Figure 5. Measured standardised impact sound pressure level L'_{nT} and simulated normalised impact sound pressure level L_n of floors F0, F1 and F3.

In case of the horizontal airborne sound insulation, the main limiting factor is the flanking path Ff through the floor structures (see Fig. 6). Covering the floor with the screed (F1) (and other flanking paths with the linings) improves the horizontal airborne sound insulation. However, the total sound insulation is still limited due to the flanking sound transmission via the floor-to-floor route. In case of the floor F3, the limiting factor is the sound reduction index of the wall itself.

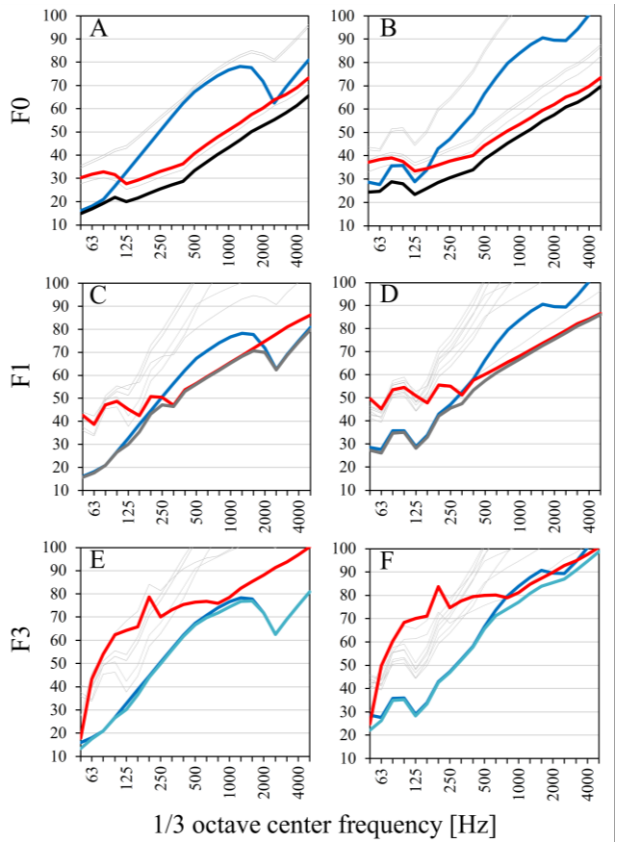

Figure 6. Airborne sound insulation (D_{nT} [dB]) between rooms. Dark blue line denotes the direct path Dd of wall A or B, red line indicates flanking path through floor, light grey lines indicate other flanking paths, and bold line denotes the total sound insulation. A. floor F0, wall A, B. floor F0, wall B, C. floor F1, wall A, D. floor F1, wall B, E. floor F3, wall A, F. floor F3, wall B. On figures A and B, the flanking elements are bare CLT. Figures C-F have linings and suspended ceiling on flanking structures.

The horizontal impact sound insulation is determined mostly by the impact sound insulation of the floor structure (see Fig. 7). For elastically mounted floor F3 the total impact sound insulation is a combination of different flanking paths: path Fd from floor to wall below 500 Hz and path Ff from floor to floor above 500 Hz. In case of the floor F1, a soft floor covering should be applied to reach reasonable impact sound insulation between rooms.
The results show that by applying the elastically mounted floor, better sound insulation can be achieved also between rooms.

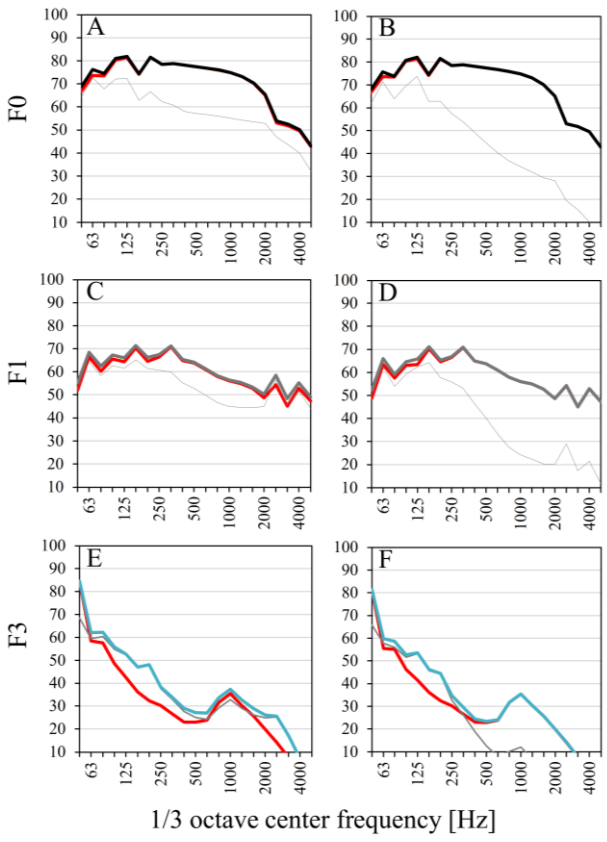

Figure 7. Impact sound insulation (L'_{nT} [dB]) between rooms. Dark blue line denotes the sound insulation of wall A or B, red line indicates flanking path through floor, light grey lines indicate other flanking paths, and bold line denotes the total sound insulation. A. floor F0, wall A, B. floor F0, wall B, C. floor F1, wall A, D. floor F1, wall B, E. floor F3, wall A, F. floor F3, wall B. On figures A and B, the flanking elements are bare CLT. Figures C-F have linings and suspended ceiling on flanking structures.

The total horizontal sound insulation results that were presented in the Figs. 6 and 7 are repeated in Figs. 8 and 9. The corresponding SNQs are presented in Tab. 3.

Table 3. Predicted single-number quantities.

Floor, wall	$D_{nT,w}$ (C, $C_{50-3150}$)	$L'_{nT,w}$ (C_I, $C_{I,50-2500}$)
F0, A	37 (-1, -2) dB	76 (-2, -1) dB
F0, B	42 (-2, -2) dB	76 (-2, -1) dB
F1, A	54 (-3, -7) dB	64 (-1, -1) dB
F1, B	55 (-4, -5) dB	63 (-1, -1) dB
F3, A	56 (-4, -9) dB	41 (2, 29) dB
F3, B	56 (-5, -5) dB	40 (2, 26) dB

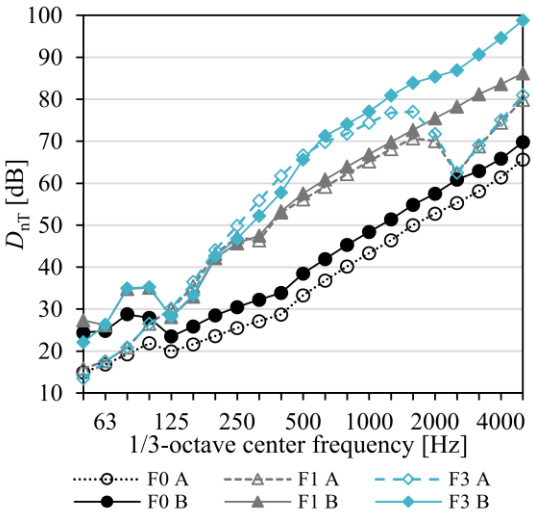

Figure 8. Standardised level difference between rooms for walls A and B.

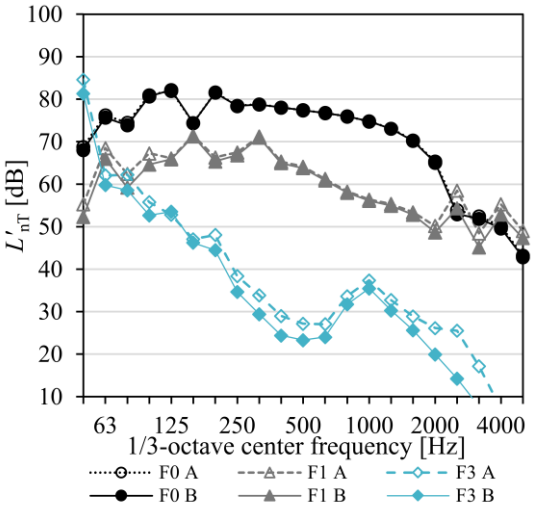

Figure 9. Standardised impact sound pressure level between rooms for floors F0, F1 and F3. The weak results for the floor F3 at 50 Hz cumulate from the simulation result (see Fig. 5), and are likely to underestimate the performance of the solution at this frequency band.

The standardized level difference $D_{nT,w}$ is significantly higher when using sound insulating linings on room surfaces. Compared to the reference case F0 with no linings, the airborne sound insulation is improved by 13–17 dB with floor F1 and 16–19 dB with floor F3. The standardized impact sound pressure level $L'_{nT,w}$ is improved by 12–13 dB with floor F1 and 35 – 36 dB with floor F3.

4. DISCUSSION

In the first part of this study (3.1) the airborne and impact sound insulation of floors F0, F1 and F3 were examined with FEM and parametric calculation methods. The calculation results were then compared to vertical field measurement results acquired in [1] (Figs. 3 and 4). The agreement between the simulated and measured results was good apart from the 50 Hz 1/3-octave band for floor F3, where a significant increase in the impact sound pressure level can be seen in the simulation result. The spectrum adaptation term $C_{I,50-2500}$ for structure F3 is determined by the divergent 50 Hz result and has a significant effect on the single-number quantities. From Figs. 3 and 4 the same decrease in sound insulation is not visible in the corresponding measurement results.

The discrepancy in the lower frequencies for F3 could be due to the boundary conditions in the FE-model. The results of [2] indicate the building boards of the elastically mounted floor were connected to the partition wall. This causes the floor assemblies to not perform as intended and affects the measured sound insulation. The building boards of the elastically mounted floor in F3 were modelled in FEM as freely supported, which differs from the *in-situ* conditions.

Floor construction F1 seems to perform better at low frequencies, which could be due to F1 not being a conventional screed floor. Typically, the cement screed is cast on top of a protective layer, and sometimes additional connectors are used to make the joint between CLT and screed stiffer. In this case, however, the underlay was a elastic bitumen-based product, which lead to the screed working as a floating floor structure rather than a compound structure. Therefore, floor F1 might have better sound insulation qualities than a conventional CLT-screed compound floor.

The CLT was modelled in FEM as a ~10 m^2 plate, whereas the CLT in the ADIVBois mock-up connected to the surrounding structures. Therefore, the total losses of the CLT were higher than in a laboratory setting, and the sound energy was spread to a wider area instead of being completely transmitted to the room below.

The sound insulation between rooms in the mock-up building, including flanking transmission, was investigated in [25] with both measurements and predictions using ISO 12354 [3, 4]. It was found that the agreement between measurement and prediction was reasonable. However, there was rather significant uncertainty in the measured vertical impact sound insulation, especially at low frequencies. Additionally, the accuracy of the predictions in [25] was worse at lower frequencies.

The horizontal sound insulation between rooms was also investigated in [25], but no comparison was done between different floor structures. Horizontal sound insulation between rooms with floors F1 and F3 was compared in Figs. 7 and 8. Fig 7 shows that the horizontal airborne sound insulation is greatly improved with the use of wall linings, floor toppings and suspended ceilings. It is also worth noting that F3 performs better than the screed solution F1.

The horizontal impact sound insulation is also significantly improved with the use of either the screed floor or the elastically mounted floor (Fig. 9). However, the elastically mounted floor again performs better than the screed floor in most of the building acoustics frequency range. The weaker apparent impact sound insulation at 50 Hz is due to the calculated impact sound insulation of floor structure F3, which was discussed above.

The elastically mounted linings effectively reduce flanking transmission via the load bearing CLT frame. According to calculation results in Figs. 5 and 6 the joints of the CLT frame can be rigid, when wall linings, suspended ceiling and floor are connected elastically. This solution is essentially a room-in-room solution, where the choice of partition wall becomes the limiting factor for horizontal airborne sound insulation.

Horizontal impact sound insulation is dependent on both the partition wall and the floor assembly. Since all impact sound is transmitted via the floor, it's the most important element. However, the performance of the floor may be superseded by a particularly weak wall structure, causing sound to be transmitted via the floor-wall path instead of the floor-floor path. An example could be a bare CLT partition rigidly connected to the load bearing floor structure. On the other hand, a completely rigid CLT frame could be a functional choice when using elastically connected lining structures. Having a rigid load bearing frame is beneficial for example for the bracing of a building.

5. CONCLUSIONS

The horizontal sound insulation in a CLT framed building was investigated with sound insulation predictions using the ISO 12354 method. The airborne and impact sound insulation of the individual building elements were determined using both the finite element method as well as parametric methods. The calculated sound insulation of the building elements was compared to field measurements with good agreement. Larger discrepancies were found in the low frequency range, which could be due to differences between calculation assumptions and *in-situ* conditions as well as measurement uncertainties.

According to the calculation results the horizontal sound insulation between rooms can be significantly improved with elastically attached linings on room surfaces. Additionally, it was found that using an elastically mounted lightweight floor topping was a superior solution when compared to a cement screed floor.

IMPACT SOUND INSULATION OF CLT FLOORS: EVALUATION OF SMALL SCALE SPECIMENS AND CORRELATION WITH LARGE SCALE SYSTEMS

Maro Puljizevic[1*] **Tadej Poljansek**[1] **Milan Grasic**[1]
[1] Knauf Insulation, Trata 32, 4220 Skofja Loka, Slovenia

ABSTRACT

CLT has emerged as widely adopted material due to its versatility and environmental benefits. However, achieving suitable impact sound insulation for CLT floor systems is challenging. Laboratory tests of impact sound insulation present an invaluable source of information for design teams, but they are time consuming due to required sample size (10-20 m^2) and complexity of installation. Performing impact sound insulation tests on small samples offers operational advantages and provides an attractive testing option for comparative purposes and design decisions. This study provides a systematic analysis of impact sound insulation measurements conducted on a variety of small scale and large scale specimens utilizing CLT reference floor. Unlike concrete reference floors, CLT exhibits significant contribution of airborne sound component induced by the tapping machine. This phenomenon necessitates careful consideration when employing small-scale specimens for impact sound insulation analysis. Study highlights the advantages and limitations of conducting impact sound insulation tests on small scale specimens, emphasizing their practicality for comparative analyses and design decision-making. Furthermore, it points to certain constraints when extrapolating these findings to large-scale systems, offering insights into refining testing protocols for CLT-based constructions.

1. INTRODUCTION

Alongside the airborne sound insulation, impact sound forms one of the cornerstones for acoustic requirements throughout the world. The robust information of impact sound levels for floor constructions is indispensable for all the parties involved in the acoustic design process. Whether in the form of laboratory test reports, published data for common building systems or computer simulations.

Compared to the substantial data available for standard monolithic floors, information concerning lightweight floors, particularly cross-laminated timber (CLT) floors, is limited. The latter is of particular importance considering relatively poor impact sound insulation performance of the basic CLT floor elements themselves; necessitating certain upgrades by means of complex floor coverings and/or suspended ceilings.

Laboratory testing, in accordance with ISO 10140-3:2021 [1], provides a reliable means to determine floor impact sound levels. However, such tests are inherently complex due to the required sample size and installation procedure.

While Bet et al. [2] previously explored the implications of sample size reduction in impact sound tests on heavyweight concrete floors, similar studies are lacking for CLT floors.

This work aims to fill this void by assessing the efficacy and reliability of small scale impact sound tests on basic CLT floor.

The discussion will commence with an overview of impact sound insulation test method, followed by an experimental investigation employing tapping machine on a variety of small scale and large scale floor coverings built on top of the CLT reference floor (without the ceiling). Concluding

remarks will summarize the main findings of the experimental investigation and the analysis of correlations between different sample sizes.

2. IMPACT SOUND INSULATION TEST METHOD

ISO 10140-3:2021 [1] details the procedure for impact sound insulation measurements and refers to other parts of ISO 10140 where appropriate.

Accordingly, the size of the test opening for floors shall be between 10 m^2 and 20 m^2, with the shorter edge length not less than 2,3 m.

Annex H of ISO 10140-1:2021 [3] introduces the concept of testing on small specimens, the minimum size of which is 650 mm x 350 mm. However, the latter procedure is introduced only for floor coverings of Category I, which include flexible coverings (plastics, rubber, cork, matting or combinations thereof).

On the other hand, typical complex floor systems built on CLT would be generally classified as Category II floors, with the requirement for specimen size of at least 10 m^2.

Therefore, the current standard does not make a provision for the testing of small samples for floor systems and/or floor coverings typically built on the basic CLT slab.

As described, the concept of tests on small specimens is indeed rooted in the ISO 10140 test standard for certain floor coverings but one of the main obstacles remains the requirement that the airborne sound transmission from the source to the receiving room is at least 10 dB below the level of the transmitted impact sound in each frequency band.

The latter requirement is particularly constraining for small samples built on basic CLT floor, as relatively low airborne sound insulation of CLT will be the limiting factor.

Regardless of the small scale build-up (and its potentially high airborne sound insulation), airborne sound component produced by the tapping machine in the source room will inevitably propagate through the basic CLT element alone.

Therefore, the measured impact sound should be corrected according to ISO 10140-4 [4].

If the condition

$$L_i - (L_{TS} - D) \geq 10\ \text{dB} \qquad (1)$$

is valid in all one-third octave bands, a correction of airborne sound transmission is not necessary.

For

$$L_i - (L_{TS} - D) \leq 3\ \text{dB} \qquad (2)$$

sound transmission is dominated by airborne sound and impact sound insulation cannot be measured correctly.

L_i is the sound pressure level generated by the tapping machine in the receiving room;
L_{TS} is the sound pressure level generated by the tapping machine in the source room;
D is the sound pressure level difference between the source and receiving room with the loudspeaker on.

3. EXPERIMENTAL INVESTIGATION

Impact sound insulation tests were carried in accordance with ISO 10140-3:2021 [1] on ten pairs of small and large scale floor samples (all without the ceiling), built on top of the basic 5-ply 140 mm CLT installed between vertically adjacent source and receiving room (V = 58 m^3).

3.1 Test samples and materials

Size of large scale sample was 15,6 m^2 and that of small scale samples around 0,54 m^2 (ca 900 x 600 mm).

Four 900 x 600 mm samples were installed for each floor type, all of them large enough to support the whole tapping machine. Number of tapping machine positions was the same as the number of small scale samples (four).

Details of tested floor systems are provided in Tab. 1, listed from top to bottom layers (from walking surface to the structural CLT slab).

Floor systems were tested with and/or without the backfill. Where used, backfill was installed directly on top of CLT.

Floor numberings in Tab. 1 are done according to the following principle: F1 – floor one without the backfill, F1B – floor one with the backfill.

Table 1. Tested floor systems.

Floor No.	Build-up
F1 / F1B	Dry screed (Backfill) CLT
F2	Dry screed PE membrane CLT
F3	Dry screed EPS CLT
F4 / F4B	Dry screed EPS PE membrane (Backfill) CLT
F5 / F5B	Dry screed GMW (Backfill) CLT
F6 / F6B	Dry screed RMW (Backfill) CLT

Density (ρ), thickness (d) and dynamic stiffness (s') of used materials are listed in Tab. 2

Table 2. Material properties.

Material	ρ (kg/m^3)	d (mm)	s' (MN/m^3)
Backfill	1750	60	-
GMW (glass mineral wool)	50	40	6
RMW (rock mineral wool)	100	40	25
EPS	-	40	-
PE membrane	-	5	-
Dry screed	1280	18	-

Fig. 1 and Fig. 2 illustrate the typical testing arrangement for small scale samples. Where used, backfill was installed inside the wooden frame and laid on top of a thin layer of geotextile.

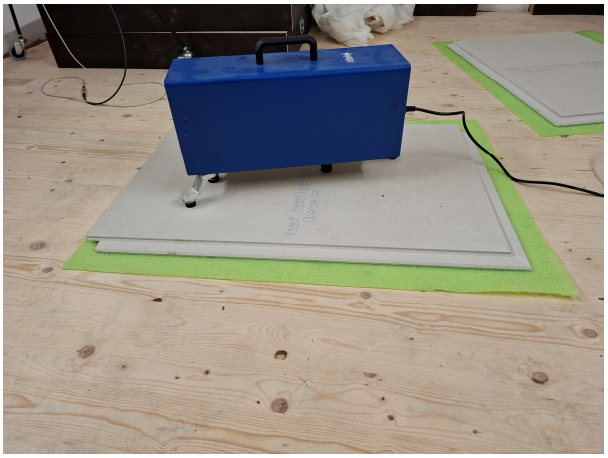

Figure 1. Test sample F2 (small scale).

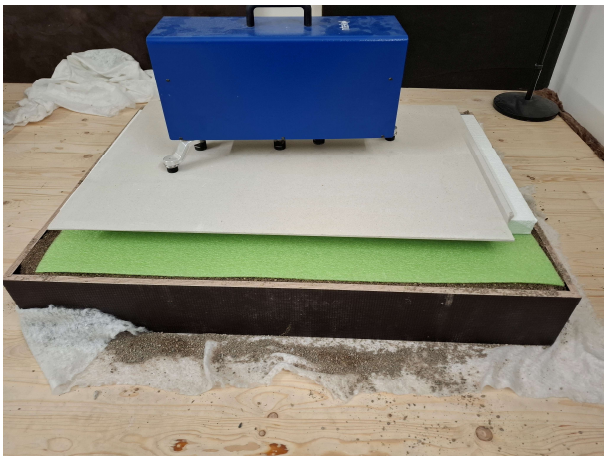

Figure 2. Test sample F4B (small scale).

3.2 Airborne sound component and testing limits

One-third octave sound reduction index (R) of basic 140 mm CLT floor is given in Fig. 3, with the corresponding single-number rating R_w 39 dB.

Such relatively low airborne sound insulation will have a determining influence on the frequency limit up to which the impact sound insulation can be measured correctly.

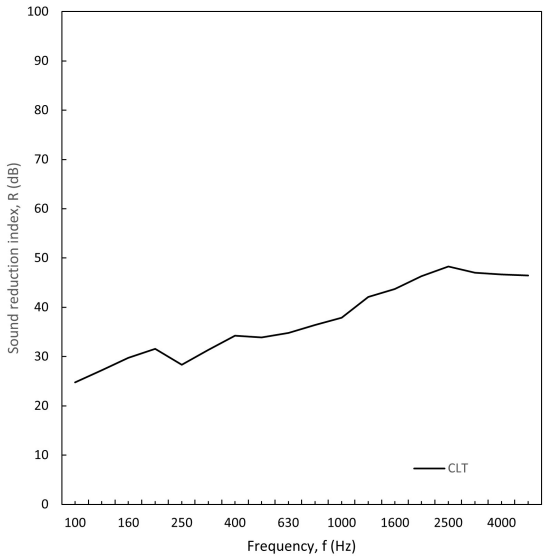

Figure 3. Airborne sound insulation of basic 140 mm CLT floor.

Sound pressure level generated by the tapping machine in the source room was measured for all the test samples.

There were minor differences observed between the sample sizes or due to the backfill. Fig. 4 illustrates the latter levels for basic CLT (solid line) and all the tested floors (shaded area).

Measured sound pressure levels in the source room were of a similar trend for all the tested floors, with relatively minor changes in the absolute values. Contribution of the top layer (dry screed) seems to be predominant, with no significant influence caused by the floors size, subsequent floor layers or backfill.

Equivalent A-weighted sound pressure level in the source room for all the test samples amounted between 93 and 95 dB(A).

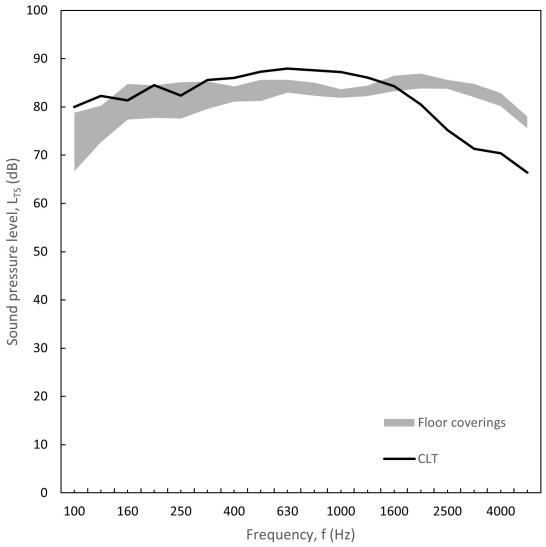

Figure 4. Sound pressure level (L_{TS}) generated by the tapping machine in the source room.

Sound pressure level generated by the tapping machine in the source room (93-95 dB(A)) will be attenuated only by the basic CLT floor (R_w 39 dB) for all the small scale samples, and by the entire floor build-up for every corresponding large scale sample.

Such constraint is the limiting factor for correct measurement of high performing floors, where airborne component will dominate on certain frequencies.

For example, Fig. 5 illustrates the normalized impact sound pressure levels (L_n) for floors F6 and F6B (small and large scale), with black-filled markers added to the frequencies where the result is dominated by the airborne sound and impact sound insulation cannot be measured correctly (result of equation (2) is $\leq$ 3 dB).

It can be noticed that such limitations can occur for small scale samples, as well as for high performing large scale samples.

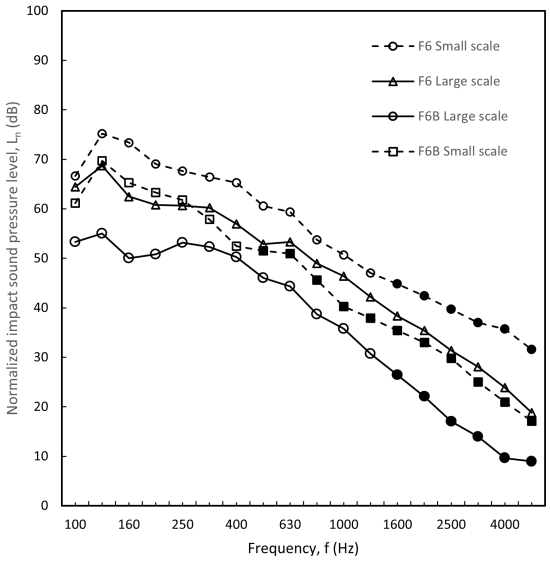

Figure 5. Limit of measurement precision for floors F6 and F6B.

Corresponding single-number ratings for airborne and impact sound insulation are provided in Tab. 3, together with the limiting frequency (f_l) where contribution of the airborne sound from source room starts to dominate and impact sound insulation cannot be measured correctly.

Prefixes *s* and *l* added to floor numberings indicate small and large samples.

Despite the fact that impact sound insulation cannot be measured correctly in the entire frequency range, single-number weighted normalized impact sound pressure level ($L_{n,w}$) can be determined as the unfavorable deviations from the ISO 717-2:2000 [5] reference curve occur below f_l.

Limit of frequencies where unfavorable deviations occur can be denoted as f_2. Therefore, as long as $f_l > f_2$, $L_{n,w}$ can be correctly evaluated.

Table 3. Test results – Floors F6 and F6B.

Floor No.	$L_{n,w}$ (dB)	R_w (dB)	f_l (Hz)	f_2 (Hz)
F6s	63	39	1600	315
F6l	56	51	-	-
F6Bs	56	39	500	250
F6Bl	46	58	1600	315

This analogy has been used to list all test results in the following chapter and indicate whether the evaluation of $L_{n,w}$ was accurate.

3.3 Test results

Complete overview of test results for all ten floors, in both sizes (together with the basic CLT), is presented in Tab. 4.

It should be noted that R_w value for all the small scale tests represents the airborne sound insulation of basic CLT (R_w 39 dB).

Table 4. Test results.

Floor No.	$L_{n,w}$ (dB)	R_w (dB)	f_l (Hz)	f_2 (Hz)
CLT	88	39	-	-
F1s	80	39	-	-
F1l	75	44	-	-
F1Bs	63	39	1600	315
F1Bl	61	54	-	-
F2s	72	39	-	-
F2l	67	47	-	-
F3s	71	39	-	-
F3l	66	48	-	-
F4s	70	39	-	-
F4l	64	49	-	-
F4Bs	61	39	800	250
F4Bl	54	57	-	-
F5s	58	39	800	250
F5l	54	52	-	-
F5Bs	53	39	400	250
F5Bl	42	58	1000	315
F6s	63	39	1600	315
F6l	56	51	-	-
F6Bs	56	39	500	250
F6Bl	46	58	1600	315

Fig. 6 illustrates a comparison of two impact sound insulation curves (floor F5), for a typical case where large scale test was not affected by the airborne component, while small scale test had a limitation already at 800 Hz. Black-filled markers are added to the frequencies where the result is dominated by the airborne sound and impact sound insulation cannot be measured correctly.

Regardless of the obvious limitations in accurately measuring the complete spectrum of impact sound for F5s, $L_{n,w}$ is determined only by the values up to 250 Hz; where airborne component was not an issue (shaded area in Fig. 6).

In other words, the unfavorable deviations from the ISO 717-2:2000 [5] reference value for floor F5s occur only between 100 and 250 Hz. Other values are not relevant for single-number evaluation.

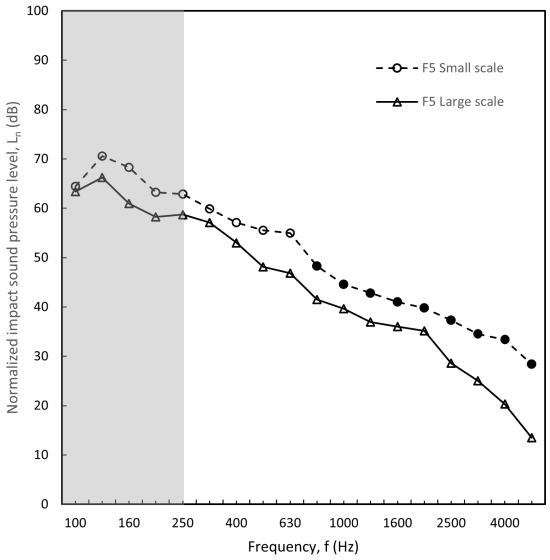

Figure 6. Impact sound insulation for floor F5 (small and large).

3.4 Analysis

Considering the results in Tab. 4, condition $f_1 > f_2$ was valid for all the floors where airborne sound component was influencing the results.

Therefore, despite the latter shortcoming the single-number $L_{n,w}$ rating could be accurately evaluated for all the tested floors.

Difference (in dB) between the $L_{n,w}$ for small scale and large scale tests is given in Tab. 5. Results for small scale tests are constantly higher than those for large scale. Hence, all the values in Tab. 5 are positive.

Table 5. Difference between $L_{n,w}$ for small scale and large scale tests.

Floor No.	$L_{n,w}$ small – $L_{n,w}$ large (dB)
F1	5
F1B	2
F2	5
F3	5
F4	6
F4B	7
F5	4
F5B	11
F6	7
F6B	10

It is indicative that differences in $L_{n,w}$ between small scale and large scale tests ($\Delta L_{n,w}$) are higher for better performing floors (floors with lower $L_{n,w}$). This trend is indicated in Fig. 7.

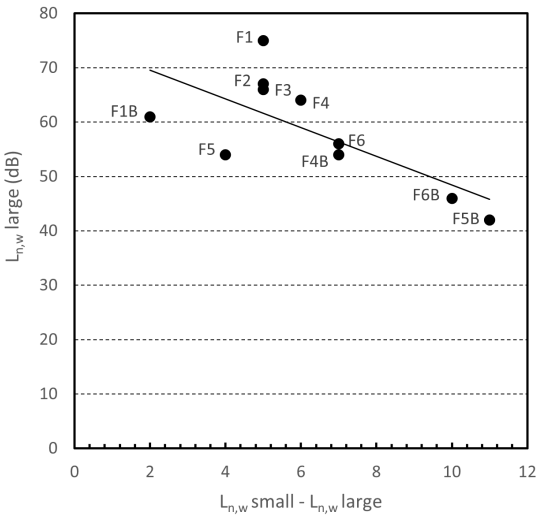

Figure 7. $\Delta L_{n,w}$ in relation to floor's $L_{n,w}$.

Finally, correlation between single-number $L_{n,w}$ ratings for small scale and large scale tests is illustrated in Fig. 8 (with an $R^2 = 0.95$).

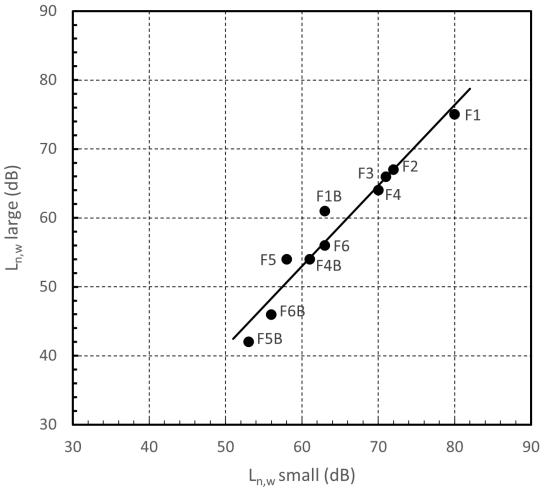

Figure 8. Correlation between $L_{n,w}$ for small scale and large scale tests.

4. CONCLUSIONS

This study provides a detailed correlation analysis of impact sound insulation tests conducted on a variety of small scale and large scale samples, built on the 140 mm CLT reference floor.

For all the small scale samples, sound pressure level generated by the tapping machine in the source room is attenuated only by the basic CLT floor (R_w 39 dB).

Such particularity of the sound propagating mechanism presents the limiting factor for accurate measurements of impact sound insulation in the standard frequency range (100-3150 Hz). Airborne component turned out to be dominant for eight out of twenty tested floors. Six of them being small scale and two large scale.

Notwithstanding the latter shortcoming, single-number weighted normalized impact sound pressure level ($L_{n,w}$) could be accurately determined as the latter value is driven primarily by floor's low frequency response.

For all eight floors influenced by the airborne component, the unfavorable deviations from the ISO 717-2:2000 [5] reference value occurred only between 100 and 315 Hz. Values on other frequencies were not relevant for single-number evaluation.

The latter frequency range was always well below the limiting frequency of the airborne component. So long as this condition is fulfilled, single-number rating can be accurately determined.

Consequently, single-number ratings could be accurately evaluated for all the tested floors and good correlation between $L_{n,w}$ of small scale and large scale tests established (see Fig. 8).

To conclude, this study demonstrated that it is possible to perform impact sound insulation tests on small samples built on CLT floor and accurately estimate the expected single-number $L_{n,w}$ for equivalent large scale samples. The established relationship presents useful tool for comparative analyses and design decision-making.

INFLUENCE OF GRAVEL ON FLANKING TRANSMISSION IN CLT BUILDINGS

Arne Dijckmans[1*] **Charlotte Crispin**[1]

[1] Buildwise, Belgium

ABSTRACT

Gravel layers are sometimes used to improve the airborne and impact sound insulation of Cross Laminated Timber (CLT) floor constructions. The gravel increases the mass and damping of the bare CLT floor and will also improve the efficiency of a floating floor. It is generally assumed that additions like linings and floating floors do not influence the vibration damping in junctions. While this is usually a reasonable assumption, the effect of the gravel on the vibration damping in CLT junctions cannot be neglected. This paper presents laboratory measurement results for the vibration reduction index of a rigid CLT junction with and without gravel. The influence of the gravel layer on the flanking transmission paths is investigated by means of the simplified SEA model of ISO 12354. SEA simulations, incorporating the effect of the gravel layer, are validated with in situ measurements.

Keywords: *sound insulation, flanking transmission, vibration reduction index, gravel layer, wooden buildings*

1. INTRODUCTION

Due to its relatively low weight and high stiffness, the acoustic performance of bare Cross Laminated Timber (CLT) constructions is limited and acoustic linings are generally necessary to achieve the required sound insulation. A well-established method to improve the impact sound insulation of CLT floors is to increase its mass, e.g. by applying a gravel ballast layer beneath the floating floor [1, 2]. The gravel adds mass that reduces the amplitude of vibrations and shifts the mass-spring-mass-resonance frequency of the floating floor to lower frequencies. In addition to the mass effect, the gravel can enhance energy dissipation, thereby reducing the radiated sound power.

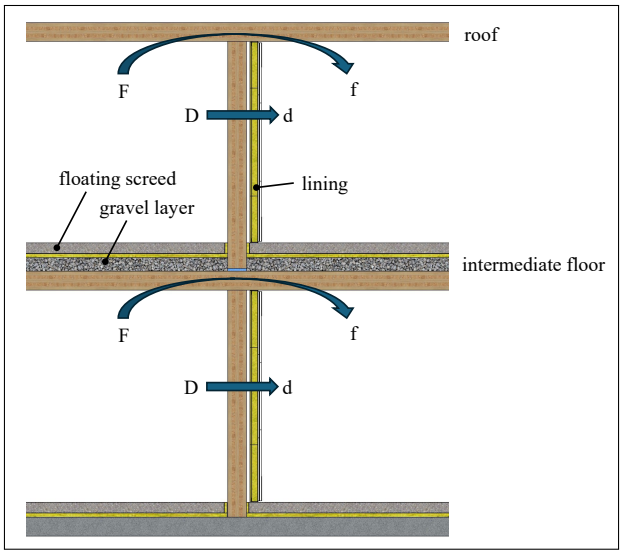

Figure 1. Application of gravel layers in a CLT building

While the influence of gravel layers on the direct airborne and impact sound insulation has been extensively investigated in literature, the effect on flanking transmission is unclear. The vibration transmission across junctions is characterized by the vibration reduction index K_{ij}, which is generally measured on bare junctions according to ISO 10848 [4]. This property can then be used in statistical energy analysis (SEA) calculations,

e.g. following ISO 12354 [5], where it is assumed that linings and floating floors do not influence K_{ij}. This assumption seems not valid for CLT junctions loaded with a gravel layer. In situ measurements in CLT apartment buildings with such floors have systematically indicated significantly higher airborne sound insulation values at intermediate floors than at the top floor (Figure 1). The observed differences cannot be entirely explained by the variation in K_{ij} of T- and cross junctions, which is on average 3 dB for heavy rigid junctions.

In this paper, the effect of a gravel layer on the flanking transmission across junctions of CLT walls and floors is investigated by means of laboratory K_{ij}-measurements (section 2) and simulations of *in situ* airborne sound insulation according to ISO 12354-1 (section 3).

2. LABORATORY MEASUREMENTS

2.1 CLT mockup

A full-scale mockup of a CLT junction was realised at the acoustics laboratory of Buildwise to measure the vibration reduction index of a reference junction without gravel, a junction with a 2.5 cm gravel layer and a junction with a 5 cm gravel layer. The horizontal L-junction consists of a 5-ply CLT-floor with thickness 14 cm and dimensions 4.93 m × 2.25 m and a 5-ply CLT wall with thickness 12 cm and dimensions 3.94 m × 2.40 m. The density of the CLT floor and wall is approximately 485 kg/m^3 and 470 kg/m^3 respectively. The wall was placed between two transmission chambers of the acoustics laboratory with the top 0.6 m of the panel protruding from the chambers. The floor panel was placed on one side on the wall panel and on the other side on concrete blocks resting on the concrete ceiling of the transmission chambers. To ensure maximum contact between the floor and the wall, a very thin layer of plaster was used to level out the slight roughness and non-flatness of the wood.

Wooden boards were screwed into the CLT floor around the perimeter to create a box to hold the gravel (Figure 2). The CLT floor was covered with a gravel layer with an average thickness of 5 cm (Figure 3). A plastic foil was placed beneath the gravel to avoid the CLT panel getting wet because the gravel was still damp when placed on the floor. However, the gravel was completely dry at the moment of the measurements. Afterwards, half of the gravel was removed and the remaining gravel was levelled to a thickness of approximately 2.5 cm. Finally,

Figure 2. Reference junction without gravel

Figure 3. Junction with 5 cm gravel

the vibration reduction index of the reference junction with box but without gravel was measured.

The gravel has a density of approximately 1080 kg/m^3, as measured in dry condition after the K_{ij}-measurements, and the size of the round aggregates varies widely with pebbles up to 7 cm. The mass loading of the gravel layer is approximately 600 kg (54 kg/m^2) and 300 kg (27 kg/m^2) for the 5 cm and 2.5 cm thick gravel layer respectively.

2.2 Measurement procedure

The vibration reduction index K_{ij} between the floor and the wall was measured according to the ISO 10848 standards series [4]. The velocity level of both panels was measured simultaneously using eight accelerometers on each panel. The accelerometers were glued to the bottom

side of the floor panel and to the outer side of the wall panel. Each panel was excited at three different locations using hammer excitation over an area of approximately $1\,\mathrm{m}^2$. The floor was excited at the underside, also for the reference measurement. The same accelerometer and excitation positions were used for the three junctions.

To limit the effect of parastic airborne noise generated by the sound radiation from the excited element [3], mineral wool was placed in the cavity below the floor element to cover the part of the wall extruding the transmission chambers (Figure 3).

The structural reverberation time T_s of each panel was measured using hammer excitation for four source positions and eight receiver positions. The integrated impulse response method with backward integration of the squared impulse response was used. Measurements not fulfilling the requirement $BT_s < 4$ (with B the frequency bandwidth), which are influenced by the filter and detector, are discarded.

At low frequencies, the measurement results are influenced by the modal behaviour of the junction, with low modal overlap factors (< 1) and low mode counts (< 5) up till approximately $400\,\mathrm{Hz}$. This means that the measured K_{ij}-values might not be relevant and might not be situation-invariant in this frequency range. Although one thus has to be careful when using the K_{ij} as input to ISO 12354, relative differences between the different measurements are relevant.

2.3 Measurement results

2.3.1 Loss factor

Figure 4 compares the loss factor η for the floor without and with gravel, calculated from the measured structural reverberation time. The loss factor of the CLT floor without gravel has a relatively constant value of $2.5 - 3\%$ up till $1250\,\mathrm{Hz}$ and decreases slightly at higher frequencies. For the floor with $2.5\,\mathrm{cm}$ gravel, the loss factor is significantly larger than the unloaded floor from $100\,\mathrm{Hz}$ upwards. For the floor with $5\,\mathrm{cm}$ gravel, the loss factor is larger from $160\,\mathrm{Hz}$ upwards and peaks between $400\,\mathrm{Hz}$ and $1000\,\mathrm{Hz}$.

At mid frequencies, where the loss factor is maximal, it was difficult to accurately measure the structural reverberation times of the floor panel, as indicated by the large standard uncertainty. Furthermore, a lot of measurements showed a very low reverberation time for which the condition $BT_s < 4$ was not met and ringing of the band pass filters influenced the measurements. The loss factor is thus probably an underestimation of the actual damping. When the measurement results with $BT_s < 4$ are not discarded, higher loss factors are obtained (Figure 4, dashed lines).

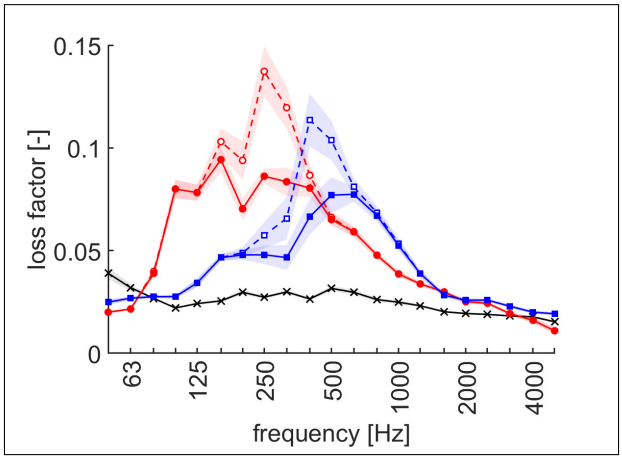

Figure 4. Loss factor of CLT floor without gravel (×), with $2.5\,\mathrm{cm}$ gravel (●) and $5\,\mathrm{cm}$ gravel (■). The shaded areas show the standard uncertainty. The dashed lines show the average values when measurements with $BT_s < 4$ are not discarded.

2.3.2 Velocity levels

The gravel layer has a significant influence on the vibro-acoustic behaviour of the CLT floor panels (Figure 5). The velocity levels L_v of the floors with gravel show a pronounced dip at mid frequencies, both when the floor and the wall are excited. For the $5\,\mathrm{cm}$ gravel layer the dip is observed around $315 - 400\,\mathrm{Hz}$, for the $2.5\,\mathrm{cm}$ gravel layer around $200 - 250\,\mathrm{Hz}$ (not shown for brevity). Furthermore, the dip in velocity level strongly depends on the accelerometer position, indicated by the large spread in this frequency range. The gravel layer thus limits the vibration of the CLT floor, especially at mid frequencies. This effects seems to be linked to a resonance phenomenon in the gravel layer, for which the resonance frequency depends on the thickness of the gravel layer.

The dip in L_v leads to a pronounced peak in velocity level difference $D_{\mathrm{v},ij}$ from wall to floor (Figure 6b). At high frequencies, $D_{\mathrm{v},ij}$ is not influenced by the gravel. When the floor is excited, the lower vibration energy in the floor panel due to the gravel layer also leads to a dip in the wall velocity level. Although it could be expected that $D_{\mathrm{v},ij}$ from floor to wall is independent of the gravel layer,

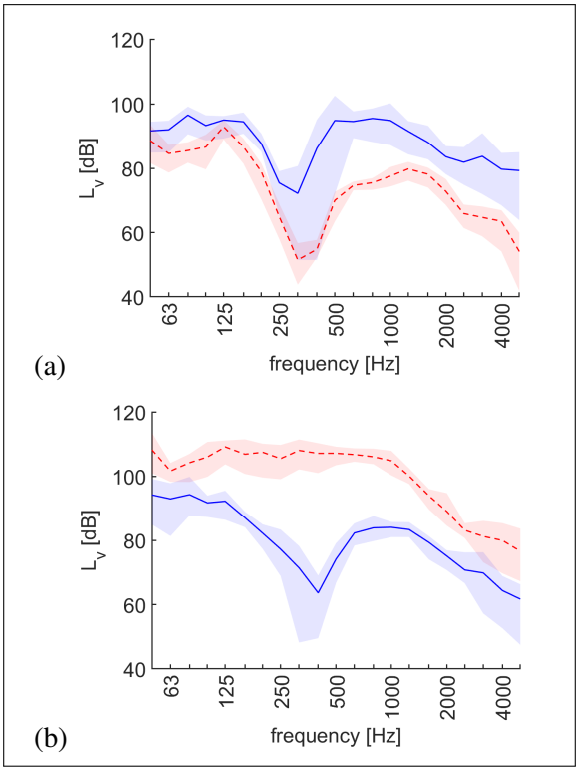

Figure 5. CLT junction with 5 cm gravel. Average velocity levels of floor (—) and wall (– –) for 1 source position on (a) floor and (b) wall. The shaded areas show the spread over 8 accelerometer positions.

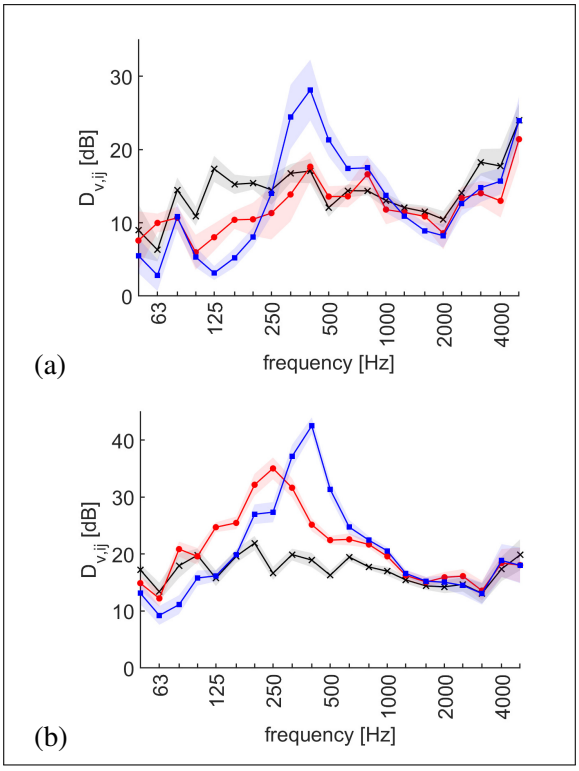

Figure 6. Velocity level difference for excitation of (a) floor and (b) wall for the CLT junction without gravel (×), with 2.5 cm gravel (●) and 5 cm gravel (■). The shaded areas show the standard uncertainty.

this is not the case at low and mid frequencies, especially for the 5 cm gravel layer (Figure 6a).

To further investigate the effect of the gravel layer on the vibration transmission across the junction, the difference in $D_{\mathrm{v},ij}$ in both directions is checked. According to SEA theory, $D_{\mathrm{v},ij}$ can be deduced from the coupling loss factor η_{ij} following:

$$D_{\mathrm{v},ij} = 10\lg\frac{\eta_j}{\eta_{ij}} - 10\lg\frac{m_i}{m_j} \tag{1}$$

where η_j is the total loss factor of element j and m_i and m_j are the mass of element i and j respectively. Using the consistency relationship, the following equality can be deduced for the difference in $D_{\mathrm{v},ij}$ normalized to the loss factor:

$$\Delta = D_{\mathrm{v},ji} - D_{\mathrm{v},ij} + 10\lg\frac{\eta_j}{\eta_i} = 20\lg\frac{m_i}{m_j} + 10\lg\frac{n_j}{n_i} \tag{2}$$

where n_i and n_j is the modal density of element i and j respectively. This normalized difference is thus only dependent on the ratio of element mass and modal density.

For the reference junction, there is a good agreement between measured values and SEA estimations in a broad frequency range, except at low frequencies where the SEA assumptions of high modal overlap and high mode count are not met, and at high frequencies where in-plane wave propagation becomes important (Figure 7). Above 500 Hz, the measurement results for the junctions with gravel also agree well with the predicted value, indicating that the gravel layer does not influence the vibration transmission across the junction in this frequency range. Below 500 Hz, the measurements show significantly higher values. This can partly be explained by the activation of the mass of the gravel layer. By including the mass of the gravel layer in the term m_i in Eqn. (2), the predicted difference is larger and agrees

better with the measured values, although there is still a large undestimation.

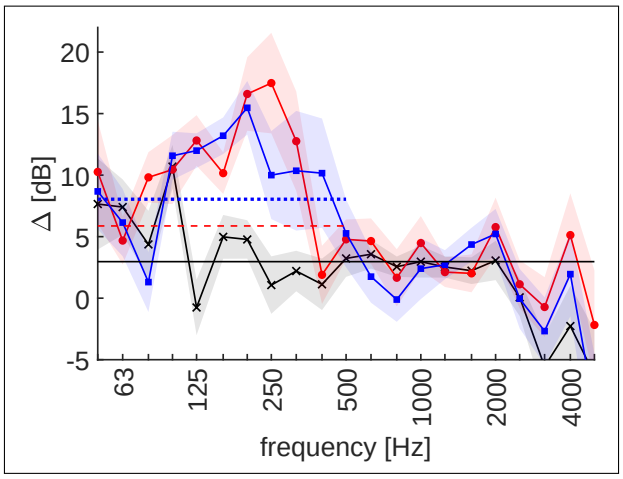

Figure 7. Difference $D_{\mathrm{v},ji}$- $D_{\mathrm{v},ij}$ normalized to the loss factors for the CLT junction without gravel (×), with 2.5 cm gravel (●) and 5 cm gravel (■). The measured values are compared with SEA predictions with $m_i = m_{\mathrm{CLT}}$ (—), $m_i = m_{\mathrm{CLT}} + m_{2.5\,\mathrm{cm\,gravel}}$ (– –), $m_i = m_{\mathrm{CLT}} + m_{5\,\mathrm{cm\,gravel}}$ (· · ·). The shaded areas show the standard uncertainty.

2.3.3 *Vibration reduction index*

The CLT wall panel is considered a type A element according to ISO 10848-1. Because the structural reverberation time of the floor panels with gravel is primarily determined by the gravel and not by the connected elements, they are considered to be a type B element. As an advantage, this eliminates the large uncertainty in the structural reverberation time measurements of the floor panels with gravel. To have a fair comparison between the K_{ij}-values of the unloaded and loaded junctions, the floor panel of the reference junction is also considered a type B element.

For a junction composed of both type A and type B elements, the vibration reduction index is determined by:

$$K_{ij} = \frac{D_{v,ij} + D_{v,ji}}{2} + 10\lg\frac{l_{ij}}{\sqrt{a_i a_j}} \tag{3}$$

with

$$a = \frac{2.2\pi^2 S}{T_s c_0}\sqrt{\frac{f_{\mathrm{ref}}}{f}} \tag{4}$$

for type A elements, and

$$a = S/l_0 \tag{5}$$

for type B elements. S is the surface area of the element, $c_0 = 343\,\mathrm{m/s}$ is the speed of sound in air, $f_{\mathrm{ref}} = 1000\,\mathrm{Hz}$ and $l_0 = 1\,\mathrm{m}$.

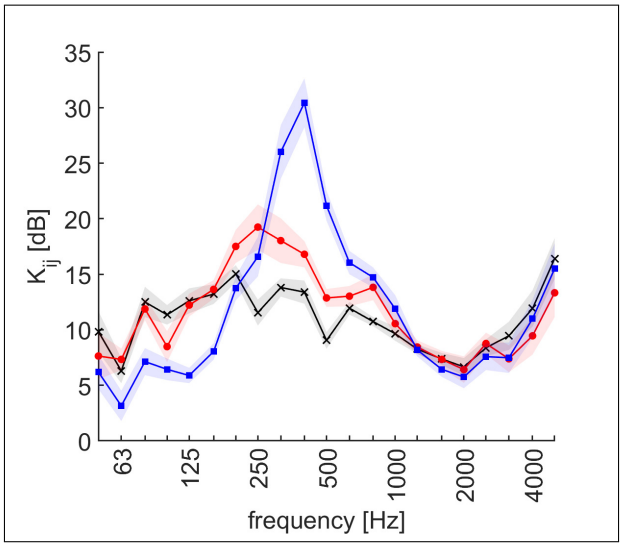

Figure 8. Vibration reduction index of the CLT junction without gravel (×), with 2.5 cm gravel (●) and 5 cm gravel (■). The shaded areas show the standard uncertainty.

The vibration reduction index of the reference junction is relatively independent of frequency, with an average value of 11.7 dB between 200 Hz and 1250 Hz (Figure 8). At high frequencies, the vibration reduction index drops, with a minimum value of approximately 7 dB at 2000 Hz. In this frequency range, the vibration reduction is strongly influenced by the connection details. Previous measurements without plaster layer showed no dip at high frequencies due to a non-perfect contact, while screws or angle brackets further reduced the K_{ij} at high frequencies.

The gravel layer does not influence the K_{ij} at high frequencies, with variations that are within the repeatability limits of the measurement procedure. At mid frequencies, a peak can be observed in the K_{ij}-values for the junctions with gravel layer, which is related to the dip in floor velocity levels. The 5 cm gravel layer significantly increases K_{ij} between 250 Hz and 500 Hz, with a peak

value of 31.5 dB at 400 Hz, i.e. 15 dB above the K_{ij} of the reference junction. The effect of the 2.5 cm gravel layer is less pronounced, but the K_{ij} is still approximately 5 dB higher in the 250 Hz octave band compared to the reference junction. At low frequencies, where global modes of the junction are important, the influence of the 2.5 cm gravel layer is negligible, but the 5 cm gravel layer reduces K_{ij} on average with 5 dB up to 160 Hz. As noted earlier, it is difficult to extrapolate these results because the SEA assumptions of the measurement method are not met at low frequencies.

3. IN SITU SOUND INSULATION

3.1 Prediction model

The airborne sound insulation between two rooms can be estimated from the element and junction properties following the standard ISO 12354-1 [5]. The SEA-based model incorporates the direct transmission path (with sound reduction index R_{Dd}) and the first order flanking transmission paths. The flanking sound reduction index R_{ij} for the transmission path between element i in the source room and element j in the receiving rooms is estimated from:

$$R_{ij} = \frac{R_{i,\mathrm{situ}}}{2} + \Delta R_{i,\mathrm{situ}} + \frac{R_{j,\mathrm{situ}}}{2} + \Delta R_{j,\mathrm{situ}} + \overline{D_{v,ij,\mathrm{situ}}} + 10\lg\frac{S_s}{\sqrt{S_i S_j}} \quad (6)$$

where R_{situ} is the *in situ* value of the sound reduction index, S_s is the area of the separating element between the rooms and $\overline{D_{v,ij,\mathrm{situ}}}$ is the *in situ* direction-averaged junction velocity level difference, which can be determined from:

$$\overline{D_{v,ij,\mathrm{situ}}} = K_{ij} - 10\lg\frac{l_{ij,\mathrm{situ}}}{\sqrt{a_{i,\mathrm{situ}} a_{j,\mathrm{situ}}}}. \quad (7)$$

For junctions composed of both type A and type B elements, the *in situ* equivalent absorption of the type B element can be taken equal to the element area:

$$a_{i,\mathrm{situ}} = S_{i,\mathrm{situ}}/l_0 \quad (8)$$

Because of the limited information available on the structural reverberation time of CLT panels *in situ*, the equivalent absorption length of the type A elements is also taken equal to the element area S in this paper, following the assumption of the simplified model in ISO 12354-1.

The *in situ* value of the sound reduction index of the CLT floor with gravel is estimated with the transfer matrix method (TMM), using an equivalent orthotropic plate model for the CLT and the measured loss factors for the CLT floors with gravel. Because the loss factor for the floors is significantly increased due to the gravel, the sound reduction index is also larger in a broad frequency range. Above the critical frequencies of the CLT panel, the improvement can be estimated from:

$$R_{\mathrm{situ}} = R_{\mathrm{ref}} + 10\lg\frac{\eta_{\mathrm{gravel}}}{\eta_{\mathrm{ref}}}. \quad (9)$$

For example, the predicted global sound reduction index $R_A = R_w + C$ of a 14 cm CLT floor increases from 35.2 dB to 37.4 dB due to the additional structural damping of the 5 cm gravel layer.

The vibration reduction index K_{ij} is not measured for all types of junctions with CLT floors loaded with gravel. Therefore, the vibration reduction index $K_{ij,\mathrm{gravel}}$ of the junction path between a CLT floor with gravel and another element is estimated from the vibration reduction index $K_{ij,0}$ of the equivalent junction without gravel,

$$K_{ij,\mathrm{gravel}} = K_{ij,0} + \Delta K_{ij,\mathrm{gravel}}. \quad (10)$$

The improvement $\Delta K_{ij,\mathrm{gravel}}$ due to the gravel layer is estimated from the improvement measured in the laboratory for the L-junction. For the transmission between two floors, the improvement $\Delta K_{ij,\mathrm{gravel}}$ is only added once to $K_{ij,0}$.

3.2 Theoretical example

As an example, the horizontal sound insulation between two rooms (with depth 3.0 m) is calculated, either disregarding the effect of the gravel or taking into account its effect on R_{situ} and K_{ij}. The separating wall with dimensions 4.0 m × 2.6 m consists of a 10 cm CLT panel and an acoustic lining. The 14 cm CLT floor and ceiling run across the separating wall. The $K_{ij,0}$ of the CLT junctions is estimated following Annex F3.2 of ISO 12354-1 [5]. A floating screed is placed on top of a 2.5 cm or 5 cm gravel layer on both the floor and the ceiling panels. Flanking transmission across the side walls is limited due to the application of a structural break at the junction with the separating wall.

The sound insulation between the rooms is dominated by the flanking transmission via the ceiling, more specifically the Ff path from ceiling to ceiling (Table 1). Only at low frequencies, the transmission through the

separating wall is the dominant path (Figure 9). When the effect of the gravel is disregarded, a global sound insulation $D_A = D_{nT,w} + C = 48.5\,\text{dB}$ is predicted. The predicted sound insulation increases to $D_A = 52.5\,\text{dB}$ and $50.9\,\text{dB}$ due to the effect of the $2.5\,\text{cm}$ and $5\,\text{cm}$ gravel layer, respectively, of which approximately $2\,\text{dB}$ can be attributed to the increase in R_{situ}. The additional improvement is related to the increase in K_{ij} between $250\,\text{Hz}$ and $1000\,\text{Hz}$. The improvement in D_A is smaller for the $5\,\text{cm}$ gravel layer due to the reduction in K_{ij} at lower frequencies.

Table 1. Sound reduction indices R_A

Path	reference (no gravel)	2.5 cm gravel	5 cm gravel
Direct - Dd	60.1 dB	60.1 dB	60.1 dB
Ceiling - Ff	49.7 dB	54.6 dB	52.6 dB
Ceiling - Fd	56.3 dB	60.0 dB	58.1 dB
Ceiling - Df	80.4 dB	84.0 dB	76.1 dB
Total	48.5 dB	52.5 dB	50.9 dB

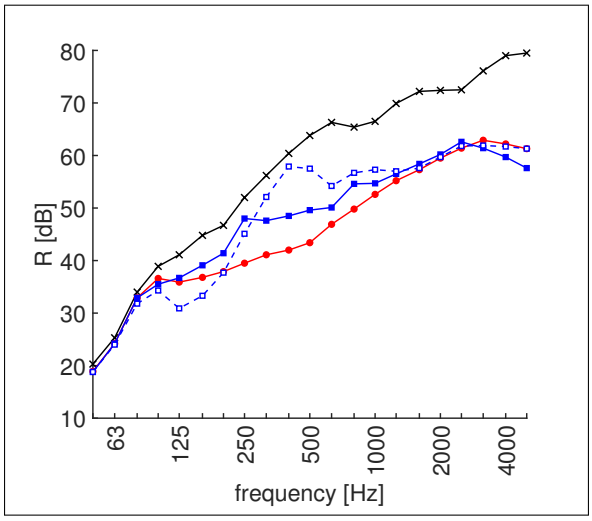

Figure 9. Sound insulation between two rooms according to ISO 12354-1 ($\times\ R_{Dd}$, $\bullet\ R'_{\text{ref}}$, $\blacksquare\ R'_{2.5\,\text{cm gravel}}$, $\square\ R'_{5\,\text{cm gravel}}$)

3.3 Case study

The prediction model is applied to a case study of a CLT apartment building. The intermediate floors consist of a $22\,\text{cm}$ CLT panel, a $9\,\text{cm}$ gravel layer and a floating screed. The ceiling of the top floor consists of a $22\,\text{cm}$ CLT panel. Above the ceiling is an empty plenum with a variable height ($60 - 170\,\text{mm}$) to create a slope for the flat roof which consists of an OSB plate, a stiff thermal insulation plate and a ballast layer. The walls consist of a $12\,\text{cm}$ CLT panel with an acoustic lining on both sides (2 gypsum boards on $50\,\text{mm}$ metal studs and a $50\,\text{mm}$ mineral wool filling). An elastic joint is inserted between the floor panels at the junctions with the separating walls between dwellings.

The sound insulation between the living room and a bedroom of two neighbouring dwellings was measured on an intermediate floor and on the top floor of the building. The sound insulation on the top floor is significantly lower with a difference in D_A of $7\,\text{dB}$ (Figure 10).

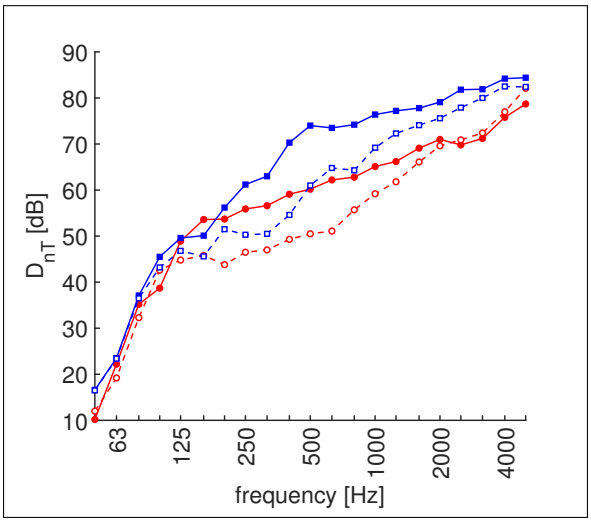

Figure 10. Case study: measured ($\bullet$) and simulated ($\blacksquare$) sound insulation between two rooms on the intermediate (—) and top (– –) floor.

For the predictions, the following assumptions have been made for the vibration reduction indices:

- The $K_{ij,0}$-value of the cross junctions is estimated from K_{ij}-measurements in a mock-up with a similar junction without gravel. The mock-up values have been reduced at mid and high frequencies to account for two effects: the loading

of the elastic layer *in situ*, which will decrease its effect [6], and the mechanical coupling present in the apartment building to assure lateral stability.

- The $K_{ij,0}$-value of the T-junction on the top floor is estimated to be 3 dB lower than the $K_{ij,0}$-value of the cross junction.
- The average $\Delta K_{ij,\text{gravel}}$-value of the laboratory measurements with 2.5 cm and 5 cm is applied. Below 200 Hz, no effect is taken into account ($\Delta K_{ij,\text{gravel}} = 0$).

The simulations indicate that the Ff path from ceiling to ceiling is the dominant transmission path in the entire frequency range of interest ($\geq$ 100 Hz), both on the intermediate floor and on the top floor, despite the elastic joint between the ceiling plates.

Although the sound insulation is globally overestimated by the model, the relative difference between intermediate and top floor is well predicted. The model difference of 7 dB in D_A-value is partly due to the difference between T- and cross junction (3 dB), partly due to the effect of the gravel layer on R_{situ} (1.5 dB) and partly due to the effect of the gravel layer on K_{ij} (2.5 dB). The overestimation may be attributed to several factors, like an overestimation of the sound insulation R by the TMM, an overestimation of the vibration reduction index $K_{ij,0}$, or the presence of other transmission paths not taken into account in the model. On the top floor, indirect airborne transmission via the plenum in the roof could e.g. further reduce the sound insulation.

4. CONCLUSIONS

While gravel layers are primarily used to improve the airborne and impact sound insulation of CLT floors, the gravel layer also influences the flanking transmission across the floor junctions in two ways. First, the gravel layer significantly increases the loss factor of the floor, and thus also the sound reduction index of the floor, especially above its critical frequency. The global improvement in $R_{A,\text{situ}}$ of typical CLT floors is estimated to be 2 dB based on TMM simulations. Second, the vibro-acoustic behaviour of the junction, as characterized by the vibration reduction index K_{ij}, is changed. The measured K_{ij}-values show a pronounced peak at mid frequencies, linked to a resonance phenomenon in the gravel layer. Simulations with the SEA-based model of ISO 12354 indicate that for situations where flanking transmission across the ceiling is dominant, the gravel layer can improve the global sound insulation with up to 5 dB. Case studies learn that care should be taken with sound transmission across ceilings at the top floor where this positive effect of gravel layers is not present, while flanking transmission across the top T-junctions is already larger than across intermediate cross junctions.

PREDICTION OF FLANKING SOUND TRANSMISSION ACROSS PERIODIC CROSS-LAMINATED TIMBER JUNCTIONS WITH AREA COUPLINGS

Stijn Moons [1,2*] **Reinhilde Lanoye**[2] **Edwin P.B. Reynders**[1]

ABSTRACT

Cross-laminated timber (CLT) has gained popularity as a lightweight, carbon-neutral material for load-bearing walls and floors. However, its poor acoustic performance poses a crucial challenge to its further adoption. A critical factor is flanking sound, where vibrational energy is transmitted between two walls across a common junction. Typically, this transmission is analyzed with models based on plate or shell theory, but their accuracy at high frequencies is limited the ratio of wavelength to wall thickness is not large. While full-scale finite element analysis is possible, its computational cost at high frequencies is prohibitive as very fine element meshes are required. In the current study, an approach is presented which exploits the spatial periodicity often exhibited by CLT junctions. This allows the use of Bloch-Floquet analysis of the junction itself and the connected walls, leading to diffuse transmission coefficients between all wave types in the junction. The junction is treated as an elastic solid as opposed to the conventional thin shell modelling which results in a line coupling. Statistical Energy Analysis (SEA) is employed to compute the vibration reduction indices of the junction from these coefficients. The prediction model is applied to rigidly connected CLT junctions.

1. INTRODUCTION

Cross-laminated timber (CLT) has gained popularity as an alternative to more carbon-intensive materials for load-bearing structures such as concrete. However, its further adoption is hindered by a generally poor acoustic performance. Especially structure-borne sound poses a problem due to the low weight and relatively high stiffness of CLT, with flanking sound transmission often dominating the overall sound transmission. In this transmission mechanism, vibration energy is exchanged between connected walls across their common junction. As a result, CLT junctions are often designed to mitigate flanking sound transmission with solutions such as resilient interlayers or pads between a wall and the floor beneath it. While these solutions are often effective, a better, deeper understanding of the vibration transmission is required to optimize their design. Computationally efficient prediction models are important tools in the further development of vibration reducing solutions and CLT junctions in general, because of the large variation in transmission paths.

In a recent publication [1], an analytical prediction model for continuous CLT junctions was presented within a Statistical Energy Analysis (SEA) framework [2]. The CLT walls are modelled as directly connected homogeneous thin plates [3, 4]. While the broadband predictions are quite accurate, thickness effects are absent in this model, leading to prediction deviations in the high-frequency range. Numerical modelling with volumetric finite elements allows to take high-frequency thickness effects into account as well as the layered nature of CLT panels. While full-scale modelling of a building junction

is possible, the computation time is a limiting factor, especially at high frequencies where fine element meshes are required. Exploiting the spatial periodicity of the CLT junctions, it is possible to model only a repeated unit cell deterministically with the finite element method and apply Bloch-Floquet analysis to each connected wall as well as to the junction itself. The resulting approach is often termed as the periodic finite element method (pFEM). In this article, a prediction model for the vibration reduction index K_{ij} of CLT junctions is presented where the connected walls and the junction itself are modelled with a pFEM approach. The vibrational energy transmission is analysed in a SEA framework. Section 2 describes the general principles behind the prediction model. The model is validated with experimental laboratory measurements on a rigid CLT X-junction in Section 3.

2. THEORETICAL FRAMEWORK OF THE PREDICTION MODEL

Fig. 1 contains a schematic representation of the type of system that is being considered. The junction is connected to a total of n walls via area couplings. The assembly is spatially periodic in the global x-direction and the corresponding unit cell length is denoted as l_x. Each wall j is also spatially periodic in its local y-direction, with corresponding unit cell width $l_{\mathrm{y},j}$. In what follows, displacements $\mathbf{u}_j$ are expressed in the local coordinate system of wall j, unless stated otherwise. The subscript j is omitted for notational simplicity wherever possible.

Free plane waves in the periodic structure adhere to the Bloch-Floquet theorem, such that the displacements $\mathbf{u}(\mathbf{x},\mathbf{n})$, expressed in the local coordinate system of a wall, in any cell with position $\mathbf{n} = (n_\mathrm{x}, n_\mathrm{y})$ relative to the reference cell of the wall satisfy

$$\mathbf{u}(\mathbf{x},\mathbf{n}) = \mathbf{u}(\mathbf{x})\,\mathrm{e}^{-\mathrm{i}\epsilon_\mathrm{x}-\mathrm{i}\epsilon_\mathrm{y}}, \qquad (1)$$

for coordinates $\mathbf{x} = (x, y)$ within the reference unit cell. The factors ϵ_x and ϵ_y are the phase constants corresponding to a given wave [5]. Unit cells of the walls and junction itself are modelled deterministically with volumetric finite elements, allowing to compute the unit cell stiffness and mass matrices $\mathbf{K}$ and $\mathbf{M}$ of each component.

Figures 2 and 3 illustrate the unit cell for a connected wall and the junction beam with interfaces between connected elements indicated in grey. The nodes and corresponding degrees of freedom in the finite element model of each wall can be distributed into separate groups related to their position within the unit cell: left bottom (LB), right bottom (RB), bottom (B), left (L), right (R), left top (LT), right top (RT), top (T) and internal (I). By imposing Bloch boundary conditions on the unit cell with phase constants in the local x- and y-direction on the degrees of freedom as in equation (1), the system can be reduced by matrix $\mathbf{R}$ with $\mathbf{u}_\mathrm{full} = \mathbf{R}\mathbf{u}_\mathrm{red}$ to a system with only degrees of freedom LB, B, L and I. For free wave propagation, the equations of motions of a wall lead to the

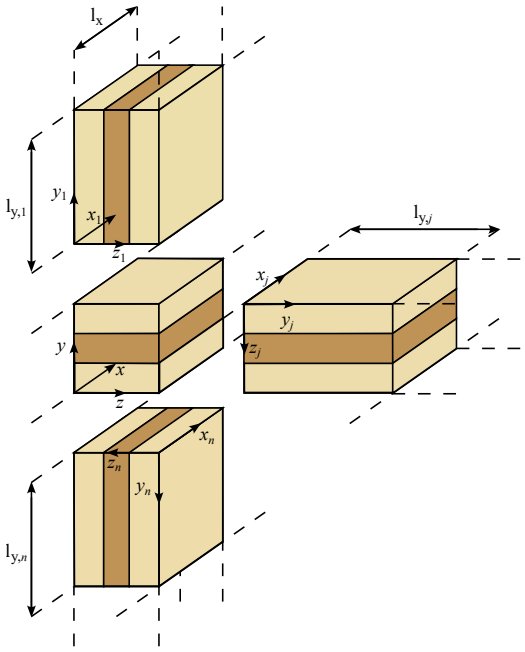

Figure 1. Exploded view of a T-junction with indication of the local coordinate systems of each element.

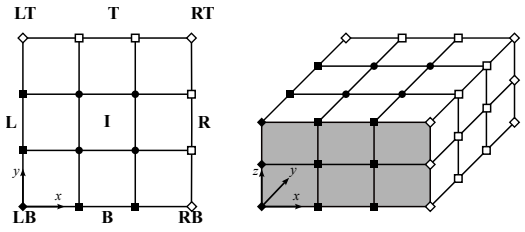

Figure 2. Unit cell of a wall with separate node labels.

following eigenvalue problem solved for eigenfrequencies ω and displacement eigenvectors $\boldsymbol{\phi}$, corresponding to the reduced degrees of freedom for displacements $\mathbf{u}_{\mathrm{red}}$:

$$\mathbf{R}^{\mathrm{H}}\left(\mathbf{K}-\omega^{2}\left(\epsilon_{\mathrm{x}},\epsilon_{\mathrm{y}}\right)\mathbf{M}\right)\mathbf{R}\boldsymbol{\phi}\left(\epsilon_{\mathrm{x}},\epsilon_{\mathrm{y}}\right)=0. \tag{2}$$

Similarly, the junction beam degrees of freedom are divided into: left (L), right (R), sleeve (S), left sleeve (LS), right sleeve (RS) and internal (I), which can be reduced to LS, L, S and I for an imposed ϵ_{x}.

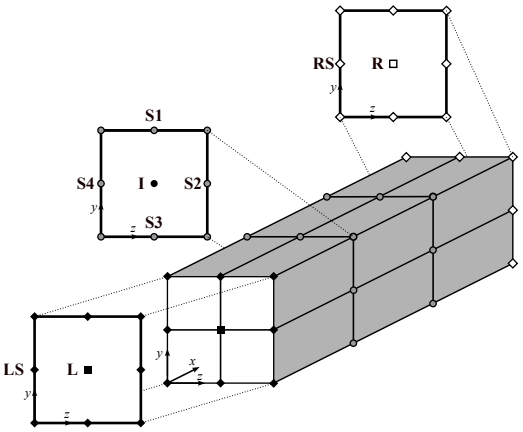

Figure 3. Unit cell of the junction beam with separate node labels.

The vibration transmission of the junction is analysed in a Statistical Energy Analysis (SEA) framework [2] with subsystems corresponding to free propagating wave types in a given connected element. In further derivations, the subscripts m and n are used to denote given source and receiver subsystems, respectively, such that a source subsystem m corresponds to wave type s in wall i and a receiver subsystem n to wave type t in wall j. The subsystems in all walls are assumed to be diffuse. Following a modal approach, this implies that each mode resonating within a given frequency band $\Delta\omega$, corresponding to a wave type with imposed phase constants ϵ_{x} and ϵ_{y}, has the same energy density e [6].

In order to study the energy exchange across the junction, the power balance of the overall SEA system is expressed in function of the subsystem energies E_m, input powers W_m, total loss factors η_m and coupling loss factors η_{mn} between subsystems m and n:

$$\begin{bmatrix}-\eta_1 & \eta_{21} & \eta_{31} & \dots\\ \eta_{12} & -\eta_2 & \eta_{32} & \dots\\ \eta_{13} & \eta_{23} & -\eta_3 & \dots\\ \dots & \dots & \dots & \dots\end{bmatrix}\begin{bmatrix}E_1\\E_2\\E_3\\\dots\end{bmatrix}=\begin{bmatrix}-W_1/\omega\\-W_2/\omega\\-W_3/\omega\\\dots\end{bmatrix}. \tag{3}$$

This system is solved for the subsystem energies E_m at each frequency of interest. The total number of subsystems and, therefore, the size of the SEA system may differ in function of frequency, as higher order wave types can cut on within the frequency range of interest. The system requires the computation of η_{mn}, η_m and W_m in function of frequency, where

$$\eta_m=\eta_{\mathrm{d},m}+\sum_{m=1}^{M}\eta_{mn}, \tag{4}$$

where $\eta_{\mathrm{d},m}$ is the equivalent internal loss factor of the subsystem. For laminates with layers with identical damping properties such as CLT, this value is equal to the material internal loss factor if edge radiation and damping are negligible.

The input power W_m per source subsystem m is derived in accordance with [7]; in the special case where the wall is excited on its top surface by a point load $\mathbf{F}$. This load is exerted in the z-direction at location $\mathbf{x}_0$ in a unit cell with position $\mathbf{n}_0$ relative to the reference unit cell. For a given surface traction $\mathbf{t}\left(\mathbf{x},\mathbf{n}\right)$, the resulting complex amplitude $a_m\left(\epsilon_{\mathrm{x}},\epsilon_{\mathrm{y}}\right)$ for a given subsystem is given by

$$a_m\left(\epsilon_{\mathrm{x}},\epsilon_{\mathrm{y}}\right)=\frac{\iint_A\boldsymbol{\phi}_m^{\mathrm{H}}\left(\mathbf{x},\mathbf{n}\right)\mathbf{t}\left(\mathbf{x},\mathbf{n}\right)\mathrm{d}X\mathrm{d}Y}{N_{\mathrm{x}}N_{\mathrm{y}}\left(\left(1+\mathrm{i}\eta_{\mathrm{d},m}\right)\omega_m^2-\omega^2\right)}, \tag{5}$$

where X and Y are the coordinates in the global coordinate system of the wall, which can also be indicated by $(\mathbf{x},\mathbf{n})$, A is the total surface area of the wall, N_{x} and N_{y} the number of unit cells in their respective dimensions and ω_m the eigenfrequency for subsystem m for an imposed phase constant combination. In the special case of an external point load, the traction corresponds to a spatial Dirac impulse with $\mathbf{t}=\mathbf{F}\delta\left(\mathbf{x}-\mathbf{x}_0\right)$ for an excitation location $(\mathbf{x}_0,\mathbf{n}_0)$. As a result, equation (6) can be simplified to

$$a_m\left(\epsilon_{\mathrm{x}},\epsilon_{\mathrm{y}}\right)=\frac{\boldsymbol{\phi}_m^{\mathrm{H}}\left(\mathbf{x}_0,\mathbf{n}_0\right)\mathbf{F}\left(\mathbf{x}_0,\mathbf{n}_0\right)}{N_{\mathrm{x}}N_{\mathrm{y}}\left(\left(1+\mathrm{i}\eta_{\mathrm{d},m}\right)\omega_m^2-\omega^2\right)}. \tag{6}$$

This amplitude is always a scalar and is computed for every source subsystem for the wave with phase constants

(ϵ_x, ϵ_y). The input power $W_m(\epsilon_x, \epsilon_y)$ for subsystem m for a point load excitation is given by

$$W_m(\epsilon_x, \epsilon_y) = \frac{1}{2}\mathrm{Re}\left\{\mathrm{i}\omega \mathbf{F}^{\mathrm{T}}(\mathbf{x}_0, \mathbf{n}_0)\, \mathbf{u}_m^*(\mathbf{x}_0, \mathbf{n}_0)\right\}, \quad (7)$$

where

$$\mathbf{u}_m(\mathbf{x}_0, \mathbf{n}_0) = a_m(\epsilon_x, \epsilon_y)\, \boldsymbol{\phi}_m(\mathbf{x}_0, \mathbf{n}_0). \quad (8)$$

The total subsystem input power per frequency band is obtained by summing the contribution of any (ϵ_x, ϵ_y) combination where its eigenfrequency ω_m lies within the frequency band of interest $\Delta\omega$. Born-Von Kárman (also termed periodic) boundary conditions are applied on the full wall to take the finite wall size into account, where the movement at opposite edges is continuous, such that the wave motion in the wall is spatially periodic. This enables the resonating modes in the wall to be composed of purely travelling waves in opposite directions. The range of imposed phase constants can be limited to the Brillouin zone of $[-\pi, \pi]$ [5]. For orthotropic structures such as CLT walls, this can be limited to $[0, \pi]$ due to symmetry.

