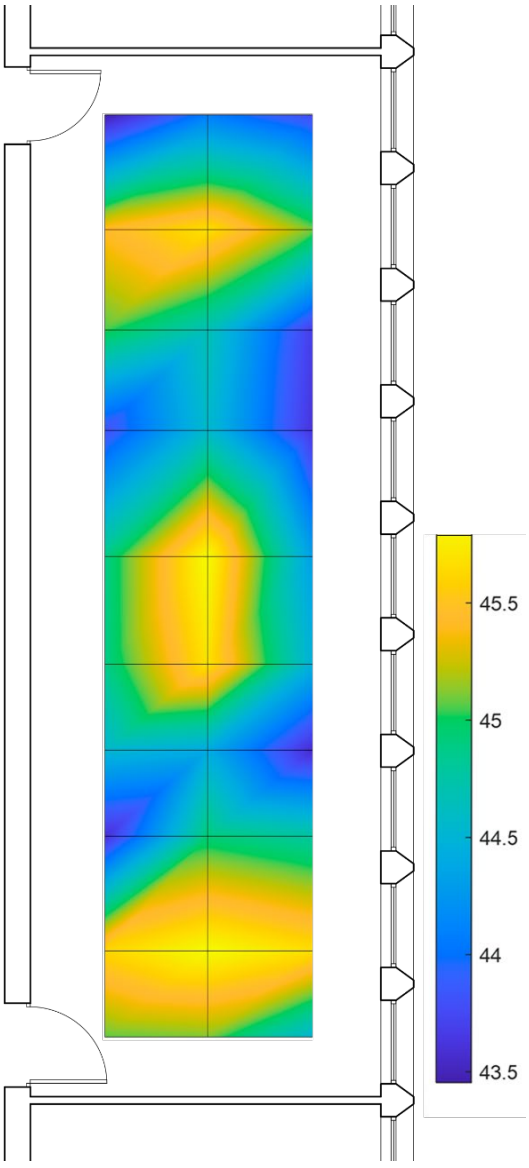

Figure 4. L_{Aeq} spatial variations in the room for the fan speed V5 and height 120 cm. Graph based on measured data. Plan view.

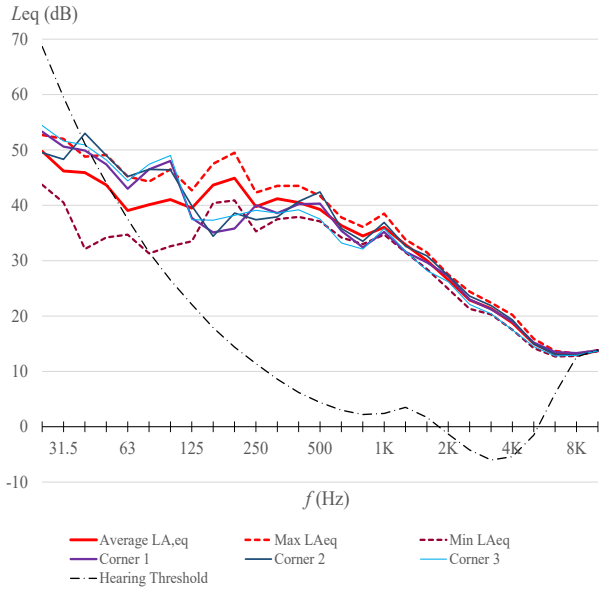
4.2 Frequency spectrum variations

Figure 5 shows the spectra of the average equivalent continuous sound pressure level obtained for the 30 points for the fan speed of V5 and height of 120 cm. The hearing threshold has also been represented, showing that part of the energy in below 50 Hz is below it Similar results were observed for measurements at fan speed V3 and height of 150 cm.



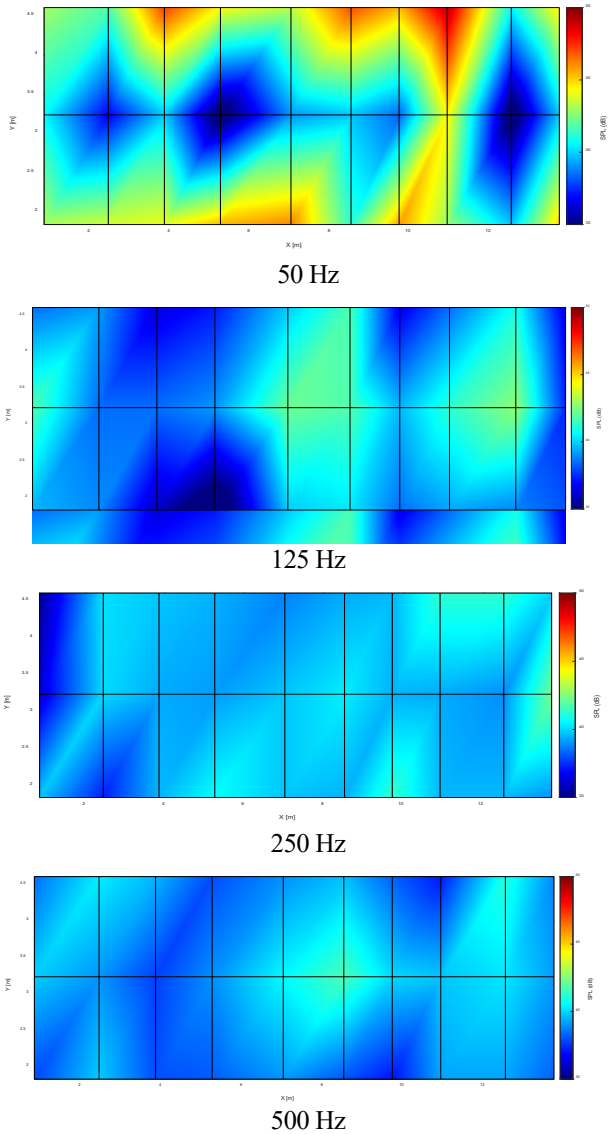


Figure 5. Average L_{Aeq} in the room for the fan speed V5 and height 120 cm.

As seen in Figure 5, most of the acoustic energy emitted by the VRF cassette units is concentrated in the low-mid frequency range.

Even though the A-weighted equivalent sound pressure level differences range from 2.4 to 4.1 dB, a closer look at the spectral results reveals differences of 7 to 15 dB in the low-frequency range (50–250 Hz). See Figure 5, which shows the average equivalent continuous sound pressure level obtained for the 30 points for the fan speed of V5 and height of 120 cm.

The Figure 6 shows the spatial distribution of the sound pressure levels in the room for the frequencies of 50, 125, 250, 500 Hz. The same color scale was used to plot all the graphs, and across the series, it is evident that the largest variations in the sound field occur in the low-frequency range. The Schroeder frequency of the room is 130 Hz, which marks the boundary between the low-frequency

range dominated by discrete room modes and the higher-frequency range where the sound field becomes statistically diffuse. As seen in Figures 5 and 6, the spatial variations become more significant bellow it due to the non- irregular modal behavior. At 50 Hz, the graph may show the influence of background noise coming from outside, caused by traffic.

50 Hz

125 Hz

250 Hz

500 Hz

Figure 6. Spatial distribution of the sound pressure levels in the room for the frequencies of 50, 125, 250, 500 Hz. Graph based on measured data. Plan view.

5. THE ASSESSMENT OF SERVICE AND EQUIPMENT NOISE

ISO 16032[1] contains the engineering method for the measurement of sound pressure levels in rooms from service equipment. It is referred in several European regulations[6] to verify compliance with requirements. This section presents the results that have been obtained using the estimation method described in ISO 16032[1] for the calculation of the average sound pressure level in the room, L_{Aeq}.

The sound pressure level is determined for a specified operating condition and duty cycle. Sound pressure levels are measured in three microphone positions, one position in a selected corner of the room and two positions in the reverberant sound field. All values were corrected for background noise.

Table 3 shows the results of the calculations. They were performed to determine the range of the average sound pressure levels, L_{Aeq}, obtainable in the room. The following criteria was used for the calculations:

- Positions with the highest sound pressure level, which are the ones beneath the internal units (P4, P14)
- Positions with the lowest sound pressure levels (P3, P13)
- Two positions chosen at random (P15, P19).

The corner position chosen was Corner C1, which is the corner that has the highest sound pressure level for both velocities (V3 and V5). This section aims to find the highest and the lowest value of the average L_{Aeq} obtainable, so positions below the VRF units are also included in the calculations, even when they are considered additional measurements in ISO 16032[1].

The differences found are 2.1 dB for V3 and 2.5 for V5.

Table 3. Calculated average L_{Aeq} in the room.

Velocity	Corner	Position 1	Position 2	ISO 16032 L_{Aeq}
V3	C1	P4	P14	40.5
V3	C1	P15	P19	40.0
V3	C1	P3	P13	38.4
V5	C1	P4	P14	45.8
V5	C1	P15	P19	44.0
V5	C1	P3	P13	43.3

5.1 Background noise levels

Background noise was measured at 9 positions across the room. Figure 7 shows a comparison of the sound pressure level of position 5, which is just beneath the internal unit and the background noise levels measured in the same position. Figure 8 shows the sound pressure levels at position 27, which was randomly selected from among the positions with average sound pressure levels. Background noise levels interfered in the positions that were far from the noise sources at fan speed 3 in the low frequency range and from 800 Hz upwards.

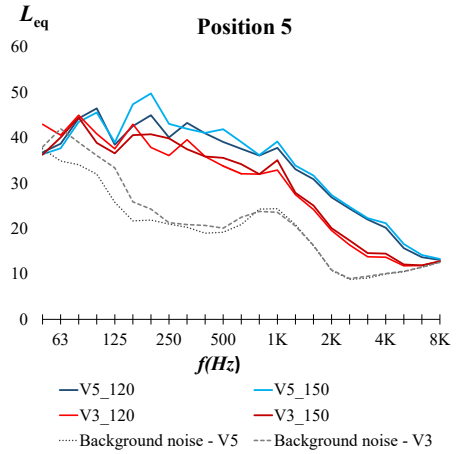

Figure 7. Sound pressure level in position 5 for two fan speed settings (V5 and V3) and two heights in comparison to background noise.

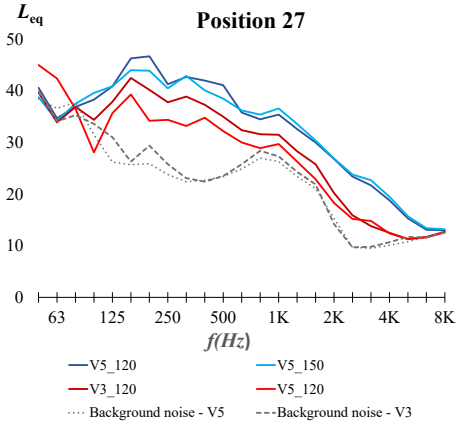

Figure 8. Sound pressure level in position 27 for two fan speed settings (V5 and V3) and two heights in comparison to background noise.

6. CONCLUSIONS

This paper is a study of the variation of the sound pressure levels in a room produced by HVAC equipment and how this affects the values of the average L_{Aeq} defined in ISO 16032.

A room in an office building was selected and measurements were performed in 30 positions, for two fan speed settings and two microphone heights: 120 cm and 150 cm, as these heights are typical occupant positions within this room.

The differences in sound pressure levels have been studied and compared in each position and in each frequency range.

Significant spatial variations of sound pressure levels were observed in the room, particularly in the low-frequency range (50–250 Hz), where differences of up to 15 dB were found between positions.

The average A-weighted differences between the two heights (120 cm and 150 cm) were minimal (~0.4 dB), indicating vertical uniformity at the range 120–150 cm of listener height, whereas fan speed changes (V3 vs. V5) resulted in much greater differences (~4.7 dB), primarily due to increased airflow.

The highest SPL values were consistently measured directly below the internal VRF units, confirming these areas as critical points for acoustic comfort.

When average L_{Aeq} levels were estimated using ISO 16032 method, differences of 2.1 dB and 2.5 dB were found between positions in this room for fan speeds of V3 and V5 respectively. Although the difference is small, it may determine whether the measured values fall within or exceed the limit values specified in national regulations.

In this particular case, it is sensible to take measurements at 1.50 m below the VRF units when assessing noise from building services, as this location represents a typical occupant position during courses and corresponds to a critical point in terms of sound exposure.

This study is part of a broader research carried out at Eduardo Torroja Institute for Construction Sciences, IETcc-CSIC, on service and equipment noise and its assessment. Other critical factors in the assessment of service and equipment noise have also been studied like the reverberation time correction[7].

A SURVEY & EVALUATION METHOD FOR SPEECH INTELLIGIBILITY OF FIREFIGHTING RADIOS CONSIDERING THE ENVIRONMENT OF THE FIRE SITE

Jeongho Jeong[1*] **Insu Yeom**[2]
[1] Fire Insurers Laboratories of Korea, Gyeonggi-do, Republic of Korea
[2] National Fire Research Institute, Chungcheongnam-do, Republic of Korea

ABSTRACT

In a firefighting site, the firefighter's radio plays a very important role in not only responding to the situation quickly but also in maintaining the life of the firefighter. In order for firefighters to communicate smoothly using the radio, they must be able to clearly deliver their voices and deliver them to the other firefighters. However, there are various noise sources at the firefighting site, as well as the influence of the main firefighting water, making it difficult to communicate using the radio. In this study, we conducted a survey on the level of speech transmission of radios used at firefighting sites and on-site noise. Firefighters mainly used radios and handy microphones, and responded that it was difficult to hear speech due to various noises at firefighting sites and howling phenomena of several radios in the same place. The main sources of noise at the site were the sirens of fire trucks and equipment noise such as pump cars. The siren sound transmitted into the interior of fire trucks was investigated to be very high at about 83 to 93 dB. In addition, it was investigated that the radio speech sound was affected by the main water supply for firefighting.

Keywords: *speech intelligibility, fire fighting, radio transmission, fire truck noise*

1. INTRODUCTION

In large-scale firefighting operations, swift fire suppression and successful rescue efforts heavily rely on rapid and clear communication between firefighters on the ground and the commanding staff. Communication at the fire site is primarily carried out through radios. Therefore, the radios used by firefighters must be capable of transmitting clear voice messages with sufficient volume. Recently, firefighter radios have evolved to resemble smartphones, incorporating various information and communication functions. There are various noise sources at the firefighting site, as well as the influence of the main firefighting water, making it difficult to communicate using the radio.

This study explores methods for developing information and communication radios that enable clear communication for firefighters at the fire site, focusing on evaluating speech intelligibility considering the noise conditions at the site.

To achieve this, the study first conducted a survey to assess the current state of speech intelligibility in firefighter radios. Secondly, the noise levels and characteristics of key firefighting equipment were investigated. Finally, the study proposes a method for measuring the speech intelligibility of radios by applying the widely used Speech Transmission Index (STI), as s standardized as IEC 60268-16[1] and ISO 3382-3[2], and by simulating the noise characteristics of a firefighting environment.

2. SURVEY ON THE NOISE OF FIRE SITE

A survey was conducted on the satisfaction with the transmission and reception of messages through radios used by firefighters, the causes of poor audibility, and the major noise sources in fire ground environments. The survey was carried out from June to July 2024, involving approximately 500 firefighters. The survey method included both paper questionnaires and an online response option.

Regarding the extent of message transmission through the radios, only 9.8 % of the respondents reported that all messages were successfully transmitted. Furthermore, in terms of satisfaction with the reception of speech, only 39 % of the firefighters expressed satisfaction with the

[*] ***Corresponding author***: jhjeong92@email.ad.

clarity of the received sound. The most commonly selected reasons for poor audibility of radio messages were the background noise at the scene and the sounds of other firefighters. This suggests that issues related to environmental noise and acoustic phenomena, such as howling, are the main causes of poor reception.

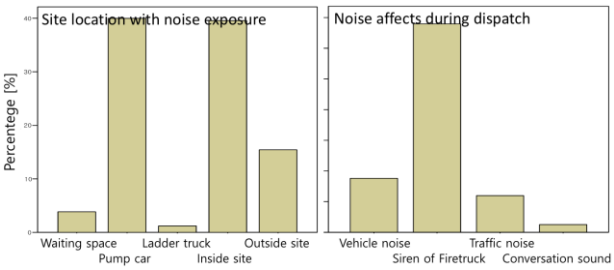

Figure 1. Results of a survey on noise at fire site

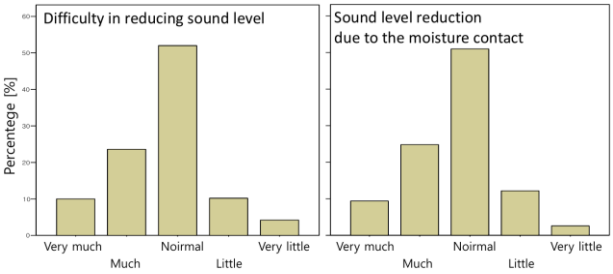

Figure 2. Survey results on difficulty in reducing level and sound level reduction due to the moisture contact

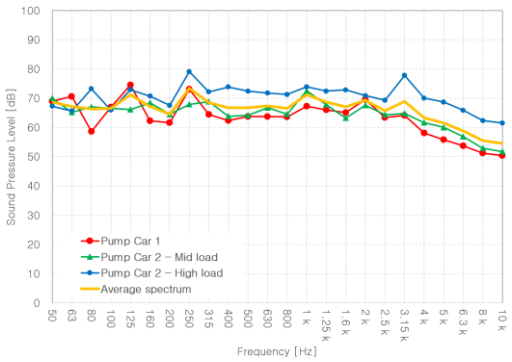
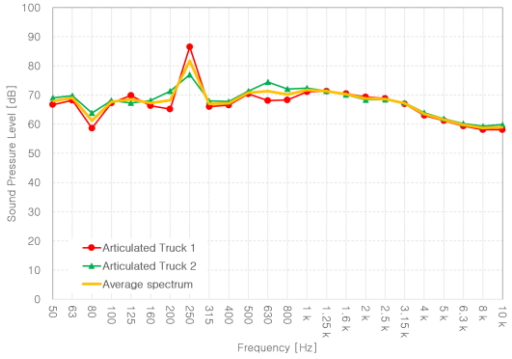
When asked about the locations and equipment that generate the most noise at fire ground operations, the results, as shown in Figure 1, indicated that pump trucks and the interior of fire scenes are the noisiest areas. During the dispatch phase, the siren of the fire truck was identified as the primary source of noise.



In terms of the reduction in radio volume and the effects of moisture, the survey results, as shown in Figure 2, revealed that 33.6% of respondents experienced difficulty due to low volume on their radios. Additionally, 34. 2% of firefighters reported experiencing difficulties due to moisture-related issues affecting the radios.

3. NOISE CHARACTERISTICS OF FIRE TRUCKS & SIREN



Based on the survey results, the noise characteristics of firefighting equipment were measured. Noise measurements were taken at several locations around the vehicles when operating pump trucks and articulated fire trucks, which are actively used by two fire stations in Gyeonggi Province. The noise from firefighting equipment was recorded throughout the entire training scenario, and noise levels were analyzed based on the operational stages and load conditions of the equipment. Figure 3 shows the firefighter training scenario and the articulated fire truck being measured.

Figure 3. The noise measurement of articulated fire trucks and firefighter training scenarios.

(a) Frequency characteristics of pump car

(b) Frequency characteristics of articulated truck

Figure 3. Sound level measurement results of fire trucks

Figure 3 presents the averaged noise measurement results for the fire pump trucks and articulated fire trucks,

categorized by each vehicle. The noise generated by the fire trucks exhibits a flat frequency characteristic, with specific noise bands occurring due to pump operation for each piece of equipment. The noise generated by a single fire vehicle typically exceeds 70 dB across most frequency bands, with noise levels around 78 dB(A) to 85 dB(A).
Figure 4 shows the frequency measurement results of the siren sound from various fire vehicles. Due to the characteristic nature of siren noise, high sound pressure levels were observed in frequency bands above 400 Hz, with a peak at 630 Hz. As the frequency increases, the sound pressure levels in the respective frequency bands decrease.

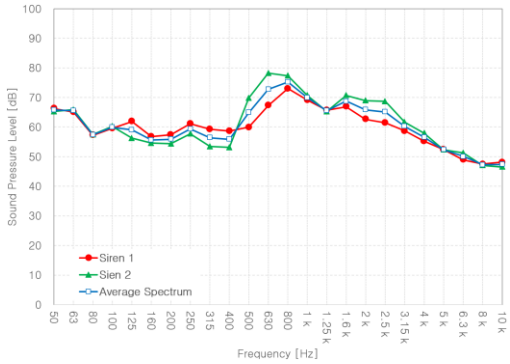


Figure 4. Sound level measurement results of sirens

The results of the firefighting equipment noise characteristics measurement were simplified for use as field sound sources when measuring the speech clarity of radios used by firefighters.

4. SPEECH TRANSMISSION INDEX MEASUREMENT OF FIREFIGHTERS RADIO

For speech intelligibility measurement of fire fighter's radio was conducted using STI (Speech Transmission Index), which is standardized in IEC 60268-16 and ISO 3382-3. The Speech Transmission Index (STI) measurement was based on IEC 60268-16. STI measurements were conducted using the NTI XL2 sound level meter and NTI Talk-Box. The sound source for the STI measurement was generated by the Talk-Box, which simulates human speech, and was then input into the transmission radio's microphone. The STI sound source transmitted through the communication network was received by the radio's speaker, and the STI of the received sound was measured.
Figure 5 illustrates the simplified measurement setup for STI measurement of the radios. The distance between the Talk-Box and the transmitting radio, as well as the distance between the receiving radio and the STI measurement microphone, was set to 10 cm, considering the actual conditions in which firefighters hold and speak into radios or listen to them. The transmission and reception of STI sound sources through the radios were conducted in a soundproofed environment to ensure adequate noise isolation.

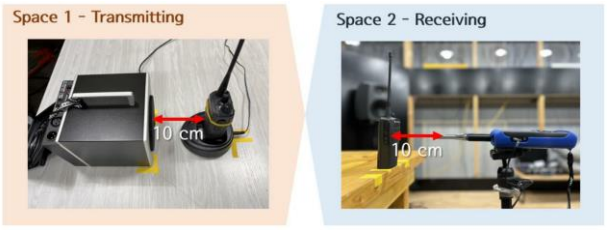

Figure 5. Speech intelligibility measurement set-up for fire fighter's radio

In addition to the STI measurement setup in Figure 5, the simplified noise characteristics of firefighting equipment were reproduced using two loudspeakers to measure the STI of firefighter radios. The noise level of firefighting equipment in the field was approximately 85 dB(A), but considering the test environment and the sound pressure levels generated by the firefighting radios, it was set to from 52 dB(A) to 72 dB(A) for the experiment.
STI measurements were conducted on three types of firefighter radios and one normal radio, comparing the values obtained in a quiet environment without firefighting equipment noise and the values obtained in conditions where firefighting equipment noise was present.

Table 1. STI measurement results of normal radio

BGN condition	STI	STI class
Low-noise	0.78	Excellent
52 dB(A) noise	0.76	Excellent
62 dB(A) noise	0.75	Excellent
72 dB(A) noise	0.42	Bad

Table 2. STI measurement results of fire fighters radio 1

BGN condition	STI	STI class
Low-noise	0.89	Excellent
52 dB(A) noise	0.54	Sufficient
62 dB(A) noise	0.31	Bad
72 dB(A) noise	0.22	Incomprehensible

Table 3. STI measurement results of fire fighters radio 2

BGN condition	STI	STI class
Low-noise	0.78	Excellent
52 dB(A) noise	0.75	Excellent
62 dB(A) noise	0.41	Bad
72 dB(A) noise	0.33	Bad

Table 4. STI measurement results of fire fighters radio 3

BGN condition	STI	STI class
Low-noise	0.92	Excellent
52 dB(A) noise	0.89	Excellent
62 dB(A) noise	0.84	Excellent
72 dB(A) noise	0.78	Excellent

The STI measurement results for the general radio (Type 1) and three types of firefighting radios are shown in Table 1 to Table 4. During the STI measurement, the volume of the receiving radio was set to its maximum. In the case of the general radio, the STI value did not change significantly as the surrounding noise level increased. However, under the 72 dB(A) condition, the STI value decreased to 0.42.
For the two types of firefighting radios, as shown in Tables 2 and 3, an increase in background noise level was found to correlate with a decrease in the STI value. However, for firefighting Radio 3, as shown in Table 4, although the STI value slightly decreased with the increase in background noise level, the evaluation grade remained "Excellent."
The different changes in STI values across the radios with increasing background noise levels are believed to be influenced by the sound pressure levels generated by the radios and the frequency characteristics of the radio microphones and speakers.

5. CITATIONS

In order to ensure rapid response and firefighter safety at fire situation, clear communication through firefighter radios is essential. However, measurement method for speech intelligibility has not been proposed that targets the entire system, including the hardware such as the transmitting radio's microphone and the receiving radio's speaker, as well as the software. Additionally, it is necessary to specify the measurement environment considering the field conditions of radio usage.

This study aimed to establish a method for evaluating speech intelligibility of firefighter radios by identifying the noise sources at fire scenes through a survey. The noise characteristics of selected firefighting equipment were measured and simplified, then presented as background noise during the speech intelligibility evaluation.
The speech intelligibility (STI) of the radios was measured and compared. Differences in speech transmission index (STI) and sound pressure levels between radio models were identified. It was found that the degree of change in speech intelligibility varied across radio models depending on the reproduction of background noise from the fire scene.
In the future, it is necessary to standardize the speech intelligibility (STI) measurement methods for radios and various products, considering the noise environments specific to their intended use.

FACADE SOUND INSULATION OF BUILDINGS VS NOISE MAP IN PAMPLONA, SPAIN

Miguel Arana*
INAMAT[2]. Department of Sciences, Public University of Navarre,
Pamplona, Spain

ABSTRACT

The Spanish Technical Building Code requires minimum insulation of facades according to the acoustic zone in which the building is located. Thus, the airborne sound insulation, $D_{2m,nT,Atr}$ between a protected enclosure (living room/bedroom) and the exterior varies from 30 to 47 dBA. The daytime noise index value, Ld, can be obtained by consulting the strategic noise maps. The urban agglomeration of the Pamplona Region (Spain) has carried out the strategic noise maps in its four phases (2007-2012-2017 and 2022) as well as their associated action plans against noise.

NASUVINSA is the public housing and urban planning company of the Government of Navarre in charge of the management of social housing in the region of Navarre. Over the last decade, numerous protected housing developments have been delivered in the agglomeration of the Pamplona region. Although not exhaustively, it has been possible to access to results of the acoustic insulation of facades since 2011. The overall results of the insulation obtained are presented in this work, as well as the correlation between such insulation and the daytime levels, Ld, obtained from the noise map in force at the date of the building project.

1. INTRODUCTION

The basic document 'DB-HR Noise Protection' [1] specifies the objective parameters and verification methods whose compliance ensures that basic requirements are fulfilled and that the minimum quality levels of the basic noise protection demands of the Spanish Technical Building Code [2] are exceeded. Internal partition walls, as well as facades, roofs, party walls and floors in contact with the outside air, which make up each part of a building, must have characteristics (in conjunction with the adjacent construction elements) which meet certain minimum requirements. Thus, for example, protection against noise generated in enclosures not belonging to the same property requires that the airborne sound insulation index, $D_{nT,A}$, shall not be less than 50 dBA.

The data over time of the acoustic insulation measured for the interior walls by newly constructed houses in our city (Pamplona, Spain) has already been the subject of previous studies [3-4]. This paper analyses the requirements of the regulations regarding facade sound insulation between a protected enclosure (bedrooms, living rooms, classrooms, offices) and the outside. Results of many measurements over the last decade will be shown.

2. INDEX FOR ASSESSING THE FACADE SOUND INSULATION FROM EXTERNAL NOISE

The acoustic index used in Spanish regulations to assess the sound insulation of facades, roofs and floors in contact with the outside air is the A-weighted standardized level difference, $D_{2m,nT,Atr}$. The final terminology ('tr') refers to the fact that the predominant noise is traffic noise, with a standardized characteristic spectrum. It is defined by the expression:

$D_{2m,nT,Atr} = -10 \cdot log \sum_{1=1}^{n} 10^{(L_{Atr,i} - D_{2m,nT,i})/10}$ [dBA] (1)

where:

$D_{2m,nT,i}$ is the standardized level difference, in frequency band i, in dB.

$L_{Atr,i}$ is the A-weighted standardized traffic noise spectrum figure in the frequency band i, in dBA

i cover all one-third octave frequency bands from 100 Hz to 5 kHz.

The normalized spectrum for traffic noise is identical (at least in the range of frequencies between 100 Hz and 3.15 kHz) with the one used in ISO 717-1:2020 [5] to calculate the adaptation term C_{tr}. If the dominant outdoor noise is aircraft noise, this index is also used for the overall assessment, but using the values of the standard aircraft noise spectrum, A-weighted, $L_{Aav,i}$. Such spectra are shown in Table 1. Of course, the overall power of each spectrum is 0 dB.

Table 1. Normalized spectrum values for traffic and aircraft noise

f_i	$L_{Atr,i}$	$L_{Aav,i}$	f_i	$L_{Atr,i}$	$L_{Aav,i}$
100	-20	-23,8	800	-9	-9,5
125	-20	-20,2	1000	-8	-10,5
160	-18	-15,4	1250	-9	-11
200	-16	-13,1	1600	-10	-12,5
250	-15	-12,6	2000	-11	-14,9
315	-14	-10,4	2500	-13	-15,9
400	-13	-9,8	3150	-15	-18,6
500	-12	-9,5	4000	-16	-23,3
630	-11	-8,7	5000	-18	-29,9

The $D_{2m,nT,Atr}$ index is not a common index in European countries. In the regulations of various countries (DIN 4109 in Germany, NF S 31-057 in France, Resistance to sound_Part E, Building regulation in England, UNI 11367 in Italy, for example) it is more common to use the indices $D_{ne,w}$ and $D_{2m,nT,w}$, together with the spectral adaptation term C_{tr}. It is not common to use the spectral adaptation term for aircraft noise.

3. REQUIREMENTS FOR FACADE SOUND INSULATION AGAINST EXTERNAL NOISE

The facade airborne sound insulation, $D_{2m,nT,Atr}$, between a protected rooms and the outside shall not be less than the values shown in Table 2, depending on the use of the building and the values of the daytime noise index, Ld, of the area where the facade building is located. The value of the Ld index is obtained from the last approved strategic noise map.

Table 2. Minimum values for the $D_{2m,nT,Atr}$ index in Spanish regulation

Ld , dBA	living room, bedroom classroom, office	kitchen, corridor waiting room
Ld≤60	30	30
60<Ld ≤60	32	30
65<Ld ≤70	37	32
70<Ld ≤75	42	37
Ld > 75	47	42

When official data of the daytime noise index value, Ld, are not available, the value of 60 dBA will be applied for the type of acoustic area with predominantly residential land use. Although the indices for assessing outdoor noise insulation could be different, the required facade sound insulation in other countries also depends on the use of the building and the ambient noise levels in the environment where the building is located. For example, in Germany, insulation requirements for facades (R'_w + C_{tr}) range from 30 dB (for Ld up to 55 dBA) to 45 dB (for Ld up to 70 dBA). In England, in areas with outdoor noise levels of 70 dB, a minimum insulation of 40 dB is required for the $D_{ne,w}$ index. In the case of Italy, the regulation UNI 11367 classifies buildings into four classes, depending on the acoustic performance achieved. The minimum facade sound insulation requirements, index $D_{2m,nT,w}$, are 32 (Class IV), 37 (Class III), 40 (Class II) and 43 dB (Class I).

Considering the main single-number quantity descriptors (R'_w , $D_{n,w}$ and $D_{nT,w}$) and their combinations with the spectral adaptation terms, 27 descriptors are obtained for the facade sound insulation index [6]. It will show here results for the descriptor of the Spanish Standard, $D_{2m,nT,Atr}$ and the most used in many European countries, $D_{2m,nT,w}$ (measured with one speaker) together with the adaptation terms C and C_{tr}. In fact, $D_{2m,nT,\ Atr} = D_{1s,2m,nT,w} + C_{tr}$.

4. DATA

Results of acoustic insulation measurements on facades carried out in the period from 2011 to 2022 by 4 accredited laboratories for this type of measurements were provided. The location of the housing developments where these dwellings are found (location described in Table 2) are shown in Figure 1. This figure shows the noise map (Phase IV) of the Agglomeration of Pamplona. All the strategic noise maps carried out in Spain are available in the Noise Pollution Information System (SICA) on the website of the Ministry for Ecological Transition and Demographic Challenge of the Government of Spain [7].

Legend:
Loc: Location of new housing (see Fig. 1)
Meas: Year of measurements
Lab: Laboratory (accredited) that performed the measurements. There were 4.
(l-b), m^2: Receiving room (**l**iving room/**b**edroom) and wall surface in contact with the outside.
D_{2m}: $D_{2m,nT,Atr}$ (dBA); Standardized level difference, A-weighted, on facades and roofs, when the dominant exterior noise is due to traffic [1].
D_{ls}: $D_{ls,2m,nT,w}$ (C;C_{tr}): Weighted standardized level difference; single-number quantity derived from one third octave band values, measured with one loudspeaker (**1s**) [5]. **C** and **C_{tr}** are the spectral adaptation terms for, respectively, pink noise and traffic noise. It can be assumed that $D_{2m,nT,Atr} = D_{ls,2m,nT,w} + C_{tr}$
Ld: A-weighted long-term average sound levels, determined over all the diurnal period (7 – 19 hours) obtained from the noise map in force at the date of the building design.

6. ANALYSIS

Although the basic document 'DB-HR Noise Protection' was approved in 2007, an adaptation period was granted, and it became mandatory in April 2009. Until this date, the previous regulation on acoustic conditions of buildings, NBE-CA-81 [8], continued to be applied. For this reason, it cannot be concluded whether current facade sound insulation requirements in force were fulfilled for measurements prior to 2012. Although the old evaluation index (R) was not the current index ($D_{2m,nT,Atr}$), the value required at that time (30 dBA) will be assumed to be equivalent (for purposes of compliance with the requirements) to the minimum value required today. It is possible to carry out such an assessment for measurements after 2012, because the sound insulation requirements were already in force and the strategic noise maps were published.

Cells whose results do not strictly comply with the requirements of the sound insulation standard are highlighted with grey background in Table 3. However, in some cases, the non-compliance is only 1-2 dBA, which is within the margin of the error of measurement. In six of the cases, the non-compliance is more than 4 dBA.

7. CONCLUSIONS

After the entry into force of the new building acoustic insulation requirements in Spain (CTE and dB-HR), a notable increase in the acoustic performance of the interior partitions of buildings has become evident. Although an increase has also been noted, it has been much lower in the case of facade insulation against external noise. The facade sound insulation obtained is lower than required in a significant percentage of measurements. In six of the cases, the non-compliance is more than 4 dBA.

More data are required to draw further conclusions. For example, it had not been possible to access to the architectural designs where acoustic insulation of facades was justified, in the light of the dB-HR requirements. This would allow confirming whether strategic noise maps are useful as well as its impact on the required sound insulation. It is the author's opinion that the great uncertainty associated with the results obtained in the elaboration of acoustic maps significantly limits the subsequent decisions that, in theory, they entail.

FINITE ELEMENT ANALYSIS OF AIRBORNE SOUND TRANSMISSION IN STUD-COUPLED LIGHTWEIGHT WALL SYSTEMS

Pedram Ayyobi[1*] **David Gomes Andrade**[1] **Luís Simões da Silva**[1]
Luís Godinho[1]

ABSTRACT*

Lightweight wall systems, widely used in aerospace and construction, offer advantages such as weight efficiency, rapid construction, and ease of replacement. However, the presence of flexible or rigid studs within these systems complicates their acoustic performance, particularly in terms of airborne sound insulation. This study employs an efficient finite element approach to accurately predict the sound transmission loss of stud-coupled double-leaf lightweight walls. This approach offers a cost-effective and time-efficient alternative to experimental and analytical methods while maintaining acceptable precision. A parametric study was conducted to investigate the sensitivity of sound insulation to various parameters, including panel thickness and stud stiffness. The results provide insights into the influence of effective parameters on the acoustic performance of lightweight coupled wall systems, facilitating the design of more acoustically effective solutions for noise-sensitive environments.

1. INTRODUCTION

Understanding the impact of studs on the sound insulation of double-leaf walls is relevant for building acoustics [1], [2]. Indeed, double-leaf walls offer improved sound insulation compared to single walls, but their performance may be affected by structural connections like studs, which act as sound bridges [3], [4], coupling the two leaves of the partition. Various approaches have been employed to analyze this effect, including analytical, experimental, and numerical methods [4–8].

Early analytical models simplified the wall system by focusing on airborne transmission through infinite, unconnected leaves, neglecting the influence of studs [9], [10]. Later models attempted to incorporate studs as rigid connections, which proved inadequate for lightweight walls with flexible metal studs [11–13]. To address this, analytical models evolved to include flexible studs, often represented as springs with translational and rotational stiffness [4], [7], [11], [14]. However, these models often required empirically derived stiffness values, limiting their predictive power for new designs [11]. Smeared models offered another analytical approach by distributing stud properties uniformly [7]. Vigran's work [3], reviving and extending Sharp's method, aimed to correct transfer matrix calculations by accounting for stud effects, initially for infinitely stiff studs and later for flexible ones using empirical data. While providing valuable insights into phenomena like mass-spring-mass resonance and coincidence, analytical models often involve simplifications in geometry and boundary conditions [4], [7], [11].

Experimental investigations have been vital for assessing the sound insulation performance of double-leaf walls with various stud configurations [5], [15]. These studies have examined the influence of stud type, spacing, cavity filling,

and the use of resilient elements [15], [16]. Researchers have measured the sound reduction index (R) and weighted sound reduction index (R_w) for different constructions. Studies by Hongisto et al. specifically explored the impact of stud characteristics and resilient channels [5], [8]. While providing real-world data for validation, experimental approaches are resource-intensive and may not offer detailed insights into the dynamic behavior of studs within the assembly [5].

Numerical methods, particularly the Finite Element Method (FEM), offer a more comprehensive approach. FEM allows for detailed modeling of stud geometry, material properties, and the interaction between studs, panels, and the cavity. It can accurately represent fluid-structure interaction (FSI), crucial for understanding sound transmission pathways. But FEM analyses are time consuming and require experts for accurately simulate the complex systems. Numerical models can also incorporate damping and complex boundary conditions. They have demonstrated good agreement with experimental results [2], [17], [18].

This study makes use of a simplified model that efficiently predicts the performance of stud-coupled infinite wall systems with reasonable accuracy while still being time efficient. Moreover, the model is designed to be flexible, allowing for the analysis of various wall configurations and stud shapes. The model tends to be efficient compared to existing FEM or analytical approach while providing acceptable accuracy.

2. FINITE ELEMENT MODELING METHODOLOGY

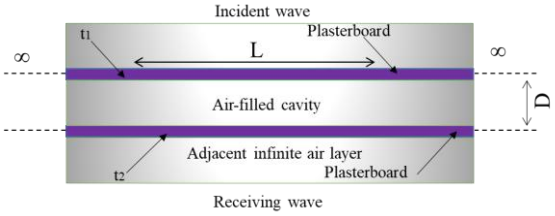

Figure 1 shows the schematic view of un-coupled and coupled wall systems, considering L as periodic unit cell length, t_1 and t_2 are panels thickness and D is cavity thickness. The system is infinite, and an incident plane wave is applied to one side of the panel, while its effect is evaluated in other side by means of nodal displacements. The finite element model uses 1D elements, see Figure 2. The plane strain Euler-Bernoulli beam element has been used to model wall panels. The air inside the cavity and receiving side is modeled using analytical frequency dependent spring, discussed in detail elsewhere [18]. The stud is modeled as equivalent two node bar element. Additionally, infinite panels with a 600 mm stud span are modeled using Bloch–Floquet boundary conditions. The numerical model is organized into two groups, each evaluating wall performance based on panel thickness and stud thickness. Material properties used in the models are listed in Table 1.

The panels' thickness is considered in two cases of identical (0.0125mm) and nonsymmetrical panels (0.0125-0.025 m). the cavity thickness is considered 0.05 m, verification models based on [7] except for experimental studies.

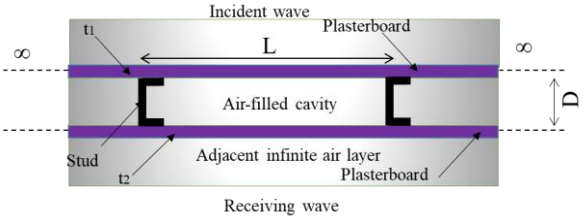

Table 1. material properties

Element	Properties		
Panels	$\rho_p = 790 kg/m^3$	$\nu_p = 0.3$	$E_p = 2.5e9\,Pa$
Stud	$\rho_s = 7850 kg/m^3$	$\nu_s = 0.28$	$E_s = 2.1e11\,Pa$
Air	$\rho_a = 1.21 kg/m^3$	$c = 343 m/s$	

* ρ is density, ν is Poisson ratio and E is module of elasticity. Air density and speed of sound are indicated by ρ_a and c, respectively.

3. MODEL VERIFICATION AND VALIDATION

The proposed simulation approach is compared with an existing analytical model [7] in normal and 45 degrees incident angle for un-coupled system (Figures 3 and 4) and coupled systems either analytical or experimental studies (Figures 5-7). For verification, the proposed model is compared against two analytical models [7], [19] and then validated with two experimental studies [3], [19].

The comparison between the proposed numerical model and the analytical model from [7] shows excellent agreement for both 45° and normal incidence (Figures 3 and 4).

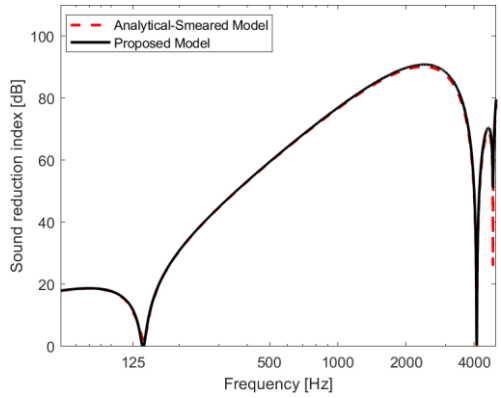

Figure 3. Comparison of Un-coupled proposed model and analytical smeared model ($\varphi = 45^o$).

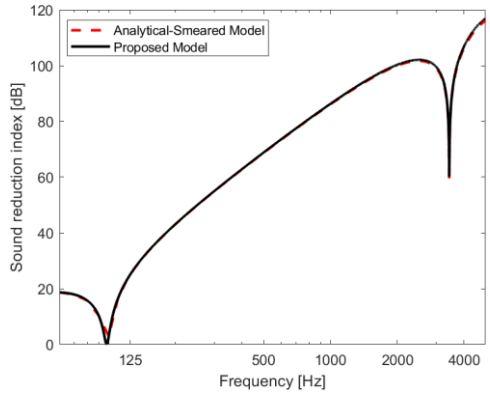

Figure 4. Comparison of Un-coupled proposed model and analytical smeared model ($\varphi = 90^o$).

Figure 5 compares the proposed numerical model with the analytical smeared model from [7]. Despite some differences, the numerical model follows the same trend, predicted the coincidence frequency, and shows acceptable agreement. Moreover, from Figure 6, comparisons with experimental studies (Vigran [3]) reveal that the model accurately predicts the mass–air–mass and coincidence frequencies, although with differences of about 5 dB in high frequency ranges. It also agrees well with the experimental and analytical results of Godinho et al. [19], even though there is an approximate 10 dB difference in the low frequency range (Figure 7).

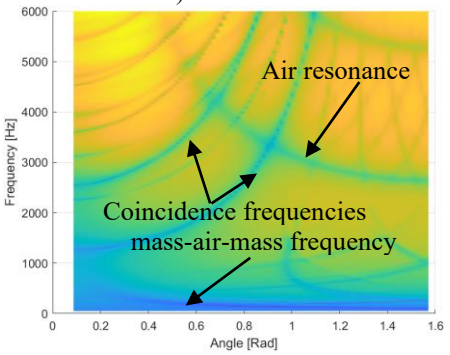
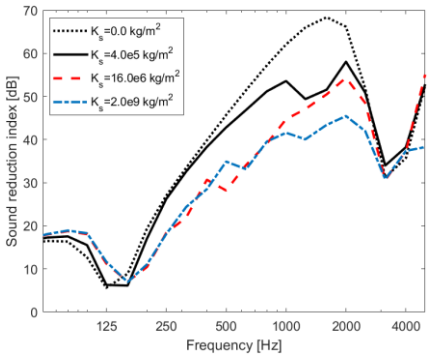
4. PARAMETRIC STUDY



The first part of the parametric study evaluates the effect of wall panel thickness on the model. As expected, using asymmetric panel thicknesses leads to different coincidence resonances. Figure 8 illustrates this effect by comparing configurations with 13 mm and 26 mm panels, both with a 65 mm air gap. The material properties for the panels and studs are provided in Table 1. In this notation, "PB 13-13/65" denotes a wall consisting of two 13 mm panels with a 65 mm cavity.

a) Panels thickness variation effect (1/3 Octave band)

b) PB13-13/65



c) PB 13-26/65

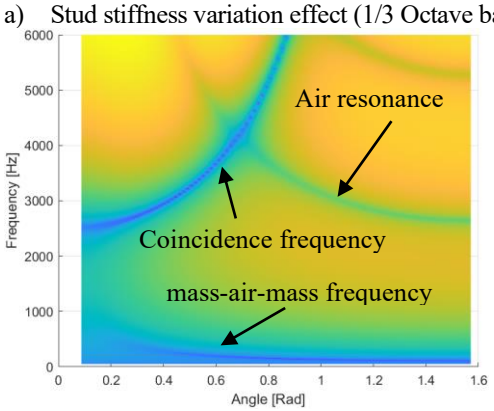


Figure 8. sound transmission index variations of double leaf wall due to geometry differences.

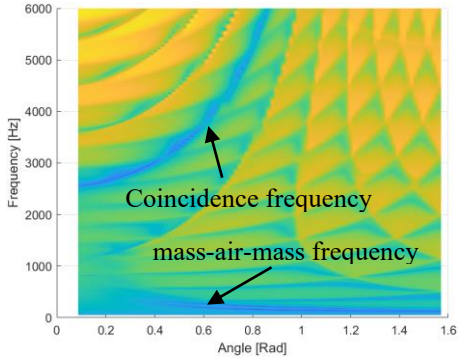
Asymmetric panel thickness produces two distinct coincidence frequencies (Figures 8b and 8c) because each panel responds differently due to its unique mass and stiffness. In accordance with the mass law, an increase in mass and stiffness generally improves sound insulation. Figure 8a illustrates that while the performance is similar at low frequencies—where the response is largely governed by mass—the stiffer, heavier configuration delivers significantly enhanced insulation at higher frequencies, achieving improvements of up to 5–20 dB. This is due to the reduced vibrational transmission and more favorable behavior of the stiffer system.



To evaluate the effect of stud stiffness on sound insulation, four cases were examined: one without a stud, two with intermediate and standard steel stud stiffness, and one with a relatively rigid stud ($K_s = 2e9 kg/m^2$, similar to wood studs). Figure 9 presents one-third octave band plots of the sound reduction index for these cases, comparing uncoupled and rigid boundary conditions across various incident angles.

a) Stud stiffness variation effect (1/3 Octave band)

b) Un-coupled system

c) Rigid stud

Figure 9. sound transmission index variations of double leaf wall due to stud stiffness.

Figure 9a shows that as stud stiffness increases, the wall's sound insulation deteriorates. For example, around 1000 Hz, an un-coupled wall achieves roughly 62 dB, while a wall with a softer stud reaches about 53 dB; this gap widens to 10–20 dB with intermediate or rigid studs. At low frequencies, all configurations perform similarly because the system's mass dominates the response. However, at higher frequencies, the increased stiffness in stud-coupled systems enhances vibrational transmission, thereby reducing insulation. Figure 9b displays the resonance frequencies of the un-coupled system, where both mass–air–mass and air resonances are evident. In contrast, Figure 9c—representing a rigid stud-coupled system—exhibits significant oscillations across all frequencies, with only the mass–air–mass and coincidence resonances clearly visible. This behavior indicates that a stiffer connection introduces additional dynamic effects, ultimately compromising sound insulation in the medium and high frequency ranges.

5. CONCLUSIONS

This study presents a simplified FEM-based model that combines finite element analysis with an analytical formulation for the fluid medium. The model shows good agreement with existing analytical and experimental data. Our findings indicate that key design parameters—such as panel thickness and stud stiffness—significantly influence the acoustic performance of stud-coupled double-wall systems. Thicker panels improve performance by increasing mass and introducing asymmetry, while more flexible studs enhance insulation in the medium to high-frequency range. Overall, the model is both efficient and accurate, and it can be further developed to incorporate cavity absorbers or extend to triple-wall systems.

POSSIBILITY OF MODELLING THE RECEIVING ROOM IN FEM CALCULATIONS

Alina Lahdensivu[1*] **Lauri Talus**[1] **Jesse Lietzén**[1]
Mikko Kylliäinen[1]
[1] AINS Group, Department of Acoustical Engineering, Finland

ABSTRACT

Timber partition floors have problems with their impact sound insulation (ISI) at low frequencies under 100 Hz. The Finnish Government has sought to increase construction from timber in recent years, which causes ISI to play an important role in the structural design process of timber floors. Literature indicates the receiving room plays a significant role in the verifiable impact sound insulation of a timber joist floor. There are very few analytical calculation methods for ISI of timber floors, and their solutions are only valid for specific cases. The most common assumptions in analytical equations are about the diffusivity of the sound field and completely rigid room boundaries. This study revisits the theory of a modal sound field in a receiving room and coupling between a simply supported floor and the sound field of a receiving room. The possibility of modelling the receiving room in FEM calculations of ISI is discussed.

Keywords: *impact sound insulation, timber joist floor, modal sound field*

1. INTRODUCTION

In recent decades, timber has become more popular as a building material due to its environmental benefits. Timber floors however have problems with their impact sound insulation at low frequencies. [1–4]
It has long been acknowledged that the sound field of a room affects the verifiable impact sound insulation (ISI) of intermediate floors especially in the low frequencies where the sound field is modal [1,5–11]. Most calculation methods, however, assume a diffuse sound field and completely rigid boundaries causing innate uncertainty [7–8,11–14].
This article is an extract from the Master's thesis of Lahdensivu [15], where the effect of the room size to the ISI was examined, and focuses on the coupling between a plate and the sound field of a receiving room. The purpose of this study is to show how the coupling between the plate and the room affects the sound pressure field in the receiving room.

2. LITERATURE REVIEW

2.1 Sound field of a receiving room

The sound field of a room is divided by the Schroeder limiting frequency into diffuse and modal sound fields [16], [17]. In 1954 Schroeder defined a minimum requirement for a diffuse sound field to have a modal overlap factor of $M = 10$ [18]. In the 1962 article [19] the modal overlap factor was revised to $M = 3$ based on other studies. In a diffuse sound field, it is assumed that the energy density is equal everywhere in the room i.e. sound can propagate from and to any direction with the same probability and reflect to any direction with equal probability. A diffuse sound field can be studied purely statistically, making calculations simpler. [16–17]
The modal overlap factor is not an adequate indicator to assume a diffuse sound field on all frequency bands in a room. A diffuse sound field cannot be assumed in small, enclosed spaces, in rooms where the longest dimension is clearly greater in comparison to the shortest dimension, in rooms with inadequate amount of scattering and diffusing elements, in rooms with many absorbing surfaces with uneven distribution as well as in very large spaces where the sound field acts locally. [16–17]

In a modal sound field, the amplitude of the sound pressure doesn't vary with time. Room modes are found on frequencies where at least one room dimension is a multiple of the half wavelength of the mode. There are three types of room modes: axial, tangential and oblique. [20]
In a room with perfectly rigid and reflective boundaries, room modes can be calculated using Eqn. (1).

$$f_{n_x n_y n_z} = \frac{c}{2}\left[\left(\frac{n_x}{l_x}\right)^2 + \left(\frac{n_x}{l_x}\right)^2 + \left(\frac{n_x}{l_x}\right)^2\right] \quad (1)$$

Where c = 343 m/s, n_x, n_y and n_z are the number of half wavelengths and l_x, l_y and l_z are the dimensions of the room. Eqn. (1) gives a reasonable estimate for the room modes in most rectangular rooms. Lightweight walls, however, cannot be considered rigid [20].
In a room where the boundaries are not completely rigid the eigenvalues of the wavefunction are complex [16–17,20]. Kuttruff [20] has proposed a simplified way to calculate the sound pressure in a receiving position with non-reflective surfaces. However, solving the system of equations requires numerical methods for iteration.
Kuttruff's equation utilizes the surface impedance of a wall, which is dependent on frequency and the material properties of the boundary. A lightweight gypsum board wall can be considered to perform as a plate resonator. The impedance of a plate resonator can be calculated for example using Eqn. (2) [20].

$$Z = r_s + \mathrm{j}\left(\omega m - \frac{\rho c^2}{\omega d}\right) \quad (2)$$

Where r_s is the flow resistivity of the absorbing material in the cavity, $\mathrm{j} = (-1)^{1/2}$, ω is angular frequency, m is surface mass of the plate, ρ = 1,205 kg/m^3, c = 343 m/s, and d is the total thickness of the air cavity.
The absorption of the plate resonator is very localized to its natural frequency. Calculating the absorption coefficient from the plate resonator impedance does not correspond to a measured absorption coefficient of a lightweight wall. The conversion also loses the information about the complex part of the impedance which corresponds to the losses at the boundary.

2.2 Modal coupling between a plate and a room

Multiple different calculation methods for the coupling between the sound field of a room and a structure have been made [7–8,13–14,21]. Most equations predicting the impact sound insulation of timber floors and coupling of the sound field of the room are based on assumptions of diffuse sound field and perfectly rigid room boundaries [7–8,13–14,21].

In 1967 Kihlman [21] suggested an equation to calculate the sound pressure level in the receiving room when the source room is excited with an omnidirectional loudspeaker. Neves e Sousa & Gibbs [7–8] modified Kihlman's [21] equation to research the modal coupling between the receiving room and a homogeneous concrete floor, when the floor is excited by a point force. The sound pressure level in the receiving room in frequency domain can be calculated using Eqn. (3).

$$p(x,y,z) = -\mathrm{j}\omega\rho \sum_{n_x,n_y,n_z=1}^{\infty} \frac{c^2(-1)^{n_z} C_{n_{x1}n_{y1}} \varphi_{n_x n_y n_z}(x,y,z)}{\left[\left(\omega_{n_x n_y n_z} + \mathrm{j}\delta\right)^2 - \omega^2\right] \Lambda_{n_x n_y n_z}} \quad (3)$$

where $\mathrm{j} = (-1)^{1/2}$, ω is the angular frequency, ρ = 1,205 kg/m^3, n_x, n_y and n_z are the number of half wavelengths of the mode, c = 343 m/s, $C_{nx,ny}$ is the coupling factor, φ is the eigenmode function of the room, $\omega_{hx.ny.nz}$ is the angular eigenfrequency of the receiving room, $\delta = 6{,}9/T$ [21], [22], [23] and $\Lambda_{n_x n_y n_z} = \int \varphi_{n_x n_y n_z}(x,y,z)\,\mathrm{d}V = V/8$.
When the floor is excited by a point force, the coupling factor is

$$C_{n_x n_y} = \mathrm{j}\frac{4\omega F}{\pi^2 m} \sum_{n_{x1},n_{y1}=1}^{\infty} \left\{\frac{\varphi_{n_{x1}n_{y1}}(x_0,y_0)}{\omega_{n_{x1}n_{y1}}^2(1+\mathrm{j}\eta) - \omega^2} D\right\}$$
$$D = \frac{[(-1)^{n_{x1}+n_x} - 1][(-1)^{n_{y1}+n_y} - 1]}{n_{x1}n_{y1}\left[\left(\frac{n_x}{n_{x1}}\right)^2 - 1\right]\left[\left(\frac{n_y}{n_{y1}}\right)^2 - 1\right]} \quad (4)$$

Where $\mathrm{j} = (-1)^{1/2}$, ω is the angular frequency, F is the point force, m is the surface mass of the floor, n_{x1} and n_{y1} are the number of half wavelengths of the plate mode, x_0 and y_0 are the coordinates of the point force, ω_{hx1ny1} is the angular eigenfrequency of the floor, $\eta = \eta_i + X/\sqrt{f}$ and n_x and n_y are the number of half wavelengths of the room mode.
According to literature, the modal sound field of the receiving room can have a significant effect on the sound pressure level and therefore on the impact sound insulation. The material properties of the plate affect the plate modes and the coupling between the plate and room modes. From the point of timber construction, it would be beneficial to examine the effect of modal coupling between the floor structure and the room sound field, since the low frequency range has been found to have problems in the ISI.

3. MATERIALS AND METHODS

The modal coupling of CLT and concrete slabs in different room configurations was studied to examine the differences in room response and modal coupling behaviour.

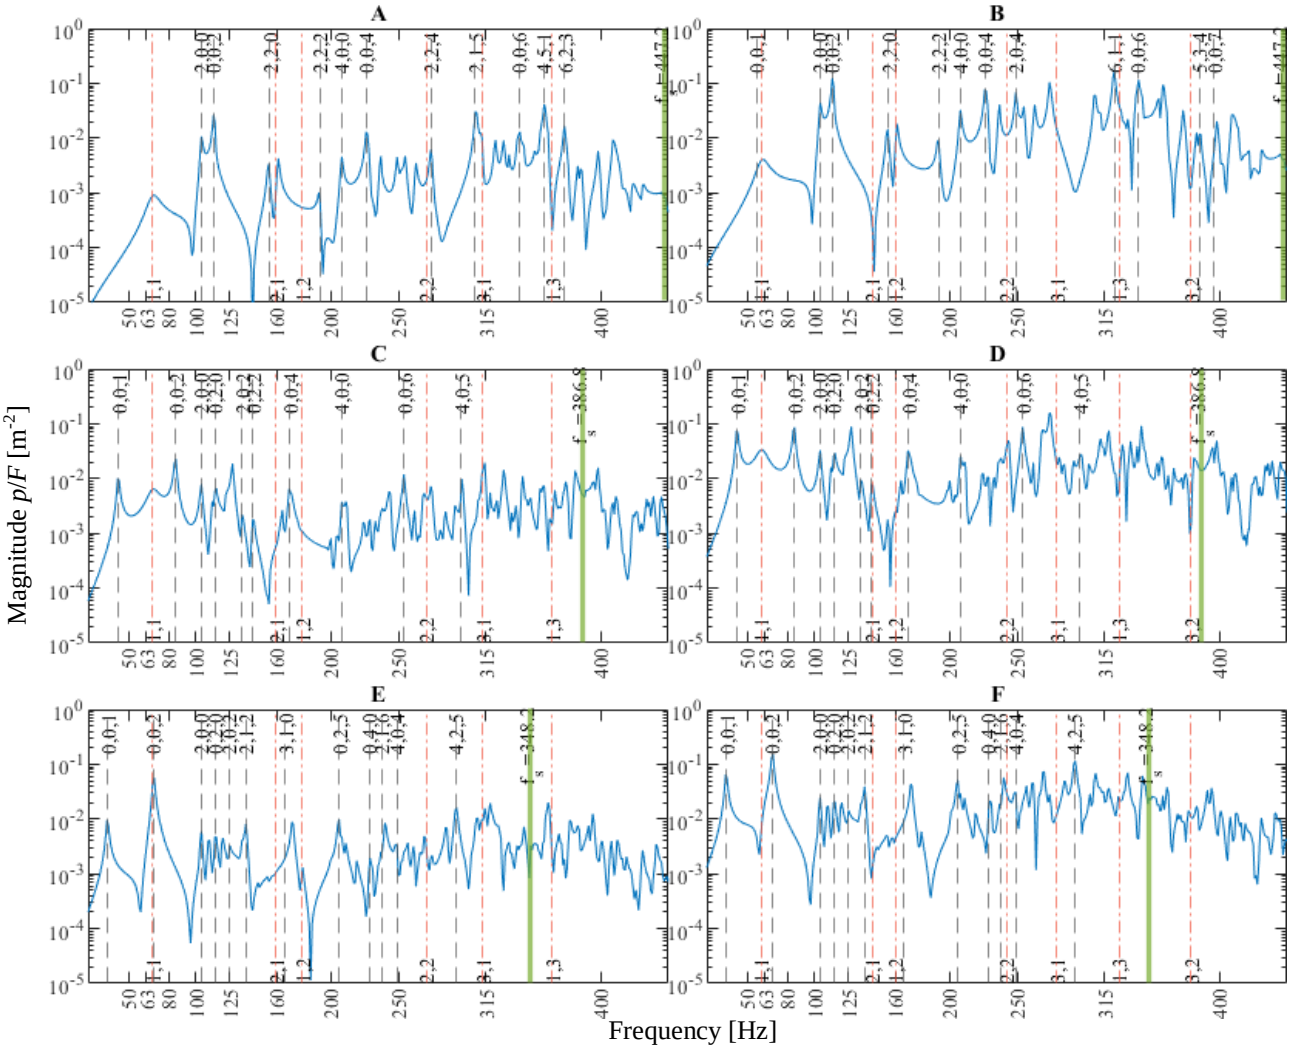

Figure 1. Magnitude of sound pressure in the middle of the receiving room caused by the vibration field of a floor. **A)** Concrete floor V = 30 m^3 **B)** CLT floor V = 30 m^3 **C)** Concrete floor V = 40 m^3 **D)** CLT floor V = 40 m^3 **E)** Concrete floor V = 50 m^3 **F)** CLT floor V = 50 m^3. The room modes are depicted with vertical dashed lines, the plate modes with vertical dotted dashed lines and the Schroeder limiting frequency with a solid vertical line. The corresponding room modes are written on the top of the graph and plate modes at the bottom.

The sound pressure in V = 30 m^3, V = 40 m^3 and V = 50 m^3 rooms were calculated utilizing Eqn. (3) at positions (0,7;0,7;0,7), (0;0;0) and (lx+0,5; ly+0,2; 1,5) from the centre of the room. A CLT and concrete plate with different dimensions were studied. The floors were excited with a 5 N point force from the middle of the floor. Material properties used in the calculations are presented in Tab. 1.

Table 1. Material properties.

Material	ρ [kg/m^3]	E [MPa]	ν [-]	η [-]
Concrete 200 mm [24]	2 500	33 000	0,2	0,015
CLT 200 mm [25]	420	4 539*	0,4	0,015

* Effective value $E_{eff} = \sqrt{E_x E_y}$

4. RESULTS

The magnitude of the sound pressure in the middle of the receiving room for concrete and CLT floors in 3 different room volumes are presented in Fig 1. The highest peaks in the magnitude of the sound pressure are on room modes f_{001} and f_{002}. The shape of the magnitude of the sound pressure is similar between the concrete and CLT slabs in same volume rooms but the magnitude is higher for the CLT slabs. The results are similar with other calculation positions and floor dimensions.

5. DISCUSSION

Neves e Sousa & Gibbs [7–8] found that the 1st vertical room mode f_{001} is the most significant for the ISI of homogeneous concrete floors. However, the calculations suggest that the 2nd vertical room mode f_{002} is significant as well. The peaks in the magnitude in Fig 1. correspond to a weaker sound insulation of the structure. The higher calculated magnitude of sound pressure for CLT floors also points to a weaker sound insulation in comparison to concrete slabs.

The problem with analytical models is the assumptions and simplifications done to derive the wanted equations. With other calculation methods, for example FEM calculations, complex boundary conditions can be considered. However, defining the boundary conditions can be difficult.

In FEM models the studied floor often radiates into an infinite space. Lietzén et al. [26] modelled the ISI of a full timber mock up floor that was also measured in a laboratory setting (V = 56 m^3). The simulated and measured results are in Fig. 2.

The simulated result differs from the measured result especially around 63 and 80 Hz octave bands. The first vertical room mode of the laboratory is f_{001} = 38 Hz and the second room mode f_{002} = 86 Hz. The second room mode could explain the difference in the low frequencies in the results shown in Fig. 2. Modelling the whole receiving room in a FEM software could lead to better agreement with the measured result on low frequencies.

To model the room and study the coupling further, the boundary conditions need to be determined with an adequate precision. Recent studies [27–32] utilising FEM modelling of the room sound field are transient or determine a single value impedance or absorption coefficient for all the surfaces of the room.

The boundary conditions that can be given for the room are impedance, sound hard and sound soft boundaries. Both sound hard boundary and sound soft boundary do not correspond to room sound fields in timber buildings.

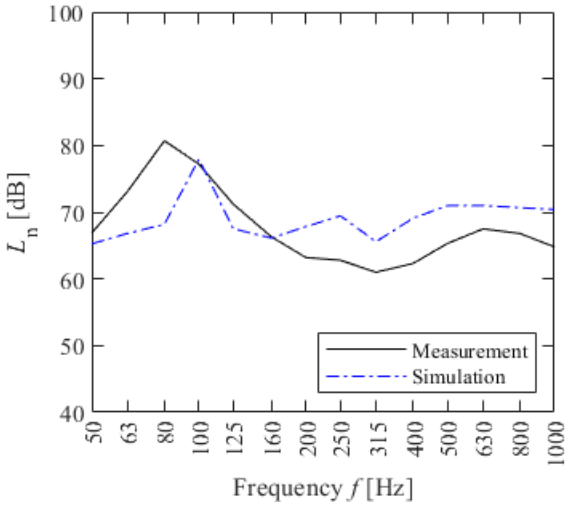

Figure 2. Measurement and simulation result of a timber mock-up floor [26].

Calculating the absorption coefficient from the plate resonator impedance does not correlate to the reverberation time in a room. The boundary condition can also be the absorption coefficient. This however only gives real value results though the reverberation time of the room would be closer to reality. Using the absorption coefficient also loses the information about the phase change.

6. CONCLUSIONS

The 1st and 2nd vertical room modes f_{001} and f_{002} cause the highest peaks in the sound pressure in the room causing the sound insulation of a plate to be weaker. Therefore, modelling the room could improve the agreement between measured and simulated ISI results on low frequencies. However, methods for defining non-rigid boundary conditions are limited to single number values of impedance or absorption coefficient. Other methods for defining non rigid boundary conditions should be investigated further.

ABSTRACT

Engineering offices and manufacturers of acoustic building systems or materials often rely on measurement data to estimate whether building solutions will be of sufficient acoustic quality. This typically involves numerous costly and time-consuming laboratory measurements, making it difficult to efficiently explore and optimize various design configurations. In this paper, a method is presented to accurately and efficiently predict the sound insulation of multilayer structures. Accuracy ensures reliability, while efficiency is crucial for optimization, where numerous simulations are needed, for example to identify the ideal layering or material properties of a(n) (inter)layer. The prediction method accounts for arbitrary layering, finite dimensions, boundary conditions and resulting modal behavior, as well as frequency- and temperature-dependent material properties. Extensive validation has been conducted using numerous examples with a specific focus on glazing, demonstrating the model's robustness and reliability. An accuracy of $1-2\,\mathrm{dB}$ in single number rating is generally achieved using default non-product specific material data. The method achieves higher accuracy when material properties are determined from testing.

1. INTRODUCTION

Engineering offices and manufacturers of acoustic building systems or materials often rely on measurement data since the alternatives regarding existing prediction software are either too slow (e.g. using finite elements), or too inaccurate (e.g. analytical expressions assuming thin plate theory). This typically results in a difficult process of exploration and optimization of various new or existing design configurations, since it involves numerous costly and time-consuming laboratory measurements. The need for sound insulation prediction methods which are both accurate and efficient is therefore of crucial importance.

In this paper, a robust method is presented, which is designed to accurately and efficiently predict the sound insulation of multilayer structures with varying elements such as wall leafs and cavities. Wall leafs can consist of layered elements of elastic, viscoelastic and poroelastic nature and are implemented using elastodynamics theory. The modal Transfer Matrix Method (mTMM) [1, 2] envelops this theory and additionally accounts for arbitrary layering, finite dimensions, simply supported or antisymmetric boundary conditions and the resulting modal behavior. The mTMM also allows for frequency-dependent material properties, which can be especially important in practical applications. Viscoelastic interlayers are a particular type of interlayer that can be present in these layered wall leafs, since the material properties depend both on frequency and temperature. This dependence on temperature is expressed through the Williams-Landel-Ferry equation [3, 4], while the dependence on frequency is accounted for using the Generalized Maxwell-Wiechert model [5]. Cavities are assumed to be 'hard-walled' with

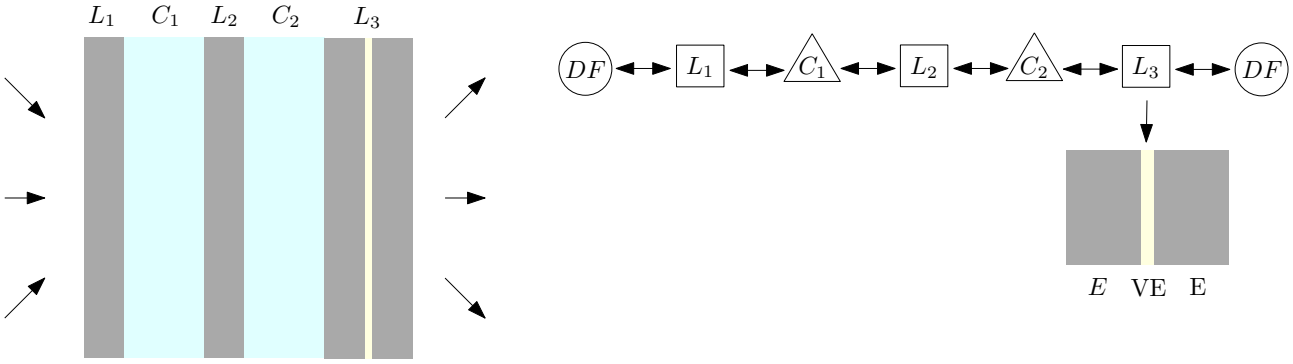

Figure 1. Glazing system with three wall leafs L_1, L_2 and L_3, separated by two cavities C_1 and C_2. The third wall leaf is layered, consisting of two elastic (E) layers with a viscoelastic (VE) in between. The outer wall leafs are coupled to diffuse fields (DF).

finite dimensions and the interaction between cavity and adjoining wall leafs is accounted for [6].

This method enables the exploration and optimization of various design configurations without the need for extensive laboratory testing. The method's robustness and reliability are demonstrated through extensive validation using numerous examples, with a specific focus on glazing. Validation on glazing is particularly interesting since all these elements (wall leafs, cavities, viscoelastic interlayers) can all occur separately or combined in any desired order. The ability to accurately predict sound insulation is crucial for optimizing design configurations and exploring new materials and material properties. By reducing the reliance on costly and time-consuming laboratory measurements for experimental design optimization, this approach facilitates the development of effective acoustic solutions for a wide range of applications.

2. SOUND INSULATION PREDICTION

Walls and floors typically consist of several structural parts, such as leafs and cavities. A wall leaf consists of at least one solid layer, and layered wall leafs can contain varying element types, e.g. an elastic layer or a viscoelastic interlayer which is used in laminated glazing. Cavities are assumed to be hard-walled, and can either be filled with fluid or with porous material. The sound insulation prediction approach is graphically represented in Fig. 1. It starts by indicating all leafs and cavities, and using the corresponding mathematical approach for each leaf or cavity, as will be discussed in the following subsections 2.1 and 2.2. The coupling between wall leafs and cavities is briefly discussed and finally the computation of the diffuse sound insulation is included.

2.1 Wall leafs

Layered elements such as wall leafs or floating floors are implemented using elastodynamics theory, which accounts for longitudinal and shear wave propagation, as well as their interaction in the form of bending waves. One of the main advantages over thin plate theory for the prediction of sound insulation is that thickness effects such as thickness resonances are accounted for due to the presence of the shear waves. The elastodynamics theory also successfully captures key physical phenomena such as the coincidence effect and the mass-air-mass resonance. This theory is enveloped by the mTMM [1, 2], which is used here. Layers with materials of an elastic or viscoelastic nature (also poroelastic layers, but these are not present in glazing) can all be implemented and combined into a single wall leaf. Material properties can be frequency-dependent, but also temperature-dependent in the case of viscoelastic interlayers. The prediction approach for these interlayers is elaborated in detail in section 3, since they are often used in glazing.

In the mTMM, the boundary conditions of a wall leaf are accounted for by decomposing the out-of-plane displacements of the leaf into sinusoidal basis functions [1], which correspond to antisymmetric boundary conditions for thick wall leafs. These basis functions represent mode shapes of the wall leaf and they occur at their respective natural frequencies, making the mTMM a modal approach. Due to the combination of this modal approach

and employing analytical solutions for the wave propagation in each layer in the frequency-wavenumber domain, a high computational efficiency is achieved.

2.2 Cavities

Cavities are modeled as 'hard-walled' three-dimensional cuboid acoustical spaces. A modal approach is applied, where the mode shapes or the basis functions of the cavity are taken to be the normalized mode shapes of a hard-walled, rectangular cuboid cavity [7]. The dynamic stiffness of the cavity is then expressed in terms of its natural frequencies and loss factor, determined by the speed of sound and mass density of the fluid and the reverberation time of the cavity or the loss factor of the fluid. Note that this is an analytical approach, such that the computational efficiency for cavities is very high. A cavity can either be filled with a specific fluid (e.g. air, argon, krypton) or with a porous material. In case of a porous filling, the porous material can be implemented as an equivalent fluid, e.g. by using the Delaney-Bazley-Miki model [8, 9], which employs the flow resistivity to determine the complex, frequency-dependent sound speed and mass density of the equivalent fluid.

2.3 Coupling of wall leafs and cavities

Coupling of the wall leafs and cavities is achieved by employing the acoustical pressure in a cavity as an excitation of the adjoining wall leaf, while the displacements of a wall leaf are used as an excitation of the adjoining cavity. Since modal approaches are used for both the wall leafs and cavities, this coupling strategy is called a modal-interaction model [6].

2.4 Diffuse sound insulation

The modal-interaction model finally allows the calculation of the diffuse sound insulation. This is not straightforward due to the finite wall dimensions, but a correct calculation is achieved by employing the diffuse field reciprocity relationship [12], so that the ensemble mean of the sound transmission coefficient $\hat{\tau}_{12}$ [10, 11] can be evaluated as

$$\hat{\tau}_{12} = \frac{8\mathrm{V}_1}{c\mathrm{S}\pi\mathrm{n}_1}\mathrm{Tr}\left(\tilde{\mathbf{D}}_{\mathrm{dir}}^{(1)}\mathbf{D}_{\mathrm{tot}}^{-H}\tilde{\mathbf{D}}_{\mathrm{dir}}^{(2)}\mathbf{D}_{tot}^{-1}\right), \qquad (1)$$

with V_1 the volume of the sending room, c the speed of sound, n_1 the modal density of the sending room and S the surface area of the interface between structure and room. $\mathbf{D}_{\mathrm{dir}}$ denotes the direct field dynamic stiffness matrix, whereas $\mathbf{D}_{\mathrm{tot}}$ represents the total dynamic stiffness matrix of the structure, including all wall leafs, cavities and their coupling. The imaginary part of a matrix is denoted with a tilde.

3. VISCOELASTIC INTERLAYERS

Laminated glazing makes use of viscoelastic (polymer) PolyVinylButyral (PVB) interlayers. The mechanical properties of these PVB interlayers are not only frequency-dependent, but they also depend on temperature. These effects can be accounted for by using the generalized Maxwell-Wiechert model and William-Landel-Ferry model [3, 4], respectively.

3.0.1 Generalized Maxwell-Wiechert model

At the small-strain regime, viscoelastic effects can be characterized efficiently by using the Generalized Maxwell-Wiechert model, taking into account the time/frequency-dependency of the shear modulus [5]. This model is constructed from parallel combinations of a spring and a damper placed in series, which are placed in parallel with a single elastic spring [13]. The elastic springs in combination with the viscous dampers provide dynamic stiffness in case of fast loading conditions, while the elastic spring represents the quasi-static stiffness. The elements in the Maxwell model can be derived experimentally using dynamic mechanical analysis (DMA) [13]. The time-dependency of the shear relaxation modulus can be expressed as [13]:

$$G(t) = G_\infty + \sum_{i=1}^{n} G_i \exp -t/\tau, \qquad (2)$$

with G_∞ the long-term shear modulus, G_i and τ_i the shear modulus and relaxation time of a viscoelastic unit (spring-damper pair), respectively. The number of viscoelastic units is denoted by n. The properties of the viscoelastic units are inversely related as follows:

$$\tau_i = \frac{\eta_i}{G_i}. \qquad (3)$$

The long-term shear modulus is related to the instantaneous shear modulus G_0 by [13]:

$$G_0 = G_\infty + \sum_{i=1}^{n} G_i. \qquad (4)$$

Substitution of Eqn. (4) into Eqn. (2) yields [14]:

$$G(t) = G_0 - \sum_{i=1}^{n} G_i \left(1 - \exp 1{-}t/\tau_i\right). \quad (5)$$

The shear relaxation modulus in the time-domain G(t) can also be expressed in the frequency domain as [5]:

$$G(\omega) = G_0 - \sum_{i=1}^{n} \frac{G_i}{(\omega\tau_i)^2 + 1} + \mathrm{i}\sum_{i=1}^{n} \frac{G_i \omega\tau_i}{(\omega\tau_i)^2 + 1}. \quad (6)$$

This expression can be subdivided into the real part representing the storage modulus, which determines the elastic behavior. The imaginary part of the resulting expression constitutes the loss modulus, representing the energy dissipation [5]. It has been demonstrated in [5] that the storage and loss moduli of several types of viscoelastic interlayer are subject to high differences due to the use of specific additives and plasticizers, and to differences in the measurement techniques.

3.0.2 Williams-Landel-Ferry equation

The dynamical shear modulus $G(T, \omega)$, which depends on both temperature and frequency, obeys the following relation:

$$G(T, \omega) = G(\mathrm{T}_0, \alpha_T \omega), \quad (7)$$

with $\mathrm{T}_0 = 20°C$ the reference temperature. The horizontal shift parameter α_T [3, 4] is proportional to the loss factor, given by

$$\alpha_T = \frac{\eta(T)}{\eta(\mathrm{T}_0)}. \quad (8)$$

For most polymer systems, the loss factor $\eta(T)$ is well-represented by the empirical Vogel–Fulcher law

$$\eta(T) = B \exp\left(\frac{\mathrm{T_A}}{T - \mathrm{T_V}}\right), \quad (9)$$

with $\mathrm{T_A}$ the activation temperature and $\mathrm{T_V}$ the Vogel temperature. Combining both Eqn. (8) and Eqn. (9) leads to [4]:

$$\log \alpha_T = -C_1 \frac{T - \mathrm{T}_0}{T - \mathrm{T}_0 + C_2}, \quad (10)$$

with two constants C_1 and C_2, defined as

$$C_1 = \log \mathrm{e} \left(\frac{\mathrm{T_A}}{\mathrm{T}_0 - \mathrm{T_V}}\right) \text{ and } C_2 = \mathrm{T}_0 - \mathrm{T_V}. \quad (11)$$

Eqn. (10) was proposed by Williams, Landel and Ferry and is known as the WLF equation. The influence of the PVB temperature and the resulting variations in airborne sound insulation of single laminated glazing is demonstrated in Fig. 2, displaying clear variations up to 4 dB in the frequency range around coincidence.

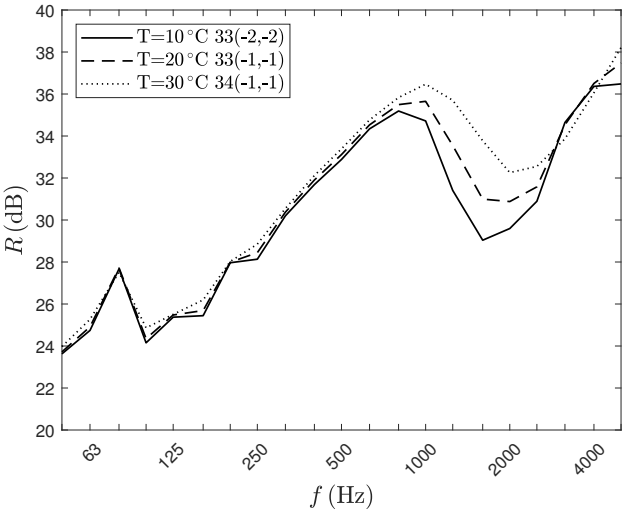

Figure 2. Influence of temperature on the mechanical properties of PVB and the resulting variations in airborne sound insulation of 44.2 glazing.

4. VALIDATION

The model can be showcased effectively using (laminated) glazing examples, since they contain all previously discussed elements: cavities and wall leafs including elastic layers and viscoelastic interlayers. The assumed default material properties of glass and the cavity fluids are listed in Tables 1 and 2, respectively. Note that a loss factor of $\eta = 0.05$ is assumed for the glass panes, which approximately consists of equal parts of internal losses and edge damping [15], i.e. energy loss due coupling of the glass panes through the mounting frame.

Table 1. Material properties of glass: density ρ, Young's modulus E, Poisson coefficient ν and loss factor η.

$\rho\,[\frac{\mathrm{kg}}{\mathrm{m}^3}]$	E [GPa]	$\nu\,[-]$	$\eta\,[-]$
2500	62	0.24	0.05

Table 2. Material properties of air and Argon: density ρ, sound speed c and cavity reverberation time T.

	$\rho\,[\frac{\mathrm{kg}}{\mathrm{m}^3}]$	$c\,[\frac{\mathrm{m}}{\mathrm{s}}]$	$T\,(\mathrm{s})$
Air	1.2	340	2
Argon	1.784	319	2

The simplest examples are single glass panes. Three single glazing examples with thicknesses of 4 mm, 10 mm and 19 mm are simulated and validated with corresponding laboratory measurements in Fig. 3. The simulations successfully capture the physical behavior of the single glazing, including the coincidence effect, resulting in accurate single number ratings with a maximum deviation of 1 dB.

Fig. 4 includes the results of simulations and laboratory measurements of two types of double glazing: 4-10-4 and 6-12-8. Fig. 4 indicates that other than the coincidence effect, also the mass-air-mass resonance is well-predicted, which also results in an accuracy of 1 dB on the single number rating.

Fig. 5 displays two examples of triple glazing: 4-10A-4-10A-4 and 6-14A-4-14A-6. Contrary to the double glazing examples, the cavities are filled with Argon instead of air to increase the airborne sound insulation. The use of argon instead of air mainly affects the anti-resonance peak just before coincidence, so around $1600-2000$ Hz in Fig. 5(a) and at approximately 1000 Hz in Fig. 5(b). Simulations have shown that the inclusion of argon instead of air does indeed improve the sound insulation at the anti-resonance frequency, where Fig. 5(a) indicates that this improvement is underestimated, while Fig. 5(b) suggests that the effect is correctly captured in the simulations. This variance can possibly be attributed to the niche effect [16]. Nevertheless, the prediction accuracy of the simulations for triple glazing is still 1 dB, as this niche effect at coincidence occurs at high frequencies and thus has a small influence on the single number rating.

Several examples are included for laminated glazing, both single (cfr. Fig. 6) and double (cfr. Fig. 7). The frequency and temperature-dependent material properties of the PVB interlayers are taken from [17], and it is assumed that the temperature of the PVB equals 20° C. Three examples of laminated single glazing are displayed in Fig. 6: 33.2, 1212.2 and 10101010.6. The prediction accuracy

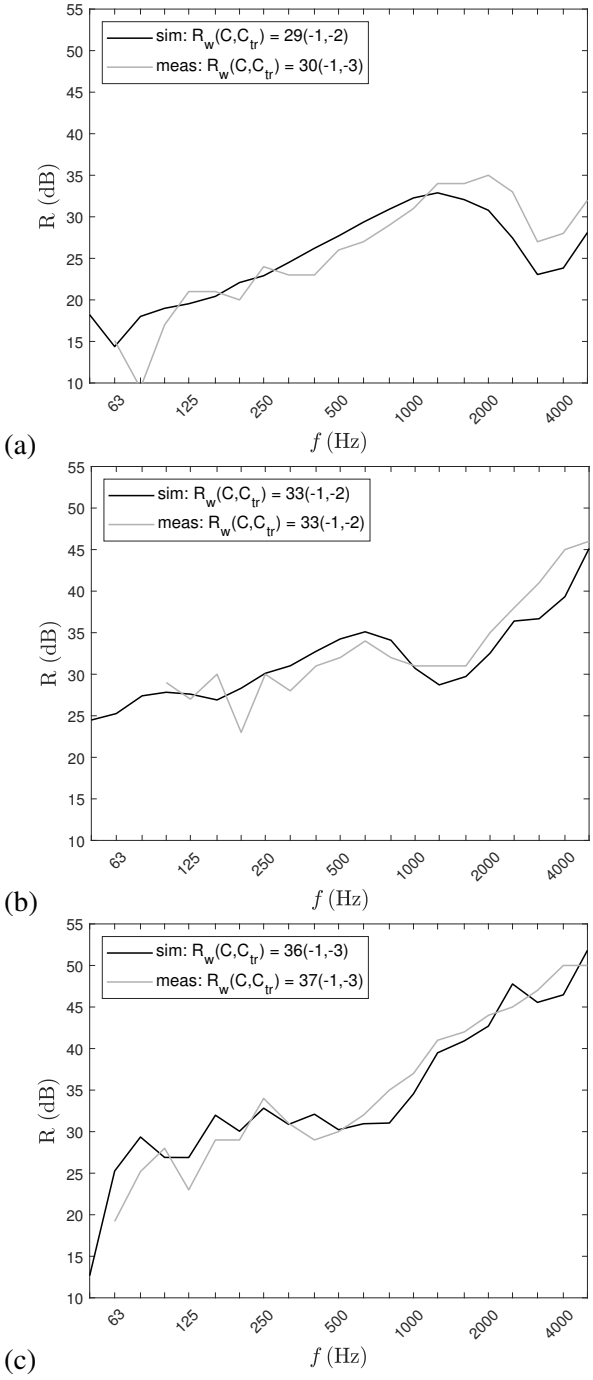

Figure 3. Single glazing: simulation (black) and laboratory measurement (grey). (a) 4 mm, (b) 10 mm and (c) 19 mm.

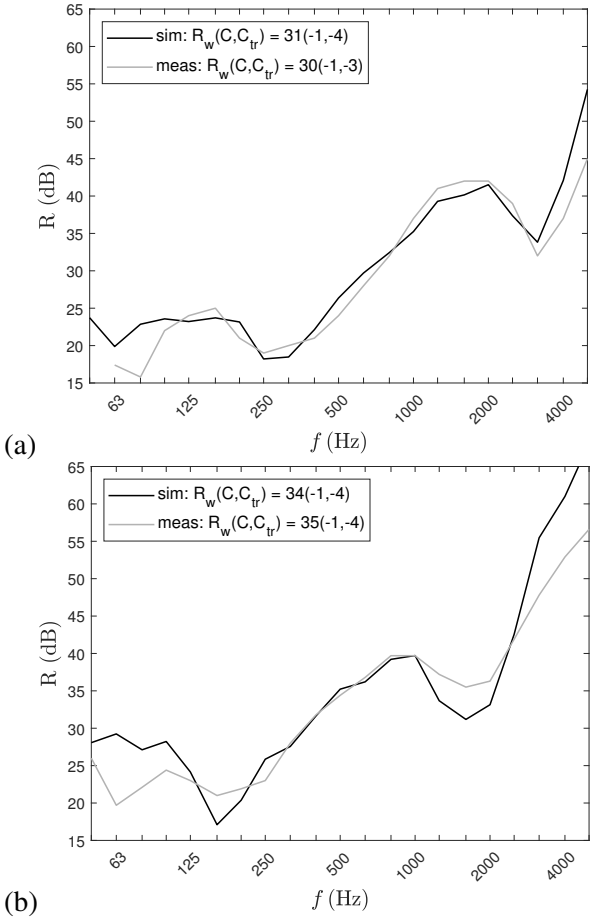

Figure 4. Double glazing: simulation (black) and laboratory measurement (grey). (a) 4-10-4 and (b) 6-12-8.

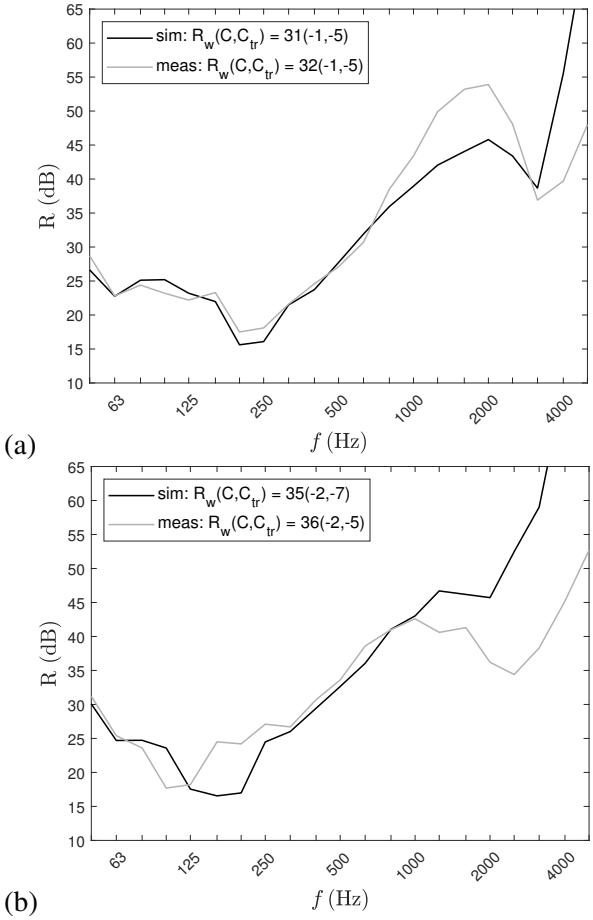

Figure 5. Triple glazing: simulation (black) and laboratory measurement (grey). (a) 4-10A-4-10A-4 and (b) 6-14A-4-14A-6.

for each of the examples is comparable to non-laminated glazing (cfr. $1-2\,\mathrm{dB}$), indicating that both the glazing properties and the assumed frequency and temperature-dependent material properties of the PVB interlayers perform with high accuracy within the prediction model.

The two validation examples for laminated double glazing provide an increasing order of complexity: Fig. 7(a) contains the results for 4-6-33.1 glazing, which has only one laminated glass panel, whereas the results for double glazing with two laminated glass panels (33.2-12-55.2) is displayed in Fig. 7(b). The simulation results for both validation examples contain a spectral shape which is very similar to the measured laboratory values. It is clear that the mass-air-mass resonance and the coincidence phenomenon are correctly simulated and that the sound insulation in the intermediate frequency range as well as low frequencies is accurately predicted. At frequencies above coincidence, however, the simulations indicate a significantly higher sound insulation than measured in the laboratory. This can be attributed to transmission through the mounting frame, which is not included in the simulations. This influence can generally be seen in glazing with high sound insulation, such as the triple glazing in Fig. 5 where this overestimation at high frequencies is also observed. As this effect only appears above coincidence, its influence on the single number rating is very limited, resulting in a prediction accuracy of $2\,\mathrm{dB}$ for both examples of the laminated double glazing.

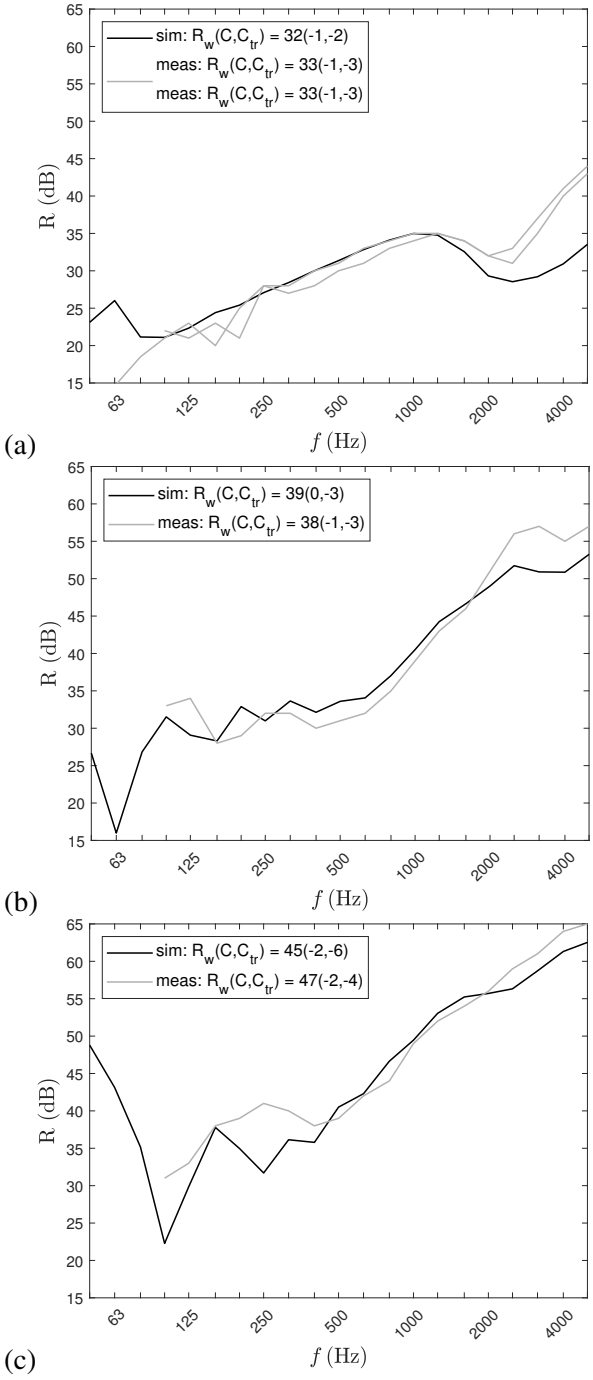

Figure 6. Laminated single glazing: simulation (black) and laboratory measurement (grey). (a) 33.2, (b) 1212.2 and (c) 10101010.6.

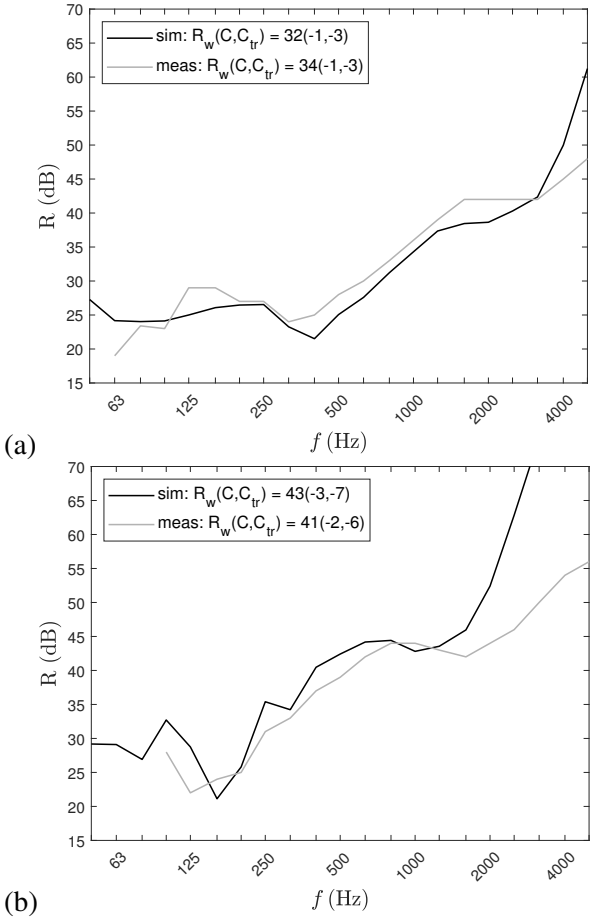

Figure 7. Laminated double glazing: simulation (black) and laboratory measurement (grey). (a) 4-6-33.1 and (b) 33.2-12-55.2.

5. CONCLUSIONS

In this paper, a robust and efficient prediction method for determining the sound insulation of multilayer structures is presented, with a particular focus on glazing examples. The proposed method accounts for various factors such as arbitrary layering, finite dimensions, boundary conditions, and frequency- and temperature-dependent material properties. The results show that the prediction method can achieve an accuracy of $1-2\,\mathrm{dB}$ in the single number rating using predefined values from a material database, and even higher accuracy is attainable when material properties are determined from testing. The method successfully captures key physical phenomena such as the mass-air-mass resonance and the coincidence effect, by using elas-

todynamics and accounting for material properties that may depend on frequency and temperature, providing reliable predictions for (laminated) single, double, and triple glazing configurations. In addition to the accuracy, the predictions maintain a low computational cost due to the modal approach

The ability to accurately and efficiently predict sound insulation is crucial for optimizing design configurations and exploring new materials and various material properties. This method offers a valuable tool for engineering offices and manufacturers, enabling them to reduce the reliance on costly and time-consuming laboratory measurements. By providing a more efficient alternative, the method facilitates the exploration and optimization of acoustic solutions for specific situations. Future work could focus on further expansion of the model to account for additional complexities, such as the influence of frame transmission, double walls with flexible studs, lightweight floors and periodic structures.

BAYESIAN ANALYSIS OF THE RW BASED ON A PARAMETRIZED PHYSICAL MODEL ACCORDING TO EN ISO 12354-1

Michael Parzinger[1*] **Ulrich Schanda**[1]
[1] Laboratory for Sound Measurement, Technical University of Applied Sciences Rosenheim, Germany

ABSTRACT

The EN ISO 12354-1 standard provides a physical model for the sound reduction index R. The results of this model can be used to calculate the weighted sound reduction index for different scenarios, which itself plays an important role in the design of a building element. This raises the question of how well this physical model actually reflects reality. In this work, the physical model is first optimized based on Bayesian inference. The optimized model can then in turn be used to simulate the sound reduction index taking into account uncertainties. These simulations then can provide an analysis of the construction in order to decide whether the minimum requirements on sound insulation will be met with a certain probability. For example, it is checked how thick a calcium silicate brick wall must be so that the weighted sound reduction index is at least 53 dB with a probability of 95 %. This is relevant as, in the best-case scenario, building elements can be optimized concerning the economization of material, which enables a cost-effective and sustainable construction.

Keywords: *Sound reduction index, Rw, Bayesian inference*

1. INTRODUCTION

For new buildings, an optimized construction in terms of sustainability is compulsory. Requirements on sound insulation have to be met as well. Often, the question arises as to how thick a solid wall should be. Thin walls would save material, whereas thick walls guarantee better sound insulation. This paper focuses on the influence of the thickness of a homogeneous wall on the weighted sound reduction index R_w using a Bayesian approach.

To investigate this issue, a physical model for the sound reduction index R is considered. This physical model is first optimized using data from laboratory measurements of walls made of calcium silicate (Ca-Si) blocks. This part was also discussed at Forum Acusticum 2023 [1] and at [2, 3], but has been expanded since then.

With this optimized model, the sound reduction index is simulated by drawing realizations from a corresponding probability distribution. The values for the weighted sound reduction index can then be calculated and analyzed. This procedure is finally used for claims about wall thicknesses that do not occur in the available data. In particular, the probability of whether a wall meets a certain requirement on the weighted sound reduction index is estimated.

2. PHYSICAL MODEL

First, a physical model for the sound reduction index R is discussed, which is based on the model in ISO 12354-1 Annex B [4] and given in equation (1). A few modifications have been implemented and are explained in DAS/DAGA [5]. All quantities in the following equations together with the chosen numerical values are listed in Table 1. The second term in equation (1) denotes the Waterhouse correction.

$$R = -10\lg(\tau) - 10\lg\left(1 + \frac{c_0 S_\mathrm{tot}}{8Vf}\right) \qquad (1)$$

The transmission coefficient in the first term is given

in equation (2), while the radiation factor σ is defined by the equation (6).

$$\tau = \begin{cases} \frac{Z_0^2}{(m'\pi f)^2}\left(\frac{\pi}{2}\frac{\sigma^2}{\eta_{\text{tot}}}\frac{f_c}{f} + \frac{2\sigma_f}{(1-f^2/f_c^2)^2}\right), & f < 0.89 f_c \\ \frac{Z_0^2}{(m'\pi f)^2}\frac{\pi}{2}\frac{\sigma^2}{\eta_{\text{tot}}}, & 0.89 f_c \leq f \leq 1.4 f_c \\ \frac{Z_0^2}{(m'\pi f)^2}\frac{\pi}{2}\frac{\sigma^2}{\eta_{\text{tot}}}\frac{f_{c,\text{eff}}}{f}, & f > 1.4 f_c \end{cases} \tag{2}$$

$$f_c = \frac{\sqrt{3}}{\pi}\frac{c_0^2}{c_{\text{L}}}\frac{1}{t} \tag{3}$$

$$f_{\text{c,eff}} = f_{\text{c}} \cdot \left(1 + \frac{1}{\gamma^3} \cdot \left(\frac{3.6}{1-\mu} \cdot \frac{tf}{c_{\text{L}}}\right)^{\frac{3}{2}}\right)^{\frac{2}{3}} \tag{4}$$

$$\eta_{\text{tot}} = \eta_{\text{int}} + \text{C}/\sqrt{f} \tag{5}$$

The calculations of the radiation factor are strongly based on ISO 12354-1, only the maximum value is adjusted due to ambiguities in the standard and because past analyses have shown that these adjustments are appropriate.

$$\sigma(f) = \min\left(\tilde{\sigma}(f); \sigma_3(f); \sqrt{1 + \frac{2(l_1+l_2)\cdot f_{\text{c}}}{5c_0}}; 2.0\right) \tag{6}$$

Further adjustments have been made in the high frequency range, where thickness resonances occur. For this purpose, a new quantity τ_0 is introduced in equation (7). The definition of c_{L1} signifies that in this work a distinction is made between the effective value c_{L} and the nominal (material) value c_{L1} for the longitudinal wave velocity.

$$\tau_0 = \left(\cos^2(u) + \frac{1}{4}\left(\frac{\rho c_{\text{L,ex}}}{Z_0} + \frac{Z_0}{\rho c_{\text{L,ex}}}\right)^2 \sin^2(u) + \eta_{\text{int}}^2\right)^{-1} \tag{7}$$

$$u = \frac{2\pi f t}{c_{\text{L,ex}}} \tag{8}$$

$$c_{\text{L,ex}} = c_{\text{L1}}\frac{1-\mu}{\sqrt{1-2\mu}} \tag{9}$$

The following variables are introduced:

$$f_{\text{T}} = \sqrt{3}(1-\mu)\frac{c_{\text{L1}}}{2\pi t} \tag{10}$$

$$\tilde{f}_{\text{T}} = \arg\min_f |\log(f) - \log(2^{2/3} f_{\text{T}})| \tag{11}$$

$$\tau_{\text{plateau}} = \frac{\eta_{\text{ref}}}{\eta_{\text{tot}}}\left(\frac{4Z_0}{\rho c_{\text{L,ex}}}\right)^2 \tag{12}$$

$$\eta_{\text{ref}} = \eta_{\text{int}} + \frac{\text{C}}{\sqrt{2^{2/3} f_{\text{T}}}} \tag{13}$$

$$\tau_{\text{w}}(f) = (\tau_{\text{plateau}}(f)^4 \tau_0(f))^{1/5} \tag{14}$$

Finally, the adjusted transmission coefficient is defined in equation (15).

$$\tau_{\text{adj}}(f) = \begin{cases} \tau(f), & f \leq \tilde{f}_{\text{T}} \\ \tau_{\text{w}}(f) \cdot \tau(\tilde{f}_{\text{T}})/\tau_{\text{w}}(\tilde{f}_{\text{T}}), & f > \tilde{f}_{\text{T}} \end{cases} \tag{15}$$

Table 1. Quantities for the sound reduction index R.

Symbol	Description	Value
f	Frequency in Hz	
c_0	Sound speed in air	340 m/s
S_{tot}	Total surface in reception room	85 m²
V	Reception room volume	50 m³
Z_0	Sound characteristic impedance of air	418 $\frac{Pa}{m/s}$
m’	Mass per unit area	440 kg/m²
σ_f	Radiation factor for forced waves	See ISO 12354-1
$\tilde{\sigma}$	Radiation factor	See ISO 12354-1
σ_3	-	See ISO 12354-1
ρ	Density of the material	1760 kg/m³
μ	Poisson’s ratio	0.25
t	Construction thickness	0.25 m
l_1, l_2	Side lengths of wall	Depends
c_{L1}	Nominal longitudinal wave velocity	2500 m/s
c_{L}	Effective longitudinal wave velocity	Fit parameter
C	Boundary loss constant	Fit parameter
η_{int}	Internal loss factor	Fit parameter
γ	Shear wave contribution factor	Fit parameter

3. DATA DESCRIPTION

For the next step, data from 24 laboratory measurements will be used to further customize the model. These originate from a round robin test carried out by the *Physikalisch-Technische Bundesanstalt* (PTB). The separating components are Ca-Si walls with a thickness of 25 cm including plaster. Further details on the laboratory experiments can be found in [6] and [7]. Figure 1 shows the mean progression of these 24 curves and the range resulting from the mean value ± 1 respectively ± 2 times the standard deviation of the measurement data.

4. BAYESIAN INFERENCE

The data is now the basis for the optimization of the physical model from section 2 by only changing some parameters but not the physics of the model. Bayesian methods are applied for this purpose. The Bayesian concept of probability is characterized by the idea that probabilities are not interpreted as relative frequencies but as degrees of belief that can be updated with new information. For the application, a distribution is assumed which represents the knowledge of our parameter before the data is known. This distribution is referred to as the prior distribution. The data y is then combined with the prior distribution to obtain a posterior distribution. This posterior distribution represents the knowledge of the parameter after the data is taken into account. Since the knowledge is expressed by probability distributions, it also contains all uncertainties of the parameters. To derive this posterior, Bayes' theorem from equation (16) is applied (s. subsection 4.1). The term $\propto$ denotes equality except for factors that do not depend on θ. The concept of Bayesian statistics is further discussed in several books like [8], [9], and [10].

$$\underbrace{\mathbf{p}(\theta|y)}_{\text{posterior}} = \frac{\mathbf{p}(\theta)\,\mathbf{p}(\theta|y)}{\mathbf{p}(y)} \propto \underbrace{\mathbf{p}(\theta)}_{\text{prior}}\,\underbrace{\mathbf{p}(y|\theta)}_{\text{likelihood}} \tag{16}$$

On the one hand, this approach is suitable when there are few data relative to the number of parameters to be estimated. This is because sample size plays a less central role in Bayesian statistics than in classical statistics. On the other hand, some of the parameters are physical quantities for which prior knowledge exists. The term $\mathbf{p}(\theta)\,\mathbf{p}(y|\theta)$ can also be interpreted in such a way that the parameters are pushed away from the data optimum in the direction of physically meaningful values.