The coupling loss factors η_{mn} between subsystems m and n are defined as

$$\eta_{mn} = \frac{W_{mn}}{\omega E_m}, \quad (9)$$

where W_{mn} is the power transmitted across the junction from m to n and $E_m = eV_iN_m$ with volume V_i of wall i and N_m the number of modes resonating in the frequency band of interest. The intensity in the local y-direction for a single resonating mode is $ec_{\mathrm{gy},m}$ with $c_{\mathrm{gy},m}$ the y-component of the group velocity. The transmitted power $W_{mn}(\epsilon_x, \epsilon_y)$ for imposed phase constants is given by

$$W_{mn}(\epsilon_x, \epsilon_y) = \tau_{mn}(\epsilon_x, \epsilon_y)\, S_{ij} e_m c_{\mathrm{gy},m}(\epsilon_x, \epsilon_y), \quad (10)$$

where S_{ij} is the area of the interface between the wall and the junction, and $\tau_{mn}(\epsilon_x, \epsilon_y)$ the transmission coefficient for an incident wave in subsystem m and transmitted or reflected wave to subsystem n. The total transmitted power W_{mn} in a frequency band is obtained by summing the contributions of each mode with resonance frequency within this frequency band, analogous to the input power.

The procedure to determine the transmission coefficients $\tau_{mn}(\epsilon_x, \epsilon_y)$ is a generalization of the approach of [3]. An incident wave of wave type s in source plate i with imposed phase constant ϵ_x and an arbitrary displacement amplitude impinges on the junction. Given that all system components exhibit the same spatial periodicity along the x-axis, all reflected and transmitted waves have the same phase constant. Additionally, the analysis is conducted at a frequency corresponding to the eigenfrequency of the incident wave. The interface forces of the unit cells of the different components, indicated in grey in Figures 2 and 3, should be in equilibrium, such that for the forces in global coordinates

$$\mathbf{f}_{\mathrm{jun}} + \mathbf{f}_{\mathrm{inc}} + \sum_{j=1}^{n} \mathbf{f}_j = \mathbf{0}, \quad (11)$$

where $\mathbf{f}_{\mathrm{jun}}$ represents the interface forces of the junction, $\mathbf{f}_{\mathrm{inc}}$ the interface forces of the incident wave in wall i, and $\mathbf{f}_j$ the interface forces of the outgoing waves in wall j. The forces in the walls for outgoing wave motion can be related to the interface displacements by exploiting the two-dimensional spatial periodicity. This leads to the dynamic stiffness matrix of wall j for outgoing wave motion, denoted as $\mathbf{D}_j(\epsilon_x, \omega)$. Furthermore, in the junction itself, the forces and displacements at the interface degrees of freedom can be coupled via a junction dynamic stiffness matrix $\mathbf{D}_{\mathrm{jun}}(\epsilon_x, \omega)$ by exploiting the one-dimensional spatial periodicity. As a result, one has that

$$\mathbf{D}_{\mathrm{jun}}\mathbf{u} + \mathbf{f}_{\mathrm{inc}} + \sum_{j, j\neq i} \mathbf{D}_j\mathbf{u} + \mathbf{D}_i(\mathbf{u} - \mathbf{u}_{\mathrm{inc}}) = \mathbf{0}, \quad (12)$$

where all displacements $\mathbf{u}$ are expressed in global coordinates. Note that $\mathbf{u}_{\mathrm{inc}}$ represents the displacements at the interface due to the incident wave motion only, which can be obtained by only considering one wavetype propagating in the $-y$-direction with fixed wave amplitude, so it is uniquely determined.

The procedure to derive the interface dynamic stiffness matrices $\mathbf{D}_j(\epsilon_x, \omega)$ follows that of [8]. The dynamic stiffness matrix of the unit cell $\mathbf{D} = \mathbf{K} - \omega^2\mathbf{M}$ is reduced to degrees of freedom LB and B by imposing ϵ_x, ω and solving ϵ_y from equation (2). This leads to an eigenvalue problem with $2N$ solutions in function of ϵ_y with eigenvectors composed of the modal displacements $\boldsymbol{\phi}_{\mathrm{u}}$ and forces $\boldsymbol{\phi}_{\mathrm{f}}$ at these degrees of freedom for all potential outgoing waves. The total interface displacements and forces $\mathbf{u}_j$ and $\mathbf{f}_j$ of wall j are computed from these eigen-

vectors as

$$\mathbf{u}_j = \sum_{n=1}^{N} a_n \boldsymbol{\phi}_{\mathrm{u}} = \mathbf{Q}\mathbf{a}, \tag{13}$$

$$\mathbf{f}_j = \sum_{n=1}^{N} a_n \boldsymbol{\phi}_{\mathrm{f}} = \mathbf{P}\mathbf{a}, \tag{14}$$

where $\mathbf{a}$ is a set of a priori unknown amplitudes. Given that $\mathbf{f}_j = \mathbf{D}_j \mathbf{u}_j$,

$$\mathbf{D}_j\left(\epsilon_{\mathrm{x}}, \omega\right) = \mathbf{P}\mathbf{Q}^{-1}. \tag{15}$$

Note that only N eigensolutions are taken into account, corresponding to outgoing waves propagating or decaying in the local $+y$-direction of the wall. For the junction beam, a similar procedure is followed to determine $\mathbf{D}_{\mathrm{jun}}$, exploiting the one-dimensional spatial periodicity along the x-axis. Solving equation (12) for the interface displacements $\mathbf{u}$ allows to determine the power related to each outgoing wavetype t in receiver wall j by decomposition of the wall edge displacements $\mathbf{u}_j$ within the full set of interface displacements $\mathbf{u}$ as in equations (13) and (14). The corresponding transmitted power per subsystem is given by

$$W_{mn}\left(\epsilon_{\mathrm{x}}, \epsilon_{\mathrm{y}}\right) := \frac{1}{2}\mathrm{Re}\left\{\mathbf{f}_{mn}^{\mathrm{T}} \mathbf{u}_{mn}^{*}\right\}. \tag{16}$$

The definition of incident wave power $W_{\mathrm{inc}}\left(\epsilon_{\mathrm{x}}, \epsilon_{\mathrm{y}}\right)$ is analogous. The transmission coefficients $\tau_{mn}\left(\epsilon_{\mathrm{x}}, \epsilon_{\mathrm{y}}\right)$ required in equation (10) are defined as

$$\tau_{mn}\left(\epsilon_{\mathrm{x}}, \epsilon_{\mathrm{y}}\right) := \frac{W_{mn}\left(\epsilon_{\mathrm{x}}, \epsilon_{\mathrm{y}}\right)}{W_{\mathrm{inc}}\left(\epsilon_{\mathrm{x}}, \epsilon_{\mathrm{y}}\right)}. \tag{17}$$

Finally, the measurement formula for the vibration reduction index K_{ij} between connected walls i and j following ISO 12354-1 [9] is given by

$$K_{ij} = \frac{\sum_{s,t} D_{\mathrm{vz},ij}^{st} + \sum_{s,t} D_{\mathrm{vz},ji}^{ts}}{2} + 10\log\frac{l_{ij}}{\sqrt{a_{\mathrm{eq},i} a_{\mathrm{eq},j}}}, \tag{18}$$

where l_{ij} is the junction length, $a_{\mathrm{eq},i}$ and $a_{\mathrm{eq},j}$ the equivalent absorption lengths of the walls and $D_{\mathrm{vz},ij}^{st}$ the transverse velocity level differences between the subsystems, defined as

$$D_{\mathrm{vz},ij}^{st} := 10\log\frac{< v_{mz}^2 >}{< v_{nz}^2 >} = 10\log\frac{E_{mz} m_j}{E_{nz} m_i}, \tag{19}$$

where $< v_{mz}^2 >$ denotes the surface-averaged squared velocity of subsystem m in the local z-direction, E_{mz} is the subsystem energy for the local z-components and m_i and m_j are the total masses of wall i and j, respectively. At resonance, the subsystem energy is given by

$$E_m = \frac{1}{4}\left|a_m\right|^2 \boldsymbol{\phi}_m^{\mathrm{H}} \left(\mathbf{K} + \omega_m^2 \mathbf{M}\right) \boldsymbol{\phi}_m, \tag{20}$$

for an amplitude a_m such that $\mathbf{u}_m = a_m \boldsymbol{\phi}_m$. Equation (3) is solved for the total band-averaged subsystem energies per subsystem E_m. The transverse subsystem energy E_{mz} can be computed by only taking the z-components of $\boldsymbol{\phi}_m$ into account. Both $E_{mz}\left(\epsilon_{\mathrm{x}}, \epsilon_{\mathrm{y}}\right)$ and $E_m\left(\epsilon_{\mathrm{x}}, \epsilon_{\mathrm{y}}\right)$ are calculated with equation (20) for each phase constant combination, after which their values are band-averaged in the same way as the input power. The subsystem energies resulting from equation (3) are then multiplied by the ratio E_{mz}/E_m per frequency band for each subsystem. In this way, all contributions to the transverse wave motion and therefore, the sound radiation, are taken into account in equation (18) for K_{ij}.

3. RESULTS AND DISCUSSION

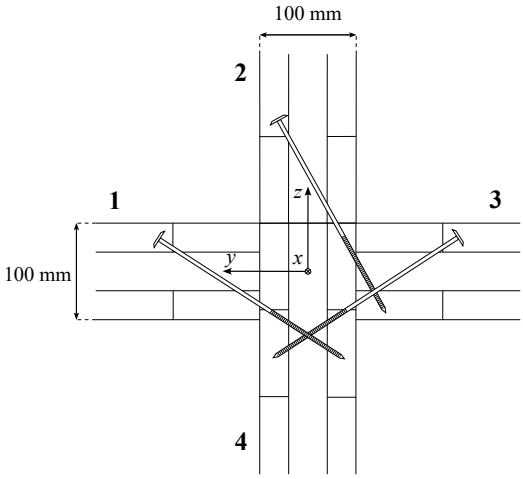

Figure 4. Configuration of the junction with screw positions.

The prediction model is validated with laboratory measurements of the vibration reduction index K_{ij} for a CLT X-junction consisting of 4 walls [11, 12]. Each wall is a 3-ply cross-laminated timber panel with a layer stacking of [0 π/2 0] relative to the global $x-$axis. The material properties of a single timber layer of strength class C24 are summarized in Table 1. Each layer has

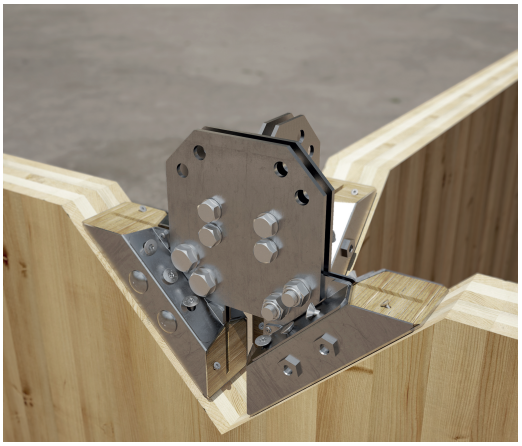

Figure 5. Rotationally stiff X-RAD connector [10].

an assumed internal loss factor of 0.02. The structural wall connections are obtained either by screws or more rotationally stiff connectors, displayed in Figure 5. Figure 4 illustrates the junction configuration including the screw positions.

The vibration reduction indices are predicted with the pFEM model detailed in the previous section, where the panels are modelled with 8-node solid volume elements, with each timber layer modelled separately. Due to the homogeneity of the CLT in the lateral directions of each wall, the unit cell can be taken arbitrarily small to reduce computation time. The junction beam is also considered as a CLT volume with a lateral dimensions corresponding to the thicknesses of the connected walls. In this example, the screws or the other connector are not modelled explicitly, but in this prediction framework this is a future possibility. Additionally, predictions with an analytical wave approach model for thin homogeneous plates, directly connected along a massless line connection [1]. This requires the mechanical properties for an homogeneous plate equivalent to the CLT panel. They are determined with the modified gamma method [14], imposing static equivalence between the transverse bending stiffness of the separate layers and an equivalent single-layer

panel, summarized in Table 2. For both models, equivalent absorption lengths $a_{\mathrm{eq},j}$ were determined from the experimentally determined structural reverberation times $T_{\mathrm{s},j}$:

$$a_{\mathrm{eq},j} = \frac{2.2\pi^2 S_j}{T_{\mathrm{s},j} c_0 \sqrt{f/f_\mathrm{ref}}}, \tag{21}$$

where $c_0 = 343\,\mathrm{m/s}$, $f_\mathrm{ref} = 1000\,\mathrm{Hz}$ and S_j the surface area of wall j. As another reference for comparison, the empirical K_{ij} formulae from Annex F of ISO 12354-1 [9] for rigid CLT junctions were applied for the transmission paths as follows

$$K_{12} = 18.8 + 3.3\log\left(\frac{f}{f_\mathrm{k}}\right), \tag{22}$$

$$K_{13} = 23 + 3.3\log\left(\frac{f}{f_\mathrm{k}}\right), \tag{23}$$

$$K_{24} = 10 - 3.3\log\left(\frac{f}{f_\mathrm{k}}\right) + 10M, \tag{24}$$

where $f_\mathrm{k} = 500\,\mathrm{Hz}$ and $M = \log\left(m"_{\perp,j}/m"_j\right)$ for surface masses $m"_j$ and $m"_{\perp,j}$ for wall j and the wall perpendicular to it. Figures 6 up to 7 display the predicted values alongside the measured values for the corner transmission paths, the coplanar transmission path and the continuous coplanar transmission path. Prediction results are illustrated by black lines; coloured lines indicate experimental values, with red lines for the rotationally stiff connector in Figure 5 and blue lines for the screwed junction in Figure 4.

While the global frequency trend established by the empirical formulae from the international standard is more or less correct with the exception of path $2-4$, they are a clear oversimplification of the actual K_{ij} as the material and geometric parameters and connection type are not taken into account, leading to deviations of over 5 dB in most 1/3 octave bands.

Both prediction models showcase a correct frequency trend with generally closer correspondence to K_{ij} for either experimental configuration than the empirical formulae. As noted in [1], the analytical prediction model typ-

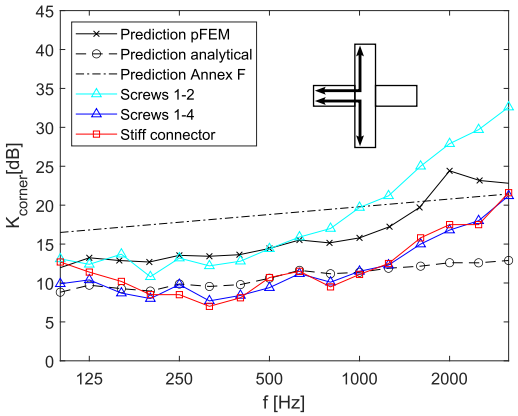

Figure 6. Vibration reduction index for the corner transmission paths in the CLT X-junction.

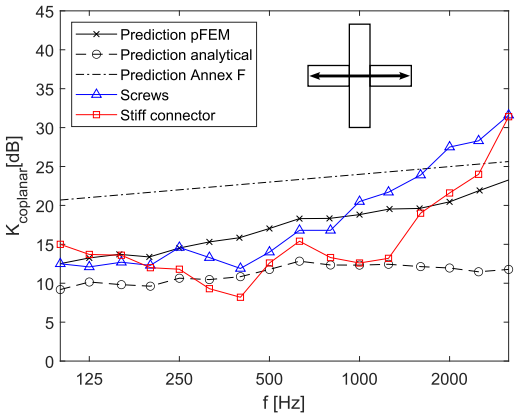

Figure 7. Vibration reduction index for the interrupted coplanar transmission path in the CLT X-junction.

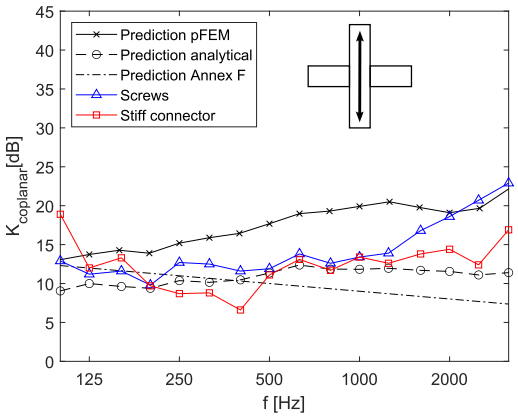

Figure 8. Vibration reduction index for the uninterrupted coplanar transmission path in the CLT X-junction.

ically offers a lower limit for K_{ij} due to the assumption of a rotationally stiff line connection. Therefore, it corresponds most closely to the results for stiffer connection types such as the X-RAD and the screwed junction for transmission path 1-4 which, unlike path 1-2, has a direct screw connection. Notably, the predictions are less accurate in the high-frequency range, where the thin plate assumption is typically invalid due to the small wavelengths compared to the wall thickness. As a result, the high-frequency K_{ij} increase is underestimated for each transmission path. Due to the inclusion of thickness effects, the new pFEM prediction model performs better in the high-frequency range. In general, the predicted K_{ij} values are several dB higher than the analytical model. One potential reason for this is the layered finite element modelling of the CLT walls, while homogenized single-layer values are used for the thin plate model which are not necessarily fully equivalent. Additionally, the junction itself has a mass and volume unlike the line connection in the analytical model, which could lead to a globally less stiff connection. While the thin plate model corresponds more closely to the stiffly connected transmission paths such as corner path 1-4 for the screws, the opposite holds for the pFEM model with the exception of the high-frequency range. Most notably, K_{24} across continuous coplanar transmission path 2-4 is better represented by the thin plate model, although the pFEM predictions are still relatively accurate. Note that the pFEM prediction results can be improved by explicitly including the screws

or X-RAD connector in the finite element model. Similarly, it is possible to implement flexible connectors (e.g. resilient pads) in future work, which allows for much design freedom and detail when modelling various building junctions. In general, the difference between the pFEM K_{ij} predictions and the experimental values lie beneath 5 dB for most 1/3 octave bands, with especially good correspondence to K_{ij} for connections with lower rotational stiffness. For example, the pFEM predictions of K_{12} differ less than 2 dB from the experimental results for the screw connection up to 1000 Hz.

4. CONCLUSIONS

The presented work introduces a prediction model for the vibration reduction index K_{ij} across CLT junctions with spatial periodicity along the junction direction, constructing finite element models for a repeated unit cell and applying Bloch analysis. The prediction model is validated with rigid X-junctions consisting of 3-ply CLT walls, connected by screws or more rotationally stiff modular connectors. The predicted values are quite accurate with differences with experimental results beneath 5 dB in most 1/3 octave bands and even lower for less rigid connections. Due to the large modelling freedom in this framework, it is possible to further improve the predictions by including resilient or stiff elements (e.g. resilient pads and screws, respectively) in future work.

EXPERIMENTAL MODAL ANALYSIS OF A CROSS-LAMINATED TIMBER L-JUNCTION WITH A VIEW TOWARDS PREDICTING FLANKING SOUND TRANSMISSION

Sven Vallely[1,2*] **Antonio Esposito**[1] **Stefan Schoenwald**[1]

ABSTRACT

The trend towards engineered wood and, as a result, lightweight constructions has led to noise and vibration design challenges. One such challenge that is currently an active research topic is flanking sound transmission through connected building elements. Mass timber buildings are typically formed by connecting cross-laminated timber panels, whereby the type and number of joints used to form a connection can vary depending on the design and purpose of the building. The variety of connector types and implementations poses challenges for the prediction process. Moreover, the connection of the simpler panel subsystems gives rise to emergent behaviour, resulting in a complex dynamic system. As a first step, to better predict flanking sound transmission and to correctly simulate the junction mechanics in vibroacoustic numerical models, it is important to understand the emergent dynamic behaviour due to the connection of these structural elements. This contribution presents a detailed experimental modal analysis of a scaled cross-laminated timber L-junction structure. The mock-up is considered representative of a cross-section that would be encountered in the practice. The experimental modal analysis examines three different L-junction configurations to deduce the contribution of both the brackets and the resulting contacting panel interfaces to the system's dynamic behaviour.

1. INTRODUCTION

Due to its lightweight yet stiff nature, Cross-Laminated Timber (CLT) is a popular structural element choice for the construction of mass timber buildings. While this property is generally beneficial, it poses vibration serviceability and acoustic design challenges.

One approach to help address these challenges is the development of methods and models to characterise and predict the behaviour of CLT structures. This has been considered at several scales, from individual elements [1–3] to operational mid-rise structures [4, 5]. While each modelling scale has its own challenges, modelling at a junction scale has a unique challenge since, here, not just material properties play a crucial role but also the intricate dynamics of the connections [6].

This contribution takes an experimental approach to considering the role of connection dynamics with the view of developing models to accurately predict flanking sound transmission across CLT elements. An experiment was designed with the intent to isolate and determine the contributions of the connectors and contact between plate interfaces on the modal response of a system. To achieve this, three structurally isolated L-junction configurations were investigated: (1) An L-junction connection with two standard steel angle brackets and contact between plate interfaces; (2) The same L-junction connection as (1), but with a 3 mm gap between the plate interfaces; (3) The same L-junction as (1), but with no angle brackets.

2. BACKGROUND AND THEORY

In order to compare and correlate the experimentally fitted modes, a shape-based index, namely the Modal Assurance Criterion (MAC), is chosen. The MAC has diverse appli-

cations not just for mode pairing, but also for for eigenmode error analysis [7]. Such an example is the use of the AutoMAC to check against spatial aliasing. For assessing MAC (and AutoMAC) indices, values of 0.9 or greater are considered to be well-correlated eigenmode pairs and values of 0.1 or less are considered to be uncorrelated eigenmode pairs for the purpose of this contribution. Further discussion of the benefits, limitations, and interpretation of this shape-based index can be found in Refs. [7, 8].

3. MATERIALS AND METHODS

3.1 Experimental set-up

The experimental set-up involved vibration measurements of three CLT L-junction configurations. The L-junction configurations were each formed by connecting two 3-ply CLT plates denominated as CLT060C1 and CLT100A1, respectively. The geometrical properties of the plates are presented in Table 1.

Table 1. Geometrical properties of the experimentally investigated plates. Namely length a, width b, individual layer thickness t_i, and lay-up.

Plate ID	a (m)	b (m)	t_i (mm)	Lay-up (°)
CLT100A1	2.87	1.14	[30/40/30]	[90/0/90]
CLT060C1	1.52		[20/20/20]	

A schematic of the L-junction formed by the two plates and the three different configurations is presented in Fig. 1. The three different configurations of the L-junctions were formed by using different joining methods to connect the two plates along their respective short edges, labeled as DA in Fig. 1. The configurations are designated as follows. 0G2B is the case for using two brackets (2B) and contact, that is, a 0 mm gap (0G) between the plates when forming their connection. 3G2B is the case for using two brackets (2B) and no contact, that is, a 3 mm gap (3G) between the plates when forming their connection. 0G0B is the case for using no brackets (0B) and contact, that is, a 0 mm gap (0G) between the plates when forming their connection.

The brackets used to form the connection for configs. 0G2B and 3G2B were standard steel angle brackets with product number. The brackets had global dimensions of $90 \times 90 \times 65 \times 2.5$ mm and were offset 150 mm from the long edge of the plate and fastened with 8 wood screws per bracket. The screws had a thread length of 40 mm and an

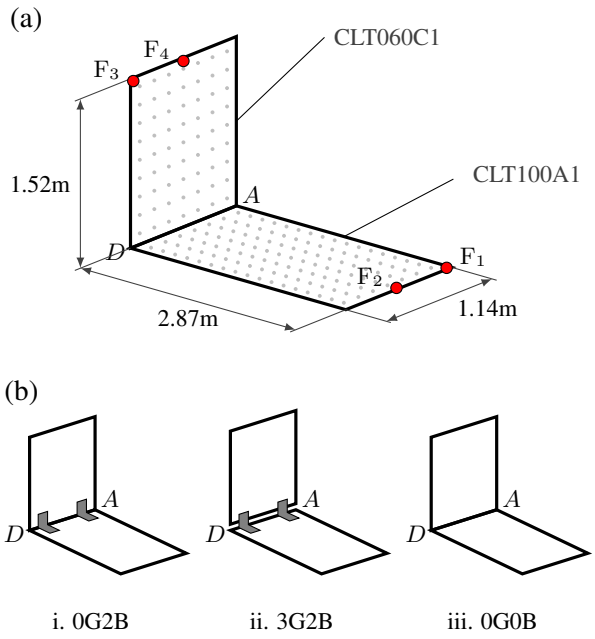

Figure 1. Schematic of the experimental set-up. (a) Schematic of the experimental set-up indicating planar dimensions, approximate measurement grid, and locations of the excitation positions. (b) Schematics of the different joining methods used to connect the two CLT plates along edge DA.

outer thread diameter of approximately 5 mm. An image of an individual bracket is presented in Fig. 3b along with the fixing point locations.

The test structure was supported on four air cushions near the corners of plate CLT100A1 in order to simulate free boundary conditions. The air cushions enabled the test object to be structurally isolated from the ambient environment while minimising the constraint effects of the supports on vibroacoustic behaviour of the system, thereby approximating free boundary conditions.

For the measurement of the vibrational response of the system, a Polytec PSV-400 Laser Doppler Vibrometer measured the normal velocities of the top-side surfaces of plates CLT060C1 and CLT100A1. The measurement grids on plates CLT060C1 and CLT100A1 were 7×9 and 7×17 Cartesian point grids, respectively. These Cartesian point grids corresponded to a spatial resolution of approximately 18 cm. The approximate measurement grids are depicted in Fig. 1a.

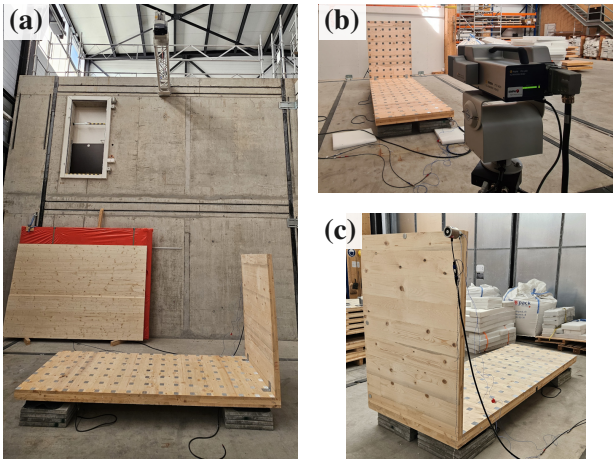

Figure 2. Images of the general experimental set-up: Configuration 0G2B is shown. (a) Acquisition of the normal surface velocities on plate CLT100A1. (b) Acquisition of the normal surface velocities on plate CLT060C1. (c) Rear view with shaker attached.

Four different excitation points were considered, two per plate, with one being approximately on a corner of the plate at the free end, and one being in the middle of the short edge of the plate. The locations of the excitation points are depicted in Fig. 1a. At the excitation points, an impedance head was attached to which a shaker was then attached. The velocity response surface was measured for each excitation point with a swept sine excitation. The transfer mobilites were then calculated based on the measured response surfaces with respect to the force signal of the impedance head. A frequency range from 0 Hz to 800 Hz with a resolution of 62.5 mHz was considered. For each measurement point, the measurements were repeated 5 times for each point, and a complex average was taken.

An overall view of the experimental set-up is presented in Fig. 2, which shows the 0G2B configuration. The 3G2B and 0G0B configurations required slight modification to the structure for safety reasons due to the reduced stability of the connection. For config. 3G2B, plate CLT060C1 was supported from behind with two air cushions. Images of the modification made for config. 3G2B are presented in Fig. 3. For config. 0G0B, guiding cross-bars at the front and back sides were constructed to ensure that plate CLT060C1 did not tip or slide away from its location. CLT060C1 was decoupled from the cross-bars with soft elastic interlayers to ensure that the cross-bars did not influence the vibroacoustic response of the system. The Images of the additional modifications made for config. 0G0B are presented in Fig. 4. It should be stated that the L-junction was constructed so that CLT060C1 was supported as much as possible by CLT100A1 and structurally isolated from the frame which acted as a secondary support.

The measurements for the modal analysis were conducted as part of a broader investigation into flanking sound transmission. See Ref. [9] for details on other excitation points and investigations in the mid- to high-frequency range.

3.2 Modal Parameter Estimation

The experimental modal parameters presented in this contribution were fitted as part of an Experimental Modal Analysis (EMA) using the combined measurement data obtained with the procedure discussed in Sec. 3.1. Further details of the EMA method can found in Ref. [8].

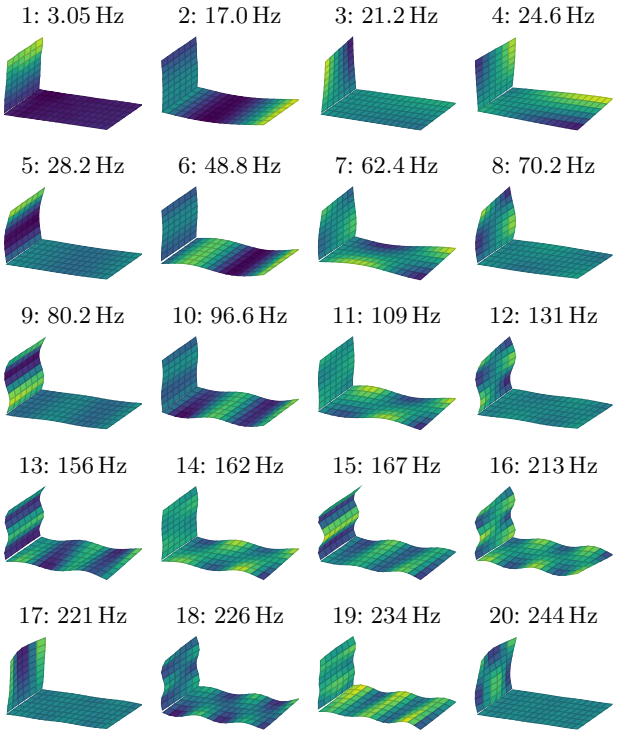

Figure 5. The first twenty identified eigenmodes with their experimental eigenfrequencies for 0G2B.

4. RESULTS AND DISCUSSION

4.1 Modal Parameter Estimation

The EMAs of each of the configurations were able to fit 20 modes for the 0G2B and 3G2B configurations and 18 modes for the 0G0B configuration. The fitted eigenmodes and their associated eigenfrequencies are presented in Figs. 5 to 7. The AutoMAC matrices of the respective eigenmodes are presented in Figs. 8 to 10. The eigenmodes, as expected, correlate exactly with themselves, i.e. $MAC_{i,j} = 1 \quad \forall i = j$ and the off-diagonal terms are mostly zero or uncorrelated, i.e. $MAC_{i,j} < 0.10 \quad \forall i \neq j$. This indicates that the mode parameter estimation is valid and that the eigenmodes contain a sufficient number of degrees of freedom to prevent spatial aliasing. A corollary of this is that the measurement grid is adequate for the identified modes.

There is, however, one pair of modes where the spatial resolution appears to be inadequate. For config. 3G2B, $MAC_{19,20} = 0.65$, indicating a moderate correlation between the modes. Visually comparing eigenmodes 19 and 20 in Fig. 6 confirms this moderate correlation and indicates a potential spatial aliasing. For config. 0G0B, a moderate correlation between modes is also found, with $MAC_{1,6} = 0.50$. Comparing these modes in Fig. 7, there appears to be an adequate spatial resolution to resolve the modes, therefore, the mild correlation is more likely due to coherent noise as a result of non-linearities at the connection caused by the rigid body motion of mode 1. For the remaining non-zero off-diagonal values in Figs. 8 to 10, it is expected that the values would be zero or much closer to zero if the MAC were to be calculated with mass normalised eigenmodes.

4.2 Auto-Comparison and Auto-Correlation of the Experimental Configurations

Considering the identified eigenmodes in Figs. 5 to 7, three different types of modes have been identified by measuring the normal surface velocities of the structure, that is; rigid body modes, torsional modes, and bending modes. The rigid body modes are modes 1 for configs. 0G2B and 3G2B, and modes 1 to 3 for config. 0G0B. The rigid body modes occur at frequencies approximately an order of magnitude lower than the fundamental bending and torsional modes for the 0G2B and 0G0B configura-

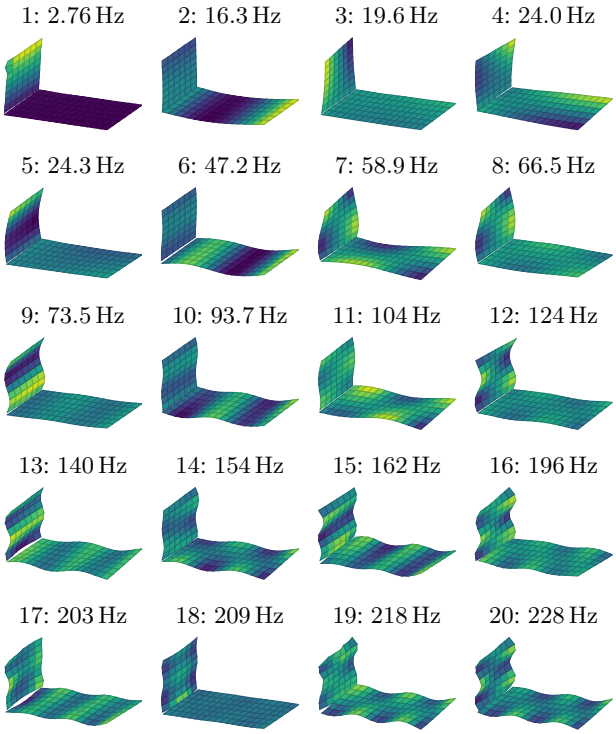

Figure 6. The first twenty identified eigenmodes with their experimental eigenfrequencies for 3G2B.

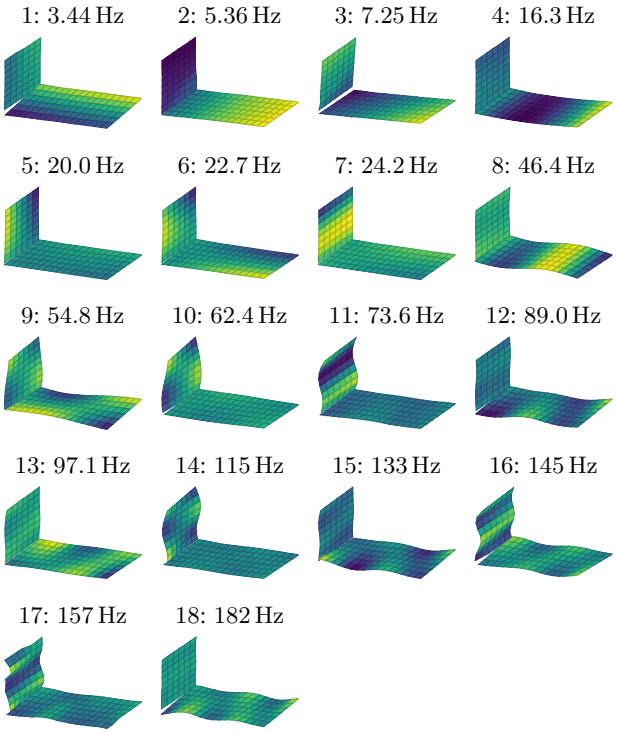

Figure 7. The first twenty identified eigenmodes with their experimental eigenfrequencies for 0G0B.

tions. These rigid body modes are associated with the deformation of the angle bracket and, in conjunction, can potentially provide valuable information for structural identification of the stiffness and damping properties of the connection. The three rigid body modes identified for config. 0G0B have higher eigenfrequencies than those of configs. 0G2B and 3G2B with the steel angle brackets. This result, at a surface level, indicates that the connection is stiffer for 0G0B; however, this additional stiffness is likely due plate CLT060C1 interacting with its supporting structure than with the joining method or, rather, lack there of. A quick visual comparison between the different configurations indicates that the torsional and bending modes do not appear to be influenced by, or at most, negligibly influenced by the supporting structure.

Considering the torsional and bending modes across Figs. 5 to 7, there appears to be cases where the individual plate modes are uncoupled, and other cases where the individual plate modes couple. An example of uncoupled individual plate modes are modes 2 and 5 in Fig. 5. On the other hand, an example of coupled individual plate modes are 13 and 15. What is particularly interesting about these coupled modes, is that they are composed of the same two individual plate modes when considering the plates as individual structural subsystems; however, considering their AutoMAC values, $AutoMAC_{13,15} = 0.05$ (cf. Fig 8), the two modes can be considered uncorrelated. The connection of these two subsystem gives rise to emergent behaviour, whereby they are coupled and moving in phase with respect to each other for mode 13, and coupled and moving out of phase with respect to each other for mode 15, resulting in an approximately 7 % shift in the eigenfrequency. This result of identifying coupling and non-coupling modes could potentially open new possibilities for addressing low-frequency flanking sound transmission. While not a standalone noise control solution, the identification of coupling modes during the design phase of a building could potentially allow for an approach to address problem frequencies for flanking sound transmission without adding additional mass to the structure. For example, by changing of aspect ratios of elements to minimise coupling across the connection, or changing the connec-

tion itself.

4.3 Cross-Comparison and Cross-Correlation of the Experimental Configurations

The MAC matrix is computed for each of the three considered experimental configurations against each other in Figs. 11 to 13.

For Fig. 11, where config. 3G2B is compared against config. 0G2B, it can be seen that the eigenmodes of both of the configurations occur in the same order and are well correlated up to the 12$^{\text{th}}$ mode, that is $MAC_{i,j} > 0.9 \quad \forall i = j \in \{1, ..., 12\} : i, j \in \mathbb{N}$. Considering the eigenfrequencies of these well-correlated mode pairs in Figs. 5 and 6, it can be seen that the eigenfrequencies for config. 0G2B are approximately 5 % higher than those of config. 3G2B. This result implies an overall global increase in stiffness of the structure to the effect of approximately 25 % due to the contact at the plate interfaces. This stiffening is even seen when when a resonance of one plate occurs uncoupled from the other, for example with modes 2 and 4. After the 12$^{\text{th}}$ mode, the eigenmode pairs are less well correlated. These results indicate that the brackets most important for coupling of the junction at lower frequencies, but the contact starts to have a greater influence on the response of the system as the frequency range increases.

For Fig. 12, where config. 0G0B is compared against config. 0G2B, it can be seen that the eigenmodes the configurations differ more than with the 3G2B-0G2B case. The modes do not occur in the same order, but this is largely due to the identification of the additional rigid body modes in the 0G0B case. Otherwise, it can be said that the significantly correlated eigenmode pairs occur in the same order. Their are 5 well-correlated mode pairs, that is, the mode pairs with indices $i, j \in \{\{4, 2\}, \{5, 3\}, \{8, 6\}, \{9, 7\}\}$. A general observation that can be made, is that the correlation between mode pairs is generally good for uncoupled plate modes.

Considering Fig. 11 where config. 0G0B is compared against config. 3G2B, it can be seen that the correlation between systems improves, with 8 well-correlated eigenmode pairs. The well-correlated pairs have indices $i, j \in \{\{4, 2\}, \{5, 3\}, \{6, 4\}, \{7, 5\}, \{8, 6\}, \{9, 7\}, \{10, 8\}, \{11, 9\}\}$. As with the case for Fig. 12, the correlation between mode pairs is good for uncoupled plate modes, but the correlation drops off once coupled plate modes start occurring. This implies that for the first several modes

where the plate subsystems are generally resonating independent of each other, the type of connection doesn't appear to play a large role in influencing the eigenmodes, but does play a moderate role in influencing the global stiffness of the system. However, once the modes of the plate subsystems start coupling, the connection type starts to change the behaviour of the system.

5. SUMMARY AND CONCLUSION

This contribution compares and correlates experimentally estimated modal parameters for three CLT L-junction configurations with the goal of better understanding the behaviour at element interfaces for predicting flanking sound transmission. Each configuration used the same two CLT plates, but the plates in each configuration were connected with slightly different joining methods. The first method involved using two commercially available steel angle brackets supporting one plate resting on top of the other. The second configuration was the top plate supported solely by the angle brackets, thus eliminating any contact between the plates. The third configuration was just the top plate resting on the top plate without angle brackets. These three experimental configurations allowed for the components that form the connection between a typical L-junction, for example, the surface contact between two connected elements and their joining mechanism, to be analysed in a deductive manner.

The analysis identified three different types of modes, namely rigid body, torsional, and bending modes that contribute to the normal response of the L-junction structure. It was found that rigid body modes with the angle brackets could be potentially used for structural identification purposes of the connection. For the first several bending and torsional modes, where the modal density was relatively low, the resonances of the plate subsystems did not couple with each other. In this region, the type of connection did not have a large influence on the eigenmodes. This implies that for the first several bending and torsional modes, aside from moderate changes in the stiffness of the system, the type of connection does not grossly influence the system's structural response. However, for higher frequencies, the modes of the subsystems start to couple, and the simpler plate subsystems give rise to emergent behaviour. That is, a system formed from the connection of simpler subsystems behaves in a way that is more complex than the individual subsystems would behave on their own. This emergent behaviour is, at first, mostly due to the brackets,

but as the frequency range increases, the contact between the elements starts to have an increasingly larger influence on the response of the system.

Further, this contribution highlights the potential for new measures in addressing flanking sound transmission performance in the low-frequency range. While the effect of the emergent system behaviour due to the coupling of modes from simpler panel subsystems and their direct influence on flanking sound transmission requires further investigation, these modes, once identified, can be shifted or even partially avoided. This could be accomplished without adding additional mass to the structure, such as by carefully selecting element aspect ratios in the design phase or changing the types of connectors themselves. This could even potentially be done remedially with other available measures, such as changing the stiffness of plates, but potentially at the expense of negatively influencing the radiation efficiency of the structure at higher frequencies.

The results of this contribution could be used as a basis for updating or validating a numerical model, such as in Ref. [9].

LOAD EFFECTS IN FLANKING TRANSMISSION OF CLT STRUCTURES WITH RESILIENT INTERLAYER

ABSTRACT

With the increasing construction of Cross Laminated Timber (CLT) buildings, the demand for enhanced acoustic performance is also rising. To improve the sound insulation, resilient interlayers are inserted in the structure, which decreases the flanking transmission. These interlayers are generally placed between the floor and the wall and are under a static load, which depends on the relative floor. Interlayers are usually viscoelastic materials with non-linear behaviour. This is why the vibroacoustic behaviour under different loading conditions is investigated in this paper. Through a full-scale mockup, the vibration reduction index K_{ij} of some resilient material with different elastic modulus is measured by placing various static loads over the junction to evaluate different performances.

The results reveal significant differences depending on the load applied to the junction. In particular, in the mid-high frequencies, the higher the load, the lower the K_{ij} due to the increase in the dynamic stiffness of the resilient layer in the compression. This supports the importance of choosing the proper resilient material in the design step and carrying out laboratory measurements of K_{ij} with the test conditions as close as possible to the actual conditions of use.

Keywords: *cross laminated timber - resilient interlayer - flanking transmission*

1. INTRODUCTION

Obtaining good acoustic comfort also requires consideration of flanking transmission in addition to wall, floor and façade sound insulation. Wooden buildings like CLT (Cross Laminated Timber) have high radiation efficiency and low mass, which makes them particularly challenging to solve in terms of sound insulation. Engineered cross laminated timber (CLT) constructions permit the reduction of the acoustic vibrations transmitted into the structure by inserting resilient strips, usually elastomers, between the floor and wall [1] [2] [3].

CLT, in the past, was mainly used for small buildings with a few storeys, but today, it is also used for large buildings up to 18 storeys. The resilient strips under the supporting walls are, therefore, subjected to large loads, particularly on the lower floors. Also, the load on the resilient strip varies depending on the floor it is located on due to the weight of the upper floors.

Nilsson et al. [4] give an in-depth overview of the current literature on vibration reduction index, in particular on CLT, and analyse the effects of loading in junctions with resilient strips and fastening systems by comparing in-situ measurements of junctions in the first floors (higher load) with junctions with similar boundary conditions in the upper floors (lower load). The effects of loading on vibration reduction index were also studied by Crispin et al. [5], but for lightweight masonry constructions.

Schoenwald et al. [6] show that the vibration reduction index of junctions without resilient interlayers and with a fastening system is influenced to a considerable amount when

the weight of the first storey is added, while the effect on the K_{ij} decreases significantly when additional storeys are added.

In the standard ISO 10848-1 (under revision) [7] for measuring the vibration reduction index K_{ij} there is no standardised methodology for measuring structures with resilient strips.

Also measuring the properties of elastomers in the dynamic regime under high loads with equipment is not easy, and there is a lack of suitable instrumentation [8]. Currently, there is the standard ISO 4664-1, also known as DMA, of which it is difficult to find ready-built machines that can perform analyses with high loads. This standard is designed for measurements at frequencies up to 200 Hz and applies to samples with a form factor of *h:d=1:1.5*, where h is the height of the sample and d is the diameter of the cylindrical sample. The results obtained are influenced by this form factor. The deformation considered is only 10%. Another standard is ISO 9052-1, which, however, is only intended for loads similar to a screed.

In this article, experimental measurements were carried out in the laboratory to see the effects of loading on the vibroacoustic properties of CLT junctions with resilient strips and without a fastening system. First by measuring the characteristics, such as the elastic modulus, of certain elastomers and then by measuring the K_{ij} after inserting them into a mockup junction.

2. BACKGROUND THEORY

Cross-laminated timber (CLT) structures are classified as Type A and therefore the descriptor for expressing the insulation effectiveness at the passage of acoustic vibrations through the junction is the vibration reduction index K_{ij} defined in ISO 10848-1 as:

$$K_{ij} = \overline{D_{v,ij}} + 10lg\left(\frac{l_{ij}}{\sqrt{a_i a_j}}\right) \quad \text{[dB]} \qquad (1)$$

with

$\overline{D_{v,ij}}$ [dB]: direction-averaged velocity level difference between elements i and j;

l_{ij} [m]: junction length between elements i and j;

a_i, a_j [m]: equivalent absorption lengths of elements i and j.

3. METHOD

3.1 Compressive elastic modulus

The compressive modulus of elasticity was measured according to ISO 844 [9] with the specifications of the EAD 042232-00-0503 [10]. In this EAD, the compressive elastic modulus is defined as:

$$E_c = \frac{\sigma_{15}-\sigma_5}{\varepsilon_{15}-\varepsilon_5} \quad \text{[MPa]} \qquad (2)$$

with

σ_{15} [MPa]: compressive stress at 15% strain (ε_{15});

σ_5 [MPa]: compressive stress at 5% strain (ε_5).

The samples had square dimensions of 50x50mm² and a thickness of 6mm. Five unlubricated samples of each material were tested. The tests were carried out using an INSTRON 8023 hydraulic press with steel plates and a compression speed of 0.01mm/s. This test was conducted under static conditions.

3.2 Vibration reduction index

A full-scale mockup of a horizontal L-junction (Figure 1) was built in the laboratories of Buildwise in Belgium. The floor is a 0.14m thick 5-ply CLT panel (panel i) with a width of 2.25m and a length of 4.93m. The wall is a 0.12m thick 5-ply CLT panel (panel ii) with a width of 2.4m and a length of 3.94m. The mockup is inside a warehouse, with the floor (panel i) supported on one side by three columns of cellular concrete blocks (height approx. 0.6m) and on the other side by panel i. Only the top 0.6m of the wall (panel i) is visible in the warehouse as it is inserted between two transmission chambers normally used for laboratory sound insulation tests. Three source points and eight receiver points were chosen for each panel. A hammer was used as the source. The velocity levels of the panels were measured using accelerometers placed at the receiver points and glued to the panel's surface with a two-component glue. Panel dimensions, source and receiver positions are compliant with ISO 10848-1. The structural reverberation time of the panels was determined from the impulse response of a hammer.

First, the vibration reduction index K_{ij} was measured for the rigid junction (without resilient strip), with panel ii just placed on panel i. Next, measurements were made by placing resilient materials in the junction between the two panels. Several resilient strips were tested, each with an equivalent length to the junction, i.e., 2.2m, width 0.08m and uncompressed thickness of 0.006m. In this case, a load is applied on the resilient material equivalent to the self-weight of the structure and thus half the weight of the floor, corresponding to 377kg and, therefore, a pressure on the resilient material of 0.021MPa.

Next, measurements were made by varying the load applied to the junction. To do this, starting with one, then two and then three reinforced concrete blocks were placed on the floor slab right above the junction (Figure 1, right). The concrete blocks were placed vertically and have a

Table 1. Measured configuration for vibration reduction index.

Configuration	Resilient interlayer	Number of concrete blocks	Pressure on the junction [MPa]	Deformation of the resilient interlayer	$K_{ij,high}$ [dB] (average 1250-5000HZ)
Conf.rigid_0	no	0	0.014	-	22.2

Conf.C_0	C	0	0.021	< 2%	29.4
Conf.C_1	C	1	0.040	< 2%	26.5
Conf.C_2	C	2	0.060	< 2%	25.3
Conf.C_3	C	3	0.079	< 2%	24.1

parallelepiped shape with dimensions: height 1m, width 0.25m and length 0.6m. Each block weighs 346kg, which in total, with the weight of the structure, becomes a pressure on the resilient material of 0.040MPa for one block, 0.060MPa for two blocks, and 0.079MPa for three blocks (assuming that the load is evenly distributed). The configuration with one block has the block placed in the centre of the junction, while the configuration with two blocks has them placed at the extremes of the junction.

All measurements were carried out within 10 minutes of the resilient material being loaded in an attempt to have approximately the same creep effects given by the loading time. All configurations are without a fastening system.

The maximum weight applied (3 blocks) to the junction is approximately 1000kg (without the self-weight of panel i). In a real service condition, we would also have other weights bearing down on the junction. For example, considering the partitions (an upper CLT wall, insulation, lining), the floating floor (floor, screed, floor finish), a ceiling, and the residential loads of normal use that would weigh on a floor with dimensions like those of the mockup, we would have an addition of approximately 2000kg on the junction. This would correspond to a pressure of 0.13MPa on the resilient strip. This load would only be that of a single storey and thus the typical load for the upper storey, in lower storeys the loads can be considerably higher as all the weights of the individual storeys are added together in load-bearing wall structures such as CLT.

4. RESULTS

Three different resilient materials (with different shore) were tested, two expanded EPDM (A and B) and one extruded polyurethane (C). Materials A (Figure 2), B (Figure 3) and C (Figure 4) were measured in compression to determine the compressive elastic modulus in static conditions. The typical non-linear behaviour of elastomers is recognisable in the graphs comparing pressure and deformation.

The summary of the configurations tested for the vibration reduction index K_{ij} has been schematised in Table 1. The measurement results are shown in Figure 5 to Figure 8.

Figure 1. Horizontal L-junction CLT mockup. On the left without extra weight. On the right with three concrete blocks.

5. DISCUSSION

It is desirable to use elastomers with low deformations and within their elastic range in building structures in order to have greater predictability of behaviour and to limit permanent deformations and structural stresses. Figure 2 to Figure 4 show the linear regression from 5% to 15% strain as in (2) to find the elastic modulus of the respective materials, indicated as the angular coefficient in the graph formula.

Figure 2 shows that for elastomer A, a pressure of 0.021MPa corresponds to a deformation of 10% (equivalent to 0.6mm), while for a pressure of 0.040MPa there is a deformation of 19% (1.14mm), with 0.060MPa it is 28% (1.68mm), and with 0.079MPa it is 35% (2.1mm). For elastomer B (Figure 3), there is a deformation of 4% (0.24mm) at a pressure of 0.021MPa, 5% (0.3mm) at 0.040MPa, 7% (0.42mm) at 0.060MPa, 9% (0.54mm) at 0.079MPa. For elastomer C (Figure 4), all loads applied in the K_{ij} tests are under 2% deformation. In Table 1 there is a summary of the relative deformation.

During the K_{ij} tests, we are within the elastic range of 5-15% deformation for elastomer A without concrete blocks and almost with one block; for elastomer B with one, two and three blocks; and for elastomer C we are significantly outside this elastic range. Although the weights are added by linear steps of 0.02MPa this is not reflected in a direct correlation of the K_{ij} measurements. There are different behaviours between the static regime (ISO 844) and the dynamic regime (ISO 10848-1).

It should be pointed out that the compressive elastic modulus measurements, following the roughness requirements of the standard ISO 844, were carried out with steel plates which produce different friction compared to wood and elastomer.

Figure 5 shows the measured results of the vibration reduction index K_{ij} of the rigid configurations without interlayer. It can be observed that there are differences in adding load to the junction. This is because adding weight will smooth out any possible gaps between panel i and panel ii caused by the roughness of the wood and the concavities in panel i. It seems that above a certain load (in this case from the second block), almost any imperfections in the contact surface between the two panels are smoothed out, resulting in a large decrease in the junction insulation. Beyond this threshold, the effects of further loading diminish drastically, as already seen in [6].

For configurations with the interlayer, the effects of the load are seen above the 400Hz band (Figure 6, Figure 7, and Figure 8). In general, as the load increases, the junction insulation decreases.

Below 125Hz, the vibration of the panels is determined by global modes, i.e. the two panels of the mockup behave as a single system and the resilient interlayer is not effective. From 160Hz local plate modes appear and the two panels operate as two subsystems. The two panels are effectively decoupled by the resilient interlayer, which is reflected in the sudden increase of the K_{ij} at this frequency (Figure 6, Figure 7, and Figure 8). Around the 250Hz band, there is an insulation gap due to parasitic airborne noise that is emitted from

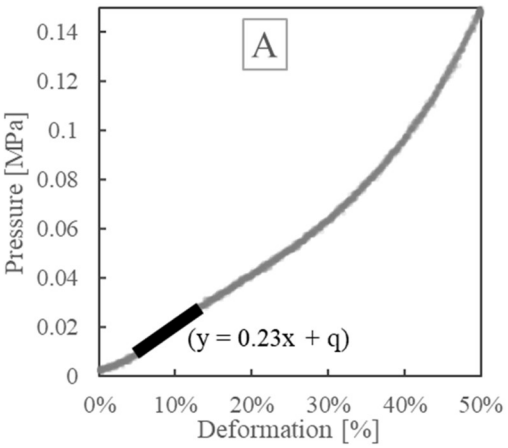

Figure 2. Compressive elastic modulus of interlayer A.

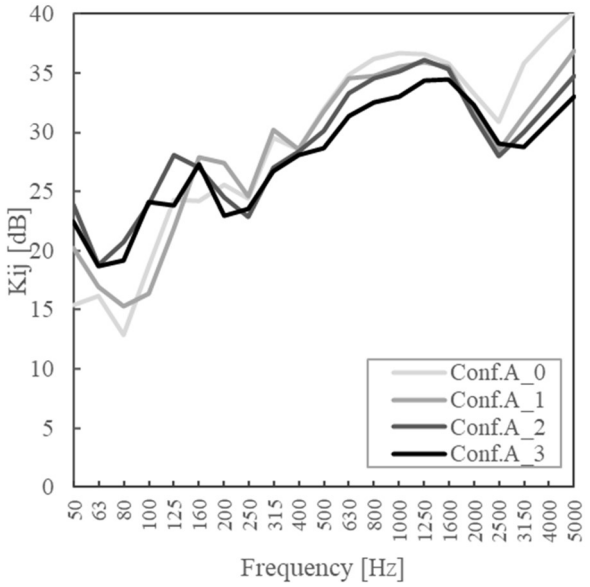

Figure 6. Vibration reduction index K_{ij} of the junction with resilient interlayer A.

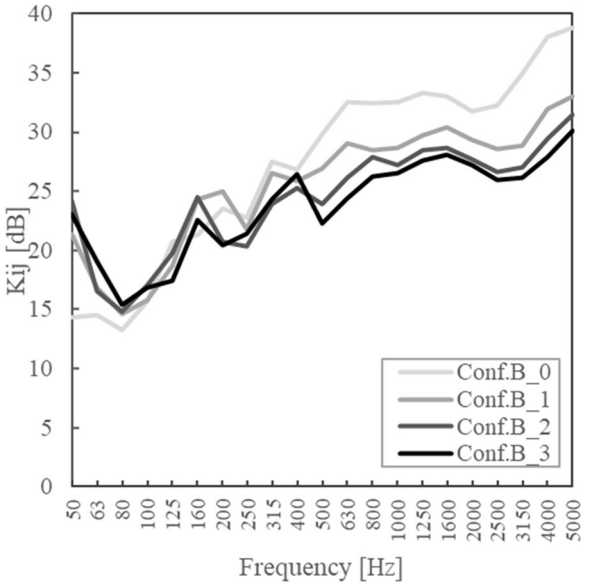

Figure 7. Vibration reduction index K_{ij} of the junction with resilient interlayer B.

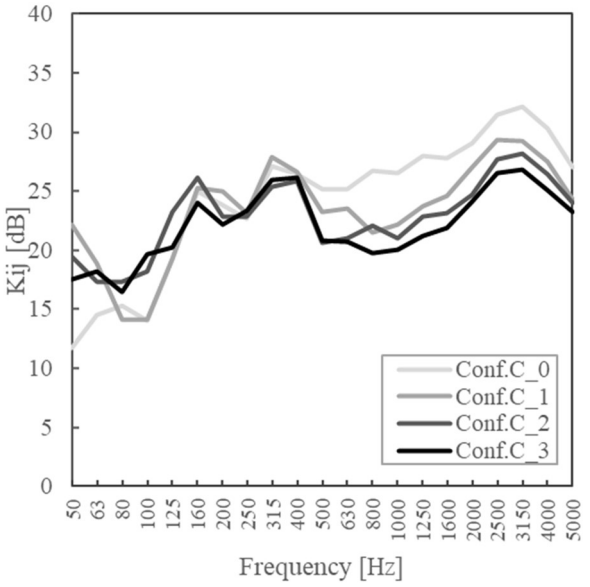

Figure 8. Vibration reduction index K_{ij} of the junction with resilient interlayer C.

the source panel and passes through the air to re-enter the receiving panel [11].

In elastomers A and B (Figure 6, Figure 7), a dip is observed in the frequency range of 2500-3150Hz for the K_{ij} values. This dip is attributed to the thickness resonance of the resilient interlayer [11]. The resonance frequency, which depends on the elastic modulus of the resilient interlayer, increases as the load on the resilient material rises.

To compare the different configurations with a single index, it is possible to use the division made by Hopkins [12] of $K_{ij,high}$ for the frequency range 1250-5000Hz, whose values for the tested configurations are summarised in the Table 1. This range is designed for isotropic homogeneous structures, whereas CLT is orthotropic and composed of several cross-layers. Indeed, the measurements shown in this article do not have a linear behaviour in this range. However, it was decided to use this method for coherence with the scientific literature and to have a curve comparison number. The difference of the unique index $K_{ij,high}$ between the configuration without added load and with loads is then made to have an easy indication of how much the performance is varying.

The difference between the $K_{ij,high}$ of the rigid configuration (Conf.rigid_0) and that with one block (Conf.rigid_1) is 1.6dB, adding a second block (Conf.rigid_2) loses another 3.9dB (5.4dB compared to Conf.rigid_0), while with three blocks (Conf.rigid_3) another 1.2dB (6.7dB compared to Conf.rigid_0) is lost.

Elastomer A comparing the configuration without added loads (Conf.A_0) with that with one block (Conf.A_1) loses 2.4dB, with two (Conf.A_2) another 0.9dB (3.3dB relative to Conf.A_0), with three (Conf.A_3) a further 1.1dB (2.3dB relative to Conf.A_0). The dynamic stiffness of the resilient strip increases significantly due to the loading and related thickness loss, reducing performance.

Elastomer B comparing the configuration without added loads (Conf.B_0) with the one block configuration (Conf.B_1) loses 3.3dB, with two (Conf.B_2) a further 1.4dB (4.6dB over Conf.B_0), with three (Conf.B_3) a further 0.8dB (5.5dB over Conf.B_0).

Elastomer C comparing the configuration with no added load (Conf.C_0) with the one block configuration (Conf.C_1) loses 3.8dB, with two (Conf.C_2) another 1dB (4.9dB relative to Conf.D_0), with three (Conf.C_3) a further 1.3dB (6.2dB relative to Conf.C_0).

For elastomers B and C, the most significant changes occur with the addition of the first block, as any gaps or lack of contact at the wood-elastomer interface are eliminated.

6. CONCLUSION

This article discusses the fact that the vibration reduction index, K_{ij}, of junctions with resilient interlayers is influenced by the load applied to the junction (for example, in this article, up to 7dB). Elastomers, usually used as resilient strips, do not have linear pressure-deformation behaviour. It is, therefore, difficult to make exact predictions of their behaviour in the dynamic regime under the design loads without measuring the appropriate conditions.

An important point to consider is the fact that in-situ measurements of K_{ij} are often performed during the construction phase when linings are not yet present. The linings (including the floating screed) can have a significant influence on the masses involved, especially for lightweight CLT structures. The measurement that is taken is, therefore, biased by a different load condition than the one that will be found when the building is finished (and foreseen in the design phase for the correct choice of resilient material based on its optimal load range) encountering the problems noted in this article. It is, therefore, important to find a method for predicting the effects to correct in situ measurements.

A method would also need to be found to measure a parameter in a dynamic regime under the right design load. One idea could be the dynamic stiffness, but the current ISO 9052-1 standard does not allow measurement under loads other than those typical of a screed (8±0.5kg on a 200x200mm², so in the range of 0.002MPa). Another possible standard could be the ISO 4664-1, but this standard is not meant for different loads and for measuring frequencies above 200Hz.

As loads in CLT buildings vary greatly, for example, between the first floors and the upper floors, there is a need to conduct K_{ij} measurements in the laboratory with the right design load to avoid overestimating the junction insulation.

It is therefore planned in the current revision of ISO 10848-1 to include a common standardised procedure for measuring the K_{ij} of structures with resilient interlayers.

It has to be said that in a real CLT building there will always be a fastening system in the junction. It is expected that the differences with varying load for such junctions are smaller as the performance of the junction is obviously lower.

7. ACKNOWLEDGMENTS

The results presented in this paper have been obtained within the frame of the projects "STABBS II" (Standards for acoustic better buildings II). The authors are grateful for the financial support from the Federal Public Service Economy of Belgium.

MODELLING CROSS-LAMINATED TIMBER PLATE CONNECTIONS: A NUMERICAL INVESTIGATION ON FLANKING SOUND TRANSMISSION THROUGH ANGLE BRACKETS

ABSTRACT

In recent years, interest has grown in numerical models to predict flanking sound transmission through Cross-Laminated Timber (CLT) junctions. The panels are typically connected with screwed metal brackets, which are differently shaped depending on the junction geometry and structural requirements. To predict the Vibration Reduction Index K_{ij}, available models rely either on empirical formulae or simplified junctions with idealized connection. In this contribution, a numerical investigation on the dynamics of a CLT L-junction is presented, starting from a detailed representation of an angle bracket. This was modelled in FEM and validated with vibrometry measurements. It was then integrated into the model of a CLT L-junction mock-up and compared to experimental datasets from two different configurations, where CLT plates were either in direct contact or separated by an air gap. Validation in the modal domain showed a good agreement of the model with both experimental configurations. The comparison with experimental K_{ij} showed a better correlation with the latter configuration, whereas larger deviations were observed above 1 kHz in the former case. This provided some insights on the modelling of bracket fastening and highlighted the need of introducing constraint conditions at the interface between CLT plates to simulate the effects of direct contact.

1. INTRODUCTION

The use of Cross-Laminated Timber (CLT) has become well established in the construction industry due to its proven benefits in terms of structural efficiency, cost-effectiveness and environmental sustainability. CLT plates are often employed as load-bearing elements, due to their orthotropy and high strength-to-weight ratio. On the other hand, this feature causes significant structure-borne sound power flow across their junctions [1]. CLT plates are usually connected with screwed metal brackets, especially for specific types like L-, T- or X- junctions [2]. Given the above, the numerical modelling of flanking vibration transmission mechanisms in CLT junctions has received particular attention, with the aim of predicting the Vibration Reduction Index K_{ij}, as defined in the ISO 12354-1:2017 [3] and the ISO 10848-1:2017 [4] standards. The computation of this quantity becomes critical since the interface between CLT plates is, in most cases, both punctual, due to fasteners, and linear, due to the contact between plates [2]. Existing predictive approaches rely either on empirical or analytical models. In particular, the ISO 12354:2017-1 standard [3] provides empirical formulae, based on laboratory measurements, to compute K_{ij} for T- and X- CLT junctions. Nevertheless, such relationships are considered valid only within a limited range of area mass density ratios between the elements. In addition to empirical models, various analytical or numerical

approaches for modelling CLT junctions can be found in the literature. Among others, Salvalaggio et al. [5] investigated the impact of sound-insulated joints on the dynamics of CLT structures. In their study, plate joints with steel fasteners were modelled as linear interface elements and angle brackets as nodal linear springs, whose stiffnesses were retrieved from a model updating process. In a recent work, Moons et al. [6] proposed an efficient analytical wave approach to predict K_{ij} through CLT junctions with and without resilient interlayers. Their model without interlayers showed deviations against experiments below 5 dB in 1/3 octave bands up to 2000 Hz. In this latter case, CLT plates were modeled as semi-infinite, assuming ideal rigid connections. In the context of the research project "Schallschutz im Holzbau", conducted in a cooperation between Lignum (Swiss Forestry Association) and Empa, the dynamic behavior of metal angle brackets was analyzed with the aim of investigating the effects of point connections between plates on CLT junctions. A steel angle bracket has been modelled in FEM and validated with laser doppler vibrometry measurements in the modal domain. It has been then integrated in a global FEM model of a CLT L-junction mock-up. The numerical K_{ij} was computed and compared against the experimental K_{ij} obtained by measuring two different setups, in which plates, connected with two angle brackets, were either in direct contact or separated by a 3 mm air gap. Based on the above, an alternative approach is proposed herein, for the dynamic characterization of CLT junction components. This may constitute a preliminary stage of a bottom-up procedure for setting up broadband versatile FEM models, which could possibly account for the effects of a change in the number and position of connectors in the junction. Please note that the graphs presented in this updated version of the paper are revised with respect to that initially submitted for the conference.

2. THEORY AND BACKGROUND

In the following subsections, the basic principles of FEM modal and harmonic analyses, conducted on the proposed models, are outlined. Furthermore, the theoretical background underlying the Vibration Reduction Index K_{ij} is summarized, since it was calculated and referred to as a validation of the numerical model of the L-junction.

2.1 Modal analysis

For an undamped multi-degree of freedom system, the equation of motion for free vibration is written as [7]:

$$[\mathbf{M}]\{\ddot{\mathbf{x}}\} + [\mathbf{K}]\{\mathbf{x}\} = 0 \tag{1}$$

where $\{\ddot{\mathbf{x}}\}$ is the nodal acceleration vector, $\{\mathbf{x}\}$ is the nodal displacement vector, $[\mathbf{M}]$ is the mass matrix and $[\mathbf{K}]$ is the stiffness matrix of the system. Assuming the displacement field solution of Eqn. (1) to be harmonic, the natural frequencies and the eigenvectors of the system can be calculated by solving the corresponding eigenvalue problem.

2.2 Harmonic analysis

When a damped system is excited by an external harmonic force $\{\mathbf{F}\}$, Eqn. (1) becomes [7]:

$$[\mathbf{M}]\{\ddot{\mathbf{x}}\} + [\mathbf{C}]\{\dot{\mathbf{x}}\} + [\mathbf{K}]\{\mathbf{x}\} = \{\mathbf{F}\} \tag{2}$$

where $\{\mathbf{F}\}$ is the external harmonic forcing vector and $[\mathbf{C}]$ is the structural damping matrix of the system.

2.3 Vibration Reduction Index K_{ij}

In order to predict the flanking sound transmission across a junction between building elements, the ISO 12354-1:2017 standard [3] introduces the Vibration Reduction Index K_{ij}. This quantity represents, analogously to the Sound Reduction Index, the attenuation of structure-borne sound at a junction. It is based on Statistical Energy Analysis simplifications on power transmission. It is frequency-dependent, expressed in decibels and defined as:

$$K_{ij} = \overline{Dv,_{ij}} + 10lg\left(\frac{l_{ij}}{\sqrt{a_i a_j}}\right). \tag{3}$$

where $\overline{Dv,_{ij}}$ is the direction-averaged velocity level difference between two elements, l_{ij} is the junction length and $a_{i,j}$ are the equivalent absorption lengths of the elements i and j. These are defined as [4]:

$$a = \frac{2.2\pi^2 S}{c_0 T_s}\sqrt{\frac{f_{ref}}{f}} \tag{4}$$

where T_s is the structural reverberation time of the element, S is the surface area of the element, f is the centre band frequency, f_{ref}, equal to 1000 Hz, is the reference frequency and c_0 is the speed of sound in air.

3. NUMERICAL MODELLING AND VALIDATION OF A STEEL ANGLE BRACKET

In the following subsections, the FEM model of a single steel angle bracket is described. The numerical and experimental setups are described and the validation of the FEM model in the modal domain is presented.

3.1 FEM model setup

An angle bracket was numerically modelled in Ansys Mechanical (Release 2024, R2) and its geometry was reproduced starting from that of a commercially available galvanized steel bracket (Fig. 1). The bracket is modelled as an elastic isotropic shell element and discretised by using 2 mm quadratic triangular mesh elements (Fig. 1), with a total number of 90546 degrees of freedom (DOFs). Elasticity parameters for DX51D galvanized steel are drawn from [8] and listed in Tab. 1.

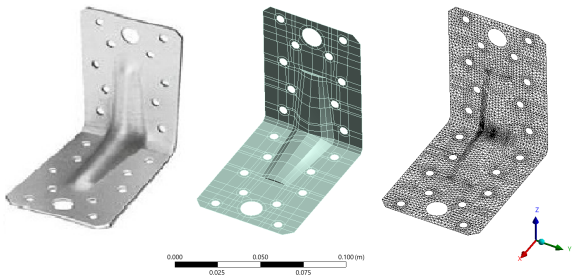

Figure 1. Left-hand side: commercial sample of the analyzed galvanized steel angle bracket. Center: CAD geometry of the bracket sample. Right-hand side: meshed geometry with 2 mm quadratic triangular elements.

Table 1. Elastic constants of DX51D galvanized steel [8].

Mass density, ρ [kgm^{-3}]	Elastic modulus, E [GPa]	Poisson's ratio, ν [-]
7830	210	0.30

A FE modal analysis is performed on the bracket, which is assumed to be in free boundary conditions. Numerical results in terms of eigenfrequencies and modeshapes are reported in the subsection 3.2 and compared to experimental data for validation in the modal domain.

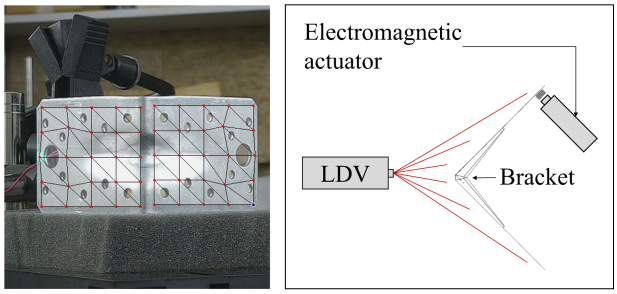

Figure 2. Setup of the experiment on a steel angle bracket. Left-hand side: laser vibrometer measurement grid. Right-hand side: schematic of the measurement setup.

3.2 Vibration measurements and validation in the modal domain

Vibration measurements on the steel angle bracket were carried out with a Laser Doppler Vibrometer. In order to ensure repeatability of the results, tests were performed on three different samples of the same bracket model. To replicate the free boundary conditions during measurements, brackets were resting on a layer of melamine foam. As visible in Fig. 2, they were excited at a corner position with an electromagnetic actuator to minimize possible alterations on mass and stiffness due to the use of a mechanical shaker. A grid of measurement points was set over the surface of the bracket to measure surface velocities (Fig. 2). Where possible, most of the points were evenly spaced on a 13 mm modular grid. The frequency range was from 0 Hz to 6.4 kHz with a spectral resolution of 500 mHz. Ten measurements were averaged at each point and point mobility was exported for each sample. As visible in Fig. 3a, the frequency response functions measured at a corner point were compared. The natural frequencies of the bracket were identified by the peaks of the mobility functions. At the corresponding frequencies, the measured modeshapes showed a good agreement with the numerical results (Fig. 3b and Fig. 3c). Furthermore, the percentage error between numerical and experimental eigenfrequencies was consistently below 5%, except for one eigenmode occurring at 3395.2 Hz, showing a 5.3% error against experimental data. Given the above, the FEM model of the steel angle bracket was considered validated.

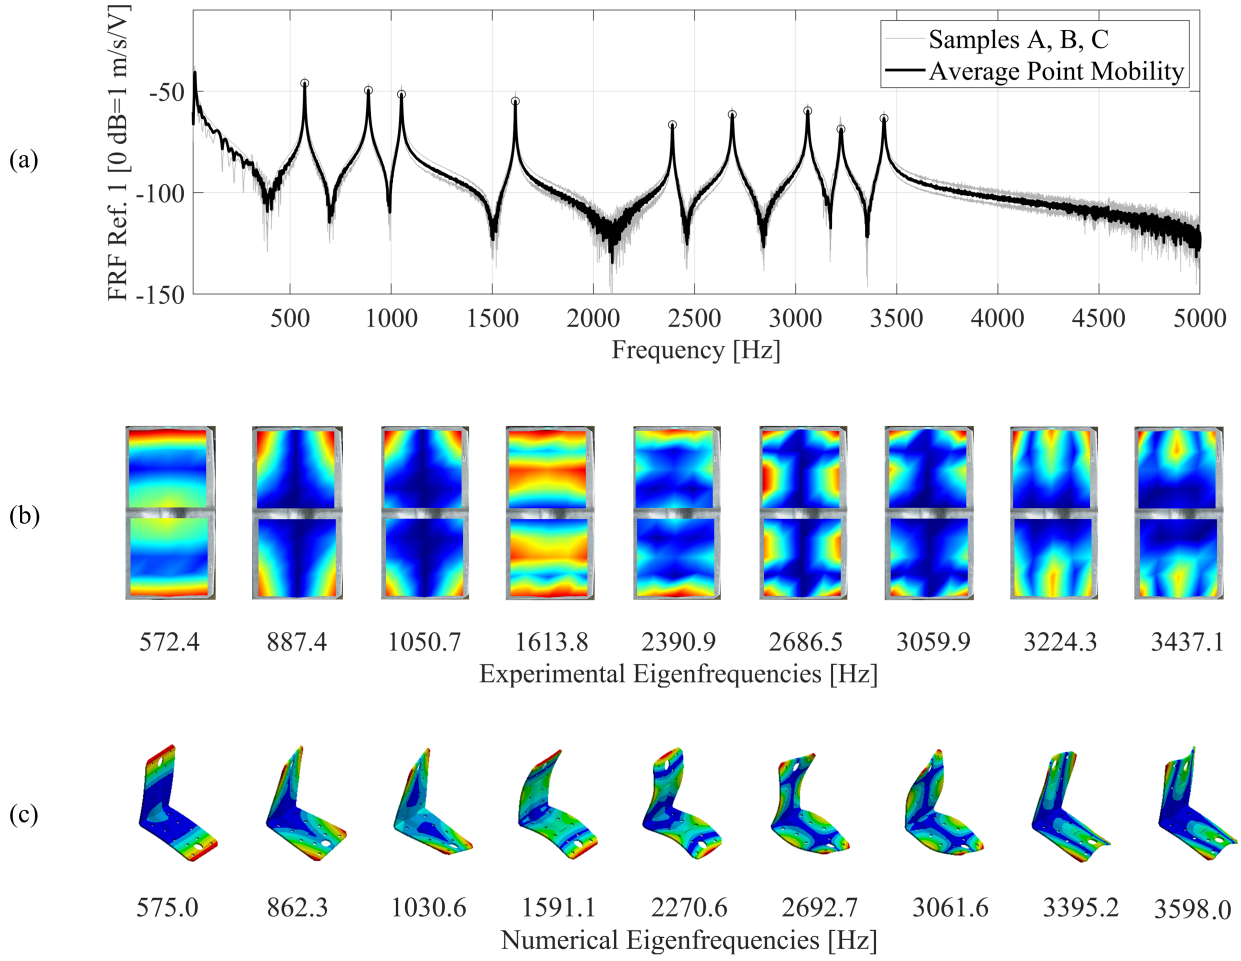

Figure 3. (a) Point Mobility response functions measured on three samples of the same angle bracket model (in gray). The average mobility is represented in black. Abscissas of circled peaks identify the eigenfrequencies of the bracket. (b) Measured modeshapes of the bracket and corresponding eigenfrequencies. (c) FEM modeshapes of the bracket and corresponding eigenfrequencies.

4. NUMERICAL MODELLING OF AN L-JUNCTION MOCK-UP

Once validated against experimental data, the FE model of the bracket was integrated into the numerical model of a CLT L-junction mock up. The latter was validated against laser vibrometry measurements in the modal domain. In the following subsections, the numerical model is described and the setup from two different experimental configurations is reported.

4.1 FEM model setup

A mock-up of a CLT L-junction has been modelled in FEM. Two CLT plates (henceforth referred to as CLT100A1 and CLT060C1) were connected along their short edge with two steel angle brackets (Fig. 4). Brackets were modelled as isotropic shells and meshed according to what mentioned in subsection 3.1. CLT plates were represented as two-dimensional orthotropic shells where the [90/0/90] orientation of the plies was implicitly modelled in a layer-wise representation. The plates were discretised

using 4 cm quadratic triangular mesh elements (Fig. 4b). Physical connections at bracket-plate interface required a specific modelling approach. Multi Point Constraint (MPC) rigid joints were defined to tie nodal displacements at the edges of the bracket screw holes to the nodes defined on the adjacent plates, lying in correspondence of the hole edges projected from the bracket onto the plate surface. With MPC formulation, individual degrees of freedom defined along these edges were eliminated and forced to have the same solution as a single node placed at the origin of the joint reference system (Fig. 4c). Along the contact edge between the two plates, no constraint condition was introduced. Geometrical and mechanical properties of the plates are reported in Tab. 2. Elastic orthotropic parameters of CLT plates were obtained using a numerical parameter estimation based on vibration measurements conducted on the same plates individually. From the same set of measurements, frequency independent structural loss factors were obtained by applying the Power Injection Method (PIM) [1]. The description of the aforementioned procedures is based on the methods applied in [9] for material property derivation. Modal and full harmonic structural dynamic analyses were conducted for the L-junction system. In the former case, eigenfrequencies and mode-shapes of the first fifteen modes were used for calculation of the Percentage Error (PE) and Modal Assurance Criterion (MAC) against experimental data for validation in the modal domain. The PE index provides the relative difference between numerical and experimental eigenfrequencies, expressed in percentage. The MAC index is defined as a squared linear regression correlation coefficient (ranging from 0 to 1) between numerical and experimental eigenvectors. The plates were excited by a transverse harmonic force at three different nodal positions for each plate, as depicted in Fig. 4a. The force amplitude was set as 1 N. The normal surface velocities were acquired as a function of frequency. The surface velocity response of the nodes were then mapped using two-dimensional linear interpolation to the grid measurement points used for the measurements with a laser vibrometer, as described in subsection 4.2. A logarithmic solution interval was defined for the full harmonic analysis, ranging from 200 Hz to 3150 Hz with 575 frequency steps.

Table 2. Geometrical and mechanical properties of CLT100A1 and CLT060C1 plates. Parameters are referred to the reference system of each plate, in which the z-axis is parallel to the plate thickness and the x-axis is perpendicular to the fibers of the top plies.

Property	Units	Plate ID

4.2 Experimental setup

The numerical setup described in subsection 4.1 was replicated experimentally in the lightweight facility at Empa (Fig. 5a). CLT100A1 and CLT060C1 plates were connected with two steel angle brackets, each of which was fixed with four wood screws to the plates (Fig. 5a). In order to isolate the dynamic effects of bracket fastening onto CLT plates in the junction, two different configurations were setup: in the first, plates were touching each other along the common edge (configuration A in Fig. 5b); in the second, a 3 mm air gap was left between the plates, in order to ensure structural coupling to be exclusively due to bracket fastening (configuration B in Fig. 5c). In order to emulate the free boundary conditions, the system was resting on four air jacks, located close to the corners of the CLT100A1 plate, the internal air pressure of which has been kept constant during the measurements. Each plate was dynamically excited with an inertial shaker emitting

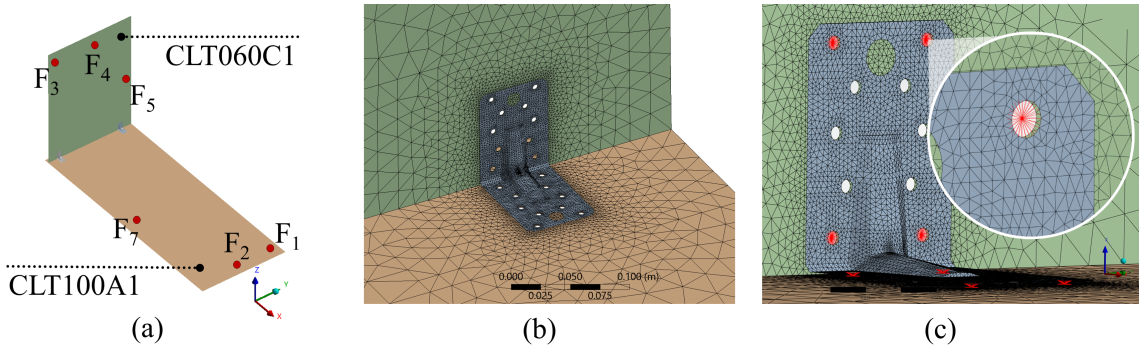

Figure 4. (a) Drawing of the FEM geometry of the L-junction. Excitation points F1 to F7 are highlighted with red dots. (b) Close-up on mesh elements: bracket was modelled with 2 mm triangular elements. Gradual size transition to the 4 cm plate mesh was guaranteed. (c) Close-up on the MPC joints defined at the screw positions.

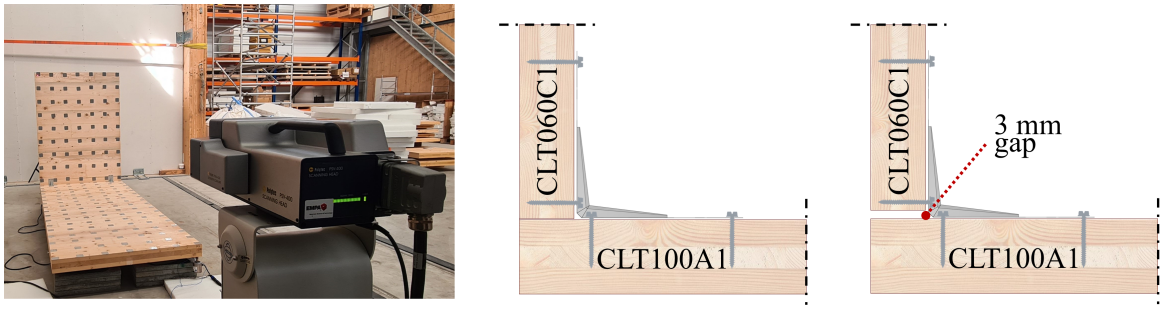

Figure 5. (a) Picture of the CLT L-junction mock-up during the laser doppler vibrometry measurements. (b) Schematization of the configuration A with plates in direct contact. (c) Schematization of the configuration B with a 3 mm air gap between plates.

a sine sweep signal. For each plate, three different excitation positions were set up, according to the schematization of the numerical model depicted in Fig. 4a. Normal surface velocities were acquired with a Polytec PSV-400 scanning vibrometer pointing normally to the plates, over a 17×7 points regular grid for the CLT100A1 plate, and over a 9×7 points grid for the CLT060C1 plate. Results were exported within the 1 Hz-5.8 kHz frequency range with a resolution of 62.5 mHz.

5. RESULTS AND DISCUSSION

5.1 FEM model validation in the modal domain

Results from the FEM modal analysis described in subsection 4.1 were compared for validation to the first fifteen bending and torsional eigenmodes of both experimental configurations, in terms of eigenfrequency PE and MAC. It should be noted that the first rigid-body mode of the junction, occurring below 10 Hz, has not been considered in this analysis. As visible from Fig. 6, a good correlation against both experimental datasets is observable. In particular, PE values were found to be below 10% and, as visible in Fig. 6a, configuration A was stiffer than configuration B, as expected. The minimum MAC value was found to be 0.7 among all modes of both configurations (Fig. 6b,c). This reveals that, in the low-frequency range, edge contact between CLT plates does not significantly affect the modal behaviour of the system. Furthermore, assuming rigid multi-point constraint at screw holes was sufficient to ensure good correlation with experimental data and no further contact modelling is needed at low frequencies.

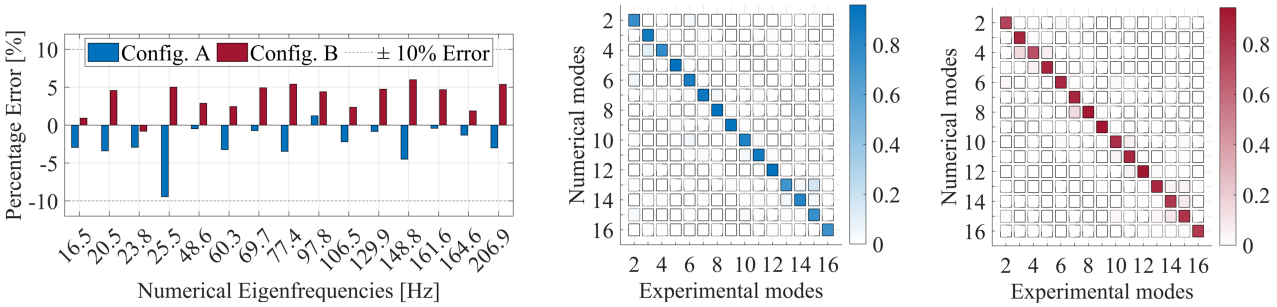

Figure 6. (a) Percentage error of numerical against experimental eigenfrequencies from configurations A and B. (b,c) Modal Assurance Criterion of numerical against experimental eigenmodes from configuration A (b) and configuration B (c).

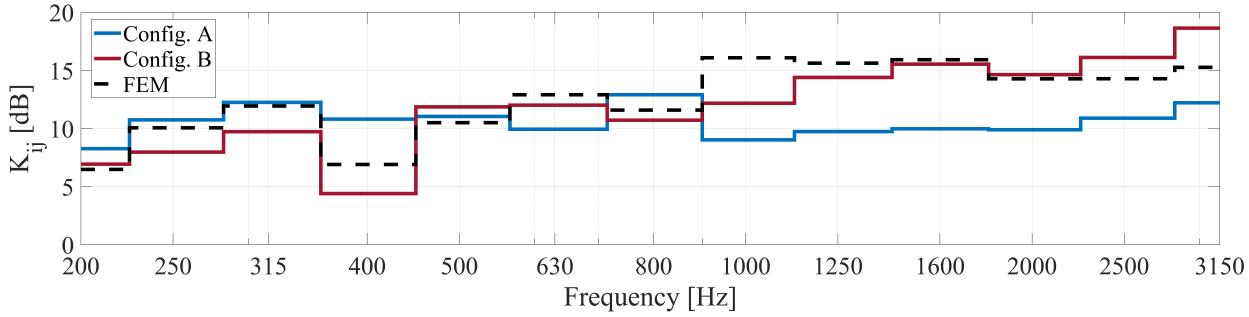

Figure 7. Comparison of numerical and experimental K_{ij} from configurations A and B in one-third octave bands.

5.2 Calculation of the Vibration Reduction Index K_{ij}

As an outcome of the FEM full harmonic analysis, the numerical Vibration Reduction Index K_{ij} was computed and compared to the K_{ij} from configurations A and B in the 200 Hz-3150 Hz frequency range, as shown in Fig. 7. Numerical data show an average deviation of 3.2 dB and a maximum deviation of 7.1 dB at 1 kHz from the experimental K_{ij} of the configuration A, in which the plates were in contact. In addition, the deviation between numerical and experimental single-number K_{ij} was calculated in the mid-frequency (250 Hz - 1 kHz) and high-frequency (1.25 kHz - 3.15 kHz) ranges, as defined in [4]. In the former case, the deviation was equal to 0.5 dB, whilst in the high frequency range it was found to be 4.5 dB. Analysing the overall trend, it appears that the FEM model underestimates the mechanical coupling between the CLT plates above 1 kHz. This can be attributable to possible effects of friction and pre-stress due to the direct contact between the plates in the configuration A, which are neglected in the numerical model. Such effects may be accounted for by introducing non-linear contact conditions or contact stiffness values at the nodes along the common edge between the two plates. These stiffness values may be retrieved from parameter estimation procedures based on curve fitting algorithms against experimental data. As visible in Fig. 7, there is a better agreement between numerical data and K_{ij} from configuration B, in which the plates were separated by an air gap. In particular, the overall trend of numerical K_{ij} is consistent with experimental data over the entire frequency range. An average deviation of 1.7 dB is observed, which almost halves the 3.2 dB mean deviation from the configuration A in the same frequency range. The maximum deviation from configura-

tion B was found to be equal to 3.9 dB at the 1 kHz third octave band. Furthermore, the deviations between numerical and experimental single-number K_{ij} in the mid and high-frequency ranges are respectively equal to 1.6 dB and 0.8 dB. This confirms that the effects of direct contact between plates plays a major role at high frequencies. As a result, it can be stated that the modelling of the bracket with screws can be considered acceptable, although still subject to possible improvements. For example, the use of rigid MPC joints at screw locations could possibly overconstrain the connections at some third octave frequency bands. On this basis, stiffnesses of the screw fastening may be obtained from further experimental investigations and introduced into the model.

6. CONCLUSIONS

This contribution presents a numerical investigation for the prediction of flanking sound transmission across a CLT L-junction, starting from the detailed representation of a commercially available angle bracket. This was modelled in FEM, validated with vibrometry measurements and integrated into a global FEM model of an L-junction mock-up. The numerical K_{ij} was compared with the experimental counterpart from measurements on two different configurations, in which plates were either in contact or separated by an air gap. The analysis provided useful insights on how to model the bracket fastening and the line connections between CLT plates. In particular, the comparison of the numerical K_{ij} with that from the experimental setup in which plates were in direct contact highlighted that the contact forces between plates play a major role and need to be included in numerical models, possibly by means of nodal stiffness values. These can be retrieved from further investigations on experimental data, conceivably with parameter estimation algorithms. A better agreement was observed from the comparison of numerical data against the K_{ij} from the configuration in which plates were separated by a gap. This suggested that modelling the bracket fastening with multi-nodal rigid joints can be partially acceptable, but still subject to possible improvements, e.g. by including nodal stiffnesses along the screw hole edge interfaces in order to reduce coupling overestimation.

7. ACKNOWLEDGMENTS

The presented results were developed within the framework of the cooperative project ”Schallschutz im Holzbau” between Lignum and Empa. The project was funded by the Swiss Federal Office for the Environment (FOEN) as part of the Aktionsplan Holz. We gratefully acknowledge this financial support.

SUGGESTION FOR A ROUND ROBIN TEST ON THE MEASUREMENT OF VIBRATION REDUCTION INDICES ON CLT JUNCTIONS

Fabian Schöpfer[1*] **Ulrich Schanda**[1] **Camille Chateauvieux-Hellwig**[1]

[1] Rosenheim Technical University of Applied Sciences, Germany

ABSTRACT

Prediction methods for sound insulation require input data for the vibration reduction indices. For heavy buildings, ISO 12354-1 provides methods based on the mass ratio of elements. The same holds for solid timber. However, these data are based on a small number of measurements in buildings without the effect of additional loads or elastic interlayers, highlighting the essential need for additional measured data. ISO 10848-1 [1] describes methods to measure the vibration reduction index. But there is room for interpretation of the guidelines given in this standard. For example previous research showed that the choice of sampling points is crucial [2]. To quantify the measurement uncertainty, this paper suggests a concept for a round robin test for discussion. This could be carried out in the laboratory at the Technical University of Applied Sciences in Rosenheim. This laboratory provides a mock-up that allows to set up either a L-junction or a T-junction formed by CLT (cross laminated timber) panels that can be reconfigured quickly with an overhead crane. The possibility to apply additional loads which can be monitored and controlled with load cells as well as the application of elastic interlayers is given. The mock-up can stay in place to have enough time for several institutions to measure.

1. INTRODUCTION

The standard ISO 10848 was first publised in 1999 with the title *Acoustics - Labaratory measurement of the flanking transmission of airborne and impact noise between adjoining rooms - Part 1 : Frame document* [3]. The scope of this standard was to describe measurement procedures to determine the characteristics of one or more building elements in terms of flanking transmission. These characteristics can be used as input data for the prediction methods given in the EN 12354 series. Measured data is particularly needed for junctions formed by timber elements. Hence this standard was used widely to gather data that can be used for prediction. Almost two decades after the publication of ISO 10848, Timpte et al. [4] collected data across Europe from six institutions with more than 200 datasets of vibration reduction indices of cross-laminated-timber (CLT) junctions. It was found that there is a significant deviation between vibration reductions indices measured at various institutes for similar junction configurations. These deviations include parameters related to the mock-up, such as the CLT element itself, construction details of the junction, the choice of optional resilient interlayers or additional loads but also parameters related to the measurement procedure and the processing of data.

The intention of this paper is to initiate an inter-laboratory test (round-robin test) on the measurement procedure including the processing of data to determine vibration reduction indices. This suggested test would not consider all parameters related to the mock-up or the CLT elements itself. It is aimed to consider one specific mock-up formed by CLT elements that will stay in place in one laboratory with different people visiting this laboratory to measure the vibration reduction index according to ISO 10848. However, this standard is currently under revision by ISO/TC 43/SC 2/WG 18 where the measurements pro-

cedure and the processing of data is considered. The suggested inter-laboratory test will include the application of the current standard in comparison with the proposed revision by WG 18.

2. INTER-LABORATORY TEST

Deviations caused by material properties or details on the construction of the junction will not be considered. Only one mock-up with a single set of CLT elements should be part of the inter-laboratory test. The suggested approach is therefore identical with the *measurement situation B* in combination with section 5.6.2 described in [5]. Following this approach the so-called *in-situ* standard deviation can be obtained.

Although the identical CLT elements will be used in the test, it is aimed to consider not only one fixed junction configuration. Each team should measure the vibration reduction index for a set of junctions formed by the same CLT elements, such as an L-junction and a T-junction with the corresponding different transmission paths. It is also aimed to consider different loads on the junction. In addition a junction configuration with an elastic interlayer should also be considered and could easily be implemented in the test procedure.

This requires a careful documentation and monitoring during the reassembly of the considered junction configurations. To ensure identical configurations, parameters such as tightening torques of screws or a measurement, respectively a monitoring of the applied load is required. In addition parameters such as temperature, humidity and moisture will need to be monitored.

3. SUGGESTED TEST FACILITY

For the suggested inter-laboratory test on the measurement of vibration reduction indices of CLT junctions, the laboratory at Rosenheim Technical University of Applied Sciences can be made available. This laboratory offers a mock-up that was already well investigated. This included a statistical study on the vibration field and the corresponding sampling to determine the plate energy [2]. Figure 1 shows the bottom of the junction with the dimensions given in Figure 2. It is possible to configure either a L-junction or a T-junction. Three CLT elements, two wall and one floor element is already in place. A reconfiguration of junctions is possible with an overhead crane.

To apply additional loads on the junction a construction with steel girders is installed. This can be seen in the section drawing in Figure 2 as well as in the photo in Figure 3. These Figures also indicate the two load cells that are installed to monitor the applied load. This mock-up can stay in place for several months in order to allow various teams to come and perform the measurements.

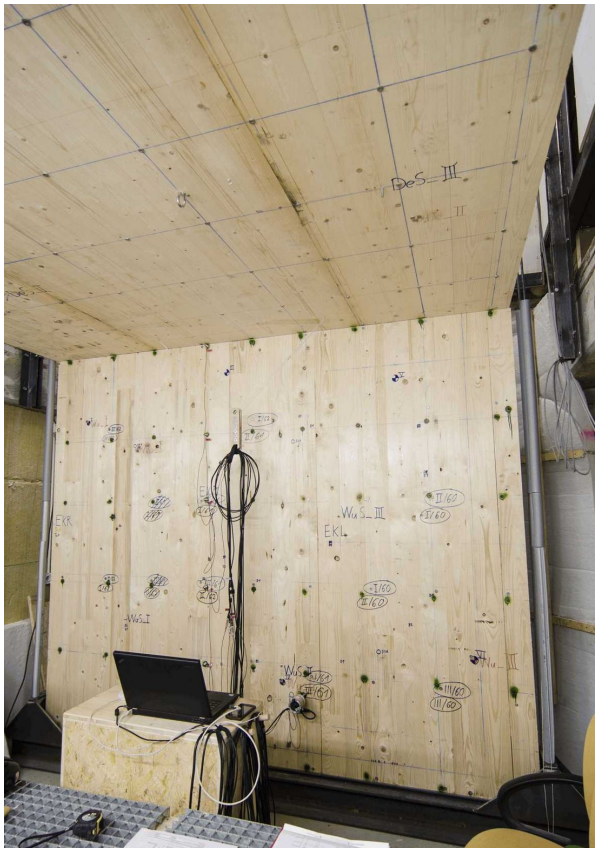

Figure 1. Bottom view of the junction mock-up.

4. CONSIDERATIONS ON THE TYPE OF AVERAGING LEVEL DIFFERENCES

In the course of the round robin test, measurements could as well be compared when applying different calculation approaches of averaging, especially the averaging of results from different excitation positions as discussed in the revision of ISO 10848.

In the current standard of ISO 10848 the velocity level difference $D_{v,ij}$ is calculated using the arithmetic mean of the $D_{v,ij,m}$ for $m = 1 \ldots M$ excitation positions (see equation (2)). Using the familiar physical approach from

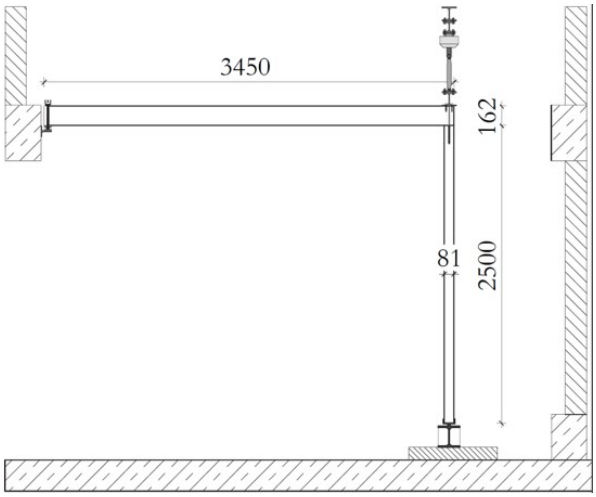

Figure 2. Section of a L-junction configuration indicating the dimensions of the elements. The width of the wall and floor elements not shown in this section is three metres.

EN ISO 10140-4 using transmission coefficients

$$\tau_{ij,m} = \frac{\overline{v_{j,m}^2}}{\overline{v_{i,m}^2}} \tag{1}$$

as the ratio of the mean squared velocity of the receiving element j and the exited element i respectively, the current definition of $D_{v,ij}$ is based on the geometric mean of the transmission coefficients for different excitation positions according to the following derivation.

$$\begin{aligned} D_{v,ij} &= \frac{1}{M}\sum D_{v,ij,m} \\ &= \frac{1}{M}\sum \left(L_{v,i,m} - L_{v,j,m}\right) \\ &= \frac{1}{M}\sum 10\lg\left(\frac{\overline{v_{i,m}^2}}{\overline{v_{j,m}^2}}\right) \\ &= \frac{1}{M}\sum -10\lg\left(\tau_{ij,m}\right) \\ &= -10\frac{1}{M}\lg\left(\prod \tau_{ij,m}\right) \\ &= -10\lg\left(\sqrt[M]{\prod \tau_{ij,m}}\right) \end{aligned} \tag{2}$$

A comparison using the arithmetic mean

$$D_{v,ij} = -10\lg\left(\frac{1}{M}\sum \tau_{ij,m}\right) \tag{3}$$

Figure 3. Top of the L-junction shown in the section drawing in Figure 2. Steel girders to apply a load on the junction. Between the two horizontal girders load cells are in place to measure the force.

or the harmonic mean

$$D_{v,ij} = 10\lg\left(\frac{1}{M}\sum \frac{1}{\tau_{ij,m}}\right) \tag{4}$$

might be evaluated with the measurement results. This would enable to derive the standard deviation using different calculation approaches for the determination of the vibration reduction index.

5. SUMMARY AND OUTLOOK

The measurement of vibration reduction indices is crucial for the application of the the prediction methods given in EN 12354. However previous research [4] showed that there can be great uncertainty in the measured values. This is not only due to deviations in the material parameters or construction details but also due to the measurement procedure and the processing of data. The suggested inter-laboratory test would enable to identify the *in-situ* standard deviation due to the measurement procedure given in ISO 10848. As this standard is currently under revision, both the current procedure as well as the proposed revision could be considered. For the inter-laboratory test the facilities at Rosenheim Technical University of Applied Sciences can be used. In advance repeatability measurements according to the *measurement situation C* in section 5.3.2 [5] would be carried out and compared with corresponding standard deviations from other laboratory setups. Furthermore the possibility to extend the measurement procedure to include the determination of the structure-borne reverberation time should be discussed with potential measurement teams before.

DETAILED ANALYSIS OF DIFFERENT SOFTWARE FOR SOUND INSULATION CALCULATIONS OF VARIOUS STRUCTURES

Klas Hagberg[1,2*] **Erik Nilsson**[2] **Delphine Bard**[2]
[1] Engineering Acoustics, Luleå Technical University, Sweden
[2] Acouwood AB, Malmö, Sweden

ABSTRACT

Easily accessible engineering software to calculate the airborne and impact sound insulation of structural components are a shortage, which hinders the development of new efficient building systems and the inclusion of new environmentally friendly building materials. There are some good possibilities today to calculate field values using commercial programs following the series ISO 12354. However, these standards need to be fed with lab measurements or calculations of each product combination, and all possible product combinations can never be measured. Therefore, calculation tools for various floor and wall configurations are the key for the future development of new building systems and the verification of new materials in the structural components. Few software are available to calculate sound insulation for walls and floors in buildings. Stora Enso offers the CLT software "Calculatis", Marshall Day Acoustics provides "INSUL 10" and the company Sonusoft provides the software "Acoulatis". The three software have slightly different approaches, and so is their capability to calculate various wall and floor structures for CLT. In this paper, a detailed comparative analysis between the software is carried out, based on CLT combinations. The results presented also include comparisons to measured lab values in third octaves, single numbers, and spectrum adaptation terms.

1. INTRODUCTION

To promote a sustainable development of future buildings with acoustically optimized building components (such as floor structures and wall structures), various calculation tools must become available to acousticians globally, but also used! To some extent acousticians are lacking helpful engineering prediction tools, especially when it comes to wooden buildings. However, acousticians show a tendency to avoid calculations and base the acoustic design in buildings by using comparable available measured data and local national tools. That is a big problem for the industry in general since this approach limits the possible material combinations when designing the building components and in addition, it creates non-scientific and unnecessary high margins to the actual requirements. Hence, the lack of prediction tools creates costly solutions due to these excessive margins usually used to make sure not to fail in the final building. Luckily, at least three different engineering tools are available to optimize the building parts, e.g., walls and floors. One software is limited to CLT structures, and two are more comprehensive.

- Acoulatis – CLT and concrete structures, and lightweight frame walls. Online software for purchase, accessible via web browsers [1].
- INSUL 10 – CLT structures and layups with other materials. Software requiring dongle [2].
- Calculatis – CLT structures based on StoraEnso CLT panels. Free online software [3].

While other tools are available that address specific transmission paths of walls and floors, such as flanking transmission following ISO 12354-1 and ISO 12354-2 [4,5], this paper concentrates on a comparative analysis of the three engineering tools aimed to calculate laboratory values, mentioned above.

2. METHOD

Some typical floor and wall buildups commonly used in the European market have been arbitrarily chosen to calculate and evaluate with the different software mentioned in section 1. The calculations are then compared with laboratory values if available. We did not have laboratory values for the exact buildup of some instances and for those, we just compare the calculated values or in some cases the values were recalculated based on field measurements of sound insulation values and the vibration reduction index, following ISO 16283-1, ISO 16283-2, and ISO 10848-1 [6,7,8].

Material data, such as dynamic stiffness, elasticity modules, and other important material characteristics vary between the construction elements. In this paper, we have done our best to use the same material data for each element, such as density, in each software. However, some material data cannot be varied in all software (for example the dynamic stiffness in INSUL and the elasticity modules in Calculatis).

2.1 Calculated wall configurations

Firstly, three bare CLT walls were calculated to compare the basic model in detail, see Figure 1. The CLT walls have a mean density of approximately 470 kg/m^3.

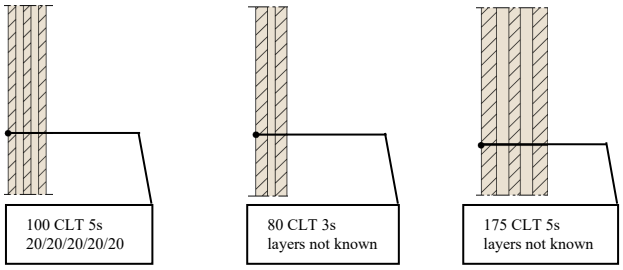

Figure 1. Bare CLT walls compared (calculation 01, 02 and 03).

Additionally, some typical "European" wall configurations are selected for modelling. They are primarily selected since data from lab measurements were accessible, which is considered valuable for the comparison. However, few walls are still selected since they represent a common configuration, but no measurements from lab are available to our knowledge. All wall configurations are shown in Figures 2, 3 and 4. The walls are then modelled in the three software and the results are compared and analyzed in third octaves from 50-5000 Hz (see section 3.1). The following wall combinations are included (apart from the bare CLT walls):

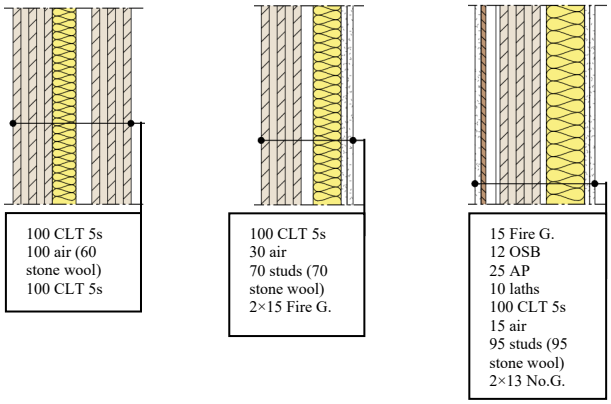

Figure 2. Wall configurations 04 to 06 with 100 CLT C5s (calculation 04, 05 and 06). Fire G. = fire gypsum; AP = acoustic profile; No.G. = Normal Gypsum

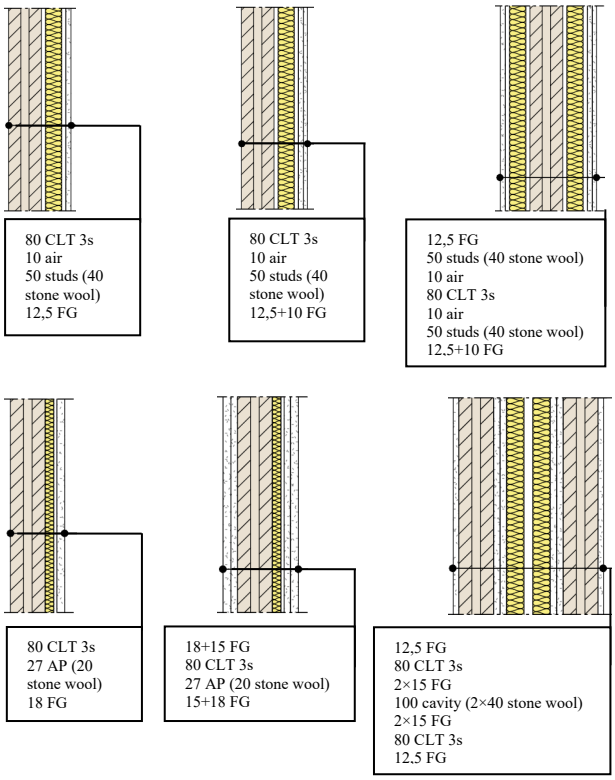

Figure 3. Wall configurations 07 to 12 with 80 CLT C3s (calculation no 07 to 12). FG. = Fibre gypsum; AP = acoustic profile.

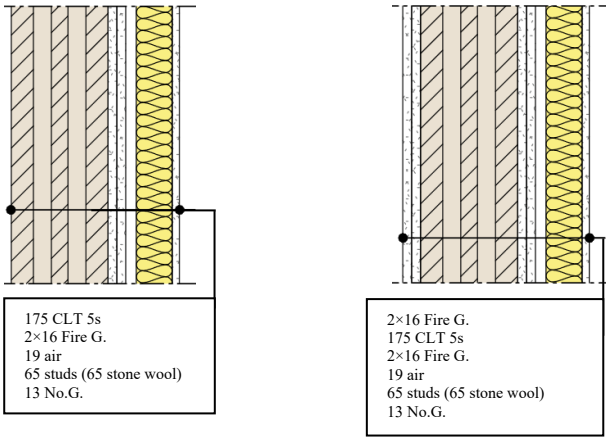

Figure 4. Wall configurations 13 and 14 with 175 CLT C5s (calculation 13 and 14). Fire G. = Fire gypsum; No.G. = Normal Gypsum

2.2 Calculated floor configurations

For the floor structures, calculations were carried out with some different thicknesses of the CLT plates and common material combinations (CLT 140, 180 and one example from a floor buildup typically used in volume elements). However, the possible combinations are close to infinity, implying that a rather small number of available floor constructions have been selected. Nevertheless, they represent some typical floor combinations, frequently used in Europe even if the manufacturers can vary from what is displayed in Figures 5 to 8.

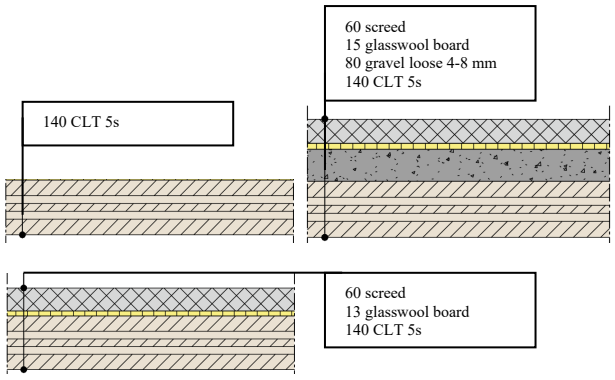

Figure 5. Floor configurations 01 to 03 with 140 CLT L5s (calculation 01 to 03).

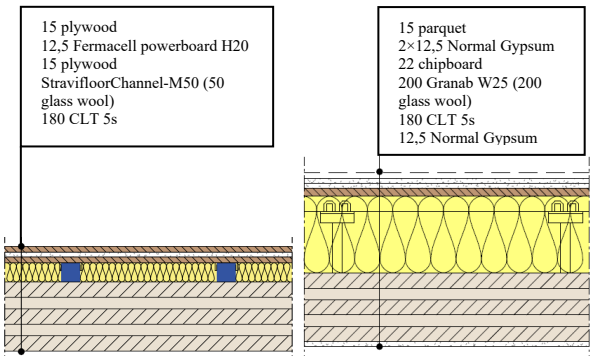

Figure 6. Floor configurations 04 to 05 with raised floor on 180 CLT L5s (calculation 04 to 05).

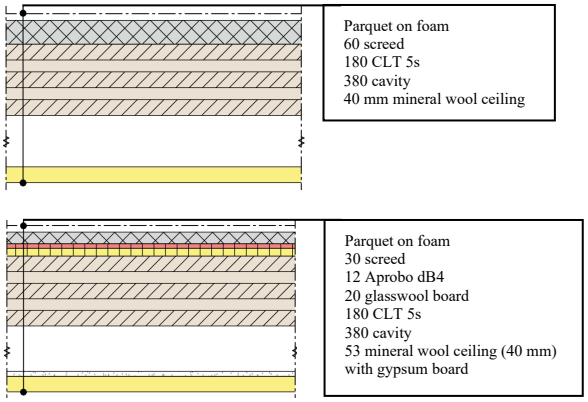

Figure 7. Floor configurations 06 to 07 with screed on 180 CLT L5s (calculation 06 to 07).

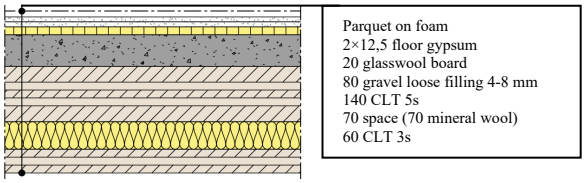

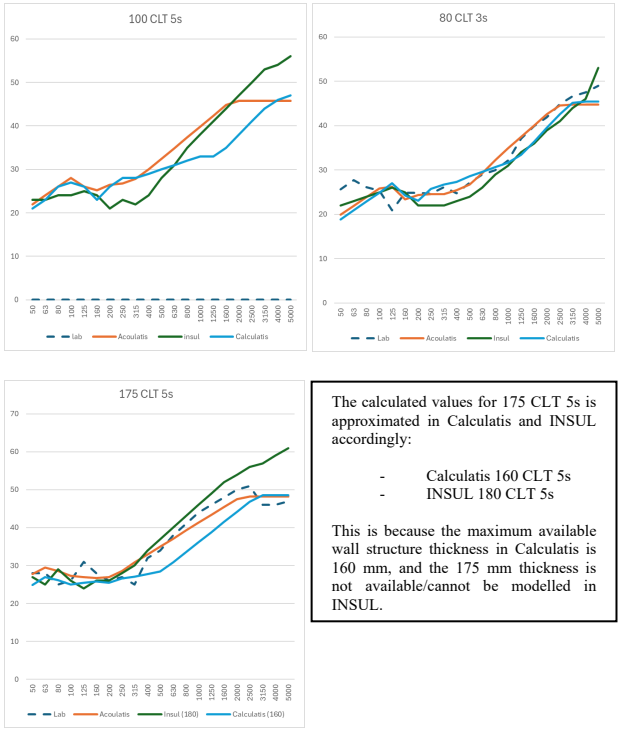

Figure 8. Floor configuration 08 (typical CLT volume elements, calculation no 08).

3. RESULTS

In this section, the results from all the different wall and floor configurations are shown. The results are shown in the same order as displayed in section 2.

3.1 Results from wall calculations

Below are the calculated results and they follow the same order as in section 2.1. In Figures 9 to 13, the results are shown in third octaves and the corresponding single number values are shown in Table 1 to Table 5 immediately after the corresponding figure with third octave band levels.

The calculated values for 175 CLT 5s is approximated in Calculatis and INSUL accordingly:

- Calculatis 160 CLT 5s
- INSUL 180 CLT 5s

This is because the maximum available wall structure thickness in Calculatis is 160 mm, and the 175 mm thickness is not available/cannot be modelled in INSUL.

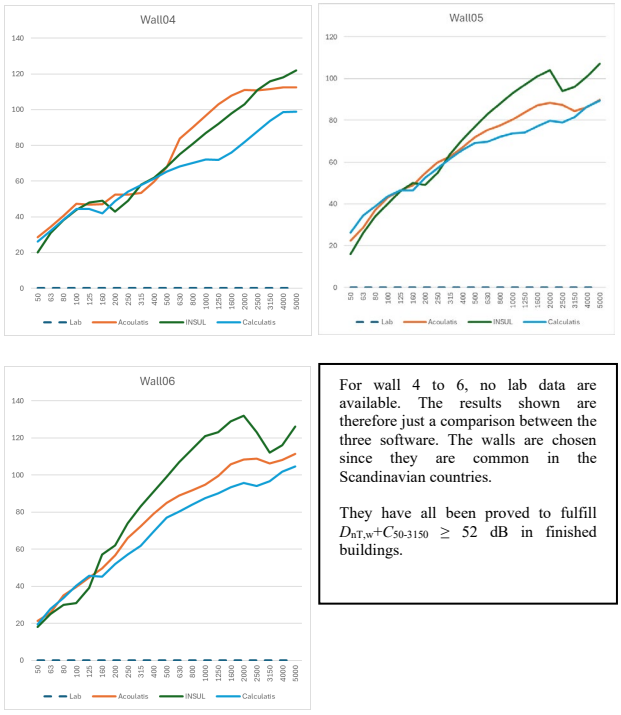

Figure 9. Bare CLT walls, calculated and measured values in 1/3rd octave bands.

Table 1. Corresponding single number values for Figure 9.

	Lab	Acoulatis	INSUL 10	Calculatis
	R_w (C, $C_{50\text{-}3150}$)			
100 C5s	--	37 (-1,-1)	33 (-1,-1)	34 (-1,-1)
80 C3s	33 (-1,-1)	33 (-1,-1)	30 (0,0)	33 (-1,-1)
175 C5s	39 (-2,-2)	39 (-1,-1)	40 (-1,-1)	35 (-1,-1)

The CLT models in INSUL 10 and Calculatis differ, since identical panels from Stora Enso exhibit different results for the 80 and 100 mm CLT plates depending on software. In reality, the panels are identical and therefore the results should be identical. For the 175 mm CLT, the differences are partly explained by the fact that 175 CLT cannot be modelled exactly in Calculatis and INSUL. The selections are fixed to specific panels. Therefore, the thickness of the CLT slab must be approximated to a thickness as close as possible to 175, that is 180 mm in INSUL and 160 mm in Calculatis.

Figure 10 shows the results from calculations of three common dwelling partition wall combinations in Scandinavia, with buildup according to Figure 2.

For wall 4 to 6, no lab data are available. The results shown are therefore just a comparison between the three software. The walls are chosen since they are common in the Scandinavian countries.

They have all been proved to fulfill $D_{nT,w}+C_{50\text{-}3150} \geq 52$ dB in finished buildings.

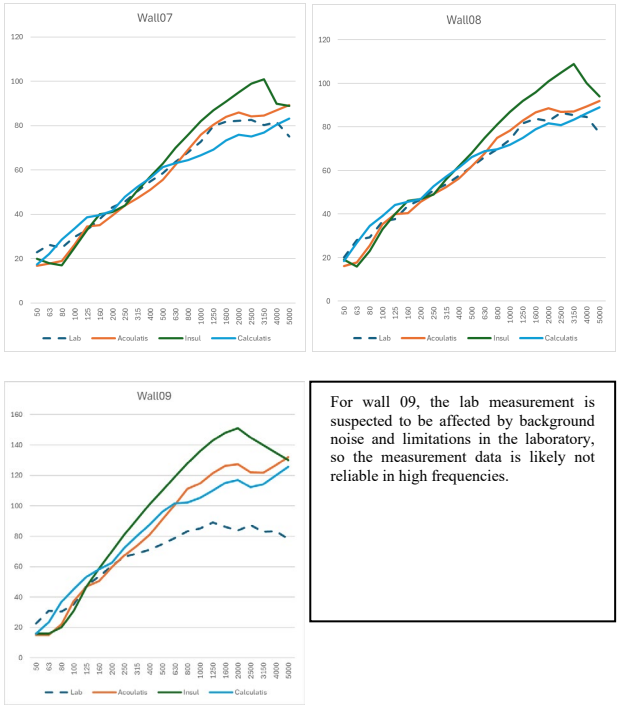

Figure 10. Three different wall configurations calculated, as described in Figure 2. No corresponding lab measurement data is available.

Table 2. Corresponding single number values for Figure 10.

	Lab	Acoulatis	INSUL 10	Calculatis
	R_w (C, $C_{50\text{-}3150}$)			
Calc. 04	--	65 (-2,-4)	65 (-4,-7)	64 (-3,-5)
Calc. 05	--	66 (-3,-10)	67 (-3,-13)	68 (-3,-7)
Calc. 06	--	70 (-6,-19)	72(-12,-19)	67 (-3,-9)

All three software can model the walls in Figure 10 without specific adaptations or additional assumptions. Still the results differ and INSUL generally result in higher values in

high frequencies and slightly lower values in low frequencies, ending up in larger negative values for the *C*-corrections compared to the other two software.
Figures 11 and 12 show the results from calculations of wall 07 to wall 09 (Figure 11) and wall 10 to wall 12 (Figure 12). Their buildups are shown in Figure 3 and CLT 80 3s is the base element. They might represent partitions for some high protection office spaces or in some countries for dwellings (wall 09 and wall 12).

For wall 09, the lab measurement is suspected to be affected by background noise and limitations in the laboratory, so the measurement data is likely not reliable in high frequencies.

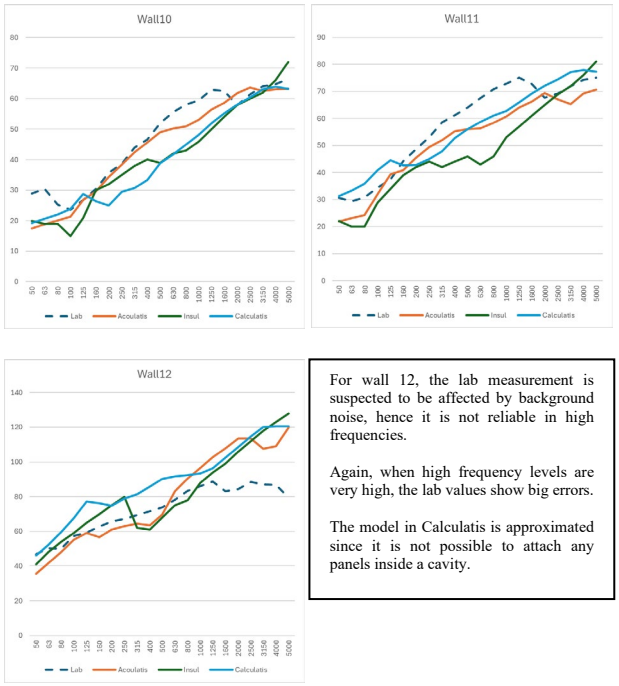

Figure 11. Three different wall configurations calculated, described in Figure 3.

Table 3. Corresponding single number values for Figure 11.

	Lab	Acoulatis	INSUL 10	Calculatis
	R_w (C, $C_{50\text{-}3150}$)			
Calc. 07	56 (-3,-5)	54 (-3,-7)	55 (-3,-9)	58 (-2,-6)
Calc. 08	61 (-2,-6)	60 (-2,-10)	61 (-2,-12)	64 (-3,-9)
Calc. 09	71 (-8,-13)	71 (-6,-23)	72(-12,-24)	77 (-5,-23)

There is generally a good agreement between the software calculations and corresponding laboratory data, except for wall 09, that has extremely good sound insulation in high frequencies compared to the laboratory measurement. For this wall, the calculated values should be more reliable than the laboratory measurement due to max values that can possibly be measured in a lab.

In Figure 12, the results for walls 10 to 12 are shown.

For wall 12, the lab measurement is suspected to be affected by background noise, hence it is not reliable in high frequencies.

Again, when high frequency levels are very high, the lab values show big errors.

The model in Calculatis is approximated since it is not possible to attach any panels inside a cavity.

Figure 12. Three different wall configurations calculated, described in Figure 3.

Table 4. Corresponding single number values for Figure 12.

	Lab	Acoulatis	INSUL 10	Calculatis
	R_w (C, $C_{50\text{-}3150}$)			
Calc. 10	49 (-2,-3)	48 (-3,-4)	43 (-3,-3)	41 (-1,-2)
Calc. 11	62 (-3,-5)	58 (-2,-6)	50 (-1,-3)	58 (-1,-2)
Calc. 12	78 (-1,-3)	74 (-2,-4) 5	75 (-2,-3)	91 (-2,-9)

Finally, in Figure 13 the results from two walls based on 175 CLT 5s are shown with buildups as described in Figure 4.

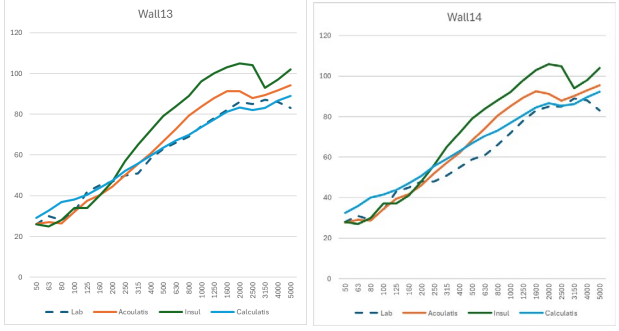

Figure 13. Two different wall configurations calculated, described in Figure 4.

Table 5. Corresponding single number values for Figure 13.

	Lab	Acoulatis	INSUL 10	Calculatis
	R_w (C, $C_{50\text{-}3150}$)			
Calc. 13	61 (-3,-6)	60 (-3,-6)	61 (-4,-7)	62 (-2,-3)
Calc. 14	60 (-2,-4)	61 (-3,-5)	63 (-4,-7)	66 (-3,-4)

These configurations are rather similar, the difference is that calculation 13 emanates from visible wood on one side while calculation 14 is supplied with two extra layers of plasterboards directly attached to the CLT on the opposite side of the cavity. The results indicate that the low frequency performance improves with the extra layers, however the weighted sound reduction index is not really affected. Calculatis shows bigger differences since plasterboards inside the cavity cannot be included in the model.

3.2 Results from floor calculations

Below are the calculated results shown for airborne and impact sound insulation, following the same order as in section 2.2. In Figures 14 to 16, third octaves values are shown and in addition, the corresponding single numbers are shown in tables immediately after the figure with third octave band levels.
INSUL cannot include gravel in its floor configurations and thus, it was modelled as cement / render. Furthermore, INSUL does not include impact boards on CLT for impact noise. Therefore, insulated panels were used instead for the impact sound calculations. The approximations are shown for floors 02 and 03 in Figure 14.

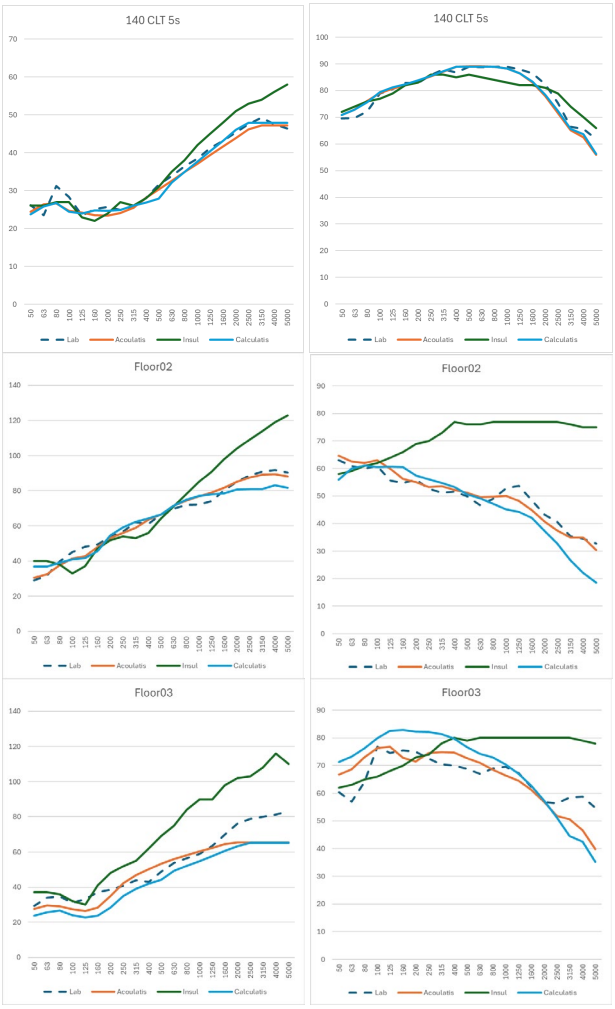

Figure 14. Three different floor configurations calculated, described in Figure 5.

Table 6. Corresponding single number values for airborne sound reduction related to Figure 14.

	Lab	Acoulatis	INSUL 10	Calculatis
	R_w (C, $C_{50\text{-}3150}$)			
CLT 140 5s	36 (-1,-1)	35 (-1,-1)	36 (-1,-1)	35 (-1,-1)
Calc. 02	68 (-2,-6)	66 (-2,-5)	62 (-1,-4)	67 (-4,-5)
Calc. 03	52 (-2,-2)	51 (-4,-4)	59 (-,-)	45 (-3,-3)

Table 7. Corresponding single number values for impact sound levels related to Figure 14.

	Lab	Acoulatis	INSUL 10	Calculatis
	$L_{n,w}$ (C_I, $C_{I,50\text{-}2500}$)			
CLT 140 5s	88 (-5,-5)	87 (-4,-4)	84 (-7,-7)	87 (-4,-4)
Calc. 02	53 (-3,1)	52 (0,3)	81(-11,-11)	52 (0,2)
Calc. 03	70 (-2,-1)	70 (-1,0)	86(-12,-12)	76 (0,0)

In Figure 15, results from calculations of two different combinations of raised floors are shown and compared to the lab values.

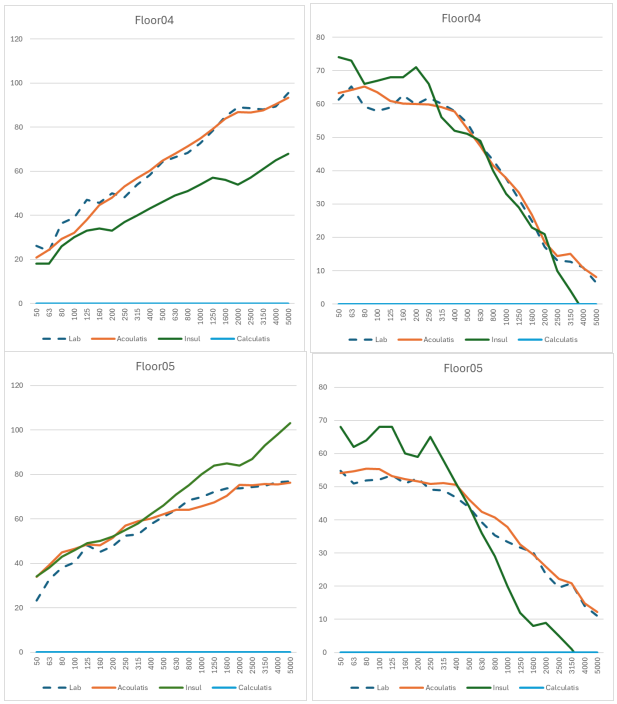

Figure 15. Two different raised floor configurations calculated, described in Figure 6.

Table 8. Corresponding single number values for airborne sound reduction related to Figure 15.

	Lab	Acoulatis	INSUL 10	Calculatis
	R_w (C, $C_{50\text{-}3150}$)			
Calc. 04	63 (-2,-6)	62 (-4,-8)	49 (-2,-3)	--
Calc. 05	63 (-2,-5)	65 (-1,-2)	67 (-1,-3)	--

Table 9. Corresponding single number values for impact sound levels related to Figure 15.

	Lab	Acoulatis	INSUL 10	Calculatis
	$L_{n,w}$ (C_I, $C_{I,50\text{-}2500}$)			
Calc. 04	54 (0,2)	54 (0,3)	66 (0,1)	--
Calc. 05	45 (0,2)	46 (0,2)	56 (1,4)	--

There are no results to present for Calculatis since raised floors cannot be modelled in that software. For INSUL, the floor in calc. 4 is replaced by Stravifloor w/HR50 and in calc. 5 with Mason EAFM Mount (explaining the deviation) since there are only a limited number of raised floors available in INSUL.

In Figure 16, results from calculations of two different combinations with screed and suspended absorbing ceilings are shown and compared to the lab values.

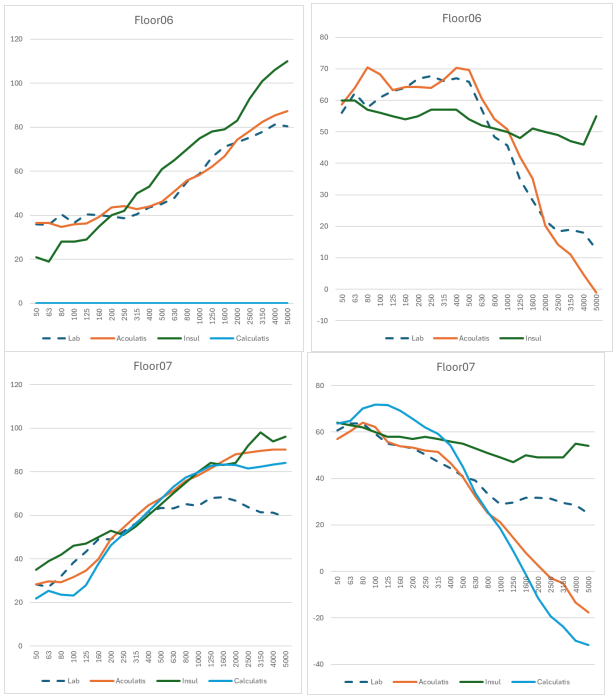

Figure 16. Two different screed floor configurations (including ceilings) calculated, described in Figure 7.

Table 10. Corresponding single number values for airborne sound reduction related to Figure 16.

	Lab	Acoulatis	INSUL 10	Calculatis
	R_w (C, $C_{50\text{-}3150}$)			
Calc. 06	51 (-1,-1)	53 (-1,-2)	54 (-2,-5)	--
Calc. 07	62 (-2,-5)	61 (-5,-6)	66 (-1,-3)	56 (-7,-8)

Table 11. Corresponding single number values for impact sound levels related to Figure 16.

	Lab	Acoulatis	INSUL 10	Calculatis
	$L_{n,w}$ (C_I, $C_{I,50\text{-}2500}$)			
Calc. 06	54 (0,2)	54 (0,3)	56 (-5,-3)	--
Calc. 07	47 (1,7)	48 (2,5)	56 (-4,0)	60 (2,3)

Calculatis has no option to model screed directly on the CLT slab and the results are therefore missing for Floor 06. For Floor 07 the ceiling is approximated with a 13 mm normal gypsum board in INSUL and Calculatis since they don't have that product available, contradictory to Acoulatis. The impact board is modelled as one single 30 mm impact board (dynamic stiffness 10 MN/m^3). For

INSUL the impact board is simulated by an insulated panel, as is the ceiling.

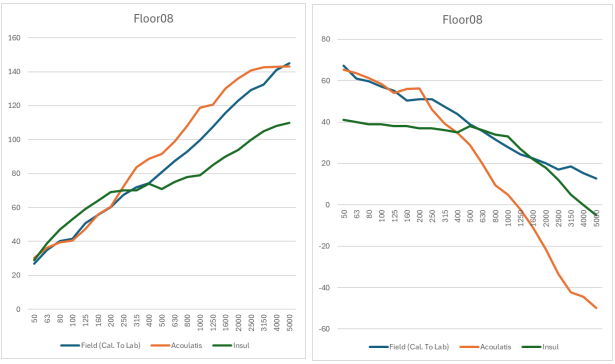

Figure 17. One type of volume element floor calculated, as described in Figure 8.

Table 12. Corresponding single number values for airborne sound reduction related to Figure 17.

	Field (re-calc.to lab)	Acoulatis	INSUL 10	Calculatis
	R_w (C, $C_{50\text{-}3150}$)			
Calc. 08	74 (-5,-11)	73 (-6,-9)	77 (-1,-10)	--

Table 13. Corresponding single number values for impact sound levels connected to Figure 17.

	Field (re-calc.to lab)	Acoulatis	INSUL 10	Calculatis
	$L_{n,w}$ (C_I, $C_{I,50\text{-}2500}$)			
Calc. 08	45 (1,9)	47 (1,7)	33 (-1,1)	--

Calculatis cannot model double CLT floors, that is why it is not included in the comparison. Furthermore the "lab value" is recalculated based on field measurements, hence not measured in lab. For the INSUL values, the impact board and the gravel are approximated by an insulated panel and sand/cement render respectively.

4. DISCUSSION AND CONCLUSION

Developing engineering software for building acoustic calculations demands a high degree of flexibility to accommodate the wide variety of floor and wall constructions encountered for future sustainable buildings. Seamless integration of new products must be possible as they become available. In parallel, developers should continuously seek and incorporate new data into the calculation model. Regular updates are essential, otherwise, the credibility and relevance of the software can quickly diminish. Engineering-based calculation models are fundamental to the future of acoustic design. Without reliable calculation tools, acousticians must rely on standard assemblies or informed guesses, which limit innovation and the ability to design novel solutions tailored to specific projects. Measurements remain crucial and calculation models must be validated against them. However, it is not feasible to measure every possible combination. Therefore, well-calibrated and frequently updated software models are a more practical and scalable solution. This paper highlights that many material options and construction variants for CLT are still missing from existing engineering software tools, like INSUL and Calculatis. As a result, modelling certain combinations may involve a high degree of uncertainty, underscoring the need for continuous development and data integration. Furthermore, for CLT structures, this paper shows that Acoulatis predicts with the highest accuracy for all wall and floor variants combined, of course pre assuming that we can rely on the measured values.

RAINFALL SOUND INSULATION OF (LIGHTWEIGHT) WOODEN ROOF CONSTRUCTIONS

Alexander Stenitzer[1*] **Bernd Nusser**[1] **Christian Lux**[1]

ABSTRACT

Rain can lead to increased noise levels in the building, especially in lightweight structures with metal roofs. To evaluate the rainfall sound insulation of roofs in the laboratory, the heavy rain simulation method according to EN ISO 10140-5:2021 Annex H is used. In this study, the rainfall sound insulation of timber roofs was determined, optimised and compared with the corresponding airborne sound insulation. The paper first presents the development of the test stand to measure both airborne and rainfall sound insulation on the same test element. The results of the measurements on different types of timber roofs are then discussed. In addition to the substructure of the roofs (exposed rafters, cross-laminated timber) and the roofing itself (concrete tiles, sheet metal, FPO membrane), the type of insulation placed on the substructure (PUR/EPS/mineral wool/wood fibre) was varied. The article shows that the roof covering has the most significant influence on the rainfall sound insulation and that there is only a limited correlation between the airborne sound insulation and the rainfall sound insulation of the roofs studied.

1. INTRODUCTION

In general, timber roofs can be divided into a) structures insulated between rafters and b) structures insulated on top of the roof. Roofs with the insulation on top are robust constructions in terms of thermal and moisture insulation, as the supporting structure is always in the warm zone and is therefore protected from condensation. From the building acoustics point of view, however, insulated roofs have disadvantages, especially around rain noise protection.
For this reason, Holzforschung Austria (HFA), together with the Technologisches Gewerbemuseum (TGM) and partners from industry, carried out the research project "Schutz.aufs.Dach", in which the airborne sound insulation as well as the rainfall sound insulation of roofs with insulation mounted on top was investigated [1]. The test setup for achieving this research objective was integrated into the large-scale test stand of the Akustik Center Austria (ACA) [2] and is presented in the following. Furthermore, the validation of the airborne sound measurements of the new implemented test stand configuration is presented. In the main part of the paper, individual constructive influences on the airborne and rainfall sound insulation of roofs are discussed.

1.1 Sound insulation requirements

The minimum requirements for the airborne sound insulation of roofs (in Austria) essentially correspond to those for external walls, although also installations such as roof windows must be considered. This means that the weighted sound reduction index of $R_w \geq 48$ dB must be achieved for opaque building elements and $R'_{res,w} \geq 43$ dB must be achieved for all external building elements including windows [3].

Similarly to the weighted sound reduction index R_w, there is also a normatively defined Single-Number Quantity (SNQ) for rainfall sound insulation, the A-weighted sound intensity level L_{IA}, which can currently only be used to compare components. In contrast to airborne noise, there are no minimum requirements for the rain sound insulation of building components. Rather, the purpose of the rain sound measurements is (according to EN ISO 10140-1:2021 Annex H) a) to assess the noise in the room under the test object, b) to design components for adequate rainfall sound insulation, c) to compare the rainfall sound insulation of components. Due to the increased use of attics as living space, as well as the increase in storm events with heavy rainfall [4], special requirements for bedrooms could be useful. The World Health Organization (WHO) itself states that a sound level of less than 30 dB(A) should prevail in bedrooms for healthy, restful sleep [5]. This is often significantly exceeded by many roof constructions during rain events.

2. MATERIALS

In the course of the work, exposed rafter roofs and cross-laminated timber (CLT) roofs are discussed. The focus of the project was the variation of the roof insulation materials, whereby the influence of the roofing was also investigated. Table 1 shows the construction details presented in this paper. In addition to the load-bearing structure (roof type), the various design influences are illustrated either for the CLT or the exposed rafter roof.

Table 1. Variations of the different layers of the discussed roofs. (s'...dynamic stiffness in MN/m³)

Layer	Variation
Roof type	CLT (120 mm) Esposed rafters
Insulation (on top)	MW: Mineral wool (s‘ = 1 MN/m³) WF: Wood fibre (s‘ = 16 MN/m³) PUR: Polyurethan (s‘ = 18 MN/m³) EPS: expanded polystyrol (s‘ = 46 MN/m³)
Roof covering	Sheet metal (Aluminium) Concrete tiles
Other	Influence of screwing Additional weight Structural mat

Underhead or double-thread screws were always used to screw the counter-battening in place. As a result of the reduced pressure of the counter-battening on the roof deck, significantly better sound insulation values can be achieved compared to a screw connection using part-threaded screw [6, 7]. Further details of the designs can be found in the final report [1].

3. METHODS

The building acoustics measurements were all performed at the ACA, with both airborne sound and rain noise measurements performed in the larger (XL) of the two test benches. The test opening for roof measurements in the XL-test stand has a surface area of 10.3 m² with an inclination of 5°. The volume underneath is approximately 150 m³. To achieve the highest possible maximum sound insulation of the test stand, the test component mask was made of reinforced concrete and acoustically equipped with additional facing layers. The performance of the airborne and rain sound measurements on the same test specimen is described below.

3.1 Airborne sound reduction

In order to validate the airborne sound measurements in the newly established XL-test stand, similar roof constructions were tested for their airborne sound insulation in the standard test stand (M-test stand, test opening: 19.8 m², volume of the receiving room: 54 m³, see also [8]) and in the ventilation test rig of the ACA (XL-test stand, test opening: 10.3 m², volume of the receiving room: 153 m³). The sound insulation values of two constructions, their deviations and the standard uncertainty according to EN ISO 12999-1:2021 are shown and discussed in section 4.1.

3.2 Sound intensity level of artificial rainfall noise

A test facility for determining rainfall noise has been installed in the source room of the XL-test stand. The 5° inclined test surface ensures that water can drain off. The test facility for generating artificial rainfall consists of the above-mentioned component mask, the irrigation system itself including a water supply system and a positioning system. The development as well as a detailed description of the artificial irrigation is to be found in [9]. To produce artificial rain drops, a tank with a perforated bottom according to EN ISO 10140-5:2021 Annex H was used. Figure 1 shows the tank placed in the positioning system described. This allows the test specimen to be easily moved to three different positions as required in EN ISO 10140-1:2021 Annex K.

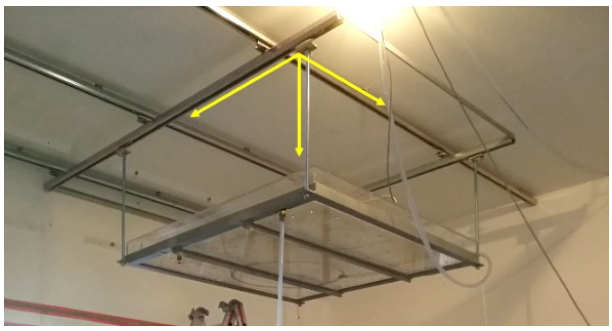

Figure 1. Water tank with perforated bottom to produce artificial rain in a positioning system with guide rails.

Prior to each measurement, the system was calibrated to ensure that the precipitation rate of 40 mm/h (heavy rain) was maintained over the measurement period (see [9). The sound intensity levels L_I in the receiving area are to be used for the evaluation of the rainfall sound insulation. The A-weighted intensity sum level L_{IA} from 100 Hz to 5000 Hz is the SNQ and must be specified to one decimal place.

4. RESULTS & DISCUSSION

The following graphs show the frequency-dependent results of the airborne sound measurements (R) and the rain sound measurements (L_I). In addition, for the airborne sound measurements, the insertion values R_w including the spectrum adaption terms for the extended frequency range $R_w + C_{50\text{-}5000}$ and $R_w + C_{tr,50\text{-}5000}$ are given in dB in the legend (according to EN ISO 717-1). For rain measurements, the SNQs L_{IA} in dB(A) are rounded to one decimal place in the legend (according to EN ISO 10140-1:2021 Annex K).

4.1 Validation of the airborne sound reduction index

As mentioned above, the first step was to carry out comparative measurements on the M- and XL-test stands. Figure 2 compares the sound reduction indices of a 120 mm CLT-roof (left) and a flat roof element (OSB – rafters, insulated - OSB) (right) in the two test stands. From a constructional point of view, the components in the test benches differ not only in area (M: 4230 mm × 5240 mm; XL: 4705 mm × 2350 mm), but also only minimally in the arrangement of the elements (CLT-roof) and in the spacing between the rafters (flat roof).
In addition to the sound reduction index of the components, the maximum airborne sound insulation of the XL-test stand is also given. As it is much higher for these two elements, the influence of it can be ruled out. The deviations lie mostly within the normative standard uncertainty, as can be seen in the lower part of the figure. However, in individual one-third octave bands, especially in the low and medium frequencies, this is also clearly exceeded. In the case of the flat roof element, the sound insulation value is shifted by one one-third octave band.

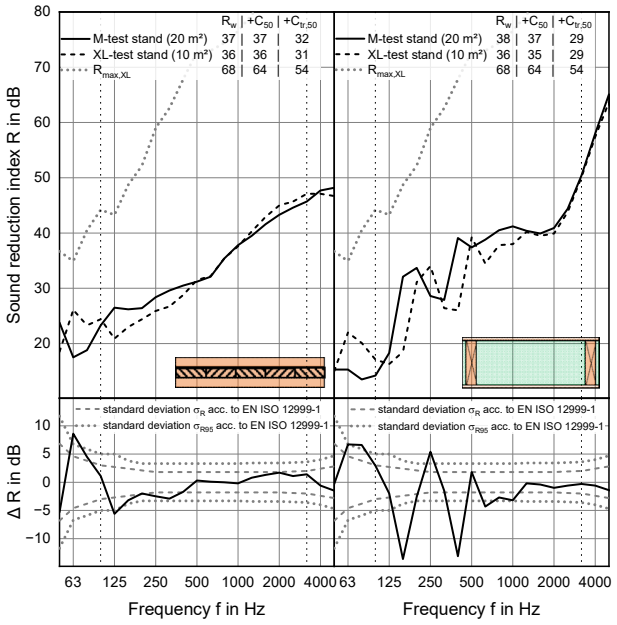

Figure 2. Comparison of the sound reduction index of a CLT element (left) and a flat roof element (right) in the two test stands at the ACA with different test openings. The differences and the standard uncertainty according to EN ISO 12999-1:2021 are shown in the lower part of the figure.

One reason for the deviations is to be found in the eigenfrequencies of the structures, as shown by the simulated velocity levels for point excitation in Figure 3. The FEM-simulations of the eigenmodes were performed using the software COMSOL 6.3. For the two flat roof elements, the eigenfrequencies are shifted to the same extent as the sound reduction indices. Due to the clear differences in the eigenfrequencies and its dependence on the element size, the different sound reduction indices in these one-third octave bands can be explained.
Only the frequency range below 100 Hz cannot be explained by the simulation, as no eigenmodes for the flat roofs occur below 125 Hz. In the authors' opinion, the size of the test opening, which is only 2350 mm in one direction

in the XL-test stand, also plays a role here, as sound transmission for low frequencies below 100 Hz is only possible to a limited extent.

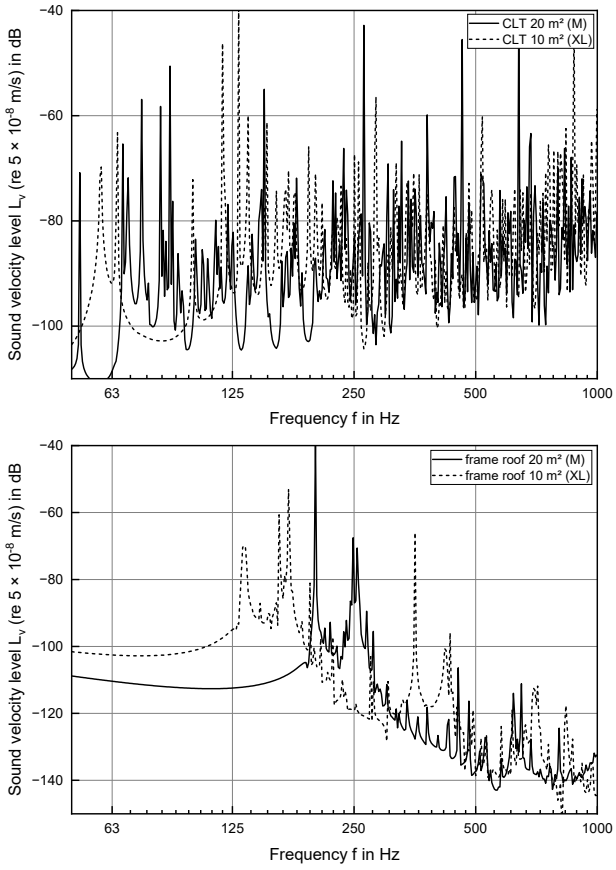

Figure 3. Comparison of the sound velocity levels of CLT elements (top) and flat roof elements (bottom) in the two test stands at the ACA with different test openings.

The large deviations beyond the standard deviation according to EN ISO 12999-1:2021 are no longer detectable in the case of practical roof constructions including roofing as well as insulation. With the explainable differences in the eigenfrequencies, as well as the approximation of the sound insulation values of structures including roofing (see project report [1]), the suitability of the XL-test stand could be ensured. However, the dependence on the test size should be considered as the simulations and comparative measurements have shown.

4.2 Influence of construction details

4.2.1 Influence of the structural roof

Figure 4 illustrates the influence of the structural roof on the airborne and rainfall sound insulation of a roof with WF or PUR insulation and sheet metal covering. As can be seen, the use of a CLT- instead of an exposed rafter roof results in a higher airborne and rainfall sound insulation over almost the entire frequency range. For the roofs with rigid foam insulation, the differences in airborne sound attenuation are even more pronounced than for the fibre insulation.
The sound intensity levels in the graph on the right also show the more favourable influence of the CLT-roof on rainfall sound insulation. The intensity levels in individual one-third octave bands differ much more from each other than the sound reduction indices in the left graph. A continuous parallel shift can be seen. This is also reflected in the SNQs in the legends. After the choice of roof covering (see section 4.2.3), the supporting structure has the greatest influence on the rain attenuation of the roof.

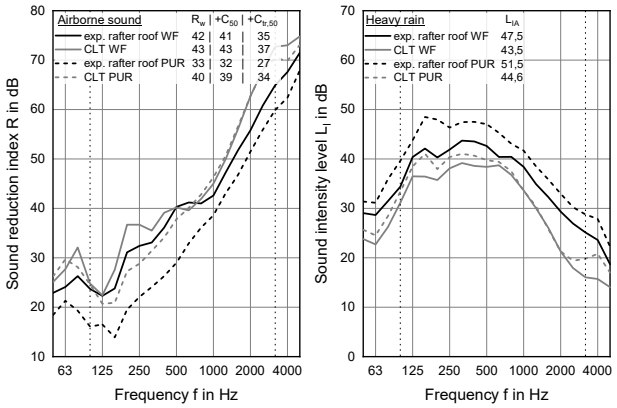

Figure 4. Influence of the load-bearing structure (exposed rafters/CLT) with roof insulation (PUR/WF) and sheet metal covering on the airborne sound insulation (left) and the rainfall sound insulation (right).

4.2.2 Influence of the insulation material type

Figure 5 shows the influence of the type of insulation on the airborne sound reduction index (left) and the rainfall sound insulation (right) of an exposed rafter roof with sheet metal covering. As can be seen, the rigid foam (PUR/EPS) and fibrous (MW/WF) insulation materials behave very differently in terms of airborne sound reduction. However, the differences within these groups of insulation materials

are small, with the WF achieving slightly higher sound insulation values in the frequency range below 160 Hz than the MW. Similarly, with EPS slightly higher sound insulation values are achieved than with PUR.
Looking at the rainfall sound insulation (right), we can see that the groups of insulation materials do not differ as clearly as in the case of airborne sound insulation. In any case, the highest levels are achieved with PUR, followed by EPS, MW and finally WF with the lowest levels due to higher mass. A similar picture can be seen for insulation layers with a thickness of 260 mm instead of 200 mm (data not shown), where the advantage of the wood fibre insulation is even clearer. Below 125 Hz, unexpectedly MW, PUR and EPS produce almost the same rain noise levels.

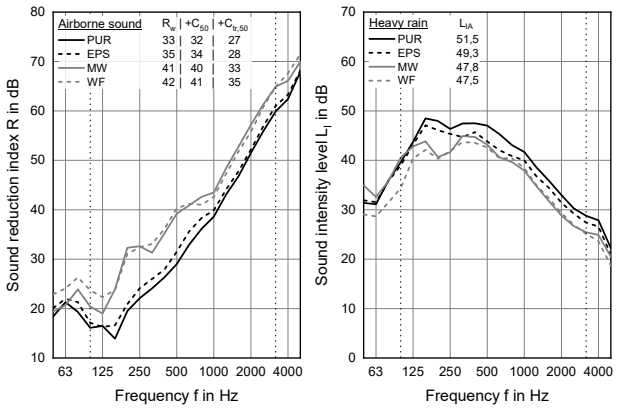

Figure 5. Influence of the insulation material (PUR/EPS/MW/WF) on the airborne sound insulation (left) and the rainfall sound insulation (right) of an exposed rafter roof with sheet metal covering.

If we look only at the SNQs L_{IA} from the rain noise measurement, we see a slightly different picture to that of the R_w-values. The L_{IA}-values of the roofs with fibre insulation materials are very close to each other, whereas the roof with EPS insulation material tends to be closer to the fibre-insulated roofs than the PUR roof as for the airborne sound insulation.

4.2.3 Influence of the roof covering

Figure 6 shows the difference in the roof covering by means of a CLT-roof with MW insulation. The roofing options are concrete tiles, a sheet metal (aluminium), and an FPO roofing membrane. As can be seen, in the mid-frequency range, a higher airborne sound insulation is achieved with a concrete roof than with sheet metal covering. However, in the frequency range below 100 Hz, the roofs with sheet metal covering have higher sound insulation values than those with concrete tiles. This was also observed in [9].
Calculated, the mass-spring-mass-resonance frequency of the concrete tiles on the MW at a CLT-roof (without consideration of the screws) is $f_0 = 31$ Hz, which may explain the lower sound insulation compared to the sheet metal covering. In the higher frequency range, the sound insulation values of the concrete tiles and sheet metal covering approach each other. With FPO a clearly different behaviour can be observed. Due to reduced mass, the airborne sound insulation is very low at low frequencies but rises very steeply due to the absorption properties of the MW underneath and the low stiffness of the FPO itself. Above 250 Hz, this element has the highest sound insulation.
The same variation was also carried out with PUR insulation (data not shown), where the FPO roofing showed the lowest sound insulation above the resonance frequency of the concrete tiles on PUR due to the low absorption properties of the foam insulation. In the case of the PUR insulation, the sheet metal covering also exceeded the sound insulation values of the concrete tiles variant in the frequency range above 1250 Hz, which can be attributed to the higher airtightness of the sheet metal covering.

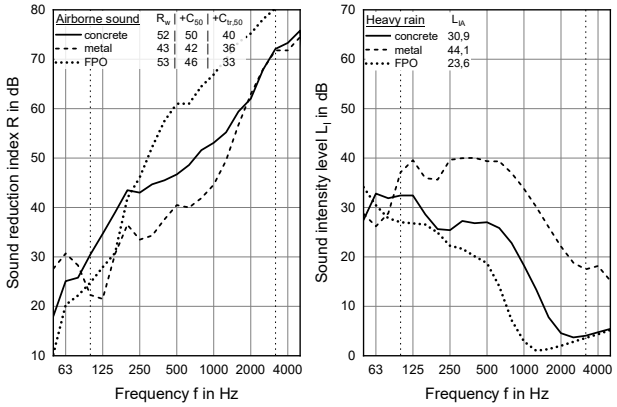

Figure 6. Influence of the covering (aluminium sheet, concrete block, FPO) on the airborne sound insulation (left) and the rainfall sound insulation (right) of a BSP roof with mineral wool roof insulation.

The rainfall sound insulation values in the graph on the right show that the concrete tiles produce significantly lower sound intensity levels than the sheet metal covering

over almost the entire frequency range. The FPO variants again behave differently depending on the insulation material. While the lowest sound intensity levels are achieved with a soft MW insulation with a FPO membrane, a much stiffer PUR insulation with a FPO membrane produces the highest rain sound intensity levels, as the variant with a sheet metal covering (data not shown).
The significant differences in the air and rainfall sound insulation provided by the different roof coverings are also illustrated by the SNQs in the legends. The choice of roof covering in combination with the insulation material has the greatest influence on the rain attenuation of the roof.

4.2.4 Influence of screwing of the counter-battening

To investigate the influence of the acoustical bridge caused by the underhead or double-thread screws on the air and rainfall sound insulation, the counter-battening was not screwed to the supporting structure during a comparative measurement but was simply laid loose on the insulation material.
Figure 7 shows the influence of the screw connection on the air and rainfall sound insulation of a CLT-roof with 200 mm WF insulation and concrete tiles. As can be seen, the screwing does not influence the airborne sound insulation up to 400 Hz, but it clearly does above 400 Hz. The drop in the slope of the sound reduction index due to the acoustical bridge is clearly visible. However, these differences do not show up in the SNQs of the airborne sound insulation.

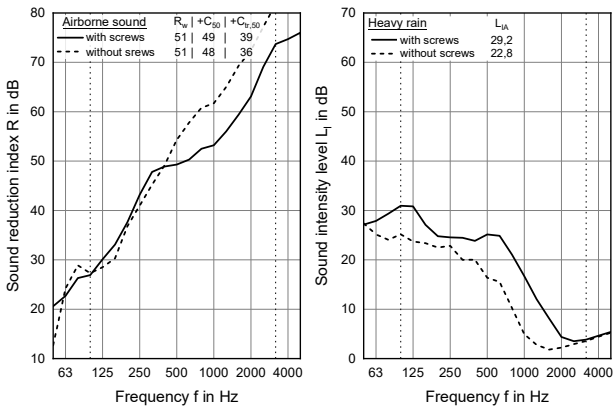

Figure 7. Influence of the screwing of the counter-battening on the airborne sound insulation (left) and the rainfall sound insulation (right) of a CLT-roof with WF insulation and concrete tiles.

Looking at the sound intensity levels in the right-hand graph; the bolted joint has a very significant effect on the rainfall sound insulation over the entire frequency range. This can also be seen from the significant difference in the L_{IA}-values in the legend.

4.2.5 Structural mat / additional weighting

Figure 8 (left) shows the effect of a structured mat underneath the sheet metal covering on the rainfall sound insulation of an exposed rafter roof with a 200 mm EPS insulation. As can be seen, the mat has a positive effect on the rainfall sound insulation above 1000 Hz. The same applies to the airborne sound insulation, which is not shown here, although the structural mat has no effect on sound insulation in the more relevant frequency range below 1000 Hz. The SNQs in the legends therefore hardly differ.
A variant to effectively reduce the rain sound intensity levels is shown in Figure 8 on the right-hand side. Two layers of gypsum board (12.5 mm) have been placed on top of the structural exposed rafter roof to increase its mass. This not only increases the rainfall sound insulation shown, but also the airborne sound insulation, which is not shown here.

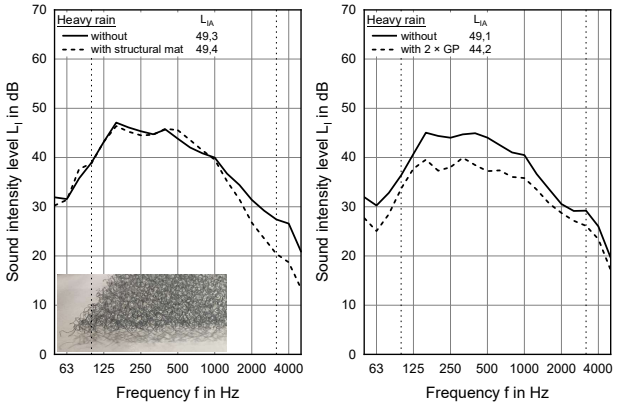

Figure 8. Effect of a structural mat beneath the roofing (left) and additional weight (2 × 12.5 mm Gypsum board) (right) on an exposed rafter roof with EPS insulation and sheet metal covering.