This is also the difference to the classical approach, also known as the frequentist approach, in which θ is chosen such that it maximizes the likelihood $\mathbf{p}(y|\theta)$. The analysis using the classic approach was presented at this year's DAS/DAGA [5].

4.1 Definitions and assumptions

First, the physical parameters to be adjusted are selected. These are the internal loss factor η_{int}, the boundary loss constant C, the longitudinal wave velocity c_{L} of the plate, and γ. Therefore, $\phi = (\eta_{\text{int}}, \text{C}, c_{\text{L}}, \gamma)^T \in \mathbb{R}^4$ is defined as the vector of physical fit parameters.

In addition to these, a covariance matrix is also necessary, which is defined as $\Sigma \in \mathbb{R}^{21\times 21}$ and indicates the third-octave band-dependent variances on the diagonal and the covariances between two third-octave bands outside of it. For this purpose, $\theta = (\phi, \Sigma)$ is denoted as the tuple of ϕ and Σ.

The measurement curves are each denoted as y_i with $i = 1, \ldots, 24$. A multidimensional normal distribution is assumed for these if ϕ and Σ are given, i.e. $y_i|\theta \sim \mathcal{N}_{21}(\text{M}_i(\phi), \Sigma)$. Here, $\text{M}_i : \mathbb{R}^4 \to \mathbb{R}^{21}$ denotes the physical model as a function of the physical fit parameters. This results in a potential model curve for each ϕ. The index in M_i indicates that the properties of the i-th wall are taken into account. This refers in particular to the side lengths.

The notation y in equation (16) represents the vector of all 24 measurement curves, i.e. $y = (y_1^T, y_2^T, \ldots, y_{24}^T)^T \in \mathbb{R}^{504}$, where $504 = 21 \cdot 24$ results from the number of third octave bands times the number of measurement curves. It is assumed that the measurement curves are independent of each other.

4.2 Prior distributions

Maximum Entropy Prior (MEP) is applied to convert physical prior knowledge into a prior distribution. The MEP was introduced by Jaynes [11, 12] and further discussed in [13], [14], [15] and others.

If prior knowledge of the expected value, variance, minimum, and maximum is available for a one-dimensional parameter, then the truncated normal distribution results as the prior distribution [15, Page 201].

The prior assumptions for the physical fit parameters ϕ are shown in Table 2. Note that for the longitudinal velocity c_{L} the effective value and not the nominal value is meant. These assumptions are based on individual experience, but this only plays a minor role for the results as long as other prior knowledge does not deviate too much from the Table 2 values.

Table 2. Prior assumptions for the parameters ϕ

Parameter	Mean	Variance	Min.	Max.
η_{int}	0.02	0.01^2	0.005	∞
C	2	1	0.25	5
c_L in m/s	1000	300^2	700	5000
γ	0.77	0.2^2	0.55	0.95

Both the variances and the correlations are required for the prior distribution of the covariance matrix. The variances are based on the work of Wittstock (2015) [16]. With MEP, this results in the exponential distribution with the calculated average as the expected value for each one-third octave band.

The LKJ (Lewandowski, Kurowicka, Joe) [17] distribution is employed to model prior knowledge about correlations. This distribution is given by $\mathbf{p}(\Omega|\nu) \propto |\Omega|^{\nu-1}$ for each correlation matrix Ω. The parameter ν represents the prior knowledge about the correlation. If ν is less than one, high correlations are assumed; if ν is greater than one, low correlations are assumed; and if $\nu = 1$, no prior knowledge of the correlation is assumed. Here, ν is modeled as an exponential distribution with an expected value of one.

The equations (17) show a summary of all prior assumptions. Here, $\mathcal{N}^{\mathcal{T}}$ denotes the truncated Gaussian, where the hyperparameter a_k, b_k, and the support S_k are chosen such that the properties satisfy Table 2 for $k = 1, 2, 3, 4$. While w_j^2 represents the variances calculated in [16] for $j = 1, \ldots, 21$.

$$\begin{aligned} y_i|\theta &\sim \mathcal{N}_{21}(\mathrm{M}_i(\phi), \Sigma), \\ \theta &= (\phi, \Sigma), \\ \phi_k &\sim \mathcal{N}^{\mathcal{T}}(a_k, b_k, S_k), \\ \Sigma &= D\Omega D, \\ D &= \mathrm{diag}(\sigma_1, \ldots, \sigma_{21}), \\ \sigma_j^2 &\sim \mathrm{Exp}(1/w_j^2), \\ \Omega|\nu &\sim \mathrm{LKJ}(\nu), \\ \nu &\sim \mathrm{Exp}(1). \end{aligned} \tag{17}$$

4.3 Posterior sampling

The software STAN [18, 19] is used to derive the posteriors. For the sampling procedure, the No-U-Turn Sampler (NUTS) is applied, which allows random numbers that are distributed like the posteriors to be drawn without calculating them analytically. The notation, $\theta^{(s)}$ represents the sample number s for $s = 1, \ldots, S$. For the following steps, $S = 4000$ samples are utilized for each parameter.

4.4 Posterior results

A summary of the results of the physical fit parameters ϕ is shown in Table 3. While c_L, γ, and η_int are credible, C deviates quite strongly from what is expected.

Therefore, a second model variant under the condition that C = 0.91, and $\eta_\mathrm{int} = 0.01$, which are the values according to ISO 12354-1, was applied. In this case, a shift of the model curve is required. Figure 1 compares these models by visualizing $\frac{1}{S}\sum_{s=1}^{S} \mathrm{M}_i(\phi^{(s)})$. As the model curves are generated for each wall, the thickness of the curves reflects the influence of the wall properties. The Figures 2, 3, 4, and 5 compare the posterior samples between these two model variants with each other and with sampling from the prior densities.

For the future steps, the focus is on the model for which η_int and C are considered as non-fixed parameters since this has the better quality according to measures such as leave-one-out cross validation (LOO-CV) and WAIC [20]. The model with fixed parameters η_int and C only serves as a comparison.

The results of the standard deviations and correlations are summarized in Figures 6 and 7. For the standard deviations, both the median curve and the corresponding quantile ranges are shown. The values are also compared with the calculations according to Wittstock. The correlation was averaged across all sampled matrices. It can be seen that the correlations in the one-third octave bands below the critical frequency ($\approx$ 240 Hz) are rather weak, whereas the one-third octave bands above correlate rather strongly. An explanation might be that below the critical frequency the sound transmission is dominated by the forced transmission. The individual structural behavior does not play a significant role.

Table 3. Posterior summary of fit parameters

Quantiles	η_int	C	c_L	γ
2.5%	0.005	3.44	1019	0.57
25%	0.007	3.91	1047	0.60
50%	0.009	4.16	1061	0.61
75%	0.012	4.41	1075	0.64
97.5%	0.020	4.85	1100	0.68

5. ANALYSIS OF R_{w}

The optimized model discussed is applied to simulate the sound reduction index. Let $W(t)$ be the properties of a Ca-Si wall with a thickness of t meter and the rest as in the data (see Table 1). As before, the notation $\mathrm{M}_{W(t)}(\phi)$ is used for the sound reduction index of a wall with the properties $W(t)$ as a function of the parameters ϕ.

The difference between the model and the measurement curve is simulated by drawing from a $\mathcal{N}_{21}(0, \Sigma^{(s)})$ distribution for each s. These 4000 simulated vectors of differences are each added to the corresponding $\mathrm{M}_{W(t)}(\phi^{(s)})$. This procedure is carried out in steps of one cm with wall thicknesses t from 0.18 meters to 0.36 meters. This results in 4000 simulated shapes of the sound reduction index R for each wall thickness, which can then be used to calculate the weighted sound reduction index R_{w} according to ISO 717-1 [21]. Note that by using all 4000 draws, the distribution and thus the estimation uncertainties of the parameters are taken into account.

The results are shown in Figure 8. The blue points in this figure show a comparison with the model variant in which the internal loss factor η_{int} and the boundary loss factor C are fixed.

These simulated values of the weighted sound reduction index R_{w} can then be utilized to estimate the proba-

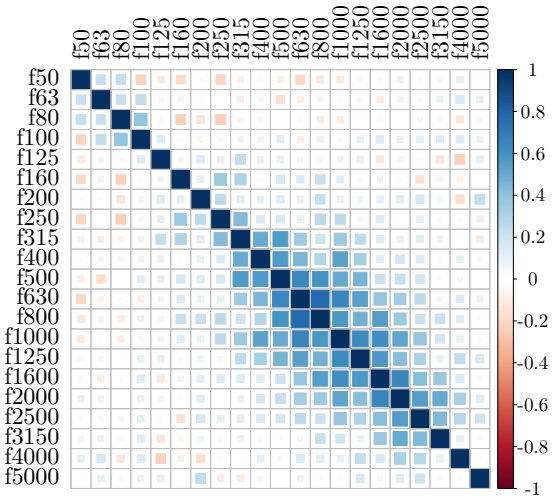

Figure 7. Averaged correlations

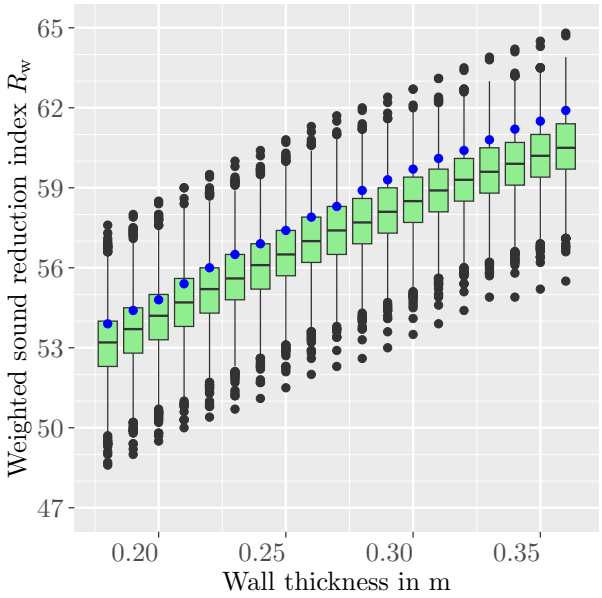

Figure 8. Simulated R_w values

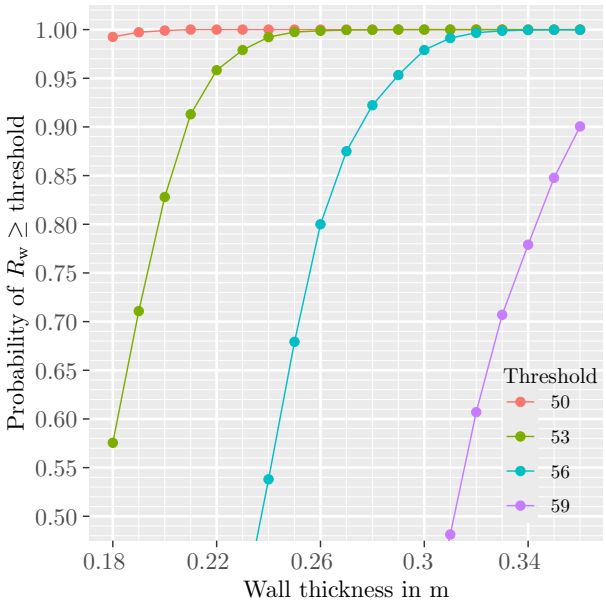

Figure 9. Estimated probability of R_w exceeding a threshold depending on the wall thickness

bility of specified threshold values being exceeded using relative frequencies. These results for probabilities of at least 0.5 are shown in Figure 9.

On the one hand, it can be seen that, according to this analysis, very high requirements of at least 59 dB need correspondingly thick walls of 36 cm to be fulfilled with a probability of about 90 %. On the other hand, low requirements of 50 dB are almost always met also with 18 cm walls.

Assuming 53 dB is set as the threshold value, the question arises as to the probability with which this should be reached. If this is to be fulfilled in at least 90 % of cases, then a thickness of 21 cm is sufficient, and for 95 % it should be 22 cm.

6. DISCUSSION

In this work, the physical model according to ISO 12354-1 was first adapted and then optimized using Bayesian methods. With the help of simulations based on the physical model and probability assumptions, sound reduction index R curves of Ca-Si walls at different thicknesses were simulated. These simulated curves were in turn taken to provide information on the distribution of the weighted sound reduction index R_w depending on the wall thickness.

However, it should be noted that the accuracy of the physical model cannot be verified for wall thicknesses other than 25 cm, but since the model itself is strongly based on the surface area mass, it is credible that the model still fits.

This procedure should therefore be repeated on the basis of other data. In addition to calcium silicate walls with different wall thicknesses, other materials such as reinforced concrete walls or lightweight concrete are also conceivable. In addition, further physical models for the sound reduction index R are to be utilized as a basis, in particular model variants based on the in-situ case.

Overall, it can be stated that this approach provides promising results, but further data and steps for validation are still necessary. However, the procedure itself remains identical regardless of the chosen physical model behind or the exact nature of the data.

7. ACKNOWLEDGEMENTS

We would like to thank the *Physikalisch-Technische Bundesanstalt* for providing the data from the round-robin test. In particular, Mr. Wittstock, who also provided us with his calculations for the one-third-band standard devi-

ations discussed in [16].
Furthermore we would like to acknowledge the funding of the research by the *Bavarian State Ministry of Education, Culture, Science and Arts*.

WAVE-BASED ANALYSIS OF FLANKING SOUND TRANSMISSION ACROSS JUNCTIONS WITH METAMATERIAL TREATMENT USING EFFECTIVE MEDIUM THEORY

Sofie Becuwe[1*] **Stijn Moons**[1,2] **Daniele Giannini**[1] **Edwin P. B. Reynders**[1]

ABSTRACT

Reducing flanking sound transmission in buildings is challenging, with current options limited to mass increase and structural decoupling. This study explores an alternative approach using resonant metamaterial treatments, where small resonators are added on a subwavelength scale to the building elements connected via the junction. These offer a promising lightweight approach to achieve vibroacoustic attenuation, by creating wave propagation bandgaps that inhibit free-traveling waves within targeted frequency ranges. Wave propagation through the junctions is modeled using an analytical wave approach, in which thin isotropic semi-infinite plates are considered, and equilibrium and compatibility equations are imposed along the junction line. The metamaterial treatment is introduced in a computationally efficient way through effective medium theory, which locally employs homogenized material properties in the connected plates to capture the essential effects of subwavelength resonators. Results show that the structural transmission loss exhibits a significant increase close to the frequency of local resonance. To explore the achievable performance of the proposed treatments, various scenarios are analyzed, by varying the extent of the metamaterial treatment, from a narrow strip close to the junction to the full receiver plate, as well as the local resonator mass and multiple local resonances to address broader band effectiveness.

1. INTRODUCTION

Ensuring a sufficiently high level of sound insulation in buildings is a challenging problem, due to the presence of a multitude of sound transmission paths between the rooms across junctions of building elements, also called flanking transmission paths, through which vibrational energy is transmitted. Current solutions to suppress flanking paths involve mass increase and structural decoupling through elastic interlayers or linings, which however do not always prove to be feasible in renovations or lightweight constructions. To address these limitations, in this paper a new solution for the suppression of flanking sound is researched, based on resonant metamaterials.

Metamaterials are artificial structures, engineered to manipulate wave propagation on the microscopic (i.e., sub-wavelength) scale, such that at the macroscopic scale, an effective material is created with unconventional wave propagation properties that surpass those of conventional materials [1, 2]. Of the various types of metamaterials that have appeared over the years, resonant metamaterials (RMMs) are particularly attractive for noise control in buildings. By small resonators (periodically) added to a host structure on a subwavelength scale, RMMs achieve the suppression of free elastic wave propagation in a targeted frequency range [3, 4], while maintaining a light weight. Furthermore, by employing resonators that possess multiple resonances, known as multi-modal resonators, multiple frequency ranges can be targeted [5].

Recent developments make it possible to efficiently

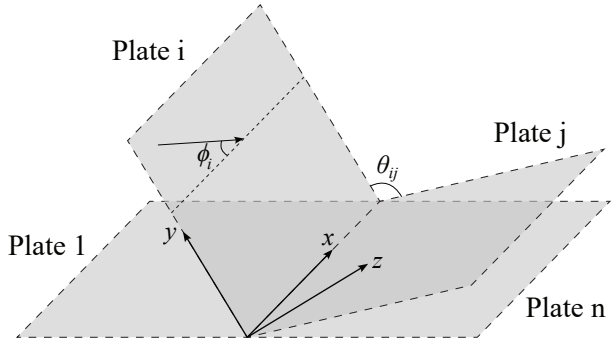

Figure 1: Schematic representation of a system of thin plates connected through a junction.

predict and quantify the influence of flanking sound transmission through junctions [6, 7], however these models only include the application of elastic interlayers, not RMMs. In this paper, the analytical model as described in [8] will therefore be expanded to include RMM applications too, by means of effective medium modeling [9]. With this technique, the effect of the subwavelength resonators is approximated by locally considering equivalent, frequency-dependent, material properties in the host structure [9].

The present paper is organized as follows. Section 2 summarizes the wave-based method to analyze flanking sound transmission across junctions, along with its extension through include RMM treatments. In Section 3, the method is used to analyze flanking transmission across a junction between two steel plates, for which different RMM treatments are considered by varying the width of the treated strip, the resonator mass, and the number of local resonances. Section 4 concludes the work.

2. METHODOLOGY

The used methodology consists of a combination of an analytical wave approach to model wave propagation through junctions [8] with effective medium theory to introduce the metamaterial treatment in a computationally efficient way as described in [9]. The considered system is a junction with n directly connected thin isotropic semi-infinite plates, each inclined at an angle θ_{ij} relative to an arbitrary reference plate (Fig. 1). The corresponding local coordinate system (x', y', z') for each plate is illustrated in Fig. 2. The metamaterial treatment can be applied both on the entire plate surface or a smaller strip close to the junction (Fig. 2). Due to both out-of-plane bending waves and in-plane longitudinal and shear waves, the plates vibrate.

The general aim is to determine the structural transmission coefficients τ_{ij}^{st} between an incident wave type s in plate i and a transmitted wave type t in plate j:

$$\tau_{ij}^{st}\left(\omega, \phi_i\right) := \frac{I_{\mathrm{y},j}^{t}}{I_{\mathrm{y},i}^{s}}. \tag{1}$$

with $I_{\mathrm{y},i}^{s}\left(\phi_i\right)$ the incident intensity and $I_{\mathrm{y},j}^{t}\left(\phi_i\right)$ the transmitted intensity in the local y'-direction per unit length of the connection. The transmission coefficient in Eq. (1) is dependent on the angle of incidence. The diffuse transmission coefficient, independent on the angle of incidence, for homogeneous isotropic plates, can be found as [6]:

$$\tau_{ij}^{st}\left(\omega\right) := \frac{1}{2}\int_0^{\pi} \tau_{ij}^{st}\left(\omega, \phi_i\right) \sin\phi_i \mathrm{d}\phi. \tag{2}$$

We here consider plane incident waves with incident angle $\phi_i = \operatorname{atan}\left(\frac{k_{\mathrm{y},i}^{s}}{k_{\mathrm{x}}}\right)$, frequency ω and wavenumbers k_{x} along the x-direction and k_{y} along the y-direction. Specifically, we consider only bending incident waves. This incident wave causes reflected and transmitted plane waves from the junction to each receiver plate j for any potential wave type t, which is considered to be a bending, shear or longitudinal wave. Compatibility at the junction imposes that the frequency ω and the wavenumber k_{x} along the x-direction, for all reflected and transmitted waves, are equal to the ones imposed by the incident wave.

The structural transmission loss in dB can subsequently be computed from the transmission coefficient as [10]:

$$R_{ij}\left(\omega\right) = -10\log\left(\tau_{ij}^{st}\left(\omega\right)\right). \tag{3}$$

The forces and displacements at the plate edge in the local coordinate system are illustrated in Fig. 2. From these, the incident and transmitted intensity can be computed as [11]:

$$I_{\mathrm{y},i}^{s}\left(\phi_i\right) := -\frac{\omega}{2}\mathrm{Im}\left(\mathbf{f}_{\mathrm{inc},i}^{s\mathrm{T}}\mathbf{u}_{\mathrm{inc},i}^{s*}\right), \tag{4}$$

$$I_{\mathrm{y},j}^{t}\left(\phi_i\right) := -\frac{\omega}{2}\mathrm{Im}\left(\mathbf{f}_{\mathrm{out},j}^{t\mathrm{T}}\mathbf{u}_{\mathrm{out},j}^{t*}\right), \tag{5}$$

with * denoting the complex conjugate. Specifically, the intensities for incident bending and transmitted bending

and in-plane longitudinal or shear waves are [8]:

$$I^{\mathrm{B}}_{\mathrm{y},i}\left(\phi_i\right) = -\frac{\omega}{2}\mathrm{Im}\left(f_{\mathrm{yz,inc},i}u^*_{\mathrm{z,inc},i} + m_{\mathrm{yy,inc},i}\theta^*_{\mathrm{x,inc},i}\right), \tag{6}$$

$$I^{\mathrm{B}}_{\mathrm{y},j}\left(\phi_i\right) = -\frac{\omega}{2}\mathrm{Im}\left(f_{\mathrm{yz,out},j}u^*_{\mathrm{z,out},j} + m_{\mathrm{yy,out},j}\theta^*_{\mathrm{x,out},j}\right), \tag{7}$$

$$I^{\mathrm{L/S}}_{\mathrm{y},j}\left(\phi_i\right) = -\frac{\omega}{2}\mathrm{Im}\left(f_{\mathrm{yx,out},j}u^*_{\mathrm{x,out},j} + f_{\mathrm{yy,out},j}u^*_{\mathrm{y,out},j}\right). \tag{8}$$

2.1 Plate model for plates without RMM treatment

In order to compute the forces and displacements in Eqs. (6) - (8) for plates without RMM treatment, the associated dynamic stiffness matrices need to be derived, which relate the forces and displacements at the plate edge. The plate edge displacements $\mathbf{u}_j\left(x', y', z', t\right)$ and forces per unit length $\mathbf{f}_j\left(x', y', z', t\right)$ for a plate j consist of contributions from the outgoing transmitted and reflected waves at the junction $\mathbf{u}_{\mathrm{out},j}$ and the incident wave $\mathbf{u}_{\mathrm{inc},j}$ [6]:

$$\mathbf{u}_j = \mathbf{u}_{\mathrm{out},j} + \mathbf{u}_{\mathrm{inc},j}, \tag{9}$$

$$\mathbf{f}_j = \mathbf{f}_{\mathrm{out},j} + \mathbf{f}_{\mathrm{inc},j}, \tag{10}$$

where $\mathbf{u}_{\mathrm{inc},j}$ and $\mathbf{f}_{\mathrm{inc},j}$ are only non-zero for the source plate.

The stiffness matrix $\mathbf{D}_j \in \mathbb{C}^{4x4}$ relating the forces $\mathbf{f}_{\mathrm{out},j}$ to the edge displacements $\mathbf{u}_{\mathrm{out},j}$, is composed of a contribution from the in-plane (IP) and out-of-plane (OOP) wave motion, represented respectively by $\mathbf{D}_{\mathrm{IP}}$ and $\mathbf{D}_{\mathrm{OOP}} \in \mathbb{C}^{2x2}$ [6]:

$$\underbrace{\begin{bmatrix} f_{\mathrm{yx}} \\ f_{\mathrm{yy}} \\ f_{\mathrm{yz}} \\ m_{\mathrm{yy}} \end{bmatrix}}_{:=\mathbf{f}_{\mathrm{out},j}} = \underbrace{\begin{bmatrix} \mathbf{D}_{\mathrm{IP}}\left(k_{\mathrm{x}}\right) & \mathbf{0} \\ \mathbf{0} & \mathbf{D}_{\mathrm{OOP}}\left(k_{\mathrm{x}}\right) \end{bmatrix}}_{\mathbf{D}_j\left(k_{\mathrm{x}}\right)} \underbrace{\begin{bmatrix} u_{\mathrm{x}}\left(y'=0\right) \\ u_{\mathrm{y}}\left(y'=0\right) \\ u_{\mathrm{z}}\left(y'=0\right) \\ \theta_{\mathrm{x}}\left(y'=0\right) \end{bmatrix}}_{\mathbf{u}_{\mathrm{out},j}}. \tag{11}$$

For compactness, the dependency from $\mathbf{D}_j$ on k_{x} is omitted in further equations. Eq. (11) can then be substituted into Eq. (10), resulting in the total force per unit length exerted by the plate on the junction:

$$\mathbf{f}_j = \mathbf{D}_j\mathbf{u}_{\mathrm{out},j} + \mathbf{f}_{\mathrm{inc},j}. \tag{12}$$

The stiffness matrices $\mathbf{D}_{\mathrm{IP}}$ and $\mathbf{D}_{\mathrm{OOP}}$ for in-plane and out-of-plane wave motion of isotropic plates can be computed according to [8]:

$$\mathbf{D}_{\mathrm{IP}}\left(k_{\mathrm{x}}\right) = \frac{Et}{k_{\mathrm{x}}^2 + k_{\mathrm{Sy}}k_{\mathrm{Ly}}}\begin{bmatrix} D_{11} & D_{12} \\ -D_{12} & D_{22} \end{bmatrix}, \tag{13}$$

with

$$D_{11} = -\frac{\mathrm{i}\left(k_{\mathrm{Sy}}^2 - k_{\mathrm{x}}^2\right)k_{\mathrm{Ly}}}{2\left(1+\nu\right)}, \tag{14}$$

$$D_{12} = \frac{\mathrm{i}\left(k_{\mathrm{Ly}}^2 + \nu k_{\mathrm{x}}^2\right)k_{\mathrm{x}}}{1-\nu^2} - \frac{\mathrm{i}k_{\mathrm{Sy}}k_{\mathrm{Ly}}k_{\mathrm{x}}}{1+\nu}, \tag{15}$$

$$D_{22} = -\frac{\mathrm{i}\left(\nu k_{\mathrm{x}}^2 + k_{\mathrm{Ly}}^2\right)k_{\mathrm{Sy}}}{1-\nu^2} - \frac{\mathrm{i}k_{\mathrm{x}}^2k_{\mathrm{Sy}}}{1+\nu}. \tag{16}$$

$$\mathbf{D}_{\mathrm{OOP}}\left(k_{\mathrm{x}}\right) = \frac{\mathrm{i}B}{k_{\mathrm{B1y}} - k_{\mathrm{B2y}}}\begin{bmatrix} D_{33} & D_{34} \\ D_{34} & D_{44} \end{bmatrix}, \tag{17}$$

with

$$B = \frac{Et^3}{12\left(1-\nu^2\right)}, \tag{18}$$

$$D_{33} = k_{\mathrm{B1y}}^3k_{\mathrm{B2y}} - k_{\mathrm{B2y}}^3k_{\mathrm{B1y}}, \tag{19}$$

$$D_{34} = \mathrm{i}k_{\mathrm{B2y}}^3 - \mathrm{i}k_{\mathrm{B1y}}^3 + \left(2-\nu\right)\left(k_{\mathrm{B2y}} - k_{\mathrm{B1y}}\right)\mathrm{i}k_{\mathrm{x}}^2, \tag{20}$$

$$D_{44} = k_{\mathrm{B2y}}^2 - k_{\mathrm{B1y}}^2, \tag{21}$$

where E is the Young's modulus, t the thickness of the plate, ν the Poisson's ratio and B the bending stiffness of the plate. k_{B1y}, k_{B2y}, k_{Ly} and k_{Sy} can be found from the equations of motion for OOP and IP motion and are dependent on k_{x} and the bending, longitudinal and shear wavenumbers, given by:

$$k_{\mathrm{B},j} = \left(\frac{\rho_{\mathrm{OOP},j}t_j\omega^2}{B_j}\right)^{1/4}, \tag{22}$$

$$k_{\mathrm{L},j} = \sqrt{\frac{\rho_{\mathrm{IP},j}(1-\nu_{\mathrm{IP},j})^2\omega^2}{E_{\mathrm{IP},j}}}, \tag{23}$$

$$k_{\mathrm{S},j} = \sqrt{\frac{2\rho_{\mathrm{IP},j}(1+\nu_{\mathrm{IP},j})\omega^2}{E_{\mathrm{IP},j}}}. \tag{24}$$

In the case of plates without RMM treatment, the mass densities $\rho_{\mathrm{OOP},j}$ and $\rho_{\mathrm{IP},j}$ are both frequency-independent.

Subsequently, the forces and moment equilibrium and displacement compatibility are imposed at the junction line. The equations are expressed in the global coordinate system, denoted with subscript g, with a transformation matrix $\mathbf{R}_j$ [6]:

$$\mathbf{u}_{\mathrm{g}} = \mathbf{R}_j\mathbf{u}_j, \tag{25}$$

$$\mathbf{f}_{\mathrm{g},j} = \mathbf{R}_j\mathbf{f}_j = \mathbf{R}_j\mathbf{D}_j\mathbf{R}_j^{-1}\mathbf{u}_{\mathrm{g}}, \tag{26}$$

where

$$\mathbf{R}_j := \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & \cos\theta_{ij} & -\sin\theta_{ij} & 0 \\ 0 & \sin\theta_{ij} & \cos\theta_{ij} & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}. \tag{27}$$

For the source plate, $\theta_{ij} = 0$, while for the receiver plate, θ_{ij} is equal to the angle between the source and receiver plate. The displacements and forces exerted on the junction by an incident bending wave are then found as [8]:

$$\mathbf{u_{inc}} = \begin{bmatrix} u_\mathrm{x} \\ u_\mathrm{y} \\ u_\mathrm{z} \\ \theta_\mathrm{x} \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ u_{\mathrm{z,inc}} \\ \theta_{\mathrm{x,inc}} \end{bmatrix}, \tag{28}$$

$$\mathbf{f_{inc}} = \begin{bmatrix} f_{\mathrm{yx}} \\ f_{\mathrm{yy}} \\ f_{\mathrm{yz}} \\ m_{\mathrm{yy}} \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ f_{\mathrm{yz,inc}} \\ m_{\mathrm{yy,inc}} \end{bmatrix}, \tag{29}$$

with $u_{\mathrm{z,inc}} = \alpha_i$, $\theta_{\mathrm{x,inc}} = i\alpha_i k_y$, $f_{\mathrm{yz,inc}} = -\alpha_i B_1(k_y^3 - (2-\nu_{1\mathrm{OOP}})k_x^2 k_y)$ and $m_{\mathrm{yy,inc}} = \alpha_i B_1(k_y^2 - \nu_{1\mathrm{OOP}} k_x^2)$. α_i represents the amplitude of the incident wave, here taken equal to unity. The incident wave power in the y-direction then becomes [6]:

$$I_\mathrm{inc} = \frac{\rho_{1\mathrm{OOP}} t_1 \omega^3 \alpha^2}{k_{\mathrm{B1}}} \sin\phi_i. \tag{30}$$

In the next step, the equilibrium equation can be rewritten for n plates with a source plate i as the sum of the forces from Eq. (12) exerted by all plates [8]:

$$\sum_{j=1}^{n} \mathbf{f}_{\mathrm{g},j} = \mathbf{0}, \tag{31}$$

$$\sum_{j=1}^{n} \mathbf{R}_j \mathbf{D}_j \mathbf{u}_j = \mathbf{R}_i \left(\mathbf{D}_i \mathbf{u}_\mathrm{inc} - \mathbf{f}_\mathrm{inc}\right). \tag{32}$$

Taking into account the compatibility requirements at the junction, Eq. (25) is substituted into this expression:

$$\left(\sum_{j=1}^{n} \mathbf{R}_j \mathbf{D}_j \mathbf{R}_j^\mathrm{T}\right) \mathbf{u}_\mathrm{g} = \mathbf{R}_i \left(\mathbf{D}_i \mathbf{u}_\mathrm{inc} - \mathbf{f}_\mathrm{inc}\right). \tag{33}$$

Eq. (33) is solved for the displacements $\mathbf{u}_\mathrm{g}$ at the junction. The displacements for every receiver plate j in the local coordinate system can then be found as:

$$\mathbf{u}_j = \mathbf{R}_j^\mathrm{T} \mathbf{u}_{\mathrm{g},j}. \tag{34}$$

From this result, $\mathbf{u}_{\mathrm{out},j}$ can be computed as $\mathbf{u}_j - \mathbf{u}_\mathrm{inc}$ when the considered plate contains the incident wave. Otherwise, $\mathbf{u}_{\mathrm{out},j}$ is equal to $\mathbf{u}_j$. The related forces can be found as $\mathbf{f}_{\mathrm{out},j} = \mathbf{D}_j \mathbf{u}_{\mathrm{out},j}$. In that way, all the input values for Eqs. (6)-(8) are determined.

2.2 Plate-strip model for plates with RMM treatment

To reduce flanking sound transmission through junctions, RMMs can be applied to a full plate or only in a strip close to the junction. When plates are fully treated with RMMs, the same methodology as described in Section 2.1 can be applied, with only one difference: in that case the mass density in Eq. (22) is not frequency-independent anymore. Due to the resonators, the OOP mass density will be influenced by inertial contributions of each resonator mode k. This results in an effective mass density, taking into account the modal effective masses. The effective mass density of a multi-modal metamaterial panel is obtained as [9]:

$$\rho_{\mathrm{eff,z}}(\omega) = \rho + \frac{1}{t} \sum_{k=1}^{n_\mathrm{m}} \frac{m''_{\mathrm{z},k}(1+\mathrm{i}\eta)}{(1+\mathrm{i}\eta) - (\omega/\omega_k)^2}, \tag{35}$$

with ρ the mass density of the host plate, n_m the modes of interest, t the thickness of the host plate, $m''_{\mathrm{z},k}$ the modal effective translational masses, η the damping loss factor of the resonators and ω_k the fixed base natural frequencies of the resonator.

If only a RMM strip close to the junction is considered, this strip has a frequency-dependent OOP effective mass density, while the OOP mass density of the untreated connected plate is frequency-independent. The IP mass density is always frequency-independent, but due to the added resonators, an additional static mass needs to be added to the mass density of the host structure. To include the effect of a RMM strip between the junction and an untreated connected plate, the prediction model as described in section 2.1 needs to be expanded, following the methodology developed in [7, 8] for thin plate interlayers. Contrary to the previously considered plates, the RMM strip has a finite dimension in the y'-direction. Thus not only the displacements and forces at the junction line (2) need to be taken into account, but also the forces and displacements at the interface between the RMM strip and the connected plate (1), as illustrated in Fig. 2. The relation between the forces per unit length $\mathbf{f}_\mathrm{l}$ and the displacements $\mathbf{u}$ at both endplanes of the RMM strip can be expressed in the local coordinate system through a stiff-

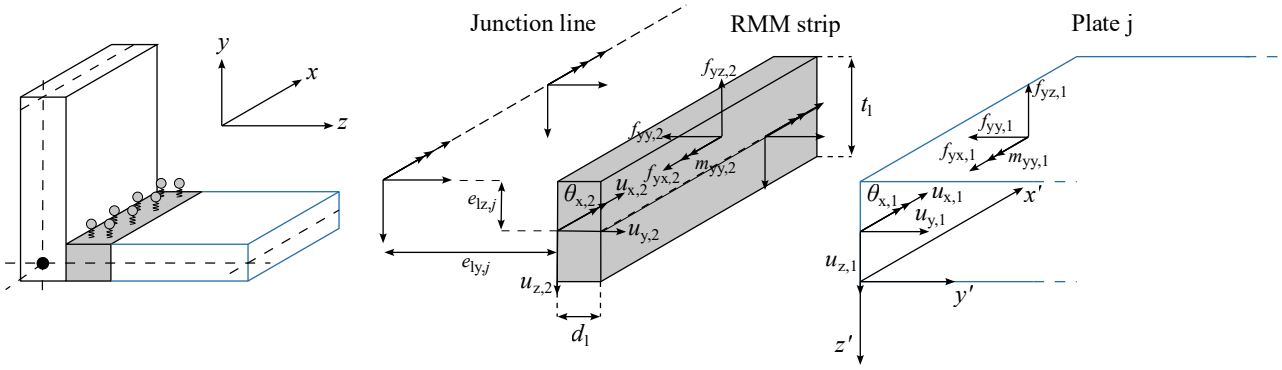

Figure 2: Exploded view of a plate/strip system.

ness matrix $\mathbf{D}_\mathrm{l}$ [8]:

$$\mathbf{f}_\mathrm{l} = \mathbf{D}_\mathrm{l}\,\mathbf{u}, \tag{36}$$

where

$$\mathbf{f}_\mathrm{l} := [\mathbf{f}_{\mathrm{l},1} \;\; \mathbf{f}_{\mathrm{l},2}]^\mathrm{T} = [\mathbf{f}_\mathrm{l}\,(y'=d_\mathrm{l}) \;\; \mathbf{f}_\mathrm{l}\,(y'=0)]^\mathrm{T}, \tag{37}$$

$$\mathbf{u} := [\mathbf{u}_1 \;\; \mathbf{u}_2]^\mathrm{T} = [\mathbf{u}\,(y'=d_\mathrm{l}) \;\; \mathbf{u}\,(y'=0)]^\mathrm{T}. \tag{38}$$

For each plate j connected to the junction through a RMM strip, the exerted forces $\mathbf{f}_{1,j}$ at position (1) and $\mathbf{f}_{2,j}$ at position (2) can be divided into a direct contribution from the plate $\mathbf{f}_{\mathrm{p},j}$ as in Eq. (11) and a contribution related to the RMM strip itself $\mathbf{f}_{\mathrm{l},j}$ [8]:

$$\mathbf{f}_j = \mathbf{f}_{\mathrm{p},j} + \mathbf{f}_{\mathrm{l},j}, \tag{39}$$

$$\mathbf{f}_{\mathrm{g},j} = \mathbf{D}_{\mathrm{g,p},j}\mathbf{u}_\mathrm{g} + \mathbf{D}_{\mathrm{g,l},j}\mathbf{u}_\mathrm{g}, \tag{40}$$

where the subscript g denotes the global coordinate system and

$$\mathbf{D}_{\mathrm{g,p},j} = \begin{bmatrix} \mathbf{R}_j\mathbf{D}_j\mathbf{R}_j^\mathrm{T} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix}, \tag{41}$$

$$\mathbf{D}_{\mathrm{g,l},j} = \begin{bmatrix} \mathbf{R}_\mathrm{j} & \mathbf{0} \\ \mathbf{0} & \mathbf{R}_{\mathrm{l},j} \end{bmatrix} \underbrace{\begin{bmatrix} \mathbf{D}_{\mathrm{l},j,11} & \mathbf{D}_{\mathrm{l},j,12} \\ \mathbf{D}_{\mathrm{l},j,21} & \mathbf{D}_{\mathrm{l},j,22} \end{bmatrix}}_{\mathbf{D}_{\mathrm{l},j}} \begin{bmatrix} \mathbf{R}_j^\mathrm{T} & \mathbf{0} \\ \mathbf{0} & \mathbf{R}_{\mathrm{l},j}^\mathrm{T} \end{bmatrix}, \tag{42}$$

with $\mathbf{D}_j$ being the dynamic stiffness matrix for a thin plate j as in Eqs. (13) and (17). The stiffness matrix $\mathbf{D}_{\mathrm{l},j}$ of a RMM strip consists of four block matrices $\mathbf{D}_{\mathrm{l},j,mn} \in \mathbb{C}^{4x4}$. The strip is considered as a waveguide, in contrary to the two steel plates which are considered as halfspaces. Due to the finite y'-dimension, waves in both the positive and negative y'-direction are considered for the deformation of the layer. The stiffness matrices can be computed in a similar way as in section 2.1, and can be found in [8].

Since the endplane of the RMM strip could have offsets $e_{\mathrm{ly},j}$ and $e_{\mathrm{lz},j}$ relative to the theoretical junction line, as illustrated in Fig. 2, the transformation matrix (27) needs to be adapted for the RMM strip as [8]:

$$\mathbf{R}_{\mathbf{l,j}} := \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & \cos\theta_{ij} & -\sin\theta_{ij} & 0 \\ 0 & \sin\theta_{ij} & \cos\theta_{ij} & 0 \\ 0 & e_{\mathrm{lz},j} & e_{\mathrm{ly},j} & 1 \end{bmatrix}. \tag{43}$$

where the transformation matrix (27) corresponded to the situation in which these offsets are zero.

The global force equilibrium per unit length is then evaluated both at the junction line and at each interface between a RMM strip and at its connected plate:

$$\sum_{j=1}^{n} \mathbf{f}_{\mathrm{g1},j} = \begin{cases} \mathbf{R}_i\,(\mathbf{D}_i\mathbf{u}_\mathrm{inc} - \mathbf{f}_\mathrm{inc}), & \text{if } j = i \\ \mathbf{0}, & \text{if } j \neq i \end{cases} \tag{44}$$

$$\sum_{j=1}^{n} \mathbf{f}_{\mathrm{g2},j} = \begin{cases} \mathbf{0}, & \text{if } j = i \\ \mathbf{R}_i\,(\mathbf{D}_i\mathbf{u}_\mathrm{inc} - \mathbf{f}_\mathrm{inc}), & \text{if } j \neq i \end{cases} \tag{45}$$

3. APPLICATION

In this Section, the methodology described in Section 2 is applied to a rigidly connected horizontal junction of steel plates, where both fully treated RMM plates and plates with only a small RMM strip close to the junction are considered. The results are compared with the junction models without any RMM treatment, to quantify the attenuation provided by RMM treatments on flanking sound transmission.

The steel plates without RMM treatment are considered isotropic and so the OOP and IP properties are the

same. The properties of the considered steel plates are: $\rho = 7850$ kg/m^3, $E = 210 \cdot 10^9$ Pa, $t = 0.002$ m, $\nu = 0.3$. From these parameters, the surface mass, shear modulus and bending stiffness can be computed as $m = \rho t$, $G = E/2(1+\nu)$ and $B = Et^3/12(1-\nu^2)$ respectively.

A distinction is made between OOP and IP material properties for the parts of the structure with RMM treatment. The IP properties remain the same as for the untreated plate, except for the mass density, where an additional static mass is added due to the presence of the resonators. In this paper, the added static mass due to the resonators will be initially taken equal to 10% of the mass of the host structure belonging to one resonator. The OOP mass density can be found through effective medium modeling with Eq. (35). The resonance frequency of the resonators is set to 500 Hz.

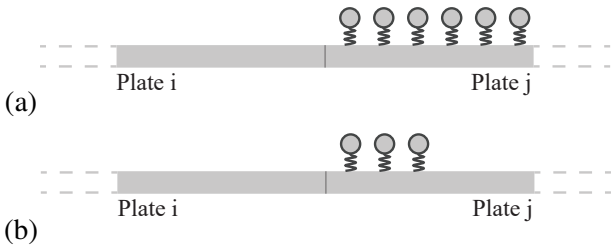

Figure 3: Junction between two plates ($\theta_{ij} = \pi$) with a fully treated RMM receiver plate (a) and with a treated RMM strip close to the junction (b).

3.1 Fully treated receiver plate

The first case we consider, is a junction of two steel plates of which the receiver plate is fully treated with resonators, as illustrated in Fig. 3a. The source plate i is further denoted as plate 1, the receiver plate j as plate 2.

The structural transmission loss for the transmitted bending waves is shown in Fig. 4 for a junction between two plates with an angle $\theta_{12} = \pi$. The receiver plate is fully treated with resonators with a damping of 0 and a local resonator mass of 10 % and 20 % with respect to the mass of the host plate. The structural transmission coefficient for longitudinal and shear waves is very small with respect to the transmission coefficient for bending waves, and therefore the structural transmission loss for these wave-types is not further considered in this paper. The graphs show that due to the RMM treatment of the receiver plate, at the resonance frequency of 500 Hz, less vibrational energy is transmitted from the source into the receiver plate and so the RMM treatment is effective to reduce wave propagation at the targeted frequency.

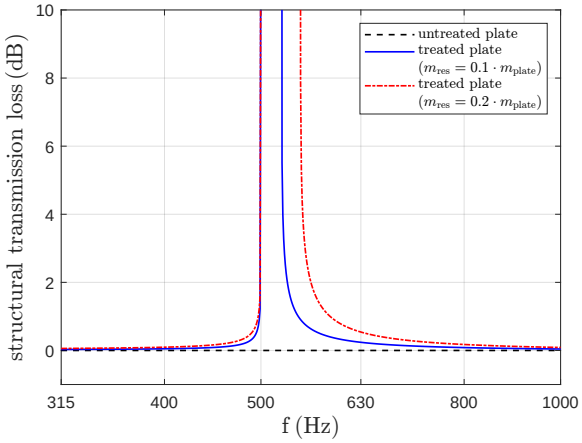

Figure 4: Comparison between the structural transmission loss for the transmitted bending waves through a junction ($\theta_{12} = \pi$) with an untreated and fully treated receiver plate with no damping in the resonators and a local resonator mass of 10 % and 20 % with respect to the mass of the host plate.

3.2 Influence of the local resonator mass

In a second case, the influence of the added resonator mass with respect to the host structure is analyzed, which is also shown in Fig. 4. In a first case, the local resonator mass is taken to be 10 % of the mass of the host structure. In a second case, the local resonator mass is taken to be 20 % of the mass of the host structure. The graphs in Fig. 4 show that in the case of 20 % added mass, the bandgap that inhibit free-traveling waves at the resonance frequency of the resonators widens, resulting in a broader frequency range in which the transmitted vibrational energy is reduced. Even though not shown here, similar results have been obtained for another resonator damping, other angles θ_{12} of the junction and in the case only a strip of resonators is applied.

3.3 Receiver plate with RMM strip

Thirdly, only a small strip of resonators is applied close to the junction, as illustrated in Fig. 3b. The strip is modeled as a part of the junction as discussed in Section 2.2,

and so the structural transmission loss is computed for the transmitted bending waves after the strip. The results are shown in Fig. 5 for a junction between two plates with an angle $\theta_{12} = \pi$, with a resonator damping of 0 (Fig. 5a) and 0.02 (Fig. 5b). The results are shown for a strip with a width of 0.03 m, 0.05 m, 0.10 m, 0.15 m and 0.3 m. From these graphs it is clear that we can achieve already a significant reduction in wave propagation from source to receiver plate at the resonance frequency by applying only a small strip of resonators close to the junction. Fig. 5a shows that the frequency range in which free wave propagation is inhibited becomes larger by increasing the width of the strip. From Fig. 5b it is clear that the larger the width of the strip is, the larger the structural transmission loss through the RMM strip will be. Similar results are obtained for another resonator damping and other angles θ_{12} of the junction. When a strip of resonators with very low damping is considered, additional drops in the structural transmission loss are visible, caused by Fabry-Perot standing waves. However, this is only significant at very low damping values, and thus has no impact in practice.

3.4 Influence of multi-modal resonators

As a fourth case, the influence of multi-modal resonators is examined. Multi-modal resonators allow to have multiple resonance frequencies, resulting in broader band effectiveness. As an example, a junction with an angle $\theta_{12} = \pi$ is considered, with a treated strip of 0.15 m close to the junction in the receiver plate and a damping of 0, 0.02, 0.05 or 0.1 in the resonators. Three resonance frequencies (500 Hz, 460 Hz, 420 Hz) are considered. The results are shown in Fig. 6. A peak is visible at each resonance frequency of the multi-modal resonator, resulting in a more broadband reduction of the transmitted vibrational energy. Even though not shown here, similar results have been obtained for another resonator damping, other angles θ_{12} of the junction and in the case a fully treated receiver plate is applied.

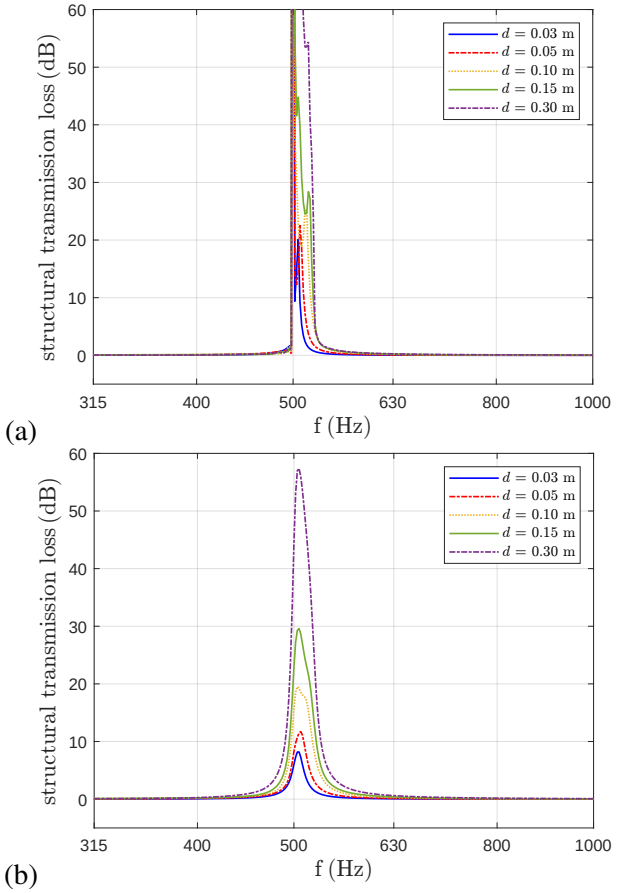

Figure 5: Comparison of the structural transmission loss for the transmitted bending waves between a junction ($\theta_{12} = \pi$) with a treated strip close to the junction in the receiver plate for a damping of 0 (a) and 0.02 (b) in the resonators. Results are shown for a strip width of 0.03 m, 0.05 m, 0.10 m, 0.15 m and 0.3 m.

4. CONCLUSION

In this paper, an analytical wave approach to model wave propagation through junctions was combined with effective medium theory to introduce a metamaterial treatment in the junction design. The proposed model has been used to study flanking transmission across junctions with steel plates, exploring various scenarios in which the width of the treated strip, the resonator mass, and the number of local resonances were changed. Varying the width of the metamaterial strip has proven that already a significant reduction in wave propagation can be obtained for sufficiently wide strips. Increasing the mass of the local resonators broadens the frequency range in which bending wave transmission to the receiver plate is reduced, but it can however conflict with lightweight requirements. Another way of widening the band of effectiveness is therefore to use multi-modal resonators, allowing to include multiple resonance frequencies. The methodology proposed in this work sets a framework to analyze and de-

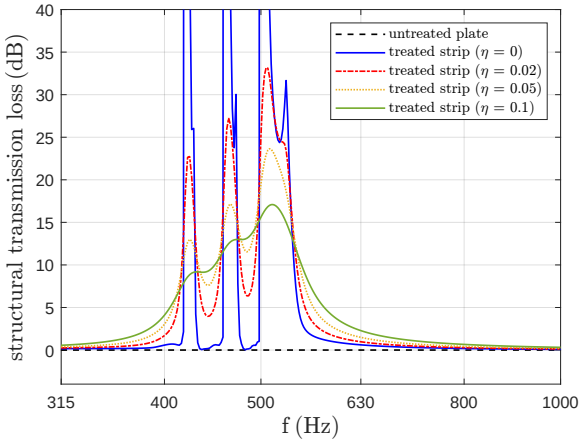

Figure 6: Comparison of the structural transmission loss for the transmitted bending waves through a junction ($\theta_{12} = \pi$) with a treated strip of 0.15 m close to the junction in the receiver plate, for a damping of 0, 0.02, 0.05 and 0.1 in the resonators. Three resonance frequencies (500 Hz, 460 Hz, 420 Hz) are considered.

sign metamaterial treatments for the suppression of flanking sound transmission across junctions of plates. Future research will focus on further validation against numerical and experimental results for practical applications.

ACOUSTIC PERFORMANCE OF PREFABRICATED REINFORCED CONCRETE WALLS FOR MODULAR CONSTRUCTIONS

Reza M. Firouz[1*] **Albano Neves e Sousa**[1]
[1] CERIS, Instituto Superior Técnico, Universidade de Lisboa, Av. Rovisco Pais 1, 1049-001, Lisbon, Portugal

ABSTRACT

Modular construction is being promoted as a solution to the problem of housing crisis as the demand for new construction continues to rise. However, the performance of this construction approach must be competitive with conventional construction methods. Therefore, beyond structural performance and safety features, indoor comfort qualities such as thermal and acoustic insulation should be considered. Acoustic transmission loss phenomena are generally governed by mass, and reinforced concrete (RC) walls are considered massive elements compared to other conventional building materials. However, it is still necessary to enhance such elements with insulation materials. In this study, the acoustic performance of double-layer prefabricated RC wall elements with embedded insulation layers is assessed under different configurations. A 3D harmonic acoustic finite element (FE) numerical model is developed and verified to evaluate the sound reduction capability of the prefabricated double-layered concrete walls with different thicknesses. The effect of using various insulation materials is also discussed.

Keywords: *Acoustic performance, building acoustics, airborne sound, prefabricated RC walls, Finite element analysis.*

1. INTRODUCTION

The construction waste, high labor costs in developed countries, and the sustainability considerations, promote modular construction as a possible approach to tackle these challenges. Adoption of modern techniques for development of mass buildings leads to affordable housing needed today for many countries. Hence, the efforts should generate solutions aiming to save energy and reducing the construction costs [1]. Maintaining quality and the level of comfort, such as thermal and acoustic comfort, etc., is essential and can't be disregarded. Pre-cast buildings minimize the construction time compared to conventional non-precast buildings which usually require multiple different phases for finishing the elements such as floors and walls, separately. However, while minimizing the number of phases in modular construction, the building must meet the construction provisions at the end of these phases [2]. Therefore, besides structural performance, considerations should be for thermal and acoustic isolations. Moreover, it is crucial to carefully configure their structural elements to avoid thermal and acoustic bridges. The insurance could be made by developing numerical analysis models, which are verified by performing experimental studies on scaled samples or using existing research data.