4.3 Correlation of Single-Number Quantities

Figure 9 shows the relationship between the SNQs R_w and L_{IA} of the air and rainfall sound insulation measurements of the investigated roof constructions with sheet metal covering and concrete tiles. As can be seen, the L_{IA}-values of the roofs differ significantly depending on the roofing,

even though their R_w-values are very similar. From the R_w-value of a roof, therefore, it is not possible to conclude on its L_{IA}-value. At the very least, a distinction must be made between the different types of roofing, with only a weak correlation between the R_w- and L_{IA}-values for roofing with concrete tiles. For sheet metal covering, the relationship between air and rainfall sound insulation shown in [10] is more likely to be present. In addition to the regression lines, the graph also shows the standard errors of the regression SER and the coefficients of determination R^2 for both roofing types. The given coefficient of determination for the sheet metal covering indicates a strong correlation between the R_w- and L_{IA}-values. In contrast, the R^2 for the (very few) concrete-covered roofs illustrates the rather low correlation between the R_w- and L_{IA}- values.
Also shown in the graph are the prediction bands, which have a 95 % probability of containing new measured values for the same roofing. Due to the relatively wide prediction bands, a practical prediction of the L_{IA}-value based on the R_w-value is only possible to a limited extent, also for the variants with sheet metal covering.

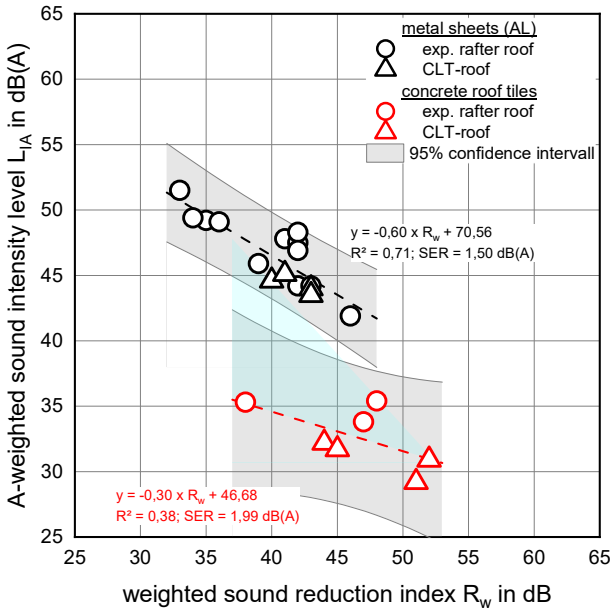

Figure 9. Relationship between the airborne sound insulation (R_w) and the rainfall sound insulation (L_{IA}) of the investigated roofs with concrete tiles and sheet metal coverings. The graphs include linear regressions lines, the standard errors of the regressions SER and the coefficients of determination R^2 for the different coverings.

5. SUMMARY & OUTLOOK

5.1 Airborne and rain noise measurements

As shown, the results of the airborne sound measurements on CLT-roofs in the developed test stand (test opening 10.3 m²) are comparable with those in the standard test stand (test opening 19.8 m²). The deviations found are mostly within the standard deviation according to EN ISO 12999-1:2021, but in some cases they are higher. The reasons for this are mainly due to the different component sizes and the resulting different natural frequencies, what was shown by FEM-simulations. The test openings for frequencies below 100 Hz are also not to be underestimated. In any case, the largest differences can be explained; the suitability of the XL-test stand for airborne sound measurements was shown.
In [9] it was shown that heavy rain according to EN ISO 10140-1:2021 Appendix K can be well realised with a water tank with a perforated bottom according to EN ISO 10140-5:2021 Appendix H. It is important to accurately calibrate the rainwater system and to continuously check the precipitation rate.

5.2 Influence of construction details

The investigations carried out have provided an in-depth look at the air and rainfall sound insulation of lightweight roof constructions. As can be seen, there is only a limited correlation between the SNQs of air and rainfall sound insulation.
It has been shown that the rain sound intensity levels are mainly determined by the covering, although factors such as the roof insulation and the supporting structure can also play a decisive role, especially in combination with the covering. High A-weighted sound intensity sum levels up to 50 dB(A) are achieved, particularly with sheet metal covering. The maximum sound pressure level of 30 dB(A) at night recommended by the WHO [5] will be exceeded by such roofs with heavy rain and may be perceived as annoying by occupants [11].
At present, it is not known to what extent the L_{IA}-values correlates with the subjective perception of rainfall sound insulation, or to what extent roof installations and "ancillary areas" (e.g. the surrounds of roof installations or attics) influence the rainfall sound insulation of roofs. These issues must be addressed in a further research project.

ACOUSTIC COMFORT OF LIGHTWEIGHT TIMBER WALLS: CORRELATION BETWEEN SUBJECTIVE EVALUATIONS AND OBJECTIVE MEASUREMENTS

Federica Morandi[1*] **Alice Speranza**[2] **Paola Brugnara**[2]
Francesca Cappelletti[3] **Andrea Gasparella**[1]
[1] Faculty of Engineering, Free University of Bozen-Bolzano, Italy
[2] Rotho Blaas GmbH, Cortaccia (BZ), Italy

ABSTRACT

Sound insulation of timber frame walls has been the object of several studies over the past 30 years. Most concerns about acoustic comfort of lightweight partitions is their poor sound insulation at low frequencies, in contrast with a high sound insulation performance at higher frequencies usually exceeding the one of traditional heavy weight structures. These characteristics are usually considered of great concern because it has been established that perceived sound insulation is strongly affected by the perception of low frequencies. This study investigates comfort levels experienced by subjects that are asked to listen to audio tracks that reproduce noises through several lightweight timber frame walls with different sound insulation properties, previously tested in laboratory conditions, and to rate the perceived annoyance. This information is then correlated to the single number ratings associated to the measurement and to the spectral adaptation constants that can be added. The results show that (i) users express different annoyance ratings for walls having the same single number rating but different spectra; (ii) the use of the spectral adaptation constants C and C_{tr} improves the correlation between single number rating and annoyance; (iii) subjects can consistently evaluate annoyance upon multiple administration of the same tracks.

Keywords: *airborne sound insulation, acoustic comfort, listening tests, spectral adaptation constants.*

1. INTRODUCTION

The development of multi storey timber construction brought the attention to the sound insulation properties of lightweight assemblies. It is well established that timber structures, due to the low density of wood in relation to its stiffness, provide good sound insulation properties at high frequencies, while poor performance in the low frequency ranges, as typical of double walls [1]. Achieving good sound insulation levels at low frequencies is of great importance in attaining good acoustic comfort performance even if it may be difficult to correlate that to the actual evaluation from the occupants, particularly in this specific frequency range. Recent literature started to investigate which metrics (including low-frequency correction terms) are most closely related to the subjective evaluation of acoustic comfort [2-3]. In this study, subjective evaluations on comfort are compared to the objective sound insulation measurements of lightweight timber construction, with the aim to gain a deeper understanding on (i) the correlation between subjective evaluation and airborne sound insulation indices (ii) the identification of spectral adaptation constants that improve such correlation and (iii) the evaluation of the reliability of the responses upon multiple administrations.

2. METHODOLOGY

2.1 Characterization of the sound reduction index of timber frame walls

A measurement campaign on timber frame walls has been conducted at the Building Envelope Lab of the Free University of Bozen-Bolzano, Italy. The measurement campaign encompassed different configurations, including three kinds of linings: (i) gypsum board plates directly fixed to the timber frame wall, (ii) gypsum board plates fixed to wood studs screwed to the structure, and (iii) completely decoupled drywall with stainless steel C profiles. Membranes and damping profiles were also tested as improvement measures that positively affect the performance whilst minimally increasing the wall thickness. Measurements were conducted both using the EN ISO 10140-4 standard [4] and by additional testing according to the EN 16283-1 standard [5].

The base timber frame wall analyzed for this study consists of timber studs (60x140 mm, 600 mm spacing), mineral wool (140 mm, 70 kg/m^3), OSB (15 mm, 550 kg/m^3). Among the wall elements tested, 6 construction solutions were selected, exhibiting different sound insulation properties:

- **Wall #1**: Timber frame wall.
- **Wall #2**: Timber frame wall. On the emitting and receiving sides: timber studs (40x60 mm, 600 mm spacing), mineral wool (40 mm, 38 kg/m^3), 1x gypsum board (12.5 mm, 720 kg/m^3).
- **Wall #3**: Timber frame wall. On the emitting side: closed cell polyethylene strip (3 mm, 25 kg/m^3), timber studs (40x60 mm, 600 mm spacing), mineral wool (40 mm, 38 kg/m^3), 1x gypsum board (12.5 mm, 720 kg/m^3).
- **Wall #4**: Timber frame wall. On the emitting and receiving side: timber studs (40x60 mm, 600 mm spacing), closed cell polyethylene strip (3 mm, 25 kg/m^3), mineral wool (40 mm, 38 kg/m^3), 1x gypsum board (12.5 mm, 720 kg/m^3).
- **Wall #5**: Timber frame wall. On the emitting and receiving side: closed cell polyethylene strip (3 mm, 25 kg/m^3), timber studs (40x60 mm, 600 mm spacing), mineral wool (40 mm, 38 kg/m^3), soundproofing bitumen sheet (5 kg/m^2), 1x gypsum board (12.5 mm, 720 kg/m^3).
- **Wall #6**: Timber frame wall. On the emitting and receiving side: 10 mm airgap, C-profiles (50 mm), mineral wool (40 mm, 38 kg/m^3), 1x gypsum board (12.5 mm, 720 kg/m^3).

The single number rating for airborne sound insulation was calculated together with the relevant spectral adaptation constants: C, $C_{50\text{-}3150}$, $C_{50\text{-}5000}$, $C_{100\text{-}5000}$, C_{tr}, $C_{tr,50\text{-}3150}$, $C_{tr,50\text{-}5000}$, $C_{tr,100\text{-}5000}$. An overview of the results of the sound reduction index measurements is presented in Figure 1, while the relevant features and single number ratings are listed in Table 1.

Table 1. Characteristics of the walls selected for the listening tests.

#	m' (kg/m^2)	R_w (dB)	C (dB)	C_{tr} (dB)
1	24.3	41	-3	-8
2	49.5	49	-4	-10
3	37.0	49	-4	-10
4	49.7	53	-5	-11
5	59.7	57	-4	-12
6	49.1	62	-7	-15

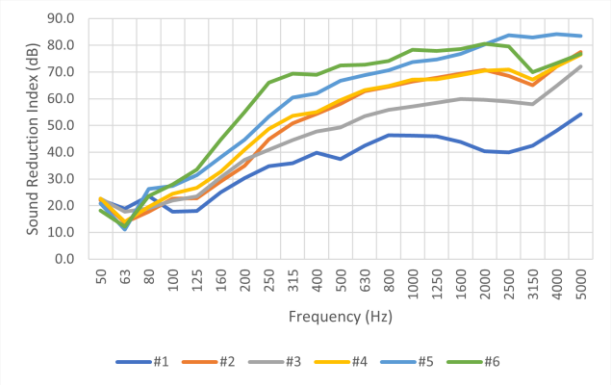

Figure 1. Sound reduction index of the 6 walls used as reference for the listening tests.

The R_w of the chosen walls ranges from 41 dB (wall #1) to 62 dB (wall #6), covering a wide range of conditions. Walls identified as #2 and #3 have the same R_w but a different spectral response, as seen in Figure 1. Other walls are characterized by different R_w and different spectral responses.

To understand how much the different frequency-dependent sound insulation performance affects comfort, and to understand which metric and spectral adaptation

term most closely matches the comfort votes expressed, listening tests were performed.

2.2 Listening tests design

A full factorial design was used in which subjects listened to 16 audio tracks and rated the perceived annoyance. The audio tracks were generated from two baseline signals, a traffic noise and a speech noise, both lasting 40 seconds. Traffic noise was chosen to mimic the response to façade sound insulation, while speech was used to evaluate the annoyance of airborne sound from adjacent environments.
The baseline signals were equalized (in terms of dBA) and filtered based on the spectra recorded when measuring sound insulation properties of the walls. Repeated tests were performed on tracks 3 and 5, to verify if the responses were consistent upon multiple administration, thus testing the repeatability of the results. As such, 8 tracks were created for both speech and traffic audio files. These audio files underwent a low pass filtering (30 Hz, slope 6 dB/oct) and a high pass filtering (16 kHz, slope 6 dB/oct), and 2 seconds of fade in and fade out effects were added.

The listening test was structured in 5 steps:

- **Part I: Introduction.** Subjects were informed about the scope of the test and signed privacy disclosure. Personal data (age, gender, living context, first language, and self-reported hearing impairment) were collected to check whether they influenced the responses.
- **Part II: Pretest A**. To allow subjects to get familiar with the audio tracks, they were fed a short portion (20 s) of three audio tracks, among those that would be tested afterwards, in the following order: the louder, the fainter, and in intermediate one. They were not asked to report any evaluation.
- **Part III: Test A** (traffic noise, 8 tracks). Listeners had to listed to 8 audio tracks, whose order was randomized. They could listen again to the tracks, if thew wanted. After each listening, they were asked to evaluate the annoyance on a digital questionnaire.
- **Part IV: Pretest B**. Same as Part II, with speech noise.
- **Part V: Test B** (speech noise, 8 tracks). Same as Part III, with speech noise.

Before starting the listening tests, subjects were given the following context: “When the sound is playing, imagine you are alone at home in an apartment building in complete peace. You are reading a magazine or a book or browsing the internet and you start hearing noises from outside/the apartment upstairs.”
The annoyance rating was introduced by the following question: “How much does the sound disturb, annoy, or bother you?” The evaluation scale was a modified version of the ISO/TS 15666 [6] annoyance scale: instead of having 11 points, the neutral point was removed resulting in 10 points, ranging from 1 (“Not at all”) to 10 (“Extremely”). If they could not hear the sound, they were asked to leave the questionnaire blank (“zero” votes in the analysis of the results).

2.3 Test environment and measurement equipment

Tests were carried out in a room located in an unoccupied area of an office building, with dimensions 3.30 x 4.50 x 3.18 m. Tests were administered during 5 working days, between 18.03.24 and 22.03.34, from 8 am to 1 pm.
The overall duration of the test was approximately 30 min for each participant. Circumaural closed-back headphones ATH-M70x and a Zoom F8 sound card were used for the reproduction of audio tracks. During the tests, environmental conditions were monitored as illustrated in Figure 2.

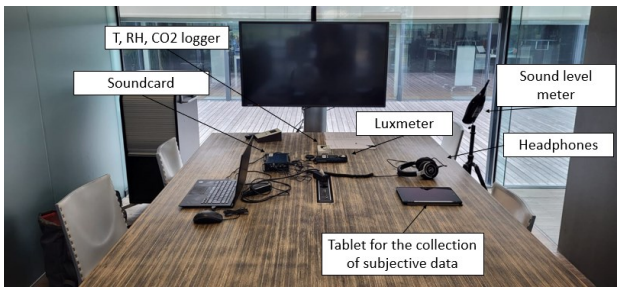

Figure 2. Test environment and equipment.

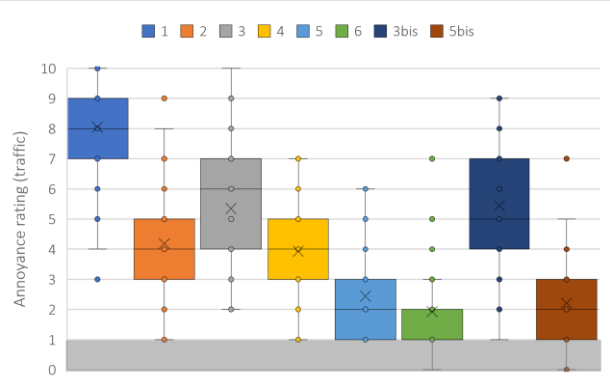
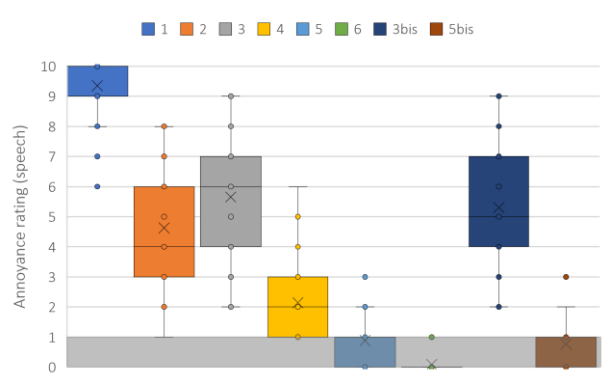


Sound pressure level was monitored close to the subject (h = 1.20 m) using a B&K 2270 sound level meter; illuminance on the desk was measured with a Konika Minolta T-10A illuminance meter, while temperature, relative humidity and CO_2 concentration were monitored using a HOBO MX1102 logger located on the desk. Subjective responses were collected using a tablet.

3. RESULTS



3.1 Overview of participants profiles

The test was completed by 43 participants, whose profiles are summarized below:

- **Age:** 40% between 21 and 30 years, 44% between 31 and 40 years, 16% between 41 and 50 years
- **Gender**: 49% females, 51% males
- **Living context**: 12% countryside, 67% small village, 21% city
- **First language**: 81% Italian, 9% Spanish, 7% German, 2% French
- **Hearing impairment**: none

(a) Traffic noise

(b) Speech noise

Figure 3. Annoyance rating for the 8 audio tracks related to traffic (a) and speech noise (b).

The environmental conditions monitored during the tests, expressed in terms of average and standard deviation, displayed a sound pressure level of (37.2 ± 1.1) dBA, an illuminance of (1460 ± 860) lx, a temperature of (23.9 ± 1.2) °C, a relative humidity of (35 ± 4) % and a CO2 concentration of (550 ± 110) ppm.

3.2 Annoyance ratings

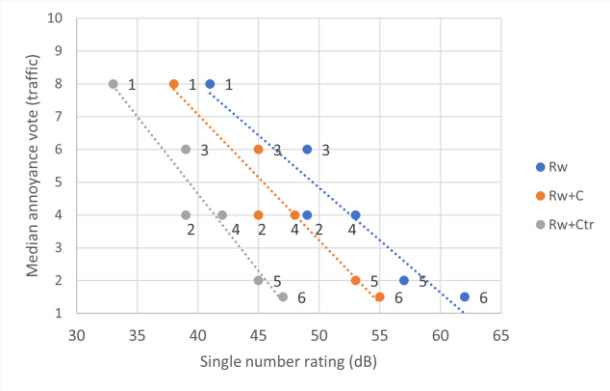
The distribution of annoyance responses is represented in Figure 3a for traffic noise and Figure 3b for speech noise.

In Figure 3, the "zero" vote in the annoyance scale, shaded in grey, was associated with subjects who could not hear the track. For speech noise, many subjects could not detect tracks #5 and #6, filtered by spectra characterized by high sound insulation values at mid-high frequencies.

Significant differences in the annoyance rating is evident between walls #2 and #3, characterized by the same R_w, a sound transmission curve dominated by low frequency and a different energy content over the whole frequency range. Wilcoxon rank sum tests were conducted to check whether the distribution of votes related to tracks 2 and 3 were had significantly different medians. The test results confirmed that the distributions have different medians at the 5% significance level, both for speech and traffic noise.

The repeated response to tracks 3 and 5, aimed at evaluating the consistency of the answers of the subjects, confirmed the ability of subjects to evaluate consistently their annoyance, both for traffic noise and for speech noise.

3.3 Spectral adaptation constants



To evaluate which spectral adaptation constant is better suited to describe the relation between single number rating and annoyance level, regression analysis was performed between the median annoyance vote expressed by the subjects and the single number rating with different spectral adaptation constants. The R^2 of each correlation is reported in Table 2.

Table 2. R^2 of the correlations between single number rating and annoyance level.

	Traffic noise	Speech noise
R_w	0.91	0.86
$R_w + C$	0.93	0.89
$R_w + C_{tr}$	0.93	0.91
$R_w + C_{50\text{-}3150}$	0.78	0.89

$R_w + C_{50\text{-}5000}$	0.78	0.89
$R_w + C_{100\text{-}5000}$	0.93	0.89
$R_w + C_{tr,\ 50\text{-}3150}$	0.06	0.14
$R_w + C_{tr,\ 50\text{-}5000}$	0.06	0.14
$R_w + C_{tr,\ 100\text{-}5000}$	0.93	0.91

The results show that the spectral adaptation constants C and C_{tr} help improve the explained variance of the correlation, while spectral adaptation constants evaluated in different frequency ranges do not necessarily do so. Correlations with C_{tr} evaluated over the ranges 50-3150 Hz and 50-5000 Hz display extremely low R^2 values, as these spectral adaptation constants tend to flatten the differences among the single number ratings. In Figure 4, the correlations between single number rating and annoyance are reported for R_w, $R_w + C$ and $R_w + C_{tr}$.

(a) Traffic noise

(b) Speech noise

Figure 4. Correlations between single number rating and annoyance for traffic (a) and speech noise (b).

It should be noted that the median value of 1.5 (Figure 4a) is estimated as the average between two numbers occupying the central position in the distribution as, for that specific case, there is an even number of occurrences.

3.4 Personal factors affecting the response

Finally, the categorical variables collected related to personal information (age range, gender, living context and first language) were used to run an ANOVA and check whether there was a significant impact of any of those features on the expression of votes. In detail, the living context might have been relevant in the evaluation of the traffic-related annoyance, while the first language might have had an impact on the evaluation of the speech noise. Statistical analysis showed that, at a significance level of 5%, none of the categorical variables listed above was significant, neither for the traffic noise nor for the speech noise.

4. DISCUSSION

The main outcomes of the presented research can be summarized as follows:

- Subjects were able to coherently rate annoyance in a proportional manner with respect to the airborne sound insulation provided by the walls and the interquartile range spans 2 or 3 votes.
- Speech noise is generally attributed higher annoyance levels compared to traffic noise.
- Both for speech and traffic noise, subjects rated wall #3 as more annoying compared to wall #2. The two walls have the same R_w but different spectra; this suggests that additional considerations should be performed when evaluating the perceptual relevance of sound insulation indices.
- Repeated exposure to the same audio track returned consistent results for both speech and traffic noise.
- The spectral adaptation constants C and C_{tr} improve the correlation between R_w and median annoyance vote, confirming the relevance that they have in relation to the expression of subjective ratings.
- The slope of the regressions for speech is steeper compared to traffic noise, indicating a much more limited range for acceptability of such conditions.
- Age, gender, living context and first language were not significantly impacting the distribution of votes, neither for speech nor for traffic noise.

Some limitations might have affected the results presented above, namely:

- Spectral filtering might be considered a suboptimal solution to perform listening tests, compared to recordings.
- Specific features of the original audio signals might have led to a visual and/or acoustic mismatch between the sound scene and the room where the tests took place.
- Tests were performed in a quiet environment; nevertheless, impulsive background noises might have affected the results for the softer tracks.
- The number of participants was relevant, but the limited variability of the personal data might have not allowed specific features to emerge.

5. CONCLUSIONS

The present study aimed at testing the perceptual effects of noise propagating through lightweight timber walls. To this aim, experimental measures of airborne sound insulation were performed on timber frame walls; a few of them were selected, and the amplitude spectra of the recorded signals was used to filter traffic and speech noise and perform listening tests. The results showed that there is a significant correlation between single number rating and annoyance, which is further improved if spectral adaptation constants are used. Nevertheless, walls having the same R_w were rated differently and the signal rated as more annoying was characterized by lower R values in the frequency range. Correlation between single number rating and annoyance was steeper for speech noise compared to traffic noise, indicating narrower acceptability ranges for that sound type.

Further work will be devoted to improving the experiment setup from the side of signal generation and reproduction, to expand the sample to study in detail the effect of personal factors, and to enlarge the number of descriptors used to characterize the listening experience.

6. ACKNOWLEDGMENTS

The research activity related to the measurement of sound insulation of timber frame walls was funded by Rotho Blaas GmbH and by the BIGWOOD project (Interreg Italia-Austria V-A, BIGWOOD, ITAT1081). The authors gratefully acknowledge the Rotho Blaas staff who took care of the accurate mounting of the test configurations and who participated in the listening tests.

[2] University of Applied Sciences Biberach, Germany

ABSTRACT

Long-span timber floors are usually designed with regard to the permissible deflection and/or position of the first natural frequency due to the serviceability requirements. Increasing the mass of the construction is often required to ensure sufficient impact sound insulation. In this research project, sound insulation and vibration measurements are carried out on floors, both during construction (without floating floors) and after completion. The focus is on the low-frequency airborne and impact sound transmission of the ceilings. In addition to classic building acoustics measurements, the influence of boundary conditions on the eigenmodes is to be clarified with the help of modal analyses of the floors. Inital results of the research project are reported here.

Keywords: *long-span timber floors, low frequencies, sound transmission, mode shapes.*

1. INTRODUCTION

Aesthetically designed and ecologically sustainable buildings are increasingly in demand. This requires the selection of construction methods and materials that are orientated towards these and future needs. Looking at CO_2 emissions in Germany, for example, the construction sector is responsible for a large percentage of these emissions. In order to reduce these CO_2 emissions, sustainable alternatives to CO_2 and energy-intensive building materials are being sought in the construction sector. Timber buildings are a viable solution due to their lower environmental impact. Lightweight construction has many positive aspects such as lighter foundations, lower transportation weight, storage of CO_2, etc., but other aspects such as the vibration behaviour of timber floors and sound insulation must also be considered. It is therefore essential to investigate the vibration behaviour and sound insulation in the low-frequency range of long-span floors in more detail.

2. PROJECT PRESENTATION

The "SchwallBe" project aims to investigate the vibration and sound behaviour of long-span timber and timber-concrete composite floors (TCC). The aim of the project is to refine the design methodology for the assessment of vibrations in long-span timber floors. Empirical studies have repeatedly shown that wooden floors exhibit better vibration properties under real conditions than predicted by calculations. This study deals with the analysis of constructed buildings to determine their actual vibration and sound insulation behaviour. In particular, it is investigated whether the measured first resonance frequency is higher in practice than expected by calculation using the existing prediction method due to boundary conditions.
This research project is a co-operation between Biberach University of Applied Sciences (HBC) and Stuttgart University of Applied Sciences (HFT). In Biberach, the main focus is on the design methodology for the evaluation of vibrations in long span wooden floors, while in Stuttgart the acoustic properties are being investigated, particularly in the low-frequency range. The project runs from May 2024 to December 2026. The analysed floors are mainly located in Germany, Switzerland and Austria. The research project is an EFRE project and is financially supported by the European Union and the state of Baden-Württemberg. This article only refers to the area of acoustics.

3. TASK IN BUILDING ACOUSTICS

The requirements for airborne and impact sound insulation are specified in building regulations in DIN 4109-1 [1]. The weighted apparent building sound reduction index R'_w and the weighted apparent normalized impact sound pressure level $L'_{n,w}$ are the characteristic requirement values. These values cover the building acoustics frequency range of 100 Hz - 3150 Hz. There are no requirements for frequencies below 100 Hz (hereinafter referred to as "low frequencies"). However, studies (e.g. Holzbauhandbuch [2]) show that the subjective perception or the level of annoyance caused by the impact sound level of people walking does not correspond particularly well with the weighted standard impact sound pressure level. However, if the spectrum adaptaion term $C_{I,50\text{-}2500}$ is considered, there is a good correlation between the measured value, the impact sound level of the person walking and the subjectively perceived annoyance of the impact sound. In Germany, the proof of sound insulation required by building regulations is provided by calculation in accordance with DIN 4109-2 [3] with single-number quantities (SNQ) without taking the low frequencies into account.
As part of this research project, measurement data for airborne and impact sound insulation is to be determined for buildings with long-span timber floors. In particular, the frequencies in the frequency range between 20 Hz and 200 Hz are to be analysed separately, as very little data is currently available for this frequency range. In addition to the influence of the supporting structure (mass timber, timber-concrete composite, ribbed floors, etc.), the influence of mass per unit area, the influence of the resonance frequency of the screed and a possible influence of the support conditions on sound transmission in the low frequency range will be analysed.

4. MEASUREMENT PROCEDURES

Measurements are carried out both after construction of the supporting structure (timber floor) and after completion of the building (occupied). Measurements of the airborne and impact sound reduction in the receiving room are not possible before the building is finished, as the transmission via the door openings determines the overall transmission. However, by means of structure-borne sound measurements on the bare floor, it is possible to determine the velocity levels when excited with the standardised ISO tapping machine or with the ISO rubber ball. These measured values can then be used to estimate SNQs according to ISO 717-2: the weighted apparent normalized impact sound pressure level when excited with the tapping machine or the maximum level when the floor is excited with the rubber ball.
The airborne and impact sound insulation in the completed buildings is carried out in accordance with DIN EN ISO 16283-1 [4] and -2 [5]. The frequency range is extended to low frequencies of up to 20 Hz. For the airborne sound measurements, a subwoofer is used in addition to the usual dodecahedron to excite the low frequencies.
Binaural recordings are also made in the receiving room when walking on the floors, as well as during excitation with the standard tapping machine and the rubber ball. An evaluation of these measurements with regard to annoyance is planned.

5. ANALYSED BUILDINGS

5.1 Building description

The long-span timber floors with spans of over 7 metres are mainly found in school buildings as well as in office and workshop buildings. Spans of over 7 metres have not yet been investigated in residential buildings. The measured values are compared with the sound insulation requirements for classrooms and office buildings. In Germany and some other European countries, the apparent weighted sound insulation index R'_w or the weighted normalized impact sound pressure level $L'_{n,w}$ are used as SNQs. In Switzerland and other countries, reverberation time related parameters: the weighted standardized sound level difference $D_{nT,w}$ or the weighted apparent standardized impact sound pressure level $L'_{nT,w}$ are used as the required quantities.
The floor constructions analysed are mainly mass timber floors (with bulk filler), timber-concrete composite floors, timber beam floors, modular floors, etc.. Some of the measurements are carried out on the bare floor, while others are carried out on floors with a heavy screed.

5.2 Results of the analysed floors with airborne and impact sound measurements

The following Table 1 shows the component description and measured SNQ of the floors where airborne and impact sound measurements were carried out.

Table 1. Component description and determined weighted apparent sound reduction indices and weighted apparent impact sound pressure levels of the floors.

Nr.	Construction	R'_w dB	L'_{nw} dB	$L'_{nw} + C_{I50\text{-}2500}$dB	$L'_{nT,w}$ dB

5.3 Detailed Results for floor #D204

Construction measurement D204 is presented below as an example. This school building is a timber construction, with the separating floors consisting of timber beams with cross laminated timber (CLT) and floating screed, the exterior walls of timber stud walls and the interior walls of metal stud walls with plasterboard.

DIN 4109-1 specifies the following minimum requirements for the airborne sound insulation of floors between classrooms for schools: weighted apparent sound reduction index $R'_w \geq 55$ dB, weighted normalized impact sound pressure level $L'_{n,w} \leq 53$ dB. The floor construction has a span of 7.5 m, with CLT-elements with a thickness of 120 mm laid on glulam beams (spacing of 3000 mm). A bulk filler of 90 kg/m² was planned on these. However, at the insistence of the building contractors, a lighter bulk filler

with only 20 kg/m² was used. The floating screed with 60 mm was applied on an insulation layer with s' = 16 MN/m³. The floor covering (5 mm linoleum) was also present in the measurement. The measurements were carried out in two pairs of classrooms of different sizes, one above the other. Figure 1 shows the frequency curve of the sound reduction index for one measurement. Here the drop in the sound reduction curve at 125 Hz is presumably caused by the mass-spring-mass resonance of the floating screed. $R'_w = 52$ dB / 53 dB are determined as SNQs for the weighted apparent sound reduction index.
This means that the required values are not achieved. The weighted apparent normalized impact sound pressure level of $L'_{n,w} = 61$ dB measured in both pairs of rooms also does not fulfill the minimum requirement of DIN 4109-1. For the maximum A-weighted impact sound level $L'_{iA,Fmax}$ when excited with a rubber ball in accordance with DIN EN ISO 16283-2, measured values of $L'_{iA,Fmax,50\ -\ 630\ Hz} = 47$ and 52 dB are determined. Due to the low surface mass of the mass timber floor in combination with the reduced mass of the fill, the available data results in a resonance frequency of approx. 100 Hz with relatively high impact sound levels in the frequency range from 100 Hz to 500 Hz.

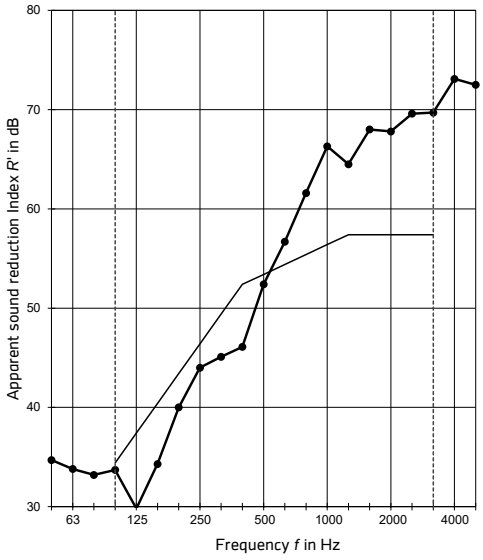

Figure 1. Measured sound reduction index of the analysed floor construction D204.

The following figure 2 shows the measured impact sound pressure level by the tapping machine and the maximum sound pressure level due to the impact of the rubber ball for two different floors in the building.

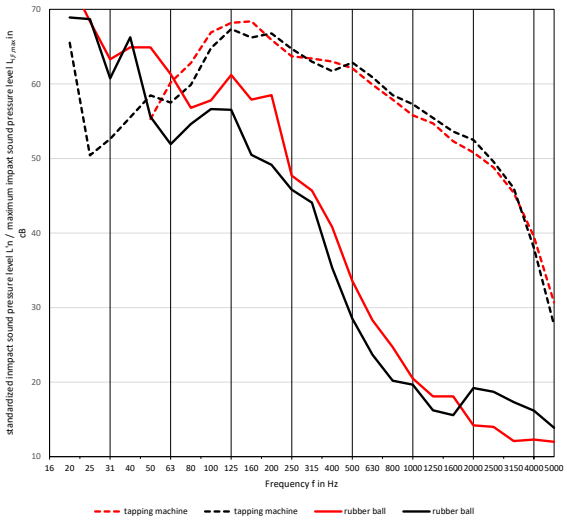

Figure 2. Measured sound pressure level due to excitation by tapping machine (solid lines) and rubber ball (dashed lines).

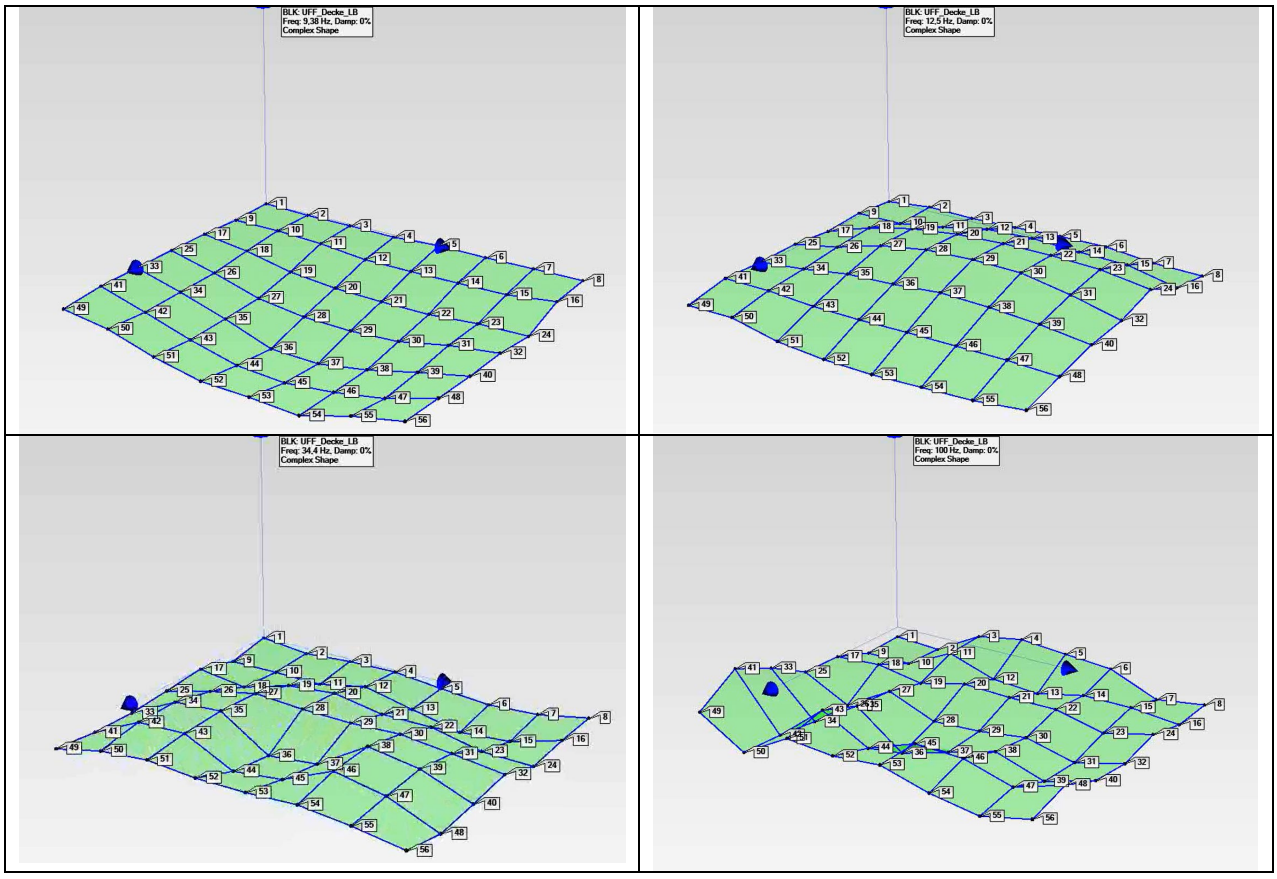
In the frequency curves from the measurements, at 125 Hz a local maximum can be recognised for both excitation with the tapping machine and with the rubber ball. However, while the level decreases towards lower frequencies with the hammer excitation, the level continues to increase towards lower frequencies with the rubber ball. The relatively large reverberation time correction of the measured impact sound level is particularly striking. With a room volume of approx. 200 m³ and a reverberation time of T = 0.5 s, which is common in classrooms today, a correction of 7.5 dB results due to the reference to an equivalent absorption area of $A_0 = 10$ m². This correction results in a very high weighted apparent normalized impact sound pressure level of $L'_{n,w} = 61$ dB (weighted apparent standardized impact sound level $L'_{nT,w} = 54$ dB).
Although the minimum requirements stipulated by the building authorities are clearly not met, the teaching staff rated the sound insulation as very good. Presumably, particularly in primary schools, the background noise levels present during lessons are higher than the impact noise from the classrooms above.



5.4 Modal Analysis

In addition to the building acoustics measurements, measurements of the vibration modes are also carried out on this object. Furthermore, the natural vibrations and eigenmodes of the solid floor are measured in selected

buildings with the reciprocal roving hammer technique. The force F is measured using an impulse hammer, which is used to excite corresponding points in a fixed grid. The acceleration is measured at a point slightly outside the center of the field. The transfer function acceleration/force is formed for each of the measuring points from the force applied and the resulting acceleration. Using the modal analysis software ME'scope, the vibrations are analysed, the first natural frequencies of the floor are determined and the corresponding vibration images are created. Due to the rough grid, it is only possible to visualise the first natural vibration modes. Even at a frequency of approx. 50 Hz, it is usually no longer possible to clearly recognize the vibration patterns of the floor.

The transfer function for the floor #D204 is determined in a grid of 1 m x 1 m at 56 points on one half of the floor (but over the entire span direction). The following Table 2 shows the maximum acceleration at different resonance frequencies.

Table 2. Measured maximum deflection of the analysed half of the floor for f = 9.4 Hz (top left) f = 12.5 Hz (top right), 34.4 Hz (bottom left) f = 100 Hz (bottom right).

The first natural frequency of the floor at 9.4 Hz is clearly recognisable and distinct in Table 2 (top left half ceiling). The second natural frequency shows a pronounced oscillation transverse to the direction of tension. Moving to higher frequencies and higher mode orders, it becomes increasingly difficult to identify the individual modes. At significantly higher frequencies (f = 100 Hz Table 2 bottom right), the modes can no longer be identified. However, it can be seen that the edges in particular experience a large acceleration. This is due to the fact that the screed slab is now decoupled from the floor slab because of the mass-spring-mass resonance. As the edges of the screed are free, they show a relatively large acceleration in the area of the resonance frequency and above, in contrast to the edges of the bare floor.

6. CALCULATION OF THE SOUND INSULATION OF TIMBER FLOORS

In Germany, airborne and impact sound insulation is verified in accordance with DIN 4109-2. However, there is currently no calculation method for calculating the direct airborne and impact sound insulation of timber floors. It is still unclear to what extent findings from solid construction can be transferred to timber construction e.g. dependence of the equivalent standard impact sound level on the mass per unit area, impact sound reduction of screeds can be described by resonance frequency. Furthermore, there are major differences between elementised load-bearing structures such as beam or ribbed floors and more homogenised structures such as timber-concrete composite floors. Here, reference is made to table values in the component catalogue for timber and lightweight construction (DIN 4109-33 [6]) or in other publications such as "Holzbauhandbuch" [2]. These table values come from laboratory measurements in accordance with ISO 10140, whereby the dimensions of the floors in the laboratories are generally only 4 - 5 metres. It is unclear to what extent this measurement data can be transferred to floors with spans of over 7 meters.

Due to the large number of new load-bearing structures (modular floors, timber-concrete composite elements on glulam beams, timber beam or timber ribbed floors, etc.) and different additional layers to the load-bearing structure (suspended ceilings, floating screeds, suspended or acoustic ceilings), it is usually difficult, if not impossible, to calculate or estimate the expected sound insulation from the values in the standard. Planners then rely on their experience or plan appropriate safety measures, usually in conjunction with an increased use of materials.

The modal analyses carried out can be used to visualise the vibration pattern of the floors. Particularly in the edge areas of the floor, it is then possible to draw conclusions about the boundary condition (hinged or nevertheless restrained to a certain extent). Initial results show, on the one hand, large deflections in mass timber floors in the area of the panel joints and, on the other hand, an influence of non-load-bearing partition walls on the vibration behaviour. An additional evaluation with the determined transfer functions with regard to the boundary conditions is planned here, as has already been successfully carried out with a bending beam [7].

7. SUMMARY

In the project described, the sound and vibration properties of long-span timber floors were and are still being measured in realised buildings. When possible, these properties are compared with mathematical approaches and the results of verification procedures. The first results of the vibration analyses will be presented at the WCTE 2025 (World Conference on Timber Engineering) in Brisbane [8]. The first results regarding the sound insulation of the analysed floor constructions are presented here. Most of the tested floors meet or even highly exceed the minimum requirements for airborne sound insulation. However, in one case, the requirements are not achieved due to the incorrectly carried out back filler, in another case due to the cavity floor used.

A different picture emerges for impact sound insulation. Here, many floors don't come close to meeting the minimum requirements. The reason for this is actually that the single number quantity, $L'_{nw,}$ prescribed in the DIN 4109 is not suited for large class rooms. It normalises to a reference absorption area of 10 m², which is much higher for the investigated and most class rooms. It should be replaced by the standardized impact sound level $L'_{nT,w}$, which is normalised toT = 0.5 s reverberation time common in class rooms.

With the visualisation of the vibration shapes using modal analysis, it was possible to clarify the initial effects with regard to the boundary conditions. Further measurements still to be carried out will provide the basis for calculating the acoustic properties in the low frequency range.

IMPROVING SOUND INSULATION OF OLD TIMBER FLOOR CONSTRUCTIONS 1917/1937 IN MULTI-STOREY HOUSING – FIELD CASE STUDY & PERSPECTIVES

Birgit Rasmussen [1*]
[1] BUILD – Department of the Built Environment, Aalborg University, 2450 Copenhagen SV, Denmark

ABSTRACT

In Denmark, the first national requirements for sound insulation in housing were published in 1961. Most complaints about neighbour noises are from people in multi-storey housing (MSH) and relate to impact sound from both children and adults, although also annoyance due to airborne sounds are common. A mapping of the housing stock timeline and construction types showed that more than half of the MSH dwellings were built before 1961 and that most housing is brick-built with timber floor constructions.
In a project investigating air particle transfer vertically between dwellings, we had the opportunity to make a case study with test of airborne and impact sound insulation before and after mounting a new independent ceiling below the existing construction.
Measurements were made for eight floor constructions in housing built 1917/1937. The acoustic classification standard DS 490 has six classes A-F with Class C being the building code requirement for new housing. Before renovation, the airborne sound classes were D-E and impact sound F. After mounting of new ceilings, R'_w values were improved ~6 dB and $L'_{n,w}$ ~12 dB, implying that all results became Class C, thus complying with limits for new-build. The paper will describe experiences from the case study and the perspectives concerning preparation of acoustic regulations for renovated dwellings and mandatory acoustic labelling.

1. INTRODUCTION

Most countries in Europe have acoustic regulations for various types of buildings, including housing. This paper deals with airborne and impact sound insulation between dwellings in multi-storey housing (MSH) and the need for improvements, especially for old housing. The results for a field case study with renovated timber floor constructions in housing from 1917 and 1937 are described. Information about the Danish requirements is found in Table 1.
Sound insulation requirements for 35 countries in Europe are found in [1]. Several countries also have acoustic classification schemes (ACS), and national regulations often refer to or correspond to a specific class in a national ACS. Information about acoustic classification schemes and sound insulation descriptors in 14 countries in Europe are described in [2]. Several ACS have none or too few classes for old housing.
Both requirements and acoustic classes relate to peoples everyday life, because neighbour noise often is a significant problem in multi-storey housing (MSH), cf. [3] and [4], both based on a social media analysis of over 700 comments to two newspaper articles about neighbour noise and acoustic labelling of dwellings. The housing stock in Denmark and the case study results are described in the following Sections of the paper.

Table 1. Sound insulation main requirements [(1)] in the Danish building regulations for walls/floors between dwellings constructed in the period from 1961 until now.

Period	Housing type	Airborne sound insulation [(1)]	Impact sound insulation [(1)]
1961[(2)] –2008	Multi-storey [(3)]	$R'_w \geq 52$ dB (horizontal) $R'_w \geq 53$ dB (vertical)	$L'_{n,w} \leq 58$ dB
Since 2008	Multi-storey and row housing	$R'_w \geq 55$ dB	$L'_{n,w} \leq 53$ dB

Note 1: Limit values until 1982 are estimated by converting to the descriptors R'_w and $L'_{n,w}$ applied in the current Danish building code.

Note 2: Before 1961, there were no general national building regulations.

Note 3: For terraced housing (row housing), the limit values were: $R'_w \geq 55$ dB from 1966 and $L'_{n,w} \leq 53$ dB from 1977.

2. MULTI-STOREY HOUSING IN DK AND THE NEED FOR IMPROVED SOUND INSULATION

In Table 2 is found an overview of classes in the current Danish classification scheme, DS 490:2018 [5], which has six classes A-F covering the Danish housing stock. The table provides simple explanations of the intended application of classes for new and old housing, see [5],[6]. It also indicates the occupants' expected evaluation of the sound insulation.

In Figure 1 is found overview of the Danish ,multi-storey housing stock with construction types in different time periods, number of dwellings and estimated acoustic performance. More information is found in [6],[7],[8],[9]. Detailed construction guidelines for new housing are found in [10] and guidelines for improvement of existing housing are found in [7].

.

Table 2. Occupants' expected satisfaction for different sound classes according to DS 490:2018 [5]. Summary based on information in DS 490.

Sound insulation between dwellings Main class criteria A-F in DS 490:2018		
Class	Airborne	Impact
A	$R'_w + C_{50\text{-}3150} \geq 63$ dB	$L'_{n,w} \leq 43$ dB and $L'_{n,w} + C_{I,50\text{-}2500} \leq 43$ dB
B	$R'_w + C_{50\text{-}3150} \geq 58$ dB	$L'_{n,w} \leq 48$ dB and $L'_{n,w} + C_{I,50\text{-}2500} \leq 48$ dB
C	$R'_w \geq 55$ dB	$L'_{n,w} \leq 53$ dB
D	$R'_w \geq 50$ dB	$L'_{n,w} \leq 58$ dB
E	$R'_w \geq 45$ dB	$L'_{n,w} \leq 63$ dB
F	$R'_w \geq 40$ dB	$L'_{n,w} \leq 68$ dB
Reference: DS 490:2018 "Lydklassifikation af boliger" (Sound classification of dwellings)		

Characteristics of DS 490 sound classes for dwellings and occupants' estimated evaluation Information from DS 490:2018		
Sound class descriptions	Good or very good	Poor
Excellent acoustic conditions. Occupants will be disturbed only occasionally by sound or noise.	> 90 %	
Significant improvement compared to minimum in class C. Occupants may be disturbed sometimes.	70-85 %	< 10 %
Sound class intended as the minimum for new buildings.	50-65 %	< 20 %
Sound class intended for older buildings with less satisfactory acoustic conditions.	30-45 %	25-40 %
Sound class intended for older buildings with unsatisfactory acoustic conditions.	10-25 %	45-60 %
Sound class intended for older buildings with clearly unsatisfactory acoustic conditions.	< 5 %	65-80 %
Note: Within each sound class the percentage of satisfied or dissatisfied occupants may depend on the type of criterion. The grouping is mainly based on the subjective assessments of airborne and impact sound from adjacent dwellings.

Figure 1. Overview multi-storey housing stock in Denmark, number of dwellings and construction types in various time periods. Building regulations, estimated acoustic performance and expected acoustic classes indicated. More information about constructions is found in [6], [7], [8].

The housing stock in Denmark consists of about 2.8 mio dwellings [11], of these almost 1.2 mio dwellings in multi-storey (MS) housing, 450.000 row houses and most others single-family houses. In Figure 2 is found a diagram with number of MS dwellings according to construction year, and with the estimated acoustic class F, E, D, C according to DS 490:2018 [5], shown for various time periods. A Danish Health and Morbidity Survey in 2017 showed that about 36 % of people in multi-storey housing are slightly or very annoyed by neighbour noise, while for row/double housing only 12 %, see [12], [13]. The disturbing/annoying neighbour noises include for example footsteps, voices/shouting/arguments, playing/jumping children, parties, barking dogs, see e.g. [3], [9], [14], and for many people, the implications are sleep disturbances and strong negative influence on own "freedom" and activities. The result is adverse influence on quality of life.

In many old dwellings, people experience an almost total lack of privacy, since they hear, what they don't want to hear, which reminds them that even one's own ordinary activities being a part of a normal life are no longer possible without involuntarily "informing" the neighbours, [3], [9].

The relevant sound insulation improvement solutions depend on the actual performance of the existing building, the wishes/goals for the future acoustic conditions and the resources available for the upgrading. For the Danish multi-storey housing stock, the highest need is for building types E1 (almost half of Danish dwellings) and E2, cf. Figure 1 and Figure 2. The main principles for improvement of sound insulation of dwellings are indicated in Figure 3.

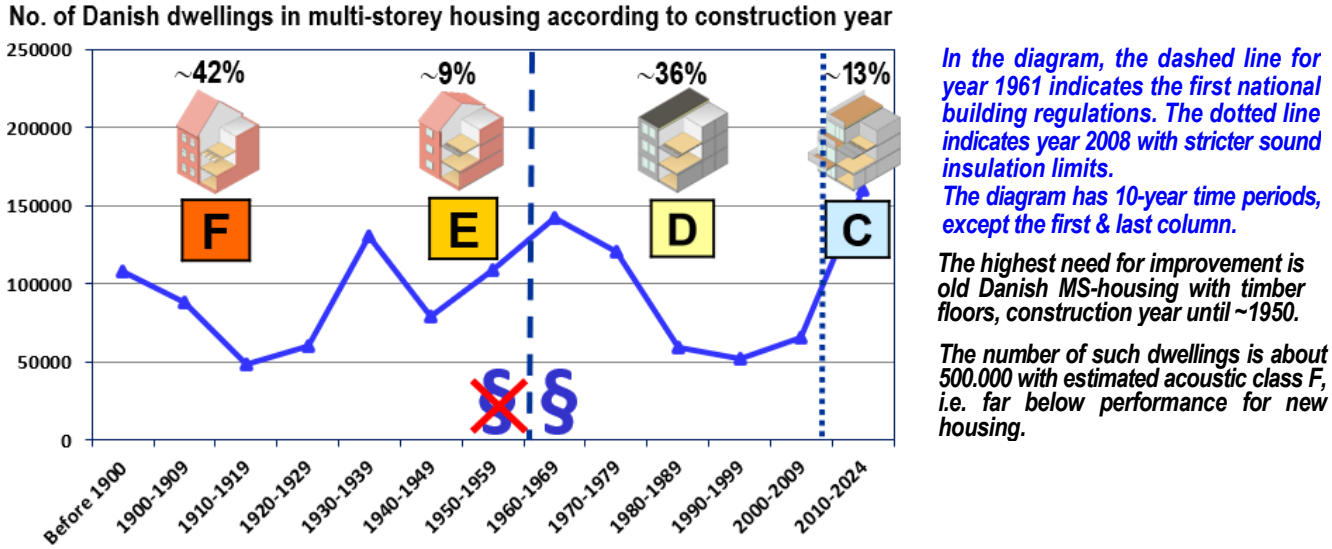

Figure 2. No. of Danish dwellings 1900-2024 in multi-storey housing according to construction year [11]. Estimated acoustic classes F, E, D, C according to DS 490:2018 [5] are indicated.

Figure 3. Left: Main principles for improvement of sound insulation in existing housing: New ceilings, wall linings, floors, see red lines. Right: A 10-page folder [9] has been published with indications of construction solutions for housing from different time periods. Detailed construction guidelines are found in [7].

3. CASE STUDY PROCEDURE AND TEST RESULTS

A case study about improvement of airborne and impact sound insulation for timber floor constructions was conducted for eight floors in two housing blocks in Copenhagen – as a supplement to a research project about air particle transfer through timber floor constructions in the same apartments.
We contacted several housing associations in the Copenhagen area, explaining the relevant construction type, purposes of project and asking about potential apartments appropriate for the case study. After inspection and evaluation, it was decided to make the renovation for eight floor constructions, four of them in apartments in 2200 CPH N (AKB, Guldbergsgade GBG, construction year 1917), and the other four in 2300 CPH S (AAB, Kirkegårdsvej KGV and Tycho Brahes Allé TBA, construction year 1937). In all cases, the occupants had made complaints about neighbour noises.
The existing timber floor constructions had a height ~27 cm, and the height of the ceiling to be installed below is ~12 cm. The ceiling consists of two gypsum plates fixed to steel profiles mounted from wall to wall and with mineral wool in the spacing above the gypsum plates, cf. Figure 4. For further details, see manufacturers' instructions. The room height in all rooms was 270 cm, and it was possible to install the ceilings without severe obstacles.

Field tests were carried out using the standardized methods [15], [16] as prescribed in the building regulations. The field tests were carried out by Rambøll [17], [18]. The project results are described in [19], section 2.
Floor areas S and room volumes V in GBG, 2200 CPH N, were 15-30 m^2, and 38-85 m^3. For KGV and TBA, 2300 CPH S, floor areas S were 14-19 m^2, and room volumes 36-51 m^3.

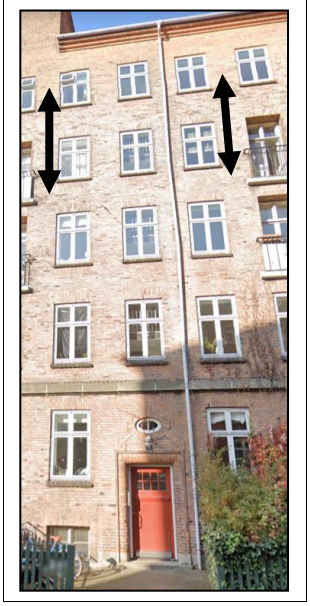

Figure 4. Timber floor constructions. The left drawing shows the original construction, the drawing to the right includes a new self-supporting ceiling. The drawings are from https://gi.dk/byggeteknisk-viden/.

The test results for GBG (CPH 2200 N) are found in [17], [19] and summarizwd in Table 3 below. The improvements in sound insulation values and classes are shown in the two last columns. The test results for CPH 2300 S were similar and also reached Class C after renovation. The results are found in [18] and in [19], Section 2.

Table 3. Test results for airborne and impact sound insulation between floor 3 and 4 before and after mounting new ceilings in GBG, rooms on 3rd floor, two rooms in each apartment (denoted Room1 and Room2). In total four constructions tested.

Address: AKB, Guldbergsgade, 2200 Copenhagen N. Construction year 1917.

Apartments 3rd & 4th floor

It must be noted that the project included only investigation of timber floor constructions, i.e. vertical tests of airborne and impact sound insulation, but not all the other tests requested for a complete classification of an apartment or building according to DS 490 [5]. These tests are for example sound insulation tests between rooms in other directions, façade sound insulation, service equipment noise and reverberation time in stairwells.

Results GBG 121, 2200 CPH N (construction year 1917).
Results due to new ceilings in the apartments:
The airborne sound insulation changed from Class D/E to C.
The impact sound insulation changed from Class F to C.
For all renovated constructions, Class C is obtained, which is the building code requirement for new-build.

Results KGV & TBA, 2300 CPH S (construction year 1937)
Results due to new ceilings in the apartments:
The airborne sound insulation changed from Class D/E to C.
The impact sound insulation changed from Class E/F to C.
For all renovated constructions, Class C is obtained, which is the building code requirement for new-build.

Summary of results for all eight renovated constructions
It was a positive surprise that all timber floor constructions renovated with a new ceiling obtained acoustic class C for both airborne and impact sound insulation. It was not on beforehand a goal to reach Class C, since it was expected that flanking transmission through the walls might reduce significantly the effect of the new ceilings. The goal was mainly to observe how far we could get.
The big question is of course whether similar results could be expected for other multi-storey housing with similar constructions? A wider project is necessary to investigate variants of the housing type E1 and also to get experience with type E2 (cf. Fig. 1) with completely different construction materials and with a lower room height, typically 250 cm.

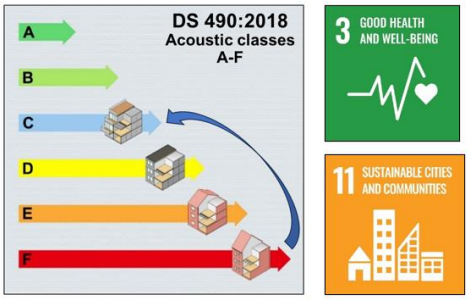
Experiences from the project process
Starting, carrying out and completing all the activities related to the renovation project depended completely on the initiatives from and active collaboration with the housing association managers and the occupants. Thus, we are grateful to all those involved during the project period, which due to Covid-19 restrictions became longer and more complicated than expected on beforehand. However, even before the mounting of new ceilings, some occupants moved, since they had found other apartments and they had already suffered from neighbour noise for a long period and didn't know how and when the renovation would end. Moving seems to be a typical way to cope with the neighbour noise situation, cf. [3] and [4], but it requires a lot of resources in more ways (expenses, find a new place, moving).

4. ACOUSTIC REGULATIONS FOR NEW AND RENOVATED HOUSING

Sound insulation requirements for New-build in 35 countries in Europe are found in [1]. Specific requirements for renovated housing are often not clear or renovation not well-defined. The increasing building costs in general and the more recent challenge to use biogenic materials (to reduce building constructions' negative influence on climate changes) is a challenge. since the building industry has very little experience with use of lightweight materials to be applied and how to fulfil sound insulation requirements and at the same time reducing costs. Since stability of constructions and fire protection *must* be complied with, reducing other performances are considered. Consequently, acoustic requirements have got "critical" attention for more reasons, one of them being uncertainty about how to design with new materials (and fulfil requirements), another one the fact that sound insulation is not visible, and parts of the building industry consider sound insulation as luxury and not something needed for wellbeing or health.
However, typical reasons for acoustic regulations are *health* related. For example, in the current DIN 4109-1 [20], the introduction refers to health protection of occupants in housing, including also confidentiality during normal speech and protection against unreasonable disturbance. It is also stated that it *cannot* be expected that noise from outside or from neighbouring apartments will no longer be perceived or found annoying, even if the requirements laid down in the standard are met. For more information about the long story behind the current DIN 4109 series of standards and the importance for building acoustics in Germany, see [21].
In Denmark, the background and development until 1994 of acoustic regulations for housing are described in [22] and current regulations indicated in e.g. [23]. Again, as in Germany, the word health is predominant in the beginning of the regulations chapter. The situation is probably similar in many other countries.
Concerning disturbing neighbour noises, results from research projects agree that impact sound (footsteps) annoy most people, see e.g. [24],[25],[26]. Several disturbing neighbour noises are listed in [27], which also – based on a representative national survey – reports examples of potential adverse health effects of neighbour noise in multi-story housing. A strong association is found between self-reported neighbour noise annoyance and perceived stress, poor mental health, fatigue, sleeping problems, sleep quality (getting enough sleep to feel rested), see [27]. In fact the DIN 4109-1 introduction refers to the EU No 305/2011 [28] stating that construction works must be designed and built in such a way that noise perceived by the occupants or people nearby

is kept to a level that will not threaten their health and will allow them to sleep, rest and work in satisfactory conditions.
Public knowledge and awareness about how to describe acoustic performance for housing seems limited. Some countries have included acoustic quality test certificate layouts in their acoustic classification schemes, cf. DAGA 103, [29]-[30], and ÖNORM B 8115-5 [31]. However, the actual quantitative use of such certificates has not been investigated.
Some people believe that fulfilling regulations means that you cannot hear neighbours or at least not get disturbed. That is not the reality, cf. e.g. the DIN 4109-1 introduction. In Table 2 about DS 490, expected percentages of people finding classes good or very good and poor These statements help understanding the need for both higher classes, but also for lower classes, which are needed. to be able to classify before renovation and decide the gap to current regulations. ISO/TS 19488 [32] and some national schemes have lower classes, cf. [2].
Regulations are useful, but must be supported by enforcement and knowledge about design, planning, workmanship and inspection. The Danish regulations require documentation [33] uploaded as a condition for getting a permit for use. We don't have statistics for fulfilment in reality, but in several cases things go wrong. Four severe cases are described in [23]. Reasons are either lack of respect for regulations and/or lack of knowledge in parts of the whole process. Some mistakes have been well-known for decades. European collaboration about constructions, mistakes and enforcement should be strengthened to learn from other countries. Experiences from ~30 countries are found in the COST TU0901 e-books [34]-[35], but need follow-up due to many new materials and practices.

5. CONCLUSIONS AND PERSPECTIVES



A case study about improvement of airborne and impact sound insulation R'_w and $L'_{n,w}$ for eight timber floor constructions in two old housing blocks 1917/1937 was conducted. New self-supporting ceilings were installed below the existing timber floors. The test results were very promising, since all results for the renovated constructions reached Class C, which is the requirement for New-build.
WHO and EEA have published several reports about influence of noise on health, e.g. [36]-[39]. Unfortunately, they don't deal with neighbour noise, since the focus is mainly traffic noise. However, they highlight sleep as a necessity for good health due to the restorative and consolidating effects of sleep. In the WHO-report [36], the health risks due to sleep disturbances are emphasized: "*Sleep disturbance is one of the most serious effects of environmental noise, causing both immediate effects and next-day and long-term effects on mental and cardiovascular health".* Sleep disturbance is also a typical neighbour noise problem, and it seems likely that the health risks are the same as for traffic noise.

Neighbour noise is potentially experienced 24h/7d, implying a need for more awareness, both for renovation of housing and New-build. In addition to the results of the case study, the following recommendations could be given:

- Regulations needed for renovated housing.
- Enforcement of regulations should always be respected to ensure fulfilment of requirements.
- Subjective (verbal) descriptions of classes could be included in more national acoustic classification schemes or in other ways to create more public awareness about the adverse influence of neighbour noise in housing and enhance consumer rights.
- Enhance consumer rights concerning access to acoustic quality. Occupants of dwellings should have "open access" to acoustic performance.
- Mandatory labelling [40] should be introduced as soon as possible, starting with New-build.
- Information about acoustic performance/class for dwellings should be mandatory in advertisements – as for energy.

Based on findings and quoted literature, it's hopefully obvious that sound insulation in housing is strongly related to health and quality of life. It's not just a question about comfort/luxury, but it's about protection from noise annoyances in everyday life. Proper regulations and enforcement would support healthy life for people and sustainable cities, cf. UN SDGs 3 and 11 [41].

Figure 5. The six acoustic classes A-F in DS 490 [5] and the improvement from F to C in the case study.

A strong recommendation is found in a Danish guideline from 1992: *"It should be ensured that renovation of homes also includes a decision on acoustic conditions, so that one is not subsequently left with a large housing stock that appears to have been thoroughly renovated, but is still acoustic slum."* The same reminder is unfortunately still highly relevant and included in the most recent version [7] from 2014.

6. ACKNOWLEDGMENTS

The author wants to thank the managers in the housing associations AKB and AAB and the occupants for great help and cooperation during the project period. Also, thanks to Rambøll for doing the field tests of sound insulation and being flexible about test dates.
Funding: The case study is a part of a project funded the Danish National Building Fund (Landsbyggefonden).

ACOUSTIC INSULATION IN PLASTERBOARD SYSTEMS WITH MINERAL WOOL

Paula Belenguer Rubio[1] **Penélope González de la Peña**[2]
[1] Técnico Saint-Gobain CITAV
[2] Responsable Saint-Gobain CITAV
[3] Saint-Gobain España, Príncipe de Vergara, 132, 28002 Madrid, España

ABSTRACT

One of the most important features in plasterboard systems with mineral wool (MW) is the acoustic insulation they provide between different rooms, with minimal space and weight requirements.

When designing this type of system, there are several factors that can influence the acoustic insulation: the number and type of boards, the spacing between the profiles, the bracing of the structure, the thickness of the system... But are they all equally important? What is the influence of the density of mineral wool in this type of system?

The paper analyses the acoustic behavior of plasterboard systems with mineral wool, and the influence of system parameters on acoustic insulation, in order to help designers to configure systems to reduce the noise between neighbors through acoustic retrofitting in residential buildings.

Keywords: *plasterboard, mineral wool, acoustic insulation,*

1. INTRODUCTION

Acoustic insulation is nowadays one of the most important features in today's building systems. Acoustic independence between rooms is one of the main requirements of internal partitions in order to guarantee the well-being of all users.

2. LIGHT VS HEAVY CONSTRUCTION

It is important to distinguish between massive and light construction systems. First ones mentioned consist of a massive structure of walls, and second ones mentioned consist of a structure of pillars and beams, including light façade systems, wood and glass structures, etc.

Massive systems work with the mass of the element. The thicker the construction element, the better acoustic insulation. However, the stiffness of the material implies a variation in the critical frequency.

Nevertheless, in lightweight systems, particularly in gypsum plasterboard (GP) partition systems, consisting of a plasterboard layer, followed by a cavity and closed again by another plasterboard layer, it is the width of the cavity that has the greater impact on the increase in acoustic insulation, as well as the mass of the plasterboard layers.

3. OPERATION OF LIGHT WEIGHT SYSTEMS

This performance is due to the fact that these systems operate as a mass-spring-mass system. The graph shows three different zones (Figure 1):

- **First zone**: The two "masses" oscillate in phase, and behave as a single-layer system.
- **Second zone**: The "masses" oscillate at the highest amplitude, where the resonance frequency is perceived.
- **Third zone**: The two "masses" oscillate independently, where the isolation is greater than in a single-layer wall.

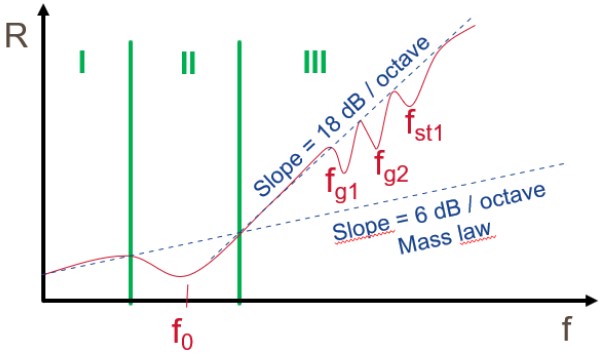

Figure 1. Operation of plasterboard systems

4. PARAMETERS INFLUENCING THE PLASTERBOARD SYSTEMS

It is also possible to optimize the acoustic performance of these systems by adding or modifying elements of their composition.

There are several parameters that influence the acoustic insulation performance of a plasterboard system:

- Insulation in the cavity and the thickness of the insulation, usually mineral wool (MW).
- Cavity width.
- Number of plasterboards.
- Distance between profiles.
- Type of profiles.
- Bracing of the structures.
- Total thickness of the system.
- Installation conditions.

However, there are aspects that are sometimes considered to be influential but are not, such as the density of the mineral wool.

5. CAVITY INSULATION AND MINERAL WOOL THICKNESS

Based on tests on the same system, 2 Placo® BA15 + M150 + 2 Placo® BA15 with 600 mm modulation between profiles, an increase in acoustic insulation can be perceived (Figure 2) by increasing the thickness of the mineral wool in the cavity:

- 0 mm MW: 47 dBA. (Figure 3)
- 65 mm MW: 52 dBA. (Figure 4)
- 150 mm MW: 53 dBA. (Figure 5)

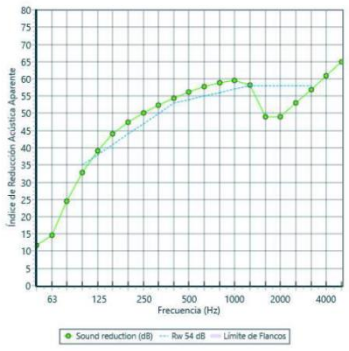

Figure 5. Simulation results from system 2 Placo® BA15 + M150 (MW 150 mm) + 2 Placo® BA15

Furthermore, it is observed that the inclusion of insulation in the plasterboard system cavity, with an air flow resistance of at least 5 kPa·s/m^2, achieves optimization of this system, as the resonance frequency is outside the range of interest for these systems, as well as reducing the loss of coincidence frequency in the overall computation of the system.

6. CAVITY WIDTH

Enlarging the cavity allows the thickness of the internal MW to be increased, giving the following results (Figure 6):

- M48 (MW): 47 dBA. (Figure 7)
- M70 (MW): 50 dBA. (Figure 8)
- M100 (MW): 52 dBA. (Figure 9)

7. MINERAL WOOL DENSITY

One characteristic of mineral wool that is often confusing is the influence of mineral wool density on plasterboard systems.

The Spanish standard UNE-EN 13162:2012+A1:2015 “Thermal insulation products for building applications” does not consider density as a performance characteristic for products manufactured under these conditions.

8. NUMBER OF PLASTERBOARDS

In self-supporting plasterboard framing systems, an increase in the surface mass of the mass-spring-mass system implies an improvement in the acoustic insulation performance. Therefore, increasing the number of boards will provide better acoustic insulation results. (Figure 10) (Figure 11) (Figure 7).

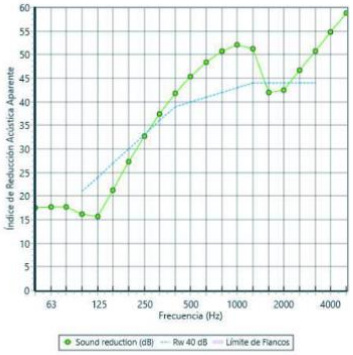

Figure 11. Simulation results from Placo® system BA15 + M48 (MW) + Placo® BA15 (38 dBA)

The increase in boards mass increases the overall acoustic insulation value by approximately 9 dBA in a plasterboard partition system by adding one layer of plasterboard on each side of the system.

9. TYPE OF PLASTERBOARDS

There are boards with improved acoustic performance. In the case of Saint-Gobain, changing from a plasterboard Placo® BA to a plasterboard Placo® PPH allows greater acoustic insulation to be obtained, specifically of 3 dBA in the solution tested (Figure 12) (Figure 13) (Figure 14).

Therefore, there may be situations in the project where this change could be an important aspect.

10. PROFILE SPACING

A profile spacing of less than 500 mm can reduce the acoustic insulation of the system by 4-5 dB. In Spain, due to the dimensions of the GP, the profile spacing is set at 400 mm and 600 mm, and a decrease in acoustic insulation is observed in structures with modulation every 400 mm (Figure 15) (Figure 16) (Figure 7).

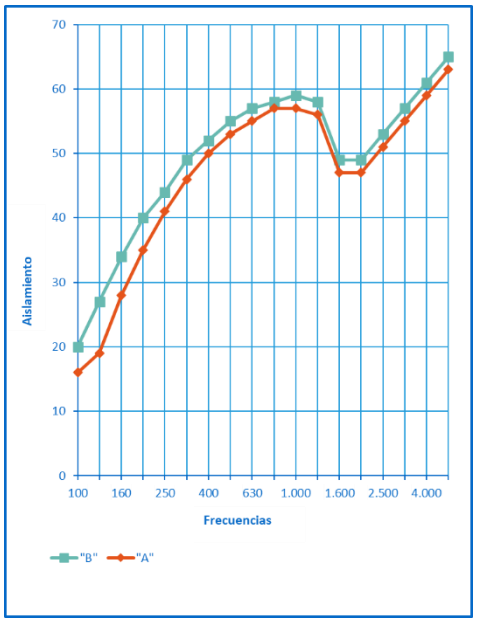

Figure 15. Comparison between systems:

2 Placo® BA15 + M48 (MW) + 2 Placo® BA15 with 400 mm modulation (sample A)

2 Placo® BA15 + M48 (MW) + 2 Placo® BA15 with 600 mm modulation (sample B)

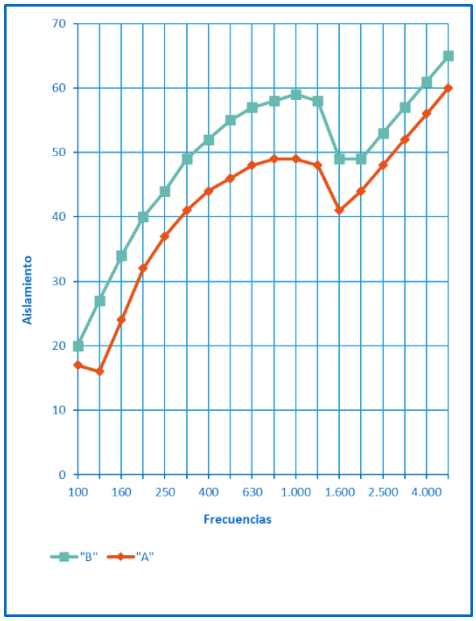

Figure 16. Simulation results from system 2 Placo® BA15 + M48 (MW) + 2 Placo® BA15 with 400 mm modulation (42 dBA)

Approximation between profiles provides more stable systems that achieve greater mechanical heights, but the system is stiffer, reducing the acoustic performance by approximately 5 dBA.

11. TYPE OF PROFILES

If we compare two systems that change the composition of their profiles, one based on the metal profiles of the plasterboard partition and wall systems, and the other based on wooden profiles, we obtain the following results (Figure 17) (Figure 18) (Figure 7):

Figure 17. Comparison between systems:

2 Placo® BA15 + 48 mm wooden profile (MW) + 2 Placo® BA15 with 600 mm modulation (sample A)

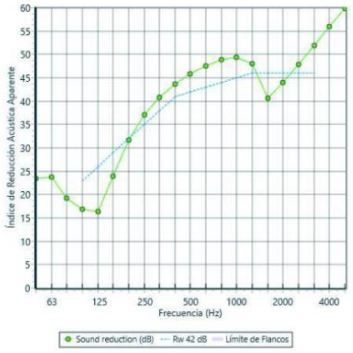

Figure 18. Simulation results from system 2 Placo® BA15 + 48 mm wooden structure (MW) + 2 Placo® BA15 with 400 mm modulation (40 dBA)

The metal profiles of plasterboard systems provide better acoustic insulation than wooden profiles, giving an improvement of up to 8 dBA. It also moves the resonance

frequency to a lower frequency, out of the range of interest.

12. BRACING OF STRUCTURES

In double-structured systems, the use of unbraced structures can lead to a significant improvement in acoustic insulation (Figure 19) (Figure 20) (Figure 21).

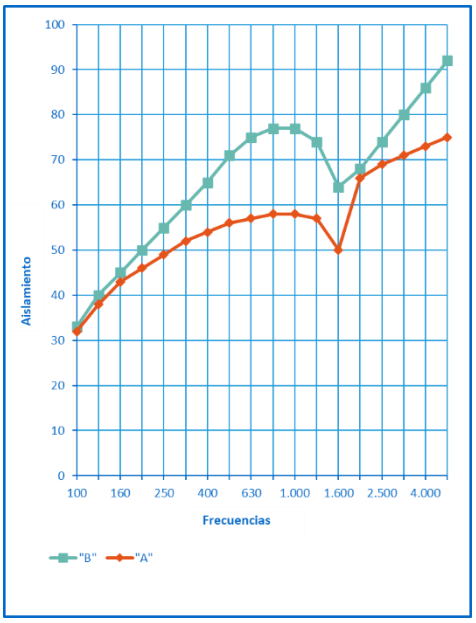

Figure 19. Comparison between systems:

2 Placo® BA15 + M48 (MW) + M48 (MW) + 2 Placo® BA15 with braced structures (sample A)

5000	92	

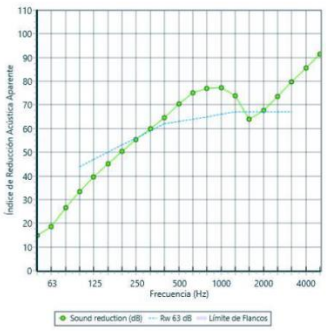

Figure 21. Simulation results from system 2 Placo® BA15 + M48 (MW) + M48 (MW) + 2 Placo® BA15 with non-braced structures (60 dBA)

Bracing between structures provides systems that reach a higher mechanical height, but as in the previous point, the system is stiffened, reducing the acoustic performance. The acoustic insulation can be reduced by approximately 5 dBA.

13. TOTAL THICKNESS OF THE SYSTEM

On the basis of each of the characteristics studied, it can be seen that increasing the overall thickness of the system brings with it a number of aspects that generally improve the acoustic performance of the system:

- Cavity width and thickness of MW in the cavity: It is observed that in systems with cavity widths up to 100 mm, there is an increase of 1 dB for every 1 cm of MW included. In addition, the inclusion of MW in the cavity means that the

resonance frequency is outside the range of interest for these systems, as well as the coincidence frequency for both layers. The difference between including or not including MW in the cavity can make a difference of about 8 dB.

- Number of boards: Increasing the plasterboard mass increases the overall sound insulation value of a plasterboard partition system by approximately 9 dBA by adding one layer of board on each side of the system.

14. INSTALLATION

Finally, it is important to mention that the quality of the construction will have a great influence on the effectiveness of the acoustic insulation of the solution, with differences ranging from 2 to 15 dB.

Acoustic bridges must be taken into account, and it is recommended that an elastic band be installed in the junction of the profiles with the support structure, as well as at the junction between the systems, in order to avoid the transmission of noise between rooms.

15. CONCLUSION

As a manufacturer of plasterboard systems, we can specify the following points based on the acoustic requirements of the project:

- Fill the air cavity of the systems with mineral wool.
- Increase the number of boards to achieve better acoustic performance.
- Use the appropriate board for improved acoustic performance.
- Use double non-braced systems for partition walls between apartments, hotel rooms, etc.
- Pay attention to the performance characteristics of each product and the complete system in each case.

IN-SITU EVALUATION OF CONCRETE INTERLAYER ADHESION BY VIBRATION IN GARAJE FLOORS

David Caballol Bartolomé[1*] **Álvaro Pérez Raposo** [1] **Francisco Gil Carrillo**[2]

[1] Architectural Acoustics Research Group, Universidad Politécnica de Madrid, Spain.

ABSTRACT

A new practice in the construction of garage floors of residential and office buildings in Spain, is to build the concrete slab in two steps: one thick layer at the beginning of the work (≈ 12-35 cm) and a second thin layer (≈ 8 cm) at the end of it. This procedure creates a cold joint between the two layers that may eventually get loose or even split and produce noise when driving over it.
We have designed a nondestructive test to perform in situ measurements to determine the level of fixation of two layers of any concrete slab that causes noise emission problems.
The test is independent of the characteristics of the slab thanks to statistical tools applied to the data.
Vibration induced by a source, the passage of a car, was measured at several locations, with loose and well-fixed layers. The vibration was recorded with a vibrometer. The test can be applied, and the results are compatible with the known state of the slab: we obtain 77.0% sensitivity and 54.5% specificity, while there are only 1.0% false positives and no false negatives. The only drawback of the test is its high number of undecidable cases, which amounts to 24.1%.

1. INTRODUCTION

Traditionally, basement floors were constructed as a single layer concrete slab, which was then polished. However, the work done on this slab often ruined the final construction treatment, which had to be repaired at the end. As a time-saving alternative, the basement floors are constructed in two layers. A first thick layer is made at the beginning, which is the support for all the works during the construction. A second thin layer is applied a few days before the inauguration of the building in order to finish the garage floor without deterioration.
However, this solution has a disadvantage in the form of a cold joint between the concrete layers. Because they are applied at different times and work has been done on top of the first layer, dirt or other debris can accumulate on top of it and weaken the joint with the second layer.
Numerous studies have been conducted about pavement health and vibration [1-6]; however, these studies do not align with the particular problem described above.
We evaluate this problem by performing a non-destructive test on the slab using vibration data.

2. METHODOLOGY

Two experimental procedures were carried out in the study, each designed for a specific purpose in relation to the evaluation of adhesion between concrete layers through vibration measurement:

2.1 Laboratory Measurements:

This first procedure is focused on evaluating the ability of vibration measurements to discern the bond state between two layers of material (concrete and MDF).

In a controlled laboratory environment, based on the facilities described in Annex A of ISO 16251-1 [7], an experimental setup was created where a concrete slab was used as the bottom layer and an MDF (medium density fiberboard) as the top layer. The two layers were bonded together with a material that simulates adhesive (gypsum), and different levels of fixation were varied between them. Vibrations were generated using a standard tapping machine and measured with a vibrometer.
This approach provided consistent and repeatable data, demonstrating that it was possible to detect differences in bonding between the layers depending on the percentage of surface area covered by the adhesive.

2.2 In-situ measurements:

The study measures vibrations in a real building's basement floors. The building, located in Madrid, was constructed between 2016 and 2017 and delivered in May 2017. A few months after the building's completion, variable noises were noticed coming from the garage floor when vehicles passed. All procedures were carried out in accordance with ISO 2631 [8].
To ensure reality's representativeness, measurements were obtained as a light vehicle (Land Rover Discovery Model HSE Sd6) traversed the pavement. The 2249-kilogram vehicle was driven at 20 kilometers per hour (the garage's maximum speed) and vibration levels were measured. The driver started moving from a certain distance to ensure the correct speed at the moment of passing in front of the accelerometer. Data acquisition began when the vehicle started moving and ended when it was far enough away for the vibration to stabilize. A time-dependent vibration history between 1 Hz and 80 Hz was obtained for each pass. The measurements were obtained using a triaxial accelerometer attached to the pavement with a wax disc. The accelerometer was positioned to allow the vehicle to pass through the central roadway. The vibrations were measured in three directions: *Z* axis, vertical; *Y* axis, parallel to the line of pillars inside the garage; and *X* axis, perpendicular to the previous one. The accelerometer was positioned 1.5 m from the nearest parking space. The accelerometer was always positioned away from cracks or defects in the pavement.
The following conditions were fulfilled in all cases:

- The standard vehicle moved forward at data acquisition, staying >1.4 m from the accelerometer.
- Vibration measurements were taken at least 60 seconds apart.
- Vehicles must be in motion forward at the time of data acquisition. Maintain 1.4 meters from the accelerometer and ensure parallel alignment with the Y-axis.
- At least 60 seconds separated each measurement to mitigate the impact of prior vibrations.
- If there was a small unevenness in the pavement that would
cause the vehicle to ‘‘jump’’ even slightly, the measurement was
discarded.
- Measurements were excluded if the pattern vehicle made contact with a manhole or drain.
- At measurement time, the pattern vehicle was the sole vehicle in the garage.

The operator stayed 1.5 meters from the accelerometer. This allowed them to qualitatively classify the vibrations by the sensation under their feet and the noise generated by movement of the vehicle.
The procedure was replicated 108 times at locations across the floors -2 and -1, so that together they represent a complete study of their surface.

3. DATA ANALYSIS AND RESULTS

3.1 Laboratory results

In the laboratory, the acceleration in the X, Y, and Z axes was measured as the response variables.
The acceleration values for a duration of one second are integrated into a single value by means of the r.m.s., resulting in a value for each second.
The vibration magnitude of the tapping machine is approximately 10^{-4} m²/s² when it is deactivated, and it fluctuates between 10^{-2} and 1 m²/s² when it is activated. This indicates that the ambient vibration is negligible in comparison to that induced by the tapping machine.

Since the vibration source is stationary, we can reduce each measurement to a unique value representing an average of the vibration. We have taken the r.m.s. value of each one. In the following we study this single value of each measurement in order to find out the role of the other variables: location of the tapping machine, location of the accelerometer and percentage of fixed surface area (figure 1).

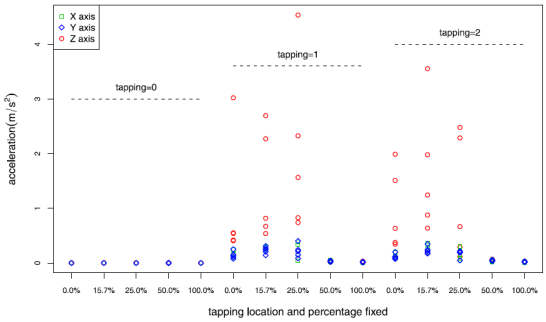

Figure 1. The r.m.s. value of each measurement in the laboratory.

In figure 1, we can see that there is a significant difference in the acceleration values in the Z axis versus those in either X or Y axes, which are significantly lower.
Moving forward, we will exclusively measure acceleration in the Z-axis because it is more sensitive to the effects of the tapping machine.
We can also observe that the percentage of fixed surface area plays an important role when it gets to 50% or higher, in which case the vibration is about 2 orders of magnitude lower than percentages of 25% or below. However, in this figure we do not appreciate differences among 0%, 15.7% or 25% of fixed surface area, nor do we appreciate differences among 50% and 100%.
Given the wide range of acceleration values, it is advisable to use the logarithmic scale for these measurements. To ensure consistency and accuracy in our analysis, it is necessary to establish a reference point for the data. Rather than selecting a single reference value for all data points, we have opted to utilize an average value as a reference point. This approach enables a direct comparison of results from laboratory tests with those obtained from measurements in actual buildings.

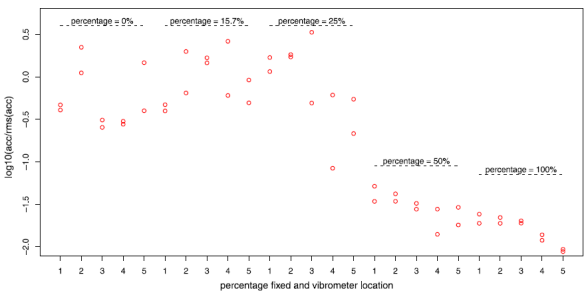

Figure 2. The r.m.s. value of the acceleration in the *Z* direction of measurements in the laboratory.

The results suggest that the recorded acceleration can distinguish between the low percentages (0, 15.7 and 25%) and the high ones (50 and 100%) but not among each of these groups

3.2 Test proposal

We propose a test to classify the degree of fixation between the two layers using vibrational data from an accelerometer. The test will categorize fixation as either low or high. The test will proceed as follows:

- Measure the vertical vibration induced, for instance, by the passage of a car, on the concrete slab. A sample of measurements in different locations is needed, both in locations suspected of abnormal fixation and locations suspected of good fixation between the layers

- Reduce the measurement at each location to a single number, such as the root mean square of the series or the maximum value.

- Compute a suitable average of all the representative values and then compute the decimal logarithm of the representative acceleration in each location relative to the average. The status of the slab layers should be classified using the following criterion:

  Low fixation: locations with a logarithm higher than −0.5.

  Uncertain: locations with a logarithm between −0.5 and −1.0.

  High fixation: locations with a logarithm lower than −1.0.

We use this criterion with data obtained in the garage of an actual building so as to check its validity. In situ results

3.3 In situ results

Figure 3 illustrates four of the 108 recordings obtained in the Madrid building, which exemplify the primary characteristics of all the measurements. Each graph in the figure distinctly captures the passage of the car. Additionally, it is observed that vertical acceleration consistently exceeds the horizontal ones in all cases.

Consequently, from this point on, we will focus exclusively on vertical acceleration.

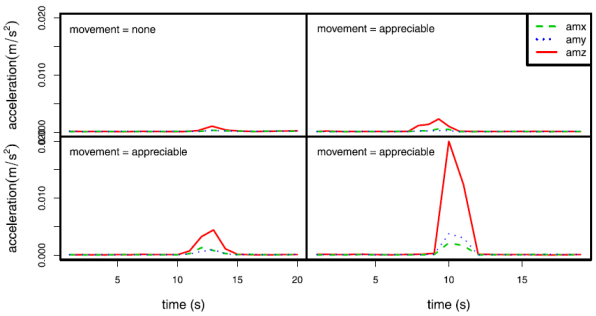

Figure 3. r.m.s. acceleration, with 1 s integration, taken along the passage of the car.

3.4 Test application

Figure 4 illustrates the maximum vertical acceleration of each series, as it relates to the qualitative classification of the movement of the top layer of the pavement. The vertical acceleration is plotted as the logarithm of the value relative to the mean value of all of them.

After applying the criterion defined in Section 3.2 to the data shown in Figure 4, the following results were obtained:

- Seven out of 108 data points, representing 6.5% of the total, have a logarithm lower than −1.0. These data points must be classified as locations where the layers are highly fixed. Only one of these seven locations does not fit into this category.
- 75 of the data, or 69.4%, have a logarithm higher than −0.5, indicating a low fixation of the layers. In this case, all the locations are classified accordingly by the operator, including the 19 locations where a test core was taken, according to EN13863-2 [9], resulting in completely separated layers.
- 26 of the data, 24.1%, cannot be clearly classified by our criterion, as their measurement lies within the uncertain range.

These numbers, though not very impressive, say our criterion may be useful as a first approximation in determining, with a very simple and non-destructive test, the status of the concrete slab in different locations of a garage.

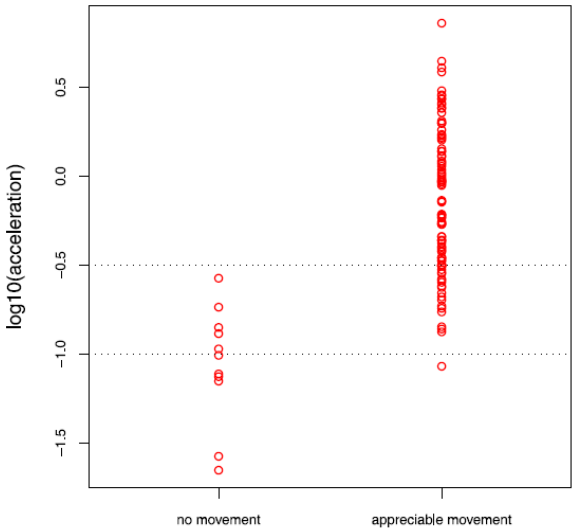

Figure 4. Maximum value of the vertical acceleration in each of the 108 recordings.

4. CONCLUSION

We have proposed a non-destructive test to check the level of fixation of the thin top layer of a concrete slab to the underlying layer using a vibrometer.

We applied our test to data measured in a real building with known fixing problems in the concrete slab of the garage floors.

We measured the vibration past a car in 108 locations within the garage and applied the test previously described.

We found quite a good predictive power of our test, for it classified 82 out of 108 cases, and only one of them was wrongly classified, that is 75.0% where correctly classified.

On the other hand, 26 of the 108 cases were not classified at all, that is a 24.1% of undecidable cases.

As a future work the test should be improved especially by narrowing the interval of undecidable cases.

We are currently extending the study by using the standardized impact machine as an exciter on real building garage floors. We hope to be able to present new results soon.

[2] Yonsei University, Seoul-Si, Republic of Korea

ABSTRACT

The floor impact sound problem, which is a living noise that can easily occur in apartment houses, is serious. In particular, Korea has a unique panel heating system called 'Ondol', which installs heating pipes on concrete slabs. Because of this heating system, Korea has a culture of taking off shoes in the living room, and this is the cause of floor impact sound problems. Reduction mats, which are widely used to solve floor impact sound in Korea, are made of various thicknesses and materials. Requirements for confirming the noise performance of the floor impact sound reduction mat are presented in the relevant standard (ISO 10140-5). The base floor is presented as a homogeneous reinforced concrete slab with a thickness of 100 to 160 mm. But, there is a big difference in floor mat noise performance between slabs including ondol structure and single slabs. Most floor in Korea are structures in which an ondol layer is installed on 210mm slab. In this study, the mat reduction performance according to the presence or absence of an ondol layer and the slab thickness was compared. However, the evaluation method used ISO 16283-2's general single number quality (SNQ) to confirm the light & heavy-weight impact sound reduction performance. Through this, it is intended to provide noise performance that can be referred to when consumers select floor mats.

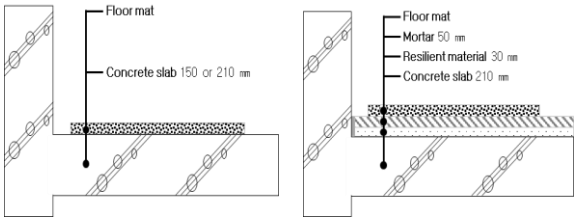
1. INTRODUCTION

Korea is a world-class country with a population density of 516 people per square kilometer. It ranks first among OECD countries. For that reason, there are many apartments where many people can live together in a narrow area. However, in co-living apartments, living noise between neighbors, especially floor impact sound problems, occurs very seriously. In addition, since Korea uses a panel heating method called ondol on concrete slabs, they live without shoes indoors. Since there are no shoes or slippers that can buffer, the floor impact sound problem becomes more serious. In Korea, it is mandatory to install a resilient material between slab ondol heating to reduce floor impact sound. Even with these efforts, the floor impact sound is the most serious cause of civil complaints in Korea.

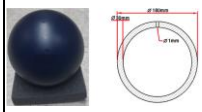


Houses with children use floor mats of various thicknesses and materials to reduce floor impact sounds. Noise performance measurement conditions for floor mats are provided in ISO 10140-5. The test slab is presented in homogeneous reinforced concrete with a thickness of 100 to 160 mm. However, the floor structure in Korea is different from the slab conditions and composition suggested by ISO because the minimum thickness is 210mm and a resilient layer must be installed to reduce floor impact sound.

The purpose of this study is to examine how these differences in floor structure affect the performance of floor mats, and to provide noise reduction performance according to conditions that consumers can refer to when choosing a floor mat

2. MEASUREMENT OVERVIEW

For the floor mat used in the experiment, 12 mats currently used in the market in Korea were selected. There are a total of 12 mats used, 6 inexpensive polyethylene-based products, 3 ethylene vinyl acetate products with excellent stability, and 3 polyurethane products with excellent eco-friendliness. In addition, in order to compare the noise reduction performance of the mat according to the thickness, an experiment was conducted on mats with different thicknesses for each material.



The section of the floor structure used in the experiment is shown in Figure 1. It is a floor structure without a Resilient layer with a thickness of 150 and 210 mm of concrete slab and a slab with a Resilient layer of 210 mm. The Resilient layer is a 'Ondol' structure on the slab, consisting of 'Concrete slab 210 mm + Resilient material (Expanded poly-styrene) 30 mm + Mortar 50 mm'. The measurement equipment used is shown in **Table 1**.

Table 1. Measurement system.

Measurement system	Products	
Real Time Analyzer	PAK MK Ⅱ (12 channel), Müller-BBM, Germany	
Microphone	46AE(1/2“), GRAS, Denmark	
Light-weight Impact Sound Source	Tapping Machine, 01dB, France	
Heavy-weight Impact Sound Source	Rubber Ball, RION, Japan	

3. MEASUREMENT AND EVALUATION METHOD OF FINISHING MATERIAL

Currently, an evaluation method for evaluating the performance of the floor finishing material is presented in ISO 717-2. However, only the light-weight impact sound single number index (ΔL_w) for the reduction performance of the upper floor coverings is defined, and there is no separate method for evaluating the weight impact sound. In the case of the existing light-weight impact sound reduction evaluation method that can evaluate finishing materials, it is difficult for users to judge performance by looking at figures because the calculation results are difficult for ordinary residents to feel. In this study, we evaluated the insertion loss by confirming the light & heavy-weight impact sound reduction performance and comparing the common single number quality (SNQ) of ISO 16283-2, which is easy to understand when users install floor mat. This method is already widely used as a method of evaluating the floor impact sound of foam mat products. Equations (1) and (2) show how to reduce light-weight and heavy-weight impact sound insertion losses.

$$\Delta L_{Lw}(dB) = L_{without\ covering} - L_{with\ covering} \quad (1)$$

Where, $\Delta L_{Lw}(dB)$: Light-weight impact sound insertion loss due to finishing materials

$L_{without\ covering}$: Floor impact sound level before finishing installation, standardized impact sound pressure level ($L'_{nT,W}$)

$L_{with\ covering}$: Floor impact sound level after finishing installation, standardized impact sound pressure level ($L'_{nT,W}$)

$$\Delta L_{Hw}(dB) = L_{without\ covering} - L_{with\ covering} \quad (2)$$

Where, $\Delta L_{Hw}(dB)$: Heavy-weight impact sound insertion loss due to finishing materials

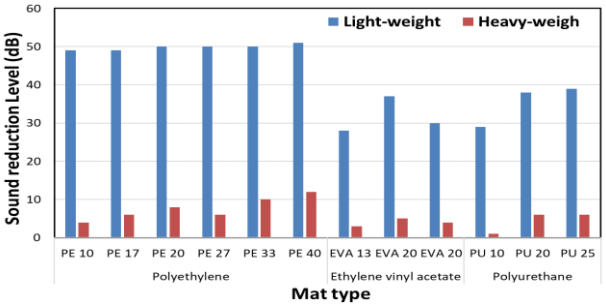
$L_{without\ covering}$: Floor impact sound level before finishing installation, standardized impact sound pressure level ($L'_{iA,Fmax}$)

$L_{with\ covering}$: Floor impact sound level after finishing installation, standardized impact sound pressure level ($L'_{iA,Fmax}$)

4. RESULTS OF MAT REDUCTION PERFORMANCE

4.1 Acoustic characteristic of floor mat

Figure 2 shows the noise reduction performance of floor mat. As a result of comparing the floor mat by material, the reduction performance of PE products is the best, followed by PU and EVA. In all materials, as the thickness increases, the reduction performance is also excellent. In particular, in the case of heavy-weight floor impact sound, the effect of thickness appears significantly.



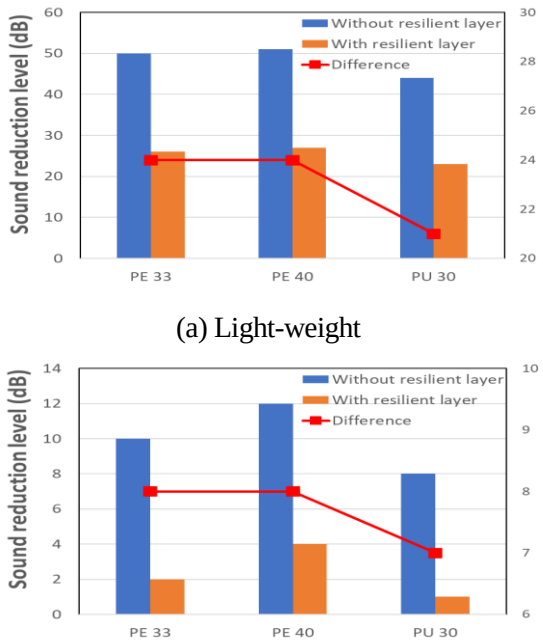


Figure 2. Sound reduction level of floor mat.

4.2 Installation of resilient layer on slab

Korea uses 'Ondol', a panel heating system, on the top of the slab in apartment houses. However, the current International Standard (ISO 10140-5) evaluates the floor impact sound reduction performance under the condition that the installation of a resilient layer on the top of the slab is not considered. Therefore, when floor mat is installed to reduce floor impact sound, on-site reduction performance in Korea may differ from results measured by international standards. Among the 12 types of mats reviewed in 4.1, three representative mats with excellent performance and high use (33 mm PE, 40 mm PE, and 30 mm PU) mat were selected. The floor impact sound reduction performance was compared according to the presence or absence of a resilient layer considering the 'ondol' structure in Korea. As shown in Figure 3, depending on the presence or absence of a resilient layer, there is a difference between 21 and 24 dB for the lightweight impact sound and 7-8 dB for the weight impact sound. Through this, if mat reduction performance is measured on the slab before installing the resilient layer as an ISO international standard measurement method, the noise performance of mat may be overestimated compared to the actual living performance in Korea. A separate evaluation method different from the ISO standard is required for floors where additional layers are installed on the slab, as in Korea.

(a) Light-weight

(b) Heavy-weight

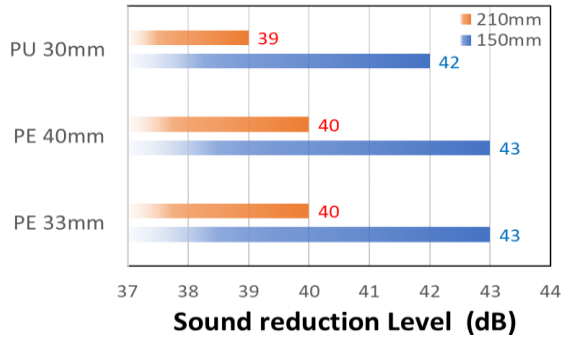

Figure 3. Reduction performance by resilient layer.

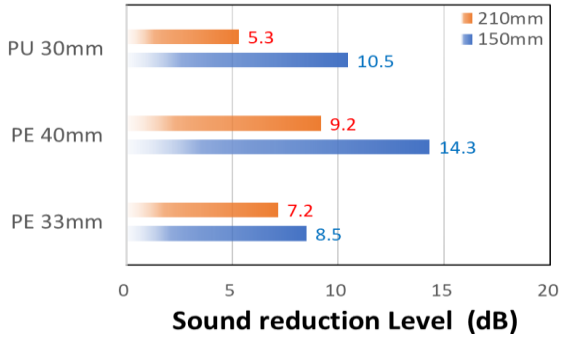
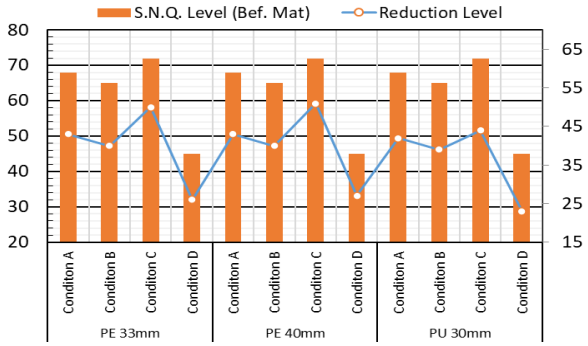
4.3 Slab thickness



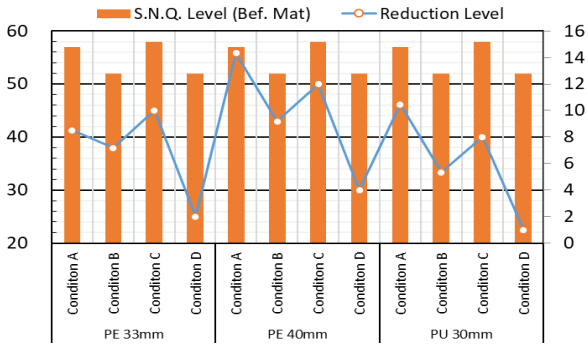
In ISO 10140-5, the reduction performance measurement condition of floor finishing material is 100-160mm in slab thickness, but the minimum slab thickness is 210mm in Korean apartments. This means that evaluating the performance of the finishing material according to ISO measurement conditions is different from the field conditions in Korea. Therefore, it is necessary to examine the possibility that the floor impact sound reduction performance of floor mat will vary according to the change in slab thickness.

The experiment was conducted on the floor mat used in 4.2. Two types of slabs, 150 and 210 mm, were compared, and the reduction performance of the mat was examined in slabs without a resilient layer.

As a result of the measurement, the reduction performance of the mat is evaluated higher by 150mm slab than 210mm. When the slab thickness increases from 150mm to 210mm, the light-weight impact sound decreases by 3dB in all three mats, and the heavy-weight impact sound decreases by 1.3dB to 5.1dB.



(a) Light-weight



(b) Heavy-weight

Figure 4. Reduction performance with slab thickness.

(a) Light-weight

(b) Heavy-weight

Figure 4. Relationship between SNQ and reduction level.

5. RESULTS

The reduction performance of floor mat varies depending on the conditions of the slab. Slab conditions are not significantly affected by finishing materials such as fly-wood that do not have high sound insulation performance, but finishing materials with high sound insulation performance such as floor mat are affected by slab thickness and the presence or absence of a resilient layer. In the case of floor mats with excellent reduction performance, the reduction performance tends to decrease when the slab thickness becomes thicker or when a resilient layer is installed. Figure 5 is the result of comparing the reduction level of floor mat with the performance before mat installation (SNQ). It can be seen that the reduction performance of the finishing material tends to be excellent when the reduction performance is measured under poor performance conditions. Therefore, in evaluating the performance of the finishing material, it is necessary to clearly present conditions such as the thickness and composition of the slab.

COMUNICATION BETWEEN CAREGIVERS AND CHILDREN REGARDING INTER-FLOOR NOISE IN MULTI-FAMILY HOUSING: A KOREAN STUDY

Miji Kwon[1] **Wonyoung Yang**[2 *]
[1] Department of Speech-Language Pathology, Gwangju University, Gwangju, South Korea
[2] Division of Architecture, Gwangju University, Gwangju, South Korea

ABSTRACT

Inter-floor noise in multi-family housing has become a significant source of social conflict leading to neighborly conflicts and legal disputes, with children's footsteps and running and resulting noise being major sources. This study examined whether caregivers' communication skills with children could help mitigate inter-floor noise problems caused by children in Korean multi-family housing. An online survey was conducted among 323 caregivers (119 male, 204 female) with minor children, using a 7-point Likert scale across three components: the Highly Sensitive Person Scale (27 items), neighbor communication survey (15 items), and inter-floor noise-related questions (5 items). Results indicated that female caregivers, more sensitive caregivers, and those with better neighbor communication skills were more proactive in conveying noise reduction messages to their children. The findings suggest that sensitive caregivers are more likely to recognize and address inter-floor noise issues with their children, while those with better neighbor communication skills demonstrate improved social consideration. The study concludes that caregivers in multi-family housing should actively engage in communication with their children about inter-floor noise to reduce disturbances through effective parent-child interactions

1. INTRODUCTION

Inter-floor noise remains a significant source of conflict in multi-family housing environments, particularly in dense urban settings [1], with children's footsteps and running and resulting noise being major sources [2]. Despite increasing awareness of this issue, to the best of our knowledge, no research has been found examining the relationship between caregiver communication and children's behavior causing inter-floor noise. This study investigates the communication patterns between caregivers and minor children regarding inter-floor noise, focusing on how caregiver sensitivity, neighbor communication quality, gender, and family composition influence these interactions. Understanding these dynamics is essential for developing effective interventions to reduce noise-related conflicts and improve community relations in residential settings, ultimately enhancing quality of life for families living in multi-unit dwellings.

2. METHOD

2.1 Participations and procedure

The subjects of this study were 323 primary caregivers (119 male, 204 female) raising minor children aged under eighteen. We developed a questionnaire on communication between primary caregivers and their children regarding noise between floors, distributed it online, and collected responses. This study was conducted after receiving prior approval from the Institutional Review Board (IRB) of Gwangju University.

2.2 Research tools

This study aimed to examine the characteristics of communication between caregivers and minor children

regarding inter-floor noise. The survey used in this study consisted of 27 items from the Highly Sensitive Person Scale (HSPS) [3], 15 items on communication between neighbors (NC) [4], and 5 items related to inter-floor noise communication between children and caregivers. After composing the entire survey, we consulted two experts and finalized the questionnaire. Each survey item was structured on a 7-point Likert scale (1 point - "not at all" to 7 points - "very much so"). The five items related to inter-floor noise communication are shown in Table 1.

Table 1. Items for the inter-floor noise-related questions

No	Questionnaire items
1	I explain to my child in advance about situations that could cause inter-floor noise
2	I inform my child that their actions causing inter-floor noise can harm our family and neighbors.
3	I give warnings when my child engages in behavior that causes inter-floor noise.
4	I stop my child when they engage in behavior that causes inter-floor noise.
5	I discuss with my child about conflicts with neighbors caused by inter-floor noise.

2.3 Data Collection and Processing

For this study, a questionnaire was created that could be distributed and collected online. It was distributed to general adults in the form of a URL address. The questionnaire specified the purpose of the research and the contact information of the research director, and included notifications about research ethics and consent to participate. Statistical analyses were performed using Minitab 22.1

3. RESULTS

Table 1 lists the main effects of the ANOVA. HSPS, NC, gender, no of family and no of age ≤ 18 significantly affected inter-floor noise-related questions scores. In terms of the Highly Sensitive Person Scale (HSPS), there was a significant difference ($F = 3.38$, $p < 0.05$) among the three sensitivity groups, with the high sensitivity group ($M = 5.70$) scoring significantly higher than the low sensitivity group ($M = 5.35$), while the medium sensitivity group ($M = 5.54$) did not differ significantly from either extreme.

Regarding neighbor communication (NC), a highly significant difference was observed ($F = 18.01$, $p < 0.001$) between the high ($M = 5.75$) and low ($M = 5.31$) groups. Similarly, gender showed a significant effect ($F = 5.07$, $p < 0.05$), with females ($M = 5.66$) reporting higher scores than males ($M = 5.40$).

The number of family members also yielded significant differences ($F = 2.50$, $p < 0.05$). Notably, households with five members showed the highest mean score ($M = 6.39$), which was significantly different from single-person households ($M = 3.47$). Families with two to four members and those with six or more members showed intermediate values that did not differ significantly from each other.

Finally, the number of family members under 18 years of age also demonstrated significant differences ($F = 3.24$, $p < 0.05$). Households with one child under 18 reported the highest scores ($M = 5.87$), significantly differing from households with three children under 18 ($M = 5.01$), while households with two children ($M = 5.72$) showed intermediate scores that were significantly different from those with three children but not from those with one child.

Table 2. Results of ANOVA (means that do not share a letter are significantly different; A > B > C)

Factor		F P	N	Mean	Group
HSPS	High	3.38 <0.05	113	5.70	A
	Medium		132	5.54	AB
	Low		78	5.35	B
NC	High	18.01 <0.001	136	5.75	A
	Low		187	5.31	B
Gender	F	5.07 <0.05	204	5.66	A
	M		119	5.40	B
No of family	1	2.50 <0.05	1	3.47	B
	2		1	5.65	AB
	3		107	5.63	AB
	4		174	5.78	AB
	5		31	6.39	A
	>6		9	6.27	AB
No of age ≤ 18	1	3.24 <0.05	128	5.87	A
	2		164	5.72	AB
	3		31	5.01	C

4. DISCUSSION AND SUMMARY

This study examined communication patterns between caregivers and children regarding inter-floor noise. Key findings reveal that highly sensitive caregivers, those with better neighbor communication skills, and female caregivers demonstrate more effective noise-related

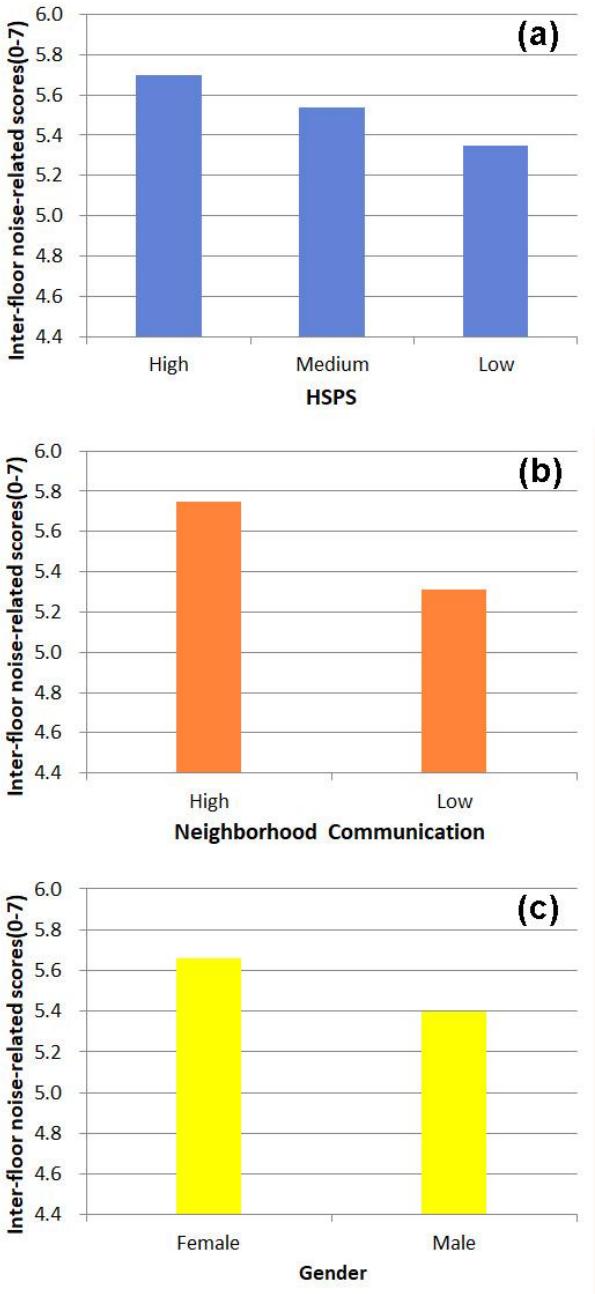

Figure 1. Inter-floor noise-related question scores according to HSPS, NC, and gender (a) HSPS, (b) Neighborhood Communication, (c) gender.

communication with children. Family composition significantly impacts communication patterns, with five-member households showing the highest levels of noise awareness communication, while families with fewer children under 18 reported more focused communication. These findings suggest that personal sensitivity, social communication skills, gender dynamics, and family structure all influence how caregivers address noise issues with children. Results highlight the importance of targeted interventions and education programs to improve noise management in multi-family housing environments. Future research should focus on longitudinal studies to assess the sustained impact of these implementation strategies and explore cultural variations in caregiver-child communication regarding environmental behavioral constraints.

5. ACKNOWLEDGMENTS

ABSTRACT

MSCA Doctoral Network projects are essential in fostering international collaboration and developing interdisciplinary, innovative solutions. The Horizon MSCA-DN project "ActaReBuild" advances sustainable retrofitting solutions for office buildings in Europe.

The unique feature of this project is that it addresses both the acoustic and thermal performance of buildings in their conversion to other uses.

The project consists of ten Individual Research Projects performed by ten Doctoral Candidates (DCs) under joint PhD supervision.

Research within "ActaReBuild" includes developing innovative materials such as customisable mycelium bio-composites, recycled plastic composites, bio-based materials optimised for acoustic and thermal performance and metamaterials. It addresses novel solutions to improve low-frequency airborne sound insulation in lightweight constructions and refines descriptors for airborne sound insulation of facades, addressing spectral and temporal noise features. In the framework of the project, advanced measurement techniques for remote in-situ measurements for building facades are developed. It explores the balance between airtightness, energy efficiency, and acoustic performance and application on biotic materials for lightweight building envelopes, which significantly reduce embodied carbon and support circular economy principles.

Keywords: *building retrofit, acoustics, thermal physics, MSCA-DN*

1. INTRODUCTION

ActaReBuild project is MSCA – DN (Doctoral Network). The scheme aims to train 10 highly skilled doctoral candidates, fostering their creativity, enhancing their innovative abilities, and boosting their employability for the future [1]. Candidates are enrolled in joint PhD programmes and are supervised by joint supervisory committees. The ActaReBuild project started on 1st September 2022 and is a 4-year project funded under the Horizon Europe scheme.

2. BACKGROUND

Recent European research initiatives have focused on mitigating climate change by implementing energy-efficient building retrofits to achieve near-zero energy use and reduce urban heat islands [2-3]. Although these projects have achieved notable advancements in material and energy efficiency, acoustic performance is often overlooked. Long utilised in construction, recent advancements in bio-composites have enhanced traditional biomaterials like wood, straw, and mud [4-7]. A promising method utilizes mycelium-based composites made from agricultural waste, offering the potential for excellent acoustic absorption while replacing non-renewable materials [8]. A well-known example of sustainable material reuse involves incorporating

[*] ***Corresponding author***: *vojtech.chmelik@stuba.sk.*

rubber or plastic to create various products that dampen vibrations in floating floor systems [9], and there is also a possibility of using such material in the concrete industry [10-12]. However, the acoustic and thermal performance of materials like granulated plastic and glass [13] requires more research.

In addition to material innovation, phase change materials (PCMs) aid in passive thermal regulation by stabilising indoor temperatures and lowering energy usage [14]. Acoustic metamaterials, designed for targeted sound insulation, show potential for lightweight partition systems; however, they are still largely overlooked in extensive building retrofits [15]. Another developing technology is ethylene tetrafluoroethylene (ETFE) cushion systems, commonly utilised in lightweight façade and roofing applications for their transparency and energy efficiency [16]. Despite this, the acoustic properties of large ETFE structures are still not adequately characterised since conventional room-based tests [17] are inappropriate for them. Advanced in-situ measurement techniques, such as surface impedance measurement with intensity probes or laser Doppler vibrometry (LDV), provide potential solutions [18-19].

Acoustic assessment methodologies also require refinement. Existing sound insulation descriptors, such as Single Number Quantities (SNQs) defined in ISO 717 [20], are often not sufficient for evaluating modern lightweight and hybrid materials, particularly at low frequencies [21]. Furthermore, Life Cycle Analysis (LCA) is increasingly recognized as essential for assessing the sustainability of construction materials, with studies indicating that substituting traditional materials with bio-based alternatives, such as timber, can halve the embodied carbon footprint [22]. However, guidelines for incorporating these materials into large-scale retrofit projects remain underdeveloped.

3. FOCUS OF THE PROJECT AND RECENT FINDINGS

So far, the following results have been obtained. Research, where myco-materials were developed using Pleurotus Ostreatus mycelium grown in various natural substrates, was performed. The materials have undergone testing for compression and tensile strength as well as thermal conductivity. The study highlights the potential of agricultural residues for sustainable construction, with sugarcane bagasse composites exceeding other samples in strength and insulation. While drying and autoclaving are still CO2-intensive, solar drying could reduce the environmental impact. Despite challenges in scaling, mycelium's ability to bind waste materials makes this method economically attractive [23]. Another study has been performed which examined the degree of accuracy on the tortuosity of a porous material using ultrasound transmission measurements. Compared to pulse measurements, the method shows improvement in signal quality. Subsequently, various configurations of tilt angle and transducer spacing were examined, and the results obtained were comparable to other studies dealing with the characterization of tortuosity [24].

Experiments on the performance of a novel bio-based material in terms of sound transmission, sound absorption coefficients as well as thermal properties were conducted. The results showed improvement in monitored parameters in comparison with conventional materials. Several ideas of possible use were concluded [25-27].

The experiments on the acoustic performance of recycled material in the form of loose plastic granules – ethylene-vinyl acetate, polyethene, and polystyrene – were performed. The measurements showed the possible alternative to conventional materials while addressing the waste disposal challenge [28]. Furthermore, the waste material was used to fill cavity resonators. Because of their sound absorption performance, they could be used as an alternative to fibrous materials, although only in exterior applications such as noise barriers [29].

Another part of the project's research focuses on applying PCMs in building construction. The results of the investigations involve composite components that are created by impregnating a highly porous material with two different paraffinic PCMs. The findings emphasize calcium silicate panels as a possible host material for PCMs [30].

A comparative study of various methods for calculating the transmission loss of double panels with the application of metamaterial, demonstrating the broader applicability of the transfer-matrix method in predicting transmission loss, was conducted [31]. The following research was aimed at the possibility of improving the sound transmission loss of a metamaterial unit comprising a membrane with a centre mass used for sound insulation of heat pumps in residential buildings [32].

The use of the LDV method for estimating sound power, as well as the exploitation of the Nyquist-Shannon sampling theorem for pressure estimation criterion in flat plates, are shown in the next study [33].

The assessment of the life cycle of materials is another topic of interest in the framework of the project. The research published in [34] emphasizes the possibility of converting fibrous agricultural resources into insulation products that require less energy. It also investigates innovative methods such as electrospinning and additive manufacturing for bio-

based applications composites. The further study provides a foundational basis for developing methodologies to influence local policies that promote sustainable strategies [35].

The study related to the relevance of various listening test methodologies for evaluating the influence of façade sound insulation on the perception of outdoor noises was also presented [36]. Another study recommends better incorporating all aspects of noise annoyance in future listening test experiments based on the overview of the methodology and sound stimuli used in previous studies [37].

Two experiments on the relation between sound insulation performance and airtightness of constructive solutions were also conducted [38-39].

Another important topic addressed in the project is the life cycle of constructions based on ETFE foils/cushions. The published study on this topic assesses the environmental impact of ETFE foil's End-of-Life scenarios using LCA, emphasizing recycling as the preferred option while considering incineration if transportation emissions are too high [40]. A different study Analyzes uniaxial hysteresis tests on ETFE foil, revealing 33 years of wind load history, supporting material reduction, and validating the method while recommending bi-axial tests for accuracy [41].

ABSTRACT

Mycelium is a biological material that consists of filamentous fungi, forming intricate networks of hyphal micro-filaments that naturally bind organic matter. This unique way of growing offers promising potential for developing innovative materials, including acoustic absorbers. A lot of variety is possible, since mycomaterial properties are highly dependent on the substrate used.

The presented research reports on the development and acoustic characterization of mycelium composites derived from diverse substrates. These include the fungal strain Pleurotus Pulmonarius, combined with leaves and grass clippings with textile waste. 3 distinct material combinations were made. For each material combination, the density and porosity were obtained by the gas pycnometer method. The sound absorption of the samples was determined using an impedance tube, in compliance with the ISO-10534-2 standard, spanning frequencies from 200 Hz to 5000 Hz. The microstructure of the samples was characterized by Scanning electron microscopy (SEM). The mycomaterials exhibited sound absorption values exceeding 50% across frequencies ranging from 1500 Hz to 4000 Hz.

1. INTRODUCTION

Mycelium-based composites (MBC) have gained interest as viable alternatives to conventional synthetic materials in construction, packaging, and acoustic and thermal applications. These biocomposites are compostable and derived from renewable or waste resources. They also exhibit promising functional characteristics, including thermal insulation and sound absorption [1], [2]. Recent studies highlight the versatility of mycelium materials, demonstrating their potential to porous absorbers in acoustic solutions. For instance, mycelium-grown substrates such as agricultural waste, spent coffee grounds, and paper industry byproducts have achieved sound absorption coefficients comparable to traditional materials like polyurethane and extruded polystyrene [3], [4]. The acoustic performance of these composites is closely tied to their microstructure, which can be tailored through substrate selection, fungal species, and processing methods [5], [6], [7]. Despite these advances,

gaps remain in understanding how specific waste streams, particularly urban biowaste (e.g., leaves, grass clippings) combined with textile waste, influence the acoustic and physical properties of mycelium composites. While prior research has explored lignocellulosic substrates like sawdust and straw [8], [9], [10], [11], the integration of textile waste into mycelium matrices requires further investigation. Textile processing methods (e.g., grinding, stripping) may significantly alter composite porosity, density, and hyphal adhesion, thereby impacting acoustic efficiency.

This study addresses these gaps by developing and characterizing mycelium composites derived from leaves, grass clippings, and recycled textiles (ground, stripped, and combined forms) using Pleurotus pulmonarius. Through impedance tube testing, helium pycnometry, and scanning electron microscopy (SEM), we evaluate how textile treatment methods affect the composites' sound absorption, density, and microstructure.

2. MATERIALS AND METHODS

2.1 Sample Preparation

The production of the composite samples was based on solid-state fermentation of Pleurotus pulmonarius cultivated on lignocellulosic and textile-based substrates. This was carried out in Medellín, Colombia, under controlled environmental conditions to eliminate the influence of external weather fluctuations.

Agro-industrial and textile residues were selected as the main substrate components, a mixture of grass cuttings and dry leaves sourced from the organic waste disposal system of Universidad Pontificia Bolivariana were used as the primary lignocellulosic materials. Additionally, recycled textile fibres were provided by a local textile recycling company and pre-processed into fine ground material and textile strips prior to use. By varying the textile processing method across samples, this study aims to evaluate its influence on the structural and acoustic properties of the resulting composites.

Preliminary treatment of the substrates included the removal of any non-organic contaminants from the grass and leaf mixture.

In order to reduce the microbial load, an autoclaving step was conducted, at 120 °C and 15 psi for 45 minutes. Excess moisture was subsequently removed from the substrates.

Each mixture was placed into sterile trays measuring and inoculated with Pleurotus pulmonarius grain spawn, with an amount corresponding to a 20 percent of the total substrate dry weight. The trays were covered with sterilized polyethylene bags to limit light exposure, then incubated at 21 °C with 50 percent relative humidity for 45 days to facilitate mycelial colonization.

Throughout the incubation period, mycelial growth was monitored. Any fruiting bodies that emerged were removed to maintain focus on vegetative mycelium development. Upon completion of the cultivation phase, the samples were removed from the bags and dehydrated in a convection oven at 65 °C for 24 hours. This post-processing step deactivated the fungal metabolism. After deactivation the samples had a thickness of 2 cm.

Table 1 shows the different sample compositions. The substrate composition consisted of 70 percent lignocellulosic material and 30 percent recycled textile by weight; with these different sample configurations the effect of the textile processing method on the structure and acoustic capabilities of the developed materials is being evaluated.

Fig. 1 to 3 show developed samples, Fig 1. Ground Textile (GT), Fig 2. Striped Textile (ST), Fig 3. Combined Textile (CT), Respectively.

Table 1. Sample composition

Sample	Composition
GT	70% lignocellulosic composite - 30% ground textile
ST	70% lignocellulosic composite - 30% striped textile
CT	70% lignocellulosic composite - 15% ground textile - 15% stripped textile

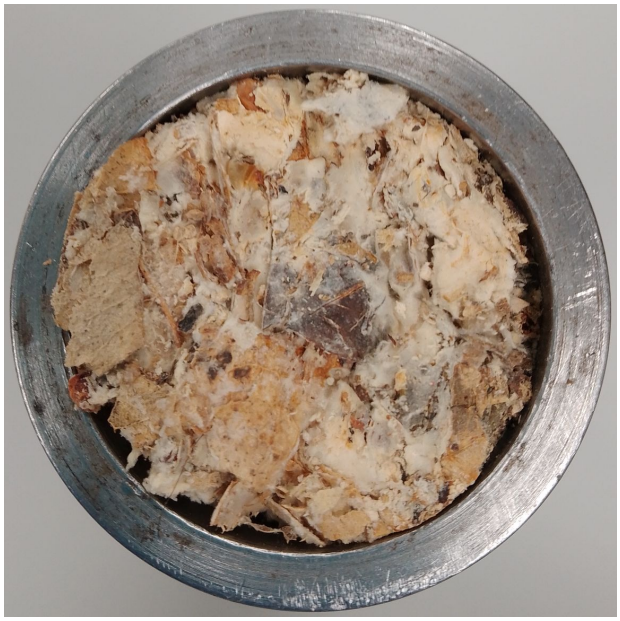

Figure 1. Ground Textile mycelium sample (GT)

Figure 2. Striped Textile mycelium sample (ST)

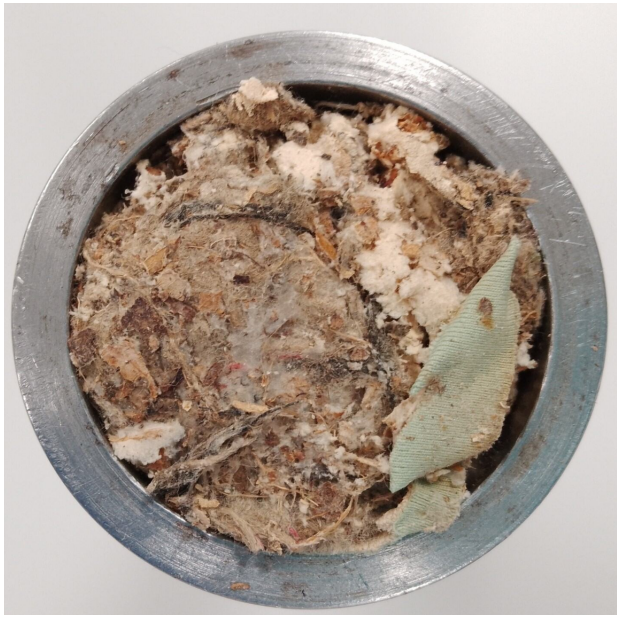

Figure 3. Combined Textile sample (CT)

2.2 Sample characterization

Following the cultivation of the mycelium-based composites, a series of physical and acoustic characterization procedures were conducted to evaluate their suitability as sound-absorbing materials.

2.2.1 Density and Porosity Analysis

The physical characterization of the mycelium composites included the determination of their bulk density and open porosity. The bulk density was calculated as the ratio between the oven-dried mass and the geometric volume of the samples. To obtain the true (skeletal) density of the solid phase, a helium gas pycnometry was performed using an AcuPyc II 1345 pycnometer, in accordance with ASTM D923. Each measurement included 50 purges and measurement cycles to ensure accuracy and stability of the results. Open porosity (ϕ) was then calculated using:

$$\phi = 1 - \frac{\rho_{Bulk}}{\rho_{Real}} \quad (1)$$

2.2.2 Sound absorption coefficient

The sound absorption spectra of the mycelium composites were determined using the impedance tube method, following the guidelines established in ISO

10534-2. Measurements were conducted using a custom-built impedance tube setup equipped with two Behringer ECM8000 condenser microphones. Pink noise was generated within the tube to simulate plane wave propagation under normal incidence conditions, the frequency range of the analysis went from 200 Hz to 5000 Hz. Cylindrical samples with a 38 mm diameter were cut to fit the inner diameter of the impedance tube, ensuring airtight contact with the tube walls. Each test was repeated three times per sample type to assess experimental variability. The resulting absorption coefficient curves were analyzed to compare the acoustic behavior of the different substrate combinations and to identify trends associated with material composition and structure.

2.2.3 Scanning Electron Microcopy

Scanning Electron Microscopy (SEM) was employed to investigate the internal microstructure and hyphal network formation within the mycelium composites. Prior to imaging, small cross-sectional fragments of each sample were cut and coated with a thin layer of gold. SEM imaging was carried out at an accelerating voltage of 15 kV.

3. RESULTS AND DISCUSSION

The physical properties of the mycelium composites are presented in Table 2. Density values ranged from 1.05 to 1.08 g/cm³,. Bulk density values, as measured via helium gas pycnometry, varied between 0.13 and 0.15 g/cm³ depending on the textile waste used.

Calculated porosity values ranged from 86% to 88%. The GT sample showed the highest porosity, while ST and CT had slightly lower porosities. These small differences suggest that the processing method of the textile component may have a subtle effect on the internal structure of the resulting composites.

Table 1. Density and porosity of leaves and grass cuttings based mycelium composites with different textiles.

Sample	Real Density (g/cm^3)	Bulk Density (g/cm^3)	Porosity (%)
GT	1.08	0.13	88
CT	1.06	0.15	86
ST	1.05	0.15	86

Examination of the acoustic performance (Figure 4) of the composites showed a typical trend for porous materials: the sound absorption increased with frequency. However, notable distinctions were observed among the different textile treatments. The GT sample demonstrated the highest absorption coefficients, particularly in the mid to high frequency range (1000–4000 Hz). In comparison, both ST and CT exhibited similar absorption, with slightly lower performance, especially at higher frequencies, whilst having greater absorption at low frequencies.

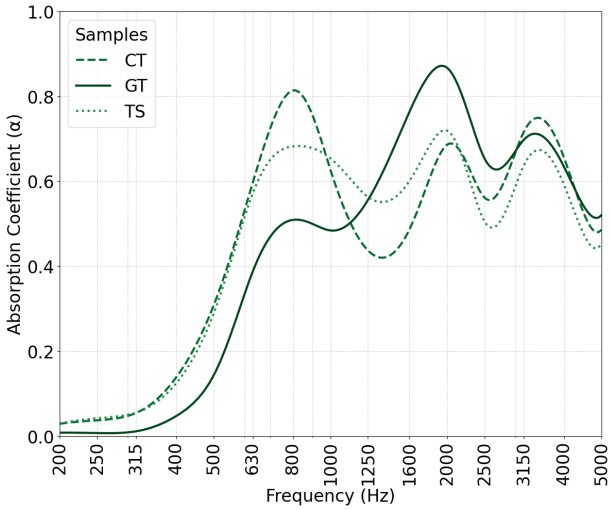

Figure 4. Sound absorption coefficient of mycelium based composites.

These differences in acoustic performance are further supported by the density and porosity results and SEM imaging, which revealed variations in the internal structures of the composites. The GT sample displayed a porous network, while ST showed a more compact and layered micro-structure with lower porosity.

The SEM images revealed key differences in the internal structure of the based mycelium composites, which help contextualize the observed acoustic and physical properties.

The GT (Ground Textile) sample (Fig 5) presents a highly irregular and open structure. The fibres are fragmented and loosely packed, creating an interconnected network with visible voids. This morphology is consistent with its higher porosity and lower bulk density. The open and tortuous structure increases the surface area available for interaction with sound waves, supporting the superior acoustic

performance observed. Fig. 6 and Fig. 7 show how mycelium does not grow over the textile fibers.

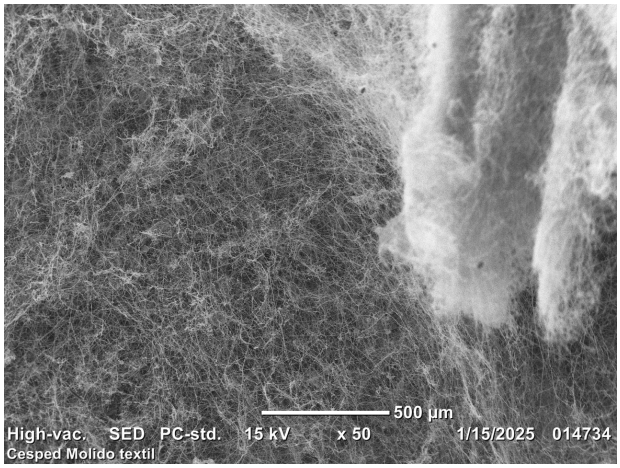

Figure 5. SEM image of the GT (Ground Textile) sample at 50× magnification, showing a fragmented and loosely packed fiber network with high porosity and open structure.

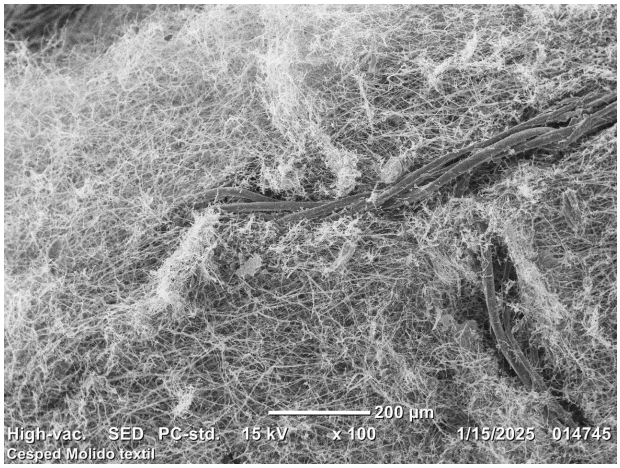

Figure 6. SEM image of the GT sample at 100× magnification. Exposed textile fibers remain largely uncovered by mycelium, suggesting limited adhesion or colonization.

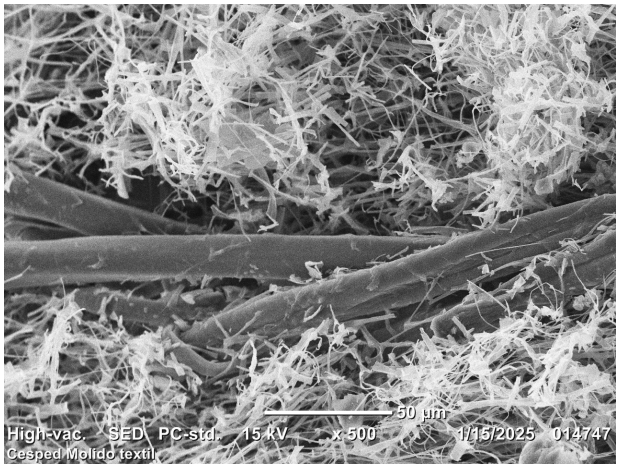

Figure 7. SEM image of the GT sample at 500× magnification. The mycelium grows around but not across the textile fibers, maintaining distinct fiber contours.

Composites with textile strips (Figs 8–10) show a more compact microstructure. Large woven threads and continuous regions of dense material are visible. At higher magnification (Fig 9), the textile structure exhibits a low porosity, compared to the GT sample.

The mycelial coverage is extensive in both samples, but the distributions of pores differ. In the GT composite, the broken-down textile allows the mycelium to colonize a fragmented, aerated matrix. In CT and ST, the woven structure may limit the internal pathway for sound wave dissipation.

These findings align with the fact that finer textile processing in GT likely facilitates better air-flow and energy dissipation, whereas the denser structure in CT and ST may restrict sound penetration to some extent, resulting in a somewhat lower absorption performance at higher frequencies.

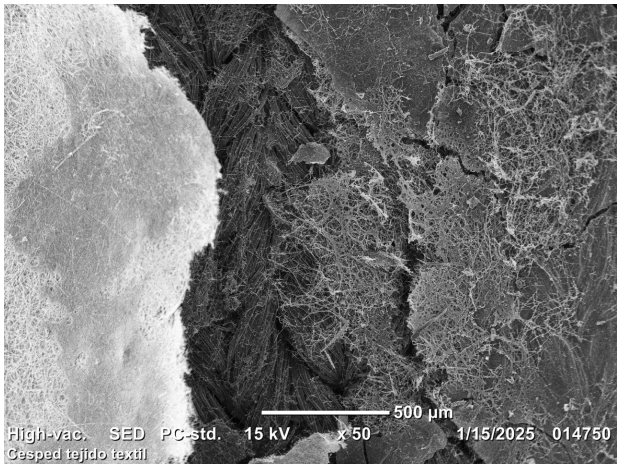

Figure 8. SEM image of the ST sample at lower magnification (50×), highlighting a more continuous and layered surface with reduced structural openness compared to GT.

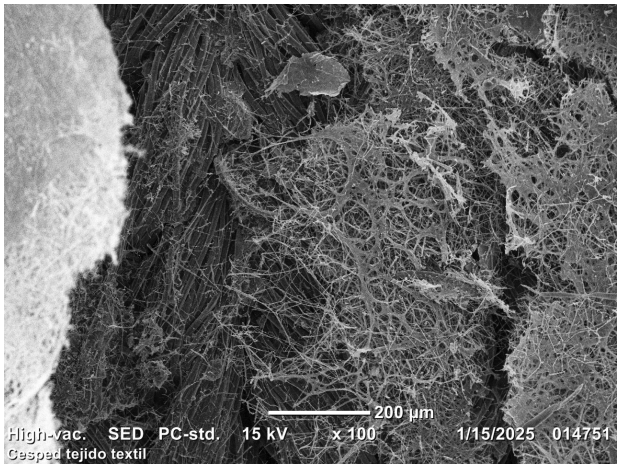

Figure 9. SEM image of the ST (Textile Strip) sample at 100× magnification. Large textile bundles and a more compact structure are clearly visible.

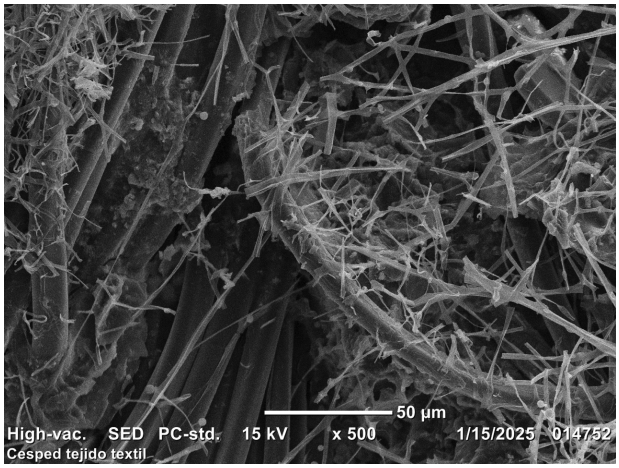

Figure 10. Higher magnification SEM image (500×) of the ST sample, revealing limited porosity and dense fiber regions surrounded by mycelial growth.

4. CONCLUSIONS

This study explored the development and characterization of mycelium-based composites using leaves and grass clippings combined with different forms of textile waste. The influence of textile processing was examined through physical measurements, acoustic absorption testing, and scanning electron microscopy (SEM).

All based composites exhibited high porosity and relatively low bulk density, confirming their potential as lightweight, bio-based acoustic materials. Among the samples, the GT (Ground Textile) formulation showed the most favorable acoustic performance, particularly in the mid-to-high frequency range. This correlated with its lower bulk density and microstructural features observed under SEM, which revealed a more open, irregular internal network with greater void content. In contrast, CS and CT samples presented slightly denser structures, with larger, more continuous fibre zones and moderately reduced sound absorption.

These results suggest that substrate processing plays a critical role in defining the physical and functional behavior of mycelium composites. Loose fibres appear to enhance porosity and acoustic absorption by promoting a more penetrable internal structure for sound wave dissipation. Overall, the findings provide preliminary support for the viability of mycomaterials as sustainable alternatives for acoustic applications, with

potentially adjustable properties through substrate formulation.

5. ACKNOWLEDGMENT

This project has received funding from the European Union's Horizon Europe research & innovation programme under the HORIZON-MSCA-2021-DN-01 grant agreement No. 101072598 – "ActaReBuild".

ABSTRACT

This study investigates the sound transmission loss (STL) and absorption performance of a membrane-type metamaterial layer through a series of controlled experiments. Measurements were conducted in an impedance tube to independently characterize the STL and absorption properties of the metamaterial layer. Based on the results from numerical simulations and impedance tube measurements, a larger-scale prototype layer was designed and tested in a transmission room configuration, for verifying the potential for application as part of acoustic insulation solutions in retrofitting applications.

Keywords: *membrane-type acoustic metamaterials, sound transmission loss, architectural acoustics, impedance tube measurement, transmission chamber test*

1. INTRODUCTION

Low-frequency noise insulation presents a significant challenge in building acoustics, particularly in lightweight structures where traditional solutions often fall short in performance. Due to its long wavelength, low-frequency sound can efficiently propagate through walls, making it difficult to attenuate using conventional porous absorbers. Increasing mass is an effective way to improve sound insulation, but in many applications, especially in retrofitting, adding substantial weight is neither practical nor desirable.

In retrofitting applications, where modifications to existing structures are constrained by space, weight, and cost, improving low-frequency sound insulation is particularly challenging. Common strategies involve adding additional panels, integrating resilient layers for decoupling, or incorporating insulation boards. While these approaches can enhance sound insulation in certain frequency ranges, they may also introduce resonance effects that degrade performance in others [1].

Acoustic metamaterials have been explored as a complementary solution to conventional sound insulation approaches by utilizing locally resonant mechanisms to enhance STL in targeted frequency bands [2–5]. Among them, membrane-type metamaterials have attracted increasing attention due to their ability to achieve strong low-frequency sound insulation with limited added mass. These metamaterials typically consist of a tensioned membrane with an attached mass, forming a resonant system that blocks sound transmission at specific frequencies [6]. Despite extensive studies on the fundamental properties of membrane-type metamaterials, their large-scale application in building acoustics remains unexplored. Most existing research has focused on numerical modeling and small-scale impedance tube measurements, with limited investigations into their performance

in configurations relevant to architectural acoustics.

This study investigates the sound transmission loss and absorption performance of a membrane-type metamaterial layer through a series of controlled experiments. The primary objectives are:

- To evaluate the STL and absorption properties of the metamaterial layer through impedance tube experiments.
- To compare numerical simulations with experimental results.
- To assess the effectiveness of a scaled-up prototype for practical building applications.

These studies lay the groundwork for future research and fine-tuning of metamaterial designs for practical applications.

2. EXPERIMENTAL AND NUMERICAL METHODS

2.1 Membrane Material

A commercially available black rubber sheet with a nominal thickness of $1\,\mathrm{mm}$ was used for the membrane, selected for its accessibility rather than specific mechanical properties, as detailed parameter measurements were not available. The density of the rubber was estimated through simple mass and volume measurements, yielding a value of $1590\,\mathrm{kg\,m^{-3}}$ with an uncertainty of $40\,\mathrm{kg\,m^{-3}}$.

2.2 Impedance Tube Measurements

The impedance tube (see Fig. 1), custom-made by KFB Acoustics for studying this case, has an internal acoustic passage diameter $102\,\mathrm{mm}$. A sample holder with steel rings was designed to clamp the membrane, with the membrane's outer diameter being $122.5\,\mathrm{mm}$.

The membrane samples for the impedance tube, as shown in Fig. 2, were manually cut and bonded to two steel rings on each side for structural support, ensuring a fixed boundary condition for the impedance tube experiments. The edges of the ring-rubber-ring sample were polished smooth, and slight unevenness was introduced during manual fabrication. The pretension in the membrane was assumed to be small, as the manual stretching process aimed only at flattening the membrane without inducing significant pre-stress. Additionally, modified samples were prepared by attaching one or two identical cylindrical steel masses ($1.85\,\mathrm{g}$ each, $10\,\mathrm{mm}$ diameter, $3\,\mathrm{mm}$

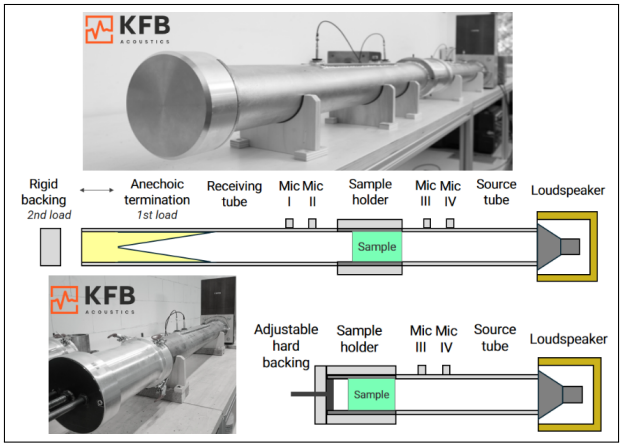

Figure 1. Impedance tube set-up for sound transmission loss and absorption measurements.

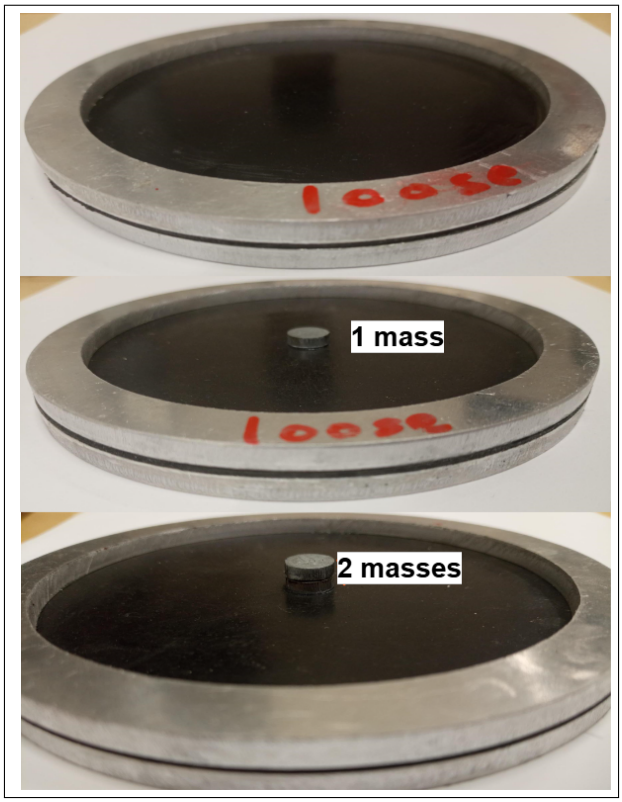

Figure 2. Membrane samples using the same $1\,\mathrm{mm}$ rubber: (1) plain membrane, (2) with one central mass ($10\,\mathrm{mm}$ diameter, $3\,\mathrm{mm}$ thick), (3) with two stacked masses (total $6\,\mathrm{mm}$). Edges clamped with steel rings.

thickness) at the membrane center. Two such masses were stacked in the two-mass configuration, resulting in a total thickness of 6 mm.

The test frequency range spanned from 50 Hz to 1600 Hz. White noise was used as the excitation source, with its level carefully adjusted to avoid nonlinear effects and prevent structural vibrations of the tube or mounting components. Each experiment was repeated three times for the sake of checking consistency.

For the STL measurements, a four-microphone configuration was employed, with an anechoic termination to minimize reflections, following ASTM E2611 [7]. Absorption measurements utilized a two-microphone setup with a rigid backing, in accordance with ISO 10534 [8]. The rigid backing distance from the sample was adjustable to explore different resonance conditions by varying the air gap between the membrane and the backing. In this study, two air gap configurations were tested, with the rigid backing positioned to create an 50 mm air gap and an 100 mm air gap.

Prior to testing, a reference measurement was conducted with an empty tube. The results confirmed that the presence of the steel rings did not introduce significant effects on measurements within the selected frequency range.

2.3 Impedance Tube Simulation

Numerical simulations were conducted using the finite element method (FEM) in COMSOL Multiphysics [9] to analyze the sound transmission loss and absorption performance of the membrane-type resonator. The simulation follows the impedance tube approach in [10] with modified material parameters and implementation. Specifically, incident wave excitation and non-reflecting boundaries were replaced by port-based plane wave excitation and termination, ensuring accurate sound power calculations. Additionally, the membrane was modeled with the Shell Module to capture its flexural motion. The tube was assumed to be rigid, and the membrane edges were set to fixed, consistent with the experimental setup.

Two simulation configurations, as illustrated in Fig. 3, were implemented to correspond with the experimental setups:

- Sound Transmission Loss Simulation: The impedance tube was modeled as a cylindrical waveguide with an internal diameter of 102 mm, matching the actual acoustic passage in the experiment. The STL was obtained by calculating the ratio of incident to transmitted acoustic power at the respective ports.
- Absorption Simulation: A rigid backing was introduced at a controlled distance behind the membrane to investigate absorption characteristics. The absorption coefficient was determined by subtracting the ratio of reflected to incident acoustic power from one at the input port.

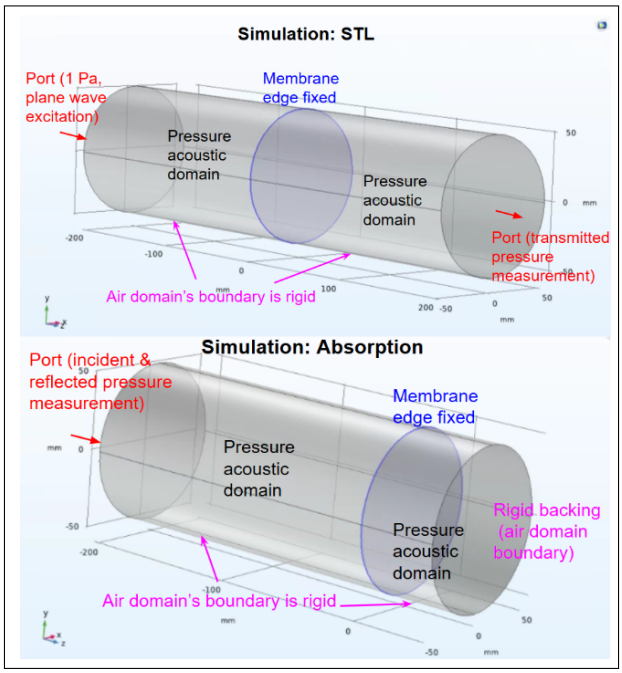

Figure 3. Schematic of the simulation setup of the impedance tube.

The computational domain was discretized using free tetrahedral elements with normal resolution, following built-in mesh size calibration for general physics applications. The number of degrees of freedom in the simulation ranged from approximately 2977 to 3033, depending on the configuration.

Since the exact viscoelastic properties of the rubber membrane were unknown, the material parameters in the simulation were taken from [11], which measured a similar type of rubber. However, these measured values have significant uncertainties, meaning the chosen parameters are only rough estimates. As a result, any differences between the simulation and experiment may be partly due to inaccuracies in the material properties.

2.4 Transmission Chamber Test

The transmission loss measurements were conducted in the V1 Laboratory test stand at the Acoustic Research and Innovation Centre (KFB Acoustics, Poland), designed for measuring airborne sound insulation of vertical partitions and components according to ISO 10140 with standardized window openings. The experimental facility is shown in Fig. 4.

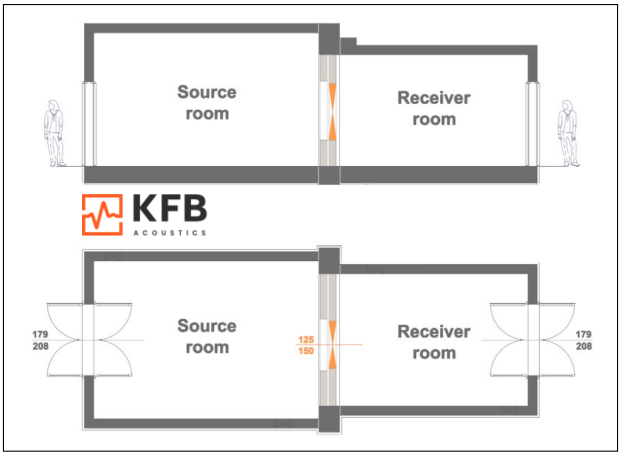

Figure 4. Experimental facility for the transmission chamber test.

Seven configurations were examined:
(1) Steel: a 1.5 mm thick steel plate
(2) Rubber: a 1 mm thick rubber layer
(3) Rubber–Air Gap–Steel: a 1 mm rubber layer with a 50 mm air gap and a steel plate
(4) Membrane Metamaterial: a 1 mm rubber layer supported by a perforated 1.5 mm steel frame with circular cutouts (102 mm diameter, 30 mm spacing)
(5) Membrane Metamaterial–Air Gap–Steel: the metamaterial with a 50 mm air gap and steel plate
(6) Metamaterial + Mass: the metamaterial with a central steel mass in each unit cell
(7) Metamaterial + Mass–Air Gap–Steel: the metamaterial with masses, plus a 50 mm air gap and steel plate.

All samples were mounted in a wooden frame to maintain consistent boundary conditions. As shown in Fig. 5, configuration (6)—a metamaterial with central masses—serves as a representative example of the tested samples, which were assembled within a standardized test window (1250 mm × 1500 mm).

Measurements were conducted following standardized procedures to evaluate the STL of large-scale samples. Two measurement approaches were employed to ensure both standardized evaluation and high-resolution analysis:

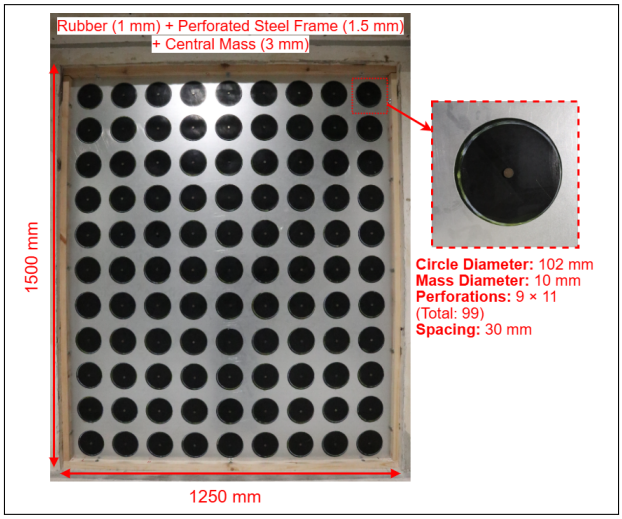

Figure 5. Configuration (6): membrane-type metamaterial consisting of a 1 mm-thick rubber layer and a perforated 1.5 mm-thick steel frame (9 × 11 circular cutouts, 102 mm diameter, 30 mm spacing), with a central steel mass (10 mm diameter, 3 mm thick) in each unit cell.

- Method 1 (ISO 10140 [12]): A calibrated omnidirectional loudspeaker generated white noise. Reverberation time (RT60) as measured via the interrupted noise method at six microphone positions. The STL measurements were performed using the Norsonic Nor850 Measurement System with a rotating boom for spatial averaging. Additionally, microphone signals were split: one for 1/3-octave band processing, the other recorded for finer-resolution post-processing.
- Method 2 (ISO 18233 [13]): A custom logarithmic sine sweep (40 Hz–2000 Hz, 10 s duration + 5 s silence) was used as excitation, played from the same loudspeaker. The signal was played and recorded using the Head Acoustic SQuadriga III module. Measurements were conducted with fixed loudspeaker and microphone positions to maintain time-invariance. The STL was computed based on the difference in impulse responses measured in the source and receiving rooms, while RT60 was de-

rived using the Schroeder integral method. This method enables post-processing in both 1/3-octave bands and finer resolution (every 5 Hz).

3. RESULTS AND DISCUSSION

3.1 STL and Absorption in Impedance Tube

Impedance tube measurements for STL and absorption (Fig. 6, Fig. 7) provide insights into membrane acoustic performance.

As observed in Fig. 6, even the plain rubber sample exhibits a notable STL peak around 200 Hz, reaching approximately 14 dB. This peak can be attributed to the lowest vibrational mode induced by the fixed boundary conditions at the sample's edges. Apart from its resonance, the overall STL trend increases with frequency, which aligns with the expected mass-law trend of a single material layer.

Introducing a small steel mass at the membrane center modifies the vibrational response, leading to a shift of the main STL peak toward lower frequencies. The STL magnitude at resonance is also enhanced, indicating improved low-frequency isolation. Using two masses amplifies this effect, showing that localized mass can tune the membrane's resonance behavior, as also reported in literature [14].

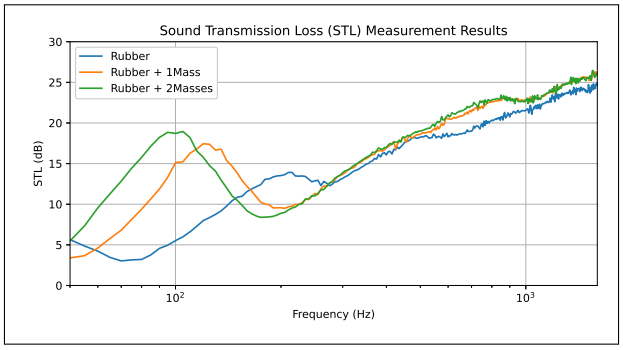

Figure 6. Impedance tube measurement for sound transmission loss of three rubber samples.

The absorption coefficients of the samples, measured under different air gap configurations (50 mm and 100 mm), are presented in Fig. 7. The plain rubber membrane exhibits multiple absorption peaks, with the first low-frequency peak becoming more pronounced and shifting to lower frequencies as the air gap increases, suggesting a significant membrane-cavity interaction, with the membrane as mass and the air cavity as a spring. The second peak corresponds to the membrane's structural mode, which is less affected by the air gap.

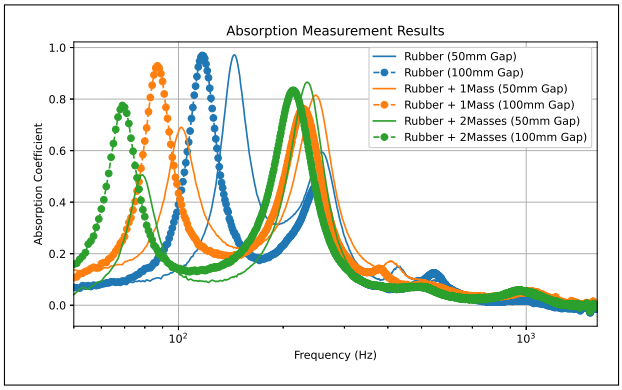

Figure 7. Impedance tube measurement for absorption of three rubber samples under different air gap configurations.

When a single steel mass is added, the first absorption peaks move to lower frequencies, similar to the trend seen in the STL results. This suggests that the added mass changes the membrane's resonance, affecting how it interacts with the backing cavity. With two masses, the resonance shifts further to lower frequencies, although the absorption amplitude becomes smaller.

To further validate the impedance tube results, another rubber sample without added mass was tested, and its STL and absorption performance were compared with simulations, as shown in Fig. 8 and Fig. 9. Due to the differences in experimental setups—STL measured for the membrane alone and absorption measured with a 50 mm air gap and a rigid backing—the two cannot be directly compared. However, both experimental and simulated results revealed a complementary relationship between STL and absorption.