The literature includes limited amounts of data regarding the acoustic performance of concrete floor and wall systems. Proença et. al. [3] performed an experimental, numerical, and analytical study of the acoustic performance of light weight composite sandwich panels as floor system. The sandwich panels were comprised of two identical glass fiber reinforced polymer (GFRP) face sheets and a rigid polyurethane (PUR) foam core and placed firmly between two chambers for the

acoustic test. Weighted sound reduction index (Rw) of 30 dB were reported by the test results. It was concluded that for such lightweight floor systems the performance index values did not fulfill the acoustic requirement of building standards. Ferreira et. al. [4] performed experimental tests of mechanical, fire resistance and airborne sound performance on sandwich panel system for non-loadbearing walls. The sandwich panels were comprised of two face sheets (gypsum board, fire resistant gypsum board, or magnesium oxide), glued to the extruded polystyrene (XPS) core and fixed by galvanized steel profiles. However, despite satisfactory results for other factors, the acoustic performance of the wall panels for the index of sound insulation was insufficient and it was proposed to add acoustic covering layers to the wall systems. Calleri et al. [2] characterized the sound insulation properties of innovative façade made by two-layer cast-in-situ light weight concrete wall with an insulation layer of non-woven fabric in between. Experimental tests were performed to evaluate the acoustic performance of this wall with or without window opening. R_w value of 48 dB were reported from the acoustic test of the façade system. Peng et al. [5], assessed the acoustic behavior of prefabricated composite wall panel, comprised layers of steel wire network, expanded polystyrene foam plastic (EPS), and fine aggregate concrete. It was reported that EPS board can enhance sound insulation in the middle (500 ~ 2000 Hz) and high frequency ranges (<2000 Hz). 42 dB of apparent sound reduction parameters were reported.

In this paper, a study on the acoustic performance of prefabricated double layer RC walls with insulation core is presented. FEM numerical acoustic model has been developed using ANSYS® software package and verified with the existing data on similar models. Then the harmonic acoustic simulation results for different thicknesses and insulation materials are analyzed. Finally, overall conclusions are drawn and suggestions for future work are given.

2. NUMERICAL MODEL

2.1 Materials and methodology

In this study, RC pre-fabricated wall panels featuring an isolation layer were modelled. The RC walls were of 3 m height, including two layers of RC wythe, with an insulation layer in between. The top and the bottom side of the walls were composed of RC section, resembling a beam section. Figure 1 shows the details of the modeled samples. The cross-sectional area as shown in Figure 1 could be of two proposed thickness, 160 mm (P18) or 220 mm (P22), including an insulation layer of 60 mm thick in between which serve as thermal and acoustic isolation, while reducing the weight of the wall system. The material of wall panels includes concrete of class C50/60. The insulation layer of EPS or PUR were considered in the modelling. Longitudinal and transversal steel reinforcement, and spatial trusses were also considered for the cross-section as shown in Figure 1. The proposed wall systems are considered be a segment of multi stories modular buildings.

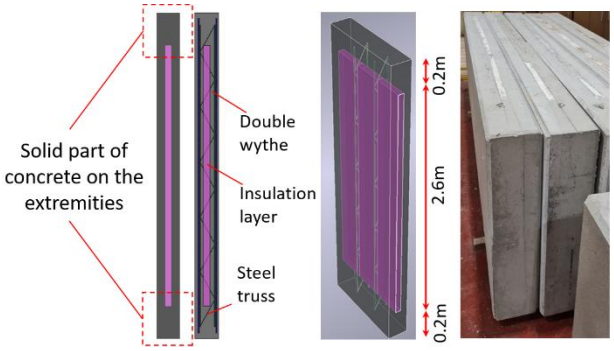

Figure 1. Description of the modelled pre-fabricated RC wall panels.

2.2 Description of the numerical model

A 3D FE model using ANSYS® was used to assess the acoustic performance of the pre-fabricated wall panels. Finite element model for the acoustic harmonic analysis of the airborne sound reduction of the pre-fabricated RC walls are shown in Figure 2. The airborne sound source of 0.01 Kg was simulated as nodal acoustic mass, which was placed in one top corner of the emitting room (Figure 2).

The relevant properties of different materials used in the model are shown in Table 1.

Both emitting and receiving chambers were of 3×3×3 m^3 dimensions. Pre-fabricated RC walls were modelled with 3 m height and 3 m width. The concrete wall panels were considered fixed in top, bottom, and sides as the displacement boundary condition of the geometry. A fluid-structure interface (FSI) was considered at the contact surfaces of the acoustic chambers and the RC wall. Absorption coefficients (α) based on different frequencies (*f*) which are shown in Table 2, were applied in the acoustic medium (air chambers) surfaces.

The model was meshed using ANSYS FLUID220 (20-node acoustic element) and SOLID186 (20-node structural solid element) element types were used, respectively for acoustic and structural domains. Mesh size of 125 mm was adopted for all elements of the geometries which led to a total number of 41580 elements.

As shown in Figure 3, six random nodes in each of the emitting and receiving chambers were considered as microphone positions to report the sound pressure level (SPL). The selection of these nodes was adopted based on the recommendations of BS EN 20140-9 [6].

2.3 Model validation

Results from the Proença et al. [3] was used to validate the presented numerical model. The study included experimental and numerical investigation of the acoustic performance of composite sandwich panels with GFRP and PUR core for lightweight floor systems. All the reported data on geometry and mechanical properties of materials were used to develop a FE model for validation. Figure 4 shows the comparison of the FEM model results, presented in this study *vs.* experimental and numerical results reported by Proença et al. It is observed that for frequencies below 1000 Hz, the FEM model shows good agreement with the experimental results. All three curves exhibit a noticeable drop in the 1000–1250 Hz range, likely due to a coincidence frequency, although some slight variations are present. While differences become more apparent at higher frequencies, the overall trend of the FEM model remains consistent with the results obtained by Proença et al., indicating acceptable predictive behavior.

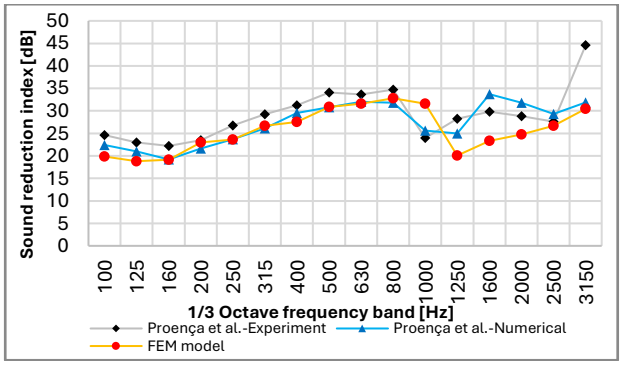

Figure 4. Numerical results of presented FE model vs. the results reported by Proença et al.

3. RESULTS AND DISCUSSION

Figure 5 and Figure 6 show the narrow bound results of the numerical model for pre-fabricated wall panels of 220 mm and 180 mm thicknesses (P22 and P18), with EPS and PUR core insulation layer. The Rw index (Table 3) was calculated using ISO 717-1 reference curve (Figure 5) and based on the methodology provided by this standard [7]. The P22 sample with EPS insulation showed relatively good behavior with Rw equal to 48 dB. Legal requirements for airborne sound transmission in most countries (as Rw indicator) are in the range of 45-55 dB [8]. The P22 sample with PUR core showed a significant acoustic performance of Rw equals to 54 dB. Both P22-EPS and P22-PUR showed a relatively similar behavior in very low and high frequencies. However, in the range of 160-1000 Hz, the P22-PUR outperformed the

P22-EPS sample. For the pre-fabricated walls of 180 mm thickness, both P18-EPS and P18-PUR showed similar behavior in the small frequencies (100-160Hz). However, the P18-EPS showed a higher drop in Rw index at 200 Hz, compared to the other and recovered this difference gradually until 1250 Hz. P18 samples show similar performance in frequencies above 1250 Hz. However, considering their calculated Rw indexes (40 and 42 dB, respectively for P18-EPS and P18-PUR), they can be used as interior walls within dwellings.

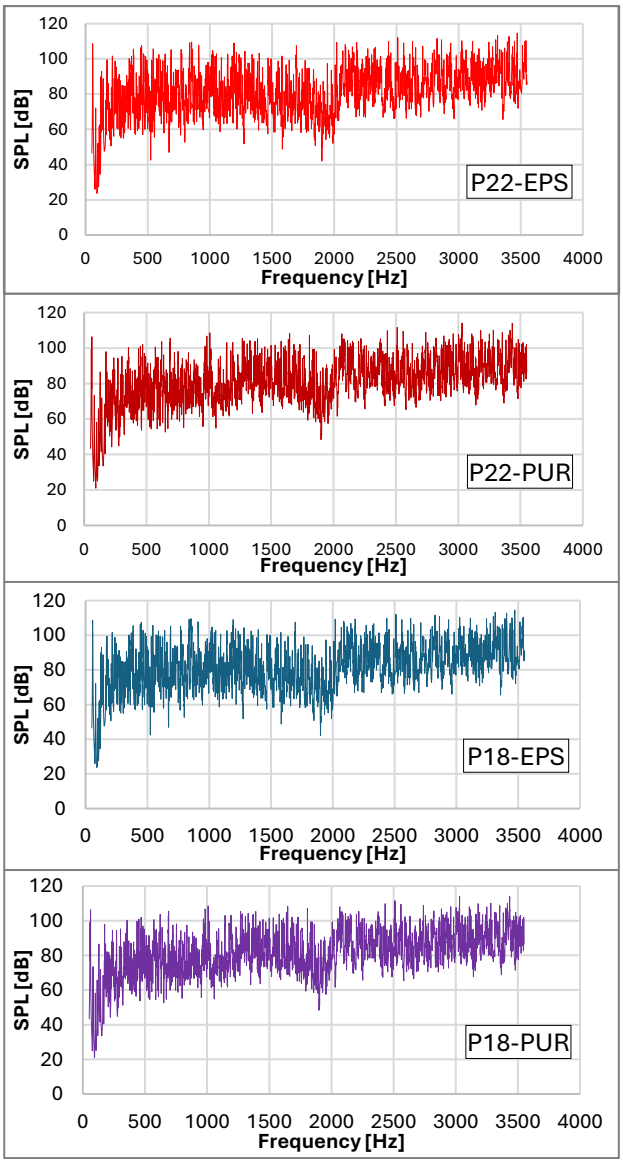

Figure 5. Narrow band results for SPL in receiving room (L2) for different samples.

The critical frequency (f_c) where coincidence effect occurs in a homogenous rectangular plate, can be calculated with the following equation [9]:

$$f_c = \frac{c^2\sqrt{3}}{\pi c_L h} \quad (1)$$

where c is the sound velocity in air (343.2 m/s), c_L is the longitudinal wave speed in plate, and h is the thickness of the plate. Considering h, as 8 mm and 6 mm thick concrete plate, for one layer of the pre-fabricated wall system, and the c_L as 4000 m/s (according to [10] for the relatively similar concrete strength) for the concrete double layer wall here. The critical frequency for the layer of the prefabricated wall where the sound is radiated would be 203 Hz and 271 Hz, respectively for P22 and P18 samples. Therefore, the dip of the transmission loss curve which is shown in Figure 6 might be attributed to the coincidence effect.

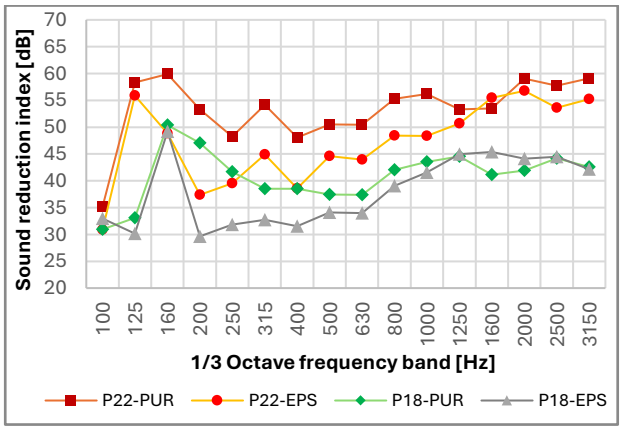

Figure 6. Microphone locations in the emitting and receiving rooms for SPL measurement.

Table 3. Rw index for different modelled samples.

Sample	P22-EPS	P22-PUR	P18-EPS	P18-PUR
Rw [dB]	48	54	40	42

4. CONCLUSIONS

In this paper, a 3D FE numerical model to evaluate the acoustic performance of pre-fabricated double layer RC wall for modular construction was presented. Acoustic performance of pre-fabricated RC walls of 180 mm (P18) and 220 mm (P22) thicknesses, with EPS and PUR as core insulation material, was assessed.

Results showed that core insulation materials have significant influence on acoustic performance. PUR significantly outperforms EPS in both P22 and P18 samples. Moreover, P22 walls shown to offer noticeably better performance in low-frequency insulation, following the mass law principle. P22-PUR was the most robust and versatile for acoustic demands. However, P22-EPS sample also showed a relatively acceptable response, close to the requirements of the building codes. P18 samples may only be viable as internal walls or where cost or weight savings outweigh performance. Moreover, a dip in transmission loss which probably caused by coincidence effect were observed in lower frequencies (about 200 Hz) for all samples.

Future works considering the flanking effects are recommended, since it is an important concern in modular buildings and solutions should be provided to avoid acoustic bridges. This study is part of a bigger project on the development of pre-fabricated concrete wall systems for modular construction. Therefore, further numerical and experimental studies are being carried out to investigate the acoustic performance of the double layer concrete wall system, comprehensively.

A STATISTICAL REGRESSION FRAMEWORK FOR EVALUATING NOISE EXPOSURE THROUGH OUTDOOR-TO-INDOOR SOUND PROPAGATION MODELS

Michail Evangelos Terzakis* **Cédric Van hoorickx** **Maarten Hornikx**

Building Acoustics Group, Department of the Built Environment,
Eindhoven University of Technology, Eindhoven, The Netherlands

ABSTRACT

Urban noise exposure has been shown to have significant adverse effects on human health. Studies based on outdoor noise levels, rather than indoor levels, risk introducing bias when identifying an exposure-response relationship with health outcomes. This bias is of particular concern for vulnerable groups (e.g., children) who spend most of their time indoors. This highlights the need for a comprehensive approach to modelling outdoor-to-indoor sound propagation for the estimation of indoor noise levels. For both outdoor and indoor propagation, energetic approaches are used, while the facade sound insulation is modeled via the Transfer Matrix Method, incorporating the facade element size and bridge connections. Validation of this modelling approach against sound insulation measurements has revealed good agreement. The employment of the developed models resulted in the generation of datasets, facilitating the implementation of statistical learning (random forest) models for estimating (equivalent) indoor noise levels using predictors associated with outdoor levels and factors related to the indoor and outdoor environment, and facade structure. The proposed approach has the potential to estimate indoor levels for entire cities from predicted outdoor noise levels (noise maps) and built environment characteristics.

1. INTRODUCTION

Urban noise exposure has been characterized as a threat for people, showing significant associations with psychophysiological, mental health, cognitive, and sleep aspects [1, 2]. Noise exposure studies are usually conducted via the outdoor noise levels rather than the indoor levels [2]. This may correspond to a systematic risk of bias in the identification of "true" exposure-response relationship with health outcomes [3]. This bias is of particular concern for vulnerable groups (e.g. children) who spend the majority of their time indoors.

To properly characterize the indoor noise exposure, various approaches have been defined to simulate the sound propagation from outdoors to indoors via building façade structures (e.g. [3–6]). In noise exposure studies, the utilisation of the auralisation-based approaches (e.g., [5, 6]) can be regarded as a strategy for characterizing the outdoor-to-indoor sound propagation in a detailed way. For adjacent room settings subjected to diffuse-field conditions, auralization approaches for airborne sound insulation based on ISO 12354-1 [7] were proposed [8,9]. Based on these approaches, auralization models for both adjacent indoor and outdoor-indoor settings were proposed [5], using closed form formulae for sound insulation. For outdoor and indoor settings, an alternative approach was proposed, where the sound insulation was modeled via closed form formulae and a spatial window technique (size correction) [10]. However, the aforementioned approaches were based on single-layer and -component structures.

The objective of this study is to develop a modelling approach for the propagation of sound from outdoors to indoors via multi-layer and multi-component façade structures and apply this approach through generated datasets

for evaluating noise exposure via a statistical regression framework. This approach facilitates the simulation of a broad range of built environments, enabling the estimation of indoor noise exposure levels based on, for instance, noise maps of the outdoor noise exposure level as well as the evaluation of the significance of diverse predictors.

2. MODELING FORMULATION

2.1 Façade Sound Insulation Modelling

Although numerical modelling approaches, such as the Finite Element Method (FEM) [11] and the Boundary Element Method (BEM) [12], can be applied for the computation of sound insulation in a precise way, these modelling approaches require high computational complexity. Alternatively, the Transfer Matrix Method (TMM) can provide a formulation for the calculation of the sound insulation of structures in an efficient way, considering the propagation of sound waves through multi-layered structures [13].

2.1.1 Infinite Incident Sound Transmission Coefficient

In the TMM framework [13], a plane wave impinges on the first layer of a material under an angle of incidence θ (i.e. angle between the direction of propagation of the incident plane wave and the normal to the plane of the layer) and propagates into the cavity, and then to a second material layer, and so on, up to the radiation (last) layer.

Assuming a multi-layer structure subject to thin-plate theory, a simple product among the transfer matrices of thin plates and fluid cavities, including the incident and radiated layer, results in the infinite sound transmission coefficient [13, 14]. However, in structures composed of diverse media (e.g. solid and poroelastic), the aforementioned conventional approach is untenable. Coupling interface matrices are included to global matrix, composed of the transfer matrices of the diverse layers, to satisfy the continuity condition between two adjacent elements and for calculating the infinite sound transmission coefficient [13].

2.1.2 Spatial Windowing Technique

A spatial windowing technique has been introduced to alleviate infinite structure behaviour effects at low frequencies via the radiation efficiency of finite size structure [10]. Considering rectangular surfaces, an efficient methodology for calculating the radiation efficiency was proposed in [15]. Based on this approach, the adjusted radiation efficiency was proposed in [16] for calculating the radiation efficiency of rectilinear surfaces (polygon surfaces in which all sides intersect at right angles) by dividing the rectilinear surfaces into isolated and adjacent (first order correlation) sub-domains (sub-surfaces).

2.1.3 Finite Incident Sound Transmission Coefficient

For calculating the sound transmission coefficient ($\tau_{\text{fin}}(\theta)$) for rectangular surfaces, the spatial windowing technique can be implied to the (infinite) incident sound transmission coefficient. Regarding a single-layer structure, the finite sound transmission coefficient can be obtained as in [17], while for a multi-layer structures, the finite sound transmission coefficient can be obtained as in [10]. For rectilinear surfaces, the same approaches can be applied so that the finite (first-order) sound transmission coefficient to be obtained as in [16].

2.1.4 Bridge Connection

The bridge connection (line or point) can be further incorporated into the finite incident sound transmission coefficient, providing a correction at high frequencies. In double-layer structures, the studs can be incorporated using a thin-plate [18] and a global matrix [19] approach.

2.2 Propagation Modelling

An example room with total dimensions 3m×3m×3m (L×W×H) was considered, assuming that its façade structure consists of a single-layer rectilinear wall (concrete of thickness 0.1m) and a single-layer (1m×1m) rectangular window (glass of thickness 0.006m) component, both of which subject to the thin-plate theory. Their material properties were taken from [16]. Furthermore, 11 sound sources (S1–S11) located in front of the façade structure were considered (road-traffic structure), covering a total length of 14m. These sound sources were positioned at three different distances from the façade (7m, 14m, and 21m), denoting the sound source formats (L1–L3). Finally, five receivers are included indoors. R1: at the centre of the room; R2: at 0.5m from the front and left wall; R3: at 0.6m from the front and right wall; R4 at 0.7m from the back and left wall; R5 at 0.4m from the back and right wall. The height of all receivers was kept constant at 1m from the ground (children's ear seated). An illustration is presented in Fig. 1.

2.2.1 Outdoor-to-Façade Propagation Modelling

For point sources with acoustic power 1W, the free-field mean squared sound pressure at any point of the iso-

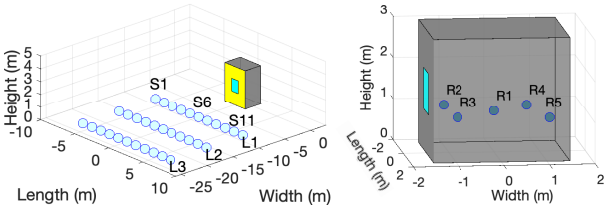

Figure 1. Representation of the example scenario.

lated and adjacent surfaces ss at a distance r_s from the sound source s can be expressed as $p^2_{ss}(f, r_s) = Z_0(\frac{1}{4\pi r_s^2})$. Hence, the incident sound power at any point of façade under free-field conditions can be expressed as [5]

$$W_{inc,s}(f, \theta_s, r_s) = \frac{1}{4\pi} \int_{S_{ss}} \frac{1}{4\pi r_s^2} |\cos(\theta_s)| dS. \quad (1)$$

For small elements and source positions that are far away, a first-order approximation can be made by assuming that θ_s and r_s do not vary significantly in S_{ss}.

2.2.2 *Façade-to-Indoor Propagation Modelling*

In façade-to-indoor propagation modelling, it was assumed that the façade elements act as sound sources. By further assuming that each sub-surface emits sound into a hemisphere, the squared pressure from the wall (p^2_w) and window (p^2_g) surface to the receiver q in the room R can be calculated as [5]

$$p^2_{w,q}(f) = Z_0 \left[\sum_i \sum_{\substack{j \in \epsilon_i \\ j>i}} W_{tr,ij,w}(\theta_{s,ij}) \left(\frac{2}{4\pi r^2_{ij,q}} + \frac{4}{A_R(f)} \right) - \sum_i \sum_i W_{tr,i,w}(\theta_{s,i}) \left(\frac{2}{4\pi r^2_{i,q}} + \frac{4}{A_R(f)} \right) \right] \quad (2)$$

$$p^2_{g,q}(f) = Z_0 \left[W_{tr,i,g}(\theta_{s,i}, r_s) \left(\frac{2}{4\pi r^2_{i,q}} + \frac{4}{A_R(f)} \right) \right], \quad (3)$$

where the transmitted sound power is defined as $W_{tr} = W_{inc,s} \cdot \tau_{fin}$. Note that the τ_{fin} term is defined in Section 2.1.3. Furthermore, $r_{ij,q}$ and $r_{i,q}$ denote the distance between the center of adjacent and isolated sub-domains and receiver q, respectively, and A_R denotes the total absorption area of the room.

2.3 Outdoor-based Indoor Impulse Response

The outdoor-based indoor impulse response per sound source and indoor receiver position can be synthesized via the inverse Fourier Transform of the sum of the frequency responses of the wall ($H_{w,q}$) and window ($H_{g,q}$) surfaces expressed as $h_q(t) = \mathfrak{F}^{-1}\{H_{w,q}(f) + H_{g,q}(f)\}$. The latter frequency responses can be calculated using the approach outlined in [5].

Finally, since the sound transmission coefficient is calculated for 31 1/3-octave frequency bands, ranging from 20Hz to 20kHz, a linear interpolation and a piecewise cubic extrapolation in the sound transmission coefficient is employed within the frequency range from zero to Nyquist frequency. Additionally, a linear (anti-symmetric) phase term based on [20] is added to $H_{w,q}$ and $H_{g,q}$ for synthesizing the outdoor-based indoor impulse response, expressed as [5, 6] $\tau_{fin}(\theta) = |\tau_{fin}(\theta)| e^{j\phi(f)}$.

3. RESULTS AND DISCUSSION

3.1 Modelling Example

Based on the example described in Section 2.2, the finite sound reduction index of the window and wall surfaces is calculated via the methodologies presented in Section 2.1. The results are presented in Fig. 2.

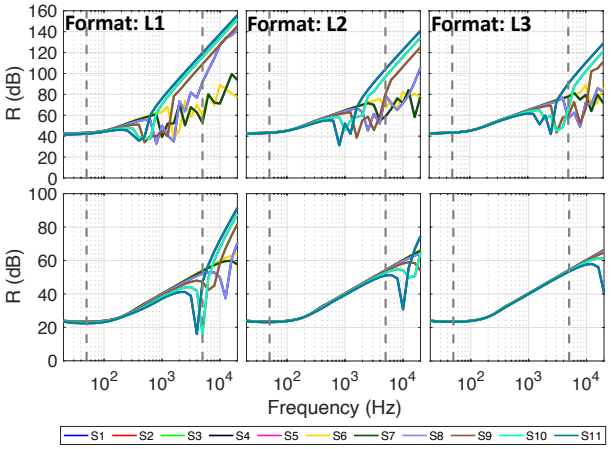

Figure 2. Sound reduction index of the wall (top) and glass (bottom) surface per source and format.

Focusing on Fig. 2 (top), the influence of all adjacent and isolated sub-surfaces to the sound reduction index of the wall surface is illustrated, similar to those presented in [16]. Since the sound source positions S1-S5 are symmetrical to those of S7-S11, the sound reduction indexes of the former are obscured by the latter. For the window surface Fig. 2 (bottom), analogous sound reduction trends to those exhibited by the wall surface are evident.

By incorporating the outdoor and indoor modelling, the outdoor-based indoor impulse and frequency responses can be synthesized with respect to five receiver positions. The results are illustrated in Fig. 3.

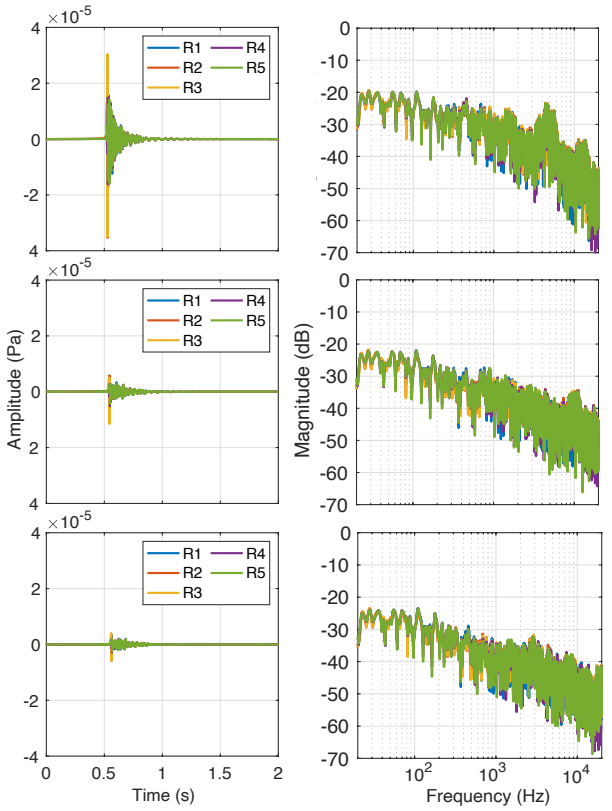

Figure 3. Average impulse and magnitude responses per receiver position across the sound sources (S1-S11) in Format L1 (top), L2 (mid), and L3 (bottom).

Regarding Fig. 3, the presence of multiple peaks in the magnitude responses denotes the (average) sound transmission from the elements of the façade structure. The most prominent peaks are presented in relation to the Format L1 among the three formats. As the distance between the sound source format and façade structure increases (from Format L1 to Format L3), a single incident character is obtained. Finally, the impact of the wall surface is only evident in the coincidence region, while in other regions, the glass surface dominates the wall surface in the total sound reduction index [16].

3.2 Experimental Validation

For validating the modeling methodology, the settings and the results of the case study presented in [21] for a 201.6m^3 lecture room were used with respect to the distribution of sound sources in the linear format. Regarding the characteristics of façade structure from inside to outside, this consists of a plaster layer, a brick layer, a poroelastic layer (mineral wool) and a steel layer with point connections. For simplicity, it was assumed that the façade structure consists of a three-layer structure composed by a brick layer ($\rho = 1900$ kg/m^3, $E = 2.4 \cdot 10^{10}$ Pa, $\mu = 0.1$, $\eta = 0.01$, and $h = 0.050$ m), a poroelastic layer ($\phi = 0.9$, $\alpha_\infty = 1$, $\sigma = 59100$ NS/m^4, $\Lambda = 10\mu$ Pa, $\Lambda' = 36\mu$ Pa, $\rho = 90$ kg/m^3, $E = 7 \cdot 10^5$ Pa, $\mu = 0.01$, $\eta = 0.01$, and $h = 0.070$ m), and a steel layer ($\rho = 7800$ kg/m^3, $E = 2.1 \cdot 10^{11}$ Pa, $\mu = 0.33$, $\eta = 0.01$, and $h = 0.026$ m), assuming that the plaster layer does not significantly influence the sound reduction index. Regarding windows, these consist of a double-leaf structure, where the thickness of each layer is 5mm and the gap between the two panes is 15mm. The reverberation time of the room was obtained via ISO 3382-2 [22]. The comparison between measured and predicted sound insulation is presented in Fig. 4.

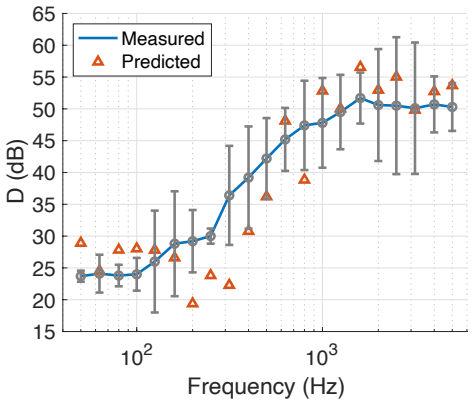

Figure 4. Comparison between the measured and calculated sound insulation, expressed via the level difference (D) in 1/3-octave frequency bands. The error-bars represent the 95% Confidence Interval.

In Fig. 4, the predicted and measured results present a good agreement. The observed discrepancies can be attributed to various factors, including deviations in the material properties, the incident field, the modal behaviour of surfaces and room, and the effect of window frames.

3.3 Application

Based on the developed modelling methodology, datasets can be generated for developing statistical learning prediction models for estimating the indoor noise exposure levels, expressed by the equivalent noise indicators, via various predictors. These predictors correspond to the outdoor noise exposure levels and factors related to outdoor environment, indoor environment, and façade structures. This approach allows for estimating the indoor noise exposure levels in areas with available outdoor levels and built environment characteristics. The block-diagram of application is presented in Fig. 5.

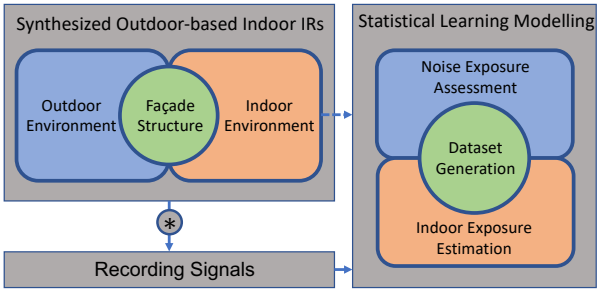

Figure 5. Application of outdoor-to-indoor models. Note that the dashed arrow denotes the additional parameters related to the outdoor and indoor environment as well as façade structure.

3.3.1 Dataset Generation

First, the impact of the room size was considered, defining three rooms (L×W×H): Room 1 (3×3×3), Room 2 (4×4×3), and Room 3 (5×4×4). Second, the façade structures were considered, defining two types of wall structures (i.e., monolithic, and filled-cavity) subject to the global-matrix approach, and three types of windows (i.e., single-leaf, double-leaf, and triple-leaf) subject to the thin-plate approach. In both wall structures, each (solid) leaf has a thickness of 0.1m and 0.2m. In the filled-cavity wall structures, a mineral wool material was considered for the cavity measuring 0.1m, while point connections ($n = 10$) between the leaves were also taken into account. Regarding the window panes, the thickness of the leafs and the (air fluid) cavity depths were set to 4mm, 8mm, and 12mm. The dimensions of the windows per room scenario are presented in Tab. 1. Finally, four façade structures composed of wall and window structures were considered: (a) single-leaf wall with single-leaf window, (b) double-leaf wall with single-leaf window, (c) double-leaf wall with double-leaf window, and (d) double-leaf wall with triple-leaf window. It should be noted that the generated dataset is constrained to the information deemed necessary for a city.

Table 1. Window scenarios (WSc) per room (R).

R	WSc	L_g(m)	H_g(m)	R	WSc	L_g(m)	H_g(m)
R1	W1.1	0.50	0.50	R3	W3.1	0.50	0.50
	W1.2	1.00	1.00		W3.2	1.00	1.00
	W1.3	2.00	2.00		W3.3	2.00	2.00
R2	W2.1	0.50	0.50		W3.4	2.50	2.50
	W2.2	1.00	1.00		W3.5	3.00	3.00
	W2.3	2.00	2.00		W3.6	3.50	3.50
	W2.4	2.50	2.50				

3.3.2 Noise Exposure Assessment

By convolving the synthesized outdoor-based indoor impulse responses with road-traffic (1-minute) recordings, the noise exposure indoors can be estimated. Similarly, the outdoor noise exposure levels can be estimated at the center of the façade structures. For the assessment of the relationship between indoor and outdoor noise exposure, the equivalent noise indicator can be calculated for one second integration time. The assessed relationships with respect to R1, Format L1 (defined in Fig. 1), and window size W1.2 per façade structure (defined in Section 3.3.1) are presented in Fig. 6.

As illustrated in Fig. 6 (top), the improvement of façade configuration with respect to the window surface leads to a reduction in equivalent indoor noise exposure levels. A lack of a significant effect of two wall thicknesses is also evident, as confirmed by the averaged spectral outdoor-to-indoor level difference presented in Fig. 6 (bottom). Although not shown here, as the surface area of window increases, the effect of wall structure is reduced, while the effect of window becomes dominant. The coincidence frequency of the thinner single wall surface is approximately 500Hz, while for the thicker single wall structure, the coincidence frequency is lower, at around 250Hz. Furthermore, it can be observed that their mass-air-mass and mass-air-mass-air-mass resonance frequencies exhibit a concurrence with the lowest coincidence frequencies of the wall surface.

3.3.3 Prediction Modelling and Verification

In order to estimate the equivalent indoor noise exposure levels ($L_{eq,In}$), averaged over a fifteen-second period, the random forest (RF) modelling approach [23] was

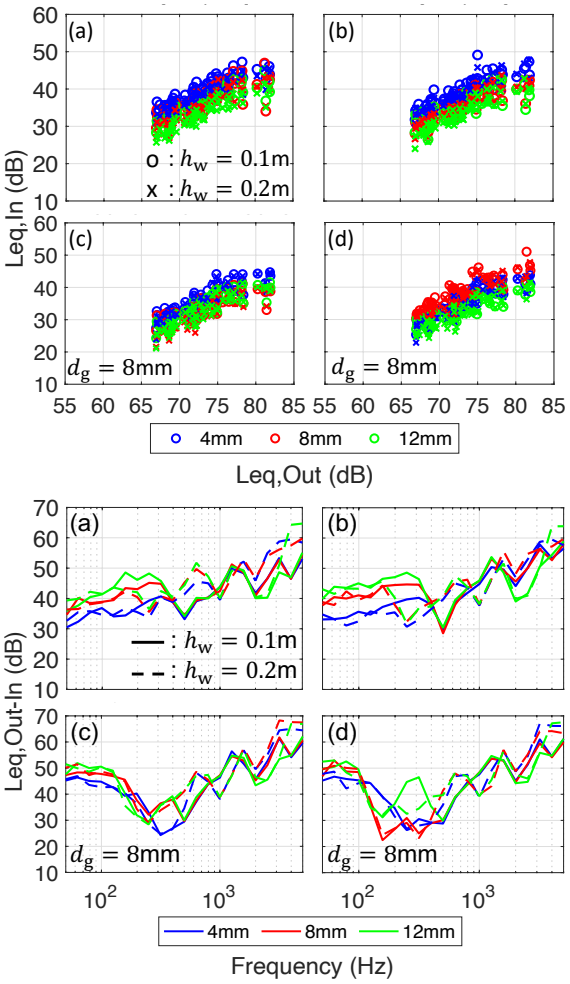

Figure 6. Relationship between the average outdoor and indoor levels (top) and time-averaged equivalent spectral outdoor-to-indoor level differences (bottom) with respect to Format L1, R1, and W1.2 per façade structure (a-d). Note that h_w denotes the thickness of the wall, while d_g denotes the window cavity width.

employed in the generated dataset via the *ranger* package [24] in RStudio. The outdoor noise exposure levels ($L_{eq,Out}$) at the centre of the façade are considered, in conjunction with parameters associated with the outdoor environment (FrmtDist: format distance), the indoor environment (RoomVol: room volume), and façade structure (SRatio: window-façade ratio, hGlass: glass thickness, hWall: wall thickness, dGlass: distance between glass panes, WinStruct: window structure, and WinStruct: wall structure). Note that the WinStruct and WallStruct predictors are categorical predictors while all the others are continuous predictors. The dataset, composed by 28080 observations (sound levels) were split into a 70% for training and a 30% for testing. For tuning of the RF models, the number of trees (n_{tr}) was selected to range from 100 to 1200 trees with an increment of 100 trees, while the number of split-variables (m_{tr}) was set to vary from 3 to 9 variables with an increment of 1 variable. The node size was ranged from 1 node to 15 nodes with an increment of 1 node. Following the tuning procedure, n_{tr} = 900, m_{tr} = 5, predictors = 9, and node size = 4.

For exploring the impact of the various predictors, the (normalized) importance of each predictor in the model was assessed, and the results are presented in Fig. 7.

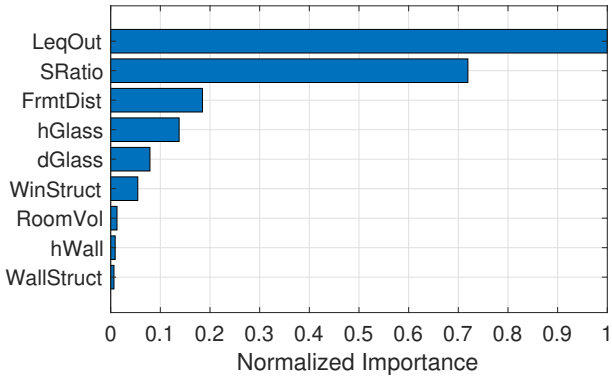

Figure 7. Importance of predictors.

As seen from Fig. 7, the outdoor noise exposure levels and the ratio between the window and façade surface correspond to the most important predictors, indicating that these predictors explained the highest percentage of the unexplained variance in the model. The wall parameters presented the less significant contribution to the model, which is also validated from Fig. 6.

Finally, the k-fold cross-validation procedure for k = 10 was adopted [25], splitting the training dataset into ten equal in-size chunks and adopting a resampling procedure. The model was developed based on nine chunks, with the objective of predicting the tenth treated as a validation set. The performance of the fitting model was evaluated via the R^2 and RMSE metric [26]. The results are presented in Fig. 8.

As seen from Fig. 8, the RF modelling approach presented a RMSE = 1.67dB with respect to the test dataset. By interpreting the error level with the ability of a healthy ear to perceive a change in broadband noise levels, cor-

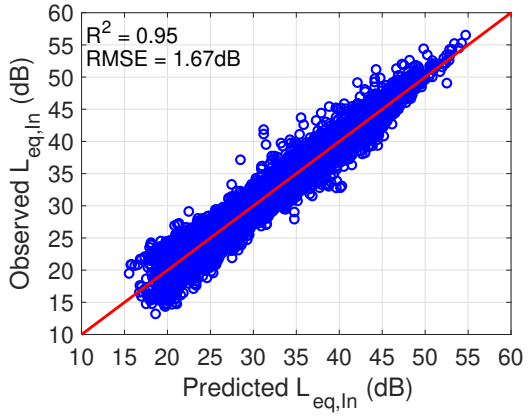

Figure 8. Modelling validation.

responding to the perceptible level difference [27]. An error level around 3dB is associated to a just audible level difference, indicating a good performance of the executed modeling approach, as the RMSE level falls below this threshold.

4. CONCLUSIONS

In this paper, an outdoor-to-indoor modelling framework, validated via sound insulation measurements, was developed. The objective of this approach is to support noise exposure studies via generated (modelling-based) datasets so that the indoor noise exposure levels can be estimated via statistical learning approaches. This approach enables a detailed and controlled characterisation of outdoor-to-indoor sound propagation, which has the potential to estimate indoor levels in cities with available predicted outdoor noise levels and built environment characteristics.

EFFECT OF MEASUREMENT POSITIONS ON STRUCTURE-BORNE NOISE LEVELS IN BUILDINGS SUBJECT TO RAILWAY VIBRATIONS

C. Guigou Carter[1*] **Pierre Ropars**[1]
[1] CSTB, Grenoble, France

ABSTRACT

In the objective of improving the comfort and even the health of occupants of buildings close to railway lines, it is appropriate to predict and measure vibration levels and ground-borne noise levels in order to limit them, particularly in housing.
In this work, the effect of tabulated transfer functions generally used for the vibration impact assessment investigations, measurement positions for both vibration levels and structure -borne noise is studied on the basis of numerical modeling. Concerning vibrations, a measurement at mid-span of the floor is generally considered; however, this position can be difficult to determine or access, especially when the floor supports several rooms, so a measurement in the center of a room is often carried out. The vibration levels can then be used to predict ground-borne sound levels. To set an acceptable threshold for occupants, it is necessary to specify one or more easily identifiable and accessible measurement positions and to adapt the limit threshold to this measurement configuration. The same problem exists for ground-borne noise measurements. Based on the results obtained, proposals concerning impact assessment investigations, measurement and prediction positions for vibrations and ground-borne noise in buildings are formulated.

Keywords: ground-borne noise, railway vibrations, building acoustics, measurement positions.

1. INTRODUCTION

In densely populated areas, the rarefication of land leads to the construction of buildings very close to railway tracks. Alternatively, the construction of new railway lines will impact existing buildings. In both cases, vibration, and noise levels especially in lodgings might be severely impacted by the proximity of underground and surface railway traffic. In France, there is still no mandatory requirement regarding limitation of vibration and ground-borne noise levels from railways, even though discussions on the subject have started a few years back. However, developers and city planners are now aware of the necessity to consider these aspects.
Prediction methods are required for designing buildings to protect inhabitants against ground-borne (structure-borne) noise from railway lines or other ground vibration sources, a European task group (CEN/TC126/WG2/TG1) is doing preliminary work on this subject.
The effect of using tabulated transfer function (ground to building foundations and building foundation to building floor) for vibration impact assessment investigations is questioned with respect to a security margin. Furthermore, it is also quite important to be able to verify the vibration and ground-borne noise levels after either a building or a new railway line construction. In this work, the effect of the measurement positions for both vibration levels and ground-borne noise is studied based on numerical modeling. Concerning vibrations, a measurement at mid-span of the floor is generally considered; however, this position can be difficult to determine or access, especially when the floor supports several rooms, so a measurement in the center of a room is often carried out. The vibration levels can then be used to predict ground-borne sound levels. To set an acceptable threshold for occupants, it is necessary to specify one or more easily identifiable and accessible measurement positions and to adapt the limit threshold to this measurement configuration. The same problem exists for ground-borne noise measurements.

2. INVESTIGATED CONFIGURATIONS

Simulations are conducted based on a 2.5D FEM/BEM model (infinite constant geometry in one-direction) implemented in CSTB MEFISSTO software [1]. The ground-borne noise levels are evaluated following the 2.75D approach proposed in [2] also implemented in CSTB MEFISSTO software.

The base configuration is shown in Figure 1: it consists in a concrete based building with an underground level and 3 stories above ground. The underground slab and walls are 40 cm in thickness; the other slabs are 20 cm in thickness, and the façade is 18 cm in thickness. The height between slabs is 2.5 m. The type and thickness of the central wall at the first and second stories are varied; the reference case corresponds to a concrete wall 18 cm in thickness. The ground is either a simple half-space (soft, medium, or hard type), or made of 2 layers (surface layer on a semi-infinite layer). The railway line platform has a height of 50 cm and a width of 6 m; for simplicity, it is assumed to be concrete. The center of railway line is located at 10 m from the building façade. The excitation in the center of the railway platform (red dot in Figure 1) is assumed to be a line of uncorrelated forces applied over the considered train length L_T (geometry infinite in the direction of the train line).

Tables 1 and 2 give the characteristics of different elements used for the prediction.

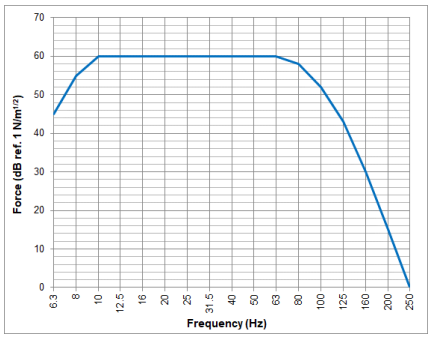

Figure 2. Force spectrum applied to platform by the train.

3. EFFECT OF TABULATED BUILDING TRANSFER FONCTION

In most vibrations impact assessment studies, the building floor velocity needs to be estimated in neighboring buildings of railway tracks. A typical configuration for such estimation is shown in Figure 3.

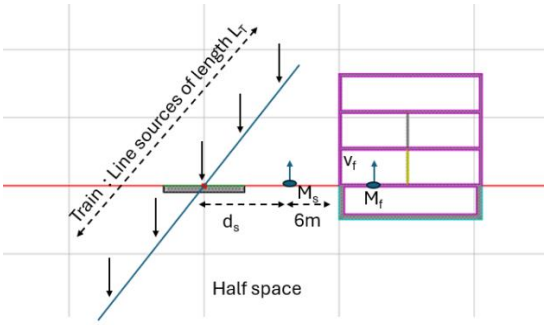

Figure 3. Typical configuration with used notation

In this case, the floor velocity v_f can be computed using a combination [3] of (i) the excitation terms as a force density spectrum (*FDS*, unit N/m$^{1/2}$), (ii) the propagation between the track center and near the building at point M_s given by a line source transfer mobility (*LSTM*, unit m/s/N/m$^{1/2}$) [3] and finally (iii) the dynamic of behavior represented by a correction factor C_b [4] :

$$v_f = FDS \times LSTM \times C_b \quad (1)$$

The correction factor C_b can be estimated by the ratio between the "global transfer function" Y_G (defined by the velocity at the receiver point M_f (floor center) for a "unit" line force applied on the track) and the *LSTM*. Nevertheless, it is not possible to measure Y_G when either the track or the building, does not exist. In practice, the *LSTM* is defined using numerical method and C_b is replaced by measured or tabulated transfer function between points M_s and M_f. Note that C_b includes C_{b2} and C_{b3} in [4] that replace TF2 representing the transfer function from free field ground (at building distance) to building foundations and TF3 representing the transfer function from building foundations to floor, in [3]. In this case, the global transfer function can be misestimated. In general, this error depends on the type of the building, the soil profile, the distance between the track and the building and the train length. Considering the same building and the same soil, the error can be expressed with the sum over the frequency band [8-250] Hz as:

$$Error(d_s, L_T) = 10 \log_{10} [\Sigma Y_G^2 / (LSTM \times C_b)^2] \quad (2)$$

In the following, the error given by Equation (2) is computed for three simple cases of homogenous half space soil (soft, medium, and hard soil type defined in Table 2); the building corresponds to the one described in Section 2. The building correction factor is taken from [4] for medium size building. The error is observed as a function of distance d_s from 7 to 40 m, and train length L_T from 1 to 100 m.

As seen in Figures 4 to 6, the use of the transfer function in place of correction factor does not have an impact on results when the train length L_T is very small. When L_T increases, for building near the track (d_s < 10 m), the transfer function is underestimated, meaning that the floor velocity is underestimated as well. On the contrary, for large distances between building and track, the transfer function and the floor velocity are overestimated. For intermediary distances, a zone for which the global transfer function is correctly estimated, exists (zone in green). The position and the size of this zone depend on soil characteristics. The results show that the zone is larger for stiffer soil; this can be explained by the fact that the transfer function from soil to building foundations (TF2 or C_{b2}) is smoother when the soil stiffness is higher. On the contrary, the transfer function FT2 or C_{b2} for lower soil stiffness has a deeper and large minimum, leading to more impact on the global transfer.

Due to these observations, tabulated transfer function must be used with caution, particularly when issued from measured point to point transfer function. It is more accurate to use a building correction factor C_b measured in situ. If impossible, a security margin of 6 dB should be considered when using tabulated transfer functions in the case of buildings located near the railway track.

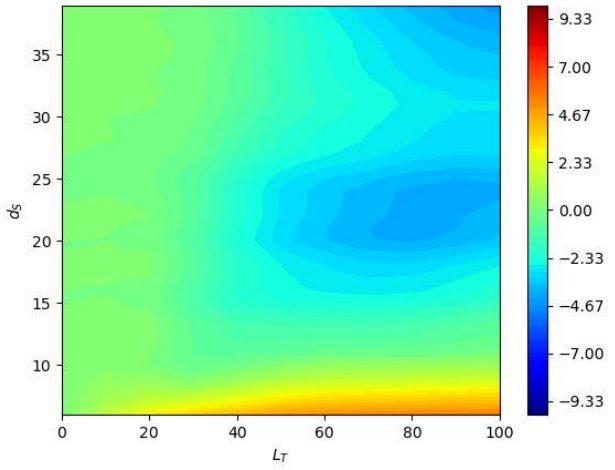

Figure 4. Maps of the error function for a 3-storey building on a soft soil half space

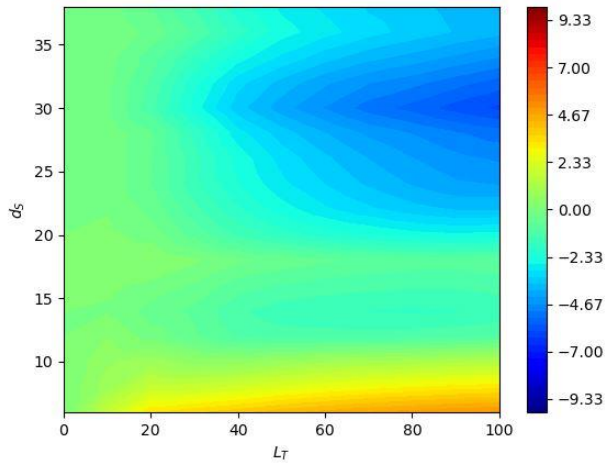

Figure 5. Maps of the error function for a 3-storey building on a medium soil half space

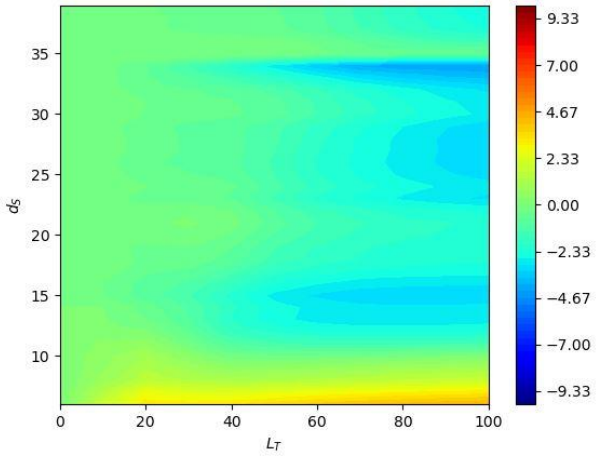

Figure 6. Maps of the error function for a 3-storey building on a hard soil half space

4. EFFECT OF EVALUATION POSITIONS IN BUILDING

In this section, the effect of the middle wall in the first and second building stories is investigated on the floor vibration level as well as on the ground-borne sound pressure level. The train is assumed to be 20, 40 or 100 m in length and the uncorrelated force are applied at 10 m from the building façade at the center of the railway platform. The ground is composed of two layers.

Indeed, it is quite important when fixing a limit for either vibration or ground-borne sound level to verify by the measurements that it is respected. In [5], measurements in the vertical direction at the floor mid-span is mentioned regarding vibration, due relevance in terms of human perception of the train passage event and possible annoyance. Following [5], ground-borne noise measurement is performed using one microphone at the one third point of a room's plan dimension (four options possible) and at a height of 1.2 to 1.5 m.

Since the prediction model is based on 2.5D approach, the vibration levels and the ground-borne sound levels are evaluated is a plane situated at the center of the train.

The middle wall in the first and second building stories can be made of either concrete (18 cm in thickness), lightweight bricks (7 cm in thickness) or an equivalent lightweight partition wall (like plasterboards on metallic frame, 10 cm in thickness). The case of no middle wall on all building stories is also considered.

4.1 Floor vibration levels

The vibration levels are evaluated along the floor slab across the building for the different situations considered. Figure 7 presents the velocity level on the concrete slab for the different investigated configurations in the case of a 100 m long train. It can be seen that the general pattern of the velocity level across the slab is rather similar for the different configurations. The presence of the wall, even for the concrete wall case, on the 1st and 2nd floors does not appear in an obvious way.

Figure 8 shows the one-third octave spectra of the concrete slab velocity for a position at one-quarter, half and three-quarter of slab length (on the left hand-side) and the global level over the frequency range (on the right side). Note that to simplify the spectra graphics the case of the equivalent lightweight partition is not shown; the behavior being close to the one for the brick type wall.

It is interesting to note that the velocity level in the 1st floor slab is pretty much the same regardless of the type of wall and the three selected positions along the slab.

For the 2nd floor slab due to the presence of a wall below and above the slab, the effect of the wall is well observed. At one-quarter of the floor length, the levels are slightly increased (except at 6.3 Hz), and the maxima slightly shifted in frequency for the concrete wall, while it is mostly increased for the other considered wall types (more lightweight). At the half length of the slab (under the wall if present), the velocity levels are lower in the presence of the concrete wall above 25 Hz, while they are higher for the other wall types (more lightweight). At three-quarter of the concrete slab, the velocity levels are generally increased compared to the case without wall.

For the 3rd floor slab and for the concrete wall, the velocity levels are increased above 20 Hz for the positions at one-quarter and three-quarter of the slab length and mostly increased below 25 Hz at the center of the slab (at the wall position). For the other wall types, the levels are increased.

For the top slab, the velocity levels are larger when the lightweight walls (brick wall or equivalent partition) are considered in the building and for the various locations considered (one-quarter, middle, and three-quarter of the slab length).

For lightweight wall, it appears of interest to evaluate the velocity level at the centre of the room (in the present case at one-quarter of the slab length) but to also investigate the center of the slab and if not taking a margin into account (margin of about 3 dB).

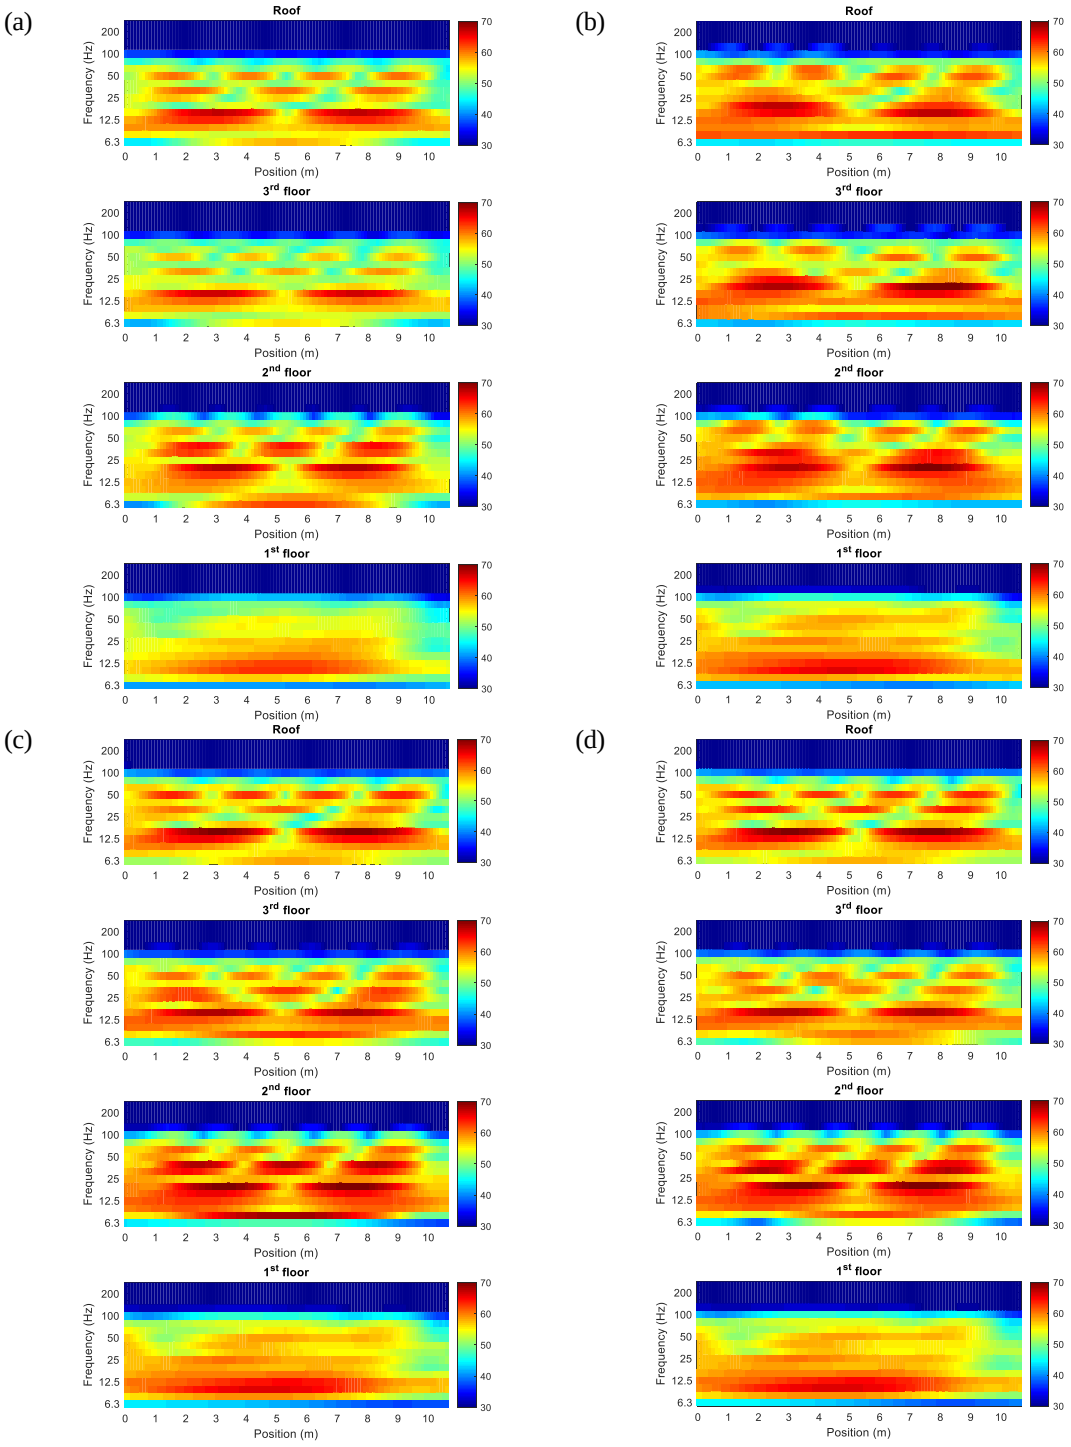

Figure 7. Slab velocity level (dB ref. 50 nm/s) for 100 m long train; (a) without wall, (b) concrete wall, (c) brick wall and (d) equivalent lightweight partition.

Figure 8. Velocity level (dB ref. 50 nm/s) for 100 m long train; at (a) one-quarter, (b) middle, (c) three-quarter, of the slab length and (d) space averaged, (left) Spectrum and (right) global value over the frequency range.

4.2 Ground-borne noise levels

Preliminary results were obtained in terms of ground-borne noise levels. Figure 9 presents the ground-borne noise levels in dB(A) over the investigated frequency range (one-third octave bands from 6.3 to 250 Hz) at a height of 1.3 m in the different rooms and for the different cases considered. Depending on the frequency, the pressure distribution across the room differs. Figure 10 shows the pressure distribution in the building rooms for the case without wall and for the case with a concrete wall at the one-third octave band of 50 Hz. These preliminary results need more in-depth analysis in order to reach any guidance with respect to measurements. A corner position could be an interesting option since it is easily identifiable and usably available for measurement in furnished room, and is expected to be an overestimate of the space average ground-borne noise level.

5. CONCLUSION

In the first part of this work, the effect of using tabulated transfer function to evaluate building floor vibration velocity was investigated. Due to these observations, tabulated transfer function must be used with caution, particularly when issued from measured point to point transfer function. It is more accurate to use a building correction factor C_b measured in situ. If impossible, a security margin of 6 dB should be considered when using tabulated transfer functions in the case of buildings located near the railway track (about 10 m).

In a second part of this paper, vibration velocity of building floors was investigated without and with several types of walls. For lightweight wall, it appears of interest to evaluate the velocity level at the centre of the room (in the present case at one-quarter of the slab length) but to also investigate the center of the slab and if not taking a margin into account (margin of about 3 dB). For heavyweight wall, the evaluation of the velocity level at the centre of the room appears appropriate.

Finally, concerning ground-borne noise inside building, the analysis of the preliminary results requires more work in order to determine general guidelines for preferable measurement positions.

Measurements are planned before the summer in a building to investigate in-situ the floor vibration velocity level distribution as well as the ground-borne noise level distribution.

METHODOLOGY FOR ASSESSING STRUCTURAL NOISE ANNOYANCE IN BUILDINGS CAUSED BY RAIL TRAFFIC. COMPARATIVE ANALYSIS BETWEEN PORTUGAL AND SPAIN

Sónia Antunes[1*] **Jorge Patrício**[1]
[1] National Civil Engineering Laboratory, Lisbon, Portugal

ABSTRACT

In recent years, the development of new construction materials and the publication of standards associated with new construction processes and evaluations have made it possible to construct buildings with high acoustic comfort. Alongside the construction of buildings with high sound insulation requirements, other aspects, such as structural noise, are becoming more important. This paper presents the evolution of the vibration and structural noise (ground-borne noise) descriptors in environmental impact studies derived from rail traffic in Portugal. However, these criteria are not regulated, but good practice guidelines are implemented by the management entities in order to contribute to the reduction of annoyance and, consequently, complaints from the nearby residents. In this context, a comparative analysis is carried out between the criteria used to assess low-frequency noise annoyance in two neighboring countries (Portugal and Spain), to encourage the drafting of possible Portuguese regulations in this area.

Keywords: *railway vibration, structural noise, comfort inside buildings*

1. INTRODUCTION

Noise regulations in Portugal is established by Decree-Law no. 9/2007 of 17 January, which approved the *Regulamento Geral do Ruído* (RGR) [1] . This law aims to prevent and control noise pollution, safeguarding public health and the population's well-being. Criteria are defined for assessing various noise sources likely to cause annoyance, including noise from transport infrastructures. To this end, maximum sound levels are established for outdoor environmental noise, depending on the time of day and the type of land use classification of the area. Regarding noise levels inside buildings, the only reference is to the minimum value (equal to 27 dB(A)), above which the annoyance assessment criterion applies. This regulation also does not specify any criteria for vibration levels inside buildings, and penalties to be considered when the sources being assessed have low-frequency components. Currently, in Portugal, there is still no legal obligation to comply with standards or regulations regarding vibrations that don't have the potential to cause damage to buildings, like explosions, even if they cause annoyance to occupants inside buildings.

The minimum acoustic performance criteria that buildings must meet to ensure user comfort and quality of life are established in the *Regulamento dos Requisitos Acústicos de Edifícios* [2], approved by Decree-Law No. 129/2002. This regulation applies to seven main building categories, namely: residential, mixed-use, and hotel buildings; commercial, industrial, or service buildings; educational institutions; hospitals; sports centers; passenger transport stations; and auditoriums. The criteria are defined based on sound insulation values for airborne and impact sound transmission, reverberation time, and noise levels associated with technical equipment and installations. Only in the latter case are values given for sound levels inside rooms where more noise-sensitive activities can take place. The noise sources should derive from the operation of equipment and installations inside the building and located in adjacent rooms. In this context, maximum permissible sound levels are established as follows: 27 dB(A) in bedrooms and living areas of residential buildings, 37 dB(A) in spaces where concentration and leisure activities take place (e.g., commercial, industrial, or service buildings), 30 dB(A) in hospital wards and libraries within educational institutions. These values apply under the

assumption of continuous operation of noise sources. Additionally, penalties are imposed when noise sources exhibit tonal components, with an added correction of +3 dB(A).

In Spain, the central administration is responsible for establishing legislation at the national level; however, the implementation and enforcement of these regulations fall under the jurisdiction of the autonomous communities. Consequently, most autonomous communities have developed their own regulatory frameworks in this domain, leading to slight variations in the indices used and the corresponding limit values. This study will therefore examine the noise and vibration assessment criteria established by the autonomous communities of Madrid and Barcelona, as well as those implemented by the city of Valencia.

2. CRITERIA USED IN PORTUGAL

Even though Portugal might not have specific regulations for ground-borne vibration and noise from rail traffic, the EU Directive 2016/797 (also known as the Railway Safety Directive) provides a framework to ensure that the levels of vibration and noise generated by rail operations do not cause annoyance. It's critical for rail operators to consider these environmental impacts, and ensure that mitigation measures are implemented if necessary, particularly in areas with sensitive uses (residential, healthcare, or industrial zones). In this context, the authors published in 2019 a methodological action guide for minimising the occurrence of potential noise and vibration annoyance situations inside homes derived from the operation of the Lisbon metro. This document indicates the criteria related to vibrations and ground-borne noise limit values inside buildings for the different phases of a railway infrastructure project (construction and operation), which are explained below (exploration phase):

2.1 Ground-borne noise

To predict ground-borne noise levels in exposed dwellings, it is recommended that, for each individual metro train passage, the vibration velocity values (RMS) be analysed within one-third-octave frequency bands ranging from 16 Hz to 250 Hz:

2.1.1 Underground track

- be less than 0.02 mm/s in the most unfavourable situations where the vibrational reduction index from the slab in question to the surrounding walls (*Kij*) are very low and the transmission between elements is very high. This case occurs when the construction solutions are very heavy and most of the connections considered are rigid;

- between 0.02 - 0.025 mm/s, in intermediate situations where vibrational reduction index of the slab in question to the surrounding walls (*Kij*) already has some relevance, so there is less vibration transmission than in the previous case are medium values. This case corresponds to the most common situations.
- between 0.025 - 0.03 mm/s, in the more favorable situations where vibrational reduction of the slab in question to the surrounding walls (*Kij*) are very high, and the transmission between elements is very low. This case will occur when the constructive solutions of the walls are lightweight.

It is acceptable to assume an average value of 0.025 mm/s, representing most situations. As an alternative option, bearing in mind that low-frequency noise is somewhat complex from the point of view of human perception, a noise limit value of 27 dB(A) can be considered, calculated for the third-octave frequency bands between 16 Hz and 250 Hz), which approximately corresponds to the response of 10 per cent of the most sensitive individuals [3].

2.1.2 Surface track

For the purpose of predicting ground borne noise that may be established in compartments of dwellings and/or other buildings of sensitive use, taking into account the specificity of the situation under analysis (noise and vibrations induced by the movement of railway traffic), it is recommended that the vibration velocity values (RMS) of the horizontal partition element (floor), vertical or horizontal component, if more relevant, integrated in the one-third-octave frequency bands between 16 Hz and 250 Hz, should be less than 0.05 mm/s. Bearing in mind that the difference between the limit values for vibration velocity between the vertical and horizontal directions correspond roughly in terms of L_{Aeq} sound level (with A weighting in each third-octave frequency band between 16 Hz and 250 Hz) is approximately 9 - 10 dB, a value of L_{Aeq} = 36 dB [16-250 Hz] is recommended for ground-borne noise indoors.

This criterion is more permissive than the one recommended for tunnelled tracks, as, there is a masking effect from airborne noise coming directly from the infrastructure.

2.2 Vibration (perception)

2.2.1 Underground track

The following criteria are recommended to assess annoyance induced by continuous or intermittent vibrations inside buildings.
1. Average effective vibration velocity value of less than 0.28 mm/s;
2. Application of the ISO 2831-2 base curve (1989 version) [4], with the multiplicative factors corresponding to intermittent vibrations for residential buildings. In this case, the spectrum of vibration velocity values (RMS), in one-third-octave bands, must be less than 0.14 mm/s, for central frequencies between 8 and 80 Hz (period 8 pm-8 am), this limit increasing to 0.4 mm/s at 2 Hz, and 0.8 mm/s at 1 Hz. For the daytime period (8 am-8 pm), the vibration velocity value, vef < 0.20 mm/s, assumed for central frequency bands between 8 and 80 Hz, and increases to 0.56 mm/s for 2 Hz, and 1.12 mm/s for 1 Hz. These values are valid for the vertical or horizontal component of the velocity, if the latter is the most significant.

2.2.2 Surface track

For the perception of vibrations inside buildings, the reference values shown in Table 1 are recommended in terms of the vibration velocity values (RMS). In this table, the vibration can be considered Perceptible during the infrastructure's operating day (08-20h) and Null during the complementary period of operation.

Table 1 - Limit values for the perception of continuous vibration inside buildings

v_{rms} (mm/s)	Sensation
$v_{rms} < 0{,}11$	Null
$0{,}11 < v_{rms} < 0{,}28$	Perceptible, bearable for short duration
$0{,}28 < v_{rms} < 1{,}10$	Clear, annoying, may affect working conditions
$v_{rms} > 1{,}10$	Very clear, very annoying, reducing working conditions

The ISO 2631-2 base curve (1989 version) can be also applied, with the multiplicative factors corresponding to intermittent vibrations for residential buildings. In this case, the spectrum of vibration velocity values (RMS) in one-third-octave bands must be less than 0.14 mm/s for centre frequencies between 8 and 80 Hz (period 20h-08h), a limit that increases to 0.4 mm/s at 2 Hz and 0.8 mm/s at 1 Hz. For the daytime period (08-20h), the effective vibration value, vef < 0.20 mm/s, assumed for centre frequency bands between 8 and 80 Hz, increases to 0.56 mm/s for 2 Hz, and 1.12 mm/s for 1 Hz. The lower value shown (0.11 mm/s) is considered the perception threshold. Although the criterion recommended for the night period (more restrictive) includes verification of the daytime criterion, in terms of corrective measures, there may be cases of operations management in which such differentiation may be applicable.

3 . CRITERIA USED IN SOME SPANISH MUNICIPALITIES

In 2003, the National Noise Law (*Ley 37/2003*) was published and developed into Royal Decree 1513/2005 [5] (on about the assessment and management of environmental noise), and Royal Decree 1367/2007 of October 19 (on acoustic zoning, quality objectives and acoustic emissions) [6]. With the updating of the European Directive on the assessment and management of environmental noise, the Royal Decree 1513/2005 has undergone some changes, specifically in its Annex II (Order PCI/1319/2018 of December 7 and Order PCM/80/2022 of February 7) and Annex III (Order PCM/542/2021 of May 31).
The aforementioned regulatory sets out the acoustic quality levels (equivalent SPLs) that ought to be met inside buildings depending on their use, as shown in Table 2. Where the indices L_d, L_e and L_n refer to the A-weighted, equivalent continuous sound level for daytime period (12 hours), evening period (4 hours) and night-time period (8 hours).
Regarding transmission between adjacent locations, without noise transmission between the emitter and the receiver through the external environment, the values indicated in Table 3 apply, depending on the type of use of the receiving location. These limit values are applied when the noise source relates to commercial, industrial activities, installations, sports or leisure establishments. The descriptor used to assess noise is the noise index $L_{keq,T}$, which corresponds to the A-weighted, equivalent continuous sound level, ($L_{Aeq,T}$), with, at least, an integration time of 5 seconds ($L_{kAeq,\ 5s}$). This value should be corrected for the presence of emergence of tonal components, low-frequency components and impulsive noise. The limits are met when the values of the acoustic indices, after assessing the existence of low-frequency components, do not exceed in any case more than 5 dB(A), the application limit values indicated in Table 3.

Table 2 - Acoustic quality objectives inside buildings, depending on their use

Building Type	Local	Ld and Le	Ln
Dwellings	Living areas	45	35
	Bedrooms	40	30
Hospitals	Living areas	45	35
	Bedrooms	40	30
Educational and Cultural Centres	Classrooms	40	40
	Libraries	35	35

Table 3 - The limits of sound levels transmitted to acoustically adjacent locations by any installation, establishment, activity or behavior (Real Royal Decree 1367/2007)

Building Use	Local	$L_{k,d}$ / $L_{k,e}$ Day/ Evening	$L_{k,n}$ Night
Dwellings	Living areas	40	30
	Bedrooms	35	25
Hospitals	Living areas	40	30
	Bedrooms	35	25
Educational and Cultural	Classrooms	35	35
	Libraries	30	30
Offices		35	35

For the assessment of low frequency noise, a detailed evaluation of the noise is carried out, introducing the appropriate corrections (Table 4) according to the following methodology:

a) Simultaneous measurement of the sound pressure level with C and A weighting.

b) Calculation of the difference between the values obtained (L_f), corrected for background noise;

c) Determining the presence or absence of low-frequency components, and the value of the correction (K_f) to be introduced, according to the values in Table 4.

Table 4 - Correction values (K_f) to be added in case of the presence of low-frequency components

$L_f = L_{Ceq,Ti} - L_{Aeq,Ti}$ (dB)	K_f (dB)
$L_f > 10$	0
$10 < L_f <= 15$	3
$L_f > 15$	6

However, the legislation only indicates the use of the above-mentioned correction factor (K_f) when dealing with noise sources located inside the building or in adjoining buildings. However, in view of the problem presented, assessing ground-borne noise annoyance in buildings caused by rail traffic, it was also decided in this work to incorporate this criterion.

Regarding the quality criteria for vibrations inside buildings, the values in Table 5 apply depending on the type of building use; the L_{aw} index refers to the vibration level according to the W_m weighting curve defined in the ISO 2631-2: 2003 standard. When assessing this criterion, the maximum RMS acceleration value with slow time constant and W_m frequency weighted is used (defined as Maximum Transient Vibration Value in ISO 2631-1: 1997). However, for transient vibrations, the W_m weighting is not used (because of the slow response of the lowest one-third-octave filters relative to the slow time constant). It is only limited to the case of stationary vibrations.

Table 5 - Acoustic quality objectives for vibrations transmitted to interior spaces

Building Type	Vibration Index L_{aw} dB re. 10^{-6} m/s^2	mm/s^2
Dwellings	75	5.6
Hospitals	72	4.0
Educational and Cultural centers	72	4.0

In the case of the community of Madrid and according to the *Ordenanza de Protección contra la Contaminación Acústica y Térmica* (2021 version), the acoustic quality objectives inside buildings are identical to those shown in Table 2 (noise). In the case of sound level measurements and for acoustic sources in the building (or adjacent buildings), the values from Table 6 are applied. The limits are met when the values of the acoustic indices, after assessing the existence of low-frequency components (Table 4), do not exceed in any case more than 5 dB(A), the application limit values indicated in Table 6.

For vibrations inside buildings, the values in Table 5 apply in addition to the limits imposed on four new building uses: hostels (78 dB/7,9mm/s2), offices (84 dB/15,8 mm/s^2), shops and warehouses (90 dB/31,6 mm/s^2), and industry (97 dB/70,8 mm/s^2).

Table 6 - The limits of sound levels transmitted to acoustically adjacent locations by any installation, establishment, activity or behavior (community of Madrid)

Building Use	Local	$L_{kAeq,5s}$ Day/ Evening	$L_{kAeq,5s}$ Night
Dwellings	Living areas	35	30
	Bedrooms	30	25
Hospitals	Living areas	40	30
	Bedrooms	30	25
Cultural	Cinemas, theaters	30	30

	Libraries	30	30
Offices	--------	35	35
Commerce	---------	50	50
Industrie	-----	55	55

In the case of the city of Valencia, the Municipal Ordinance for Protection against Acoustic Contamination, approved in February 2023, states criteria for sound levels inside buildings derived from airborne and structural transmission. Regarding airborne transmission, the most stringent values are for residential buildings (55 dB(A) during the day and evening, 45 dB(A) at night), and for hospitals and schools (45 dB(A) during the day and evening, and 35 dB(A) at night). These higher permissible values are related to the microphone position that should be placed in the window opening at the plane of the exterior facade and orientated towards the sound source. (windows open). The values for structural transmission are presented in Table 6. Also, when low-frequency components are detected in the noise measurement process, a detailed evaluation of the noise is carried out, introducing the appropriate corrections (identical to Table 4 correction values).
Like in Madrid, the values in Table 5 are also used as quality objectives for vibrations applicable to the interior habitable space of buildings intended for housing, residential, hospital, educational, or cultural uses.

Table 7. Assessment levels inside buildings, derived from structural transmission (city of Valencia)

Building Use	Local	Day/Evening dB(A)	Night dB(A)
Dwellings	Living areas	40	35
	Bedrooms	40	30
Hospitals	Living areas	45	35
	Bedrooms	40	30
Cultural	Concert halls	35	35
	Libraries	35	35
	Museums	45	45
	Exhibitions	45	45
Educacional	Classrooms	40	35
	Libraries	35	35
Offices	--------	40	40
Commerce	---------	45	45

For the autonomous region of Catalonia, Decree 176/2009, approving Law 16/2002 about protection against noise pollution, sets out the objectives for noise quality inside buildings intended for residential, hospital, educational and cultural use, identical to the ones shown in Table 2. About admissible sound levels for acoustically adjacent locations by any installation, establishment, activity or behaviors, values similar to those shown in Table 6 apply, except that in this case, the index used is the A-weighted equivalent continuous sound pressure level, corresponding to the daytime (7 am to 9 pm), evening (9 pm to 11 pm), and night-time (11 pm to 7am) periods.

Regarding the low-frequency assessment, the procedure differs slightly from the previous one. Thus, if the difference between simultaneous measurement of the sound pressure level with C and A-weighting is greater than 20 dB, a detailed assessment of low frequency components carried out, according to the following procedure:

a) Obtaining the low-frequency audible level, which is calculated for each third-octave band between 20 and 160 Hz, from the difference between the measured value of each one third octave band (unweighted) and the human hearing threshold published in ISO 226:2003.
b) Obtaining the L_B value, corresponding to the energetic sum of the values corresponding to the one-

third-octave bands between 20Hz and 160Hz, and whose difference obtained in a) is greater than zero.
c) Determining the presence or absence of low-frequency components and the correction parameter K_f by applying the criteria in Table 8.

Table 8 - Correction values to be added in the presence of low-frequency components

L_B (dB)	K_f (dB)
L_B< 25 dB	0
25<=L_B<=35	3
L_B>35	6

For vibrations, and like in the city of Valencia city, the values in Table 5 are applied, corresponding to quality objectives applicable to the interior habitable space of buildings intended for housing, residential, hospital, educational, or cultural uses.

3. CASE STUDIES

3.1 Case 01

The building under evaluation is a semi-detached house, with a basement, ground floor, and first floor. The metro tunnel is located at a depth of approximately 20 m from the ground surface. The sound environment outside the residence is characterized mainly by road traffic noise and air traffic noise. Inside the house, given the sound insulation against airborne sounds provided by the walls and windows (made up of double glazing), the noise from the external sound environment is almost imperceptible. Three 01 dB Symphonie measurement systems were used (located on the railway platform, tunnel wall structure and inside the residence) and a Pulse measurement system from Bruel & Kjaer (located inside the residence) to which one microphone (GRAS 40AF microphone) and accelerometers (IMI 626A04 and PCB, model 393A03) were connected. Inside the residence, measurements were taken on the ground floor (living room, labeled as S and nº of measurement) and on the 1st floor (bedroom, labeled as Q). All measurements taken inside the house were accompanied by simultaneous and synchronized measurements of the metro train passages with the accelerometers placed on the railway platform, and in the tunnel wall structure. Tables 9, 10 and 11 present the results of vibration measurements taken on the ground floor. Tables 9 and 10 refer to individual passages of metro trains. In contrast, Table 11 shows the results obtained in three measurements, each lasting 30 minutes, with the noise levels already corrected from residual sound values.

Table 9 – Vibration values for single metro train passages in the living room (ground floor)

The tables above show the results for vibration acceleration level (L_a), W_m weighted vibration acceleration level (L_{aw}), Maximum Transient Vibration Value (MTVV, calculated by multiplying 1.5 by the RMS acceleration value), and RMS velocity value (v_{rms}, in mm/s), for frequencies between 1 and 80 Hz (v_{rms} (mm/s) [1-80 Hz] and for frequencies between 16 and

250 Hz, (v_{rms} (mm/s) [16-250 Hz]). The column labeled as ISO 2831-2, presents the results of applying the base curve (1989 version) of this standard, with the multiplicative factors corresponding to intermittent vibrations for residential buildings. Tables 10 and 11 also show the A-weighted sound equivalent levels (L_{Aeq}), measured during single metro train passages (for the definition of the duration of each passage, -10dB rule was used in relation to the maximum value). These levels refer to the frequencies between 16-250 Hz. The results of the calculations for assessing the existence of low-frequency components are also shown, namely the Lf values (Royal Decree 1513/2005) and the L_B value (Catalonia, Decree 176/2009). Table 12 refers to the measurement results for the bedroom on the first floor of the house. The labels for each column have the same meaning that the previous tables.

Table 12- Vibration values and noise levels for single metro train passages in bedroom (first floor)

3.2 Case 02

The measurements were taken on the first floor of a 4-storey urban building with a reinforced concrete structure. The vibration levels of the metro single metro train passages were measured in the center of the floor and on two side walls. The microphone was placed in the center of the room. Two measurement chains were used, each consisting of a real-time analyser with two channels, brand 01dB, model Symphonie, to which the respective microphone (GRAS 40 AF) and accelerometers (PCB model 393B04) were connected, and which carried out simultaneous measurements in 3 different directions. The ground-borne noise derived from each metro train passage was clearly audible, standing out from the residual sound. Table 13 refers to vibration and noise levels for single metro train passages in the living room (first floor)

Table 13- Vibration values and noise levels for single metro train passages in the living room (first floor)

Nº Mes.	L_a dB	L_{aw} dB	MTVV dB	v_{rms} (mm/s) [1-80 Hz]	v_{rms} (mm/s) [16-250Hz]	ISO 2831-2 [Hz]	L_{Aeq} [16-250 Hz	L_f /L_B

4. COMPARATIVE ANALYSIS

4.1 Vibration

The bold values in the MTVV column of Tables 9,10,12, and 13 correspond to acceleration vibration levels that exceed the threshold values established in the Spanish criteria for assessing vibrations in residential buildings (as specified in Table 5). Similarly, the bold values in the v_{RMS} (mm/s) [1-80 Hz] column denote metro train passages where the measured vibration velocity surpasses the general threshold outlined in the Portuguese criteria (v_{RMS}=0.28 mm/s). However, as none of the recorded measurements exceed this limit, no bold values appear in the referenced tables. Furthermore, the values in the ISO 2631-2 column indicate a "PASS" when the measured values for each third-octave band remain below the thresholds established in the ISO 2631-2:1989 standard. If a threshold is exceeded, the corresponding frequency band is specified. Consequently, only the metro train passages listed in Table 13 (passages 1-10) fail to comply with the vibration assessment criteria applicable in Portugal. The comparison of results, particularly for Case Study 1 (as presented in Tables 8, 9, and 11), suggests a higher sensitivity of the criterion employed in Spain concerning the assessment of vibrations.

4.2 Ground-borne noise

According to Spanish regulations, the assessment of railway traffic noise inside residential spaces requires a minimum of three series of measurements. Each series must comprise multiple measurements (at least 3), with a minimum duration of five minutes per measurement. Furthermore, the time interval between consecutive

measurement series must exceed five minutes. The final noise level assessment is determined as the energy average of the three series. Based on the values presented in Table 10, the resulting noise level is 23 dB(A).

In the context of noise assessment and the comparative study, additional considerations were incorporated that are not explicitly specified in Spanish regulations. Specifically, the evaluation included the assessment of sound levels generated by an individual passage of a metro train, categorized as noise resulting from an activity, as outlined in Tables 3, 6, and 7. To achieve this, three series of measurements were conducted, each lasting longer than five seconds. The maximum recorded value from each series was retained, and the presence of low-frequency components was analyzed. The results of this assessment are presented in Table 14. The bold values in the v_{RMS} (mm/s) [16-250 Hz] column denote metro train passages where the measured vibration velocity surpasses the general threshold outlined in the Portuguese criteria for ground-borne noise. Similarly, the bold values for the L_{Aeq} columns (Real Decreto and Barcelona) indicate that the admissible sound levels are exceeded, considering the most critical situations for residential buildings during the night (equal to 30 and 25 dB(A), or 35 and 30 dB(A) in the case of the city of Valencia).

Table 14- Assessment of noise levels for individual metro trains passages

Nº Mes./ Table	v_{rms} (mm/s) [16-250 Hz]	L_{Aeq} [16-250 Hz]	L_{Aeq} Real Decreto	L_{Aeq} Barcelona
S7/9	**0,028**	30	**36**	30
S11/9	0,022	30	**36**	30
S13/9	0,016	33	**39**	33
S17/9	**0,046**	28	**34**	28
Q3/11	0,013	19	25	19
Q5/11	0,013	21	**27**	21
Q8/11	**0,064**	27	**33**	**27**
3/12	**0,25**	50	**56**	**53**
4/12	**0,24**	50	**56**	**53**
8/12	**0,24**	50	**56**	**53**

Regarding the assessment of sound levels, only the evaluation of individual metro train passages yields values exceeding the established criteria. Additionally, a greater degree of harmonization is observed between the two countries in this context.

5. CONCLUSIONS

The evaluation of vibration and ground-borne noise based on measurements presents significant challenges due to the small amplitudes involved and the presence of residual vibration and noise in the surrounding environment. However, the analysis of the two case studies provided insights into the higher sensitivity of the criterion applied in Spain for vibration assessment, which classifies vibrations based on the type of building use.

Regarding ground-borne noise, harmonization of results between the two countries is achieved only when individual pass-by values and criteria related to activity operation are considered. Additionally, differences in the criteria for evaluating low-frequency components in Spain have a direct impact on the final assessment outcomes. Nevertheless, it is important to emphasize that in both case studies, residents reported significant annoyance due to ground-borne noise.

BUILDING BASE ISOLATION DESIGN: QUANTIFICATION OF VIBRATION TRANSMISSION USING POWER FLOW ANALYSIS

Hamid Masoumi[1*] **James Talbot**[2]
[1] CDM Stravitec , Overijse, Belgium
[2] Department of Engineering, University of Cambridge, UK

ABSTRACT

This paper reports on ongoing work aimed at developing practical guidance for designing BBI solutions. This includes examining the mechanisms by which ground-borne vibrations from railway activities are transmitted into buildings, in particular, the soil-structure interaction (coupling loss), the role of the isolation system and the influence of structural elements within the building using power flow analysis. Power flow analysis provides valuable insight into the vibration transmission through the system, offering an effective basis for isolation design. This analysis requires estimating the mobility of the substructure (foundation and ground), the isolation system and that of the superstructure. The paper presents a series of experimental measurements of these essential parameters, made at various stages of construction in a recent BBI project. The mobility of the substructure was measured using hammer impact, and vibration levels due to train passages were recorded both at the beginning of construction, before the construction of the superstructure and after the completion of the building. Since the mobility of the superstructure cannot be measured directly, this was estimated by numerical simulation. The characteristics of the isolation system were determined by laboratory tests under loading conditions representative of the operating state of the building.

1. INTRODUCTION

Buildings, especially those near railway or subway networks, can be subjected to ground-borne vibrations that result in unacceptable levels of structure-borne noise and vibration for the occupants of the building. In order to protect a building from such disturbance, it is necessary to decouple the building from the surrounding sources at the foundation level or on the columns or walls in an upper level by introducing a building base (vibration) isolation solution.

A true assessment of any isolation solution requires comparing noise or vibration levels inside the building with and without the isolation system. This indicator is known as the insertion loss. In practice, once a building is isolated, the non-isolated condition is unavailable, making the true insertion loss unmeasurable.

Today, the performance of a Building Base Isolation (BBI) system is often defined solely in terms of transmission loss, where vibration levels are typically measured above and below the isolation 'cut' in the completed isolated building. However, these measurements do not accurately reflect true isolation performance as they focus on the forced response of a limited section of a complex structure. Furthermore, in an isolated building, increased vibration in the foundation (substructure) may lead to an inaccurate assessment of isolation performance compared to a non-isolated building [1]. Transmission loss and insertion loss indicate the same performance only when the building acts as a SDOF mass-spring system.

A comprehensive study of vibration transmission between the ground and a building was conducted by Edirisinghe and Talbot [2]. They investigated the fully coupled three-dimensional behavior of a tunnel–foundation–building system, analysing the effects of

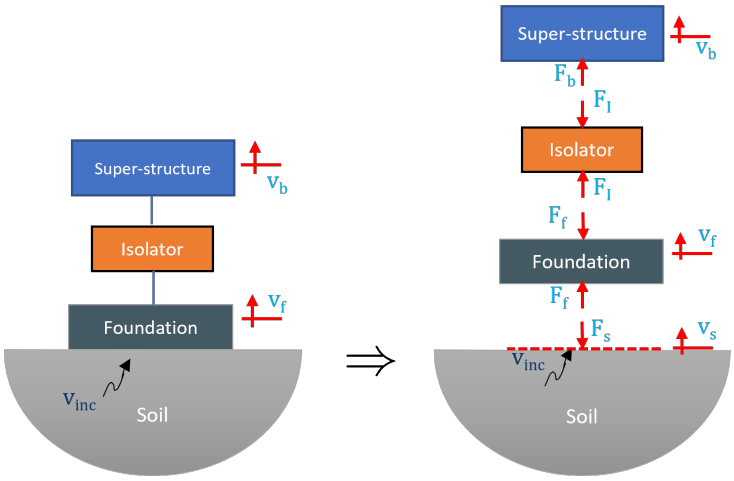

Figure 1. A general overview of the ground-foundation-building interaction.

the source location (the tunnel) relative to the building, the foundation configuration and the flexibility of the building structure. The results showed that simplified models, which capture the fundamental soil-structure interaction (SSI) of the system without including tunnel interaction, can provide sufficiently accurate predictions of vibration transmission through the building.

Using numerical modelling and experimental measurements, Kuo et al. [3] studied the coupling loss of a building subjected to railway-induced vibrations. Their field measurements and numerical studies also showed that a simplified SSI model, which does not include the track or tunnel, provides a sufficiently accurate estimation for the purposes of design. Additionally, their results showed that ground conditions significantly influence coupling loss, whereas the building geometry and foundation type have a more limited impact.

Disregarding the effect of any source-building interaction, the vibration transmission through the system can therefore be decomposed into three main parts: (1) vibration transmission from the ground to the building foundation, (2) vibration transmission through the isolation system and (3) vibration transmission through the building floors above the vibration cut.

One approach to quantifying the vibration transmission process between the different domains (the substructure, the isolator and the superstructure) is to evaluate the vibration energy flux using structural power flow analysis [1,4]. In this paper, theoretical expressions of this analysis are first presented, and the essential parameters governing the interaction between the domains are described. A recent building base isolation project is then used to illustrate how these quantities may be derived from experimental in-situ measurements and then used to estimate the power flow into the building.

1.1 Application of structural power in Building Base Isolation

Focusing on vibration levels at the ground-building interface accounts for transmission at only one location and in one direction. In contrast, power flow analysis can provide a global measure of isolation performance by evaluating the vibrational power at multiple locations and in several directions, leading to a more accurate evaluation of the transmissibility process.

Figure 1 shows the two main coupled domains with the intermediate isolation system, where the substructure (the foundation) has been excited by an incident wave $\mathbf{v}_{\text{inc}}$. The interaction force between the domains depends not only on the excitation but also on the dynamic characteristics of each domain, which can be represented by the mobilities of the coupled domains.

To analyse vibrational/structural power transmission through a building, we need to determine the power in terms of the interaction forces (F) and velocities (v) at each domain's interface. Based on the domain decomposition shown in Fig. 1 for the isolated building, these can be expressed in terms of the 'free' velocities of either the foundation or the soil, that is, the velocities measured at the interface between either the foundation and the future

superstructure before the superstructure is constructed, or the velocities measured on the ground surface before the future foundation is constructed (Fig. 2):

$$\begin{aligned} \mathbf{v}_\mathrm{f} &= \mathbf{v}_\mathrm{f,free} - \mathbf{Y}_\mathrm{f} \cdot \mathbf{F}_\mathrm{f} \\ \mathbf{v}_\mathrm{b} &= \mathbf{Y}_\mathrm{b} \cdot \mathbf{F}_\mathrm{b} \\ \mathbf{v}_\mathrm{b} - \mathbf{v}_\mathrm{f} &= \mathbf{Y}_\mathrm{I} \cdot \mathbf{F}_\mathrm{I} \end{aligned} \tag{1}$$

where, $\mathbf{v}_\mathrm{f,free}$ is the foundation's free vibration, and $\mathbf{Y}_\mathrm{f}$, $\mathbf{Y}_\mathrm{b}$, and $\mathbf{Y}_\mathrm{I}$ are the mobility of the foundation, the building and the isolator, respectively.

Since the mobility of the superstructure cannot be measured directly, it is estimated through numerical simulation. In contrast, the mobility of the substructure (the foundation-soil system) can be obtained via either numerical simulation or measurement using a conventional hammer impact test. For a complex substructure, an averaged mobility can serve as a representative value for varying mobilities at different points. The mobility of the isolation system is defined by the bearing dynamic stiffness, which is determined through laboratory tests under load conditions representative of the building's operational state.

Since the isolator is assumed to be massless, $\mathbf{F}_\mathrm{b} = \mathbf{F}_\mathrm{f} = \mathbf{F}_\mathrm{I}$, and the interaction forces and velocity responses can be obtained from Eqn. 1 as follows:

$$\begin{aligned} \mathbf{F}_\mathrm{I} &= \|\mathbf{Y}_\mathrm{b} + \mathbf{Y}_\mathrm{I} + \mathbf{Y}_\mathrm{f}\|^{-1} \cdot \mathbf{v}_\mathrm{f,free} \\ \mathbf{v}_\mathrm{b} &= \|\mathbf{Y}_\mathrm{b}\| \cdot \|\mathbf{Y}_\mathrm{b} + \mathbf{Y}_\mathrm{I} + \mathbf{Y}_\mathrm{f}\|^{-1} \cdot \mathbf{v}_\mathrm{f,free} \\ \mathbf{v}_\mathrm{f} &= \|\mathbf{Y}_\mathrm{b} + \mathbf{Y}_\mathrm{I}\| \cdot \|\mathbf{Y}_\mathrm{b} + \mathbf{Y}_\mathrm{I} + \mathbf{Y}_\mathrm{f}\|^{-1} \cdot \mathbf{v}_\mathrm{f,free} \end{aligned} \tag{2}$$

For the non-isolated case, the free velocity of the foundation can be expressed in terms of the free-field velocity measured on the ground surface before the future foundation is constructed (Fig. 2):

$$\mathbf{v}_\mathrm{f,free} = \|\mathbf{Y}_\mathrm{f}\| \cdot \|\mathbf{Y}_\mathrm{f} + \mathbf{Y}_\mathrm{soil}\|^{-1} \cdot \mathbf{v}_\mathrm{inc} \tag{3}$$

The transmitted vibrational power to the foundation, and that transmitted through the building's columns and floors, is given by:

$$\begin{aligned} \Pi_\mathrm{f} &= \frac{1}{2}\Re\left\{\mathbf{F}_\mathrm{f}^\mathrm{H} \cdot \mathbf{v}_\mathrm{f}\right\} \\ \Pi_\mathrm{b} &= \frac{1}{2}\Re\left\{\mathbf{F}_\mathrm{b}^\mathrm{H} \cdot \mathbf{v}_\mathrm{b}\right\} \end{aligned} \tag{4}$$

where the superscript "H" denotes to the Hermitian transpose operation.

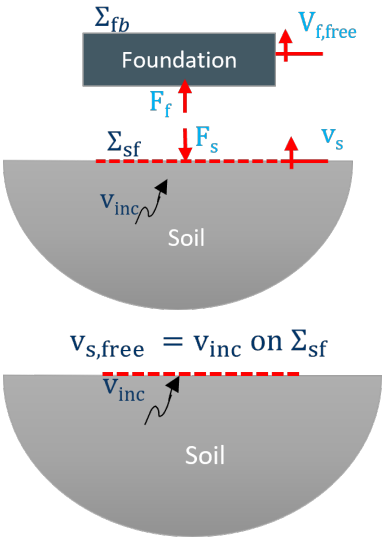

Figure 2. An overview of (bottom) the ground free vibration and (top) the free foundation vibration.

Introducing Eqn. 2 to Eqn. 4, the transmitted power can be written in terms of the measurable free vibration velocity and the mobilities:

$$\Pi_\mathrm{b} = \frac{1}{2}\Re\left\{\mathbf{v}_\mathrm{f,free}^\mathrm{H} . \mathcal{H}^{-\mathrm{H}} . \mathbf{v}_\mathrm{f,free}\right\} \tag{5}$$

with

$$\mathcal{H}^{-\mathrm{H}} = \|\mathbf{Y}_\mathrm{b} + \mathbf{Y}_\mathrm{I} + \mathbf{Y}_\mathrm{f}\|^{-\mathrm{H}} . \|\mathbf{Y}_\mathrm{b}\| . \|\mathbf{Y}_\mathrm{b} + \mathbf{Y}_\mathrm{I} + \mathbf{Y}_\mathrm{f}\|^{-1} \tag{6}$$

It is worth noting that, since the mobility of the foundation is independent of that of the superstructure, the total mobility is often approximated as the sum of the individual mobilities, i.e., $\|\mathbf{Y}_\mathrm{b} + \mathbf{Y}_\mathrm{I} + \mathbf{Y}_\mathrm{f}\|^2 \approx \|\mathbf{Y}_\mathrm{b} + \mathbf{Y}_\mathrm{I}\|^2 + \|\mathbf{Y}_\mathrm{f}\|^2$. This approximation neglects the phase interaction between the mobility terms but does not introduce significant errors in the calculation under the assumption of weak coupling.

1.2 Application in SSI impact and coupling loss estimation

Power flow analysis is helping to further our understanding of SSI and its significance in the response of buildings to ground-borne vibration. By analysing the mean vibrational power input to a building, it is clear that SSI must

be accounted for to avoid over-predicting building vibration levels. The constraining of the soil by foundation and building structures, and the radiation damping provided by the soil to the building, all act to limit vibration levels in the building to below those predicted when SSI is neglected.

SSI should therefore be accounted for in any assessment of building base isolation. However, there is growing evidence that this may be achieved by using either simplified models or limited site measurements to estimate the coupling loss introduced by constructing a building and its foundation [2].

1.3 Application in building isolation performance evaluation

The isolation performance of a BBI system can be defined in terms of power-flow insertion gain as the ratio of the power transmitted by the isolator to the superstructure to that transmitted by a rigid connection for the non-isolated building [1]:

$$\mathrm{PFIG}\,[\mathrm{dB}] = 10\,\log_{10}\left(\frac{\Pi_{\mathrm{b,\,iso}}}{\Pi_{\mathrm{b,\,non\text{-}iso}}}\right) \tag{7}$$

where $\Pi_{\mathrm{b,\,iso}}$ and $\Pi_{\mathrm{b,\,non\text{-}iso}}$ are the total mean power flows entering an isolated and non-isolated building, respectively.

The power flow transmitted through the non-isolated building can be determined by setting the mobility of the isolator to zero in Eqn. 5, ensuring a rigid contact between the foundation and the building.

In the frequency range from 16 to 250 Hz, BIOVIB [5, 6] proposed an approximation to the PFIG formulation and justified a new performance indicator that may be more easily evaluated via in-situ measurements. Assuming that the vibration transmission is dominated by vertical vibration, and that the isolator mobility is large compared to that of the foundation, this is expressed in terms of the transmission loss (TL) through the isolator and the mobilities of the building and foundation:

$$\mathrm{PFIG}\,[\mathrm{dB}] \approx \mathrm{TL} + 10\,\log_{10}\left(\frac{\|\mathbf{Y}_\mathrm{b} + \mathbf{Y}_\mathrm{f}\|^2}{\|\mathbf{Y}_\mathrm{b}\|^2}\right) \tag{8}$$

The first term of Eqn. 8, the transmission loss, is defined as the ratio of the vibrational input power to that transmitted to the isolated building:

$$\mathrm{TL}\,[\mathrm{dB}] = 10\,\log_{10}\left(\frac{\Pi_{\mathrm{b,\,iso}}}{\Pi_{\mathrm{f,\,iso}}}\right) \tag{9}$$

This approximation offers the advantage that the vibrational power transmission into an isolated building can be obtained either through in-situ measurements or from the mobilities of the isolator and the building:

$$\mathrm{TL}\,[\mathrm{dB}] = 10\,\log_{10}\left(\frac{\|\mathbf{Y}_\mathrm{b}\|^2}{\|\mathbf{Y}_\mathrm{b} + \mathbf{Y}_\mathrm{I}\|^2}\right) \tag{10}$$

The application of this performance indicator (Eqn. 8) within the framework of the BIOVIB project has been validated through laboratory and in-situ measurements [7, 8].

2. CASE STUDY: PERFORMANCE ASSESSMENT OF AN ISOLATED BUILDING

In the following, a hybrid experimental-numerical methodology is used to determine the parameters necessary for assessing the performance of an isolated building by means of power flow analysis. The proposed methodology has four steps:

1. Determine the mobility of the building (superstructure) using numerical calculation, such as Finite Element Analysis (FEA) in the frequency domain.

2. Determine the isolator mobility based on the dynamic characteristics of the bearings, $\mathbf{Y}_\mathrm{I} = |i\omega/K^*_{\mathrm{iso}}|$. The complex dynamic stiffness of the isolation bearing ($K^*_{\mathrm{iso}} = K_{\mathrm{iso}}(1 + i\eta)$) and the bearing loss factor η are defined under the specific bearing design load by a dynamic test following the procedure described in ISO 4664-1 [9].

3. Determine the substructure mobility through an in-situ hammer impact test at the bearing locations before installing the building (superstructure), following the measurement procedure described in ISO 7626 [10].

4. Measure train pass-bys at the substructure (i.e., the free vibration of the foundation) before the building (superstructure) is installed, following the measurement procedure described in ISO 14837-31 [11].

5. Measure train pass-bys on the substructure below the vibration isolation system and on the floors above it, following the measurement procedure described in ISO 14837-31 [11].

Given that the quality of the rail-wheel contact surface (a crucial factor in the induced vibrations) may degrade over time, the measured free vibration levels of the foundation or soil should be normalised using a reference vibration level recorded at a point near the source, before calculating the contact force in the completed building using Eqn. 2.

This methodology is examined for the real case study of a two-story building constructed on footings adjacent a railway station in Barcelona. The building is isolated on elastomeric bearings on top of the foundation footings.

2.1 Mobility of the building (super-structure)

To determine the mobility of the building, a Finite Element (FE) model of the superstructure is developed. Since the building structure exhibits a repeated section along its length, a section of building perpendicular to the track with three supports is modelled (Fig. 3). A unit force is applied at each support, and the building response — both at the same support and at the other supports — is calculated to enable the assembly of the building's $N \times N$ mobility matrix, $Y_{b,ij} = v_{b,j}/F_{b,i}$, where N represents the number of bearing locations.

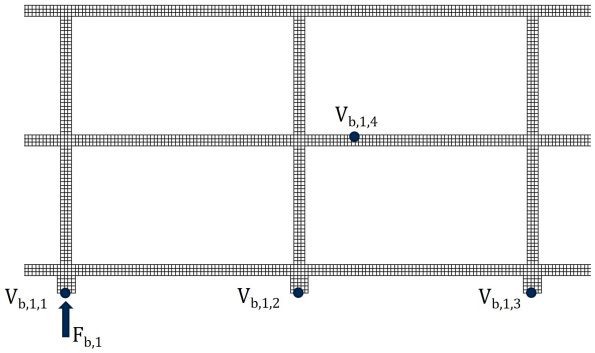

Figure 3. 2D - Finite Element modeling of the building.

Figure 4 shows the direct mobility (the diagonal terms) at each isolator location. Despite the peaks and troughs caused by the bending modes of the structure, the building mobility is primarily dominated by the mass effect, expressed as $Y_b \approx |1/\omega M_b|$.

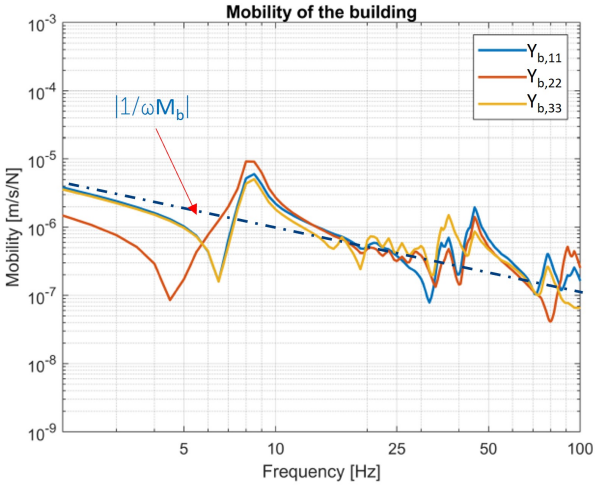

Figure 4. The mobility of the building calculated by FEA.

2.2 Mobility of the foundation (sub-structure)

In the second step, an in-situ measurement campaign is carried out to obtain the foundation mobility using an instrumented hammer, following the measurement procedure described in ISO 7626 [10]. At each bearing location, the mobility of substructure is obtained by applying a hammer impact at each bearing location and measuring the substructure response at the impact location as well as at the other supports. The mobility of the substructure is then assembled as an $N \times N$ matrix, $Y_{f,ij} = v_{f,j}/F_{f,i}$.

In this case study, since the footings are similar, the mobility has been measured only at one of the footings, and only the direct mobility is taken into account. The cross-mobility between the horizontal and vertical foundation responses has been found to be negligible relative to the direct mobility, as illustrated in Fig. 5.