In the STL results, the simulation captures the first and second resonance peaks observed experimentally, while the absorption simulation identifies three primary peaks, aligning well with the measurements. The main STL peak and absorption peaks appear in similar frequency regions, confirming that the numerical model accurately represents the essential resonance behavior of the membrane.

This complementary relationship is reflected in the resonance characteristics: STL peaks correspond to absorption dips, as strong resonance blocks sound transmis-

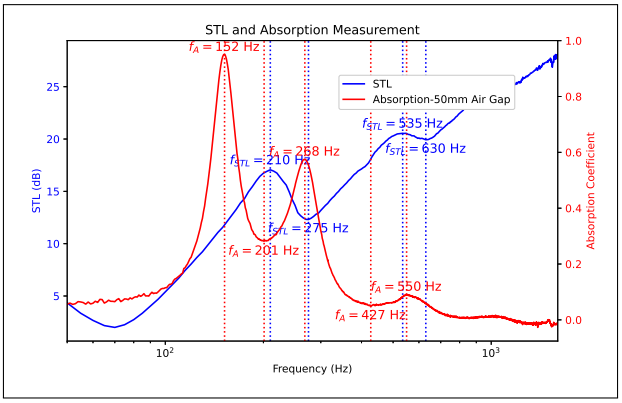

Figure 8. Measured sound transmission loss (STL) and absorption coefficient of a rubber sample without added mass. Peaks and dips are marked to indicate resonance behaviors.

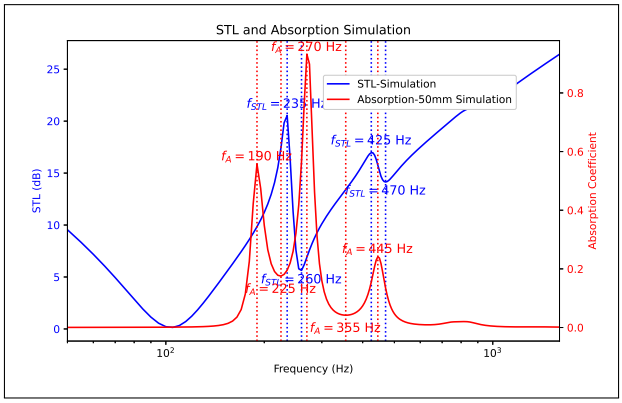

Figure 9. Simulated STL and absorption coefficient of a rubber sample without added mass. Marked peaks and dips highlight resonance effects captured in the model.

sion but increases reflection, reducing energy dissipation. Conversely, absorption peaks occur when the membrane couples more effectively with the backing cavity, enhancing energy dissipation and reducing STL. However, in the STL experiment, the membrane vibrates without the rigid backing, so while STL and absorption show a complementary trend, their peaks and dips don't always align.

It is further important to recognize that the precise values of STL and absorption in the simulation are highly dependent on the assumed material parameters. Factors such as mass per unit area, elastic properties, pre-stress conditions, and damping characteristics can all impact the frequency and amplitude of the response. Though not detailed here, these factors are relevant for future model refinement.

3.2 STL Results in the Transmission Chamber

Figures 10 and 11 show STL measurements in 1/3-octave bands from the transmission chamber, obtained using the Norsonic analyzer for both single-layer and double-layer configurations, with the single value Rw included.

In the single-layer case (Figure 10), the steel panel shows the highest STL across the full frequency range, following the expected mass law behavior. In contrast, the much lighter rubber panel exhibits significantly lower STL. A dip around 80 Hz for both steel and rubber may result from the coupling of the room and sample. It should be noted that results below 100 Hz are presented for informational purposes only, as they fall outside the effective measurement range of the laboratory setup, where uncertainties in the data may arise. The membrane metamaterial (rubber bonded to a perforated steel frame) improves the STL over plain rubber, performing better above 160 Hz. The dip observed around 80 Hz for steel and rubber appears shifted in the metamaterial, likely due to changes in resonance behavior. Adding a central mass to the membrane further enhances the STL below 200 Hz, indicating a local resonance mechanism.

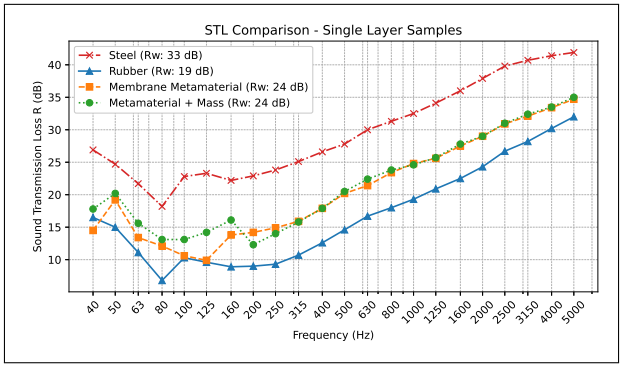

Figure 10. STL of single-layer samples measured using the Norsonic analyzer.

The double-layer samples (Figure 11) represent a more realistic wall structure, consisting of a decoupled cavity between a front rubber layer and a steel panel. Compared to single-layer configurations, the rubber–air–steel structure already achieves higher STL in the

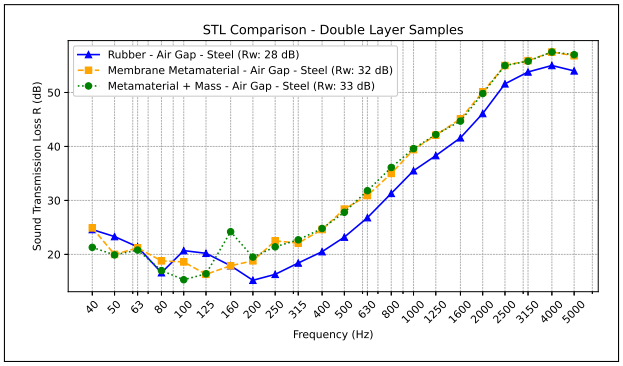

Figure 11. STL of double-layer samples measured using the Norsonic analyzer.

mid-to-high frequency range due to added mass and decoupling. However, a low-frequency dip appears around 200 Hz, resulting from the mass-spring-mass resonance, within the range predicted by a typical resonance calculation (e.g., [[1]]).

Replacing the rubber layer with a membrane metamaterial, the 200 Hz dip of the rubber–air–steel configuration becomes less noticeable. The overall STL improves in the mid-to-high frequency range, due to increased surface density. More significantly, the metamaterial introduces an STL enhancement around 250 Hz, attributed to local resonance effects. Adding a central mass shifts the resonance to around 160 Hz, improving the STL by about 6 dB compared to the rubber–air–steel configuration at this frequency.

The low-frequency STL enhancement observed in the transmission chamber is consistent with impedance tube measurements. In both setups, adding a central mass shifts the dominant resonance toward lower frequencies and increases STL, though the resonance peaks appear at different frequencies due to boundary conditions and interactions with the surrounding frame and air cavity.

This confirms that locally resonant metamaterials can improve sound insulation in both idealized tube and realistic large-scale wall applications.

To complement the standardized ISO 10140 measurements, two alternative methods—noise recording and swept-sine signal excitation—were used to extract the level difference between the source and receiver rooms at finer frequency resolution. The level difference improvement, shown in 1/3-octave bands (Figure 12) and at finer frequency resolution (Figure 13), quantifies the increased isolation achieved by the metamaterial samples compared to the rubber reference.

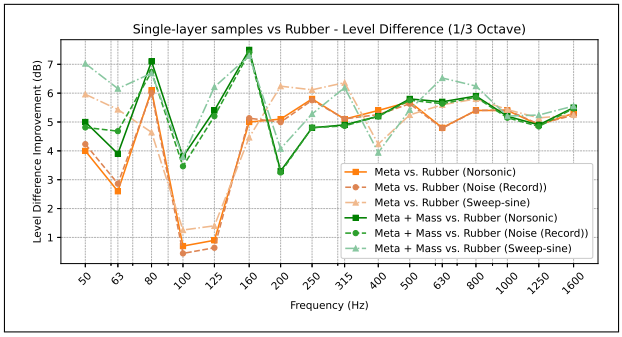

Figure 12. Effect of single-layer metamaterial samples on sound pressure level difference between source and receiving rooms, compared to the rubber reference, in 1/3-octave bands using three methods.

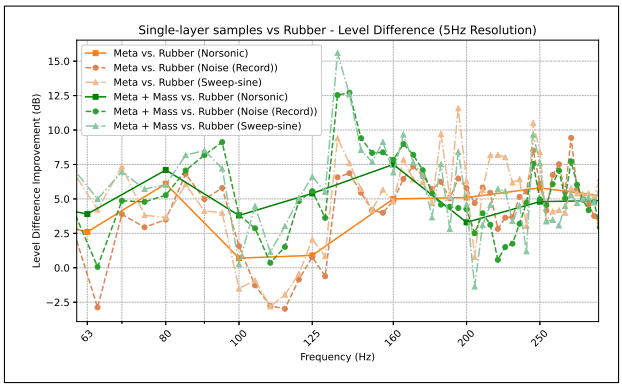

Figure 13. Level difference improvement (60–300 Hz) of single-layer metamaterials over rubber, 5 Hz resolution.

In 1/3-octave bands, all methods show similar trends. The noise recording data aligns well with Norsonic data, while swept-sine shows greater deviation. At finer resolution (5 Hz), swept-sine reveals sharper low-frequency peaks, suggesting better sensitivity to local resonance, although small mismatches due to timing, filtering, or noise remain.

Given the current stage of development, the ISO 10140 method provides the most stable and interpretable data for comparison across configurations and is therefore used as the primary dataset in this study.

4. CONCLUSION

This study investigated the sound insulation performance of a membrane-type acoustic metamaterial layer through a combination of numerical simulations, impedance tube measurements, and scaled-up transmission chamber tests. The results confirm the presence of low-frequency STL enhancement due to local resonance effects, particularly when central masses are added to the membrane. These effects were consistently observed across both small and large experimental configurations, demonstrating the metamaterial's potential for application in lightweight and retrofittable wall systems.

Despite the promising results, several limitations remain. Variations in sample fabrication, limited control over membrane pretension, and measurement uncertainties—especially in fine-resolution methods—may affect the accuracy of the results. Additionally, material parameter uncertainties in simulations restrict direct quantitative comparisons.

Future work will focus on improving sample consistency, refining structural designs to better control resonance frequencies, and implementing higher-precision measurement workflows. These developments aim to further explore and optimize the practical application of membrane-type metamaterials in building acoustics.

ABSTRACT

This study investigates the effect of load plate mass on the dynamic stiffness determination of resilient materials used in acoustic applications, specifically through the single mass method outlined in ISO 9052-1. The standard method, primarily designed for materials under floating floor conditions, may not be applicable for acoustic material stiffness determination in constructions used in cavity dampening solutions (e.g. wall linings) or heavy machinery foundations, due to differing load conditions. The study aims to assess how varying load plate masses influence the apparent dynamic stiffness of several resilient materials, including EPS, mineral wool, wood fibre, and foamed polyurethane elastomers. Experiments were conducted using load plates with total mass range from 0.868 kg to 7.665 kg . The results show a significant reduction in dynamic stiffness when the material is subjected to lower loads. Notably, for lighter load plates, nonlinearities and contact disruptions between the load plate and the material were observed, impacting the accuracy of dynamic stiffness measurements following the ISO 9052-1 measurement procedure. This study highlights the importance of considering load conditions when interpreting dynamic stiffness values in acoustic applications, especially in structures like double walls, where load and deformation conditions differ from those prescribed in ISO 9052-1.

Keywords: *dynamic stiffness, load plate mass effect, experiment, case study).*

1. INTRODUCTION

The ISO 9052-1 standard [1] is frequently employed in building acoustics to determine the dynamic stiffness of resilient materials. Originally, this method was specifically designed for evaluating materials used beneath floating screeds, particularly those with smooth surfaces laid in a continuous layer. However, the applicability of this standard is limited to materials subjected to compressive loads between 0.4 kPa and 4 kPa. It is therefore unsuitable for materials experiencing lower loads, such as those found in wall cavities, or higher loads, such as in machinery foundations. Despite these specified limitations, dynamic stiffness values obtained using the ISO 9052-1 method are often referenced in studies analysing the sound insulation performance of lightweight wall systems to often used to predict the mass-spring-mass resonance frequency, even though the materials in such constructions are subjected to markedly different loading and boundary conditions. This inconsistency prompted us to investigate the extent to which variations in compressive loading influence the dynamic stiffness of resilient materials. Understanding this relationship is particularly relevant when examining how loose-form resilient materials contribute to a wall's

acoustic behaviour. This need has been repeatedly emphasized in cases of studying the stiffness of loose form materials implemented in double [2–4] walls, but also in the case of research related to the stiffness of ETICS [5]. Building upon findings reported in previous studies [6, 7], we hypothesized that resilient materials exhibit reduced stiffness under lower loads. The mechanical behaviour of elastic, soft, and porous materials is often complex and subject to varying interpretations. Their apparent stiffness is influenced not only by the degree of compression or applied load [8], but also by the boundary conditions under which the material is installed [9, 10]. In particular, the material's response is affected by factors such as the sealing of contact surfaces, the geometric dimensions of the resilient layer, and the compliance or stiffness of the applied load mass. These variables can significantly alter the measured stiffness, complicating the evaluation of the material's performance in real-world applications. This study highlights the importance of considering load conditions when interpreting dynamic stiffness values in acoustic applications, especially in structures like sandwich panels, where load and deformation conditions differ from those prescribed in ISO 9052-1. The case study focusing on how the mass of the load plate affects the measured dynamic stiffness of commonly used resilient materials is presented in this paper.

2. CASE STUDY DESCRIPTION

2.1 Materials under test

A case study was conducted with the objective of comparing commonly utilized resilient materials frequently encountered in practical applications. The investigation accounted for the assumption that material stiffness would decrease under reduced loading conditions. The materials selected for evaluation were as follows:

All test samples had a lateral edge dimension of 0.20 m, except for the PU elastomer sample, which measured 0.10 m. Testing procedures were conducted in accordance with ISO 9052-1, with minor deviations: no plaster intermediary layer was applied between the steel plate and the material sample (goal was to simulate boundary conditions similar to conditions applied in dry building processes), and the interface between the test base and material was not sealed. These deviations are not expected to significantly influence the experimental outcome, as the primary aim was not the precise quantification of dynamic stiffness, but rather to examine the influence of varying load magnitudes on relative stiffness variation, particularly in the context of resonance response behaviour.

Table 1. Thicknesses of individual resilient materials.

Material	thickness in m
EPS	0.04
XPS	0.04
Light MW	0.02
Heavy MW	0.01
Wood Fibre Board	0.01
PU Elastomer	0.025

Figure 1. Example of a measurement setup - measurement of a sample marked Light MW.

2.2 Measurement setup and procedure

Three types of loading plates were employed in the testing. Two plates had dimensions of height × 0.20 m × 0.20 m and masses of m_{lp1}= 7.665 kg and m_{lp2}= 1.263 kg, respectively. The third plate had dimensions of height × 0.19 m × 0.19 m and a mass of m_{lp3}= 0.868 kg see (Fig. 1). The motivation behind this variation of unequal surface dimension case was to assess the effect of localized deflection in the damping material at the periphery of the load plate on

the measured dynamic stiffness. A logarithmic frequency sweep signal was applied to excite the specimens using a shaker, and the resulting data were extrapolated to a zero-force amplitude condition. Excitation was provided by a TIRAvib 50018 shaker driven by a TIRA E60 analog power amplifier. The dynamic response was captured using a Dytran 3055B2 accelerometer and a Dytran 1051V1 force sensor, with data acquisition handled via NI 9234 hardware. Data analysis was performed using an automated routine developed in MATLAB.

3. RESULTS

A series of dynamic stiffness measurements were performed for selected resilent materials that can be encountered in practice in horizontal and vertical building structures. The measurements were performed using three different load plates as explained in the previous chapter. Apparent dynamic stiffness was determined by extrapolation to zero excitation force in agreement to standard [1] (see Fig. 3). Individual resulting dynamic stiffness values are presented in Tab. 2.

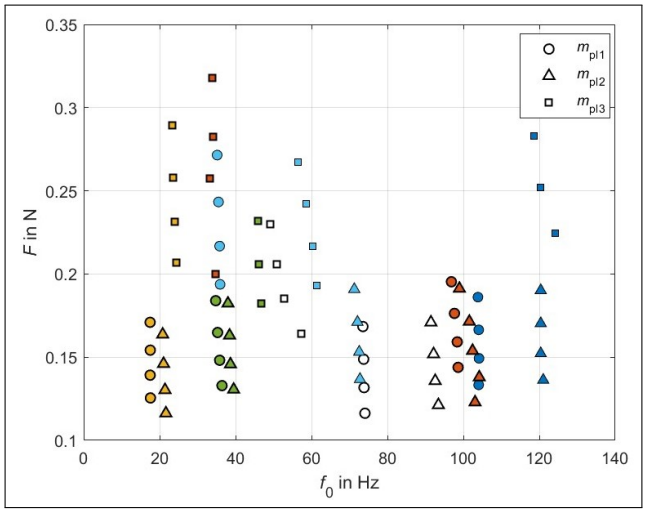

Figure 2. Measured resonance frequencies for three load plate variants and individual material types. Markers sequentially indicate the specific load plate used during the experiment: ○ - m_{lp1}; △ - m_{lp2}; □ - m_{lp3}. Materials are color coded - EPS (white); XPS (dark blue); Light MW (yellow); Heavy MW (green); Wood Fibre Board (red); PU Elastomer (light blue).

First of all, it should be noted that the use of a low-mass load plate can be associated with several problems. The first is the self-resonance of the load plate. The used load plates had their first natural resonance frequency in free boundary conditions (steel plates only) at frequencies $f_{0,\mathrm{m,lp1}}$=1942 Hz, $f_{0,\mathrm{m,lp2}}$=331 Hz and $f_{0,\mathrm{m,lp3}}$=367 Hz. Therefore, it is important to have the assumed resonance of the measuring system under strict control when evaluating selected materials. As was shown in the experiments, the effect of reducing the load had such a significant effect on the reduction of stiffness that resonance phenomena always occurred in the region below 130Hz.

Here, a second important note was opened: the assumption is that individual materials will show significantly lower stiffness when loaded by a light plate. This is related to the compression of the tested samples due to the pull. Zhou has already addressed this issue [6].

The third complication is the bouncing of the plate with a low mass. Of course, applying a thin layer of plaster could have helped slightly here to achieve a better connection of the load plate and the individual layers. However, since the aim was to test the samples under conditions that can be encountered in dry construction processes as well as in applications in vertical structures (e.g. wall cavities, double walls), plaster was not additionally applied. The aforementioned bouncing of the load plate was already evident at low excitation values in the materials Wood fibre boards, EPS and XPS. This was of course also reflected in the results themselves. Table Tab. 2 presents a significant decrease in stiffness recorded in all samples by reducing the load mass. However, the unsystematic behaviour of the resonance response was evident precisely in the mentioned relatively stiffer materials

The PU Elastomer sample had smaller area dimensions than each of the load plates. In this case, the effect of the load on the resulting actual stiffness of the resilient material was clearly demonstrated. The dynamic stiffness, depending on the type of load plate, decreased from 43.56 MN/m^3 to 18.94 MN/m^3. The loading effect effect was of course also evident in the MW type fibrous materials. In this case, load plates 1 and 2 had the same area dimensions as the area of the damping pad. Here, the actual stiffness decreased from 2.37 to 0.71 MN/m^3 and from 12.5 to 2.29 MN/m^3, respectively. Since load plates 2 and 3 have the same mass per unit area (24 kg/m^2) but different contact areas, we could expect slight differences in the determined results of the actual dynamic stiffness in this case. In both cases, MWs showed a slight increase in stiffness by applying m_{lp3} (3 to 28 %). This can be explained by the effect of increased flow resistivity on the resulting actual stiffness

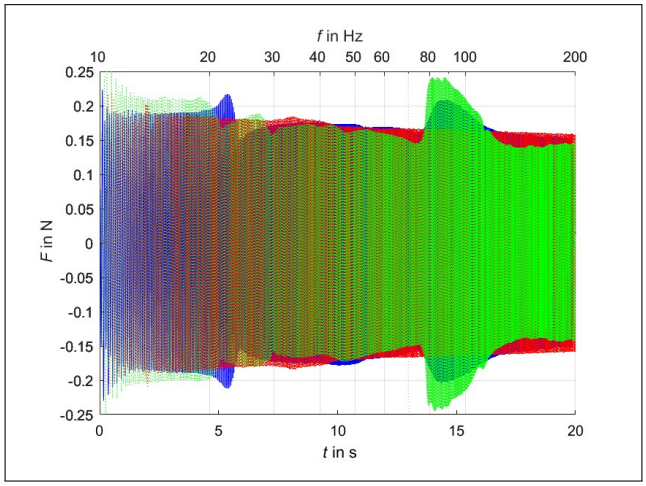

Figure 3. Example of a time record of force during logarithmic sweep excitation. Tested material XPS. Load plate type applied was color coded - m_{lp1} (red); m_{lp2} (blue); m_{lp3} (green);

of the sample as well as local overpressure of the sample at the edge of the light load plate. A similar effect can also be observed for the XPS sample. However, this result must be taken with a "grain of salt" since the XPS had a lattice texture on the surface.

Table 2. Determined dynamic stiffness depending on the load.

Material	s' in MN/m^3		
Load plate	m_{lp1}	m_{lp2}	m_{lp3}
EPS	42.78	11.95	5.52
XPS	82.81	18.63	19.82
Light MW	2.37	0.71	0.91
Heavy MW	12.5	2.29	2.36
Wood Fibre Board	81.61	14.84	1.21
PU Elastomer	43.56	29.35	18.94

4. CONCLUSIONS

This study investigated the effect of the weight of the load plate on the determination of the dynamic stiffness of soft materials used in acoustic applications, in particular according to the method defined by ISO 9052-1. The results showed that reducing the weight of the load plate leads to a significant decrease in the measured dynamic stiffness. This effect was particularly pronounced for materials with higher elasticity. However, this was due to the occurrence of nonlinearity associated with the interruption of contact between the plate and the material. This is very important, for example, for accurate prediction of $f_{\text{m-s-m}}$, which plays a role in evaluating the low-frequency performance of building elements.

Especially in vertical structures such as wall cladding or double walls, the materials are not exposed to the same load as in floor structures. Therefore, it is necessary to develop or recommend a measuring set-up that can accurately determine the actual stiffness of these materials. This set-up must: - eliminate the effect of the shaker pressure, which can affect the accuracy of the measurement, - ensure permanent contact between the load plate and the damping material even without the use of a gypsum layer.

The obtained results show that current measurement methods can distort dynamic stiffness values, especially under low load conditions, thus underlining the need to develop a more suitable variation of measurement techniques for soft structural elements loaded by low mass in various applications.

ABSTRACT

The development of sound absorbers made from PET fibres from recycled PET bottles presents a cheap and attractive solution for building retrofit applications. PET fibres of about 2-4 mm width are processed into a structure through random compaction and heat treatment, resulting in a sample that retains its shape. The normal incidence sound absorption coefficient of the samples was derived through measurements in an impedance tube, exhibiting potential effectiveness as a sound absorber. An innovative application of this material is the creation of transparent devices. This unique feature allows for sound attenuation without sacrificing natural light infiltration, addressing the common conflict between acoustic treatment and daylight access in architectural design. These items can serve as transparent partitions, sound absorbers, or design gadgets for lighting in areas near windows. Furthermore, using recycled PET fibres not only contributes to waste reduction but also promotes sustainability in construction, aligning the research's aim with contemporary environmental goals. By offering functional aesthetic solutions that enhance both acoustic comfort and visual appeal, these PET fibre-based sound absorbers hold potential for improving the habitability of retrofitted spaces.

1. INTRODUCTION

The polymerisation process yields polyethylene terephthalate (PET), which involves two main chemical reactions: 1) esterification Reaction: this involves the reaction between terephthalic acid and ethylene glycol; 2) trans-esterification Reaction: The latter process involves the reaction between ethylene glycol and dimethyl terephthalate. In both processes, the resulting product is PET in the form of a molten, viscous mass. This can then be spun into fibres or extruded and moulded into various shapes. Commonly used for beverage packaging, polyethylene terephthalate (PET) bottles have found interesting applications. Their unique material properties, such as lightweight, durability, and ease of manipulation, make them suitable for acoustic applications. Mainly, researchers have explored the use of PET bottles in constructing sound-absorbing panels, resonators, and diffusers. These applications leverage the inherent characteristics of PET to enhance sound quality and control noise reflection in different environments. There may be some environmental advantages to using PET bottles in acoustics. For example, recycled PET bottles are used to make PET felt acoustic panels, which helps keep plastic trash out of landfills. This recycling method reduces the total environmental impact by using less water and energy compared to producing new fabric materials. The current manuscript explores the idea of using a material made from PET bottles that uses even less energy. PET felt panels also emit fewer volatile organic compounds (VOCs), which improves the quality of the air indoors. These panels' resilience and recyclability contribute to their sustainability and support a circular economy. Several studies have demonstrated the effectiveness of PET bottles in acoustic applications. One study investigated the acoustic properties of rigid polyurethane foam mixed with shred-

ded PET bottle waste, finding that the composite material exhibited improved sound absorption properties [1]. Another study highlighted the use of PET felt acoustic panels, which are made from recycled PET bottles and offer enhanced acoustic performance along with environmental benefits [2]. Additionally, research has shown that PET bottle-based materials can be used to create effective sound diffusers. A study explored the use of PET bottles filled with different materials to create Helmholtz resonators, which were found to significantly improve sound absorption at specific frequencies [3]. Another investigation focused on the use of PET bottles in HVAC systems as Helmholtz resonators, demonstrating their potential to reduce annoyance from ventilation ducts [4]. These examples underscore the potential of PET bottles in creating sustainable acoustic solutions.

2. MATERIALS AND SAMPLES

The samples were prepared starting from plastic PET bottles fraied using a tool developed in the Applied Acoustics Laboratory (Figure 1). In this way, it was possible to obtain long PET filaments that were 0.5 mm thick and 4 mm wide.

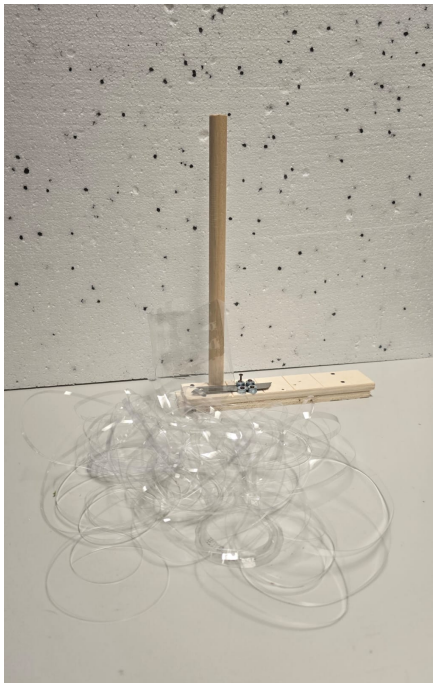

Figure 1. Tool used to obtain the PET filaments.

The filaments were placed inside the sample holder, an aluminium tube with a diameter of 46 mm and a length of 100 mm. Given the stiffness of the PET filaments, they cannot remain in place inside the tube because they tend to regain the original shape. For this reason, the PET filaments and the sample holder were placed inside an air fryer for 5 minutes at a temperature of about 80 °C. As shown in Figure 2, at the end of the thermal treatment, the sample could easily keep the desired dimensions and was ready to be tested in the impedance tube.

Figure 2. Example of a sample after thermal treatment and a 100 mm sample ready to be tested in the impedance tube.

3. EXPERIMENTAL SETUP

3.1 Impedance tube measurements

We tested the sample in a four-microphone impedance tube in accordance with the ASTM E2611 standard [5]. The applied technique allows the determination of the sound pressure and particle velocity at either side of the sample and thus its transfer matrix. As standard results, the normal incidence sound absorption, and the Transmission Loss (TL) of the sample are available at the end of the testing procedure. Nonetheless, the available results

can be extended to other quantities, like the wave number, the speed of sound in the material, the surface impedance, and the characteristic impedance (inside the material). For the preliminary study presented in the current manuscript, only the sound absorption and the TL will be presented and discussed.

At one endpoint of the tube, a loudspeaker generates a wide-band white noise test signal. The tube mounts the sample for testing in its central section, sandwiched between two pairs of microphones. You can equip the tube's second endpoint with either anechoic or reflecting termination, enabling you to conduct tests with two distinct boundary conditions. Being able to compare signals from four microphones helps to separate the sound wave into the parts that are coming in and bouncing back on both sides of the sample. The custom-made impedance tube consists of two segments of length 1200 mm and internal diameter 45 mm. The corresponding cross-section allows keeping the plane-wave assumption valid up to about 3800 Hz. The source endpoint features a loudspeaker of 100 mm enclosed in a sealed volume, while the second endpoint can be connected to a rigid reflective termination or to an anechoic termination. The microphone ports for high-frequency measurements are spaced 45 mm apart; the ports for low-frequency measurements are spaced 500 mm. The sample can be placed in a separate segment of tube of the most appropriate length, which can subsequently be installed between the two measurement sections described above. Four BSWA Type MPA416 microphones housed in o-ring-equipped ports have been used. The diaphragm of the microphones is recessed with respect to the side wall of the tube. We connect the transducers to an OROS Type OR36 analyser, which measures the complex transfer functions between the microphones. During the measurements, the coherence function is also monitored to check that the signal-to-noise ratio is high enough over all the frequency range of interest. The white noise employed as a test signal is generated by the analyser itself.

For symmetric samples, only a single boundary condition for the tube termination is necessary. To avoid strong standing waves, we decided to apply a soft end boundary condition (as much absorbing as possible) in the case at hand. The standard procedure adopted in the laboratory implies switching the microphones positions to correct the transfer functions for amplitude and phase mismatches. This time a new calibration system was developed and tested so that all the necessary corrections between the reference microphone and the other three can be computed only once, avoiding having to repeat the measurement four times. The part of the tube representing the calibration section of the tube was 3D printed using a Bambu Lab A1 Mini with a Bambu PLA filament (Figure 3). The calibration device is placed in the central section of the tube, as in the sample case.

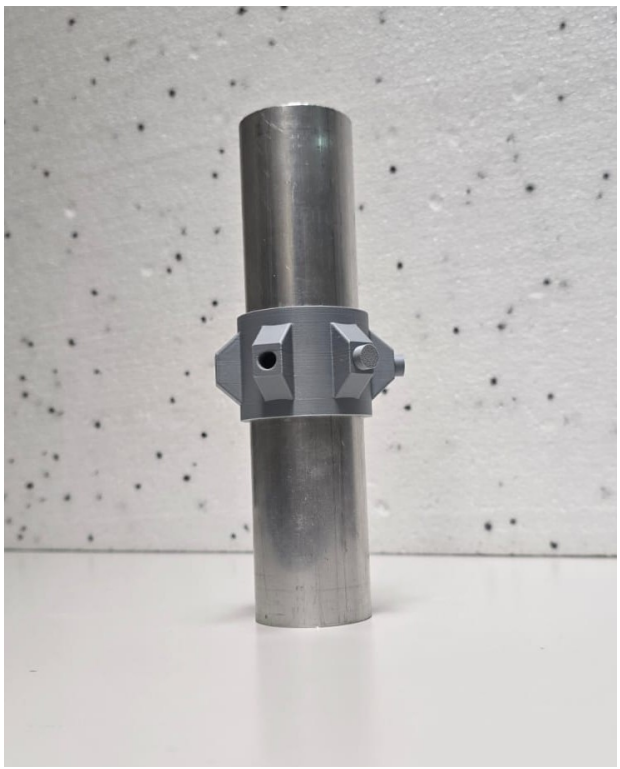

Figure 3. Calibration device.

4. RESULTS AND DISCUSSION

Figure 4 shows the normal incidence sound absorption coefficient for the tested sample. A sample inside a four-microphone impedance tube behaves like a 1/4 wavelength resonator. This means that at room temperature, for a 100 mm thick sample, an absorption resonance should occur at around 850 Hz. In the case at hand, the absorption coefficient curve shows a maximum at 610 Hz, meaning that the celerity of the sound wave is slowed down by the tortuosity of the material. As a matter of fact, the speed of sound in the material has an asymptotic behaviour, with a maximum celerity of 244 m/s (Figure 5). This allows us to determine also the tortuosity of the sample, which results in being around 2.

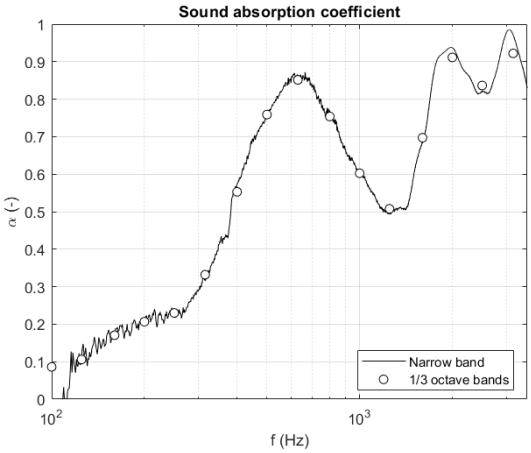

Figure 4. Normal incidence sound absorption coefficient.

The sound absorption graph shows good values also above 600 Hz, with a decrease of the coefficient around 1250 Hz ($\alpha = 0.5$) and then a sudden increase to values of 0.92, 0.84 and 0.92 for the 2000 Hz, 2500 Hz and 3150 Hz 1/3-rd octave frequency bands.

Finally, Figure 6 shows the TL values. The sample is so porous and light that the resulting insulation is lower than 6 dB in the investigated frequency range. for this reason, if the PET filaments must be used as soundproofing material, it would be necessary to improve the mass per unit area and lower the porosity.

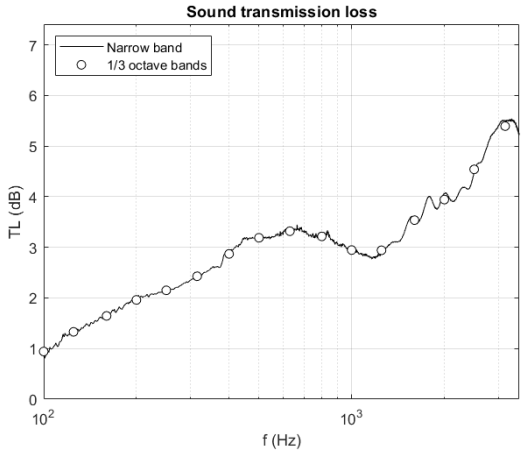

Figure 6. Transmission loss

5. CONCLUSIONS

The experimental analysis of PET filaments from plastic bottles using a four-microphone impedance tube has yielded interesting results regarding their acoustic properties. The findings indicate that PET filaments exhibit excellent sound absorption capabilities, making them a promising material for applications requiring effective noise reduction in confined spaces. The advantage of this type of material is that since it is transparent it allows the light to come through so it can be a potential solution for making windows less reflective. However, the sound insulation performance of PET filaments was found to be suboptimal, suggesting that while they can absorb sound efficiently, they are less effective at preventing sound transmission.

These results highlight the potential of PET filaments in environments where sound absorption is critical without sacrificing natural light infiltration, such as in acoustic panels for correction of rooms placed close to windows. Nevertheless, for applications where sound insulation is equally important, further modifications or alternative materials may be necessary to achieve the desired acoustic performance. Future research should focus on enhancing the sound insulation properties of PET filaments or exploring composite materials that can offer a balanced combination of sound absorption and insulation.

ABSTRACT

Assessment of the building envelope quality in terms of airtightness and sound insulation is a critical factor to properly design an optimal retrofitting action plan. Therefore, the development of reliable and non-destructive measurement techniques for assessing these factors pre- and post-retrofitting is a crucial milestone, impacting costs, precision, and time efficiency. This study explores the use of an acoustic camera in evaluating airtightness performance in residential buildings. A measurement campaign was conducted across two houses in Valladolid, Spain, integrating blower door tests, smoke generator, and acoustic camera methods to assess air leakage and its interplay with sound transmission. The main goal of this research case study is to better understand the interplay between airtightness and acoustic performance within a real building façade.

1. INTRODUCTION

One of the main goals of building retrofitting is to improve a building's energy performance. Air infiltration is widely recognized as a major cause of energy loss, typically occurring through façade cracks or construction defects. According to recent European studies, air leakage may account for 30–50% of the total energy consumption in the building sector [1]. Therefore, addressing infiltration points is essential during the renovation process. Accurately identifying the location of these cracks and quantifying their impact is critical to planning effective retrofitting strategies, and post-retrofit evaluations help determine the success of such interventions. Currently, no single method exists that can both quantify and localize air infiltration in building envelopes. Traditional methods such as the blower door (fan pressurization) test are commonly used to estimate the volume of air leakage under an artificial pressure difference [2]. However, this method cannot pinpoint the specific locations of leaks, often requiring additional tools like smoke generators or tracer gases [3]. These combinations are not only time-consuming and costly but also require technical expertise for proper setup and analysis.

In recent years, research has increasingly focused on alternative, non-invasive methods to assess airtightness. One promising approach is the use of acoustic-based methods, which are generally quicker, non-destructive, and potentially more precise. For instance, [4] and [5] used sound pressure level measurements in building acoustic frequency range to assess airtightness and conclude an empirical equation. However, significant

research efforts have been devoted to leak detection and localization, spanning from early work by [6] to recent contributions by [7] and [8]. These efforts have evolved from utilizing basic acoustic equipment to employing modern acoustic cameras and advanced beamforming techniques. Acoustic cameras, based on beamforming technology, offer the added advantage of visualizing leak locations in real time. However, while promising for detection, these methods face challenges in quantifying the infiltration rate. This quantification might be achieved by studying the interplay between sound transmission characteristics and airflow behavior through openings. Although previous studies highlight the complexity of this relationship [9], [10], [11], advances in acoustic technology may pave the way toward a practical solution. To explore this potential further, experimental campaigns must be conducted to test modern tools like acoustic cameras in real-world settings. The present study aims to contribute to this effort by demonstrating the effectiveness of acoustic methods in evaluating airtightness. Our work follows the direction of earlier studies and contributes modestly to ongoing efforts aimed at improving diagnostic tools for building envelope assessment.

2. METHODOLOGY

The method consisted in using an acoustic camera as measurement device to identify the potential air leak points, assuming that air leaks, under special conditions, should produce sound. Although the type of sound produced at air leak points could be different depending on the physical origin (forced air or real sound) the position of the air leak points should be coincident.

2.1 Overview

The measurement campaign was conducted in two occupied residential buildings located in Valladolid, Spain. These buildings were selected to represent typical Spanish multi-family housing stock, with conventional building envelopes and standard terrace window installations.

House 1 was a two-story family home in a residential compound. This unit served as a baseline scenario, without any specialized ventilation features as shown in Fig.1 and Fig.2. **House 2**, was a second floor of typical apartment in a mid-high residential building in Valladolid City, as depicted in Fig.3, featured micro-ventilation openings integrated into its terrace window frames. Both houses underwent a full testing sequence including pressurization, depressurization, and sound transmission analysis using both sides of the façade internally and externally. For House no.2 the measurements were performed with the micro-ventilation openings in both open and closed positions to study their impact. A smoke generator test was also performed in both houses to visually confirm major leakage points identified acoustically.

2.2 Equipment

The experimental campaign employed three main types of equipment: a blower door and an omnidirectional sound source as “exciting devices” and an acoustic camera as measurement device. Additionally, a portable smoke generator was used to visualize air leaks.

The blower door system used combined with a DG-700 digital pressure gauge as shown in Fig.4. This system allowed for controlled pressurization and depressurization of the interior space by creating artificial pressure differentials of 50 Pa and 80 Pa, thereby forcing air infiltration through leaks and enabling airflow quantification through the envelope which could then be localized using the acoustic camera.

An omnidirectional sound source, as depicted in Fig.2, was also used during the measurement campaign to try to identify airborne sound leakage paths. This device emitted broadband white noise within a range of 40 Hz to 16 kHz and was placed strategically inside or outside the dwellings depending on the test configuration. The noise served as a reference signal to help determine the extent and location of sound transmission paths through the façade.

To localize potential leakage paths and visualize sound transmission, the HEAD VISOR 7500ff acoustic camera was utilized shown in 3 and a schematic drawing of it illustrated in Fig.5. This high-resolution beamforming system consists of a 56-microphone spiral array paired with three synchronized industrial cameras. The system operates over a wide frequency range from 300 Hz to 20 kHz, offering both real-time and post-processed visualization of sound sources. The portable smoke generator was used to release non-toxic visible smoke into the interior space during pressurization / depressurization. Leakage paths were identified by observing smoke escaping through façade discontinuities from the exterior / interior. This method provided a qualitative visual reference to complement the acoustic recordings.

2.3 Measurement procedure

In both houses the same measurement protocol was followed to ensure comparability between test cases. For House 2, the measurement protocol was performed twice to analyze the impact of window micro-ventilation

features: first with window micro ventilations closed and then with window micro ventilations open. This enabled a comparative analysis of acoustic and airflow behavior under varying boundary conditions, offering insight into how these small architectural features influence both airtightness and sound insulation

The measurement protocol was the following:

The Acoustic Camera (AC) was placed outside the house in front of the terrace window (as in Fig.1 and Fig.3) and measurements were made under different excitation conditions:

- No forced excitation: This set up was chose to assess environmental noise and thus establish baseline acoustic conditions. These preliminary recordings helped identify uncontrollable ambient noise sources—such as birds, street traffic, or nearby recreational areas—and allowed later to filter them out during analysis. In each configuration, at least two or three random baseline recordings were performed to improve the robustness of the dataset.
- Blower door mounted to force air in/out potential leak paths: the blower door was installed in the main entrance of the apartment to enable full control over the internal pressure. Blower door tests were then conducted in both pressurization and depressurization modes at pressure differentials of 50 Pa and 80 Pa. During each steady-state phase, the acoustic camera recorded for 30 seconds to capture noise emissions through the façade.
- Omnidirectional speaker placed inside the house and activated to emit white noise, simulating real-world sound transmission while the acoustic camera recorded also for 30 seconds to capture noise emissions through the façade.

Additionally, for House 1 the measurements related to the blower door tests were repeated placing the acoustic camera inside the house to assess the influence of directionality on leak detection and source visualization.

3. RESULTS

All the images shown in this section correspond to a specific moment within a preselected short time period (2 to 3 seconds) and within a selected limited frequency range. The acoustic camera software allows to analyze the video recording filtering both according to a selected frequency range and to a selected time period. Results shown have consistently been observed over time and over different frequency ranges as it will be explained hereinafter.

3.1 SPL peaks spots within House 1

Fig.6 and Fig.7 show persistent SPL peaks in the same position (upper right section of the terrace window frame), in different moments and under blower door pressurization 50 Pa conditions. This position is also seen when performing the smoke generator test integrated with blower door as shown in Fig.8. These SPL peaks points were found across multiple frequency bands and are shown for the following intervals: 580–715 Hz and 1647–1829 Hz. Due to its position on the edge of the window frame, these spots are preliminary identified as potential air leakage spots.

On the other hand, when using the sound source as an excitation signal, a sound peak is detected close to the previous location across the frequency band of 1016–1211 Hz as shown in Fig.9. Due to its position slightly away from the frame edge and directly on the window (curtains behind the sound peak shown in figure 10), it is not considered a potential air leakage spot but rather an external sound reflection or glass vibration.

When the tests were performed with the blower door under depressurization conditions (50 Pa and 80 Pa) and the acoustic camera was placed inside the house, SPL peaks were detected exactly between window frames 1 and 2, as shown in Fig.10 and Fig.11, notably in higher frequency band: 4833–5695 Hz. Other sound peaks have been identified within different time periods and across different frequency bands as summarized in Tab.1. All these spots shown in Tab.1 are potential air leakage spots due to their position.

1759 – 2143 Hz	1759 – 2143 Hz	2169 - 2750 Hz	2169 - 2750 Hz	2699 - 3836 Hz	2699 - 3836 Hz
					

3.2 SPL peaks spots within House 2

The evaluation of House No. 2 focused on verifying and analyzing air leakage detected visually via smoke generator. Fig.12 shows two key locations where fog was observed to come out when the fog generator was used inside the house. Fig.13 identifies the upper frame area as position A and the lower frame zone between adjacent window segments as position B. In fact, position B corresponds to the position of a small open/close micro-ventilation opening.

Both air leaks have been consistently detected by the acoustic camera independently of the type of excitation used (pressurization/depressurization at 50/80 Pa or loudspeaker). The leaks are seen at specific frequencies which need to be identified among the full data set. For example, sound pressure level peaks were consistently identified at position A in the frequency band of 1412 - 2120 Hz and at position B in the 1000 - 1841 Hz band. Some of these findings are summarized in Tab.2 and Tab.3, which compile results across various test conditions. Similar images are found at different moments within the full recording periods.

When the sound source is used as excitation signal, a SLP peak is also observed at the same location but at a higher frequency band of 3387 - 4112 Hz as shown in Fig.14.

As mentioned earlier, in some of the acoustic camera tests conducted in House 2, the micro-ventilation feature on the window was intentionally left open. As it can be seen in Tab.4, the SPL values increase in all cases when the micro-ventilation is open, as it was expected.

4. DISCUSSION

4.1 House 1

The results from House 1 can be used to discriminate whether a SPL peak corresponds or not to an air leakage path. To support this type of classification, we refer to the study by Schiricke et al. [12], which introduced the Acoustic Assessment Score (ASS). This score ranges from 0 to 3 and is used to assess the likelihood that a detected peak corresponds to a real leakage point—helping distinguish between unlikely and likely leakage sources. In this case study three different SPL peaks spots have been identified:

The SPL peaks shown in Fig.6 and Fig.7 (upper right corner of the window façade) is located on the edge of the frame and aligns with the smoke generator results, strongly supporting the conclusion that, at this location, there is an air leakage path.

On the contrary, the SPL peak observed in Figure 10 is located over the glass. Since the glass was visually inspected and confirmed to be intact with no cracks or defects, this signal is likely the result of structure-borne sound or vibration rather than air leakage.

Lastly, another SPL peak zone was consistently identified under depressurization conditions, at a location which was not observed with the smoke generator. This is around the lower edge of the frame, near the junction of both frames. This SPL peak zone was detected very consistently at middle frequencies as shown in Tab.1, but it was more precisely spotted at higher frequencies as shown in Fig.10 and Fig.11. According to its position, it is very likely an air leak path. If we assume this is a crack or infiltration path, it is likely very narrow—possibly too thin to be detected by the smoke method and better detected at higher frequencies. This suggests that the acoustic method is particularly sensitive to small or layered cracks that may not be visible using smoke or fog-based techniques. Lower frequency bands (as shown in Tab.1) also detected the signal, but with less accurate localization.

4.2 House 2

In this house, the analysis focused on validating the leakage locations identified by the smoke generator method using the acoustic camera. The two-leakage points A and B detected with the smoke were confirmed across multiple frequency bands. Additionally, the consistency of such detections within specific frequency ranges suggests a potential link to the type or characteristics of the cracks when analyzing the sound spectral properties at these locations. This needs to be further explored.

Concerning the effect of the window micro-ventilation system whether in open or closed configuration, the results shown in Tab.3 indicate that, even when the feature is closed, there is measurable sound transmission with relatively high sound power. This suggests that air leakage may still occur through the micro-ventilation component even when it is closed. While the system appears to function as intended, the observed sound peaks while not activating it and the difference in sound power between closed ad open cases should be taken into account when evaluating the need for potential renovation or design improvement.

Overall, the acoustic data aligned well with the visual smoke-based observations while offering a more detailed and frequency-sensitive picture of infiltration behaviour, reinforcing the value of acoustic camera data both as confirmatory and diagnostic tool in complex façade assessments.

4.3 General insights

The combined findings from House 1 and House 2 strongly support the feasibility and added value of using acoustic cameras for airtightness evaluation. In both case study, the acoustic camera successfully detected leakage spots confirmed by smoke and, in some cases, it was possible to identify additional narrow leak paths which were visually undetectable with smoke. This detection was observed at high-frequency bands which most likely can provide information about the thin and narrow nature of the leak path. Overall, the findings confirm that acoustic imaging can complement or even exceed traditional air leakage localization methods, especially when visual cues are weak or absent.

The results further emphasize that it is not possible to identify all leakage points in a single acoustic image, as leakage signatures appear at different locations depending on the frequency band. Therefore, it is necessary to have a multi frequency band visualization, where the sound peaks are distributed across the façade, varying between lower and higher frequencies. This observation aligns also with findings reported by Schiricke et al. [12], confirming that a sequence of images across third-octave or narrow-band frequency bands is necessary to detect all potential leakage areas. Therefore, comprehensive leakage visualization requires multi-frequency acoustic analysis to account for the variability in spectral responses caused by differences in geometry, crack size, and flow behavior.

4.4 Further research

Finally, these findings support the work of Schiricke et al. [12], who demonstrated that acoustic cameras could detect small leakage points that are often missed by traditional tools such as blower door tests, smoke generators, or gas tracer methods. However, Kölsch and colleagues highlighted that additional knowledge is still required to reliably distinguish between true leak sources, reflected signals, and airborne sound transmission, especially in complex real-world settings. This remains an open research question and presents a critical avenue for further development.

Therefore, one of the key ongoing tasks in our study is to analyze the spectral characteristics of each confirmed leakage point, with the goal of establishing acoustic signatures or spectral patterns that may correlate with leak size, type, or severity. This spectral approach could form the basis for developing more automated or semi-automated leakage classification tools using acoustic data. As also discussed by Schiricke et al. [12], the spectral fingerprint of a leak may offer valuable diagnostic insight, and future work will aim to explore this potential in depth.

5. CONCLUSIONS

House 1 demonstrated the potential ability of the acoustic camera to show sound pressure peaks that could correspond to subtle air leaks where the smoke testing failed to produce a visual cue. The existence of the sound peak at relatively high frequencies and between the frames most likely corresponds to a fine or narrow leak. This highlights a key advantage: acoustic tools offer higher sensitivity to narrow or complex leakage paths, especially in the mid to high frequency range. House 2 provided an opportunity to evaluate the influence of micro-ventilation features. The integration of multiple source types (blower door and speaker) revealed consistent detection at smoke-identified positions.

Overall, this study shows the potential use of acoustic beamforming as a complementary, or in some cases with further research as independent, tool to traditional diagnostic techniques. Their ability to visualize, localize, and interpret leak behavior in real time provides a user-friendly and highly effective solution for both researchers and practitioners. Importantly, the integration of sound-frequency analysis with pressure-based testing opens the door to more detailed diagnostics that could evolve into hybrid quantification models in the future. Our findings confirm that single-frequency images are insufficient for capturing all leakage paths. A multi-frequency approach is necessary to visualize the full range of leakage behavior.

6. ACKNOWLEDGMENTS

This project has received funding from the European Union's Horizon Europe research & innovation programme under the HORIZON-MSCA-2021-DN-01 grant agreement No. 101072598 – "ActaReBuild". We would also like to express our gratitude to the homeowners for their support and flexibility throughout the testing process

ABSTRACT

In this contribution, we discuss preliminary research results obtained within the framework of one of the ten individual research projects of the EU-MSCA-DN, "ActaReBuild", which focuses on the development of acoustic resonators based on lightweight concrete using recycled aggregates. In particular, we examine using loose granules of flo-pak plastic as material to fill and absorb sound in the resonator cavity. The sound absorption of the granules was measured in a reverberant room and compared with the sound absorption properties of melamine foam, a common porous material of the same thickness. Also the absorption of a wooden resonator (1) filled with melamine and (2) filled with loose plastics was determined and compared to that of (3) an empty resonator. The results show that adding granules in the cavity leads to an increase in resonance frequency, likely due to their closed pores reducing the effective cavity volume and increasing stiffness. Also broadening of the absorption peak is observed.

1. INTRODUCTION

In architectural acoustics, sound absorption plays a key role in regulating the reverberation time, reducing noise levels from sound sources in the room, and improving the overall acoustic quality of a space. By reducing echoes, flutter echoes, and standing waves, sound absorption ensures clarity, comfort, and functionality in various environments, such as auditoriums, offices, classrooms, and recording studios.

In situations when sound containing mid and high-frequencies needs to be absorbed, the usage of porous absorbers is convenient. Typically, the lowest absorbed frequency is the one for which a quarter wavelength corresponds with the distance between the most protruding porous material and the rigid wall behind. In practice, this makes the use of porous materials as absorbers impractical or even impossible for bass frequencies, and the use of resonators becomes necessary. One of the possibilities is the use of a cavity resonator.

Empty Helmholtz resonators exhibit a sharp absorption peak, of which the (typically low) frequency depends on the dimensions of the neck and cavity. The absorption is a consequence of viscous loss effects of the air velocity oscillations in and near the neck. By inserting porous materials, preferably near the neck, additional sound energy is absorbed, broadening the absorption peak.

Besides conventional fibrous and foam-based materials, recycled polymer waste is gaining attention as a promising option for sound absorption. These materials are typically

processed into granular form, influenced by factors such as grain size, and internal structure. These variables can significantly affect the acoustic performance across specific frequency ranges. A classification framework for granular absorbents - such as vermiculite, perlite, granulated rubber, and nitrile foam - was introduced by Voronina and Horoshenkov [1]. Studies show that granules obtained from recycled products like tires and cables offer favorable properties for the development of tailored acoustic solutions. Further evidence of the acoustic viability of recycled rubber granulate comes from Swift and Horoshenkov [2], who demonstrated that rubber crumb not only supports broadband absorption but can also be modeled effectively using a semi-empirical approach that captures both viscous and thermal losses in porous structures. Their findings underline the impact of grain shape, flow resistivity, and packing density on absorption characteristics, especially within mid- to high-frequency ranges.

Notably, plastic granulated materials showed effectiveness in providing relatively wide-band sound absorption [3-5]. By adjusting parameters such as granule size and material thickness, one can fine-tune the absorption peak to align with target frequencies. Research by Bumanis et al. on recycled expanded polystyrene granules revealed efficient sound absorption in the range of 600–700 Hz [6].

Although flo-pak granules - EPS-based loose-fill foam products - have been previously evaluated in terms of their mechanical performance [7], their acoustic behavior has not yet been comprehensively studied. In this work, we consider the use of this type of granules in a way to dissipate acoustic energy in the resonator's cavity, compared to foam material - melamine.

2. METHODS

2.1 Samples preparation

Two resonators were used for measurement, made of MDF (medium-density fibreboard) plates. Each of them had internal dimensions of 100x100x7 cm^3 (Figure 1). The thickness of the perforated plate t = 9 mm, with holes at an axial distance of 20 cm and a hole diameter of 25 mm.

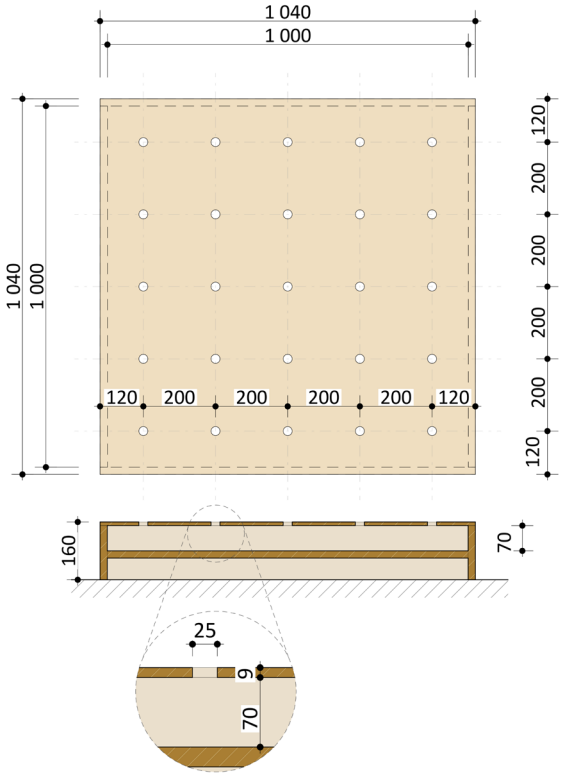

Figure 1. Dimensions of the used resonator (in millimeters)

Two types of porous materials were characterized. The melamine foam (Figure 2a) was used for reference as a well-known open-cell, lightweight foam with a density of approximately 7-11 kg/m³. Melamine foam is widely known for its excellent sound absorption capabilities due to its fine, interconnected pore structure, which enhances sound wave dissipation. The foam used in the study had a dimension of 100x100 cm2 and a thickness of 50 mm.

The sample of main interest consisted of flo-pak granules. The granules have sizes around 10x20x30 mm3, and a variety of different shapes (“S-shape”, “8-shape”). The bulk mass density was 4 kg/m³. This type of loose-fill packaging material is commonly used for cushioning and protecting items in boxes during shipping and handling. Granules are made from both expanded PS (EPS) and extruded PS (XPS). It is a lightweight, rigid, and versatile material. Although this material is often made of recyclable PS and can be reused, it rarely happens, and most of it ends up in landfills or incinerators. For this reason, we found it interesting to look for possibilities of reuse in a new context, i.e. as an absorber in acoustic applications.

Figure 2. Detailed view of investigated materials: Left: melamine foam (cylinder cut out of the 50mm thick panel. Right: Selection of flo-pak granules from the 50 mm loose stack

2.2 Reverberant room measurements

The spectrum of the sound absorption coefficient per 1/3 octave band was determined inspired by the conventional ISO 354 method in the reverberant room. While the reverberant room is suitable for ISO 354 measurements (197 m3), due to practical constraints, the sample surface size (2 m²) was lower than the required size (10-12 m2) Measurements were performed by means of impulse response with exponential sweep signal (duration of 23.8 seconds) generated in the room through an omnidirectional loudspeaker. The acoustic absorption of a flo-pak granules (Fig. 4) layer of about 50mm thickness was characterized both in loose form and as cavity-filling material under a 9 mm thick perforated plate with 25 mm diameter holes arranged on a cubic grid with 20 cm interspacing. The melamine reference layer had a thickness of 50 mm and was tested loose and in the cavity configuration. Also, the empty cavity configuration was characterized. The average of measured sound absorption was based on 18 measurements – 6 microphone positions for each of 3 sound source positions.

The temperature, relative humidity, and atmospheric pressure were carefully controlled during the measurement procedure, and taken into account in the analysis.

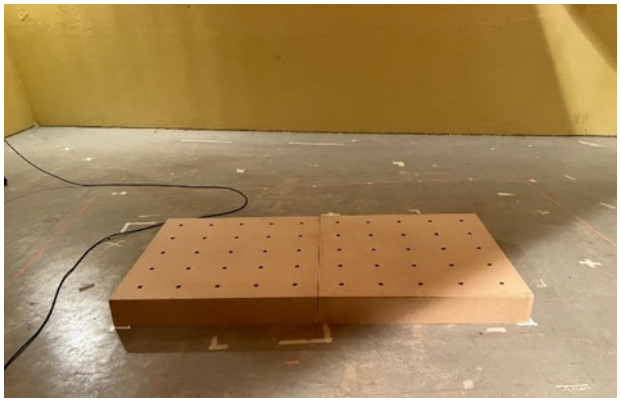

Figure 4. Two adjacent wooden resonators placed in the reverberant room

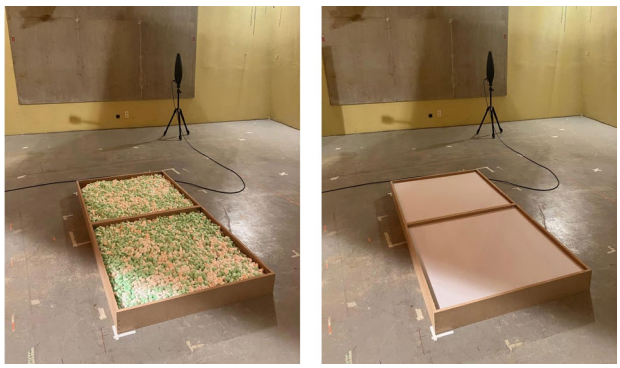

Figure 5. Open resonators with flo-pak granules (left) and melamine foam (right)

3. RESULTS AND DISCUSSION

The sound absorption (α) spectra of the open resonators with porous materials are presented in Figure 5. Melamine foam shows the typical behavior of foam or fibrous porous material, with low α values at low frequencies (α=0.17 at 125 Hz), followed by a gradual increase with increasing frequency, reaching 100% absorption at frequencies of 630 Hz and higher. As expected, due to its much lower porosity and large pores, the absorption of the flo-pak granule layer is substantially lower than the one of the equally thick melamine. Nevertheless, the absorption values between 0.2 and 0.8 across the audio range give the potential for using recycled flo-pak granules for acoustic absorption applications. The weakly pronounced maximum around 1250 Hz, combined with a speed of sound of 340 m/s of the air in the large pores, corresponds with a quarter

wavelength of 7 mm, a bit more than 5mm, the nominal thickness of the flo-pack layer.

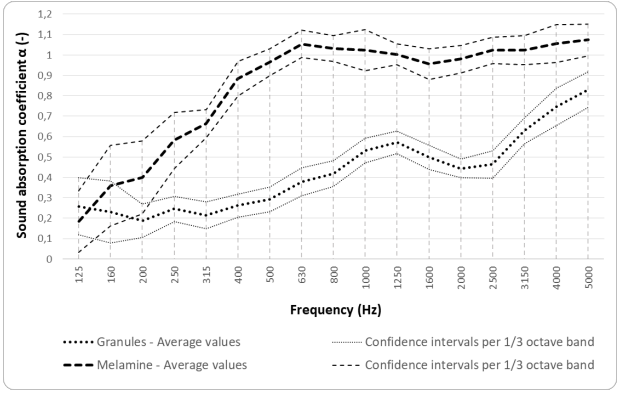

Figure 6. Sound absorption spectrum of a 50 mm layer of melamine foam (dashed line), and flo-pak granules (dotted line)

The α spectra of the perforated panel resonator with different filling conditions are presented in Figure 6. Combining the dimensions of the resonator (Figure 1), its resonance frequency can be calculated as [8]:

$$f_r = \frac{c}{2\pi}\sqrt{\frac{A_{perf}}{A_{panel}.d_{cavity}.t_{eff}}}$$

where c is the speed of sound in air (340 m/s) and teff = t + 2δr = 0,02325 m with $\delta = 0.85(1 - 1.47\varepsilon^{1/2} + 0{,}47\varepsilon^{3/2}) = 0{,}57$. $\varepsilon = A_{perforation}/A_{panel}$ denotes the porosity of the plate. The calculated value of the resonance frequency (140 Hz) is consistent with the sound absorption peak (α=0.55) of the empty resonator in the 160 Hz 1/3 octave band.

Compared to the empty cavity, filling the resonator with flo-pak granules induces a shift towards the 200 Hz-250 Hz 1/3 octave bands, in accordance with the effect of a reduction of the free cavity volume due to the granules. The absorbing function is similar to the one of the empty resonator (α=0.57), but it acts across a wider frequency range.

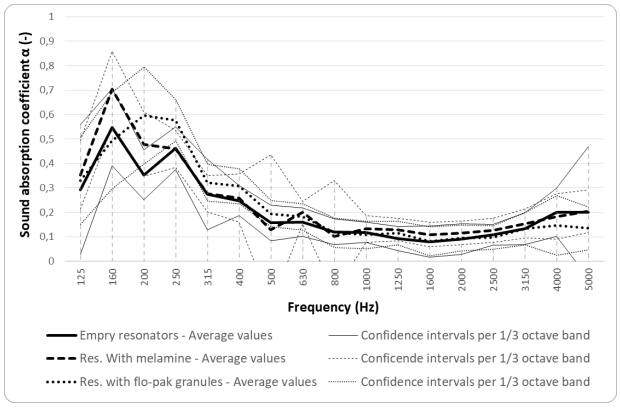

Figure 7. Sound absorption spectrum of the perforated panel resonator with different cavity filling conditions: melamine foam (dashed line), flo-pak granules (dotted line), and empty (solid line)

4. CONCLUSIONS

This study explored the potential of recycled plastics in acoustic resonators, focusing on flo-pak granules as cavity fillings and comparing them to melamine foam. The results confirm that granule filling influences the resonator performance, increasing the resonance frequency (as a consequence of the reduced free volume) and broadening the absorption peak.

As expected, also filling the resonator cavity with melamine increased damping. Still, the overall absorption remained relatively low, possibly due to insufficient perforation or improper placement of melamine (2 cm gap between the melamine and perforation).

The sample dimensions were smaller than the standardized sizes required by ISO norms, which may have influenced the absorption measurements by reducing the overall impact of the material on the acoustic environment. While these recycled materials offer promising applications for sound absorption, challenges remain in optimizing their performance. Future research will focus on refining cavity-filling configurations, analyzing the dynamic stiffness of granules, and conducting larger-scale measurements to assess their viability in real-world noise mitigation solutions.

ABSTRACT

Due to different environmental challenges, using sustainable materials has become increasingly important. Mycelium-based materials show promising potential in many applications within architecture, such as sustainable acoustic absorbers. Here we present results on the acoustic and thermal performance of mycelium panels that use paper waste as substrate for the growth of Pleurotus Ostreatus. Regarding the substrate choice, the potential application of the widely accessible residue material in combination with acoustic application was examined. Mycelium-based materials show a sustainable life cycle, which is amplified by using residual materials as a base. The panels were created using different growing times and mixtures of inoculated and non-inoculated substrate and dried in convection ovens to deactivate the fungi and remove the moisture excess. Samples were tested using an in-situ method with a Pressure-Particle velocity probe (PU probe). The acoustic absorption turns out to be highly dependent on the processing method, growing time and mixture use, though overall maximum absorption is found around 1kHz. The thermal conductivity was found to be around 0.07 W/(m.K).

1. INTRODUCTION

The increasing urgency of environmental challenges has led to a growing interest in developing sustainable and functional materials. Mycelium-based composites have emerged as a particularly promising class of biomaterials due to their biodegradability, renewability, and ability to repurpose waste. Formed from the filamentous root structure of fungi, mycelium can bind together various lignocellulosic substrates into lightweight, insulating, and biodegradable composites. Their potential as an alternative to conventional, resource-intensive construction materials positions them at the forefront of sustainable innovation in architecture and design [1].

Among the various applications of mycelium-based materials, acoustic conditioning is gaining traction. Mycelium panels have shown significant sound absorption capabilities, particularly in the mid-frequency range around 1kHz, making them suitable for use in interior environments seeking eco-friendly acoustic solutions. The structure of the mycelium network, combined with the porosity of the substrate, contributes to these properties. Traditional acoustic materials such as fiberglass and polystyrene often come with health or environmental drawbacks, thus supporting the application of mycelium as a safer, greener alternative [1].

Most fungal strains used for the development of mycelium composites are saprotrophic Basidiomycota, thus, nutrient-rich lignocellulosic materials such as wood, hemp, straw, or cotton are effective substrates for mycelium growth [2]. Paper waste, an abundantly available lignocellulosic material, was chosen as the substrate for this research. Cultivating mycelium on paper waste has substantial potential to be a cheap and sustainable solution. Paper waste follows a complex life cycle, typically beginning as virgin fiber harvested from trees and processed into paper products for packaging, printing, or hygiene purposes. After use, a part of this material enters recycling streams, while the rest, especially low-grade or contaminated paper, ends up in landfills or incinerators, contributing to carbon emissions. Even when recycled, paper fibers degrade in quality, eventually becoming unsuitable for further reuse and becoming a waste burden. Repurposing this terminal-stage paper waste as a substrate for mycelium growth presents a sustainable alternative that intercepts the material before disposal. Rich in cellulose, this waste becomes a nutrient source for fungal colonization. Using waste cardboard and paper not only diverts significant volumes of material from landfills but also enhances the circular economy by transforming low-value residues into high-performance biomaterials [3]. Moreover, this approach reduces the environmental footprint of the material production process and opens up possibilities for decentralized, local manufacturing of building materials.

The fabrication of mycelium composites requires careful control of several variables, including substrate composition, moisture levels, pH, temperature, and sterilization procedures. Failure to optimize these conditions can result in contamination, uneven growth, or insufficient binding strength. Research has shown that substrates rich in cellulose and hemicellulose, like paper products, can support fungal growth, especially when paired with fungi such as Pleurotus Ostreatus [1], [3].

Recent studies have also highlighted the role of processing variables such as growing time and the use of mixed inoculated and non-inoculated substrate batches. These parameters significantly affect the mechanical and acoustic properties of the final composites [2]. For instance, longer growth periods typically lead to denser mycelial networks [4], while different substrate blends can influence porosity and structural cohesion. Post-growth treatments like oven-drying are critical to halting fungal activity and stabilizing the material [3], [5].

This paper investigates the performance of mycelium panels grown on wastepaper substrates in combination with fungal species Pleurotus Ostreatus, emphasizing their acoustic absorption and thermal conductivity and the influence of different parameters. Section 2 defines the methodology followed to develop the mycelium composites and the techniques used for its characterization, section 3 includes the results and discussion on the materials performance.

2. MATERIALS AND METHODS

2.1 Materials and sample preparation

Shredded paper and Pleurotus Ostreatus spawn were acquired from the Universidad Politécnica de Madrid recycling center and by a local provider in Spain, respectively.

The general procedure for the development of the mycelium composite consisted in different stages: sterilization of the substrate, inoculation and mixing, cultivation and a drying process.

Paper was introduced into a pot with water taking it to the boiling point for approximately two hours to reduce potential contamination. After cooling, mycelium spawn and the sterilized substrate were mixed in a food processor, avoiding paper paste lumps and distributing the mycelium spawn in the substrate, resulting in a looser and lighter texture. The mix was filled into 3D printed square molds, of 15 x 15 x 4 cm^3, with small openings on four sides allowing for airflow, promoting uniform growth. The samples were placed inside a curing chamber, which kept the humidity at relative 90%, and the temperature at 22°C. Upon reaching the desired growth time, the samples were dehydrated in a convection oven at a temperature of 40˚C until reaching constant weight. Fig. 1 shows a generalized procedure on the mycelium composite development process.

Three different mycelium composite types were developed. In all cases the amount of mycelium spawn, substrate and the total mass of the mixture before drying were kept constant at 68.5% for paper waste and 31.5% mycelium spawn and 0.4 kg for the total mass of the composite, corresponding to a density of 0.44 g/cm^3.

The main variable was the incubation time, Group A was let to grow for 4 days, group B for 14 days and group C 19 days. Fig. 2 shows a diagram of the compositions and growing time for each sample group.

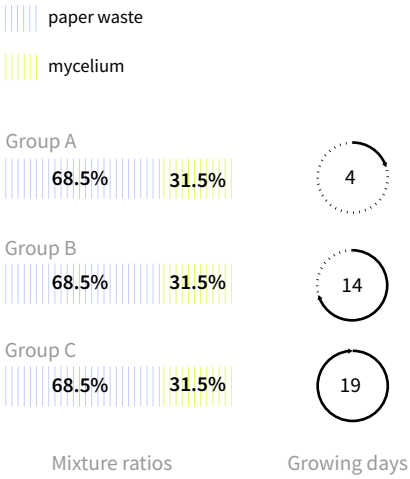

Figure 1. Generalized paper-based mycelium composite developing process.

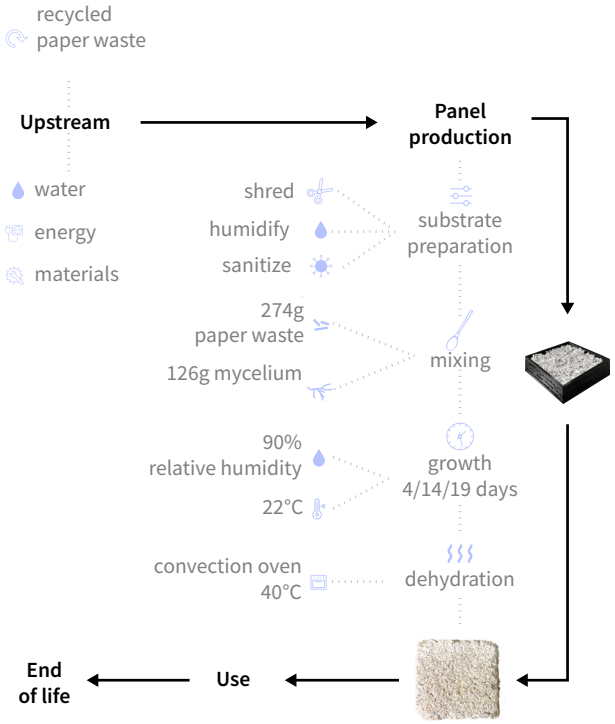

Figure 2. Mixture ratio and growing times for different paper-based mycelium composites.

2.2 Sound absorption coefficient

A Microflown Technologies' PU impedance gun (In-situ sound absorption testing setup), was employed to perform sound absorption measurements. This equipment includes a spherical loudspeaker along with a combined pressure and particle velocity sensor (PU probe). The measurements were conducted across a frequency range of 500 Hz to 8 kHz. During the tests, the loudspeaker generated broadband noise, and the PU probe simultaneously captured pressure and velocity data. The plane wave model was selected for calculating the sound absorption coefficient in this study, owing to its minimal sensitivity to variations in the measurement environment and the distance between the probe and sample surface, as well as its alignment with results from the impedance tube method [6]. Atmospheric conditions (pressure and temperature) were integrated into the model. While reflections from surrounding objects could theoretically influence outcomes, their effect was negligible in practice due to the proximity between the sample and the PU probe. Nevertheless, prior to measurements, the impedance gun was calibrated under free-field conditions to minimize interference. The absorption coefficient was determined as the average of three measurements conducted at the sample's. center.

2.3 Thermal conductivity

The thermal conductivity of the samples was measured using the heat flow meter method. A heat flow meter model HFM 436 Lambda was used, samples were placed between two heated plates, set at different temperatures. A calibrated heat flux transducer measured the heat flow through the sample, following EN ISO 12667 standard. The thermal conductivity was measured at 5-degree intervals over the temperature range of 15°C to 35°C.

3. RESULTS AND DISCUSSION

Once the growing and drying of the mycelium based composites was finished, the density of the samples was calculated, Table 1, shows the results by each composite group.

Table 1. Density of Mycelium composites after drying for the different sample types.

Sample	Density(kg/m³)
A	318 ± 21
B	240 ± 18
C	257 ± 51

The average results for sound absorption coefficient on each sample type and standard deviations are shown in Fig 3. Typical porous materials behaviour is observed for all samples, with the sound absorption being low at low frequencies. Towards higher frequencies, the three groups showed a similar particularity, with a first peak around 1 kHz, and a considerable dip around 2.5kHz. There are also some systematic differences between the different sample groups. Group C shows as an offset from the other curves, thus might be due to a reduced porosity, given the longer cultivation time, the mycelium had more time to grow over the porous network of the samples.
It is expected that the first absorption peak would be related to a particle velocity maxima associated with the thickness of the sample. It was observed that the first absorption peak was obtained around 1 kHz instead of 1.7 kHz, suggesting that this material has a high tortuosity which would slow down acoustic waves, effectively making the path of the wave larger.

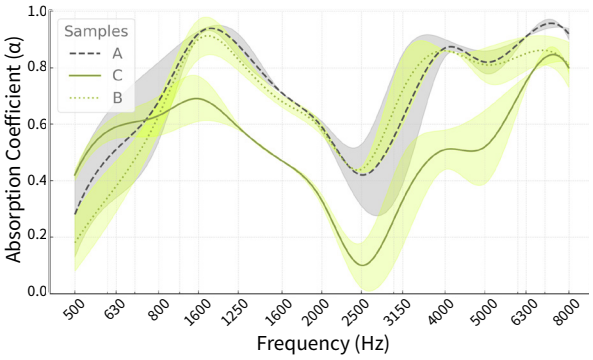

Figure 3. Sound absorption coefficient for different paper based mycelium composite samples.

Figure 4 shows the thermal conductivity for the developed samples in the range of temperatures from 15 to 35 in steps of 5. It is observed that the as temperature increases so does the thermal conductivity, aside from that, by a small margin, group B has a increased performance compared to the other types of samples, with group C showing the higher thermal conductivity consistently thorough the temperature range.
As heat transport is strongly influenced by the porosity and density of a material, the differences in thermal conductivity between group C and the others could be associated with a decreased porosity as shown in table 1, the densities of sample group C and B are comparable, and regardless of that it shows higher thermal conductivity.

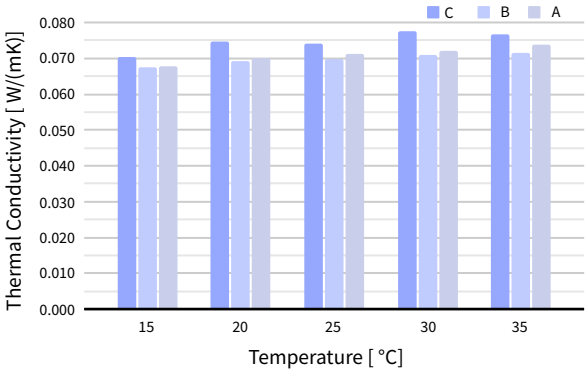

Figure 4. Thermal conductivity in function of temperature for different the developed mycelium composites.

Table 2 shows the average thermal conductivity of the samples after testing them at temperatures ranging from 15-35°C. All types of samples showed low variance in thermal conductivity among the different temperatures.

Table 2. Thermal conductivity for mycelium composites.

Sample	Thermal conductivity (W/m·K)
A	0.071 ± 0.002
B	0.070 ± 0.002
C	0.075 ± 0.003

Thermal conductivity performance shows more insulating capabilities that other mycelium based materials and are close to 0.06 W/(m·K), below which the material could be considered thermally insulating. Thus if the fabrication method is slightly improved it could position the material as a potential replacement for mineral-based wools for instance in vertical partition walls.

4. CONCLUSIONS

This study confirms that paper-based mycelium composites are also effective as absorbing materials, particularly in the mid-frequency range. The findings emphasize the importance of substrate selection and growth duration in tuning both acoustic and thermal performance. The peak absorption around 1 kHz in a 4 cm thick sample suggests a surprisingly high tortuosity which should be confirmed on a later stage by direct characterization.

Among the three sample types, those with longer incubation time, hence higher colonization, showed lower sound absorption coefficient.These insights support the continued development of mycelium-based composites as low-impact alternatives to synthetic insulation materials. Future work should explore optimized mold geometries, thicker sample configurations for low-frequency performance, and quantitative modeling using Johnson-Champoux-Allard frameworks to further refine acoustic predictions.

ABSTRACT

The European Community has introduced several directives and initiatives to promote the digitalization of buildings, aiming to improve enviromental efficiency and reduce carbon emissions. The obligation of BIM (Building Information Modeling) in Europe is regulated by Directive 2014/24/EU on public procurement, which promotes the use of BIM to improve efficiency and transparency in public projects. In several European countries the law require the use of open and interoperable formats, such as IFC (Industry Foundation Classes), to ensure of read the data for many years. The evaluation of noise emitted by HVAC (Heating, Ventilation, and Air Conditioning) systems using BIM models in open IFC format represents an innovative and precise approach. BIM models allow the integration of acoustic data directly into the project, facilitating noise analysis at different stages. The use of the IFC format ensures interoperability between different software, enhancing collaboration among professionals. This approach helps identify and mitigate noise sources, optimizing the acoustic comfort of buildings and complying with current regulations. In summary, the integration of IFC-BIM in HVAC noise evaluation offers an efficient and collaborative solution. This work analyzes all the information managed by the IFC format on HVAC system noise emission, highlighting deficiencies and proposing improvements.

1. INTRODUCTION

Building Information Modeling (BIM) for buildings, and particularly Mechanical, Electrical, and Plumbing (MEP) is a methodology that enables the design, management, and maintenance of a building's technical systems in an integrated and collaborative manner. At the European level, the adoption of BIM is regulated by various standards, including in Italy the BIM Decree (DM 560/2017) and its subsequent amendments, which make the use of BIM mandatory for public works above a certain amount. The Ministerial Decree 560/2017, known as the BIM Decree, establishes the methods and timelines for the progressive introduction of electronic modeling methods and tools for construction and infra-structure in Italy. The obligation to adopt BIM in public procurement was introduced gradually from 2019 to 2025. The decree also defines EIR (Employer's Information Requirements), known in Italy as "Capitolato informativo", interoperable platforms, and open formats. The main objective is to improve the efficiency, transparency, and quality of public construction projects. The latest Public Procurement Code, updated with Legislative Decree 36/2023, confirms the obligation to use BIM for a wide range of public projects starting from 2025. This obligation applies to new construction projects and interventions on existing buildings with an estimated project value exceeding 2 million euros, and for cultural heritage with a threshold of 5.538 million euros. The code also provides technical incentives for the use of BIM procedures and promotes the adoption of interoperable platforms and open formats such as IFC and OpenBIM. The

goal is to improve the efficiency, transparency, and quality of public construction projects. **Figure 1** provides an overview of the regulations and strategies adopted by various European countries for the adoption of BIM procedures at the governmental level. Among the most active nations on this issue is Lithuania, where the obligation to use Building Information Modeling (BIM) methods was established starting from January 1, 2021. This obligation applies to high-value construction projects in the public sector, with the aim of improving efficiency and resource management.