The building is isolated using steel reinforced rubber bearings (type Stravibase VHS) installed between the concrete distribution beams of the superstructure and the footings, as shown in Fig. 6. The measured dynamic stiffness, including the loss factor of the bearings (under the design load), has been used to determine the mobility of isolator at each support. The isolation bearings are designed to exhibit a rigid-body resonance frequency of 10 Hz under the Acoustic design load (in an equivalent SDOF system). Figure 7 shows the averaged vertical mobility of the foundation, as well as that of the building and isolator at each

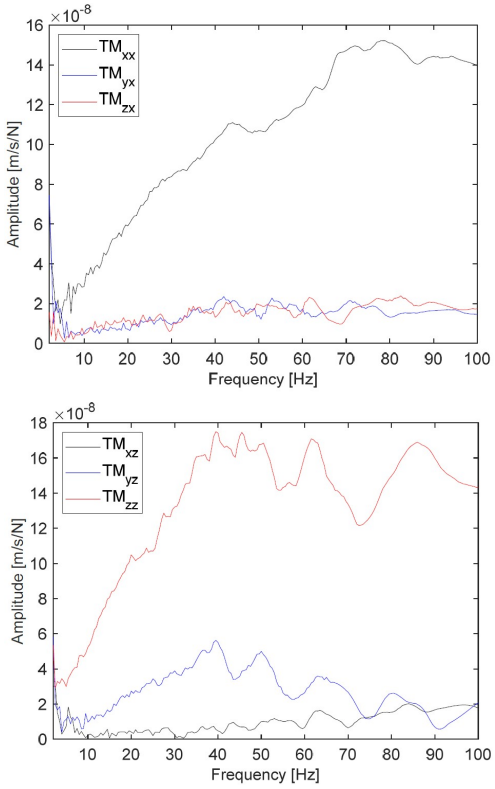

Figure 5. (Top) The three components of the foundation mobility measured under horizontal impact; (Bottom) The three components of the foundation mobility measured under vertical impact.

Figure 6. The isolation bearing, type Stravibase VHS, installed between the concrete distribution beams and the footings.

bearing location. The comparison clearly shows that, at frequencies above 30 Hz, the building and isolator mobilities dictate the foundation-isolator-building behavior that governs the transmission mechanism.

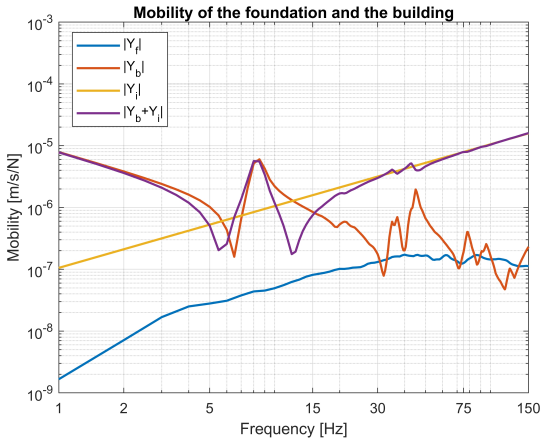

Figure 7. The average measured vertical mobility of the foundation (blue line) compared with the calculated mobility of the building superstructure (red line) and the measured isolator mobility (orange line).

2.3 The building and foundation responses due to train pass-bys

Train pass-bys were measured at different stages of construction, following the measurement procedure described in ISO 14837-31 [11]:

1. After the foundation construction and before the building superstructure installation, on the foundation, to measure the foundation's free vibration.

2. After the building construction, to measure the isolated building response at both the substructure and superstructure levels.

In the first phase, train pass-bys were measured on top of the foundation. The vibration level on the free foundation is used, to evaluate the coupling loss considered in the early-stage vibration study, and to apply any final adjustments to the isolation design before installation, if required.

In the second phase, the building and foundation vibration levels were measured after the building was completed and furnished, once the bearings had received their intended design load, for which their performance was optimized.

During each phase, train pass-bys were recorded simultaneously at a reference point near the railway, to normalize the building's performance, making it independent of any changes in the source strength.

Figure 8 displays the spectra of the train pass-by vibrations measured on the foundation before the installation of superstructure and those measured at the end of construction on the ground floor (above the vibration cut) and on top of the foundation (below the vibration cut).

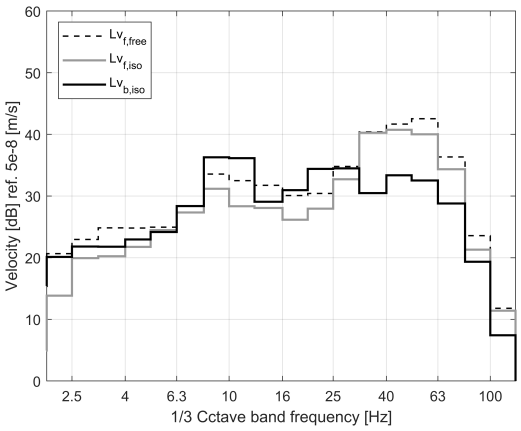

Figure 8. The average train pass-by vibrations measured on top of the free foundation (dashed line), and those measured after completion of the building at the foundation (grey line) and on the ground floor (black line).

A comparison is presented in Fig. 9 between the estimated power flow transmitted to the non-isolated building (i.e., on rigid supports) and that of the building supported by the designed isolation bearings. The power flow is calculated using Eqn. 4, while the interaction force is obtained from Eqn. 2 using the measured foundation free vibration $v_{f,free}$. Since the non-isolated building is not physically available, Equation 2 has also been used to estimate the building vibration for the non-isolated case.

In Fig. 10, the direct PFIG, defined in Eqn. 7, is compared with the performance indicator established by BIOVIB (Eqn. 8). Despite a reasonable correspondence

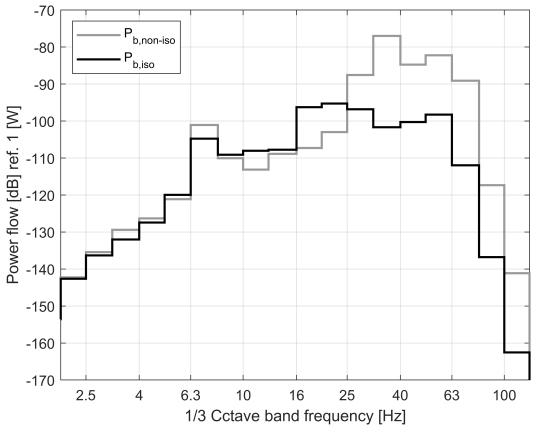

Figure 9. The power flow transmitted through the non-isolated building (gray line) and isolated building (black line).

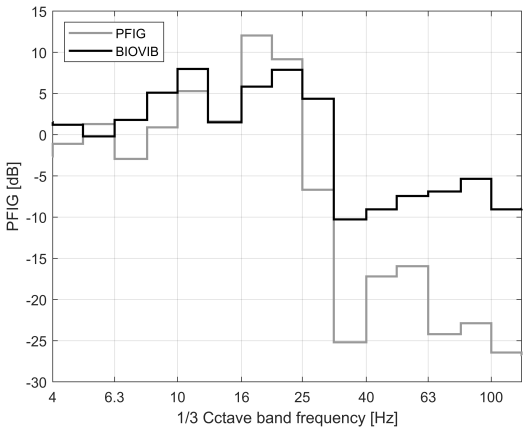

Figure 10. The power flow transmitted through the non-isolated building (gray line) and isolated building (black line).

at frequencies below 25 Hz, reflecting the isolation system's resonance around 10 Hz and the dominant bending modes of the building floors at 20–25 Hz, at higher frequencies, the direct PFIG indicates a higher level of isolation than the BIOVIB indicator. This discrepancy appears to be due to an overestimated vibration level for the non-isolated building, calculated (rather than measured) using Eqn. 5, which may be due to an inaccurate estimation of the building mobility at higher frequencies.

3. CONCLUSIONS

This paper has illustrated the use of power flow analysis for quantifying the vibration transmission into a building, as an effective basis for isolation design. The analysis is based on a hybrid approach that estimates the mobility of the substructure (foundation and ground) and isolation system via measurement, and that of the superstructure via calculation (Finite Element Analysis). The work is part of ongoing research aimed at developing practical guidance for designing building base isolation solutions.

ABSTRACT

When addressing ground-borne vibration issues, such as those caused by railways, the state-of-the-art for new building projects typically includes various Building Base Isolation (BBI) solutions. However, some projects face constraints that complicate the implementation of such systems. Specifically, when isolation measures are introduced late in the planning phase, a Box-in-Box (BiB) isolation system can be a practical alternative to achieve the required vibration reduction. This paper discusses the mitigation of ground-borne vibrations in a building near a metro line using a BiB system. It emphasizes the importance of detailed design and rigorous quality control during construction to ensure the system's success. The case study also demonstrates the feasibility of BiB systems as a practical alternative to BBI in constrained situations, while offering recommendations on decoupling details to achieve promised performance in vibration isolation projects. This study highlights challenges posed by the acoustic bridges, which led to performance deficiencies in some areas. In contrast, sections where decoupling measures were carefully followed achieved the expected performance, as verified through in-situ measurements.

1. INTRODUCTION

Buildings located near railway infrastructure are often subjected to ground-borne vibration (GBV), which is generated by passing trains and transmitted through the soil to the building structure. Train-induced vibrations can cause discomfort for habitant due to both floor vibrations and re-radiated (structural) noise inside the rooms. This requires a decoupling and mitigation strategy either between the surrounding ground and the building foundation, or inside the building between the building's main structural element and the sensitive spaces. Such an approach demands a multi-disciplinary effort, involving a comprehensive understanding of the railway infrastructure and the train types and speeds (as the source of vibration), on the dynamic characteristics of the ground (as the vibration propagation path), the building structural dynamics (for vibration response), and acoustics of the sensitive spaces (as the receivers), [1].

Two primary strategies used for ground-borne vibrations mitigation in buildings are:

- Building Base Isolation (BBI): This method involves isolating the entire building by decoupling it from the ground at the foundation level or at least at one storey below the sensitive spaces. BBI effectively mitigates low-frequency ground-borne vibrations using elastomeric bearings or structural coil springs. Once BBI is implemented at a certain level, the entire structure above the vibration cut remains decoupled from the incoming ground-borne vibrations.
- Box-in-Box (BiB) Solutions: This technique in-

Table 1. Comparison between BBI and BiB solutions for building vibration isolation.

	BBI (Building Base Isolation)	**BiB (Box-in-Box)**
Primary Function	Reduces vibration transmission through the entire building (superstructure) above the vibration cut.	Creates an acoustically isolated space within the building by decoupling its floors, walls, and ceilings.
Efficiency Range	Highly effective in mitigating low-frequency ground-borne vibrations (e.g., from railway traffic).	Optimized for controlling high-frequency vibrations, including both airborne and structure-borne noise within the building.
Structural Adaptation & Design Challenges	The serviceability of the building, must be carefully checked under all load conditions; performance improves with increased stiffness of both the superstructure and substructure.	Effectiveness is enhanced by incorporating an independent "floating" space within the building, requires a detailed design for decoupling the floor, walls, and ceiling.
Installation challenges	Easy installation on a flat, clean surface in a protected area against water inundation, with possible fire protection requirements, for placing BBI bearings.	Precise execution is required to prevent conflicts between new elements and the existing non-isolated structure, ensuring the avoidance of acoustic bridges.
Suitability	Ideal for isolating the entire buildings with a high number of vibration-sensitive spaces, especially those in close proximity to railway infrastructure.	Best suited for buildings with a limited number of sensitive spaces, where both internal and environmental (external) noise and vibration sources need to be controlled between different areas.
Impact on Occupants	Significantly reduces both ground-borne noise and perceptible vibrations for occupants.	Effectively minimizes both vibration and noise transmission into and out of sensitive environments.

volves creating an independent, locally isolated space within the building by incorporating isolated floors, walls, and ceilings. A conventional BiB is effective particularly in controlling high-frequency noise and vibration in specific sensitive areas, such as recording studios, rehearsal rooms, cinemas, or laboratories. However, achieving higher performance against low-frequency ground-borne vibrations (GBV) may require a low-frequency isolation system combined with heavy floating floors, walls and suspended ceilings.

Table 1 presents a comparison of key characteristics and critical aspects of BBI (Building Base Isolation) and BiB (Box-in-Box) solutions for building vibration isolation:

Although Building Base Isolation (BBI) is often considered a more practical solution for mitigating train- induced vibrations, as it provides a one-time payment system to isolate the entire building at once, some projects face constraints that complicate its implementation. These challenges include the retrofitting and restoration of existing (older) buildings or cases where isolation systems are introduced late in the planning phase. In such situations, the Box-in-Box (BiB) system can serve as an effective alterna-

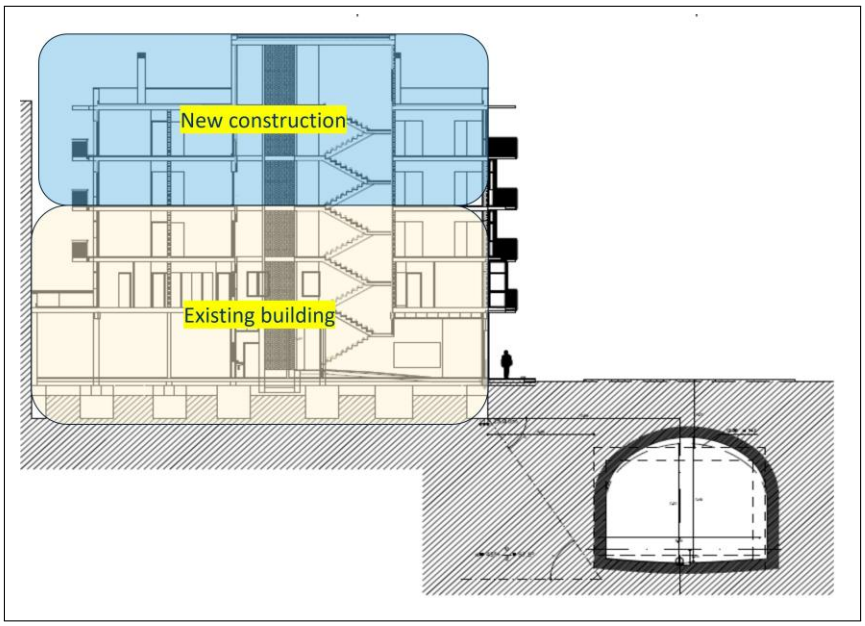

Figure 1. General overview of the building and the metro tunnel.

tive to achieve the required noise and vibration reduction.

While BiB is a viable solution, its effectiveness depends largely on high-quality installation and precise execution during construction. This case study highlights challenges which resulted in performance deficiencies in certain areas, emphasizing the critical role of execution accuracy. This paper explores the mitigation of ground-borne vibrations in a building located near a metro line through the application of a BiB system. It presents both pre- and post-construction vibration measurements, analyses the system's overall performance, and examines the key installation challenges encountered during the process.

For the evaluation of vibrations inside a building in Spain, the vibration measurement is processed according to Decree 176/2009, Annex 7 "Immission of vibrations into the interiors of buildings." The limit levels of immission established in this Annex are shown in Tab. 2, based on the building's use. The vibration levels are presented in terms of weighted acceleration level according to ISO 2631, [2].

2. CASE STUDY: ISOLATION OF NEW STORIES ON AN EXISTING BUILDING

The case study involves a residential building with a ground floor and two upper floors. The project aims to add two additional floors on top of the existing structure, resulting in a building with a ground floor and four upper floors.

Table 2. Vibration Limit Values.

Building Use	L_{aw} [dB]
Dwelling and Residential	75
Healthcare	72
Educational or Cultural	72

The building is located adjacent to a metro tunnel, which is very close to the surface (at a depth of 4 meters) and situated 6 meters away from the building's edge.

Following the vibration study and on-site measurements, the maximum recorded vibration levels on the second floor ranged between 70 and 73 dB. Although these levels are below the legal limit of 75 dB for residential buildings, as stipulated by law, the vibrations are perceptible and could cause discomfort to future occupants.

Given that structural modifications and the addition of floors could amplify vibrations due to floor resonance, potentially exceeding the limit on the upper floors. To prevent these potential risks, based on the results of the vibration study, the acoustic consultant has proposed implementing a vibration isolation system from the third floor

Figure 2. Box-in-Box solution .

upwards. The system involves using Stravitec SEB elastomeric bearings at 12 Hz on top of the third floor to isolate the new structure from the existing one.

However, in practice, the proposed BBI isolation system was introduced late in the construction planning, and instead, a Box-in-Box (BiB) isolation system was proposed to achieve the required vibration reduction.

Figure 2 illustrates a general overview of the proposed Box-in-Box system, where the base slabs are decoupled using a concrete floating floor, 80 mm thick, on elastomeric bearings at 12 Hz (Fig. 3). Additionally, the structural walls are decoupled using elastomeric strips and double gypsum with an intermediate mineral wool layer.

3. VALIDATION OF VIBRATION LEVEL

Vibration level validation was conducted in the building at the completion of construction, following the addition of two floors, to assess compliance with current regulations on vibrations from the nearby metro line L1. The objective of the study was to determine whether the renovated building, now consisting of a ground floor and four upper floors (following the addition of two floors on top of the existing structure), meets the vibration standards set by Decreto 176/2009 due to the passage of passenger trains on the adjacent metro line L1.

Since the apartments are in their final construction

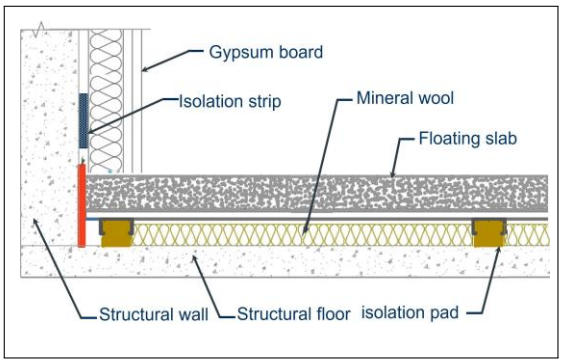

Figure 3. Section of the floating floor and the structural wall decoupling.

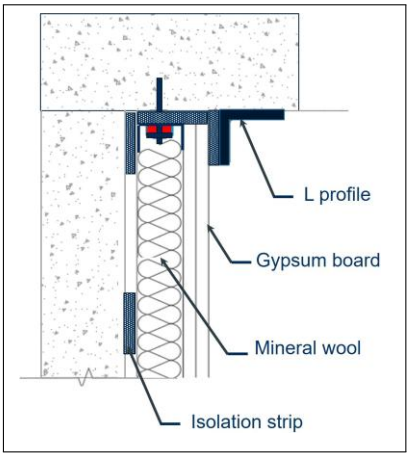

Figure 4. Section of the floating floor and the structural wall decoupling.

stage, with finished walls, floors, doors, and windows, vibration measurements have been carried out at four control points: three in the bedroom and two in the living room of the apartment closest to the metro line. These measurements were taken on each of the three floors with residential units (PL2, PL3, and PL4, as shown in Fig. 5).

A summary of the vibration measurement results is presented in Tab. 3. While the majority of measurement points across different floors of the building show compliance with current vibration regulations, one critical location— a bedroom on the third floor closest to the metro line—exhibits vibration levels exceeding the permissible limit. This non-compliance raised concerns regarding potential discomfort for occupants and regulatory adherence,

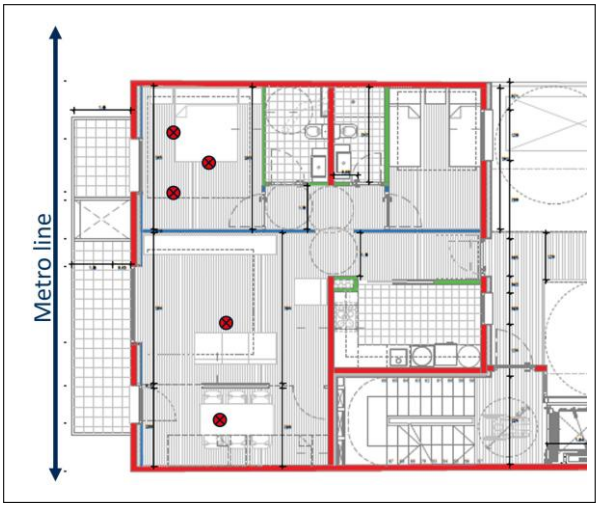

Figure 5. Measurement points in the apartment closest to the metro line.

Measurement Point	Background L_{aw} [dB]	Maximum L_{aw} [dB]
PL2 Bedroom	44.6	71.1
PL3 Bedroom	49.2	76.3
PL4 Bedroom	51.7	71.1
PL2 Living Room	44.7	73.4

necessitating a more detailed investigation.

To further assess the issue, a follow-up measurement campaign was conducted within the affected bedroom, with vibration levels recorded at four distinct points, as illustrated in Fig. 6. The results of this secondary assessment, presented in Tab. 4, indicate that while three of the measured positions remained within acceptable limits, one location continued to exceed the regulatory threshold of 75 dB.

Following this assessment, a technical inspection of the building's structural elements was carried out to identify possible causes of the elevated vibration levels. The investigation revealed the presence of a mortar bridge beneath the balcony door frame, which was likely facilitating the transmission of vibrations from the structural floor (non-isolated part) to the bedroom floating floor (see Fig. 7). This rigid connection was suspected to be a significant contributing factor to the non-compliant vibration levels in the affected area.

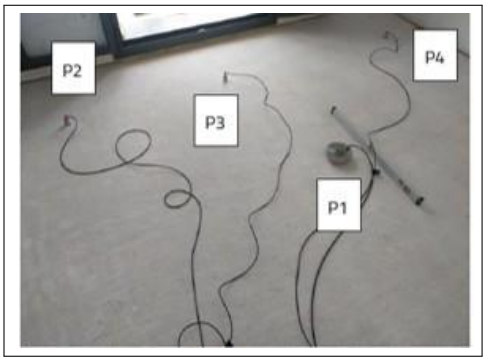

Figure 6. Measurement points in critical bedroom.

Figure 7. Acoustic bridges in critical room.

To address the identified issue, a series of corrective measures were implemented to eliminate the acoustic bridges beneath the balcony door frame. These measures involved removing the rigid connections and ensuring that no direct pathways remained for vibration transmission. Special attention was given to the interface between the door frame and the floating floor to prevent any residual mechanical coupling that could compromise the effectiveness of the isolation.

Figure 8 provides a detailed illustration of the corrective measures undertaken. Following the modifications, a repeat measurement campaign was conducted at the same four positions within the affected bedroom to verify the effectiveness of the intervention. The updated results, presented in Tab. 5, confirm that vibration levels at all measurement points now fall below the legal limit of 75 dB, ensuring compliance with current regulations.

These findings indicate that the applied mitigation measures successfully addressed the excessive vibration issue, restoring the acoustic performance of the space and minimizing potential discomfort for future occupants.

Figure 8. Removing the acoustic bridges before the final assessment.

P4 Bedroom	45.0	63.2

4. GUIDANCE AND RECOMMENDATION

The successful implementation of a Box-in-Box (BiB) system for vibration mitigation requires careful planning, precise execution, and thorough quality control at every stage of construction. Based on the findings of this study, the following key recommendations should be considered for future projects involving BiB systems in vibration-sensitive environments:

- Isolation Efficiency at low frequency: While BiB systems are generally effective for high-frequency isolation, their performance at lower frequencies—such as those typically generated by railway traffic—can be highly sensitive to the flexibility of both the floating floor and the substructure, which exhibit multiple vibration modes within the 25-30 Hz range.

  In predicting isolation performance, it is essential to consider the mobility of both the base slab and the floating floor, as their dynamic interaction can lead to practical performance deviations from those predicted by a single-degree-of-freedom (SDOF) model. This effect can result in lower vibration reduction in spaces with larger spans compared to those with shorter spans, where structural flexibility of the structural floor plays a more significant role.

- Quality Control and Inspection During Construction: Proper execution is critical to achieving the expected vibration reduction. Special attention should be given to junctions between walls, floors, and ceilings to prevent rigid connections that could bypass the isolation system.

  Frequent inspections should be conducted at key milestones, such as after the installation of the floating floor and before closing walls, to identify and rectify potential acoustic bridges before they compromise system performance.

- Effective Communication Between Architects and Contractors: Successful BiB implementation requires clear coordination and communication between the architects, acousticians, and contractors throughout the project. The architect should provide detailed construction drawings and specifications highlighting vibration isolation requirements, verified by acoustical consultant of the project. The Contractor must be fully informed of BiB system sensitivities, especially regarding structural decoupling and the avoidance of rigid connections. Regular coordination meetings should be held to review and address potential challenges, and ensure compliance with the intended design.

IMPACT NOISE HORIZONTALLY WITH 80 MM CONCRETE SLAB AND UPPER 80 MM POLYSTYRENE SPLITTED WITH CONTINUOUS POLYSTYRENE BENEATH

Bernt Mikal Larsen[1*]
[1] Multiconsult Norway, Fjellgata 6, 4612 Kristiansand, Norway

ABSTRACT

Measurement of impact noise horizontally for slab on ground has been done between different rooms in a residence building. The construction is with vinyl coating fastened with adhesive Casco Proff Extra on concrete. The thickness of the splitted concrete slab is 80 mm on 3 mm continuous thick tar coating. In administration part of the building the upper layer of 80 mm polystyrene is splitted, and the two lower layers of polystyrene beneath (total thickness 160 mm) are continuous. Corrected for the damping of the flooring (2 dB for vinyl coating with adhesive) and to receiving room volume of 100 m^3, the measurement shows 62 dB horizontally for impact noise without any flooring on the concrete. Between living room and common room the situation is with splitted concrete slab, continuous 3 mm thick tar coating and all three layers of polystyrene splitted and $L'_{n,w}$ sideways of 53-55 dB. The comparison shows that continuous tar coating does not transmit significantly impact noise horizontally or limits impact noise through the polystyrene, but that the transmission to neighbor room is through continuous layers of polystyrene.

1. INTRODUCTION

Few studies have been made in field on impact noise horizontally with concrete slab on ground and layers of polystyrene beneath [1]. This paper shows impact noise levels with splitted concrete slab and upper layer of polystyrene splitted as well as the case with splitted concrete slabs and all layers of polystyrene splitted. For all situations there is a continuous 3 mm tar coating between the concrete slab and the upper layer of polystyrene.

2. METHOD AND MEASUREMENTS

The impact noise levels were measured with tapping machine Norsonic 211 in finished building. The measurement with concrete slab and upper layer of polystyrene splitted was done in administration part of a healthcare building, while the measurement with both concrete and all layers of polystyrene splitted was done between living room and neighbor room. The results are given for bare concrete slab, corrected for damping effect of floor coating and to receiving room volume of 100 m^3. Above the concrete slab, there was vinyl coating fastened with adhesive. The damping effect of vinyl coating with adhesive is assumed to be 2 dB, as for tiles fastened to concrete with adhesive. The frequency spectrum is also given in figures for both measurements. The results are compared with paper from year 2021 [2].

3. CONCRETE SLAB AND UPPER LAYER OF POLYSTYRENE SPLITTED

The construction was as follows in the administration, where the concrete and upper layer of polystyrene were both splitted:

- Vinyl coating fastened with CascoProff Extra adhesive

- 80 mm concrete (splitted)
- 3 mm continuous tar coating
- 80 mm EPS (polystyrene splitted)
- 2 x 80 mm continuous EPS (polystyrene)

The measured $L'_{n,w}$ for this configuration was 56 dB. Corrected for floor coating and to receiving room volume of 100 m^3, the $L'_{n,w}$ is 62 dB. When only concrete slab is split with plastic film below the concrete, results from 2021 [2], showed $L'_{n,w}$ of 66 dB, which shows a reduction of 4 dB by splitting the upper layer of polystyrene and still with continuous film/coating between concrete and polystyrene. The measured result shows very good correspondance with given values in paper from 2021 [2] with similar configuration, where values of $L'_{n,w}$ for similar configuration was 58-61 dB. Difference in results could be explained by the 3 mm tar coating below the concrete for results presented here, and thin plastic film between layers of polystyrene in the measurements presented year 2021. The measurements from 2021 [2] show lower values in the highest frequencies due to a coating with much better damping effect above the concrete slab.

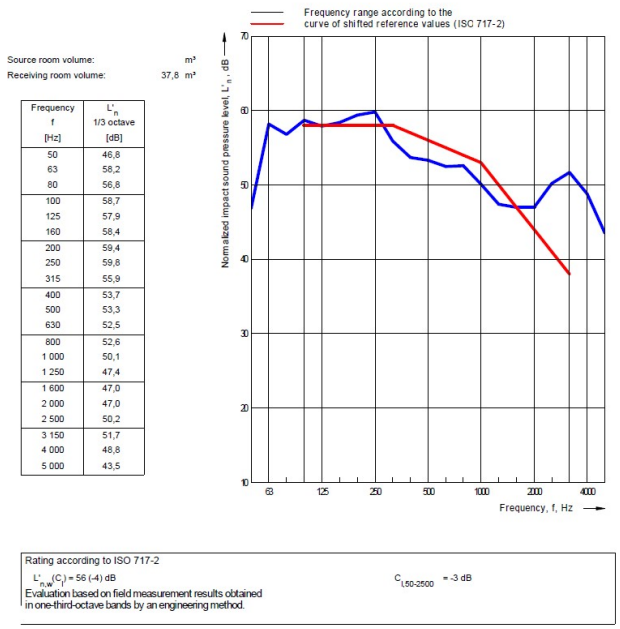

Figure 1. Impact noise level for slab on ground, with concrete and upper layer of polystyrene splitted

The reason for limited reduction in the higher frequencies is due to continuous layers of polystyrene and due to limited damping effect of vinyl coating fastened with adhesive to the concrete slab. The 3 mm continuous tar coating transfers impact noise in the frequency range from 315 to 630 Hz, in a similar way like connection points across concrete for a situation not properly splitted.

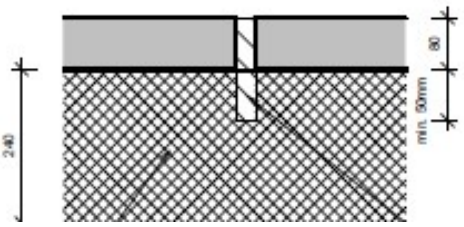

Figure 2. Splitting of concrete and polystyrene in administration part of healthcare building

The figure shows the splitted 80 mm concrete with 3 mm continuous tar coating below and splitted upper layer of polystyrene.

4. CONCRETE SLAB AND ALL LAYERS OF POLYSTYRENE SPLITTED

Between living room and neighbor room both the concrete slab and all three layers of polystyrene were splitted. The construction was as follows:

- Vinyl coating fastened with CascoProff Extra adhesive
- 80 mm splitted concrete slab
- 3 mm continuous tar coating
- 3 x 80 mm EPS (polystyrene) splitted

The measured $L'_{n,w}$ for this configuration was 48 dB. Corrected for floor coating and to receiving room volume of 100 m^3, the $L_{n,w}$ is 55 dB. The results shows very good correspondance with given values in paper from 2021 with similar configuration. There is a significant reduction of impact levels in the high frequency range due to the splitting of all layers of polystyrene. The detailed result is shown below in figure 3.

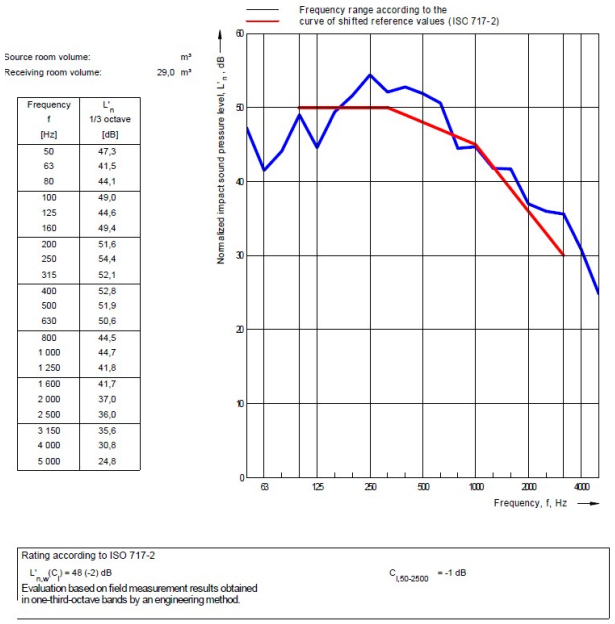

Figure 3. Impact noise level for slab on ground, with concrete and all layers of polystyrene splitted.

The result shows significant reduction in the whole frequency range, compared with the situation where only concrete slab and upper layer of polystyrene are splitted. At frequency 500 Hz the level is almost similar. From comparison of the two measurements, the continuous tar coating is seen to transmit significant impact noise in the frequency range from 315 to 630 Hz. Outside that range, the impact noise levels are at least 10-15 dB lower when the construction is splitted down to the ground. The splitting for results in figure 3 is shown below in figure 4. Comparison with similar splitting and plastic film between layers of polystyrene in [2] proves that the high levels in frequency range 315-630 Hz are transmitted through the continuous 3 mm tar coating below the concrete.

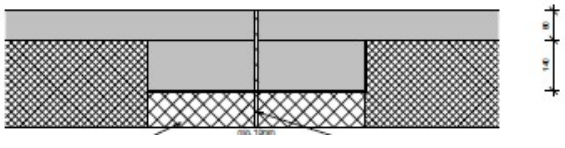

Figure 4. Splitting between living rooms.

There was also a measurement with splitting of concrete and all layers of polystyrene, but with continuous pipes of plastic for water and heating in the first and second layer of polystyrene. The result of this measurement is given in figure 5.

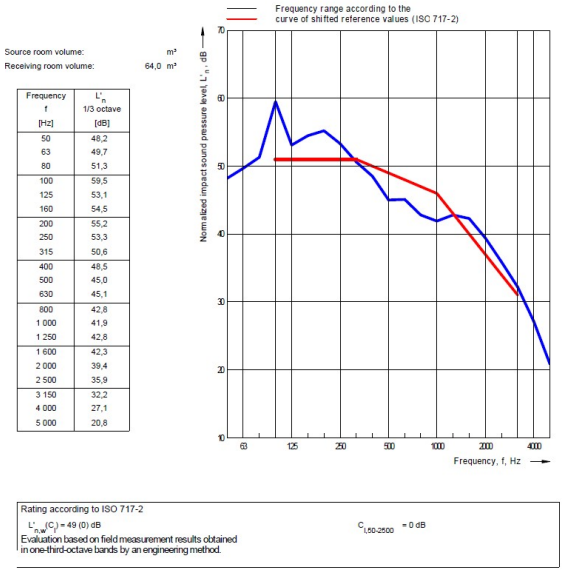

Figure 5. Impact noise level for slab on ground, with concrete and all layers of polystyrene splitted. Water pipes of plastic are continuous 5 cm down in upper layer of polystyrene, while heating pipes of plastic are continuous in the second layer of polystyrene.

The result in figure 5 corrected to 100 m3 is $L'_{n,w}$ of 53 dB, and shows that continuous pipes in the polystyrene will not increase horizontally impact noise.

5. CONCLUSION

The measurements done for concrete slab with 3 mm tar coating below the concrete and splitted upper layer of polystyrene shows very good correspondance with similar measurements in 2021 [2]. With splitting of concrete and upper layer of polystyrene, $L'_{n,w}$ is 62 dB compared with 58-61 dB from the measurements in 2021. The difference of 1-4 dB is supposed to be due to transmission through continuous tar coating and because earlier measurements had plastic film between splitted and continuous layers of polystyrene. When concrete and all layers of polystyrene are splitted (but with continuous tar coating and continuous

pipes of plastic in the polystyrene), $L'_{n,w}$ horizontally is 53-55 dB, which is similar with measurements summarized in [2] with continuous foundation below the layers of polystyrene. The correspondance with earlier measurements confirms that it seems to be correct with 2 dB damping effect of vinyl coating fastened to concrete slab with adhesive. The situation with continuous tar coating below the concrete and continuous foundation below all layers of polystyrene both give the same value of sideways $L'_{n,w}$.

5.1 Effect of continuous tar coating below the concrete

The measurements show that with polystyrene splitted to the ground, a continuous 3 mm tar coating (and continuous pipes for water and heating) seems not to limit achieved $L'_{n,w}$ of 53-55 dB compared with earlier results for similar configuration [2] when there is continuous foundation below splitted layers of polystyrene. It seems that the dominating impact noise horizontally is through the continuous layers of polystyrene. In Norway the need for continuous tar coating is critical in areas with radon gas. The measurements show that such a solution may be used to achieve good results for impact noise. The continuous tar coating below the concrete is not thought to limit single-value of horizontally impact noise, because reduction from 62 to 53-55 dB is achieved only by splitting more layers of polystyrene. Because the impact noise level is similar (1-4 dB difference) with only concrete slab and upper layer of polystyrene splitted with earlier experience [2], there is no reason to assume that continuous 3 mm tar coating transfers significant impact noise sideways. It seems that the tar coating transfers impact noise in the frequency range from 315 to 630 Hz, by comparing figure 1 and 3. This is confirmed by comparing the levels in figure 1 with earlier measurements where concrete and first layer of polystyrene are both splitted and a with a plastic film below the upper layer of polystyrene which shows lower levels in the range 315-630 Hz. From earlier measurements with all layers splitted to the ground [2] and $L'_{n,w}$ 46 dB, a continuous tar coating below the concrete seems to give 7-9 dB higher value sideways than with all layers splitted.

5.2 Meaning for future projects

The experience shows that it is possible to achieve limits in Norwegian rules with a continuous tar coating below concrete slab, which may be necessary due to radon gas from the ground. With splitting of layers of polystyrene and proper floor coating, this kind of solution may both give low impact noise levels, and good sound insulation between apartments. The achieved R'_w for the situation with concrete slab and all three layers of polystyrene splitted was 64 dB. The sideways $L'_{n,w}$ with concrete splitted, continuous 3 mm tar coating and upper layer of polystyrene splitted corresponds very well with earlier measurements and experience.

6. SUMMARIZING POEM

Impact noise to the side is transmitted
Even though flooring on top is splitted
Below the concrete a continuous tar coating
On upper splitted polystyrene is floating
The result for splitted polystyrene was like expected
Effect of continuous tar coating – to be neglected

Continuous polystyrene gives impact high
Measurements show we cannot deny
The reduction is big for the impact sound
When polystyrene is splitted to ground

7. ACKNOWLEDGMENTS

May I give my biggest acknowledgements to Kristiansand kommune, who allowed me to present results from measurements in their building with valuable information on impact levels from slab on ground.

PREPARATORY WORK TOWARD EXPERIMENTAL ESTIMATION OF WATER EXCITATION TERMS IN WASTEWATER SYSTEMS

Yohko Aoki[1*] **Sven Öhler**[1] **Bernd Kaltbeitzel**[1]
[1] Fraunhofer Institute for Building Physics IBP, Department Acoustics, Stuttgart, Germany

ABSTRACT[*]

Structure-borne sound generated by wastewater pipe systems often dominates noise emissions from sanitary installations in buildings. This paper presents a preparatory investigation aimed at estimation of the water excitation terms by the inverse method. The experimental setup followed EN 14366-1:2023 and the vibration response of the pipe was quantified in terms of the blocked force at the wall fixing points. Noise from wastewater systems is generated by turbulent annular flow and the impact of water at the inlets, tees, and bends. These excitation terms were estimated through a methodical, stepwise approach. First, a customized impact-free inlet was installed to the pipe to eliminate water inlet effects, and thus the annular flow served as the primary excitation source in a straight pipe configuration. Subsequently, the impact of the flow turning elements was evaluated. The numerical model of the drainpipe was then introduced and experimentally verified. Using this model, the inverse method was tested to indirectly identify the applied force acting on the pipe. These presented results serve as the essential basis toward the development of a mathematical model of the stochastic water loads applied to the pipes.

Keywords: *drain pipe, structure-borne noise, EN 14366-1*

1. INTRODUCTION

Wastewater noise is often a problem in adjacent rooms in buildings. When water flows through the pipe, running water induces the pipe vibrations. Due to the connection of the pipe system to the installation wall with fixing elements, like pipe clamps, the vibrations are led into the building structure, and consequently, radiated as airborne sound.

Knowledge of flow induced force magnitudes and its predominant frequency is crucial for designing acoustically optimized drainpipes. The drainpipe system is generally not designed to be fully filled with water, to minimize the risk of backflow or overflow. Instead, the flowing water adheres to the inner walls of the pipe, creating a thin film of water with small air bubbles, while air continuously flows through the central region of the pipe. This type of axial two-phase flow pattern is classified as annular flow [2]. The turbulent annular flow causes the unsteady random wall pressure fluctuation. Furthermore, geometrical discontinuities at flow-turning pipe elements such as bends, inlets and tees also have a substantial impact [3]. Finally, the pressure fluctuation on the wall and impact at flow-turning elements causes vibrations on the pipe wall and the system itself.

Simulation of two-phase gas-liquid flow in pipes requires considerable computational efforts due to its great complexity, and thus a large degree is still not characterized by modern-day fluid dynamic models [4]. It is also difficult to experimentally identify the stochastic water excitation terms by transducers. Numerous attempts were made to numerically and experimentally determine the force excitation at the bend and discontinuing element of the pipe [5], however, yet comprehensive analytical model of the water excitation is not available.

On the other hand, the vibration response of the pipe can be conveniently measured [6]. Under these circumstances, indirect methods are preferred, where the input of a system, i.e. water excitation, is reconstructed from its output by inverting the model of a mechanical system. Considering that the water flow is primarily influenced by the internal geometry of the pipe and the friction factor of the inner wall, while the interaction to the pipe vibration is relatively weak, the water excitation term remains unchanged for pipes with comparable geometries and friction factors. Thus, the identified water excitation is applicable to other pipe systems with similar inner geometries and friction

factors, such as the same pipe configuration but are constructed from new materials like biopolymers or recycled polymers.

A key objective of this study is to establish a methodology for identifying the excitation water force for adapting the excitation model to changes in pipe geometry. This paper presents preparatory work to develop a mathematical model of the stochastic water loads applied to the pipe, using both the experimental responses of the pipe system and a computational dynamical model. First, the experimental setup designed to separate each water excitation term is described, followed by a discussion of the measured results. The numerical model of the drainpipe system is then introduced and experimentally verified. Finally, the inverse method was applied to this numerical model with the measured response to identify the applied point force.

2. PHYSICAL ARRANGEMENT

Figure 1 shows the setup of wastewater systems at the Fraunhofer Institute for Building Physics IBP in Stuttgart. The pipe is made of PP-MD (polypropylene with mineral additives, density 1.7 kg/m^3) with the outer diameter of 110 mm, and the wall thickness of 3.2 mm. The steel pipe clamps with rubber inserts connect the pipe to the installation wall with M10 screws.

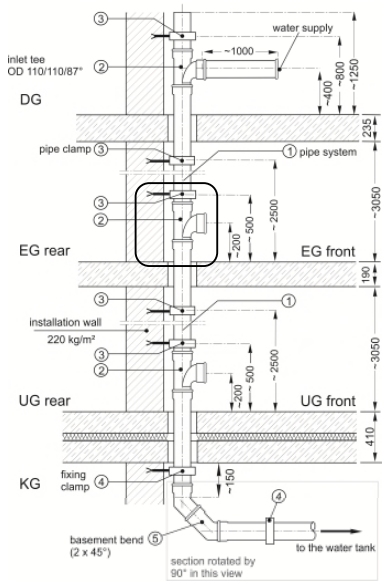

Figure 1: Test facility with the standard wastewater system set-up at Fraunhofer IBP, Stuttgart for measurements according to EN 14366-1:2003 [1].

The structure-borne and air-borne noise measurements are performed according to EN 14366-1:2003 [1]. The test facility is specially designed for measuring very low sound levels and can be used to test all types of domestic installations under practical conditions. The installation wall in the test facility has a surface density of 220 kg/m² and thus corresponds to the lightest single-shell solid wall permitted for mounting sanitary installations according to the German Standard DIN 4109 without special proof of suitability. These wall properties also comply with the specifications of EN 14366-1:2003 [1].

2.1 Blocked Force

Since wastewater systems are connected to the installation wall solely through six clamping points, the vibration response of the pipe was assessed in terms of the forces at these contact points. The contact force between the *i*-th pipe clamp and the installation wall was measured using a force transducer placed between the wall and the clamp (see Fig. 2). Two accelerometers were positioned on the wall near each fixing screw to measure the wall velocity. With this configuration, the power transmitted from the pipe system to the wall via the clamp can be quantified as the real part of the cross-power spectrum of the contact force and the velocity.

The RMS values of the blocked force level at *i*-th clamp position, expressed in dB reference to 10^{-6} N, was indirectly determined using the measured *i*-th installed power, $L_{Ws,i}$, and the pre-determined mobility of the test wall, Y_R [7].

$$L_{Fb,i} \sim L_{Ws,i} - 10 \log_{10} \mathrm{Re}\left\{\frac{Y_{R,i}}{Y_0}\right\} \quad (1)$$

where Y_0 = 1 m/sN, the reference value of mobility. The installed power L_{Ws} is expressed in decibels relative to the reference nominal power W_0 = 10^{-12} Nm/s. The blocked force on the installation wall can be used as an input to estimate the structure borne noise in the adjacent rooms [7].

Figure 2. A force transducer and two accelerometers on the installation wall.

2.2 Separation of Excitation Sources

As shown in Fig. 1, the standard pipe system extends four floors. The system consists of the straight pipes with the water inlet in the attic ('DG' in Fig. 1), two tees (closed with a lid) situated on the ground and the underground floors ('EG' and 'UG'), and the bend with 2 x 45-degree angle in the basement ('KG').

The excitation sources of this pipe are separated into the following four components: (1) turbulent water flow on the pipe wall, (2) impact force at the water inlet, (3) waterfall at the tee on EG and UG, and (4) waterfall on the basement bend. It is assumed that the air-borne noise generated by the system doesn't influence vibrations of the pipe. To effectively isolate each excitation source, the pipe setup needs to be modified from the standard arrangement.

2.2.1 Tees and basement bend

To eliminate the effects of the tees, each tee can be replaced with straight cylindrical pipes of the equivalent length. Similarly, the basement bend can be decoupled from the system and replaced by a bend with a larger diameter than that of the pipe system, to ensure no physical contact between the bend and the upper drainpipe. A thin waterproof membrane loosely covers the lower end of the drainpipe system to prevent splashing water falling onto the bend (see Fig. 3).

The flow impacting the disconnected basement bend generates noise, which may be comparable to or exceed the excitation caused by the turbulent water flow. To suppress airborne noise from the bend, the bend is covered by mass-loaded pipe insulation. The laboratory measurements indicated that the vibration caused by the airborne noise from the insulated bend is at least 10 dB lower than that caused by the turbulent annular flow.

Figure 3: The decoupled basement bend covered by mass-loaded pipe insulation with the loose waterproof membrane cover.

2.2.2 Impact-free inlet for laboratory testing

The impact-free inlet (see Fig. 4) was designed for the laboratory tests presented in this paper to eliminate the effects of water hammer caused by the water inlet. This inlet consists of a thin metal pipe with a closed-end short cylinder. The metal pipe is inserted into the cylinder and welded to its bottom cap. Near the welded edge, three rectangular openings are formed, each measuring 10 mm by 20 mm with rounded corners. The total opening area exceeds 600 mm², which is larger than the inner cross-sectional area of the metal pipe (560 mm²), ensuring smooth water flow from the metal pipe to the cylinder. Finally, the cylinder with the metal pipe is inserted into the drainpipe to a depth of 325 mm from the top and is carefully positioned at the center of the drainpipe. This impact free inlet was first fixed to the 20 mm wooded board, and the board was fixed to a separate wall section via 25 mm of elastomeric material, made of polyurethane foam. The inlet has no direct contact to the main drainpipe to prevent the structure borne excitation from the flow conditioner to the drainpipe.

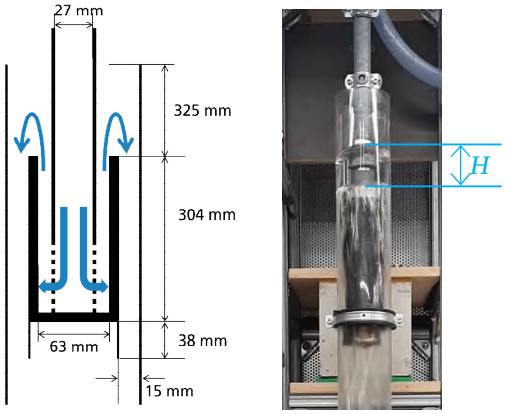

Figure 4: (a) The design of the impact-free inlet, (b) photo the impact-free inlet during operation.

Initially, water flows through the metal pipe and then flows into the cylinder through the side openings. In the cylinder, water runs upward, and then spills over from the upper opening of the cylinder. Finally, water moves into the gap between drainpipe and the cylinder. To prevent water from flowing to the back side of the bottom cap and dripping off, the outer wall of the cylinder is vertically extended by 38 mm using a thin metal sheet.

The flow conditioner begins functioning at a flow rate of 0.7 l/s and operates stably above 1.0 l/s. At flow rates below 0.7 l/s, water tends to flow along the cylinder wall rather than the drainpipe wall. Additionally, due to the constraints of the inner pipe's size, the maximum achievable flow rate

is limited to 3.0 l/s. Therefore, in this study, the water flow rates examined are 1.0 l/s, 1.5 l/s, 2.0 l/s, and 3.0 l/s, while the common flow rates of 0.5 l/s and 4.0 l/s [1] were not included in the measurements.

2.3 Water Velocity

When the volume flow rate exceeds approximately 1.0 l/s, the upward water in the cylinder flows beyond the top edge of the cylinder and fills the drainpipe above. The surface of the filled water is softly rippled due to the upward water flow underneath, but the height remains relatively constant over time. Table 1 summarizes the measured filled heights from the upper edge of the cylinder, shown as H in Fig. 4 (b). Starting from this upper surface, the flow continues to accelerate due to gravity until it reaches a terminal point, where the gravitational force is equal to the wall shear stress. The velocity at this point is referred to as the terminal velocity. According to [8], the terminal velocity of the annular flow, v_t, and the vertical distance required to achieve terminal conditions, d_t, are respectively expressed by the following formulas:

$$v_t = \left(\frac{1}{n^2}\frac{1}{\pi^{\frac{4}{3}}}\right)^{0.3}\left(\frac{Q_w}{D}\right)^{0.4} \quad (2)$$

$$d_t = \frac{1.42}{g}v_t^2 \quad (3)$$

where Q_w is the volume flow rate, D is the inner diameter of the drainpipe, and g = 9.81 m/s^2. The coefficient n is related to the surface roughness suggested by Manning and was set to 0.007 in this study [8]. The predicted values for each flow rate are summarized in Table 1.

Table 1. The terminal velocity v_t, the terminal distance d_t, and the filled height H with reference to the flow rate.

Flow rate	v_t [m/s]	d_t [m]	H [m]
1.0 l/s	3.89	2.2	0.02
1.5 l/s	4.31	2.7	0.04
2.0 l/s	4.63	3.1	0.075
3.0 l/s	5.12	3.8	0.13

The terminal point, at which the flow reaches terminal velocity, should be measured from the upper surface of the filled water, where the vertical velocity of the water is zero. As the filled water prevents air from being drawn in or released from the pipe, the water in the narrow gap between the cylinder and the drainpipe flows without air, at least partly. In this region, the acceleration of the flow is zero, i.e., constant velocity due to mass conservation law. Therefore, total the length of the cylinder with the extended cover, 342 mm, should be added to the distance calculated by Eqn. (3). The terminal point is explicitly shown in the Fig. 5 for each flow rate. These heights are valid for the pipe system using the impact free inlet, but not for the standard pipe setting.

It must be noted that terminal conditions are strongly influenced by the surface roughness of the pipe, n, which depends not only on the material, but also on manufacturing process and the environmental factors. The applied value n = 0.007 is appropriate for the very smooth surface. When the actual surface roughness is higher than the applied value in this paper, the terminal velocity decreases and thus the flow reaches the terminal condition at higher position than drawn in the Fig. 5. Therefore, the presented values in Table 1 should be regarded as the upper limit rather than definitive values. Nevertheless, this estimation indicates that the flow velocity is rather constant in the underground section, while the flow continues to accelerate on the ground floor.

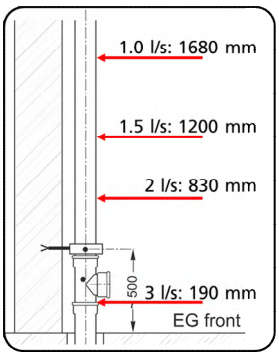

Figure 5: The magnified view of Fig. 1 around the ground floor with the position reaching terminal velocity for each flow rate.

3. EXPERIMENTS

Three different pipe arrangements were tested with four different flow rates. The 1st configuration is the standard model (shown in Fig. 1) with all flow turning elements, while the straight drainpipe, the 2nd configuration, is composed of the straight cylindrical components only. The water runs into the pipe from the impact free inlet, and the bend is disconnected. Under this configuration, the straight pipe is excited only by the annular turbulent flow. The 3rd model is composed of the straight pipe with a tee on the ground floor.

3.1 Straight Pipe

Figure 6 shows the blocked force of the straight pipe at four clamp positions on EG and UG with the flow rate of 2.0 l/s, which empirically exhibited the highest repeatability.

For all cases, the blocked force keeps decreasing with minor oscillations as frequency rises. In the absence of additional pipe components, the blocked force values at all four clamp positions were comparable. Particularly, the forces measured at clamps on the underground floor (green and black curves) overlaps quite well across the entire frequency range. The red curve shows slightly lower values than these two overlapping curves, while the blue curve was again slightly below the red curve. It comes from the fact that the flow reached the terminal velocity near the ground level of the ground floor. According to Fig. 1, the 2.0 l/s flow reaches the terminal velocity at around 300 mm above the lower clamp position on the ground floor. Therefore, the speed of the annular flow in the pipe was constant over the vertical direction in the underground floor, while the flow still accelerates in the upper section of the ground floor.
The sharp drop of the red curve around 2 kHz may come from the weak contact of the accelerometer on the wall with the surface coating. It is expected that the red line remains between the blue and black lines.

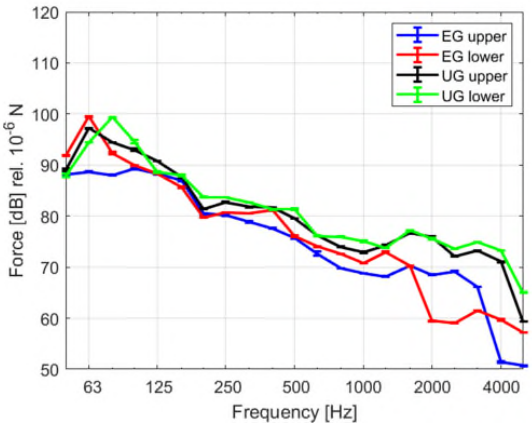

Figure 6: The blocked force of the straight pipe (#2) on four clamp positions on EG and UG with the flow rates of 2.0 l/s.

3.2 Maximum Achievable Reduction

Four plots in Fig. 7 visualizes the difference between the blocked force of the standard pipe (#1) and that of the straight pipe (#2) at four clamp positions. The difference of the blocked forces reaches even above 15 dB at every position, because the standard pipe has additional excitation sources to the straight pipe, such as an inlet, tees and a bend. The difference highlights the potential for maximum achievable reduction by optimizing the geometry of these flow-turning elements, to the point where the excitation forces are theoretically reduced to zero. Although this is not feasible, Fig. 7 represents the upper limit of possible reduction.
The difference varies with the flow rate and frequency, but in general is more prominent at the low flow rate and low frequency. Above 2 kHz, the difference is diminishing. It indicates that the annular flow dominates the vibration of the pipe, or at least the annular flow is comparable with other excitation sources.

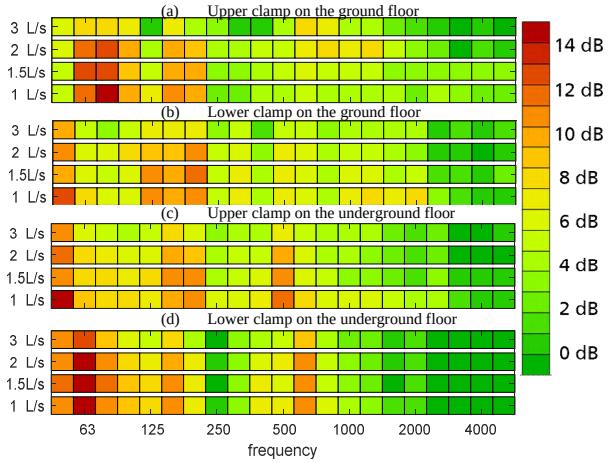

Figure 7: The difference between the blocked force of the standard pipe (#1) and that of the straight pipe (#2), measured on the upper (a, c) and lower (b, d) clamps on the EG (a, b) and UG (c, d) with different volume flow rates.

3.3 Effect of the Tee

Figure 8 shows the difference between the blocked force of the straight pipe with (#3) and without (#2) the tee on the ground floor. The effect is most prominent in plot (b): the blocked force at the clamp located only 300 mm above the tee. The peak appears around 1.5 kHz, and the effect is stronger with low flow rate. The effect also clearly visible in Plot (c): the adjacent clamp located approximately 1000 mm away from the tee in the downstream. The affected frequency range becomes broader, particularly towards lower frequency. It indicates that the effect of the tee is not only the local impact, but also the flow distortion toward downstream. When water flows through the pipes with the tee, the tee is partially filled with water, and thus the water movement around the circular perimeter of the tee is not uniform. Finally, the tee causes the flow disruption.
On the other hand, the tee effect is only fairly visible at the first clamp, which is located approximately 2 m above the tee. The effect is similar to that of the nearest clamp, but much lower amplitude, because the impact propagates

along the pipe with energy loss. On the furthest clamp in plot (d), the effect of the impact is merely visible. Only broadband effect is slightly visible at the lowest flow rate of 1 l/s. It indicates that the length necessary for the flow to stabilize again after the tee disruption varies with the flow rate. It probably comes the different film layer thickness. Theoretically, the layer thickness at the terminal velocity depends on the flow rate [8] and reaches 1 mm (1 l/s) to 2 mm (3 l/s). With low flow rate, this thin film does not fully coat the entire inner surface of the pipe; instead, it only partially covers it. When the water layer is thicker, the effect of the disruption can be quickly recovered.

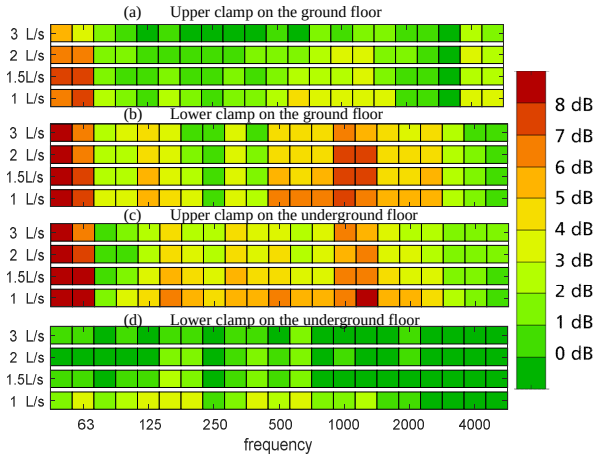

Figure 8: The difference between the blocked force of the straight pipe (#2) and that of the straight pipe with the tee on EG (#3) in dB, measured on the upper (a, c) and lower (b, d) clamps on the EG (a, b) and UG (c, d) with different volume flow rates.

4. NUMERICAL MODEL

In addition to the experiments, a detailed numerical model of a drainpipe was built by the commercial Finite Element (FE) software COMSOL (version 6.3) to simulate vibration due to structural excitation. However, direct measurement or CFD simulation of the random dynamic loads generated by the turbulent flow within the pipe is very challenging [4]. Therefore, it is necessary to indirectly identify the random dynamic loads from the measured blocked force with the aid of the numerical model.

The identification of stochastic loads applied to dynamical systems using uncertain computational models with experimental data is a classic but still active topic [9]. This problem is challenging, because the inverse method often amplifies both numerical model uncertainties and experimental data uncertainties, resulting in inaccurate solutions. Therefore, numerous papers have been published focused on robust identification methods to suppress the impact of uncertainties. Nevertheless, the final reconstructed load heavily relies on the quality of the numerical model. A FE approach is a promising solution to construct a reliable detailed model of the dynamic system. However, it is computationally extremely complex to model all the details of the drainpipe. Furthermore, even a finely constructed numerical model cannot reproduce exactly the real behavior of a structure due to limitations of the model itself.

Therefore, the following simplifications were applied to the model to keep a balance between simulation accuracy and computational efficiency: (1) The pipe structure is modelled by shell elements, while the screw is modelled by solid elements. (2) The pipe is fixed to the impervious rigid wall. Although the mobility of the installation wall affects the measured results particularly at low frequency, they are essentially not related to the acoustic performance of the drainpipe. (3) Air-borne noise, both the noise in the pipe and the radiated sound from the pipe the room, is ignored. (4) the pipe clamp with the rubber inlay is modelled by the single layer shell with the equivalent damping of two layers.

4.1 Experimental Verification

The developed FE model should be verified with reference to the experimental data obtained from the actual structure to assess its predictive capability. Instead of stochastic water excitation, the deterministic point force generated by a small inertia shaker was applied to the pipe. The shaker was attached to the pipe on 300 mm above the ground on the 1st floor (‘DG’ in Fig. 1) via the 2 mm thick steel clamp and was oriented normal to the wall (see Fig. 9). The shaker was driven by the band limited pink noise, and the exerted force was measured by the force transducer attached between the shaker and the pipe clamp.

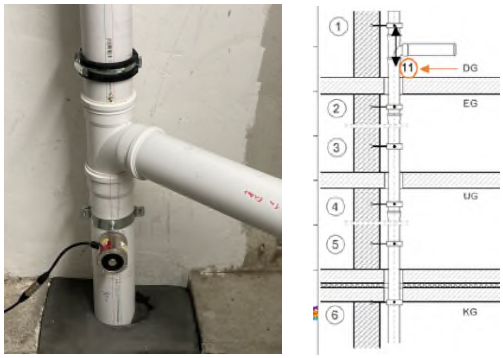

Figure 9: The configuration of the pipe with the attached shaker.

The measured exerted force by the shaker was used as input force in the FE model. The material parameters of the pipe are summarized in Table 2, while the geometrical parameters are visualized in Fig. 1. The Young's modulus of elesticity and the loss factor of the pipe were experimentally identified by the modal analysis using a 2 m long pipe piece. The vibrations of the pipe were simulated in 1/24th octave band frequency resolution between 44 Hz and 1.4 kHz, which are respectively the lower and the upper frequency limits of the octave band, centered at 62.5 Hz and 1 kHz.

Figure 10 compares the measured (black) and simulated (red) blocked forces at the lower clamp on the ground floor. Although some discrepancies are observed, particularly at low frequencies below 100 Hz, the overall agreement is substantial in terms of both amplitude and peak frequencies. The narrowband spectra show that most peaks and dips are accurately represented by the simulation, although minor shifts in peak frequencies are noticeable.

Table 2. Material parameters of the drainpipe systems used in the FE model

Parameter	Pipe	Clamp
E-modulus	3.92 GPa	200 GPa
Poisson ratio	0.3	0.3
Density	1700 kg/m^3	7850 kg/m^3
Loss factor	0.055	0.1

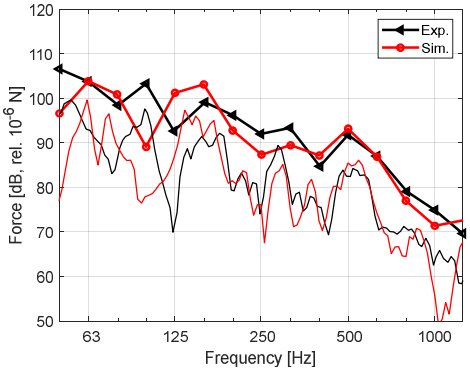

Figure 10: Comparison of the measured (black) and the simulated (red) blocked force at the lower clamp on EG.

4.2 Inverse Determination of the Point Force

As the simplest case study for the verification of the inverse method, the pipe system in the previous section is considered. The applied point force is identified through an inverse analysis using the FE model and the measured blocked forces. The accuracy of the identified primary force can be readily assessed by comparing it to the measured primary force.

The blocked force at i-th clamp position, f_{bl}^i, can be expressed as follows:

$$f_{bl}^i(\omega) = H^i(\omega) f_p(\omega) \tag{4}$$

where H^i is the transfer function between the point force and the i-th blocked force, and f_p is the point excitation force. The transfer functions of the FE model can be easily obtained from the simulation results with trivial primary force, such as, f_p = 1 N. Solving Eqn. (4) under the given boundary condition, e.g. the measured blocked force, leads to the unknown point force, f_p. The Least Square Method (LSM) is used to compute the frequency-dependent point force, f_p, by minimizing the sum of the differences between the measured and simulated blocked forces.

$$\epsilon = \sum_{i=1}^{6} \left| f_{bl,\,m}^i(\omega) - H_s^i(\omega) f_p(\omega) \right|^2 \tag{5}$$

where the subscript m and s denotes "measured" and "simulated", respectively.

This is a straightforward approach without any advanced methods to enhance its robustness against uncertainties. As shown in Fig. 11, the predicted point force (blue curve) doesn't align well with the measured applied force, though the simulated values fluctuate around the measured values. Both numerical model uncertainties in H^i and experimental data uncertainties of $f_{bl,m}$, result in inaccurate prediction of the primary force.

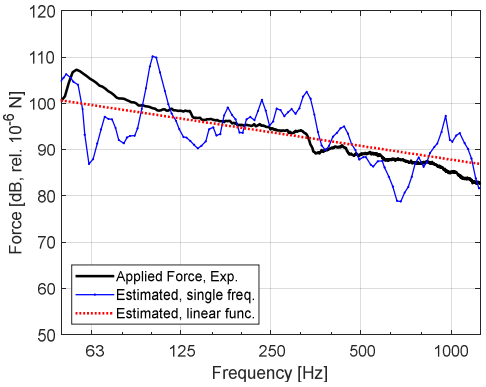

Figure 11: Comparison of the measured excitation force by the shaker (black), and the estimated point force by the direct inverse method without (blue with dots) and with the predefined excitation function (red dotted).

To improve the prediction accuracy, additional constraints must be imposed on the model. Assuming that the primary force is a linear function in double logarithmic scale,

$$f_p(\omega) = b \cdot \omega^a \tag{6}$$

the coefficient *a* and *b* can be estimated by the LMS method. The estimated point force was plotted by the red dotted line in Fig. 11. The agreement was significantly improved. The gradient of the predicted force in double logarithmic scale was -2.96 dB per octave, which is very similar to the pink noise characteristics. This case study proves that the inverse method can predict the input excitation terms using the FE model of the drainpipe and the measured blocked forces, but additional constraints are crucial for reliable results.

5. CONCLUSIONS

This paper presented preparatory work to develop a mathematical model of the stochastic water loads applied to the pipes.

Through experiments, the impact of each excitation source was separately investigated, and their contributions were quantified. The excitation terms generated by water flow within the drainpipe was separated by using the impact-free inlet as well as the decoupled or replaced flow turning elements. The analysis highlighted the significance of annular flow at high frequencies, while flow turning elements have significant influence at low frequency. Their effect is more prominent with low flow rates.

The three-dimensional finite element (FE) model of the drainpipe was developed and demonstrated a good agreement with measured blocked forces. Using this FE model, the inverse method was tested to identify the point force acting on the pipe. By incorporating additional constraints, the primary force was predicted with high accuracy. This approach emphasizes the importance of additional constraints to improve the accuracy of the results. Although the point force itself is considered deterministic rather than stochastic, this study verified the applicability of the inverse method with the measured blocked force and the developed FE model.

Future work will focus on the development of a mathematical model of the stochastic water loads applied to the pipe using both experimental responses of the pipe system and a computational dynamical model of it. The water excitation and structural response are regarded as a stochastic process and should be described in the form of a power spectrum density (PSD). To derive appropriate additional conditions for the inverse method, it is essential to measure the homogeneous flow velocity, because these parameters are known to influence the turbulence, the impact force, and its peak frequency [2]. Additional measurements are planned to assess the effect of other flow turning elements.

FH-IPTOOLS: PREDICTING WASTEWATER NOISE IN TIMBER CONSTRUCTIONS - A PROJECT INTRODUCTION

Tobias Kruse[1*] **Andreas Mayr**[1] **Ulrich Schanda**[1]
Fabian Schöpfer[1]
[1] Rosenheim Technical University of Applied Sciences, Germany

ABSTRACT

The research project FH-IPTOOLS is a joint project between Rosenheim Technincal University of Applied Sciences (THRo) and the University of Applied Sciences Döpfer (HSD) in collaboration with industrial partners and timber construction associations. The aim is to develop prediction tools for sound insulation, focusing on acoustic comfort and the perception of noise from technical service equipment. The project focuses on wastewater systems in timber and lightweight constructions.
Concepts need to be developed to ensure that acoustic comfort is taken into account in the design process. HSD is working on the psychoacoustic aspects. Signal detection theory will be used to formulate suitable evaluation methods to assess noise from building service equipment. Listening tests and field measurements will be used to develop criteria for sound insulation in timber construction to improve acoustic comfort.
As part of the project, structure-borne sound characterisation will be carried out at THRo on a reception plate test rig. Therefore a reception plate with similar properties to timber frame constructions will be used. The aim is to develop methods for the direct measurement of structure-borne sound power in timber and lightweight constructions, while also determining airborne sound power. Initial results will be presented in the paper.

1. INTRODUCTION

Timber constructions are in the focus of the transition towards sustainable and energy-efficient buildings. Sound insulation is a key issue, as it is crucial for the acceptance and perceived quality of timber buildings. However, regulatory uncertainties and the lack of planning tools hinder the reliable prediction of acoustic comfort, particularly with regard to noise from building service installations, such as wastewater systems. These systems can exhibit an increased disturbance potential in timber and lightweight structures. The latest revision of DIN EN ISO 12354-5 [1] provides prediction methods for estimating the sound pressure levels in receiving rooms due to service equipment. In most cases however, the source input data required for such predictions are not available. In addition, predictions are not suitable to describe the subjective perception of disturbance experienced by occupants.

2. PROJECT INTRODUCTION

The research project FH-IPTOOLS (”Research in Timber Construction for Engineering-Based and Psychoacoustically Validated Planning and Advisory Tools for Sound Insulation”) is a joint initiative between THRO and HSD in close cooperation with renowned industry partners. The primary objective is to develop engineering-relevant and psychoacoustically validated methods that enable a reliable prediction and optimisation of acoustic comfort in timber and lightweight buildings. The project covers the whole acoustic transmission chain. This starts with the sound source (with a focus on wastewater systems), then energy transmission into the building structure, propagation within the building, and finally perception and assessment by the occupants. Building acoustics measurements

are carried out under real building conditions to compare with the applicable normative requirements, while simultaneous binaural recordings are performed for listening tests aiming psychoacoustic evaluation.

2.1 Project targets

HSD is focusing on the development of psychoacoustically based assessment methods. These methods reliably predict the subjective perception of acoustic comfort by building occupants. Technical and psychoacoustic parameters are combined to establish an evidence-based prediction model that provides realistic and reliable estimates of the expected acoustic quality. In collaboration with partners from industry, legally robust and practice-oriented tools for prediction and consultancy that can be used by construction companies, designers and users are developed. These tools aim to contribute to the acceptance and quality of sustainable timber buildings. THRo focuses on the characterisation of wastewater systems specifically for the application in timber constructions. This includes the use of methods introduced in EN 15657:2009-10 [2]. New measurement techniques for the indirect determination of the structure-borne sound power under installed building conditions will be developed. ISO 20270:2019 [3] already provides methods for the indirect measurement of the installed source power and these may also be applicable within building environments. However, the associated measurement effort is considerably great compared to conventional building acoustics measurements. For prediction purposes, a technically simplified method with acceptable uncertainties is derived from the existing procedure. Also, the project will identify and quantify the acoustic optimisation potential of wastewater systems in timber frame buildings.

3. TEST RIG

To determine the spatially averaged vibration velocity on the surfaces of conventional timber frame building elements is a challenging task. Structural inhomogeneities, caused by stiffening timber frames and multilayer claddings, lead to significant fluctuations in the spatial distributions of velocity levels [4–6]. Therefore, in an initial methodological development phase, an idealised receiving structure is employed. This structure is intended to exhibit vibro-acoustic characteristics comparable to those of typical timber frame constructions. The driving-point mobility of such an idealised reception plate

Figure 1: Test Rig showing the 15 mm perspex reception plate coated with a highly reflective surface layer (silver-grey) in combination with a 3D Laser Scanning Vibrometer.

should lie within a similar order of timber frame structures. For this purpose a 15 mm thick perspex plate was chosen. The objective is, that the installed power of building service equipment, due to similar structural properties, will be in comparable range one either the 15 mm thick perspex plate or any typical timber-frame structure. The perspex reception plate is mounted at the reception plate test rig at THRo and is coated with a highly reflective surface layer to enable measurement of vibration velocities using a 3D laser doppler vibrometer (see Figure 1). In accordance with the support requirements for reception plates with high mobility, as defined in [2], the perspex reception plate is currently mounted on a fully elastic support and has no direct contact with adjacent structural elements. Investigations of lightweight reception plates made from a perforated steel sheet [7] showed, that boundary conditions significantly influence the damping loss factor of a plate. The perspex plate is joined (cold welded) perpendicularly at two positions across its width, as the material is not available in the required dimensions of 3.7 m × 2.18 m and a thickness of 15 mm.

4. FIRST RESULTS

To enable the characterisation of structure-borne sound sources in accordance with EN ISO 15657:2019-10 [2], the properties of the receiving structure must be well de-

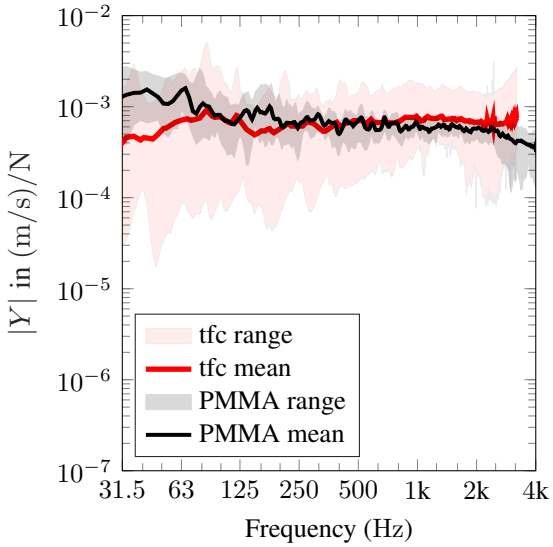

Figure 2: Magnitude of the point mobility from the perspex reception plate (PMMA) and timber frame construction (tfc). Shaded areas represent the envelopes of all measurement points (range).

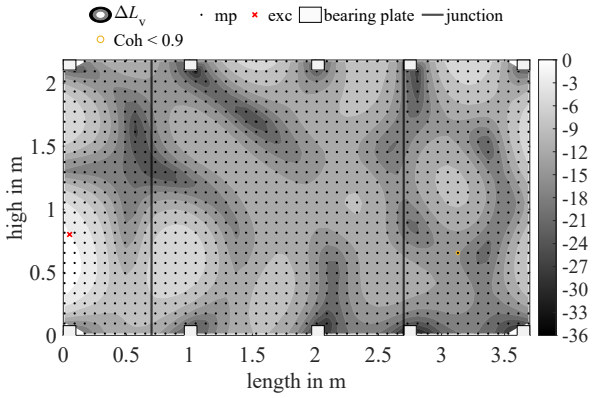
fined. It is essential to ensure that the joints in the plate do not exert any significant influence on the spatial distribution of velocity levels. A series of measurement-based investigations have been carried out to characterise the perspex reception plate. This includes the determination of the longitudinal wave velocity, the velocity level distribution with point excitation and the loss factor of the plate.

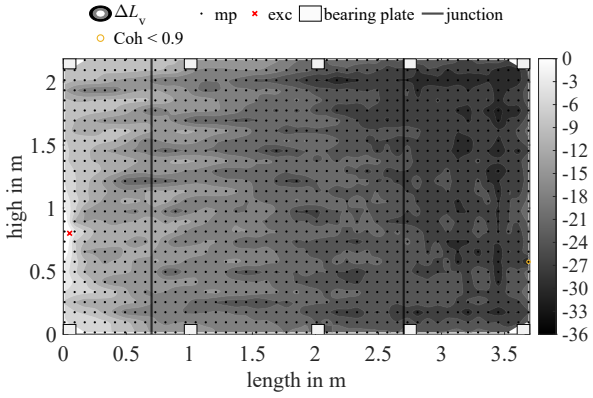
4.1 Mobilities of reception structures

Figure 2 shows the arithmetic mean of driving-point mobilities of typical timber frame walls (tfc) in black and the perspex (PMMA) reception plate in red. The shaded areas represent the envelopes of the individual measurement points for the perspex plate and the range of mobilities across 20 measurements on different timber wall specimen which is in the order of $10^{-3}\,(\mathrm{m/s})/\mathrm{N}$ [8, 9]. The mobility behaviour of timber frame walls typically shows a decreasing mobility characteristic in the low frequency range, corresponding to that of an infinite beam, and a flat mobility characteristic in the higher frequency range, similar to that of an infinite plate. In the transition zone the mobility increases [6, 8]. This transition is also evident in the trend of the averaged mobilities considering the envelope in particular.



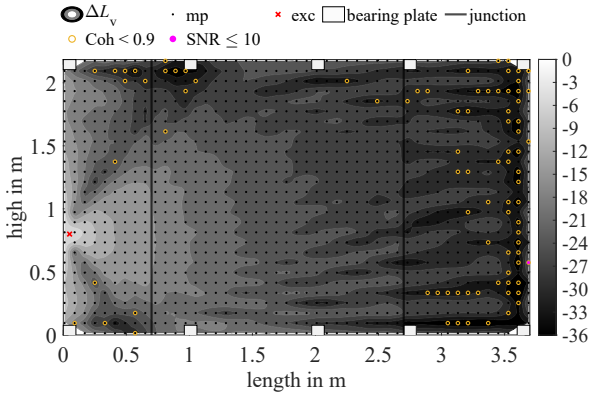
The averaged mobility values of the PMMA plate were determined at a distance of $0.87\,\mathrm{m}$ from the edge, with vertical increments of $10\,\mathrm{cm}$. This area corresponds to potential mounting positions of pipe clamps used in the wastewater systems under investigation. The PMMA mobility curves show a relatively flat frequency response, indicating high material damping and exhibit significantly less scatter compared to the timber structures. The decreasing trend in the PMMA mobility between $31.5\,\mathrm{Hz}$ and $100\,\mathrm{Hz}$ is investigated as it differs from the typical behaviour of timber-frame walls in this frequency range. Nevertheless, the magnitude of the mobilities of both receiving structures is of the same order, allowing for meaningful comparison.

4.2 Contour plots from measured velocity levels



The velocity level distribution was measured by exciting the (PMMA) plate on the backside using point excitation with an electrodynamic shaker. The vibration velocities on the plate surface were measured on a grid with a resolution of $8\,\mathrm{cm} \times 8\,\mathrm{cm}$. The contour plots shown in Figure 3 correspond to the one-third octave bands at $31.5\,\mathrm{Hz}$, $1250\,\mathrm{Hz}$ and $3150\,\mathrm{Hz}$, respectively. These are normalised to the velocity level at the excitation point. The colour gradation is shown in steps of $3\,\mathrm{dB}$. Measurement points with a mean arithmetic coherence < 0.9 in the one-third octave band are marked with a yellow circle and measurement points with a signal-to-noise ratio (SNR) $\leq 10\,\mathrm{dB}$ are marked with a purple dot.
In Figure 3a, distinct vibration antinodes and nodal lines are visible, indicating modal shapes within the $31.5\,\mathrm{Hz}$ band, with differences reaching up to approximately $18\,\mathrm{dB}$. In contrast, Figure 3b and Figure 3c show no identifiable modal patterns. But here, a clear decay in velocity level with increasing distance from the excitation point is observed. The decay is up to $20\,\mathrm{dB}$ in the $1250\,\mathrm{Hz}$ one-third octave band and up to $36\,\mathrm{dB}$ in the $3150\,\mathrm{Hz}$ one-third octave band. At the cold welded junction (shown with a gray line in Figure 3), there is no significant drop in velocity level due to the continuous adhesive bonding. It is therefore assumed, that the receiving plate, consisting of three bonded elements, can be considered as a homogeneous structure up to approximately $3150\,\mathrm{Hz}$.

5. CONCLUSION



The project will be conducted over the next three years. It will generate further insights and identify optimisation potentials specifically in the area of wastewater noise in

(a) 31.5 Hz

(b) 1250 Hz

(c) 3150 Hz

Figure 3: Contour plot of velocity level across the perspex plate for selected one-third-octave bands. Levels are normalized to the velocity at the excitation point. Legend entries: $\Delta L_\mathrm{v} = L_\mathrm{v,mp} - L_\mathrm{v,exc}$, shading in 3 dB steps; mp: measuring point; exc: excitation point.

timber buildings. At the start of the project, fundamental investigations to characterise the idealised reception plate as a substitute for timber frame constructions are carried out. The results obtained so far are promising and indicate that the selected perspex receiving structure is suitable. It exhibits similar and more homogeneous properties compared to conventional timber stud wall constructions.

6. OUTLOOK

Further measurements and evaluations will be carried out to characterise the reception plate in more detail. The determination of the loss factor will be extended by additional methods, such as the power injection method, in order to investigate the influence of boundary conditions on the dynamic behaviour of the plate. In addition, suitable buildings for acoustic measurements and binaural recordings for listening tests will be selected and carried out in cooperation with industry partners. Surveys conducted in collaboration with timber construction associations will provide an overview of the currently prevailing installation conditions for wastewater systems in timber buildings.

7. ACKNOWLEDGMENT

The research project (FH-IPTOOLS, ref.no.: 13FH076KA2) is funded by the German Federal Ministry of Education and Research and the state of Bavaria as part of the funding programme ”Forschung an HAW”. Also thanks to Müller-BBM VibroAkustik Systeme GmbH for their support in measurement technology at THRo.

FROM CLASSIFICATION TO PREDICTION: APPLYING EN 14366-1 TO FRESHWATER SYSTEMS

Lukas Däuble[1*] **Jochen Scheck**[1] **Berndt Zeitler**[1]
[1] Stuttgart University of Applied Sciences, 70174 Stuttgart, Germany

ABSTRACT

Sound emission of and transmission in plumbing systems are currently standardized with different approaches for waste water and fresh water applications. While EN 14366 provides characterization methods for waste water systems that deliver essential input data for the prediction of sound levels in buildings, DIN EN ISO 3822 focuses solely on the classification of individual water appliances, which are the predominant acoustic sources in fresh water installations. However, the methodology outlined in DIN EN ISO 3822 exhibits significant limitations, leading to inconsistencies between different laboratories and focusing solely on classification rather than prediction purposes. This research explores the potential application of EN 14366-1 characterization methods to freshwater systems by experimentally investigating complete installations – including appliances, pipes, and pipe clamps – to assess the necessity of developing a new standard that characterizes entire systems based on the approach used in EN 14366-1.

Keywords: *building acoustics, freshwater, structure-borne sound transmission, sanitary installations, pipe noise*

1. INTRODUCTION

Noise from building equipment is a topic that has been addressed intensely in the last two decades. Numerous case studies on various types of sources to determine the acoustic properties have been performed and led to the development of the test standard EN 15657 in 2009 that has been revised in 2017 to account for all installation conditions [1]. The results according to EN 15657 serve as input data for predictions of the sound propagation in buildings according to EN 12354-5 [2] that was recently revised. The general methods in EN 15657 have been implemented in EN 14366-1 [3] for testing wastewater pipes. While experience with this new standard is gained by numerous laboratories, a current work item of CEN/TC 126 WG7 aims to develop a second part: 14366-2 for water supply installations. The idea is to keep the methods and test facilities the same as for waste water systems and include installations with different components, not only different appliances (e.g. taps or valves), but also different piping configurations and mounting elements. Previously, only the appliances like taps and valves in water supply systems were characterized by EN ISO 3822 which exhibits significant limitations [4]. However, this method only allows the appliances to be categorized into sound classes without delivering input data for predictions. This paper aims to demonstrate the suitability of the methods from EN 14366-1 for the characterization of fresh water pipe systems.

2. TEST SETUP

For the here shown investigations, first, a fresh water system from previous publications [5,6] is used, for which the blocked force has already been determined using the reception plate method by EN 15657. This freshwater system consists of a 1-inch galvanized steel pipe connected to the building via 2 pipe clamps. The test setup on the reception plate is shown in figure 1. The internal noise source of the pipe system is the installation noise standard (INS) by EN ISO 3822, which is a reference source used to characterize appliances like taps and valves. The system is driven by a water supply pump with a controlled flow pressure of 3 bar, leading to a flow rate of 16.4 l/min, mainly determined by the INS. This short pipe section is

installed on the 2nd floor of an installation test stand shown in figure 3.

Figure 1. Short pipe section from previous investigations on the reception plate [5,6], the same pipe system is investigated in the installation test stand. Blue arrows depict the water flow direction.

In a second step, the system is exchanged for a longer pipe system running through several floors of the installation test stand. This longer pipe is expected to be more building-like than the short pipe section and follows the configuration in EN 14366-1 for testing waste water pipe systems. Schematic sketches of the test setups are shown in figure 2.

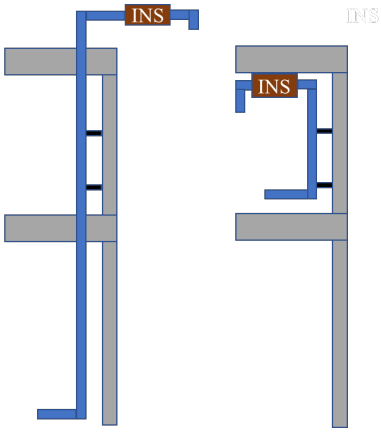

Figure 2. Schematic setup of the pipe systems in the building-like test stand, left: long pipe over several storeys, right: short pipe section within one storey.

3. APPLICATION OF EN 14366-1 TO FRESHWATER PIPES

The concept behind EN 14366-1 is to use a structure-borne sound power substitution method in order to determine the blocked force. Therefore, a calibration source with known power input is needed.

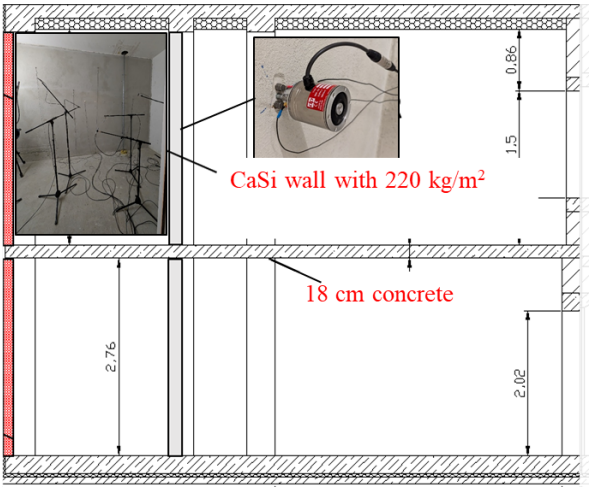

Figure 3. Cross section of the installation test stand. The mean sound pressure level and wall velocity level are measured in the sending room side. The calibration source is mounted on the test wall on the receiving room side.

In this investigation the calibration source is an inertial shaker that is screwed into the threading of the metal expansion anchors in the wall used to mount the pipe clamps of the fresh water pipe. The shaker force is measured via a force transducer while simultaneously the velocity at the contact point is measured via accelerometers. From the cross product of force and velocity at the contact point, the structure-borne sound power of the calibration source is determined. By comparing the response for shaker excitation (mean wall velocity and airborne sound power in the room) to the response for the fresh water pipe system, the source data (blocked force, airborne sound power) of the fresh water pipe system is determined. The wall velocity is captured simultaneously with 6 accelerometers on the test wall and the sound pressure level with 6 microphones in the test room, as shown in figure 3.

Note: So far, the EN 14366-1 (and EN 15657) methods are restricted to stationary excitation. For the characterization of sources with transient excitation (here e.g. closing of a water tap), a new method is explored in [7].

3.1 Structure-borne sound characterization

To determine the structure-borne sound power of the fresh water pipe system, it is assumed that the structure-borne

sound power of any source is proportional to the squared mean plate velocity [1]. This leads to the following relation between the structure-borne sound power and mean squared velocity for the source (pipe system) and the calibration source (shaker).

$$\frac{W_{source}}{\langle v^2_{source} \rangle} = \frac{W_{cal}}{\langle v^2_{cal} \rangle} \qquad (1)$$

As can be seen in figure 4, the mean wall velocity is well above background noise in the investigated frequency range and so is the mean sound pressure level (not shown).

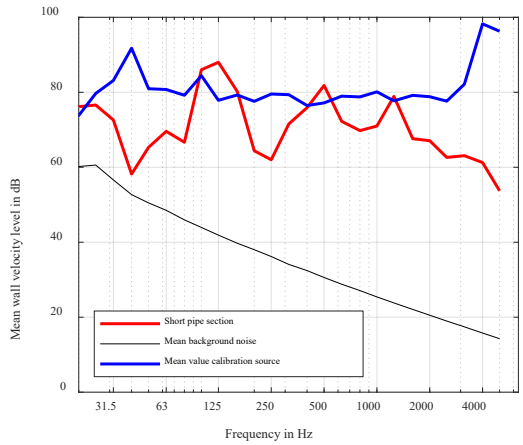

Figure 4. Mean velocity levels on the test wall with the calibration source (blue), with the short pipe section (red) and without excitation (black).

For several contact points j, expressed in levels[1] and rearranged to the structure-borne power of the source, equation (1) becomes:

$$L_{Ws} = 10\lg\left(\sum_j 10^{\frac{L_{Ws,cal,j}}{10}}\right) + L_{\langle v \rangle} - 10\lg\left(\sum_j 10^{\frac{L_{\langle v \rangle,cal,j}}{10}}\right) \qquad (2)$$

As can be seen by comparing figure 4 and 5, the difference of structure-borne power levels and wall velocity levels between calibration source and test specimen are equal.

[1] For the calculation of levels, the reference values of EN 14366-1 and EN 15657 are used.

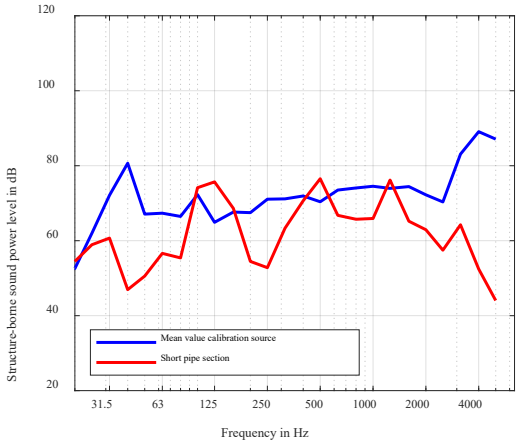

Figure 5. Structure-borne sound power levels of the calibration source (blue) and the short pipe section (red)

Assuming a force source condition, where the receiver mobility Y_R is much lower than the source mobility Y_S, the blocked force level $L_{Fb,eq}$ is calculated using the real part of the equivalent receiver mobility $Y_{R,low,eq}$:

$$L_{Fb,eq} \approx L_{Ws} - 10\lg\left(\frac{\mathrm{Re}(Y_{R,low,eq})}{Y_0}\right) \mathrm{dB} \qquad (3)$$

The blocked force is independent of the receiving structure and is used as input data for predictions in heavyweight building situations using EN 12354-5, which has already been shown in [6]. For the short pipe section, the blocked force is shown in figure 6.

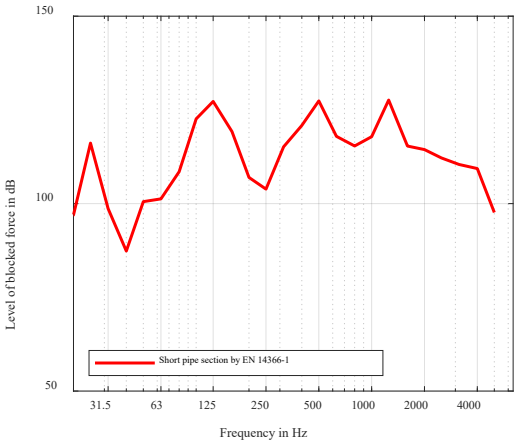

Figure 6. Blocked force of the short pipe section determined according to EN 14366-1

3.2 Airborne sound characterization

To determine the airborne sound power of the test specimen, first the mean total sound pressure level $L_{p,total}$ is measured in the test room. With the reverberation time and the volume of the test room, the normalized total sound pressure level $L_{n,total}$ is calculated.

$$L_{n,total} = L_{p,total} - 10\lg(T_R) + 10\lg\left(\frac{0{,}16V}{10}\right) \quad (4)$$

The total airborne sound power $L_{Wa,total}$ in the test room is:

$$L_{Wa,total} = L_{n,total} + 4\ \text{dB} \quad (5)$$

Since the fresh water system is a combined structure-borne and airborne sound source, the total airborne sound power in the room $L_{Wa,total}$ is a combination of direct radiation of airborne sound by the pipe L_{Wa} together with the airborne sound radiation of the wall $L_{Wa,struc}$ due to structure-borne excitation of the wall at the pipe contacts. Therefore, the airborne sound power of the pipe system itself can be separated using:

$$L_{Wa} = 10\lg\left(10^{\frac{L_{Wa,total}}{10}} - 10^{\frac{L_{Wa,struc}}{10}}\right) \quad (6)$$

To determine the airborne sound due to structure-borne excitation $L_{Wa,struc}$, the structure-borne sound power level of the calibration source $L_{Ws,cal}$ is compared to the structure-borne sound power level L_{Ws} of the test specimen. With the difference between those two and the radiated airborne sound power level $L_{Wa,struc,cal}$ radiated by the structure-borne excitation of the calibration source, calculated using equations (4) and (5), the radiated airborne sound power level of the wall $L_{Wa,struc}$ can be determined:

$$L_{Wa,struc} = 10\lg\left(\sum_j 10^{\frac{L_{Wa,struc,cal,j}}{10}}\right) + L_{Ws} - 10\lg\left(\sum_j 10^{\frac{L_{Ws,cal,j}}{10}}\right) \quad (7)$$

The separation according to equation (6) is only applicable if $L_{Wa,total}$ is greater than $L_{Wa,struc}$. As seen in figure 7, the radiation of the wall due to structure-borne excitation is dominant up to 600 Hz. This is already a hint that for the prediction of the sound transmission in a real building, airborne sound radiation of the pipe is negligible compared to structure-borne sound transmission.

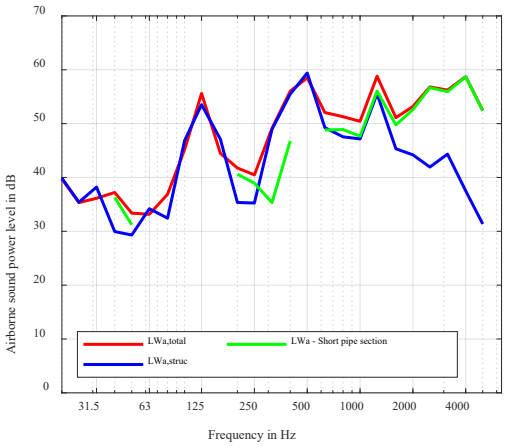

Figure 7. Separation of total airborne sound power (red) of the short pipe section into shares of wall (blue) and pipe (green).

It should be noted that for the short pipe section, the airborne sound in the room is influenced by the noise of water running out of the pipe system and into and through a drainage pipe without any connection to the wall. The radiation by the fresh water pipe itself could then be even lower than shown here.

3.3 Source mobility

To assess the validity of the force source condition, the equivalent source mobility Y_S is determined according to EN 14366-1 indirectly from the equivalent free velocity $v_{f,eq}$ of the contact points when the pipe is disconnected from the test wall and the beforehand measured equivalent blocked force of the pipe system:

$$|Y_{S,eq}|^2 = 10^{\frac{L_{vf,eq} - L_{Fb,eq}}{10}} \cdot 10^{-6} \quad (8)$$

The equivalent free velocity level of the pipe can be calculated by energetically summing up the free velocity levels at each contact point:

$$L_{vf,eq} = 10\lg\left(\sum_j 10^{\frac{L_{vf,j}}{10}}\right) \quad (9)$$

For comparison, the source mobility has also been determined directly by impact hammer excitation at each contact point while keeping the accelerometer at the same position as for the free velocity measurement , see figure 8. The equivalent magnitude of source mobility is then the

arithmetic average of the measured mobilities at each contact point.

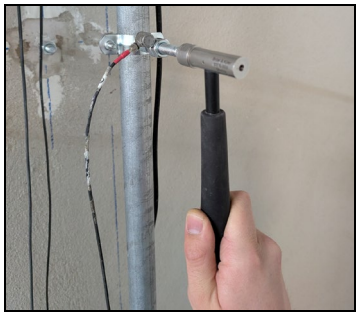

Figure 8. Direct measurement of source mobility at a contact point (threaded rod) of the pipe system.

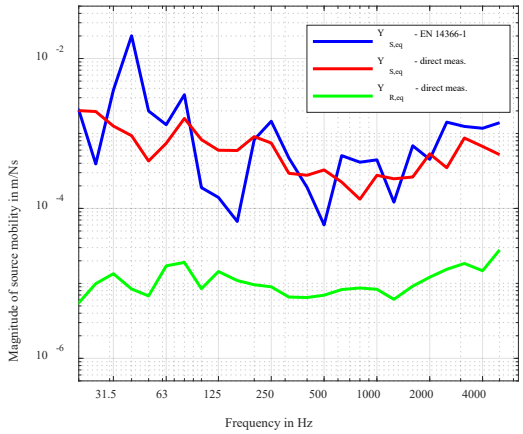

Figure 9. Mean mobility of the test wall (green) and the short pipe section (red) directly measured and the equal mobility of the short pipe section by the standardized method (blue).

Figure 9 shows the measured mobilities of source and receiver together with the source mobility determined by the EN 14366-1 method. Because the source mobility is much higher than the receiver mobility, the force source condition holds true, even though the agreement between the source mobility methods is not perfect.

4. PREDIICTION

With the blocked force from equation (3), predictions of the normalized sound pressure level in a receiving room due to structure-borne excitation of the fresh water pipe system can be made according to DIN EN 12354-5 [2] using

$$L'_{ne,s} = L'_n + L_{Fb,eq} - L_{Fb,eq,stm} \quad (10)$$

where L'_n is the apparent impact sound pressure level of the wall caused by the ISO tapping machine and $L_{Fb,eq,stm}$ is the blocked force of the ISO tapping machine. The apparent impact sound pressure level L'_n can either be calculated using EN 12354-2 [9] or measured using the normalized spatial average transmission function $D_{TF,av,n}$ from ISO 10848-1 [8]. The determination of L'_n using transfer functions has been implemented in the recently published EN 17823 [10] and can be calculated according to

$$L'_n = D_{TF,av,n} + L_{Ws,stm} \quad (11)$$

where $L_{Ws,stm}$ is the structure-borne sound power of the ISO tapping machine calculated using its blocked force $L_{Fb,eq,stm}$ and the equivalent mobility of the test wall $Y_{R,low,eq}$:

$$L_{Ws,stm} = L_{Fb,eq,stm} + 10\lg\left(\mathrm{Re}\left\{\frac{Y_{R,low,eq}}{Y_0}\right\}\right) \quad (12)$$

The normalized spatial average transfer function $D_{TF,av,n}$ by ISO 10848-1 is determined from the spatial average transfer function $D_{TF,av}$ which is the energetical average of the transfer functions $D_{TF,k}$ between structure-borne sound power and sound pressure level in the test room for each excitation position k:

$$D_{TF,k} = L_{p,cal,k} - L_{Ws,cal,k} \quad (13)$$

$$D_{TF,av} = 10\,lg\left(\sum_j 10^{\frac{D_{TF,j}}{10}}\right) \quad (14)$$

$$D_{TF,av,n} = D_{TF,av} + 10\,lg\left(\frac{A}{A_0}\right) \quad (15)$$

It should be noted that, since a force source condition is assumed for equation (12), the same evaluations could be made using directly measured forces instead of using the structure-borne sound power W_s of the calibration source. Since the mobility of the test wall still has to be determined to check if the force source condition holds true, no measurement effort can be saved.

The apparent impact sound pressure level of the test wall in the installation test stand using the two methods are shown in figure 10.

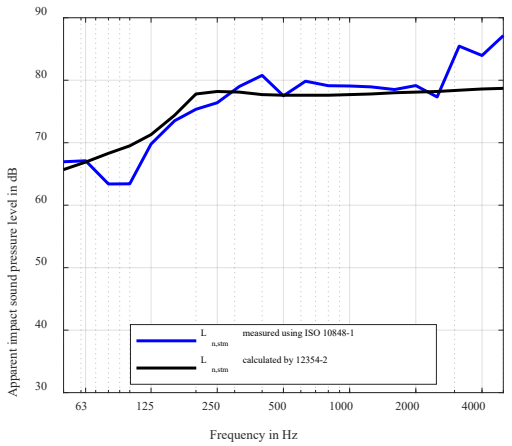

Figure 10. Apparent impact sound pressure level calculated by EN 12354-2 and measured using transfer functions from ISO 10848-1.

EN 14366-1 already uses a similar approach with transfer functions for the determination of the radiated airborne sound power of the wall due to structure-borne excitation $L_{Wa,struc}$ of the fresh water pipe system, compare equations (4), (5) and (7). The main difference is the determination of the average transfer function $D_{TF,av}$. While the ISO 10848-1 averages the transfer functions themselves (see equation (14)), EN 14366-1 sums the power input at all contact points and the mean sound pressure levels caused by each power input. The average transfer function EN 14366-1 implicitly uses is:

$$D_{TF,av,EN14366} = 10\lg\left(\sum_j 10^{\frac{L_{p,cal,j}}{10}}\right) - 10\lg\left(\sum_j 10^{\frac{L_{Ws,cal,j}}{10}}\right) \quad (16)$$

If the power input is the same for each contact point the two methods deliver the same results. If the power input at any contact point is much higher than at other contact points, which is easily possible for impact hammer excitation, the resulting average transfer function from equation (16) is dominated by the result of that point. For the investigations made here, there are only minor differences caused by the inconsistent determination of average transfer functions, because the shaker delivers nearly identical structure-borne excitation at each contact point and the individual transfer functions of each point also only show small deviations.

The predicted normalized sound pressure levels in the receiving room of the installation test stand using equation (10) with calculated and by ISO 10848-1 determined apparent impact sound pressure levels are shown in figure 11. The by EN 14366-1 predicted normalized sound pressure levels $L_{n,struc} = L_{Wa,struc} - 4$ dB, compare equation (5), shows small deviations to the prediction with the transfer function from ISO 10848-1, which is only due to the different averaging, see equations (13) (14) and (16). The measured and predicted sound pressure level in the receiving room is in good agreement for all prediction methods.

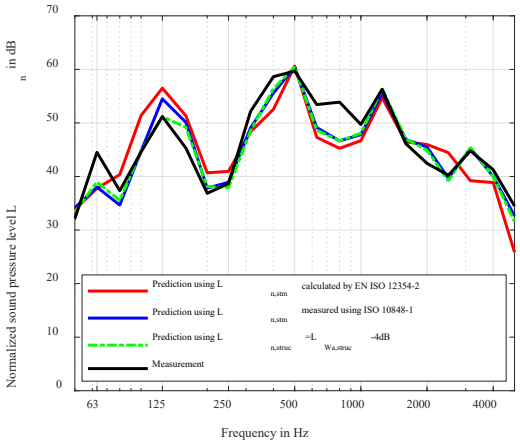

Figure 11. Normalized sound pressure level in the receiving room caused by the short pipe section excited by the INS.

5. COMPARISONS

To validate the blocked force determined by EN 14366-1 a comparison with the results on the reception plate by EN 15657 [5] is made in figure 12. The results show good agreement between the two methods from 50 Hz upwards. This shows, that the EN 14366-1 method is suitable to characterize fresh water pipe systems as structure-borne sound sources.

For the long pipe section, the blocked force of the pipe system is much lower than for the short pipe section. Such large differences were not expected, since in previous studies on the reception plate [5], only minor variations of the blocked force with respect to the pipe geometry were found.

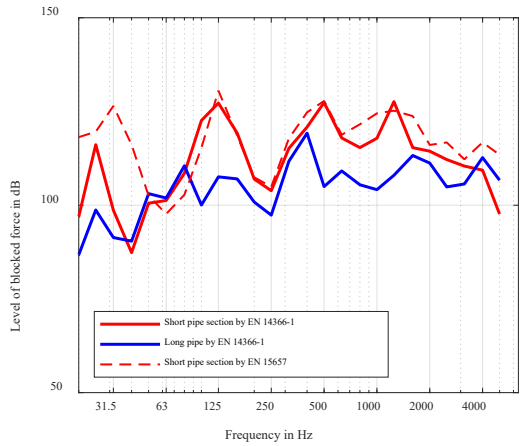

Figure 12. Blocked force of the long pipe (blue) and the short pipe section (red) by EN 14366-1 method in comparison with the blocked force of the short pipe section on the reception plate by EN 15657 (red dashed).

In the previous investigations on the reception plate [5], it has been shown that the insertion loss is independent of the excitation of the pipe but dependent on the specific combination of pipe and pipe clamp. To verify these results, the long pipe system is mounted with pipe clamps with a rubber inlay. The influence of the pipe clamp inlay on the blocked force is shown in following figure.

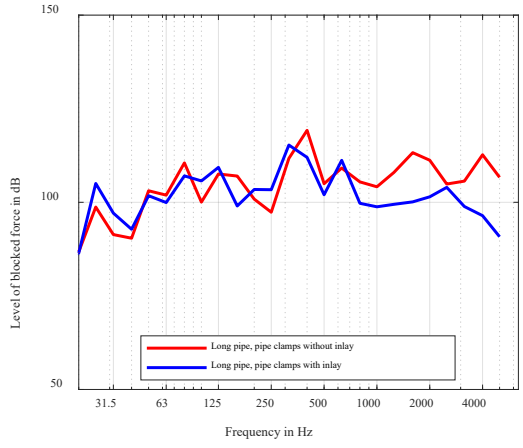

Figure 13. Effect of a rubber inlay in the pipe clamps of the long pipe.