Figure 1. Countries of the European Community

In Lithuania, the adoption of BIM is promoted through various initiatives and regulations. The Lithuanian government has recognized the importance of BIM to improve the efficiency and quality of construction projects. In 2018, the Ministry of Environment introduced guidelines for the implementation of BIM in public projects, encouraging the use of this methodology for all new construction projects funded with public funds. Additionally, Lithuania follows international and Europe-an standards, such as the ISO 19650 series[1–6], which provides a framework for managing information related to construction and civil engineering works using BIM. These standards help ensure interoperability and consistency of information among the various stakeholders involved in projects. The adoption of BIM in Lithuania is seen as a crucial step to modernize the construction sector, improve transparency, and reduce project costs and completion times. Other non-European Union countries have also contributed to the development of BIM. The United Kingdom has been one of the pioneers in adopting BIM. The main regulation is PAS 1192, which has been replaced by international standards ISO 19650. Since 2016, the use of BIM has been mandatory for all public projects, with the goal of achieving BIM Level 2 maturity. The "Digital Built Britain" program aims to bring the construction sector to BIM Level 3 maturity by 2025. In Singapore [7,8], the government actively promotes the use of Building Information Modeling (BIM) in the construction sector. Since July 1, 2015, all projects with a gross floor area of 5,000 m² or more must be submitted in BIM format. The Singapore BIM Guide provides detailed guidelines for BIM implementation [9], covering modeling and collaboration specifications and procedures. Additionally, the country has introduced Integrated Digital Delivery (IDD) to integrate digital technologies throughout the construction lifecycle. In the United States, BIM is widely used, with mandates for public projects in many states. In Canada, BIM is rapidly gaining ground, with national standards under development. The United Arab Emirates has adopted BIM to improve efficiency in their ambitious construction projects. In Australia, BIM is used for infrastructure and building projects, with national guidelines pro-moting its adoption. In China [10] and Japan [10,11], BIM is also widely adopted to im-prove efficiency and quality in construction projects. An open and interoperable BIM format is essential to ensure collaboration among the various project stakeholders. The Industry Foundation Classes (IFC) format [12,13], standardized by buildingSMART In-ternational, is one of the most widely used for interoperability between different software platforms. IFC allows data exchange between different BIM platforms, ensuring that all information is accessible and usable by all project participants.

2. DATA STRUCTURE IN THE IFC FORMAT FOR HVAC SYSTEMS

The authors can submit for the EAA FA2025 Conference either a short paper from 2 to 4 pages or a long paper of maximum 8 pages, all written in English, and not previously published. Each length indicated is intended as overall and includes figures, tables, references and acknowledgments.

The Industry Foundation Classes (IFC) format is an open standard for data representation in Building Information Modeling (BIM), which facilitates interoperability between different software applications in the construction sector. Within IFC, HVAC (Heating, Ventilation, and Air Conditioning) systems are represented through a series of specific entities that describe components and equipment used for environmental control in buildings. HVAC entities in the IFC format are included in the IfcHvacDomain subschema, which defines the fundamental concepts for

interoperability in the HVAC domain. This schema includes entities that represent both the segments and fittings of distribution systems (such as ducts and pipes) and the equipment typically used in building services, such as boilers, chillers, fans, and pumps. It also considers vibration isolation associated with these components. Examples of HVAC entities in the IFC format include:

- IfcAirTerminal: represents air terminals such as diffusers or grilles.
- IfcBoiler: represents a boiler used for heating.
- IfcChiller: represents a chiller for cooling water.
- IfcFan: represents a fan used for air movement.
- IfcPump: represents a pump for fluid circulation.

These entities can have detailed properties such as location, dimensions, manufacturer, operational status, and other relevant parameters. Managing acoustic properties in the IFC format is essential for evaluating and controlling the sound performance of buildings. One of the main properties used is AcousticRating, which indicates the sound transmission resistance of a given object through a standardized index. This property is often specified according to national building codes and provides an indicative value of the element's acoustic insulation capacity. AcousticRating can be applied to various entities in the IFC format, including:

- IfcWall: to evaluate the acoustic insulation of walls.
- IfcSlab: to determine the acoustic performance of slabs.
- IfcDoor: to analyze sound transmission through doors.
- IfcWindow: to evaluate the acoustic insulation of windows.

Integrating these acoustic variables into the BIM model allows professionals to simulate and analyze the acoustic performance of buildings during the design and subsequent phases, helping to ensure acoustic comfort and compliance with current regulations. Additionally, the use of open standards like IFC facilitates the integration of acoustic information with other aspects of building design, promoting a holistic and multidisciplinary approach in the design and construction process. In the Figure 2 is show the entity in IFC space

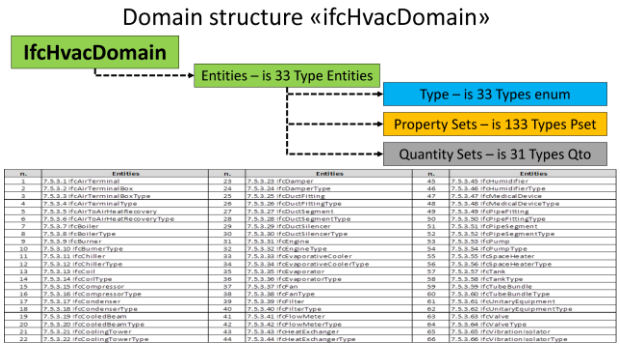

Figure 2. Entity into IFC format

3. DATA FLOW FOR DESIGN AND CHECK WITH THE PHONOMETER

The workflow with Building Information Modeling (BIM) tools for acoustic design and instrumental noise verification allows for an integrated and multidisciplinary approach to designing acoustic comfort in buildings. The process develops in several stages, each supported by interconnected digital tools. Figure 3 shows the workflow from the initial modeling phase to the verification of results. The initial phase involves the architectural modeling of the building in BIM software such as Revit, Archicad, or Allplan, where building elements (walls, floors, fixtures) and systems (HVAC, water, electrical) are inserted. BIM objects must be equipped with relevant acoustic properties, such as Rw (sound insulation index), Ln,w (impact noise), DnT,w (apparent sound insulation), and surface mass. These properties can be added manually or imported from standardized digital dictionaries like the bSDD (buildingSMART Data Dictionary) [14] or manufacturer databases. Subsequently, the model is exported in IFC format to be analyzed with acoustic simulation software such as CATT-Acoustic, Odeon, Insul, or SoundPLAN, GEAR [15]. These tools allow for the simulation of sound propagation in indoor environments and insulation between rooms, considering materials, geometries, volumes, and sound sources. At this stage, the project can be optimized, for example, by modifying stratifications, adding suspended ceilings, sound-absorbing panels, or acoustic barriers. After construction, in-situ instrumental verification is carried out by competent technicians with sound level meters and standardized sound sources. The detected data (such as sound pressure levels, reverberation times, or insulation indices) are compared with the design values. The results can be inserted into the BIM model through parametric properties, creating an acoustic as-built. Finally, all

documentation (technical reports, graphs, measurements) can be attached to the BIM model as informational objects, making the project consultable, traceable, and updatable over time. This workflow allows for the design of buildings compliant with regulations (such as UNI 11367 [16] or ISO 12354 [17–22]), improves the quality of acoustic comfort, and reduces the risk of disputes.

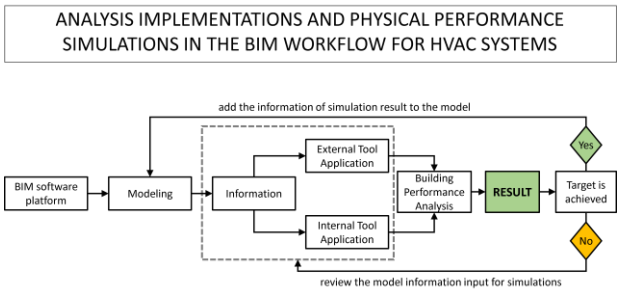

Figure 3. Entity in to IFC format

The IFC data structure does not contain all the necessary information for acoustic calculation. The default property sets contain only a few very limited parameters. To address this, it is necessary to define a bSDD [14] at the standard level for acoustic calculation and verification, within which all the variables present in the various technical standards used are included. Figure 4 shows the workflow that can be followed in the modeling phase and in the code checking phase for the verification of acoustic parameters

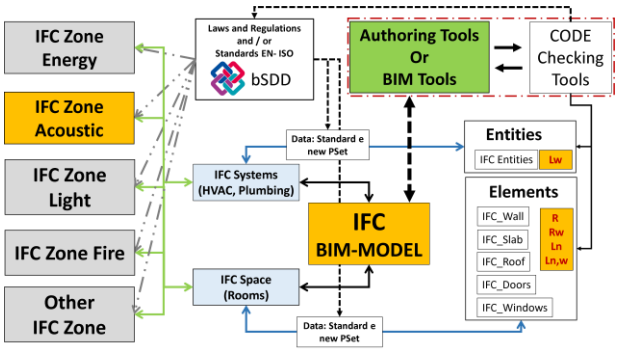

Figure 4. Entity in to IFC format

4. CONCLUSION

In conclusion, the integration between BIM modeling and acoustic design represents a significant breakthrough for the construction sector. The use of digital tools allows for a more precise, coordinated, and informed approach, capable of improving both design quality and environmental comfort. The interoperability between software, data traceability, and the ability to anticipate acoustic issues from the early stages of the project provide tangible benefits for designers, companies, and clients. The synergy between technologies and skills promotes a holistic vision of the building, where sound is considered an integral part of well-being. Investing in acoustic design through BIM is not only a technical choice but also a cultural and sustainable one. In a context increasingly focused on quality of life and energy efficiency, acoustic comfort becomes an essential requirement. Today, digitalization offers all the tools to achieve it effectively. It is up to us to use them to their fullest potential.

ABSTRACT

The obligation of BIM (Building Information Modeling) in Europe is regulated by Directive 2014/24/EU on public procurement, promoting its use to improve efficiency and transparency in public projects. In Italy, the New Procurement Code (Legislative Decree 36/2023) mandates BIM for public works above a specific value starting January 1, 2025. In contrast, Poland does not currently mandate BIM, with its implementation driven by the private sector voluntarily. However, the Ministry of Infrastructure and Construction in Poland is working to integrate BIM into public procurement contracts to achieve significant savings for the State Treasury. The use of BIM is growing, with many technical standards requiring open and interoperable formats like IFC (Industry Foundation Classes) defined by an ISO standard to ensure collaboration among stakeholders. This work analyses the information managed by the IFC format for acoustic purposes with an automated verification approach through an IDS (Information Delivery Specification) file. Additionally, it defines the main variables provided by reference standards and not present by default in the IFC file through the use of the bSDD (building SMART Data Dictionary), where all variables should be described in geometric and physical terms.

1. INTRODUCTION

The Building Information Modeling (BIM) is a digital process that involves the creation and management of digital representations of the physical and functional characteristics of buildings. BIM integrates multidisciplinary data to produce a digital model that covers the entire lifecycle of a building, from design and construction to operation [1,2]. This approach enhances collaboration, visualization, and resource management, enabling more informed decision-making and greater efficiency. The integration of BIM with open interoperable formats such as IFC [3], IDS [4], and bSDD [5] provides a powerful tool for managing construction projects, improving collaboration, efficiency, and the quality of information. Specifically, for building acoustic assessments, these tools ensure that acoustic requirements are met, improving the comfort and quality of life for occupants. The Open BIM IFC format (Industry Foundation Classes) [3] is an open and standardized file format for exchanging BIM models. Developed by buildingSMART [6], IFC enables interoperability between different BIM software tools, ensuring that data can be shared without loss or distortion [7–9]. IFC facilitates collaboration among various project stakeholders by allowing them to consistently input, extract, update, or modify model information [10,11]. Checks on the IFC format can be carried out using another data format called IDS (Information Delivery Specification) [4,10]. IDS is a standard that defines the specific data required for a BIM project. An IDS file ensures that all parties involved understand what information must be provided and how it should be structured. In particular, IDS helps standardize data, improve interoperability, and perform automatic compliance checks, reducing errors throughout the different

project phases. All acoustic and non-acoustic parameters, including those not defined within the IFC file, can be included using the bSDD (buildingSMART Data Dictionary) [5]. bSDD is a library of standardized concepts and attributes — for example, a bSDD can be created for all parameters from ISO 12354 [12–17] or ISO 16283 [18–20], which can then be used to manage the acoustic requirements of buildings. Using bSDD, it is possible to clearly define acoustic requirements, classify objects and materials for sound insulation, and integrate this information into BIM models. This approach allows for automatic control and validation of acoustic data, ensuring that the requirements are properly implemented [21–29].

2. MAIN FEATURES OF IDS AND BSDD FORMATS

Below is an overview of the main features of the IDS (Information Delivery Specification) and bSDD (buildingSMART Data Dictionary) formats, which is necessary to introduce the use of these formats in digital processes based on the open BIM IFC data format [21,22,30,31].

2.1 Information Delivery Specification (IDS)

The IDS format is a standard developed by buildingSMART to define information requirements in a form that can be interpreted by both humans and computers. It implements the following key features:

- Clear specifications: Allows for detailing which information must be provided in a BIM model, specifying objects, properties, values, and units of measurement.
- Automated validation: Facilitates the automatic verification of IFC model compliance with defined requirements, improving quality control and data consistency.
- dìIFC integration: Designed to work in synergy with the Industry Foundation Classes (IFC) format, the open standard for BIM model exchange.

In other words, this open data format allows for the definition of requirements and specifications for the project that designers can use to develop their work. The same IDS file will later be used, at the end of the project or during an intermediate or subsequent phase, to verify that the required specifications have been implemented in the model.

2.2 buildingSMART Data Dictionary (bSDD)

The bSDD "database" is a collection of interconnected data dictionaries that provide definitions of terms used to describe the built environment. In practice, within the bSDD it is possible to define all the variables required for acoustic calculations according to ISO 12354, as well as all the variables needed for acoustic classification of buildings according to ISO/TS 19488 [32]. The bSDD includes the following main features:

- Centralized library: Provides an online repository of classes (terms) and properties, including allowed values, units, and translations, promoting terminological consistency.
- Interoperability: Facilitates the integration of existing national and international standards, improving compatibility across different systems and software.
- Open access: Offers a free service accessible by all software solutions, allowing for easy use and integration.

he bSDD is a library based on the IFD ISO 12006-3 standard [33]. The IFD (International Framework for Dictionaries) is a system developed by buildingSMART to facilitate data interoperability in the construction sector. It is a framework that allows the creation, management, and use of standardized data dictionaries to describe the built environment. The IFD focuses on creating an ontology of common concepts and terminologies that can be shared among different software and BIM applications [34].

2.3 IDS and bSDD

In summary, IDS focuses on defining and verifying the information requirements in BIM models, and the same file can be used to communicate to designers which parameters are required within the BIM model. The same IDS file can then be used once a specific project phase is completed to check if it contains all the specified data. bSDD, unlike the IDS format, provides a standardized dictionary of terms and properties to describe the built environment, supporting interoperability and data consistency within the construction sector. Within a bSDD, various rules or variables can be standardized, such as acoustic standards for design and/or on-site verification, to be used automatically by tools. The use of bSDD allows for the implementation of any regulation, technical standard, or requirement in BIM processes without needing to modify the IFC data format. Once defined, the bSDD is published on the buildingSMART International website and, after being validated, is accessible to all operators who request its use.

3. USE OF IDS AND BSDD FORMATS IN BIM PROCESSES FOR ACOUSTICS

The bSDD can be used, either alone or in conjunction with the IDS format, to manage the acoustic requirements of buildings in various ways. Definition of acoustic requirements: The bSDD allows for the clear definition of acoustic requirements using standardized and shared terms. This ensures that all project participants have a uniform understanding of the acoustic specifications. Meanwhile, the IDS file can be used to verify the presence or absence of parameters and/or information regarding acoustic aspects.

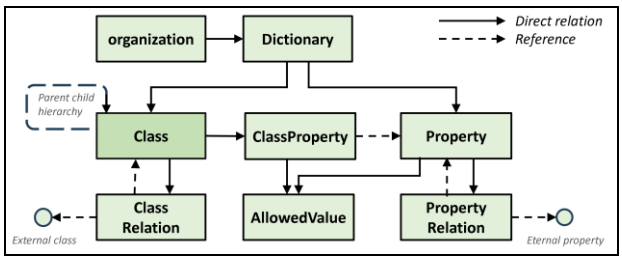

Figure 1. bSDD organization - https://technical.buildingsmart.org/services/bsdd/data-structure

In Figure 1, the following are represented:

- **Classification of objects**
  Objects and materials used for acoustic insulation can be classified in the bSDD. This facilitates the selection of appropriate materials and the verification of their acoustic properties.
- **Integration into BIM models**
  The bSDD can be integrated into BIM (Building Information Modeling) models, allowing acoustic requirements to be directly associated with the elements of the model. This helps ensure that acoustic specifications are met during design and construction.
- **Control and validation**
  By using the bSDD, automatic control and validation of acoustic data can be performed. This reduces communication errors and ensures that acoustic requirements are properly implemented.
- **Extension of property sets or new Psets**
  The bSDD allows the extension of property sets to include specific requirements, such as acoustic ones. This enables the dictionary to be tailored to the particular needs of a project.

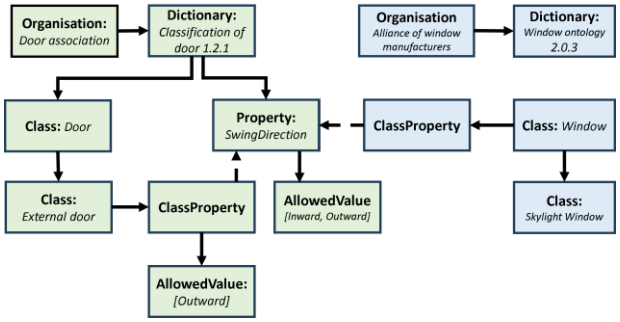

Figure 2. Example demonstrating the usage of the above concepts [4,5]

The bSDD is a service to facilitate the distribution of data dictionaries (read below about what those are) published by independent organisations. The diagram Figure 1 and Figure 2 shows the simplified data model behind the bSDD.

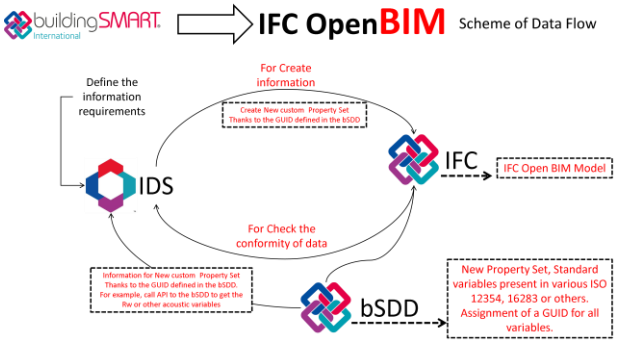

Figure 3. Flow of information for acoustic goals

In Figure 3, the information flow that the various data follow is shown. In particular, it can be observed that the definition and use of one or more bSDD allows, in a standardized way, to define all those variables that are not present in the default property sets provided by the IFC standard. In fact, when a bSDD is created for any purpose, such as project calculation or acoustic tests, a GUID is assigned to the various variables, which allows these to be included in new customized property sets without losing the reference to the standard.

4. CONCLUSIONS

In this work, the procedures that need to be followed for various acoustic issues when using open BIM models have been analyzed. The use of these models created by

buildingSMART International is essential for obtaining standardized calculations and projects within a digital project. The use of the IDS format together with the bSDD dictionary format allows for acoustic issues to fill the information gap that the default IFC open format presented. With the analysis carried out in this work, it has evolved to show how the data flow and various information can be defined within a design or verification process that relies on the use of open BIM models thanks to the open IDS and bSDD formats

ACOUSTIC CALCULATIONS AND WORKFLOW BASED ON LIST OF ACOUSTICALLY DISTINGUISHABLE SPACES

Andor T. Fürjes
aQrate Acoustics Ltd., Csákvár (HU)

ABSTRACT

Acoustic consulting often requires to make decisions and do calculations based on simplified data, such as list of rooms to support other relevant fields involved in the design of buildings. In general, a list of rooms contains a summary of data sheet for each room. For acoustic calculations basic geometry (floor area, height), comfort category, number and type of noise sources, exposure to adjacent disturbances, sound absorbing surfaces and objects etc. are useful. The paper provides an overview on what types of acoustically important aspects can be derived from such simple descriptions, using database relations, including room acoustics, sound isolation, MEP noise and electroacoustics. The aim is to create a simple to use integrated tool to increase efficiency and accuracy of the work of acousticians.

Keywords: *room list, architectural acoustic calculations, workflow optimization, room acoustics.*

1. INTRODUCTION

The design process is similar for solving any engineering problem: establishing requirements, assessing constraints, selecting solutions (materials, build-ups, details) to meet requirements, checking compliance by calculation, documenting the results (Figure 1).
It is no different in acoustics practice.
The author's own experience is that most of the time spent on design is spent searching for and organizing data, and that with no other solution at hand, this process is supported almost exclusively by his own collection of technical literature and Excel templates and MatLab routines.

Moreover, the vast majority of tasks do not require complex calculations, while thoroughness requires that attention be paid to every room and structure of the planned facility.

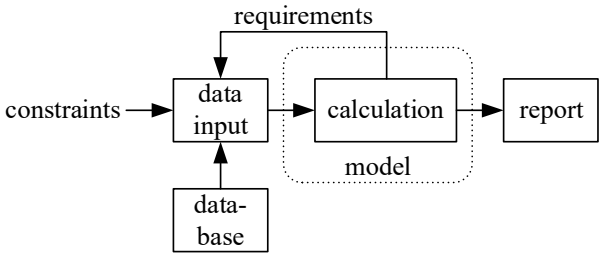

Figure 1. Generic design process.

According to the popular saying, a job can be done quickly, accurately and cheaply, but typically only two of the three aspects can be met.
The aim of the study is to find a more optimal workflow to support acoustic design, by developing a bespoke database-driven approach for generic situations.
Examples are given for room acoustic problems, but other disciplines of acoustics (e.g. sound isolation, MEP noise and isolation, electroacoustics, etc.) can be applied similarly.

2. KEY ELEMENTS OF THE WORKFLOW

The key to optimize design workflow is to a) find a repeatable and algorithmic representation of the problem and b) a scheme that requires minimum effort in calculations.

2.1 Data input: Room Schedules

The author found, that lists of acoustically distinguishable spaces (or room schedules) are the most effective interface to other engineering disciplines in terms of understanding, communicating and to specify generic architectural acoustic problems. With the appropriate support of databases, it can be the center of an efficient workflow in acoustics (Figure 2). A tabular representation of the most important data is easy to input, maintain, import, export or process further. Moreover, most related data (e.g. set of requirements, material properties) are also given in tabular formats anyway.

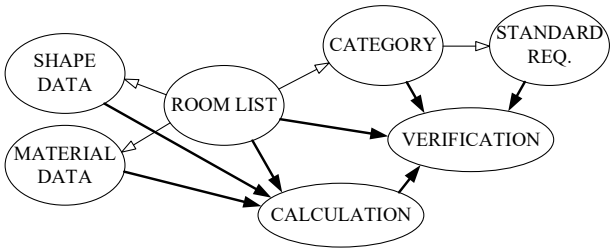

Figure 2. A room schedule (or room list) supported by appropriate databases can be the center of an efficient workflow (hollow arrow: reference, solid arrow: data).

2.2 Calculation Model: Accuracy vs. Complexity

The next question is then to find the minimum number of data, that are sufficient to describe each room in the list to meet the required accuracy of the set of specifications.
Generally speaking, the more effort (input data, complexity and quantity of calculation etc.) is put into a calculation model, the more it should approximate reality. Accuracy of a proper model is surely an asymptotic function of efforts, while the required resources will stay monotonically increasing (Figure 3).

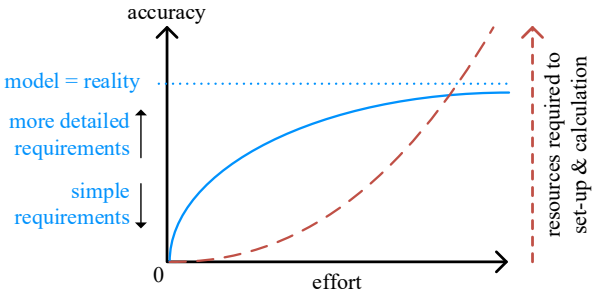

Figure 3. Generic hypothetical functions of accuracy and required resources vs. efforts put into a model.

2.3 Formulating Criteria: Generalization

From a purely engineering point of view, it is rather unfortunate, that still there is no unified and consensual set of metrics and thresholds in regulatory and standard documents yet. A generalization of requirements is therefore necessary in order to be able to adapt different regulatory schemes within the same project.

2.4 Databases: Generalization, Uncertainties

No calculation model is of much use, if there are no reliable databases of sound sources and materials. An acoustic calculation requires at least sound absorption data.
Sound absorption data in form of sound absorption coefficients or sound absorbing power are usually available in various forms (tabular, graphical) for surfaces meant for acoustic treatments in 1/1 or 1/3 octave resolution between 100Hz and 5kHz. Properties of generic ("non-acoustic") types of surfaces or objects are often found in literature, but more often can be estimated only. This resolution and dataset are acceptable, if the aim is to ensure a minimum quantity of absorption to meet usual acoustic requirement metrics. A metric for uncertainty would be nice, though.

2.5 Reporting

As soon as all the data and results are at hand, generating reports can be automated as well:
- summaries of requirements
- calculation results in the required details (tabular or graphic)
- bill of quantities.

3. ROOM ACOUSTIC CRITERIA

On a basic level, setting up room acoustic criteria should be an easy task, if there are any local regulations. The task is cumbersome, however, as soon as the situation is beyond the scope of local regulation or there are other types of standards to be considered.
The reason is, that room acoustic quality is expressed in many different ways with seemingly few consensual conclusions.

3.1 Acoustics Parameters vs. Input Data

Room acoustic criteria should be sorted in the order of complexity with respect to efforts (input data required, calculation complexity etc.) needed for verification.
An informative overview of the most common room acoustic parameters and the minimum required data for their estimation is shown in Table 1 (using [1], [2] and [3]). Important distinctions are around consideration of shape

(V/S ratio or different derivations of mean path lengths between reflections), effects of distance and directivity on early-late energy ratios.
As one can see, a fairly small amount of input data can be sufficient to estimate relevant quality descriptors.
Please note, that since standard measurements of room acoustic descriptors assume omnidirectional sources and receivers, directivity considers only the type of mounting (free, on or near wall, on or near corners etc.).
The next leap in calculation efforts is when mean path length and source-receiver distances are calculated in more detail. Nevertheless, requirements related to spatial deviations are rather rare and neglected in most room acoustic specifications.

Table 1. Overview of estimations of room acoustic descriptors with respect to input data required.

calculated parameter			required or considered input data

3.2 Mean of Frequencies

Acoustic parameters depend on frequency. Single value requirements use arithmetic means, direct weights or tolerances with allowed deviances across frequency bands.
For room acoustic parameters, the 'mean' value in most cases means the arithmetic mean of values at different frequency bands. Usually, 1/1 octave bands, namely 250 Hz, 500 Hz, 1 kHz and 2 kHz bands are considered.
The author denotes $m1$ if 500 Hz, $m2$ if 500 Hz and 1 kHz, $m3$ if 500 Hz, 1 kHz and 2 kHz and $m4$ if all the four octave bands are used. Please note, that notation might change from standard to standard and using arithmetic means might be just a formal habit with no physical meaning (e.g. summing decay times or energy ratios).
Unfortunately, if different standards need to be applied at the same time, a conflicting definition of 'mean' cannot be resolved, because neither type of mean is more inclusive than the other. On the other hand, measured results show low deviation of different means (e.g. $m2$ vs. $m4$).
Definition of a mean requires flagging considered frequency bands and the type of calculation (arithmetic mean, harmonic mean, power mean), in the form like $\{m_{31.5Hz} \dots m_{8kHz}; m_{type}\}$ for each parameter type.

3.3 Mean Sound Absorption (A_m)

A requirement of minimum of sound absorption represents the aim to reduce noise levels within the rooms. A general form based on formulas found in standards (e.g. [4], [5]) could be

$$A_m \geq \frac{a_A}{[1+b_A \cdot log_{10}(H/H_0)]} \cdot V + c_A \cdot S + d_A \cdot S_f \quad (1)$$

where A_m is the mean sound absorption requirement, V is the volume of the room, S is the total surface area of the room, H is the height of the room, $H_0 = 1m$, S_f is the floor area in the room and $\{a_A; b_A; c_A; d_A\}$ are parameters depending on the category of the room.
The above formulation considers only architectural surfaces (i.e. not air absorption, not furniture or occupants), meaning that c_A is actually the average absorption coefficient $\bar{\alpha}_{arch}$ of architectural boundaries.
For example, a requirement of MSZ2080 (see [6]) of $A_m/V \geq 0.20\frac{m^2}{m^3}$ of corridors with max. 3.2 m height can be translated to $\{0.20; 0; 0; 0\}$ terms. Similarly, a $\alpha_{m2} \geq 0.30$ requirement is translated as $\{0; 0; 0.30; 0\}$ or a DIN18041:B2 $h > 2.5m$ situation $A/V \geq [4.8 + 4.69lg(h/1m)]^{-1}$ is translated to $\{0.208; 0.977; 0; 0\}$ terms.

3.4 Mean Reverberation Time (T_m)

A maximum reverberation time or maximum length of sound level decay requirement is a simple tool to limit detrimental effects caused by late or ongoing reflections. Also, it is a very illustrative descriptor to both non-professionals and musicians.
As an overall ruler, a limited reverberation time will also limit other quality descriptors in favor of higher early/late energy ratios. That explains most correlations found with other parameters.
Please note, that while definitions of T_{60} rely on the *length* of sound decay, estimations except given in [3] approximate

the *slope* of the decay only, which are not the same. The difference in these is significant only when the early/late energy ratio is affected by directivity or local reflections at either the source or receiver side.

Using formulas found in standards (e.g. [4], [7]), one may use the general formula of setting maximum mean reverberation time requirement as

$$T_m \leq a_T \cdot log_{10}(V/V_0) + b_T \cdot (V/V_0)^{c_T} + d_T \quad (2)$$

where T_m is the mean reverberation time requirement, V is the volume of the room, $V_0 = 1m^3$, and $\{a_T; b_T; c_T; d_T\}$ are parameters depending on the category of the room. For example, a DIN18041:A2 requirement is described by $\{0.37; 0; 0; -0.14\}$. In addition, these forms also come with a minimum and maximum of V or T_m.

To the author's knowledge, both the parameters and the formulas used in standards are empirically chosen with no direct physical explanation.

A minimum mean reverberation time requirement can be added where an acoustic source needs support from reverberation in the room.

3.5 Reverberation Time Frequency-Dependence

Requirements controlling frequency dependence of reverberation time have usually the same mission, but differ significantly from standard to standard (Figure 4). The aim of using tolerances is to keep deviation from a mean reverberation time to a reasonable minimum as a function of frequency, while allowing longer reverberation at low frequencies to support moderately loud operation and to avoid excessive high frequency attenuation overall.

Frequency dependent specifications can be absolute (e.g. [8], [9], [10]) or adjusted to the mean reverberation time by a ratio (e.g. [4], [11]) or a difference (e.g. [7]).

For the sake of simplicity, tolerances can be considered at 1/1 octave bands only. This way, a tolerance requires values to specify minimum and maximum for each frequency band, and a flag if is related to the mean value.

3.6 Considering Room Conditions

Conditions of occupancy (in percentage) and furnishing ("yes" or "no") must be clearly stated in a definition of room acoustic criteria, because these have significant effect on their interpretation.

Atmospheric conditions are usually not mentioned in standards of room acoustics. This is important however to set for frequency dependent tolerances, because deviations in temperature or relative humidity can cause room acoustic parameters to change noticeably (>5%) at 2 kHz and higher frequencies (see [12]).

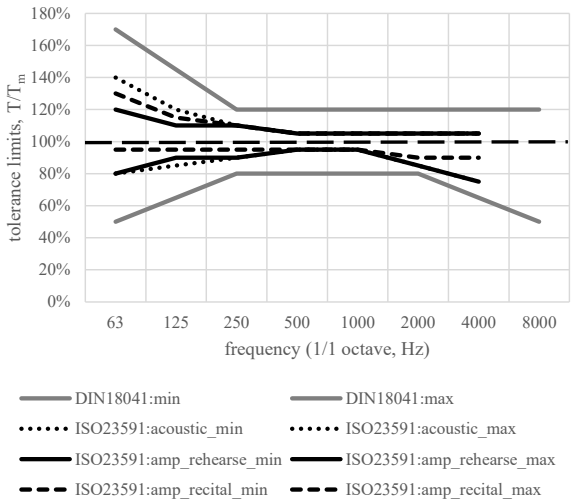

Figure 4. Mean-related frequency-dependent tolerances of reverberation times are different.

3.7 Additional Criteria

Additional technical parameters can be used to refine expectation of room acoustic qualities.

Loudness of reverberation can be expressed as the actual reverberating sound level relative to the free-field sound level of a sound source. This is called Gain, defined in [13], given in dB, used in [11]. Frequency dependence is not considered.

The ratio of early/late energy portions of an impulse response in dB correlates to perception of clarity (see [13]). Minimum mean speech clarity like $C_{50,m3}$ (see [14]) uses early-late time limit of $t_e = 50ms$. Frequency dependence is not considered.

Perceivable acoustic parameters change also from position to position within a room. Parameters discussed so far assume a spatial average, though requirement standards usually are not explicit in this respect or refer to definition standards. Spatial decay rate is an important issue for open spaces with multiple simultaneous activities. By using distance-dependent estimations of room acoustic effects, requirements like $D_{A,S}$ (in-situ attenuation of speech) or $D_{2,S}$ (spatial decay rate of speech) of [9] can be calculated. Frequency dependence is not considered, A-weighting is used.

Calculation of sound level requires the sound power level L_w of the source and its directivity factor Q, or if Q is not of concern, the free-field sound level at a reference distance to be known. For example, $L_{p,A,S,4m}$ (A-weighted sound

pressure level of speech at 4 m) of [ISO22955] is defined by a reference sound level at 1 m distance for octave bands.
Preferred ratios of dimensions can be used to avoid unfavorable situations, like e.g. uneven frequency response at low frequencies due to modal behavior (see [11], [7], [15]). A generic form of these requirements can be:

$$sign(a_R \cdot L + b_R \cdot W + c_R \cdot H) = d_R, \quad (3)$$

where for example equality of [11] $L/H = 2.36\,W/H - 1.38$ can be translated to $\{1; -2.36; 1.38; 0\}$ or unequality of [7] $1.1 \cdot W/H \leq L/H$ can be translated to $\{1; -1.1; 0; 1\}$.
In cases, where room conditions require to define occupancy and the number N of occupants is known, ratios of N/S_f or N/V can by added to the set of requirements, because occupants have a significant effect on room acoustics.

4. CALCULATION FORMULAS

4.1 Main Dimensions

For box-shaped rooms, main dimensions of L, W and H can be read from drawings and volume V, surface S, floor area S_f can be calculated easily.
Dimension-related criteria can be verified directly.
The mean path length between reflections in a box-shaped volume is

$$\bar{l}_{stat} = 4\,V/S, \quad (4)$$

which can be derived in different ways (e.g. [1]), even using mirror image sources (i.e. not assuming diffuse reflections). This suggests, that multiple different reflection paths can be approximated by a single repeating reflection with length $\bar{l}_{stat}$ and $\bar{l}_{stat}/c$ average time, when c is the speed of propagation.
Room schedules often present only floor area S_f and height H. With no further information, an estimation of $L = W = \sqrt{S_f}$ can be used as a worst-case scenario, because a square floor area has the highest V/S ratio and longest $\bar{l}_{stat}$ estimation of box-shaped geometries.

4.2 Room Shape

The author found, that formulas can be rewritten meaningfully when normalizing the mean path length $\bar{l}_{stat}$ and source-receiver distance r by $\sqrt{S}$:

$$\bar{l}_n = \bar{l}_{stat}/\sqrt{S} = 4\sqrt{V^2/S^3} \quad (5a)$$

$$r_n = r/\sqrt{S} \quad (5b)$$

The importance lies in the fact, that $\bar{l}_n$ depends only on the shape of the room, but not its dimensions, like a shape factor.
If the room is not rectangular or absorption is extremely irregular (e.g. open ceiling), estimation of $\bar{l}_{stat}$ or $\bar{l}_n$ requires more complex calculations.
This is where using prepared simple convex volumetric shape-models can help. Using only a specification like $\{L_1; W_1; H_1; L_2; W_2; H_2; X_1; X_2\}$ (see Figure 5) can describe most typical situations convincingly, without the need to build 3D room acoustic models. Values of X_1 and X_2 can be additional sizes or the number of segments approximating continuous arcs.
Shape-models are then useful also to generate valid source and receiver positions and from that, valid source-receiver distances and effects of source directivity can be considered as well.

4.3 Sound Level

The sound level L_p consists of the direct sound and the sum of reflections.
Classic theory suggests, that the sum level of reflections is constant across the room:

$$L_p = L_w + 10 \cdot log_{10}\left[\frac{Q_{SR}}{4\pi \cdot r^2} + \frac{4}{A}\right], \quad (6)$$

where L_w is the sound power level of the source, r is the distance, Q_{SR} is the directivity factor for the given source-receiver constellation and A is the total sound absorption of the room.
A is simply the sum of A_S absorption of boundaries, A_O absorption of objects and A_V absorption of the volume:

$$A = A_S + A_O + A_V. \quad (7a)$$

Absorption of boundaries A_S can be calculated as

$$A_S = -ln(1 - \bar{\alpha}) \cdot S, \quad (7b)$$

using the Eyring-formula, and

$$\bar{\alpha} = \alpha_0 \cdot (S - \sum S_i) + \sum \alpha_i \cdot S_i \quad (7d)$$

where $\bar{\alpha}$ is the average sound absorption coefficient of surfaces, α_i is the sound absorption coefficient of the material with surface S_i and α_0 is the sound absorption coefficient of the default (untreated) surface. Obviously, condition $S \geq \sum S_i$ must be preserved.
Absorption of free-standing objects is

$$A_O = \sum A_j \cdot n_j, \quad (7c)$$

Where A_j is the sound absorption and n_j is the quantity.
Absorption of the volume is

$$A_V = 4 \cdot m \cdot V, \quad (7d)$$

where m is the sound absorption of the air.
Room schedules include references to material databases and quantities S_i and n_j. Material databases contain frequency-dependent properties α_0, α_i and A_j. Absorption of air can be calculated from standards, but must be converted from single-frequency values to 1/1 octave band values beforehand (see [12]).

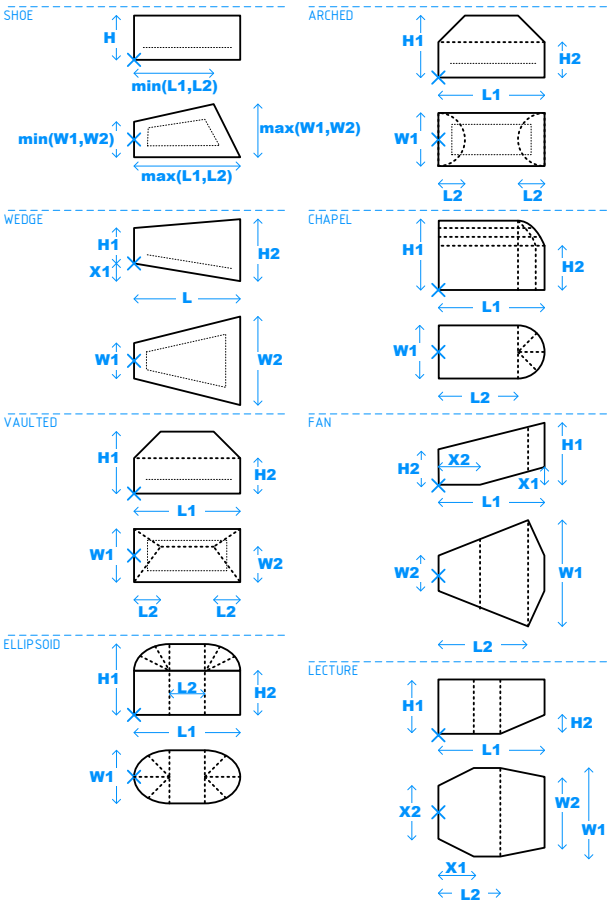

Figure 5. Typical convex room shapes for fast entry and calculation of shape-dependent parameters.

More recent approximations follow the experience (see [2]), that sound level of reflection is not constant across the room, but decrease with distance. Classic theory in (6) still can be used for worst-case approximation of noise levels.
Revised approximation of sound level, considering shape-factor (see [3]) is

$$L_p = L_w + 10 \cdot log_{10}\left[\frac{Q_{RS} \cdot e^{-m \cdot r}}{4\pi \cdot r_n^2} + \frac{4 \cdot (1-\alpha^*)^{r_n/\bar{l}_n+1}}{\alpha^*}\right] - 10 \cdot log_{10} S, \quad (8)$$

where $e^{-m \cdot r}$ is the sound absorption of the air to the direct sound, and the total average sound absorption α^* includes sound absorptions of surface, objects and air.
It is important to see, that according to Eq. (8), reverberating sound level depends more on absorption α^*, shape r_n/l_n and total surface area S, than volume V.
Equation (8) has been tested and found following measured tendencies well (see [3]) and can be completed by adding Waterhouse-correction $C_W = 10 \cdot log_{10}(1 + 2\,\lambda/\bar{l})$ at low frequencies and small rooms when necessary.

4.4 Reverberation Time as Decay Rate

Classic theory suggests, that reverberation time governed by reverberating volume and absorbing power:

$$T_{60,stat} = 24 \cdot ln(10) \cdot \frac{V}{A}, \quad (9a)$$

which can be rewritten in the form

$$T_{60,stat} = 6 \cdot ln(10) \cdot \frac{\bar{l}}{c} \cdot \frac{1}{\bar{\alpha} + [A_O/(4 \cdot V) + m] \cdot \bar{l}}. \quad (9b)$$

The latter form reflects, that temporal rate of decay depends on the average time $\bar{l}/c$ spent between reflections the average energy loss α^* during each cycle, as

$$\alpha^* = \bar{\alpha} + [A_O/(4 \cdot V) + m] \cdot \bar{l}. \quad (10)$$

If $\alpha^* > 1$, $\alpha^* = 1$ must be used.
It is important to note, that $T_{60,stat}$ is not the length, but the rate of decay of reverberation. This is why it is valid to consider it constant across the volume of the room, as long mean path length and characteristic absorbing properties are seen constant across the volume of the room.

4.5 Reverberation Time as Measured

At any point in a room, the response is a sum of the direct sound and the sound coming from reflections. When the source is visible to the receiver, direct sound always arrives first, reflected sound follows. Energy-time response (ETC) can be converted to the energy decay curve (EDC), which is the ratio of remaining energy of the response and the total energy of the response (see Figure 6).
When reverberation time T_{60} is defined as a length of the response where EDC drops below -60 dB, it can be calculated as

$$T_{60} = \frac{60dB + EDC_{t_{0+}}}{60dB} \cdot T_{60,stat} \quad (11a)$$

where $EDC_{t_{0+}}$ is the first drop in EDC

$$EDC_{t_{0+}} = -10 \cdot log_{10}\left[1 + 10^{DRR/10}\right] \quad (11b)$$

and DRR is the ratio of the direct sound and the reflected sound

$$DRR = 10 \cdot log_{10}\left[\frac{Q_{SR} \cdot \alpha^*}{16\pi \cdot r_n^2 \cdot e^{m \cdot r \cdot (1-\alpha^*)^{r_n/l_n+1}}}\right]. \quad (11c)$$

Measured reverberation time according to [13] is a linear regression of the EDC between two points. For example, reverberation time T_{20} from the of EDC -5 dB and -25 dB points can be approximated as

$$T_{20} \approx \frac{(25dB + EDC_{t_{0+}}) \cdot (15dB - EDC_{t_{0+}})}{25 \cdot 15\ \mathrm{dB}^2} \cdot T_{60,stat} \quad (12)$$

assuming that $EDC_{t_{0+}} > -25$ dB (i.e. response contains enough reverberant energy).

This approach explains, how different reverberation time definitions relate to each other (see Figure 7) and agrees well with measured tendencies.

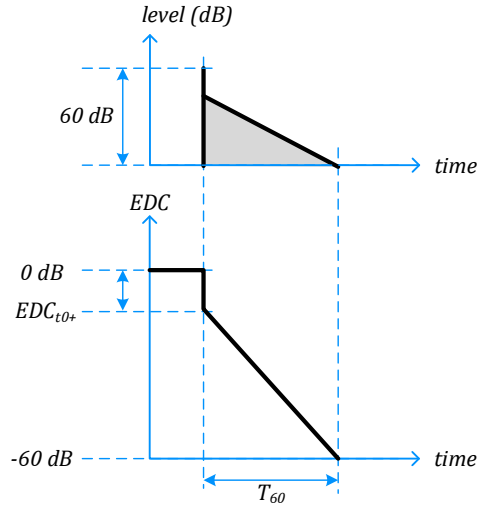

Figure 6. The simplest form of response shown as energy time curve (ETC) and energy decay curve (EDC).

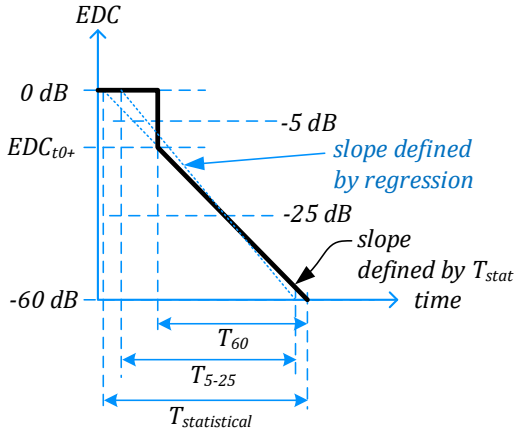

Figure 7. Comparing different reverberation times.

4.6 Early Decay Time as Measured

In a similar manner, early-decay time EDT_{10} can be approximated, when $EDC_{t_{0+}} > -10$ dB as

$$EDT_{10} \approx \frac{(10dB+EDC_{t_{0+}})\cdot(10dB-EDC_{t_{0+}})}{10\cdot 10\ \mathrm{dB}^2}\cdot T_{60,stat} \quad (13)$$

assuming that $EDC_{t_{0+}} > -10$ dB. This condition explains also, why evaluation of EDT_{10} can be ambiguous when DRR is high.

4.7 Early-Late Ratios

Early-late ratios can be taken directly from EDC at any given early-late t_e time limit from the onset of the direct sound (t_{0+} point):

$$C_{t_e} = 10\cdot log_{10}\left(10^{-EDC_{t_e}/10}-1\right), \quad (14a)$$

where

$$EDC_{t_e} = EDC_{t_{0+}} - \frac{t_e}{T_{60,stat}}60\mathrm{dB}. \quad (14b)$$

4.8 Parameters Considering SNR

Certain standards use speech transmission index (STI) in order to specify speech clarity requirements. STI is not a room acoustic measure, but a parameter for electroacoustic transmission, as it is developed to consider signal to noise ratios (SNR) and possible distortions along the transmission, with many correction options for perceptual masking or non-native speaker issues for example. If STI is applied assuming linear transmission, without perceptual corrections, an STI requirement will implicitly call for a minimum signal-to-noise ratio as well.

Without considering SNR, measurement results show STI to correlate many of the room acoustic parameters fairly well (see [17]). The tendency is, that STI correlate early-late ratios directly within ± 0.05 error, while reverberation time allows a 'worst case' STI estimate:

$$STI_{C_{80}} \approx 0.022\cdot C_{80,m4} + 0.53, \quad (15a)$$

$$STI_{EDT_{10}} \approx -0.165\cdot ln\left(EDT_{10,m4}\right) + 0.594, \quad (15b)$$

$$STI_{T_{20}} \geq -0.2\cdot ln\left(T_{20,m4}\right) + 0.55. \quad (15c)$$

When SNR must be considered, a better option is to calculate useful-to-detrimental ratio

$$U_{50} = 10\cdot log_{10}[E_0^{50}/(E_{50}^{\infty}+E_N)] \quad (16a)$$

or

$$U_{50} = C_{t_e} - 10\cdot log_{10}\left[1+\frac{10^{-SNR/10}}{10^{-EDC_{t_e}/10}}\right], \quad (16b)$$

where $SNR = L_p - L_N$ and $t_e = 0.05s$.

According to [16]

$$STI \approx 0.114\cdot U_{50} - 0.54 \quad (16c)$$

is a good estimate.

4.9 Application

Figure 8 shows an example of graphic report of calculation results of T_{20} reverberation time when applying the "lecture" shape. Setting up and running similar calculations can happen in real time for all listed parameters. Most of the work is done by checking input data and setting up requirements. More advanced calculation methods (low order image sources, diffuse radiosity) for better precision can also happen in seconds, but can be run in batch mode, after setting up the room schedule.

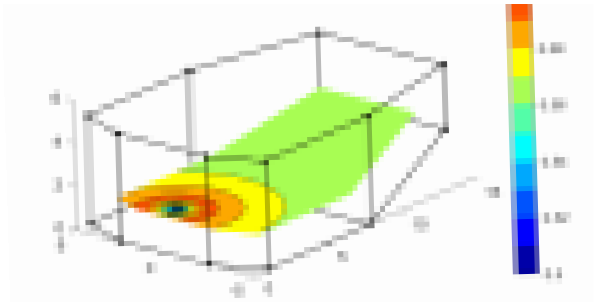

Figure 8. Calculation example: reverberation time T_{20} in a "lecture" shape with dimensions {15;10;5;8;7;2;1;5} and {0.40;0.10;0.50} absorption coefficients on the floor, walls and ceiling respectively, from one omni source

5. SUMMARY

It is important in acoustic engineering practice to be efficient and thorough at the same time, in order to fulfill the ever-growing number of acoustic requirements. Calculation schemes, however are not scalable: one either uses oversimplistic statistical formulas in spreadsheets with minor efforts or creates acoustic models with disproportionate efforts required. Diverse formulation of requirements in different standards and recommendations is also a problem.
The paper suggests to use room schedules, which can be used to generate simple models for calculations. Room schedules are usually available from architectural data, but even the cost of manual data input or its maintenance should not be a problem in most cases.
Most relevant acoustic requirements can be verified using revised formulas without the computation cost of conventional acoustic modelling. Results can be used to generate reports in any required format from graphical representations to simple spreadsheets of bill of quantities.
The next step is to interface to more advanced calculation methods and add functionalities of other fields of acoustics (noise, sound isolation, PA). Also, simple algorithms can suggest solutions or indicate weaknesses automatically.

INTRODUCTION OF A GRASSHOPPER WORKFLOW FOR THE INTEGRATION OF THE ACOUSTIC ANALYSIS IN A MULTI-DOMAIN BIM MODEL

Andrea Gerbotto[1*] **Louena Shtrepi**[1] **Fabio Favoino**[1] **Arianna Astolfi**[1]
[1] Department of Energy, Politecnico di Torino, Italy

ABSTRACT

The growing demand for sustainable, energy-efficient buildings underscores the need for integrated modelling and simulation tools that support informed decision-making during early design stages. Among these, simulation of building physics performance, mainly acoustic analysis, has emerged as a critical focus area. Addressing multi-domain perspectives poses challenges, primarily due to interoperability issues and the varied data management approaches across specialised tools. This paper presents a workflow for integrating acoustic performance calculations within a BIM (Building Information Modeling) model. It details the development of an acoustic assessment tool in Grasshopper, utilising Rhino.Inside Revit, for preliminary evaluations of facade acoustic insulation. The tool supports the selection of transparent and opaque elements while accounting for potential conflicts with other performance criteria, such as thermal and lighting properties. Developed as part of the iclimabuilt project, this workflow aims to advance decision-making through seamless interoperability, enhancing efficiency, sustainability, and architectural performance outcomes.

Keywords: *BIM, BPS, facade insulation*

1. INTRODUCTION

A multidomain simulation workflow was developed, integrating Rhino.Inside® Revit to connect the BIM tool Revit with the Building Performance Simulation (BPS) tools in Grasshopper within Rhino. Specifically, 'Honeybee' was utilised for energy and daylighting simulations via EnergyPlus and Radiance engines. The interoperability between BIM and BPS was enhanced through the use of Python scripts, ensuring the accurate linkage of geometry and material performance parameters between Revit and Grasshopper. Additionally, the workflow was extended to incorporate acoustic analysis for façade sound insulation and the 'Bombyx' tool for Life Cycle Assessment (LCA). This expansion enabled a more comprehensive evaluation, including occupant comfort and the embodied energy of materials, which complemented the assessment of operational energy for cooling, heating, and lighting.

2. DEVELOPMENT OF THE RHINO.INSIDE REVIT SIMULATION WORKFLOW

A comprehensive analysis of the current workflow involving BIM models, either within authoring software or through external IFC-compliant tools, has been conducted to define the integration of acoustic simulations into the multi-domain workflow. This analysis demonstrates that there is great potential in integrating building and room acoustics into architectural models to make more informed decisions about acoustic characteristics in the design phases of a building; however, several challenges have so far prevented such large-scale integration [1].

Most studies focus on reverberation time calculations and, in some cases, impulse response and auralization, with a specific emphasis on environments such as auditoriums and classrooms. Some contributions have explored the connection between BIM and acoustic software:

- Kim, Coffeen, and Sanguinetti [2] linked Revit with EASE to enhance collaboration between acousticians and architects;
- Mastino et al. [3] developed a workflow for integrating acoustic assessments into BIM processes;
- More recently, McGinley et al. [4] proposed an OpenBIM workflow to improve collaboration between designers and acoustic consultants, while Starowicz and Zielinski [5] analyzed the potential of Artificial Intelligence in acoustic design.

The findings suggest that although partial approaches exist, fully interoperable tools between BIM and acoustic analysis software are still lacking. A major obstacle is the absence of a structured acoustic ontology within the IFC standard [6], which hinders the full integration of acoustic analysis into BIM models.

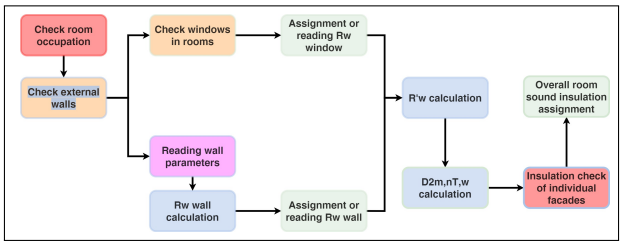

Figure 1. Rhino.Inside Grasshopper workflow.

2.1 Airborne sound insulation against outdoor noise

The workflow has been developed to calculate the standardised level difference of the façades of the occupied rooms $D_{2m,nT,w}$ as:

$$D_{2m,nT,w} = R'_w + \Delta L_{fs} + 10\log\left(\frac{C_{sab}V}{T_0 S}\right) \quad (1)$$

where:

- R'_w is the apparent sound reduction index of the façade;
- ΔL_{fs} is the level difference due to façade shape, in dB;
- C_{sab} is the Sabine constant, $C_{sab} = 0.16$ s/m;
- V is the volume of the receiving room, in m^3;
- S is the total area of the façade as seen from the inside, the sum of the area of all the façade elements, in m^2;
- T_0 is the reference reverberation time, $T_0 = 0.5$ s.

The volume and surfaces can be derived from the model, while ΔL_{fs} must be manually defined for each façade, as specified in Table C.1 (EN ISO 12354-3, Annex C).

The apparent sound reduction index R'_w of the façade is the sum of the sound reduction index R_w of the façade and a contribution due to the flanking transmissions of the surrounding elements. This contribution usually is negligible; however, if rigid components, such as concrete or brick, are connected to other rigid elements within the receiving room, such as floors or partition walls, flanking transmission can contribute to the overall sound transmission; so, in cases with rigid elements, flanking transmission can be incorporated globally by reducing the sound reduction index subtracting 2 dB (EN ISO 12354-3).

The sound reduction index of the façade, then, is the average of the sound reduction indexes of the elements composing it, mainly walls and windows, because it's possible to have different distributions of windows, with different areas and sound reduction indexes, in the façades, it's convenient, in the implemented workflow, to calculate an average sound reduction index and a total area of the windows of the single façade.

2.2 Model geometry

It has been considered, as a case study, a typical 4-floor office building constructed with a concrete structure and brick walls (Figure 2), featuring an additional external layer of high-density insulating mineral wool. From each office room, it has been derived, thanks to Rhino.Inside components, all the geometric inputs needed for the analysis, in particular:

- the volume $[m^3]$ of each room;
- the surface $[m^2]$ of each external wall;
- the dimensions $[m]$ of each window in the external walls of the considered rooms;
- the thickness $[m]$ of the layers of the wall stratigraphy.

2.3 Acoustic parameters

Due to the insufficient implementation of acoustic ontology in the IFC schema, it has been necessary to define some shared parameters in the Revit project to correctly insert acoustic parameters into the model, which can be queried for analysis, updated, or compiled at the end.

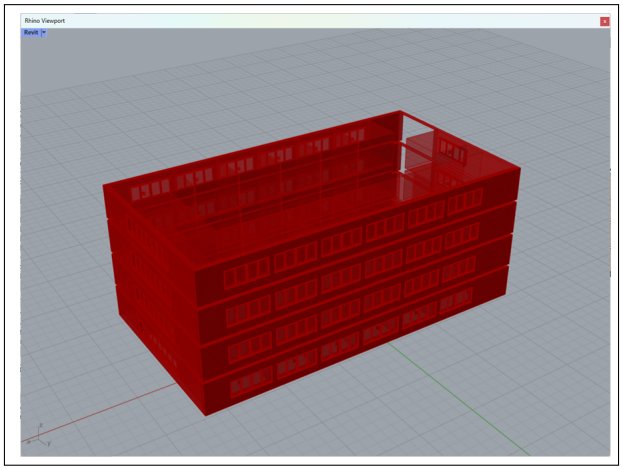

Figure 2. BIM model analysed.

This shared parameters could be of two different types:

- Type parameters, which define common properties shared by all instances of a specific type;
- Instance parameters, which represent unique properties of individual occurrences.

2.3.1 Input parameters

As input parameters, it is necessary to define the **Sound Reduction Index** of the elements involved, specified as a type parameter, because it is derived solely from the stratigraphy or the specific construction type of the element. In particular, while the sound reduction index of the windows is usually derived from facility testing and certified due to the standardised way they are produced, for the walls, it could be defined from facility testing in very specific conditions or, more often, derived from semiempirical formulas, like the ones suggested in the EN ISO 12354-1, where it's also defined how to calculate the ΔR_w due to additional layers, like wall linings or thermal insulation systems. Other necessary parameters are mainly instance parameters because they are specific for each element, like the **Occupancy** of each room, the **Façade Shape Factor**, potentially different for each external wall, or the **Flanking**, defined by the type of connections between external and internal walls.

2.3.2 Output parameters

As output parameters, it has been necessary to define a Sound Insulation parameter for each room into which to insert the calculation results and permit the automatic validation of the model according to EIR specifications in the IDS file.

Table 1. Input parameters.

Parameter	Typology	Data type
Sound Reduction Index	Type	integer
Façade Shape Factor	Instance	integer
Flanking	Instance	boolean
Occupancy	Instance	text

Table 2. Output parameters.

Parameter	Typology	Data type
Sound Reduction Index	Type	integer
Sound Insulation	Instance	integer

2.4 Outputs

Given the input parameters, the workflow calculates the standardised level difference of the façades ($D_{2m,nT,w}$), with a graphic and intuitive preview of the results to highlight those that need improvement, by changing the Sound Reduction Index of the windows or defining a new typology that could be selected from a database and instantly update the model (Figure 3).

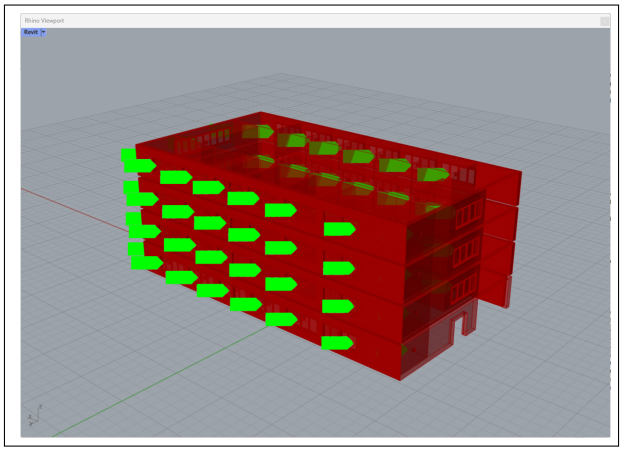

Figure 3. Façade insulation verified.

It is possible to export schedules or views from Revit

with all the correct data directly in the right families and instances (Figure 4) and, defined the proper PSets according to EIR specifications, it is possible to export an IFC that can be validated with the IDS file.

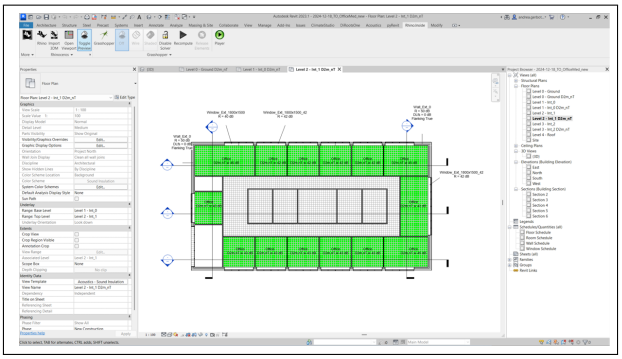

Figure 4. Floor plan with parameters.

3. CONCLUSIONS

This paper presented a novel workflow for integrating acoustic performance evaluation within a BIM-based multi-domain simulation framework. By leveraging Rhino.Inside Revit and Grasshopper, the approach ensures seamless interoperability between geometric and simulation tools, allowing for early-stage acoustic analysis alongside other performance criteria such as energy and daylighting. The proposed method enables the automated extraction of key geometrical and material parameters from BIM models, ensuring accurate and efficient façade sound insulation assessments.

The results demonstrate that incorporating acoustic analysis within the BIM workflow enhances decision-making by providing designers with immediate feedback on the acoustic performance of façade elements. The automated parameter integration and visualization capabilities further facilitate optimization, reducing manual errors and improving efficiency in the early design phase.

Some limitations remain. Certain parameters, such as the façade shape factor and flanking transmission contributions, still require manual input, which may introduce variability and reduce automation. Additionally, the Sound Reduction Index for walls often needs to be calculated externally using different theoretical models better suited to specific conditions, limiting full automation in material property assignment.

Future developments will focus on expanding the workflow to include more advanced room acoustics simulations and improving the implementation of curtain walls, given their widespread use in both new buildings and renovations, particularly in office and multifunctional spaces.

4. ACKNOWLEDGMENTS

The experimental activities presented in this paper were carried out as part of the H2020 project “iclimabuilt—Functional and advanced insulating and energy harvesting/storage materials across climate adaptive building envelopes” (Grant Agreement no. 952886).

MACHINE LEARNING-BASED PREDICTION OF AIR SOURCE HEAT PUMP NOISE ANNOYANCE

Volkan Acun[1*] **Simone Graetzer**[1] **Antonio J. Torija Martinez**[1]
[1] Acoustics Research Centre, University of Salford, United Kingdom

ABSTRACT

Air Source Heat Pumps (ASHPs) are pivotal in decarbonising domestic heating and air conditioning, yet noise emissions remain a significant barrier to their wider adoption. This paper presents a machine learning-based approach to predicting annoyance caused by ASHP noise emissions to address the complexity of human perception of noise by integrating psychoacoustic metrics, emotional responses, and demographic factors. Seven predictive models were evaluated, including tree-based methods (Gradient Boosting and Random Forest) and traditional regression approaches (Support Vector Machine, Lasso, Linear Regression, Ridge, and ElasticNet). Among these, the Gradient Boosting method demonstrated superior performance (test R^2 = 0.846, RMSE = 0.910) compared to linear methods, highlighting the non-linear nature of annoyance response. Feature importance analysis revealed emotional responses (Arousal and Valence) as the dominant predictors, collectively accounting for 92.3% of the model's predictive capability, while Zwicker's Psychoacoustic Annoyance (PA) and Tonality showed moderate correlations with these emotional factors, suggesting indirect influence and mediation effect. Despite limitations in available training data that did not allow full implementation of neural network approaches, the current model provides a robust foundation for predicting annoyance caused by ASHP noise emissions and highlighting the impact of subjective perception

1. INTRODUCTION

Switching from fossil fuels to renewable options is key for reducing carbon emissions in domestic heating and air conditioning around the globe. In Europe, buildings are the largest consumers of energy. Most of these buildings waste energy. They account for 36% of greenhouse gas emissions and 40% of total energy use [1]. One way to tackle this issue is by replacing old fossil fuel heating systems with energy-efficient options like air source heat pumps (ASHPs).

ASHPs are easy to maintain and cost-efficient. The thermal energy produced by an ASHP can be well over 100% of the amount of energy they use[2]. However, noise emissions from these units have raised concerns among the public. The spectrum of the ASHP noise varies depending on the operating condition of the unit. Low-frequency content dominates the ASHP signal, but it also typically includes both narrowband and tonal components [3], with becoming particularly more tonal in the low-frequency region. These components can significantly contribute to the annoyance caused by noise emissions.

The most common policy around ASHP noise emissions is regulating the A-weighted sound pressure levels. In addition, some countries, such as Germany, Finland, and the Netherlands, included tonal penalties in their noise assessment regulations to address the annoyance that could be caused by the tonal character of the signal [4]. These policies, in general, fell short of including the human perception of ASHP noise and solely relied on objective measures. People's subjective responses should

be used alongside the A-weighted sound pressure level-based measurement to ensure best practice in the policy.

This paper presents the preliminary results of a more extensive study to incorporate Machine Learning (ML) based models to predict the noise annoyance caused by ASHP noise emissions. This paper aims to investigate which acoustics and non-acoustic factors and ML methods are most suitable for developing a robust model that accurately predicts noise annoyance caused by ASHP noise emissions. By incorporating additional data from diverse datasets in the future, this research aims to develop a fast and accessible tool for supporting decision-making based on relevant acoustic and non-acoustic metrics. This will facilitate effective planning and placement of ASHP units to minimise noise impact on communities.

2. METHODS

The data used for this study were gathered through a listening test conducted at the Acoustics Research Centre of the University of Salford. This listening test was concerned with human perception of ASHP noise at various source distances, background noise levels, and under different loads. It consisted of two parts, each examining different aspects of the ASHP noise under different background noise levels and source distances. The first part of the experiment considered people's reactions to continuous ASHP noise. In contrast, the second part concerned the response to transient ASHP noise. However, the scope of this study does not include the investigation of the responses to continuous and transient noise, source distances or the effect of different background noise levels. Instead, the focus is on understanding how the subjective response and psychoacoustic character of ASHP noise affects perception and how it can be used to develop an ML-based prediction model. Therefore, only a brief overview of the experimental procedure is provided.

2.1 Audio Stimuli

The audio stimuli used in this experiment were based on recordings conducted as part of the IAE HPT Annex 51[4][5]. These recordings had a sampling rate of 96 kHz and were calibrated to the original levels based on a 94 dB(A) 1 kHz calibration tone.

Two recordings were selected from this original recording dataset and trimmed into shorter segments of two different lengths for two distinct parts of the experiment (20 s for Part 1 and 60 s for Part 2). Responses to both parts of the experiment were used in this ML implementation. The sound levels (L_{Aeq20s} and L_{Aeq60s}) of these excerpts were calibrated in the Listening Room of the University of Salford's Acoustics Labs to ASHP-receiver distance attenuation target levels (36.5 dB(A) at 15 m, 40 dB(A) at 10 m, and 46 dB(A) at 5 m).

In addition, ambient background noise is added to the ASHP signal. Instead of a soundscape recording, a shaped pink noise is used as the ambient background noise. To achieve this, pink noise is filtered to represent a typical traffic noise spectrum based on the filter curve detailed in the BS EN ISO 717-2020 [7]. The shaped-pink noise was then calibrated to 39.5 dB(A) and 31.5 to represent the ambient daytime and nighttime background noise levels of a typical rural area [8].

Lastly, these stimuli were propagated indoors through a partially open window (0.05 m^2) following a filter curve provided by [9]. A total of 114 audio stimuli were used for parts one (84 stimuli) and two (30 stimuli). The participants were pseudo-randomly presented with half of the stimuli (57 stimuli) from the stimulus sets for each part of the experiment. Additionally, three control stimuli (2 stimuli for Part 1 and 1 stimulus for Part 2), which only included the shaped pink noise as ambient background noise, were presented to each participant.

2.2 Experimental Procedure

Listening tests were conducted in the University of Salford's Listening Room following ethical approval (Ref: 2024-0145-228). Participants listened to 60 audio stimuli across two parts (Part 1: 42 audio stimuli + 2 control stimuli; Part 2: 15 Audio stimuli and one control stimulus), with responses submitted via a custom Python GUI. The playback system included a Motu 4Pre interface, Genelec 8030A loudspeaker, and 7020B subwoofer, with participants seated 2 m from the source.

Each session lasted approximately 70 minutes and included breaks between parts. Before starting, participants completed consent forms, demographic questions, and the NoiSeQ noise sensitivity scale. After each stimulus, they rated Valence and Arousal on a 9-point Self-Assessment Manikin (SAM) scale, reflecting pleasantness and alertness. Annoyance was rated using a 0–10 scale (0 – "Not Annoying at All," 10 – "Extremely Annoying") adapted from ISO/TS 15666:2021 [10].

In Part 2, participants responded to two temporal points per stimulus to capture perceptual changes, resulting in 75 total responses per participant.

2.3 Participants

The dataset used for research consisted of 50 volunteers that participated in the experiment: 35 male (70%) and 15 female (30%), aged between 19 and 57 years (mean = 32.1, SD = 8.95). Nearly half of the participants reported having expertise in audio or music (n= 24, 48%), while just over half stated they had no previous experience (n= 26, 52%). Most participants lacked expertise in environmental noise or urban planning (n=40, 80%). In terms of housing, 18 participants resided in apartments (36%), nine in terraced houses (18%), six in semi-detached houses (12%), five in detached houses (10%), and the rest lived in student accommodation or shared housing.

2.4 Data Analysis

ArtemiS Suite 15.6 is used to calculate the sound quality metrics (SQM) of the audio stimuli, including Loudness, Sharpness, Roughness, Fluctuation Strength, and Tonality. Loudness and Sharpness metrics are calculated according to DIN 45631/A1[11] standard, while ECMA 418-2(1st)/(2nd) [12] is used for calculating Roughness, Tonality and Fluctuation Strength.

In addition to SQM, Zwicker's Psychoacoustic Annoyance (PA)model [13] is calculated using the formula:

$$PA = N_5\left(1 + \sqrt{w_S^2 + w_{FR}^2}\right) \tag{1}$$

Where:

- N5 percentile loudness in Sone

$$w_S = \left(\frac{S}{\text{acum}} - 1.75\right) \cdot 0.25 \log\left(\frac{N_5}{\text{sone}} + 10\right) \quad \text{for} \quad S > 1.75\ \text{acum} \tag{2}$$

- describing the effect of Sharpness in S and

$$w_{\text{FR}} = \frac{2.18}{(N_5/\text{sone})^{0.4}}\left(0.4 \cdot \frac{F}{\text{vacil}} + 0.6 \cdot \frac{R}{\text{asper}}\right) \tag{3}$$

- describing Roughness R and Fluctuation F.

To quantify the application of ML methods to predict annoyance from ASHP noise emissions, Python 3.13.1 was used with relevant data analysis and visualisation libraries, including scikit-learn, statsmodels, matplotlib, and seaborn.

As previously mentioned, the dataset used for this experiment consisted of responses from 50 participants, each submitting a total of 75 responses, resulting in 3750 data points. Because of this relatively small sample size, ANN-based models were not considered in the prediction model. Instead, the study employed a range of ML-based linear regression models, including Ridge, Lasso, Elastic Net and Linear; tree-based models, including Random Forest and Gradient Boosting; and Support Vector Machine regression (SVR). These models were selected to compare performance across different regression approaches, balancing interpretability and prediction accuracy.

To optimise the hyperparameters of these models, GridSearchCV from the scikit-learn library was employed. This tool is commonly used for tuning the hyperparameters for ML algorithms by automating the process of finding the optimal combination of hyperparameters by exploring a predefined grid of parameter values and evaluating each combination using cross-validation [14]

To ensure the robustness of the results, 5-fold cross-validation (k=5) was used. This method partitions the dataset into five subsets, using each one for validation while the remaining four subsets are used for training. The use of cross-validation helps mitigate overfitting and provides a more reliable estimate of model performance, particularly given the relatively limited sample size in this study.

3. RESULTS AND DISCUSSION

The main focus of developing this prediction model was to incorporate the subjective response and psychoacoustic characteristics of ASHP noise using SQM. Performances of different feature combinations are compared across the previously listed regression and tree-based ML methods to determine which features to include in addition to the subjective response variables of Valence and Arousal and the SQM.

Table 1: Comparison of VIF values for training features that include Psychoacoustic Annoyance (PA) and Sound Quality Metrics (SQM)

Variance Inflation Factor (VIF) values:		
Feature	SQM as Predictors	PA as a Predictor
Tonality	8.673	8.456
Valence	8.08	6.161
Arousal	13.668	5.751
Age	12.258	10.231
PA	NA	10.539
Loudness	27.238	NA
Roughness	23.52	NA
Sharpness	27.557	NA
Fluctuation	4.618	NA

Multicollinearity analysis was conducted as part of the model comparisons, which revealed substantial interdependence among the original SQM. VIF values for Loudness (27.238), Sharpness (27.557), and Roughness (23.52) in the initial model exceeded recommended thresholds, indicating problematic collinearity (Table 1). When these metrics were replaced with the composite Psychoacoustic Annoyance (PA) parameter, the model's multicollinearity was substantially reduced. The PA-inclusive model demonstrated improved VIF values across predictor variables, with Arousal showing the most dramatic reduction (from 13.668 to 5.751). Although PA exhibited a VIF (10.539) value right at the cutoff value, it remains considerably lower than the metrics it replaced. The replacement of individual sound quality metrics with PA not only addresses multicollinearity concerns but also provides a more compact model while preserving essential psychoacoustic information. A-weighted sound levels are not included in this model, as they provided extreme VIF values and did not significantly contribute to the predictive power in any of the tested models.

The only demographic variable included in the models was Age. While other demographic variables were initially considered, such as gender and noise sensitivity data from NoiSeQ responses, they either produced extremely high VIF values (e.g. NoiSeQ VIF = 32.780 when used alongside the final features) or were found to not meaningfully contribute to the model based on correlation and feature importance analysis.

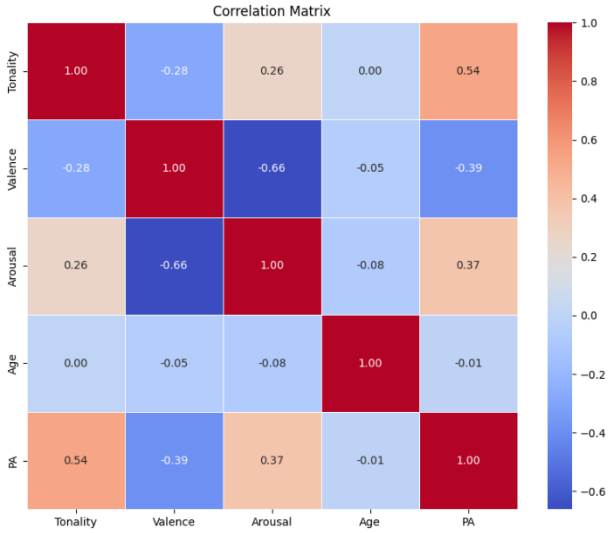

Figure 1: Heatmap representing the correlation matrix between the final set of predictor variables.

Figure 1 shows the correlation matrix between the final set of predictor variables used in the model comparison, providing further justification for the variable selection strategy explained in the VIF analysis. PA and Tonality are the strongest predictors in the matrix. The moderate correlation between PA and subjective response variables (Valence: -0.30, Arousal: 0.37) indicates that while PA effectively consolidates the SQM, it remains sufficiently distinct from other subjective response variables. Age shows the weakest correlation among all the predictors. It is kept as an independent factor in the model since a correlation matrix only captures the linear relationships, while models like Gradient Boosting and Random Forest can capture non-linear patterns and interaction effects that may not be evident in a correlation matrix.

A comprehensive evaluation of predictive models was conducted to identify the optimal approach for estimating acoustic responses. Performance metrics, including R^2, Mean Absolute Error (MAE), Mean Squared Error (MSE), and Roost Mean Squared Error (RMSE), were calculated for training and test datasets across seven distinct modelling techniques (Table 2). Among all the models compared, the Random Forest achieved the highest training R^2 (0.917), suggesting excellent data fitting; however, the slightly lower test performance (R^2 = 0.834) indicated potential overfitting. Linear models (SVR, Lasso, Linear Regression,

Table 2: Comparison of train and test performance of different models.

Model	Train R^2	Test R^2	Train MAE	Test MAE	Train MSE	Test MSE	Train RMSE	Test RMSE
Gradient Boost	0.902	0.846	0.543	0.677	0.525	0.829	0.725	0.910
Random Forest	0.917	0.834	0.500	0.703	0.447	0.889	0.668	0.943
SVR	0.758	0.757	0.875	0.877	1.298	1.301	1.139	1.140
Lasso	0.751	0.750	0.892	0.892	1.339	1.341	1.157	1.158
Linear Regression	0.754	0.753	0.888	0.889	1.321	1.326	1.149	1.151
Ridge	0.754	0.753	0.888	0.889	1.321	1.325	1.150	1.151
ElasticNet	0.753	0.752	0.890	0.891	1.330	1.331	1.153	1.154

Ridge, and ElasticNet) exhibited comparable performance patterns, with test R^2 values ranging from 0.750 to 0.757, substantially lower than the ensemble methods. The consistency between training and test metrics for these linear models, particularly SVR (training $R^2 = 0.758$, test $R^2 = 0.757$), suggests stable performance despite lower overall accuracy. A significant performance gap between tree-based ensemble methods and linear models was observed, with approximately 10% improvement in explained variance and almost 20% reduction in prediction error, highlighting important non-linear relationships in the data.

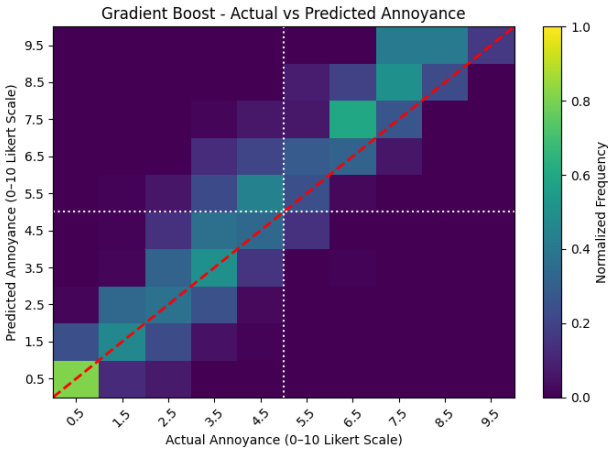

Figure 2: Heatmap showing the normalised frequency of predicted vs annoyance ratings for the Gradient Boost model. Each cell's colour represents the proportion of test samples falling into the corresponding (actual, predicted) bin. The red dashed line diagonal represents the perfect prediction.

The consistency between training and test metrics for these linear models, particularly SVR (training $R^2 = 0.758$, test $R^2 = 0.757$), suggests stable performance despite lower overall accuracy.

Among the models compared, the Gradient Boosting model demonstrated the best balance between predictive accuracy and generalisation. It achieved the highest test R^2 (0.846) while maintaining the lowest test error metrics (MAE = 0.677, RMSE = 0.910), indicating superior performance on unseen data and capturing potentially non-linear relationships. While Random Forest showed a slightly better prediction power over the training data, as it showed evidence of overfitting, the Gradient Boosting model was chosen to be used. In addition, the Gradient Boost method effectively handles multicollinearity. Based on the VIF values shown in Table 01, this is a requirement of the model, as both PA and Age are at the critical thresholds for multicollinearity.