The effect of the inlay in the pipe clamp on the blocked force is limited to the high frequency range above 600 Hz, except for the 3150 Hz 3rd-octave band. Below 600 Hz, the resilient inlay has only a minor effect. The difference in blocked force level will lead to the same difference in sound pressure level in the receiving room, which effectively is the insertion loss, displayed in figure 14. To evaluate the validity of this result, the insertion loss determined on the reception plate for the small pipe section with the same pipe clamps [5] is also shown.

The insertion loss of the pipe clamps determined via the EN 14366-1 methods for the long pipe system show the same trend as for the short pipe section characterized on the reception plate. This approves the expectation from previous investigations that the insertion loss of pipe clamps has a minor dependency of the geometry of the pipe but is heavily dependent on the combination of pipe and pipe clamp.

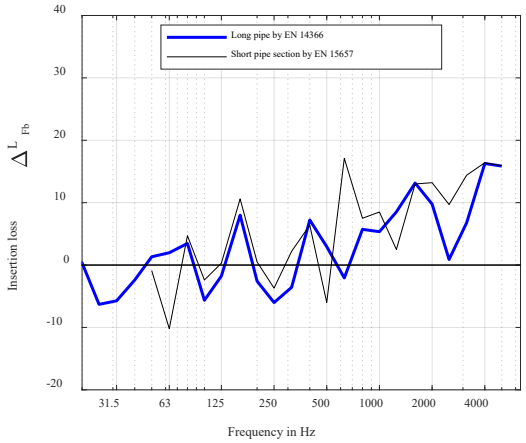

Figure 14. Insertion loss of the pipe clamp with a resilient inlay determined by the blocked force for the long pipe system by EN 14366-1 and for the short pipe section by EN 15657 at the reception plate.

6. CONCLUSIONS

It was shown that the methods of EN 14366-1 are in principle suitable for characterizing fresh water pipe systems. The blocked forces determined for the short pipe section according to EN 14366-1 are in good agreement with the results from measurements on the reception plate method according to EN 15657. The airborne sound power can also be determined in accordance with EN 14366-1, however the valid frequency range is limited here as the structure-borne sound component dominates up to 600 Hz.

The source quantities free velocity and mobility can also be determined using the methods in EN 14366-1.

The blocked force for the long pipe is significantly lower than for the short pipe section, which was not expected from previous investigations. This indicates that the pipe length has a relevant effect that has to be investigated in further detail. The consequence so far is that a laboratory test set-up needs to be as building-like as possible which requires an installation over more than one storey as for waste water pipe systems.

7. ACKNOWLEDGMENTS

ON-SITE APPLICATION OF NOISE REDUCTION TECHNOLOGIES FOR BATHROOM DRAINAGE IN APARTMENT BUILDINGS

Guk-Gon SONG[1*] **Jin-Yun CHUNG**[1] **A-Hyeon JO**[1]
[1] Korea Conformity Laboratories, Republic of Korea

ABSTRACT

In Korea, most apartment bathrooms use an under-slab-piping method, causing drainage to occur through the ceiling of the lower floor when the upper floor bathroom is used, inevitably leading to drainage noise issues. Especially in older apartment buildings, noise reduction measures have not been considered, resulting in significant harm to residents.

This study aims to apply noise reduction technology to older apartment buildings vulnerable to bathroom drainage noise and verify its effectiveness. The target site is an apartment built in 1997, with an exclusive area of 84 m². The existing PVC drainage pipes, asbestos slate ceiling material, and wooden doors were replaced with low-noise PVC pipes, sound-absorbing ABS ceiling material, and ABS doors.

The noise reduction performance was evaluated at maximum noise levels during toilet, sink, and bathtub drainage. Measurement results in the main bathroom showed a reduction of 22.9 dB(A) for toilet drainage noise and 16.6 dB(A) for sink drainage noise. In the family bathroom, reductions were 10.1 dB(A) for toilet drainage noise, 5.9 dB(A) for sink drainage noise, and 12.0 dB(A) for bathtub drainage noise. Applying this technology is expected to reduce living noise issues between neighbors in apartment buildings.

1. INTRODUCTION

According to the 2023 KOSIS survey, approximately 80% of Koreans reside in multi-unit housing such as apartments, villas, and studio flats [1]. Multi-unit housing is vulnerable to noise transmitted from neighbors due to shared walls, floors, and ceilings between adjacent units. In particular, floor impact noise caused by children running or adults walking has intensified conflicts between households, becoming a significant social issue. However, survey results on living noises in apartment buildings revealed that in the main bedroom, more respondents reported being affected by drainage noise from bathrooms rather than floor impact noise [2]. Unlike the living room, where the family gathers and spends time together, the main bedroom is used as a space for rest and sleep. As a result, background noise in the main bedroom is lower compared to other spaces, making individuals more sensitive to even small noises. Since floor impact noises, such as children running, mainly occur in living rooms or hallways, they are evaluated as being relatively less sensitive. On the other hand, bathroom drainage noises, which occur more frequently in main bedroom, are analyzed to have a higher sensitivity level. In particular, the method of installing drainage pipes beneath the slab in multi-unit housing is commonly used, which is believed to cause significant noise-related issues.

This study applied technologies designed to reduce bathroom drainage noise in multi-unit housing and evaluated their effectiveness on-site.

2. DRAINAGE NOISE REDUCTION TECHNOLOGIES

Technologies for reducing bathroom drainage noise in apartment buildings include low-noise piping, sound-absorbing ceiling boards, and high-soundproof doors.

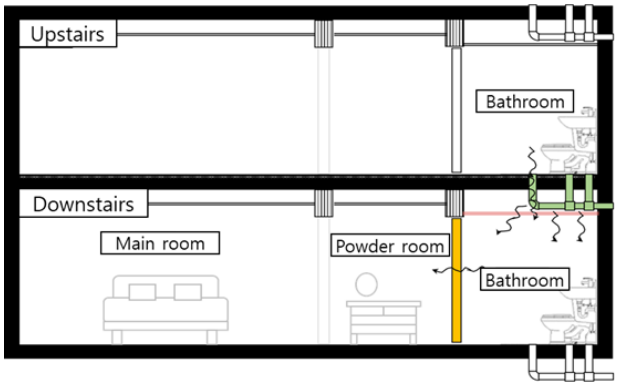

Figure 1. Section and drainage noise transmission path.

2.1 Low noise piping

Low-noise piping is designed with two or three layered structures to reduce internal noise through vibration isolation and sound insulation, while also preventing the transmission of noise externally. This technology has the greatest impact on reducing drainage noise and demonstrates highly effective noise reduction capabilities. The sound insulation performance of the piping can be evaluated in laboratories using ISO [3] and KS [4] standard test methods.

2.2 Sound absorbing ceiling board

Sound-absorbing ceiling materials are a technology designed to reduce the transmission of noise, generated by drainage pipes installed beneath the slab, to the interior of the downstairs bathroom. Typically, PVC, SMC, or ABS ceiling materials are used, with PU foam sound-absorbing material attached to the upper side of the ceiling material, aiming to reduce noise through absorption within the ceiling. This technology is expected to be particularly effective in narrow spaces within the frequency range of 500 Hz or higher, where the effects of sound absorption are more noticeable. Laboratory measurements can be conducted according to ISO 10140-2 standard [5].

2.3 High-soundproof door

High-soundproof doors can reduce the transmission of bathroom noise to the master bedroom. They are effective not only in minimizing noise caused by upstairs neighbors using their bathrooms, but also in decreasing the noise from family members within the same unit, making it less audible in the master bedroom. Generally, doors used indoors do not have high air-tightness or soundproofing performance. By enhancing the soundproofing performance of the door itself and improving the air-tightness of the door set, the soundproofing effect can be increased. The soundproofing performance of the door set can be evaluated using ISO 10140-2 test method [5].

3. ON-SITE APPLICATION

To verify the effectiveness of noise reduction technologies for bathroom drainage noise in actual multi-unit housing settings, these technologies were applied on-site. The target site was an apartment built in 1997, approximately 28 years old, with an exclusive area of 84 m² and a layout featuring one bathroom adjacent to the master bedroom and another to the living room. While the main focus of this study was noise reduction in the master bedroom bathroom, the same technologies were applied to the living room bathroom for comparison purposes.
The applied technologies included low-noise piping, sound-absorbing ceiling materials, and high-soundproof doors. Additionally, the walls, floor tiles, and sanitary fixtures were all reconstructed.

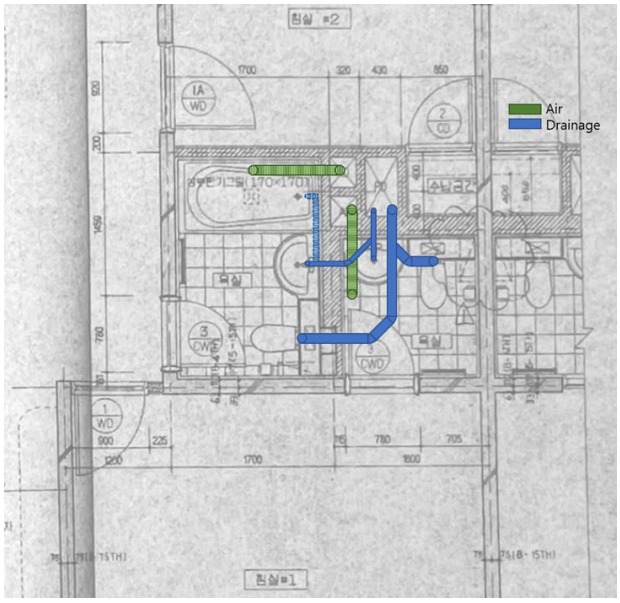

Figure 2. Plan of apartment noise reduction technology applied.

Figure 3. Images of bathroom before noise reduction technology application.

Figure 4. Images of bathroom after noise reduction technology application and measurement.

4. MEASUREMENT AND ASSESSMENT

4.1 Measurement method

The measurement of drainage noise followed the test methods outlined in KS F 2871 [4]. Noise levels were measured at the central point inside the downstairs bathroom and at a location 1 m in front of the bathroom door outside. During the whole drainage time, noise was measured after filling 6L of water into the flush toilet, 6L into the washbasin, and 60L into the bathtub. Both the equivalent noise level (L_{eq}) and the maximum noise level (L_{max}) were measured using the Fast time characteristic. Three measurement data were averaged.

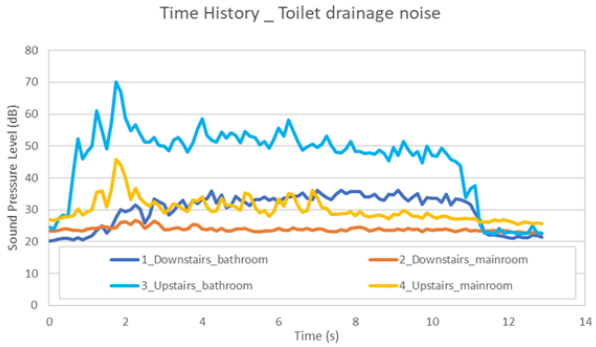

Figure 5. Time history graph of bathroom toilet drainage noise measurement after technologies application.

4.2 Measurement before and after application

To evaluate the noise reduction performance of drainage noise mitigation technologies, measurements were taken before and after the application of the technologies. To ensure comparability, the measurement locations and conditions were kept identical, and measurements were repeated three times under the same conditions. The arithmetic mean of the results was then compared. The noise reduction effects were evaluated for each sanitary fixture, including the toilet, sink, and bathtub.

Based on Figure 5, the noise was measured by identifying the time when noise occurred relative to the background noise, including the time during which the drainage process was ongoing.

4.3 Noise reduction

Changes in noise levels due to drainage time delays were anticipated, so the noise reduction performance was evaluated using the maximum noise level.

The toilet drainage noise from the bathroom adjacent to the master bedroom was reduced by 22.9 dB, from 59.8 dB to 36.9 dB, while the sink drainage noise decreased by 16.6 dB, from 49.1 dB to 32.5 dB. In the shared bathroom adjacent to the living room, the toilet drainage noise was reduced by 10.1 dB, from 45.5 dB to 35.4 dB, while the sink noise decreased by 5.9 dB, from 43.0 dB to 37.1 dB, and the bathtub noise was reduced by 12.0 dB, from 50.5 dB to 38.5 dB.

As shown in Figure 1, the drainage pipes of the living room bathroom were constructed to merge with the ceiling space

of the master bedroom bathroom and meet the vertical pipes in the pipe duct (PD) space. Since the internal pipe length in the living room bathroom ceiling is shorter, the noise level was measured to be relatively lower than in the master bedroom bathroom, and the noise reduction effect due to the applied technology was also less significant.

Table 1. Maximum sound pressure level of bathroom drainage noise.

Room	Fixture	L_{Amax} (dB)	L_{Amax} (dB)	ΔL_{Amax} (dB)
Main bathroom	Toilet	59.8	36.9	22.9
	Sink	49.1	32.5	16.6
Public bathroom	Toilet	45.5	35.4	10.1
	Sink	43.0	37.1	5.9
	Bathtub	50.5	38.5	12.0

5. CONCLUSION AND DISCUSSION

5.1 Conclusion

This study aimed to verify the effectiveness of technologies applied on-site to reduce toilet drainage noise in apartment buildings. It assessed the current drainage noise condition in an apartment building approximately 28 years after completion, and applied technologies such as low-noise pipes, sound-absorbing ceiling materials, and high-soundproof doors. To verify the effectiveness of these technologies, noise was measured before and after construction for each drainage fixture, confirming the noise reduction performance of the technologies.

As a result of the application, maximum noise levels showed reductions of 22.9 dB for toilet noise and 16.6 dB for sink noise in the master bedroom bathroom, and reductions of 10.1 dB for toilet noise, 5.9 dB for sink noise, and 12.0 dB for bathtub noise in the shared bathroom adjacent to the living room. Following the application of these technologies, all drainage conditions presented low noise levels of under 40 dB. Particularly, the drainage noise reduction effect was significant in the master bedroom bathroom, where the piping from the shared bathroom and the master bedroom bathroom merged and connected to the pipe duct (PD).

5.2 Discussion

This study aimed to verify the field performance of noise reduction technologies, specifically targeting aging apartment buildings. While the significance of confirming the performance of technologies validated in existing experimental facilities and applying them on-site was acknowledged, the study was limited to results from a single site, making generalization difficult. Therefore, it is necessary to obtain additional field data to enhance the reliability of the findings. Furthermore, the testing methods for measuring drainage noise on-site require review and discussion.

IMPROVEMENT OF THE AIRBORNE AND IMPACT SOUND INSULATION OF A TIMBER STUD WALL

ABSTRACT

The airborne and impact sound insulation in wooden buildings is often poor, in particular at low frequencies. For a German manufacturer of prefabricated houses, the sound insulation of a separating wall was investigated and improved in the laboratory. By constructive measures such as using a planning filled with silica sand that provides a high internal damping and the partial separation of the wooden studs a considerable improvement of the airborne sound insulation could be achieved. In a next step the impact sound insulation of a standard wooden stair was successfully optimized by isolation measures at the contacts of stair and wall.

Keywords: *building acoustics, separating wall, laboratory tests, airborne sound insulation, impact sound insulation.*

1. INTRODUCTION

Wooden buildings are gaining popularity, also in Germany. The use of renewable raw materials, lower costs and shorter construction times are advantageous in comparison to heavyweight constructions made of concrete and bricks. However, the airborne and impact sound insulation is often poor, in particular at low frequencies which can cause complaints by inhabitants. The construction of the separating wall in-between residential units plays an important role for the total sound transmission. Within the scope of a master thesis [1], the sound insulation of a separating wall of the German manufacturer Keitel-Haus GmbH was investigated and improved in the laboratory of STEP GmbH.

2. TEST STAND

The airborne and impact sound insulation of the separating wall was measured in the test stand of STEP GmbH that was constructed in 2001 with the main purpose of testing lightweight and heavyweight stairs (Figure 1).

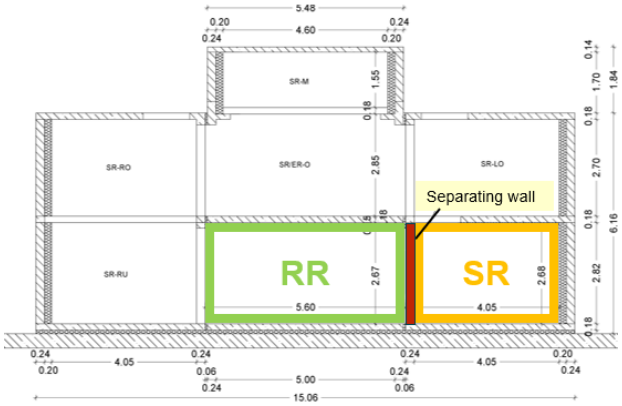

Figure 1. Test stand with sending and receiving room used for the investigations.

The test stand is in accordance with EN ISO 10140-5 [2]. Flanking transmission is avoided by structural linings and the reverberation time in the rooms was conditioned by using absorbers to be within 1s ≤ T ≤ 2s in the frequency range between 50 Hz – 5 kHz.

3. BASIC CONSTRUCTION

The frame construction of the timber stud wall consisted of studs, sills and frames with a depth of 200 mm made of wood (Figure 2). The studs were mainly arranged in a grid of 62.5 cm. Individual areas of the wall had a smaller stud spacing for the later planned connection of a staircase. The compartments were filled with mineral wool.

Figure 2. Frame construction of the timber stud wall.

Figure 3 shows the basic construction chosen for the investigations. For this construction, the planking of the timber stud wall consisted of coarse chipboard (OSB) with a thickness of 12 mm and a mass per unit area of 7.4 kg/m^2, which was screwed to the studs, sill and frame. Additionally, gypsum plasterboard fire protection boards (GKF) with a thickness of 12.5 mm and a mass per unit area of 10.2 kg/m^2 [3] were used, which were screwed onto the OSB plate.

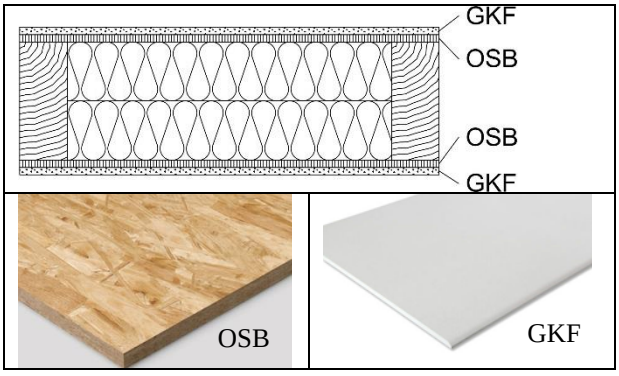

Figure 3. Basic construction of the timber stud wall with OSB and GKF planking.

4. AIRBORNE SOUND INSULATION OF THE BASIC CONSTRUCTION

The airborne sound insulation was determined according to EN ISO 10140-2 [4]:

$$R = L_1 - L_2 + 10\,lg\,S/A \qquad (1)$$

L_1: averaged sound pressure level in sending room [dB]
L_2: averaged sound pressure level in receiving room [dB]
S: wall area [m^2]
A: equivalent absorption area in receiving room [m^2]

The single number value and spectrum adaptation terms were evaluated according to ISO 717-1 [5]. In the following the spectrum adaptation value $C_{50\text{-}5000}$ that accounts for the low frequency sound transmission down to 50 Hz is also given as in [6].

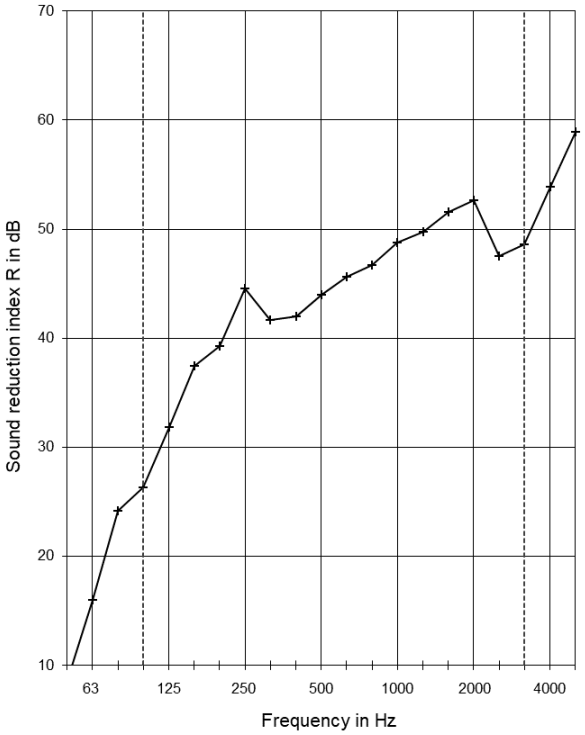

Figure 4. Sound reduction index of the basic construction of the timber stud wall with OSB and GKF cladding; R_w ($C_{50\text{-}5000}$) = 47.8 (-3) dB.

The basic construction achieved a weighted sound reduction index of **R_w ($C_{50\text{-}5000}$) = 47.8 (-3) dB**.

Figure 4 shows the frequency-dependent sound reduction index. Below 200 Hz a strong decrease is visible. An improvement of the sound insulation, particularly in the low-frequency range, was the aim of the design modifications.

5. VARIATION OF THE CLADDING

The cladding of a timber stud wall is known to have a significant influence on the sound reduction index, which is why the optimization of the wall construction was initially started here. In order to improve sound insulation, [6] recommends the use of multi-layer, flexible planking with a high mass per unit area.

Two commercially available additional layers named "Silentboard GKF" [7] and "Phonestar ST Tri" [8] were used. Both layers have a thickness of 12,5 mm and a mass per unit area of 17.5 kg/m^2. They were inserted in-between the OSB and GKF layers, the connection was screwed (Figure 5, Figure 6).

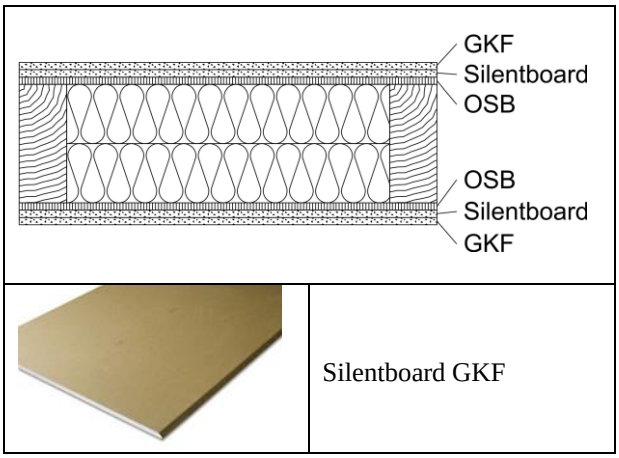

Figure 5. Timber stud wall with an additional layer "Silentboard GKF" [7], a gypsum board recommended for exceptional sound insulation in drywalling.

In Figure 7 are compared the sound reduction indices of the basic construction and with the additional layers.
With the Silentboard a weighted sound reduction index of **R_w ($C_{50\text{-}5000}$) = 50.6 (-1) dB** and thus an improvement of the basic construction by ΔR_w = 2,8 dB is achieved.

With the Phonestar a weighted sound reduction index of **R_w ($C_{50\text{-}5000}$) = 55,7 (-3)** and thus an improvement of the basic construction by ΔR_w = 7.9 dB is achieved.

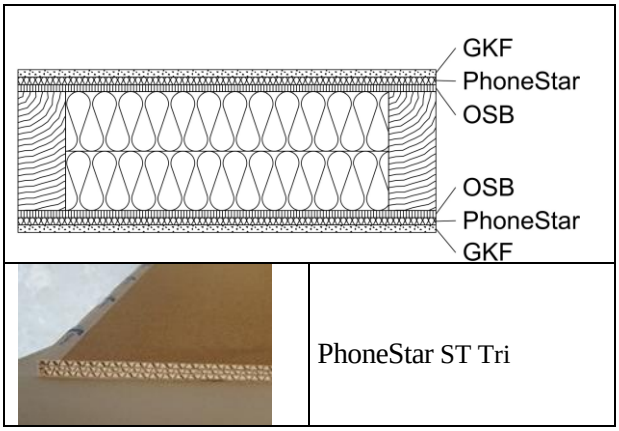

Figure 6. Timber stud wall with an additional layer "PhoneStar ST Tri" [8], a three-layer corrugated board filled with fine, loose quartz sand.

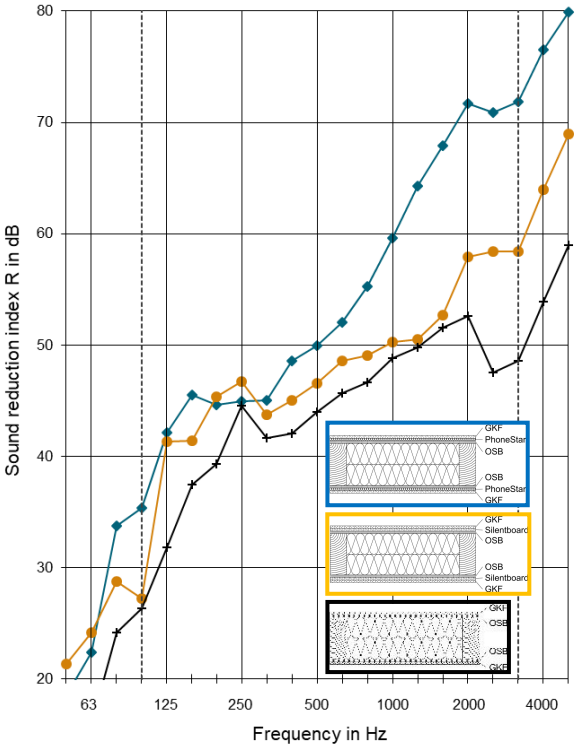

Figure 7. Sound reduction index of the wall with different claddings:

Table 1: Single number values for the frequency spectra in figure 7.

OSB + GKF	R_w ($C_{50\text{-}5000}$) = 47.8 (-3) dB
OSB + Silentboard + GKF	R_w ($C_{50\text{-}5000}$) = 50,6 (-1) dB
OSB + Phonestar + GKF	R_w ($C_{50\text{-}5000}$) = 55,7 (-3) dB

The performance of the Phonestar is clearly better. At low frequencies up to 200 Hz the improvement is about 10 dB. Above 250 Hz the increase of the sound insulation is much steeper than with the Silentboard. It is assumed that this is mainly due to high internal damping caused by the loose sand in the panels. Due to the better performance PhoneStar ST Tri was used for the further investigations.

6. SEPARATION OF THE WOODEN STUDS

The planking of the two sides of the wall is coupled via studs, sills and frames. According to [6], improvements in sound insulation can be achieved by separating the two wall shells. In order to achieve a solution that is as practical as possible, the studs were separated, while the sill and frame remained continuous (Figure 8). In this way, complete decoupling of the two wall shells is not achieved, but the wall can be manufactured, transported and assembled in one piece. This meets the prefabricated house industry's desire for a high degree of prefabrication. As before, the wall with separate studs was cladded with OSB, PhoneStar ST Tri and GKF (Figure 9).

Figure 8. Timber stud wall with separated studs and continuous sill and frame.

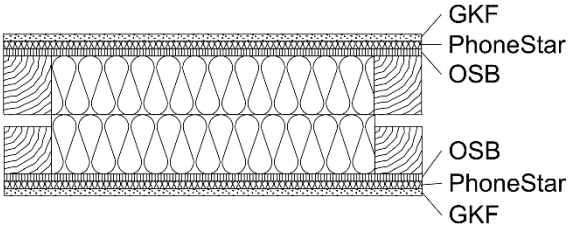

Figure 9. Timber stud wall with separated studs and cladding with OSB, Phonestar ST Tri and GKF.

In Figure 10 are compared the sound reduction indices of the basic construction, with the additional layer Silentboard and without and with separated studs.

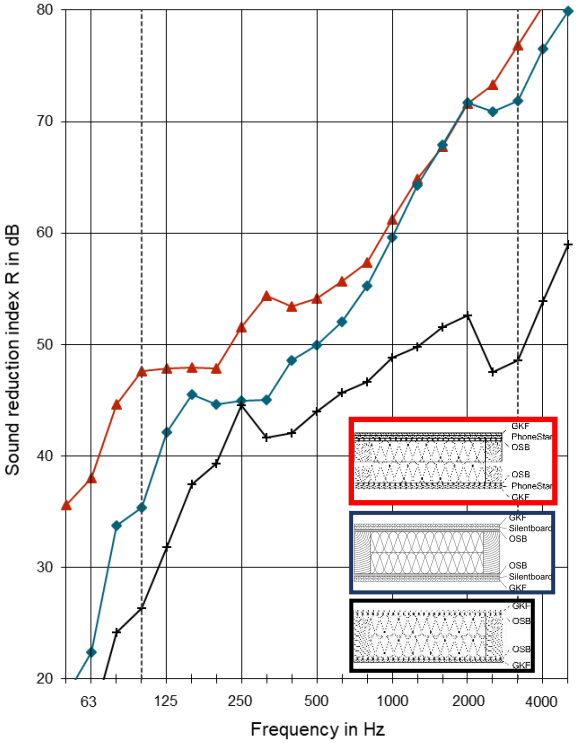

Figure 10. Sound reduction index of the wall with different claddings:

The separation of the studs leads to a significant improvement of the sound insulation below 1 kHz and especially in the low frequency range where the improvement of the previous construction is about 10 dB.
With the separated studs a weighted sound reduction index of **R_w ($C_{50\text{-}5000}$) = 60,4 (-1) dB** and thus an improvement of the basic construction by ΔR_w = 12.6 dB

is achieved. According to the German standard DIN 4109-5 the "increased" requirement in multi-family houses is $R_w \geq 56$ dB. This value is met by far even when the spectrum adaptation term is added. In a building of course flanking transmission has to be taken into account. Calculations and a measurement in a real building [1] indicate that with this wall construction and so far used flanking element constructions the targeted value is still met with safety.

Table 2: Single number values for the frequency spectra in figure 10.

OSB + GKF	R_w ($C_{50\text{-}5000}$) = 47.8 (-3) dB
OSB + Phonestar + GKF	R_w ($C_{50\text{-}5000}$) = 55,7 (-3) dB
OSB + Phonestar + GKF; separated studs	R_w ($C_{50\text{-}5000}$) = 60,4 (-1) dB

7. IMPACT SOUND INSULATION

On the optimized wall construction with OSB, PhoneStar ST Tri and GKF cladding on both sides and with separated studs (Figure 9) a quarter-spiral wooden staircase with stringboard was installed in the test stand (Figure 11). A side wall was also added here, which was bolted to the partition wall. In the original state, the stair stringboard was rigidly bolted to the partition and side wall and had no distance to them.

Figure 11. Wooden staircase with stringboard connected to the optimized wall construction with separated studs (Figure 9) and optimized corner support.

Based on this standard construction used so far, the screw connections to the wall were loosened and the staircase was moved away from the wall. Statically, a corner support was then required, which was screwed to the side wall, as shown in Figure 11. In addition, an elastomer isolating element was placed under the corner support to decouple the stair string board and rubber sleeves were used to decouple the screws for connecting the stair to the corner support.

The impact sound insulation was determined according to EN ISO 10140-3 [9]:

$$L_n = L_i + 10\ lg\ A/A_0 \quad (1)$$

L_i: averaged sound pressure level in receiving room [dB]
A: equivalent absorption area in receiving room [m²]
A_0: reference absorption area, $A_0 = 10$ m²

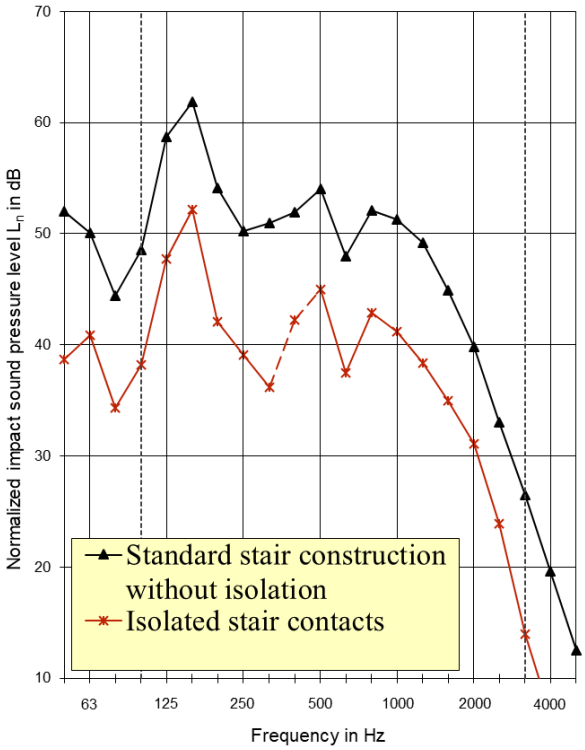

Figure 12. Normalized impact sound pressure level of the stair attached to the optimized wall:

The single number value and spectrum adaptation terms were evaluated according to ISO 717-2 [10]. In the following the spectrum adaptation value $C_{I,50\text{-}2500}$ that

accounts for the low frequency sound transmission down to 50 Hz is also given as in [6].

Table 3: Single number values for the frequency spectra in figure 12.

Standard stair configuration without isolation	$L_{n,w}$ ($C_{I,50\text{-}2500}$) = 51.2 (0) dB
Optimized stair configuration with isolated wall contact	$L_{n,w}$ ($C_{I,50\text{-}2500}$) = 41.2 (0) dB

The results for the two stair configurations are shown in Figure 12.
The isolation of the stair leads to a significant improvement of the normalized impact sound pressure level in the whole frequency range and especially in the low frequency range where the improvement is about 10 dB. For the non-isolated stair a weighted normalized impact sound pressure level of **$L_{n,w}$ ($C_{I,50\text{-}2500}$) = 51.2 (0) dB** is obtained.
With the isolated stair contacts a weighted normalized impact sound pressure level of **$L_{n,w}$ ($C_{I,50\text{-}2500}$) = 41.2 (0) dB** and thus an improvement by $\Delta L_{n,w}$ = 10 dB is achieved. According to the German standard DIN 4109-5 the "increased" requirement in multi-family houses is $L_{n,w} \leq 47$ dB. This value is met by far even when the spectrum adaptation term is added. Again, in a building situation flanking transmission has to be considered but it is unlikely that this will dramatically worsen the laboratory value.

8. SUMMARY

The airborne sound insulation of a timber stud wall was to be determined and optimized by constructive measures, for which measurements were carried out in a test stand. Starting from a basic wall construction and a weighted sound reduction of R_w ($C_{50\text{-}5000}$) = 47.8 (-3) dB the final value achieved was R_w ($C_{50\text{-}5000}$) = 60,4 (-1) dB. The significant improvement was obtained by adding an additional cladding - a three-layer corrugated board filled with fine, loose quartz sand - and a separation of the wall studs.
In a second step the impact sound insulation of a standard wooden staircase attached to the optimized wall was improved by isolation measures at the stair-wall contacts from $L_{n,w}$ ($C_{I,50\text{-}2500}$) = 51.2 (0) dB to $L_{n,w}$ ($C_{I,50\text{-}2500}$) = 41.2 (0) dB. The constructive modifications are highly effective in the low frequency range that is mainly problematic in wooden buildings.

SOUND INSULATION PERFORMANCE OF TIMBER FLOORS WITH ELASTICALLY MOUNTED AND SUSPENDED LAYERS

Jesse Lietzén[1*] **Lauri Talus**[1] **Alina Lahdensivu**[1]
Aitor Lopetegi[2] **Ander Aldalur**[2]

[2] AMC Mecanocaucho, Spain

ABSTRACT

Massive timber buildings are often equipped with concrete or cement screed floors to increase the mass of the structures and to improve the sound insulation between rooms. However, the use of concrete is more and more often seen as an unfavourable option due to the increasing need to decrease the carbon dioxide emissions of the construction sector. A recent field study performed in a mock-up CLT-framed building showed that the sound insulation can drastically be improved without concrete by mounting the upper layers of the floor and the suspended ceiling elastically to the load-bearing timber slabs. In comparison with the conventional screed solution, the vertical airborne and impact sound insulation was improved with the elastically mounted floor up to 13 and 20 dB in terms of the single-number quantities $D_{nT,w}$ and $L'_{nT,w}$. This study aims to investigate the sound insulation performance of the conventional and elastically supported floors by conducting computational assessments which were compared with the field measurement results. Furthermore, the assessments were broadened to study the sound insulation between rooms in the horizontal direction. These computations based on FEM and parametric models reveal the superior performance of the elastically mounted floor both in horizontal and vertical directions.

1. INTRODUCTION

Massive timber such as cross-laminated-timber (CLT) is a typically applied load-bearing frame solution in different timber building types. When timber apartment buildings with high sound insulation requirements are considered, the frame is usually partly decoupled and supported with elastic bearings and partly covered with sound insulating structural layers such as elastically suspended ceilings. The reason for these solutions is to avoid flanking sound transmission between adjacent rooms.

One conventionally applied solution to improve sound insulation performance of massive timber buildings is to pour concrete or cement screed on the massive timber floors. This increases the mass of the floors, but on the other hand, the use of concrete or cement increases the carbon dioxide emissions of the building.

An alternative solution to improve sound insulation is to cover the massive timber floors with elastically attached building board layers. A recent field study performed in a CLT framed mock-up building showed that the sound insulation of the building can be improved in comparison with the conventional concrete solution [1]. Based on the study, the improvement of sound insulation in vertical direction due to the elastically mounted floor was up to 23 and 36 dB in terms of the single-number quantities (SNQ) $D_{nT,w}$ and $L'_{nT,w}$.

The purpose of this paper is to further compare the sound insulation of CLT floors with cement screed, and elastically mounted floor. In the first part, the sound insulation of the floors was computationally assessed in vertical direction. Second part of the study involved application of the results to predict the horizontal sound insulation between two adjacent rooms in an imaginary CLT framed building. The computational assessments were performed with the finite element method and with parametric calculation models.

2. MATERIALS AND METHODS

2.1 Studied floors

2.1.1 Floor assemblies

The sound insulation of five timber floors F0–F4 was studied. In all the cases, the load-bearing structure was a 140 mm thick 5-layered CLT slab, which also acted as the reference floor F0. The rest of the studied floors had either a cement screed (F1–F2) or an elastically mounted floor (F3–F4) as floor toppings. Two of the studied floors (F2 and F4) had also elastically suspended ceilings installed below the CLT slab. None of the floors had floor coverings in the study. Briefly, the studied floors were:

- F0: CLT 140 mm
- F1: Screed 50 mm + underlayment 3 mm + F0
- F2: F1 + elastically suspended ceiling
- F3: Elastically mounted floor + F0
- F4: F3 + elastically suspended ceiling

The study aimed to compare the sound insulation performance of the floors F1 and F3 (Fig. 1). Floors F1 and F2 were equipped with the cement screed on the CLT slab. An elastic underlayment of thickness 3 mm (a bitumen-based product with dynamic stiffness 120 MN/m^3) was installed below the screed. Floors F3 and F4 had an elastically mounted floor topped with 18 mm OSB and two 12,5 mm Fermacell fibre gypsum boards. The elastic floor mounts (AMC Mecanocaucho Akustik+Sylomer® 25 Floor Mount) were installed between the CLT slab and the 50 mm timber battens in a 500/600 mm spacing. The space between the CLT slab and the elastically mounted floor was filled with 75 mm thick glass wool.
Floors F2 and F4 were equipped with a suspended ceiling. Two 13 mm thick plasterboards were hanged from the CLT slab with elastic elastomer hangers (AMC Mecanocaucho Akustik+Sylomer® 15 Type B) which were installed in a 500/1200 mm spacing and attached to metal frames (spacing c/c 1200 mm) for the plasterboard installation. The air gap between the gypsum boards and the CLT slab was 100 mm including 75 mm of glass wool.

2.1.2 Measurements

Airborne and impact sound insulation of the floor assemblies F0, F1 and F3 has previously been measured in a timber mock-up building [1]. The measurement results for the floors have been presented in Tab. 1 in SNQs, in a case where the main flanking sound transmission routes were covered with sound insulating wall linings.

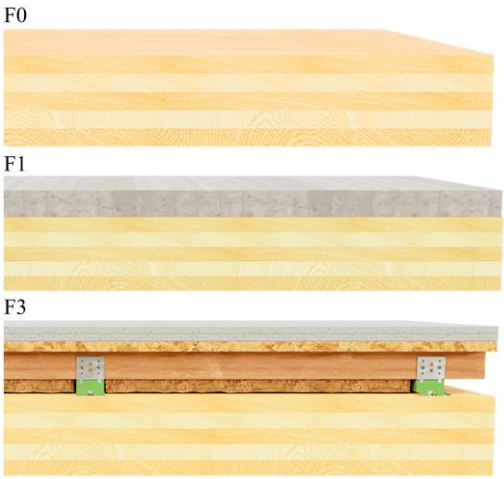

Figure 1. Studied floor assemblies F0, F1 and F3.

Table 1. Airborne and impact sound insulation of the floors F0, F1 and F3 measured in vertical direction in a timber mock-up building [1].

Floor	$D_{nT,w}$	$L'_{nT,w}$
F0: CLT 140 mm	39 dB	86 dB
F1: Screed 50 mm + underlayment 3 mm + F0	49 dB	70 dB
F3: Elastically mounted floor + F0	62 dB	50 dB

The measurements were performed in the field in the vertical direction in a three-story high timber building. In the measurement situation, the source room (V = 51 m^3) was located on the second floor and the receiving room (V = 26 m^3) on the ground floor. The area of the measured floor structures was 9,5 m^2. However, it must be noted that the flanking structures were not equivalent with each other in different measurement arrangements.
The measurement results clearly indicate a superior performance of the elastically suspended floor (F3) compared to the screed floor (F1) in vertical direction. In terms of $D_{nT,w}$ and $L'_{nT,w}$, the improvement of sound insulation of the elastically mounted floor was 23 and 36 dB whereas the effect of the screed floor on the sound insulation was only 10 and 16 dB, respectively.
The sound insulation performance of the floor solutions was not compared in a horizontal direction, although the effectiveness of the elastically mounted floor in this respect has previously been shown [2]. Because of this, the effect of the solutions on the horizontal sound insulation was studied computationally in this paper.

2.2 Sound insulation between adjacent rooms

In a complete building, the sound insulation between adjacent rooms depends on the room properties and flanking sound transmission between rooms. Thus, the effect of the studied floors on the horizontal sound insulation cannot directly be explained by the performance of the floors. To study further how the floors influence the horizontal sound insulation between rooms, a flanking transmission analysis was carried out for an imaginary timber building setup.

In the analysis, airborne and impact sound insulation between two rooms (Fig. 2) was computationally determined applying the methods presented in the parts 1 and 2 of the ISO 12354 [3,4] and the computational results for the floors based on the methods presented in Section 2.3. All the load-bearing structures surrounding the studied rooms were 140 mm thick CLT plates and the T- and X-junctions between the CLTs were rigid. The dimensions of the adjacent rooms were 3 m x 2.8 m x 3.8 m of which the area of the wall separating the rooms was 3 x 2.8 m^2.

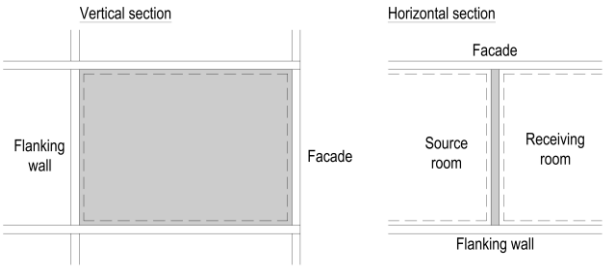

Figure 2. Flanking sound transmission setup. Rooms were surrounded with 140 mm thick CLT plates with rigid junctions. The grey areas represent the wall separating the rooms, and the dashed lines illustrate the ceilings, wall linings and floor coverings.

Sound insulation between the rooms was determined in six different cases: for the floors F0, F1, and F3 with two different partition walls. The studied walls were:

- A: 2 plasterboards 13 mm + steel frame 45 mm and mineral wool + air gap 27 mm + steel frame 45 mm and mineral wool + 3 plasterboards 13 mm
- B: CLT 140 mm + air gap 30 mm + 45 mm and mineral wool + 2 plasterboards 13 mm

In all the cases, except for the case with the floor F0, the other indirect flanking transmission routes were covered with wall linings (the same CLT lining as in wall B), or suspended ceilings (see floors F2 and F4, in Section 2.1).

2.3 Simulation procedures and model descriptions

The sound insulation of floors F0, F1 and F3 was examined using a similar approach as in a previous study [5], in which the benefits of an elastically suspended ceiling was investigated. Similarly to the previous study, both parametric calculation models as well as the finite element method were used to examine the impact and airborne sound insulation of the floors.

The analytical models were used to analyse the frequency range 250–5000 Hz, whereas the FE-model was used in the low frequencies between 50–200 Hz 1/3-octave bands.

In addition to floors F0, F1 and F3 the aforementioned calculation methods were used to examine the partitions and other flanking constructions of the CLT building setup described in Section 2.2.

2.3.1 Material properties

The material properties used in the calculation of sound insulation have been presented in Tab. 2.

Table 2. Applied elastic material properties.

Material	ρ [kg/m^3]	E [MPa]	ν [-]	η_s [-]
CLT	510	4600*	0.28	0.02
Screed	2200	30000	0.20	0.01
Fermacell	1270	3800	0.28	0.01
OSB	490	2210	0.28	0.01
Plasterboard	710	3100	0.28	0.01

* Equivalent isotropic value based on the ref. [6].

The static airflow resistivity of the glass wool was 10000 Pa·s/m^2. Spring constant and structural loss factors of the elastic floor mounts and the elastic hangers were 122990 N/m and 0.07 and 29960 N/m and 0.07, respectively.

The CLT plate and the floor topping of floor F3 were modelled as equivalent isotropic plates in an approach similar to the one used in [6]. The bending stiffnesses of the structure in the different main directions B_x and B_y were first determined, and the equivalent bending stiffness was:

$$B_{eq} = \sqrt{B_x B_y} \tag{1}$$

From the equivalent bending stiffness, the equivalent Young's modulus can then be determined from:

$$E_{eq} = \frac{B_{eq}}{I} \tag{2}$$

where E_{eq} is the equivalent Young's modulus, and I is the second moment of area.

2.3.2 Finite element method

The FE-modelling of floors F0, F1 and F3 was carried out using COMSOL Multiphysics 6.2. The same finite element model was used for both airborne and impact sound insulation, with the only difference being the type of excitation used. The model was a fully coupled analysis with two-way acoustic-structural interaction between the structural and acoustical parts of the model, and it was built to correspond to laboratory conditions. The CLT was simple supported and the other structural parts were connected to the CLT but otherwise the boundary conditions were free. The geometries of the FE-models of the floors F1 and F3 are presented in Fig. 3.

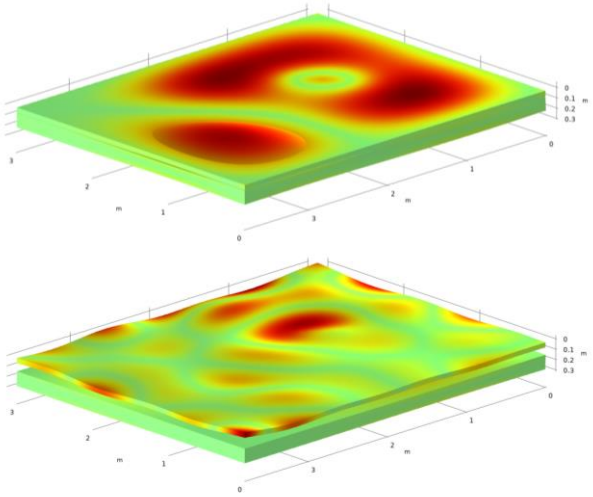

Figure 3. The FE-models of the floors F1 (above) and F3 (below) presenting the floor displacements at 100 Hz during the impact excitation.

The governing equation of motion for the structural parts of the model was:

$$\nabla \cdot \boldsymbol{S} = -\rho\omega^2\mathbf{u} \tag{3}$$

where $\boldsymbol{S}$ is the second Piola-Kirchhoff stress tensor, ρ is the material density, ω is the angular frequency and $\mathbf{u}$ is the displacement vector [7]. The acoustical domains were governed by the Helmholtz equation:

$$\nabla \cdot \left(-\frac{1}{\rho_0}\nabla p\right) - \frac{\omega^2 p}{\rho_0 c_0} = 0 \tag{4}$$

where p is the time harmonic sound pressure, ρ_0 is the density of air and c_0 is the speed of sound in air [8].

The sound absorbing materials in the air cavities of the suspended ceiling and the floor topping of floor F3 were modelled using the modified Champoux-Allard equivalent fluid model [8, 9].

The elastic floor mounts and ceiling hangers were modelled as spring-damper components as in [5, 10, 11]. The use of spring-damper components as a substitute for a full 3D-model of an elastic ceiling mount was previously found to yield good results [5]. The spring-damper components were given a spring coefficient k and loss factor corresponding to the pre-loaded state of the elastic mount. The natural frequency f_0 of the ceiling hangers was 9,5 Hz and the mass per hanger was 8,4 kg. The natural frequency of the floor mounts was 16 Hz and the mass per mount was 12,2 kg.

To solve the radiated sound power, a half-infinite acoustic domain representing the receiving airspace was modelled on the receiving side of the floor constructions. The fully absorptive boundary condition of the half-infinite domain was achieved using perfectly matched layers.

The mesh of the FE-model was built using hexahedral quadratic elements. The mesh was frequency dependent with the element size being a fifth of the wavelength of sound according to [8].

The airborne sound insulation of the floor constructions was assessed by applying a diffuse sound field excitation modelled after [12]. The excitation applied on the surface of the floor construction was a sum of N plane waves evenly distributed over a half-sphere with random phase. The FE-model was then used to determine the radiated sound power. Then the sound reduction index of the floor construction was determined from:

$$R = 10\log\left(\frac{P_{dif}}{P_{rad}}\right) \tag{5}$$

where P_{dif} is the sound power generated by the diffuse field excitation on the sending side of the structure and P_{rad} is the radiated sound power on the receiving side.

The impact sound insulation of the floors was determined using an ISO tapping machine excitation modelled as a series of point forces on the floor surface after [13]. Again, the sound power radiated by the structure was solved from the FE-model. The normalized impact sound pressure level was then determined from:

$$L_n = \log\left(\frac{P_{rad}}{P_0}\right) + 10\log\left(\frac{A_{ref}}{A_0}\right) \tag{6}$$

where P_0 is the reference sound power 10^{-12} W, and A_{ref} and A_0 are the reference sound absorption areas 4 and 10 m^2.

2.3.3 Parametric models

The airborne and impact sound insulation of the were examined in the mid and high frequency range with parametric calculation tools developed by AINS Group.
The airborne sound insulation of the floor constructions was examined with a tool that combines a number of different calculation models based on statistical energy analysis, lumped mechanical models and forced transmission approaches. The calculation method is based on Refs. [3, 14–18].
The impact sound insulation of the floor structures was calculated using a method based on Refs. [4, 19–23]. In addition to the features of the airborne sound insulation model, the impact sound insulation model takes into account the force interaction of the ISO tapping machine and the floor surface.

3. RESULTS

3.1 Sound insulation of the floor assemblies

Simulated sound reduction index R and normalised impact sound pressure level L_n of floors F0, F1 and F3 are presented together with the measured standardised level difference D_{nT} and standardised impact sound pressure level L'_{nT} results in Fig. 4 and Fig. 5. Thus, discrepancies between the results are partly explained by the differing quantities.
Fig. 4. shows that the calculated sound reduction index correlates well with the measured level difference. The effect of the bare CLT slab (F0) accumulates to the results of F1 between 80 and 400 Hz in both the measured and simulated results. Having an elastically mounted floor (F3), the effect of the CLT slab is no longer displayed.
The correlation between the simulated and measured impact sound pressure levels is weaker than for airborne sound yet acceptable (Fig. 5). The calculation result for F0 seems to have shifted to lower frequencies compared to the measured result. The effect of the CLT slab can be seen also on the other simulated results.
Calculation results underestimate the sound insulation of floor F3 on low frequencies below 250 Hz. The resonance frequencies of floor F3 are shifted higher by 1/3 octave on the simulated results compared to measurements.

3.2 Sound insulation between adjacent rooms

The predicted total sound insulation between rooms and all flanking transmission paths between rooms are presented in Fig. 6 and Fig. 7 for all examined cases.

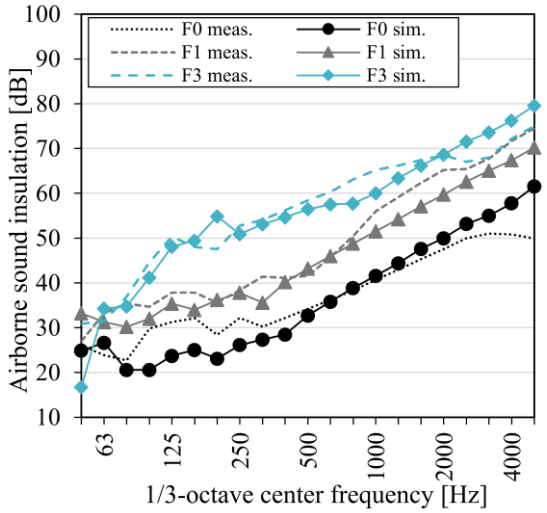

Figure 4. Measured standardised sound level difference D_{nT} and simulated sound reduction index R of floors F0, F1 and F3.