Figure 2 illustrates the predictive performance of the model by comparing the actual and predicted values. The heatmap demonstrates a strong linear relationship between predicted and actual Annoyance values. Overall, the model aligns strongly with the prediction diagonal (red dashed line) but shows some deviation and mild underprediction for higher annoyance values.

Finally, feature importance scores were computed for the Gradient Boost model to understand the relative contribution of each predictor. The highest feature importance scores were observed for Arousal (0.550) and Valence (0.373), which accounted for 92.3% of the predictive power, which are also affected by the ASHP noise. Feature importance scores show that Age contributed

0.0659, while PA (0.0078) and Tonality (0.0026) had minimal impact. While these results indicate that psychoacoustic factors and tonality have a minimal direct impact on this model, their role in shaping the primary predictors should not be overlooked. When these results are considered with the insights from the correlation matrix (Figure 1), it shows that PA and Tonality are moderately correlated with Arousal and Valence, which are the most influential features. This indicates a potential mediating effect, where PA and Tonality influence the prediction indirectly via Arousal and Valence. This emphasises the importance of gaining a deeper understanding of the subjective responses to ASHP noise emissions and considering the soundscape approach.

4. LIMITATIONS AND FUTURE WORK

The main aim of this research was to create a robust ML-based prediction model and leverage ANN models. At the time of writing this paper, this is only partially achieved due to the lack of access to relevant datasets. The first step in future work will be supplementing this research with further data from similar acoustic studies. This will allow the development of more sophisticated ANN-based models capable of capturing the complex non-linear relationships observed in the Gradient Boost implementation. The significant performance gap between ensemble and linear models suggests that deep learning approaches offer additional predictive power with sufficient training data.

Future iterations of the model can also include temporal dynamics ASHP operation cycles. While the dataset from this study included different operating conditions and transient events, possibly due to sample size limitations, they were not found to be significant in any of the top-performing models. The temporal dynamics of SMQ and PA should also be further investigated. Incorporating time-varying acoustic features could better represent real-world ASHP operational conditions.

5. CONCLUSION

This study investigated the prediction of Annoyance responses to Air Source Heat Pump (ASHP) noise using machine learning (ML) approaches. The comparison of various regression models demonstrated that tree-based models, particularly Gradient Boosting, outperformed linear regression techniques. This superior performance highlights complex non-linear relationships in the perception of annoyance that simpler models fail to capture adequately. The PA is implemented as a composite metric to address multicollinearity issues present in the original SQM, resulting in a more compact and robust model.

Feature importance analysis revealed that emotional responses, specifically Arousal (0.550) and Valence (0.373), were the dominant predictors of annoyance, collectively accounting for over 92% of the model's predictive power. While PA and Tonality showed minimal direct contributions, their moderate correlations with the primary predictors suggest an indirect influence through emotional responses. This finding underscores the complex interplay between objective acoustic parameters and subjective emotional responses, supporting the adoption of soundscape approaches in noise annoyance research. The observed relationships emphasise the necessity of considering both acoustic and non-acoustic factors when evaluating and mitigating ASHP noise impacts.

The successful development of this predictive model represents a significant step toward practical applications in sustainable urban development. Despite limitations in available training data, the model demonstrates considerable potential for real-world implementation. Future work will focus on expanding the dataset to enable more sophisticated neural network implementations and incorporating temporal variations in acoustic features. The ultimate goal remains the integration of these predictive capabilities into accessible tools for optimal ASHP placement, thereby supporting the widespread adoption of this sustainable technology while minimising community noise impacts. This balanced approach could substantially contribute to meeting climate goals without compromising acoustic comfort in residential environments.

6. ACKNOWLEDGEMENTS

This study was supported by the University of Salford's Pump Prime Funding and the Future Homes Project, which is funded through the Innovation Accelerator programme by Innovate UK (Project No. 10054845).

CHARACTERISATION AND CONTROL OF AERO-ACOUSTICAL INFLOW NOISE SOURCES OF THE EVAPORATOR FAN IN HEAT PUMPS

Frieder Lörcher* **Sandra Hub**

ZIEHL-ABEGG SE, 74653 Künzelsau, Germany

ABSTRACT

Recent heat pump fans are nowadays often optimized towards a very low self-noise level. Still less effort is expended in the field of additional noise sources generated by spatially and temporally inhomogeneous inflow to the fan, in particular the tonal unsteady loading noise and the broadband turbulence ingestion noise, which depend mainly on the upstream installation conditions and are therefore called “inflow noise”. It is shown for a state-of-the art air-to-water heat pump with 12 kW rated capacity and an evaporator heat exchanger in L-form that the inflow noise exceeds the self-noise of the fan given by the fan supplier. The conclusion is that the optimisation potential considering the inflow noise is more promising than considering a further self-noise optimisation of the fan.
For the considered device, the inflow noise is analysed and characterized along with the causal inhomogeneous inflow conditions to the fan. Both numerical and experimental results are presented. Some optimizing approaches to reduce the inflow noise are investigated, considering both the fan design and installation arrangement. The A-rated total noise emission can be reduced, but, more important, the annoying tonal character of the noise can be attenuated significantly.

1. INTRODUCTION

Heat pumps have become established as efficient and environmentally friendly solutions for the heating and cooling of buildings. Despite their numerous advantages, the noise emitted by the outdoor units (evaporators) poses a significant challenge - particularly in residential areas where low sound levels are required. A substantial proportion of this noise arises from aeroacoustic phenomena associated with the operation of the evaporator fans.
The analysis and control of these noise sources are essential for improving acoustic comfort and enhancing the acceptance of heat pump systems. In recent years, fan researchers and manufacturers have made considerable progress in reducing the sound power levels of their products. However, the focus of such development work is often limited to the fan's intrinsic noise under laboratory conditions, as for example the tip gap noise [2] or stall-related noise [3]. When integrated into actual heat pump systems, significantly higher noise levels are frequently observed. Installation effects of fans in heat pumps concerning efficiency have been investigated in [4]. In [5], the installation fan noise induced by upstream located heat exchangers is investigated.
This study focuses on the mechanisms responsible for the additional aeroacoustic noise (installation noise) generated by evaporator fans in heat pumps, which go beyond the fan's self-noise. These mechanisms are categorised into two principal types: tonal and broadband installation noise. Based on numerical simulations and experimental measurements carried out on a specific evaporator configuration from the publicly funded collaborative "WarmHome" project [1], models for these noise sources are presented, along with strategies for their mitigation.

2. EVAPORATOR AND REFERENCE FAN IN THE WARMHOME PROJECT

In the WarmHome project, a specifically designed L-shaped evaporator heat exchanger with dimensions Width x Depth x Height = 1070 mm x 315 mm x 1200 mm is used to enable particularly compact integration into the heat pump's installation space. The L-shaped geometry induces a deflection of the airflow within the outdoor unit, resulting in more inhomogeneous inflow conditions at the evaporator fan. These installation-specific conditions form the basis for the aeroacoustic effects investigated in this study. A sample of the heat exchanger mounted in a wooden mock-up of the airside of the evaporator is shown in Figure 1.

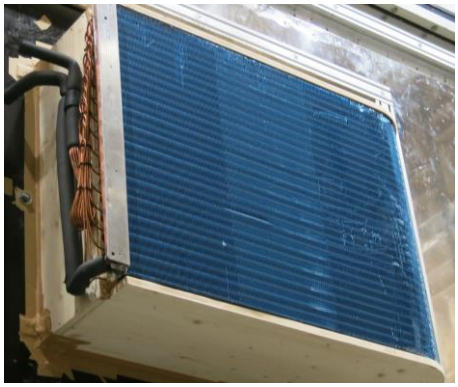

Figure 1. The L-shaped evaporator heat exchanger mounted in the test chamber.

To investigate the relevant noise generation mechanisms and possible optimization approaches, a reference fan was selected that reflects the current state of the art. The chosen axial fan is the commercial fan ZIEHL-ABEGG FPowlet [6] with rotor diameter of 630 mm, 3 impeller blades and a maximum rotation speed of 770 rpm. It is suitable for an operating point of 5000 m³/h at 17 Pa at rotation speed 475 rpm and features low self-noise emission levels. The total sound power of the self-noise given in the data sheet at the nominal operating point is 49 dB(A). This makes it a suitable match for the air-to-water heat pump with a heating capacity of 12 kW to be developed within the project, using the selected evaporator heat exchanger. A model of the fan is shown in Figure 2. The with aerodynamic parts are made of glass fibre reinforced polypropylene

The combination of the L-shaped heat exchanger and the reference fan represents the system under acoustic investigation. This system and variations of it were analysed both experimentally under controlled conditions in a free-field environment and numerically using Lattice-Boltzmann simulation methods.

Figure 2. Reference fan FP063.

3. EXPERIMENTAL SETUP

Aeroacoustic experiments are performed in the ZIEHL-ABEGG anechoic facility with experimental fan testing according to ISO 5801 [7]. The test rig consists of two large anechoic rooms separated by a partition wall. The fan or evaporator unit were attached und integrated with in the partition wall between an upstream and a downstream plenum. Both the inlet plenum (Figure 3) and the outlet plenum have non-reflective walls down to 100 Hz and have dimensions of 9 m x 9 m x 9 m.. Using this experimental setup, the baseline evaporator configuration, the baseline fan and variations thereof are analysed. The volume flow rate Q_V, the static pressure rise Δp_{stat} between the plenums and the shaft input power P_1 are recorded for different duty points, as well as the A-rated specific sound power levels L_W5 and L_W6 on the suction and pressure side, respectively, with the hull surface method. To obtain the total sound power level, the two sound power levels can be summed up using the logarithmic summation rules for level quantities.

Figure 3. Inlet plenum of the anechoic test facility with fan mounted in separation wall.

In addition to the sound power levels, a narrow band spectral decomposition of the emitted sound can be

obtained using the recorded sound signals of the 2 x 12 microphones used for sound analysis.

4. NUMERICAL METHOD

4.1 Numerical Setup

For deeper insight to flow phenomena, numerical simulations using the commercial PowerFLOWsolver 5.5a based on the Lattice-Boltzmann Method (LBM) are performed. The LBM is naturally transient and compressible providing a direct insight into hydrodynamic mechanisms responsible for the acoustic sources but also into acoustic propagation. The LBM tracks the time and space evolution of a truncated particle distribution function on a lattice grid. The particle distribution evolution is driven to the equilibrium by the so-called collision operator. The discrete Lattice-Boltzmann equations are solved with 19 discrete velocities for the third order truncation of the particle distribution function, which has been shown sufficient to recover the compressible Navier-Stokes equations for a perfect gas at low Mach number in isothermal conditions [8]. In PowerFLOW, a single relaxation time is used, which is related to the dimensionless laminar kinematic viscosity [9]. This relaxation time is replaced by an effective turbulent relaxation time that is derived from a systematic Renormalization Group procedure detailed in [10]. It captures the large structures in the anechoic room but also the small turbulent scales that develop along the wall surfaces in a Large Eddy Simulation manner. The particular extension developed for rotating machines can be found in Pérot et al. [11]. The computational domain includes the two coupled anechoic rooms as shown in Figure 4.

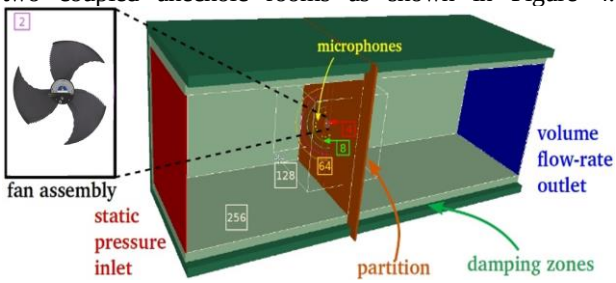

Figure 4. Computational domain and refinement volume definitions. Numbers in squares provide the mesh size in mm for the outlined refinement

The square cross section of the simulation volume has a width of 10 m and the upstream and downstream plenums are also 30 m and 20 m long, respectively. The atmospheric pressure p = 101325 Pa is imposed on the left red surface, while the volume flowrate Qv is imposed on the downstream blue surface. The convergent inlet nozzle and detailed geometry of the fan impeller are considered. Only the motor and its shaft are discarded in the numerical setup. The mesh resolution in the domain is defined through successive embedded volumes, outlined in Figure 4, the mesh size being decreased by a factor of 2 between them. The resolution around the fan blades and the inlet nozzle wall is 0.5 mm. The volume around the fan is defined as a rotating volume at a rotational speed. Extended logarithmic wall functions to account for adverse and favourable pressure gradients [12] are applied on all wall surfaces. The total numerical domain counts 98 million cells and 7 million surface elements. Simulations are performed for several flow rates. First, the setup is initialized in two steps from pre-converged flow obtained from simulations with coarser meshes without the highest resolved refinement regions (50 revolutions computed on the mesh with maximum resolution of 2 mm and subsequently, 25 revolutions computed on the mesh with maximum resolution of 1 mm). Then, the finest mesh is used for performance prediction. The convergence is obtained after 2 fan revolutions on the finest mesh, and data are acquired for 5 fan revolutions. Static pressure is recorded at the exact locations of the microphones in the experiments. In addition, some cross-sections including the one at mid-blade height (midspan) and blade surface are recorded at high frequency sampling for frequency analysis.

4.2 Ingestion Turbulence Modelling

The modelling of the turbulence generated by the heat exchanger is crucial to get a good prediction of the installation noise for the installed condition. Three variants have been considered: Treatment of the heat exchanger as porous block; the same with modelled cooling liquid tubes downstream of the porous block and the use of a turbulent seeding with data obtained from a highly resolved simulation of a small heat exchanger segment. The latter is quite complex, and as the version with the modelled tubes gave similar results, it was applied for the present study.

4.3 Quality of numerical results

The numerical model presented above is validated through the comparison of performances with experimental measurements acquired on the certified ISO 5801 ZIEHL-ABEGG facilities. In Figure 7, a simulated sound power spectra comparison of the fan alone and the fan in installation situation is shown. The results must be seen in

comparison with the experimentally measured ones in Figure 6. At least the trend between the two, and thus the installation sound, is captured well by the simulations.

5. CHARACTERISATION OF INSTALLATION NOISE

5.1 Decomposition to Self-Noise and Installation Noise

The overall sound level of an evaporator fan in a heat pump primarily consists of two components: the self-noise of the fan and the installation noise, which arises from the specific integration of the fan into the device. Additional aerodynamic noise sources may also contribute, such as protective grille noise, but these are not considered in this study. Installation noise can be calculated as the difference between the total sound level in the installed condition and the isolated self-noise of the fan, typically determined under laboratory conditions. This approach applies to both overall sound power levels and their spectral representation.

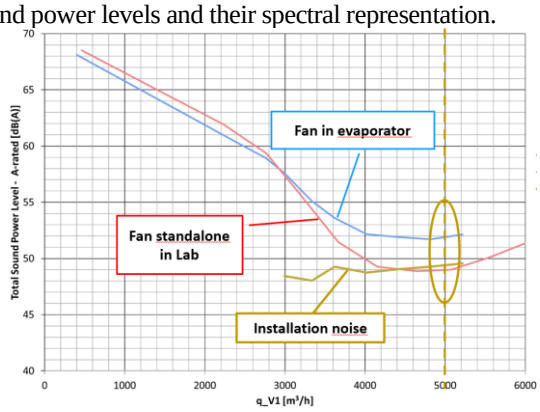

Figure 5. Decomposition of the fan noise in the evaporator installation condition

Figure 5 shows A-weighted overall sound power levels based on experimental measurements of the standalone fan and the fan installed within the evaporator for constant rotation speed and varying airflow Q_V (varying device resistance). The figure also includes the computed difference between both conditions (note that the subtraction must be performed using de-logarithmised sound power values). This difference is referred to as the inflow noise component associated with the heat exchanger measurement. It reaches a magnitude comparable to the fan's self-noise. At the highlighted operating point—corresponding to the nominal design point of the heat pump of Q_V=5000 m³/h—the installation noise component is even slightly higher than the fan's self-noise.

In typical heat pump applications, installation noise can significantly exceed the fan's self-noise—especially when an already acoustically optimised fan is used, as the optimisation typically focuses on the fan's self-noise emission. Consequently, the targeted reduction of installation noise represents a particularly promising strategy and an important measure for improving the overall acoustic performance of the system.

5.2 Spectral Analysis of Installation Noise and Tonality

The subtraction method for determining installation noise, as described in the previous section, can also be applied to sound power spectra, i.e. the frequency-resolved representation of sound power levels. Figure 6 shows a spectral comparison between the self-noise of the reference fan and the total noise measured in the installed configuration within the evaporator at the nominal operating point of Q_V= 5000 m³/h. The abscissa indicates the dimensionless frequency, expressed as multiples of the blade passing frequency (BPF), which is defined as the product of the number of blades and the rotational frequency of the impeller.

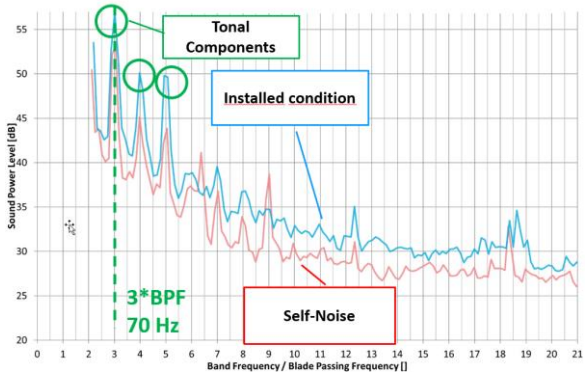

Figure 6. Total sound and self-noise (exp.)

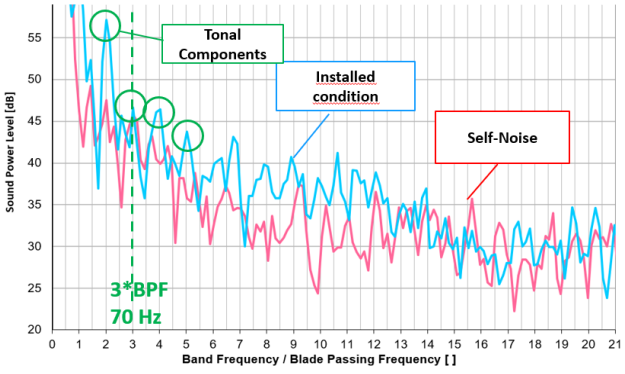

Figure 7. Total sound and self-noise (sim.)

The figure clearly reveals that tonal components are amplified at integer multiples of the BPF, and that the broadband noise level also increases in the installed condition. Figure 8 illustrates the resulting installation noise—i.e. the difference between total and self-noise—along with the self-noise spectrum for comparison. While both exhibit similar overall sound power levels, the installation noise in the current configuration shows a significantly more tonal character. This is a common observation in heat pump noise measurements, and it results in a perceptibly more tonal quality of the sound emission, as also evident in Figure 6.

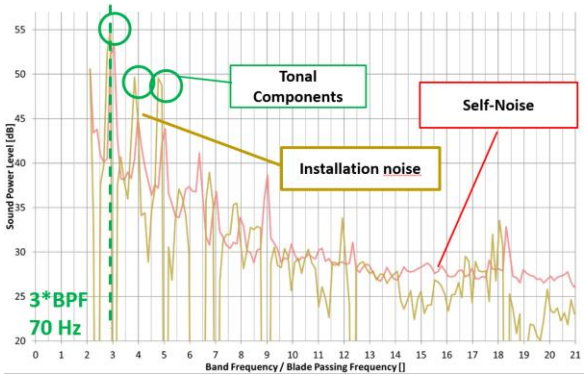

Figure 8. Spectral decomposition of installation noise and self-noise

Tonal sound components are generally perceived as more annoying. Therefore, standard [13] defines a concept of a tonality penalty, which adds a level adjustment in (dB) in cases where prominent tonal peaks occur in the noise spectrum. This approach is increasingly applied in the heat pump industry. According to Figure 6, the self-noise of the fan does not justify any tonality penalty, whereas the total noise measured in the installation condition results in a penalty of +2 dB. Consequently, from an acoustic design perspective, the tonal component of the installation noise should be a key area for system-level optimisation.

5.3 Generation Mechanisms

Installation noise can be divided into two main components:

- **Tonal components**, which appear as narrowband peaks in the frequency spectrum
- **Broadband components**, which manifest as a spectrally distributed sound power over a wide frequency range

These two types of noise result from distinct underlying physical mechanisms. A brief description of these is provided to better support the optimisation strategies discussed in later sections.

5.3.1 Generation Mechanisms of Tonal Installation Noise

Tonal noise components are typically caused by **unsteady aerodynamic loading**, which arises from time-averaged asymmetric inflow conditions. These may be induced by skewed or one-sided inflow, transitions from rectangular ducts, inflow grilles, bends, or obstructions in the intake region. Such features create a non-rotationally symmetric pressure field at the fan inlet, through which the rotor blades pass periodically. The resulting sound radiation occurs at discrete frequencies, often at multiples of the blade passing frequency (e.g. 3×BPF ≈ 70 Hz), and significantly contributes to the perceived tonality of the total sound.

5.3.2 Generation Mechanisms of Broadband Installation Noise

Broadband noise components primarily originate from the **interaction between the fan and turbulent structures** in the inflow, which are inherently unsteady and time-varying. Due to the stochastic distribution of their size, intensity, and form, the resulting sound has a broadband spectral character. These turbulent structures may arise from sharp flow deflections, abrupt geometry changes, structural elements such as struts, flow separations at the heat exchanger, or large stationary vortices.

The interaction with these turbulence-induced structures results in broadband pressure fluctuations at the blade surfaces, which are converted into acoustic emissions. The frequency content of this noise is related to the characteristic scale of the vortices—larger vortices generally lead to lower-frequency components. While this type of noise typically has less impact on the fan's aerodynamic performance, it can significantly contribute to the radiated sound power.

Notably, mechanisms that generate tonal noise—such as time-averaged inhomogeneous inflow fields—can also induce **secondary broadband noise components**, due to the additional generation of turbulence in the vicinity of the rotor.

6. OPTIMIZATION APPROACHES CONCERNING THE TONAL INSTALLATION NOISE

Three optimization approaches specifically aiming at the reduction of tonal installation noise by homogenising the inflow have been tested and are briefly described in this section.

6.1 Optimization of component arrangement

This is often the most cost-effective approach to reduce tonal—and potentially also broadband—installation noise, as it requires no additional components. Instead, the existing elements, particularly the fan, are arranged within the heat pump to achieve the most symmetrical inflow conditions possible at the fan inlet.
Figure 9 shows a visualisation of the time-averaged inflow velocity field—specifically, the circumferential velocity component VT—on a plane upstream of the fan impeller. The reference evaporator configuration, as analysed in Section 5, serves as the basis. A pronounced asymmetry in the inflow distribution can be observed, which is likely caused by the L-shaped geometry of the heat exchanger.

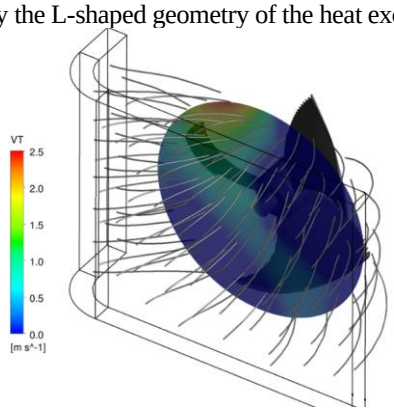

Figure 9. Time-averaged fan inflow velocity VT (reference configuration, simulation)

Shifting the fan approximately 10 cm towards the short branch of the L-shaped heat exchanger results in a more homogeneous inflow distribution, as shown in Figure 10.

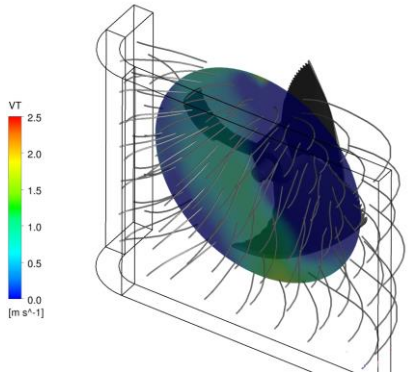

Figure 10. Time-averaged fan inflow velocity VT (optimized configuration, simulation)

The corresponding sound power spectrum, in comparison with the reference configuration, is presented in Figure 11. A substantial reduction in tonal components can be observed. According to [13], no tonal penalty is applicable in the optimised configuration—representing a significant acoustic improvement, even though the A-weighted total sound power level (not shown) remains nearly unchanged. In conclusion, careful spatial arrangement of components—particularly to achieve the most symmetrical and undisturbed fan inflow possible—proves highly effective in reducing the tonal content of heat pump noise emissions.

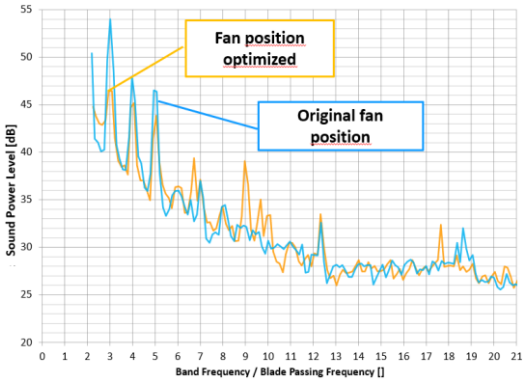

Figure 11. Spectral decomposition of the total noise (fan position optimization)

6.2 Use smooth flow-guiding wall elements

The flow-guiding elements depicted illustrated in Figure 12 were designed to reduce tonal noise by promoting a smoother and more symmetrical inflow distribution to the fan—primarily through the suppression of so-called corner vortices, potentially also reducing inflow turbulence and associated broadband noise. Previous investigations on a planar heat exchanger demonstrated that the implementation of four such elements, realised as 3D-printed parts and placed in each of the four corners, resulted in a significant reduction in installation noise tonality. In the present configuration, however, only a marginal improvement was achieved, and the tonal penalty could not be eliminated. This underlines that the effectiveness of such measures is highly case-specific. Therefore, the potential benefits of flow-conditioning elements should always be assessed through numerical simulations or prototype testing.

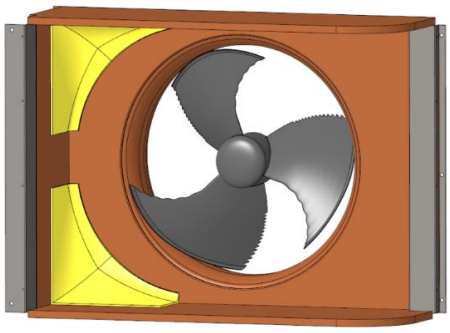

Figure 12. Flow-guiding wall elements (CAD, yellow)

6.3 Use of an inflow grid

To homogenise the inflow to the fan and reduce tonal as well as low-frequency broadband noise associated with large-scale vortical structures, inflow grids represent a promising solution. Figure 13 shows the CAD model of an inflow grid investigated in the present study.

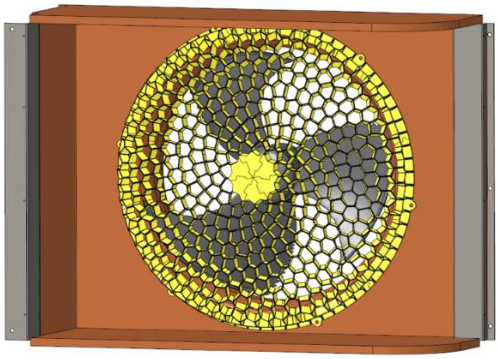

Figure 13. Inflow grid (CAD, yellow)

The corresponding comparison of the sound power spectra is shown in Figure 14. Similar to the optimised fan position (note: in this case, the fan position is not optimised), the tonal components are noticeably reduced, resulting in the elimination of the tonality penalty. In contrast to Figure 11, a broadband reduction in sound power is observed in the low-frequency range—likely due to the smoothing of large-scale vortical structures by the inflow grid. However, at higher frequencies, the installation noise increases, as the grid itself generates fine-scale turbulence. As a consequence, the A-weighted total sound power level is elevated when the inflow grid is used, making this approach less favourable than fan position optimisation in the present configuration.

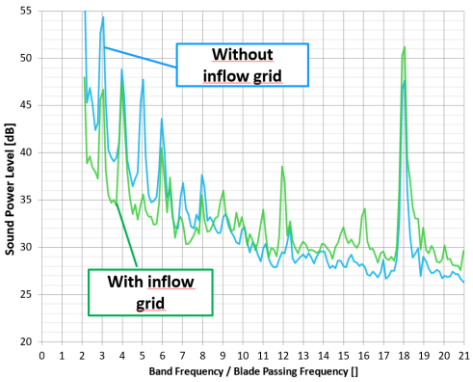

Figure 14. Spectral decomposition of the total noise with and without inflow grid

7. OPTIMIZATION APPROACHES CONCERNING THE BROADBAND INSTALLATION NOISE

In this section, some results concerning optimisation approaches with respect to broadband installation noise are briefly given in Tab. 1. The measures, located at the impeller blades, aim at reducing the emitted sound power when flow inhomogeneities as vortices collide with the blades. So in principle, they are also suitable to reduce tonal noise, but in practise, the effectiveness is more given for smaller vortical structures and thus higher frequencies where broadband noise dominates.

Table 1. Investigates measures at impeller blades to reduce sound emissions.

Description	Photograph	Best Results
Slotted Leading edge region		Tonality +-0 dB Broadband -1 dB(A) Efficiency -1%
Porous leading Edge Region		Tonality +-0 dB Broadband +2 dB(A) Efficiency -1%

8. CONCLUSIONS

An investigation of the aeroacoustic installation noise of an evaporator fan in a 12-kW air-to-water heat pump, featuring an L-shaped heat exchanger, is presented in the present work. While modern axial fans often exhibit low self-noise in standardised laboratory conditions, significantly higher noise levels can be observed once integrated into the system. The analysis revealed that the installation noise—arising from the upstream flow conditions—can exceed the fan's self-noise and substantially contribute to the perceived tonality of the emitted sound.

A combination of experimental and numerical methods, including Lattice-Boltzmann simulations and measurements in a certified anechoic facility, enabled a decomposition of self-noise and installation noise. The spectral analysis confirmed that tonal components are amplified due to asymmetric and broadband components due to turbulent inflow, both being strongly influenced by the geometric integration of the fan within the heat exchanger housing.

Three optimisation strategies were tested to reduce tonal components of installation noise: (1) optimised fan positioning, (2) flow-guiding elements, and (3) inflow grids. Among these, shifting the fan towards the short branch of the L-shaped evaporator yielded the most significant acoustic improvement, effectively eliminating tonal penalties without increasing the overall sound power level. While flow-guiding elements and inflow grids showed some positive effects, their performance was highly case-dependent and, in the case of the inflow grid, introduced additional high-frequency noise.

The findings highlight that system-level integration and spatial arrangement of components play a critical role in the aeroacoustic performance of heat pump fans. Future work should focus on the automated optimisation of inflow conditions using simulation-driven design and on establishing robust guidelines for low-noise fan integration in compact heat pump units.

IMPROVE HEAT PUMP PLACEMENT CONSIDERING FREQUENCY RESOLVED ACOUSTIC DIRECTIVITY DATA: CREATION OF AN OPEN DATABASE

Reichl Christoph[1*] **Bessac Francois**[2] **Klein Georg**[1]

ABSTRACT

Heat pumps are becoming increasingly popular due to their efficiency, carbon neutrality and use of renewable energy resources. Air-to-water heat pumps are often chosen because of their low cost and ease of installation. However, optimal placement to minimise acoustic emissions is mandatory for a barrier-free deployment. At present, the assessment of noise propagation for outdoor units suffers from a lack of information on the frequency content, and particularly the directivity of the sound source. During heat pump certification, standardised test procedures using the sound intensity measurement technique provide frequency-resolved partial sound power levels for the five different surfaces surrounding the heat pump. This gives the basic directivity information needed for optimised placement recommendations. In the framework of IEA HPT Annex 63, an anonymous database has been designed that combines dimensions, operating conditions and a generic description of each of the 5 sides (fan(s), heat exchanger, blind sides) with their corresponding frequency spectrums. Initially, about 30 heat pumps measured at CETIAT and AIT will be included in the database and a first exploitation will be presented. The database will be enriched by the authors during the year 2025 with the possibility of contributions from other interested laboratories during this period.

Keywords: air-to-water heat pumps, acoustics, directivity, database

1. INTRODUCTION

For many potential future users of heat pumps, noise remains one of the main reasons for their reluctance to switch to this method of energy production: noise to themselves, but more importantly, noise to their neighbours. The most reliable acoustic data available to end users is that obtained through certification. This is because the values displayed are verified by independent third party laboratories that follow a certification protocol based on international measurement standards. The certified value is the overall sound power level in $dB(A)$, which is already very valuable information. However, the laboratories all measure the sound power level spectrum in third octaves, which is not publicly available. This is a gap in the acoustic description of heat pumps, which may be missed by acousticians who want to implement noise attenuation measures, or optimise the placement of outdoor units. Another missing piece of data is the directivity of the units; this data can be very useful in a predictive calculation of the positioning of the outdoor unit in a dense urban environment. The noise requirements are such that the intelligent use of radiation directivity can become a parameter to be exploited. This data is not generally available, including from manufacturers, and is not directly part of the certification process. The EN 12102-1 standard authorises several acoustic measurement methods, the two most commonly used being the reverberation chamber and intensimetry. The latter, which measures the sound power

level per surface, ultimately provides information on the directivity of the unit. Admittedly, it is a bit crude, but it is very interesting, because it gives the sound power level per surface for each 1/3 octave frequency. It is this level of directivity that is the constitutive idea of the database that we propose in the framework of IEA HPT Annex 51 [1] and IEA HPT Annex 63 [2] to build and make available to stakeholders in the field.

2. DATABASE CONSTRUCTION

The database is provided as an *Excel* sheet starting with anonymous results from two certification laboratories on outdoor heat pump units (sometimes reversible), see Fig. 1. It consists of a header part (lines 1-8 with the header in line 6, the items in line 7 and their corresponding units in line 8), and several blocks of data each consisting of 6 consecutive lines (e.g. lines 9-14 for entry 1, named *A06*, lines 15-20 for entry 2, named *B01* in the example given in Fig. 1).

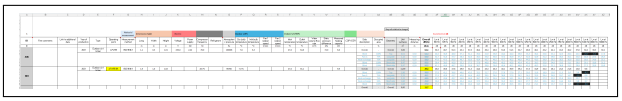

Figure 1. Overview of header line and two entries in the database

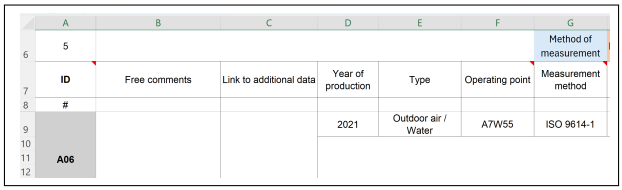
Most of the entries are free entries, only some of the fields contain formulas and are calculated automatically. Notes can (and should) be added to the fields to clarify specialities. Some items in line 6 contain notes detailing its usage. No field is mandatory but it is intended to include as much information as possible allowing for various ways of database exploitation, e.g. depending on the laboratory in charge of the measurements not all frequencies are reported, compressor frequencies have been recorded or fan speeds might be available. During discussions in the Task 2 meetings of IEA HPT Annex 63 several additional fields have been added (e.g. Coefficient of Performance, COP), which might be interesting for special analysis routes.



From left to right, content per block is organized in the following sections:

- leading part, *col. A-G*
- dimensioning, electrics & refrigerant, *col. H-N*
- boundary conditions & fan speeds, *col. O-Y*
- geometric description, *col. Z-AD*
- acoustic data description, *col. AE-AZ*

These blocks are described in detail in the following subsections.

2.1 Leading part - general information

The leading part (see Fig. 2 first assigns an unique identifier (*col. A*), which is constructed using a capital letter followed by two numbers. The letter is used to differentiate the contributing sources (e.g. laboratories) to the database. A field for free comments is presented in *col. B*, links to additional data should be given in *col. C*. All additional data should be made available as *zip*- or *7z*-archives with their names beginning with the identifier given in *col. A* followed by the dash symbol, e.g. *A06-waves.zip*. A detailed description should be placed in a *readme.txt*-file inside the corresponding archive. The leading part concludes with the year of production (*col. D*) and the type (*col. E*) of the unit as well as the point, which the unit was operating in (*col. F*). This operating point of the unit includes the temperature conditions on the ambient air, for example 7(6) °C , and on the water, for example 47-55 °C , summarized in the abbreviation *A7W55*.

	A	B	C	D	E	F	G
6	5						Method of measurement
7	ID	Free comments	Link to additional data	Year of production	Type	Operating point	Measurement method
8	#						
9	A06			2021	Outdoor air / Water	A7W55	ISO 9614-1
10							
11							
12							

Figure 2. Leading part of the database

Finally the leading part includes the measurement method in *col. G*. It is highly recommended to use data acquired utilizing either the ISO 9614-1:1993(en) Acoustics — Determination of sound power levels of noise sources using sound intensity — Part 1: Measurement at discrete points or the ISO 9614-2:1996(en) Acoustics — Determination of sound power levels of noise sources using sound intensity — Part 2: Measurement by scanning.

2.2 Dimensioning, electrics and refrigerant

First, in *col. H-J* the unit dimensions (see Fig. 3 in m are provided (length, width, height). This is followed by the necessary voltage supply to operate the unit (*col. K*) in V

and the power supplied to the unit *col. L* in kW. The compressor frequency in Hz is provided in *col. M* and the refrigerant entered in *col. N* using the ASHRAE 23-2022 standard [3], e.g. R290 for propane.

	H	I	J	K	L	M	N
	Dimensions of **unit**			Electric			
	Long	Width	Height	Voltage	Power supply	Compressor frequency	Refrigerant
	m	m	m	V	kW	Hz	
	1,1	0,5	1,01	230,0	2,42	78,0	

Figure 3. Dimensioning, electrics and refrigerant section of the database

2.3 Boundary conditions & fan speeds

The atmospheric pressure during the measurements is given in Pa in *col. O*, followed by the data characterising the outdoor unit. This includes the dry (*col. P*) and wet (*col. Q*) bulb temperatures in °C as well as the fan speeds in turns/minute (rpm) for up to two fans in (*col. R* and *col. S*), see Fig. 4. The boundary conditions for the indoor unit are the inlet (*col. T*) and outlet (*col. U*) temperature of the water given in °C , the water volume flow rate (*col. V*) given in m^3/h, the static pressure difference (*col. W*) in kPa and the measured heating capacity (*col. X*) in kW. Finally a field for the Coefficient of Performance (COP) is included in *col. Y*.

	O	P	Q	R	S	T	U	V	W	X	Y
		Outdoor (AIR)				Indoor (WATER)					
	Atmospheric pressure	Dry bulb temperature	Wet bulb temperature	Fan 1 rotation speed	Fan 2 rotation speed	Inlet temperature	Outlet temperature	Water volume flow rate	Static pressure difference	Measured heating capacity	COP / EER
	Pa	°C	°C	tr/min	tr/min	°C	°C	m³/h	kPa	kW	-
	100008	7,6	6,3			47,0	54,9		72,0	6,6	

Figure 4. Boundary conditions & fan speed section of the database

2.4 Geometric description

From here on the single data line (see Fig. 5, line 9) expands to 6 lines (lines 9-14). The unit is expected to consist of five faces (top, two long sides and two short sides). Each of these five faces is then described with the following options in *col. Z* (see Fig. 5, lines 10-14. For a better post processing workflow (avoiding typing errors and ambiguities), these options are made available via a dropdown menu.

- presence of fan (1 or 2), e.g. Fan x1, Fan x2;
- presence of a heat exchanger;
- ... or none of these elements, then the surface is described as "blind".

For the *fan* and *heat exchanger* elements, the proportion of surface area occupied by these elements is briefly described in *col. AA*, with four possible surface proportions: 25, 50, 75, or 100 %.

	A	Z	AA	AB	AC	AD
6	5					
7	ID	Side description	Occupied area	Geometry	Unit surfaces	Measuring distance
8	#	-	%		m^2	m
9	A06	Overall	-	Overall	3,69	
10		Blind	100%	Top	0,51	0,50
11		Fan x1	75%	Long side	1,12	0,50
12		Heat exchanger	75%	Long side	1,12	0,50
13		Blind	100%	Short side	0,47	0,50
14		Blind	100%	Short side	0,47	0,50
15	B01	Overall	-	Overall	11,59	
16		Blind	100%	Top	1,98	0,50
17		Fan x1	75%	Long side	3,13	0,50
18		Heat exchanger	75%	Long side	3,13	0,50
19		Heat exchanger	50%	Short side	1,68	0,50
20		Blind	100%	Short side	1,68	0,50

Figure 5. Geometric description including the unit and the distance of measurements

The grey cells in *col. AB* and *col. AC* should not be altered. The unit surfaces in *col. AC* in m^2 are extracted using the data in *col. H*-*col. J*, the overall unit surface is calculated and presented in the above the 5 unit surfaces in m^2. Finally, *col. AD* shows the distance between the surfaces and the measurement probe in m.

2.5 Acoustic data description

Six spectrums are required, one for the sound power level of the unit, as it is given as official result. The five other are partial sound power levels for each side (long side, short side, top side). Data are given in 1/3 octave bands, at least between 100 Hz and 5000 Hz, but the bands 50-63-80 Hz and 6300-8000-10000 Hz bands can be provided.

The acoustic data (see Fig. 6) consists of the (calculated) sound power level spectra of each face (*col. AE*), as well as the spectrum of the entire unit (*col. AF*-*col. AZ*). The sound power level corresponds to the fictitious surface located a few dozen centimetres from the actual surface of the machine which is given by the measurement distance for each face (*col. AD*).

The third octave band spectra data (blue values, *col. AF-col. AZ*) are entered in dB into the database for each of the five faces (e.g. into lines 10-14) allowing for a full set of 21 times 5 equals 105 entries. Black fields mark negative sound levels from intensity measurements (sound oriented from outside to the unit rather from being radiated from the unit to the outside and thus coming in to the mesh).

For each frequency band (100 Hz up to 10000 Hz), an overall sound level in dB is calculated automatically and presented in the first line (e.g. line 9) of the entry (above the data of the five sides). Out of these frequency resolved data, an overall *A-weighted* sound power level in $dB(A)$ is calculated and given in *col. AE*. Note, that the entry in the first line in *col. AE* (e.g. field *AE9*) will typically be the one reported on a certification label.

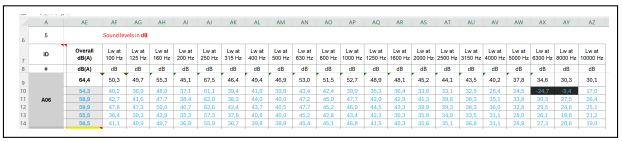


Figure 6. Acoustic data description using frequency resolved spectra

3. CONTRIBUTING TO THE DATABASE

Other parties than CETIAT and AIT, both inside and outside of the IEA HPT Annex 63 consortium are invited to contribute to the database. The template can be downloaded from the IEA HPT Annex 63 website following `https://heatpumpingtechnologies.org/annex63/database`. [4]. For further questions related to the format and usage of the database template, please contact `christoph.reichl@ait.at` (AIT) or `francois.bessac@cetiat.fr` (CETIAT). It is intended to initially expand the database till end of the first quarter of 2026.

4. EXAMPLE EXPLOITATION

A first exploitative analysis is done on the 27 available data sets (see Fig. 7). It focuses on the overall directivity based on the *max-min* of data from each side. The *max-min 5 sides* average corresponds to average of the *max-min* for the 5 sides (4 lateral + top), whereas the *max-min horizontal* average only includes the data for the 4 lateral sides, excluding the top. Then, *max-min vertical long side* and *max-min vertical short side* considers lateral sides and top side, either on the long side, or on the short side, respectively.

For the sake of readability, calculation & results are given based on the data transformed in octave bands, from 125 to 4000 Hz band. The overall directivity given by *max-min* (dark blue bars) shows, that it falls between 5 to almost 10 dB, the highest values being at higher frequencies. This means, that compared to the overall spectrum, a difference from ± 2.5 to almost $\pm 5\,dB$ can be extracted, depending on the location of the hearing point and on the frequency. The consideration of *max-min vertical* directivity is smaller, especially for the short side (light blue bar).

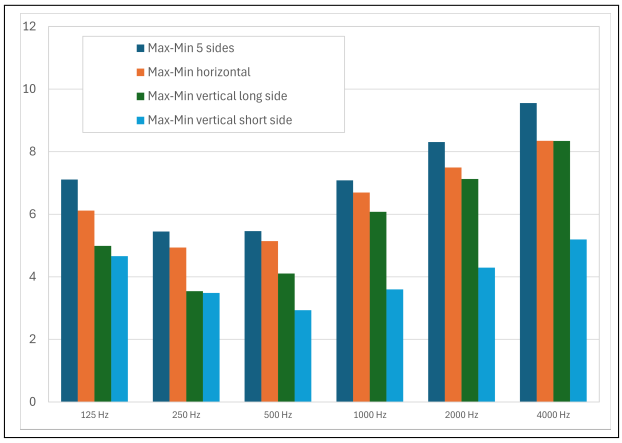

Figure 7. Max-Min directivity, averaged on the 27 data sets.

There are 16 results for lateral fan(s) units and 11 with top fan(s) units in the data set (see Fig. 8). When analysing the results considering the location of fan(s), the *max-min horizontal* average on all sides shows a bigger influence of the fan(s) located on the lateral side (orange bars). The overall directivity is then higher, especially at low and high frequencies, with a general envelope between 5.5 and almost 9 dB.

This is also the case when considering the vertical directivity (see Fig. 9), the top fan(s) configuration (dark green bars) being then smaller than the lateral fan(s) (orange bars) configuration.

5. CONCLUSION AND OUTLOOK

In the framework of IEA HPT Annex 63, a database consisting of frequency resolved acoustic directivity data to

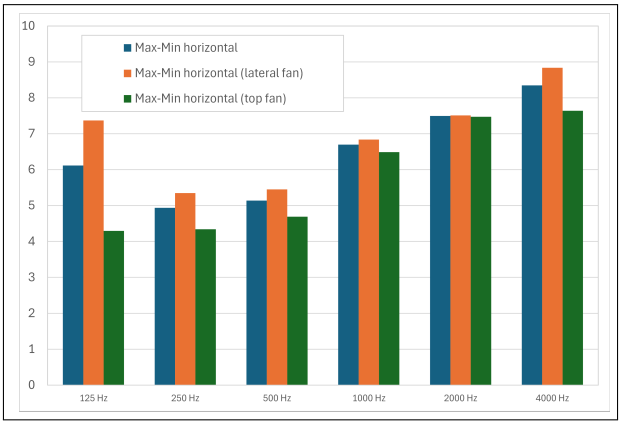

Figure 8. Max-Min directivity, on 5 sides, all data, and considering the location of fan(s).

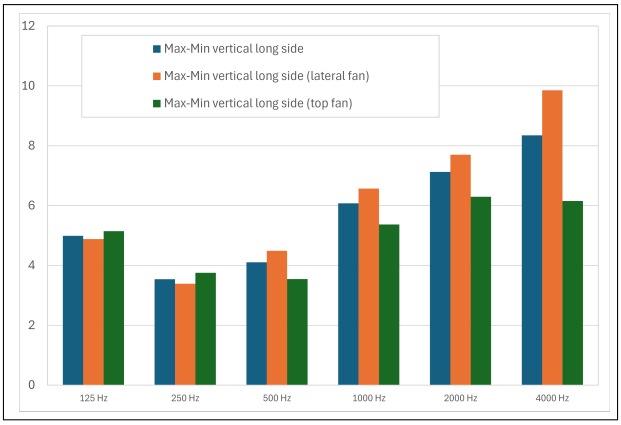

Figure 9. Max-Min horizontal directivity, all data, and considering the location of fan(s).

improve heat pump placement has been constructed. An initial set of 27 datasets from the laboratories of CETIAT, France and AIT, Austria consisting of a leading part, comments, dimensions, boundary conditions, geometric descriptions and acoustic data have been implemented. Both, the initial database and the template for contributing to the database are available for download on the IEA HPT Annex 63 website [4].

Although priority is currently being given to the collection of data measured according to the ISO 9614 protocol, additional content for measurements (e.g. more detailed data on dome measurements, wave files with raw acoustics, images) could be implemented, as well as (depending on request), inclusion of sound pressure level measurements is intended. These updated, will also be accessible through the database website.

An initial exploitation of the data base is presented based on *max-min* averages. The overall directivity falls between 5 to almost 10 dB with higher values extracted at elevated frequencies. These results, compared to the overall spectrum, to a difference from ± 2.5 to almost $\pm 5\,dB$.

It is intended to expand the database till the first quarter of 2026 with both entries from CETIAT and AIT and other parties. Further work with the data base will include expanded analysis on the directivity as well as utilization of the frequency content of the presented measurements.

6. ACKNOWLEDGMENTS

We want to express our gratitude to the consortium of IEA HPT Annex 63, especially to the contributors to Task 2 *Urban Acoustics Impact of Heat Pumps*. This work was funded in the framework of the Austrian FFG IEA cooperation project IEA HPT Annex 63, *Placement Impact on Heat Pump Acoustics* [2].

CETIAT thanks its industrial members for supporting its participation and work in the IEA HPT Annex 63.

THE ROLE OF MEASUREMENT LOCATIONS IN LOW-FREQUENCY NOISE ASSESSMENT

Luka Čurović[1*] **Jurij Prezelj**[1]
[1] Faculty of Mechanical Engineering, University of Ljubljana, Slovenia

ABSTRACT

With the increasing use of heat pumps as a sustainable solution for heating and cooling, their acoustic impact on the environment has become of crucial importance. Heat pumps are acoustically complex sources that can be controlled by smart algorithms and have specific low-frequency characteristics that differ from well-studied sources. An accurate noise assessment of heat pumps requires careful consideration of the measurement locations, as these have a direct influence on the characterization of noise emissions and their potential impact on the environment. In this study, the influence of the measurement locations on the low-frequency noise levels is investigated, including the positions in front of the façade, on the façade and in the free field. A loudspeaker and a custom-built low-frequency sound source are used to generate the low-frequency sound. The results show significant differences in the measured sound pressure levels depending on the position of the receiving point in relation to the low-frequency sound source. By emphasizing the importance of selecting appropriate measurement locations, this work is intended to assist acoustics professionals and policy makers in establishing robust standards for the assessment of heat pump noise.

1. INTRODUCTION

Sound levels are often assessed in dwellings, at the most exposed façade where the sound field is determined by reflections and diffraction. To ensure reproducibility and comparability of results, guidelines such as ISO 1996-2 [1] or ISO 16283-3 [2] suggests a +3 dB correction when the microphone is located between 0.5 and 2 m from a reflecting surface, and up to + 6 dB (with default value of +5,7 dB) correction when the microphone is placed directly on the surface. However, factors such as the source-receiver geometry, the nature of the noise source (e.g., point source vs. line source), the composition of the façade materials, and the presence of other reflective or scattering surfaces can influence the actual reflection contribution. Research has indicated that in many practical measurement situations, the +3 dB and +6 dB approximations might not be appropriate, with some studies suggesting smaller correction values. Furthermore, the source-façade distance (D) and the microphone-façade distance (d) have been identified as important parameters influencing the reflection effects [3–11]. Given the potential for discrepancies between standardized corrections and real-world measurements, ongoing research is essential to refine the guidelines for noise assessment near building façades. This includes investigating the accuracy of existing correction factors for new sound sources such as heat pumps, which are becoming an integral part of the built environment. Heat pumps are acoustically complex sources that can be controlled by intelligent algorithms, differ from well-studied sources by their specific frequency and operational characteristics and are often placed in locations where the resulting sound field is affected by multiple reflections or where the receiver is in the near sound field. An accurate noise assessment of heat

pumps requires careful consideration of the measurement locations, as these have a direct influence on the characterization of noise emissions and their potential impact on the environment. The aim of this study is to carry out an initial experimental investigation of the influence of the measurement locations on the measured low-frequency sound levels. A loudspeaker producing 125 Hz octave band noise is used to perform measurements in an otherwise anechoic room and a custom-made sound source emitting a 50 Hz tone is used to perform measurements in the real environment. The acoustic measurements include the positions in front of the façade, on the façade and in the free field. The analysis of the measured sound levels should provide initial insights into the correction factors for façade measurements of low-frequency sound and their dependence on relevant parameters.

2. METHODOLOGY

In the experimental study, two low-frequency sound sources were used and the signals were recorded with class 1 sound level analyzers, which were checked with a sound calibrator before and after the measurements. The measurements were carried out in an anechoic chamber and in a real environment. To gain an initial insight, various incidence configurations and different microphone positions were investigated.

2.1 Measurements performed in an anechoic environment

The signals were recorded using Norsonic 140 Class 1 sound analyzers with a 1/2-inch preamplifiers type 1209 and a Nor1225 free-field microphones. The preamplifier and microphone were connected to the analyzer via a cable. A windscreen was not used. The source was a B&K HP 1001 loudspeaker driven by a B&K type 4205 generator. The loudspeaker was used to generate a wide band signal (white noise) in the frequency range from 100 Hz to 100 kHz and a 125 Hz octave band noise. The sound power level was set to 95 dB. The microphone locations included positions on the facade and in the free field. For the free-field position, the microphone was placed in front of the wall of the room made of pyramid-shaped glass wool elements. For the position on the facade, the microphone was mounted against a painted 20 mm chipboard panel. In both cases, the microphone was directed towards the sound source at an 90^0 degree angle of incidence. Two series of measurements were performed with different microphone and source positions to simulate normal (0^0) and parallel (90^0) incidence:

a) For the first configuration, the loudspeaker was placed at a distance of 2 m in front of the microphone.

b) For the 90^0 incidence, the loudspeaker and the microphone were placed in the same horizontal plane. The distance between the loudspeaker and the receiver was 1.55 m. The measurement setup with the loudspeaker and the free field microphone is shown in Fig. 1

In both series, the signals (125 Hz octave band and 100 Hz – 10 kHz white noise) were first recorded with the microphone at the facade position. Then the plate was removed, and free-field measurements were made. Each recording was at least 3 minutes long.

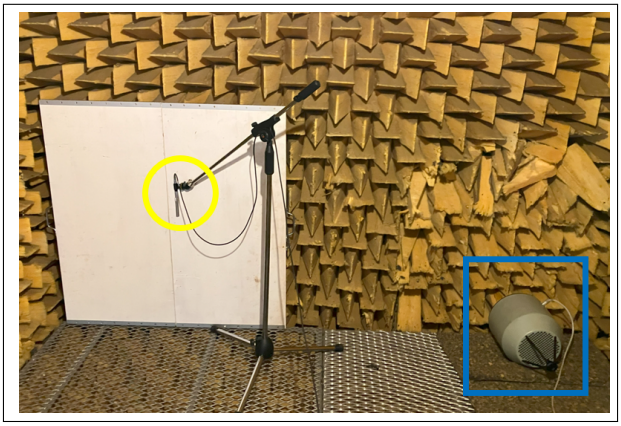

Figure 1. The 90^0 incidence measurement setup in the anechoic room with the loudspeaker (blue square) and the facade microphone (yellow circle).

2.2 Measurements performed in the real environment

The measurements were carried out on a two-storey house. The south façade (S façade) of the house is made of brick and has two windows and a door. The length of the S façade is 13.5 m, and the maximum height is around 8 m. The ground in front of the S façade is an acoustically hard. The western part of the brick façade (W façade) has 4 windows, is 15 m long and 7 m high. The ground in front of the façade consists of grass (soft ground).

The signals were recorded with two Norsonic 140 Class 1 sound analyzers and the windscreen was used. The sound source was a loudspeaker connected to an electrical transformer and housed in a square wooden box measuring 500 mm x 500 mm x 500 mm. The source emitted a

very intrusive 50 Hz tonal sound. The emission characteristics of the source was determined by measurements at a distance of 2 m and at a height of 2 m from the surfaces of the box in four directions. The equivalent continuous A-weighted sound pressure level ($L_{\mathrm{Aeq,T=2min}}$) was in the range of 55.9 dB(A) to 56.9 dB(A). The equivalent continuous C-weighted sound pressure level ($L_{\mathrm{Ceq,T=2min}}$) was in the range of 83.1 dB(C) to 83.5 dB(C). The equivalent continuous sound pressure level in the 50 Hz one-third octave band ($L_{\mathrm{eq,50Hz,T=2min}}$) was in the range of 84.7 dB to 83.3 dB. Based on the emission measurements, the source was considered omnidirectional. At a distance of 4 m from the source, $L_{\mathrm{Aeq,T=2}}$ min, $L_{\mathrm{Ceq,T=2min}}$ and $L_{\mathrm{eq,50Hz,T=2min}}$ min were reduced by 5.5 dB(A), 6 dB(C) and 6 dB respectively, so that the source was considered to be a point source.

The microphone locations included positions on the façade (façade position), near a façade (near position) and in the free field. Three series of measurements were carried out with different microphone and source positions:

a) In the first series, the interference pattern expected due to façade reflections was investigated. The sound source was placed on the ground at a distance of 12.4 m from the S façade. One microphone was placed on the façade at a height of 3.6 m relative to the source height. The distance of the second microphone to the source was varied at 2 m, 4 m, 9.2 m and 10.8 m.

b) In the second series, the influence of the distance between the facade and the source was tested. The source were initially positioned on the ground at a distance D = 15.1 m from the S façade. One microphone was placed on the façade at a height of 3.6 m relative to the source height. The position of the second microphone was varied. It was placed in the free field (10 m from the source and 5 m from the SW edge of the house) and in the near field, where strong interference effects are expected, at 1.7 m and 3.2 m from the façade. The measurements were repeated, only this time the source was placed at a distance D = 10.0 m from the S façade and the second (free field) microphone at a distance of 10 m from the source.

c) In the third series, the influence of the angle of incidence was investigated. The source was placed on the ground at a distance of 0.3 m from the W façade. The microphones were placed at a distance of 4.5 m on the same horizontal plane to simulate the 90^0 incidence. One microphone was placed on the façade and the other microphone in the free field (2.8 m from the SW edge of the house). The measurement setup with the loudspeaker and the free field microphone is shown in Fig. 2.

For each series and each microphone–source configuration, the source signal was averaged for at least 10 minutes. All unwanted sound events and removable residual noise signals were removed. The recordings included distant low-amplitude background noise sources, such as birdsong and distant road noise, which could not be excluded.

Figure 2. The 90^0 incidence measurement setup with the loudspeaker (blue square) and the free field microphone (yellow circle).

3. RESULTS AND DISCUSSION

3.1 Measurements performed in an anechoic environment

The measurement results for both series include A- and C-weighted levels (Tables 1 and 2) and 1/1-octave frequency analysis in the 16 Hz – 20000 Hz range (Figure 3). The integration time interval was 3 minutes long.

At normal (0^0) incidence, the expected difference between the levels at the facade and free field positions is about 6 dB, assuming perfect reflection, and should be less otherwise [4, 12]. At normal incidence, the L_{Aeq} values at the façade for both sources were about 6 dB(A) higher than in the free field, which is to be expected if perfect reflection is assumed. The difference in L_{Ceq} values was 2.2 dB(C) and 6 dB(A) for the 125 Hz octave band and the broadband signal respectively. The same trend was observed for the $L_{\mathrm{eq,125Hz}}$ level, emphasising that L_{Aeq} cannot always be used to evaluate the difference between façade and free field when the level difference comes from

Table 1. $L_{\mathrm{Aeq,T=3min}}$ and $L_{\mathrm{Ceq,T=3min}}$ levels in the anechoic room for normal (0^0) and parallel incidence (90^0) for the 125 Hz octave band source.

0^0	Facade	Free-field
L_{Aeq}	59.4	53.6
L_{Ceq}	72.3	70.1
90^0	Facade	Free-field
L_{Aeq}	56.1	56.8
L_{Ceq}	71.5	73.7

Table 2. $L_{\mathrm{Aeq,T=3min}}$ and $L_{\mathrm{Ceq,T=3min}}$ levels in the anechoic room for normal and parallel incidence for the wide band 100 Hz - 10 kHz source.

0^0	Facade	Free-field
L_{Aeq}	86.2	80.8
L_{Ceq}	86.0	80.5
90^0	Facade	Free-field
L_{Aeq}	78.9	73.4
L_{Ceq}	79.5	75.3

low frequencies.

At 90^0 incidence the expected difference between the facade and free field levels should be close to 0 dB. However, the measurement results indicate that the levels in the free field can be even greater than the levels at the façade, as observed in the case of the 125 Hz octave band source. The difference between the A-weighted façade and free-field levels for the low-frequency source was positive (+0.7 dB), while the difference between the $L_{\mathrm{eq,125Hz}}$ levels was negative (-2.5 dB). L_{Ceq} followed the $L_{\mathrm{eq,125Hz}}$ trend. The level differences for the broadband noise source, to which the high frequencies make a significant contribution, are probably largely determined by their directivity pattern.

3.2 Measurements performed in the real environment

Fig.4 shows a typical one-third octave band spectrum in the range 20 Hz – 20 kHz, measured at a distance of 2 m from the source. The spectrum is characterized by a pronounced tone at 50 Hz. The results therefore include A-weighted (L_{Aeq}), C-weighted levels (L_{Ceq}) and one-third octave band levels in the 50 Hz band $L_{\mathrm{eq,50Hz}}$.

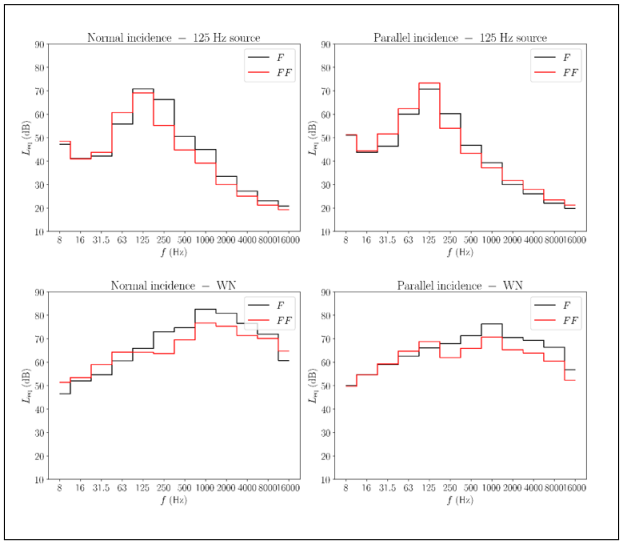

Figure 3. Octave band sound pressure level spectra, measured in an anechoic room for the low-frequency 125 Hz octave band sound source for (a) normal and (b) 90^0 incidence and for the wide band sound source for (c) normal and (d) 90^0 incidence.

3.2.1 Interference pattern

The levels $L_{\mathrm{Aeq,T=10min}}$, $L_{\mathrm{Ceq,T=10min}}$ and $L_{\mathrm{eq,50Hz,T=10min}}$ as a function of distance from the source are shown in Fig. 5. The distance between the source and the facade is 12.4 m. The measured values are shown as dots. The dashed prediction curves represent the sound attenuation due to the geometric spreading for a point source.

L_{Ceq} and $L_{\mathrm{eq,50Hz}}$ points far from the source and are located near and on the façade deviate significantly from the prediction curve. The levels at a distance of 3.2 m from the façade are similar to the façade levels and the levels at a distance of 1.7 m from the façade are significantly lower, which is in good agreement with the theoretical analysis of the sound fields at the boundaries. The L_{Aeq} levels show less variation near and at the façade and the interference pattern is not clear.

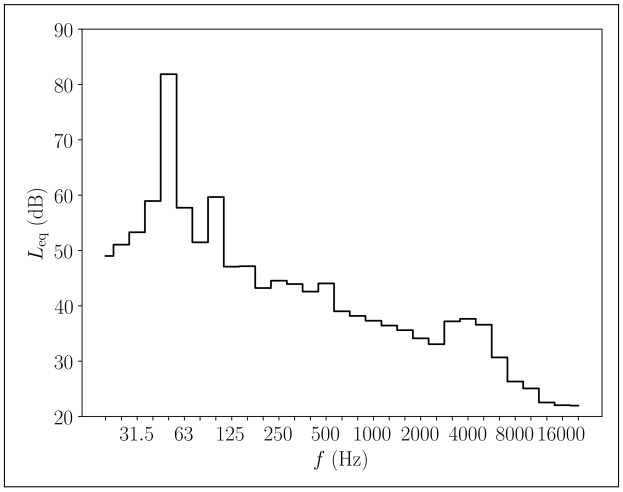

Figure 4. Third-octave band sound pressure level spectrum in the range 20 Hz – 20 kHz, measured at a distance of 2 m from the source.

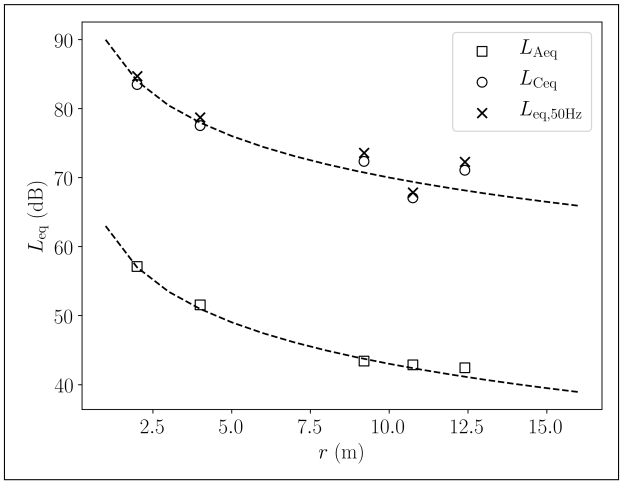

Figure 5. The levels $L_{Aeq,T=10min}$, $L_{Ceq,T=10min}$ and $L_{eq,50Hz,T=10min}$ as a function of distance from the source

3.2.2 *Source-facade distance*

The levels $L_{Aeq,T=10min}$, $L_{Ceq,T=10min}$ and $L_{eq,50Hz,T=10min}$ and the distance between source and microphone (r) in the near field (1.7 and 3.2 m from the façade), at the façade and in the free field when the source was placed at a distance of D = 15.1 m and D= 10 from the façade are shown in Tables 3 and 4 respectively.

Table 3. $L_{Aeq,T=10min}$, $L_{Ceq,T=10min}$ and $L_{eq,50Hz,T=10min}$ at source – facade distance D = 15.1 m and different microphone positions. NF (3.2 m) = near field (3.2 m from facade), NF (1.7 m) = near field (1.7 m from facade), F = facade, FF= free-field

r (m)	$L_{eq,50Hz}$	L_{Aeq}	L_{Ceq}	Position
11.9	68.0	42.9	67.1	NF (3.2 m)
13.4	63.8	43.4	63.5	NF (1.7 m)
15.1	68.5	42.6	67.6	F
15.1	64.6	42.5	63.2	FF

The $L_{eq,50Hz}$ was highest at the façade and at the near-field position at 3.2 m from the façade. The $L_{eq,50Hz}$ was lower at the free-field and near-field positions (1.7 m from the façade). As expected, L_{Ceq} reflects the trend at 50 Hz, while L_{Aeq} values are consistent across all positions. The L_{Aeq} values do not follow the interference pattern. This behaviour is very consistent at both distances between source and facade. The L_{Ceq} and $L_{eq,50Hz}$ level differences between the façade and free-field positions are uniform at around 4 dB.

Table 4. $L_{Aeq,T=10min}$, $L_{Ceq,T=10min}$ and $L_{eq,50Hz,T=10min}$ at source – facade distance D = 10.0 m and different microphone positions. NF (3.2 m) = near field (3.2 m from facade), NF (1.7 m) = near field (1.7 m from facade), F = facade, FF= free-field

r (m)	$L_{eq,50Hz}$	L_{Aeq}	L_{Ceq}	Position
6.8	73.3	46.0	72.1	NF (3.2 m)
8.3	67.4	44.4	66.8	NF (1.7 m)
10	73.3	45.2	72.2	F
10	69.4	44.4	68.3	FF

3.2.3 *90^0 incidence*

The levels $L_{Aeq,T=10min}$, $L_{Ceq,T=10min}$ and $L_{eq,50Hz,T=10min}$ at the façade and in the free field are shown in Table 5 respectively.

The free-field $L_{eq,50Hz}$ and L_{Ceq} values were slightly

Table 5. $L_{\mathrm{Aeq,T=10min}}$, $L_{\mathrm{Ceq,T=10min}}$ and $L_{\mathrm{eq,50Hz,T=2min}}$ at façade and free field positions for the 90^0 incidence configuration in the real environment. F = facade, FF= free-field.

Position	$L_{\mathrm{eq,50Hz}}$	L_{Aeq}	L_{Ceq}
F	79.5	52.0	78.3
FF	80.3	51.6	79.2

higher than the façade values, while L_{Aeq} showed the opposite trend. The differences were not considered significant, however the higher low frequency level in the free field was also observed in the anechoic room. A default facade correction would probably not be justified in such cases, as the façade seems to have only a very small influence on the measured values.

4. CONCLUSION

The evaluation of the difference between façade and free-field sound pressure levels is a complex task, even when a simple low-frequency sound sources is investigated. In this study, the A-, C-weighted, octave and one-third octave band sound pressure levels in front of the façade, on the façade and in the free field were experimentally investigated in order to gain initial insights into the façade correction factors for low-frequency noise. The experiments were carried out in a controlled environment (anechoic room) and in a real environment.

In the anechoic room, a 125 Hz octave band sound signal was used to determine the difference between L_{Aeq}, L_{Ceq} and $L_{\mathrm{eq,125Hz}}$ levels at the façade and the free-field microphone positions at normal and 90^0 incidences. The results showed that the characterization of the façade correction in the anechoic room using A-weighted levels was only successful at normal incidence using a wide band white noise signal with sufficient energy in the high frequency range. For the low-frequency 125 Hz octave band source, C-weighted and band levels were better suited to characterize the effect of sound reflection and angle of incidence on the resulting sound field. At 90^0 incidence, the measurement results showed that the free-field levels can be even greater than the façade levels when a 125 Hz octave band source was used.

A custom-built source emitting a 50 Hz tone was then used to conduct field experiments in a real environment. Three series of measurements were carried out to investigate the interference pattern, the effect of the distance between the source and the façade and the façade corrections for 90^0 incidences of low-frequency tonal sound at 50 Hz. The L_{Ceq} and $L_{\mathrm{eq,50Hz}}$ values were closely correlated and could be attributed to the interference patterns, the effects of the angle of incidence and the lower reflection characteristics associated with low-frequency sound. One of the test results is also that low-frequency sound levels could be underestimated if the standard façade factor (5.7 dB(A) or 6 dB(A)) is used to correct the A-weighted sound pressure levels measured at the façade at large angles of incidence.

IN-SITU TRANSFER PATH ANALYSIS OF A ROOF MOUNTED AIR SOURCE HEAT PUMP

L Barton* **J Hargreaves**[1] **V Acun**[1]
A Torija Martinez[1] **S Graetzer**[1] **D Waddington**[1]
[1] Future Homes Project, Acoustic Research Centre,
University of Salford, United Kingdom

ABSTRACT

To combat carbon emissions and move towards Net Zero, many EU countries have begun phasing out fossil fuel domestic heating in favour of air source heat pumps. The UK government has set a target of installing 600,000 air source heat pumps per year from 2028.Though restrictive installation guidelines for air source heat pumps have been revised, this does not negate the issue of suitable unit placement for retrofit in existing UK housing stock. In many cases, the existing homes are attached, terraced homes with little outdoor space to accommodate a heat pump. An option is to mount the heat pump in the attic space, by attaching to the roof. This provides a reasonable alternative to using up potentially limited outdoor space and may utilise unused interior space. This approach presents its own challenges, however, notably the potential for structure-borne noise transmission to the dwelling and adjoining homes, due to the attachment to the roof, and potentially airborne noise transmission, due to the proximity of bedrooms etc. With the aim of better understanding – and therefore mitigating – these potential issues, this paper explores the benefits of in-situ Transfer Path Analysis – a method normally employed for vehicles and mechanical structures – for this application.

1. INTRODUCTION

As retrofit becomes a realistic prospect for the development of net-zero heating in domestic homes using Air Source Heat Pumps (ASHPs), suggestions for options of ASHP placement within the loft space of homes has become a popular idea. Due to the comparatively large existing housing stock in the UK, retrofit is necessary to meet the UK government targets for becoming carbon neutral. Many of these houses have limited outdoor space, or have close borders to neighboring dwellings, which creates challenges for external ASHP placement when considering existing noise and boundary regulations. As roof mounting an ASHP is a relatively new concept, especially in the UK, a method for the determination of structure and air-borne noise transmission is required for the analysis of the acoustic impact of the system. This paper proposes an in-situ methodology for the characterization of structural transmission paths of a roof-mounted ASHP. Using a Transfer Path Analysis (TPA) [1] approach, which is commonly applied to all manner of structural problems and applications, such as in vehicles [2] and buildings [3]. The blocked forces are measured at the frame from to which the ASHP is attached, with excitation by a pair of shakers within the ASHP external case at the mounting positions. Noise predictions are made for response positions at remote accelerometers on the adjacent roof structure, remote microphones in the loft space, and microphones in the bedroom and the bedroom below.

2. THEORY

The methodology proposed in this paper is based on the in-situ TPA method [4]. This involves the characterisation of a coupled structure in terms of a source and receiver, with an interface. The blocked forces are the for which is

needed to constrain the velocity of the device under test to zero [5].
The method does not require the separation of source and receiver and, as no assumption is required for the behaviour of the receiver structure, the in-situ method is most likely more reliable than the previous TPA approaches. Another advantage of the in-situ approach is that the operational blocked forces are independent of the receiver structure, meaning that they remain valid for different assemblies by re-measuring or modelling the transfer function for a different assembly [6].

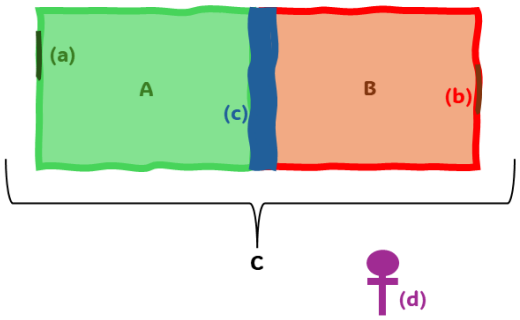

Figure 1. Schematic diagram illustrating the source (A), receiver (B), and couple assembly (C).

Figure 1 illustrates an arbitrary source- receiver assembly, where in this case the source 'A' is the ASHP, and the receiver 'B' is the frame attached to the roof. The responses (d) are remote accelerometers on other structural roof beams, and microphones in the loft space and the bedroom below the ASHP. The blocked forces are calculated by:

$$\dot{\bar{f}}_{A,c} = \boldsymbol{Y}_{C,cc}^{-1} \dot{\boldsymbol{v}}_{C,c} \quad (1)$$

Where $\boldsymbol{Y}_{C,cc}^{-1}$ is an inverted matrix of mobilities, measured using a force hammer at the accelerometer positions on the frame. These excitations were made either side of the accelerometers and were averaged due to a lack of access for direct excitation. $\dot{\boldsymbol{v}}_{C,c}$ is a vector of operational mobilities, measured when the source (in this case, a pair of shakers) is running, and is the transfer function between the shaker voltage and the acceleration measured at the frame accelerometers.
The predicted pressure is then given by:

$$\dot{\boldsymbol{P}}_{C,d} = \boldsymbol{H}_{C,db} \dot{\bar{\boldsymbol{F}}}_{A,c} \quad (2)$$

In this paper, the transfer functions used for $\boldsymbol{H}_{C,db}$ are referred to as $\boldsymbol{H}_{pf}$, as they are the acoustic transfer function between the response and the hammer excitation, as pressure due to force. For the remote validation measurements, these are acceleration due to force, but for consistency the transfer function name remains the same.

3. METHODOLOGY

The experiment was conducted in Energy House 2.0, a climatic chamber at The University of Salford. The facility consists of two climatic chambers, which can produce a multitude of environmental conditions and temperatures. The HVAC system of the chamber was deactivated during the course of this measurement.

Figure 2: The Future Home at Salford University's Energy House 2.0

The ASHP is mounted in the loft space of a detached brick house, as shown in **Figure 2.** The roof frame where the ASHP attaches to the rafters was instrumented with 15 accelerometers; 5 on each of the 3 accessible sides, which are shown in **Figure 3** and **Figure 4**.

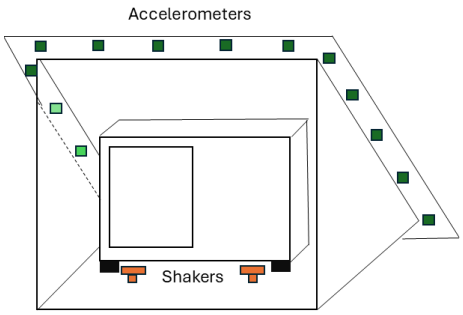

Figure 3. Diagram of ASHP in housing, with accelerometers and shakers shown.

Due to access limitations, only three sides of the frame were accessible for measurement. However, the rear side of the frame does not have a beam and does not appear to be rigidly connected to the ASHP housing.

Figure 4. Photograph of accelerometers

The ASHP was enclosed in plastic housing, with a hatch for access inside. The external roof above the ASHP had a large vent for airflow. Due to logistical restrictions, it was not possible to use the ASHP as an operational source during this measurement. Instead, two small shakers were mounted next to the connecting feet at the base of the ASHP inside the plastic casing, shown **in Figure 5.**

Figure 5. Photograph of one of the shakers

The shakers were measured in various operational combinations using both pink and white noise, and a voltage reference was taken from the supplying noise source. Two accelerometers were attached to struts in the loft space as remote validation points. These were vertical beams attached to the floor and ceiling, and not directly in contact with the ASHP housing. Three microphones were located in the loft space as illustrated in **Figure 6**.

Figure 6. Diagram of microphone placement

A further four microphones were located in the bedroom immediately below the ASHP, as shown in **Figure 7**. These were located to the left side of the room near the window directly below the ASHP, in the centre of the room, at the right hand side of the room near the door, and at a position just above the pillow area of the bed.

Figure 7. Microphones in bedroom

A modal hammer was used to make excitations either side of the accelerometers and averaged using the finite difference approach to measure the Frequency Response Functions (FRFs) for the interface. A voltage reference was used to measure the shakers.

4. RESULTS

For the results presented here, both shakers were operational using a pink noise signal, as this most resembled the ASHP noise. Firstly, the raw data is shown in terms of Power Spectral Density (PSD) to establish that the signal is sufficiently above the background noise.

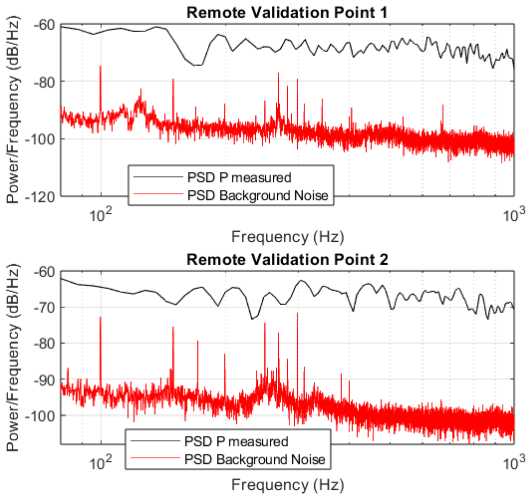

Figure 8. PSD of measured acceleration, in black, and background noise, in red, for remote validation points 1 and 2, from 80 Hz to 1kHz.

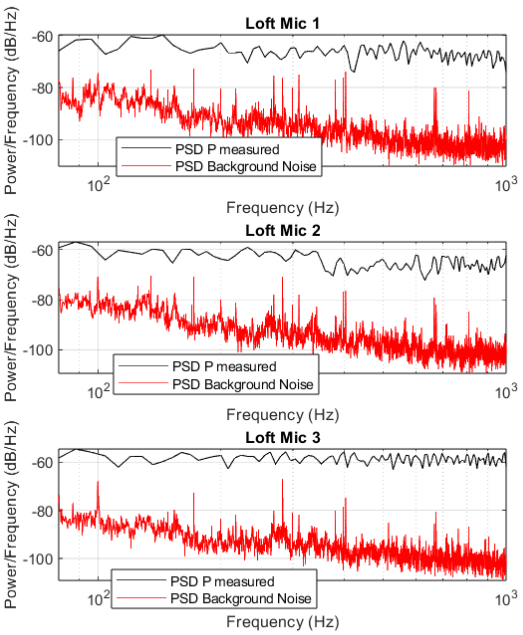

Figure 9. PSD of measured pressure in black, and background noise, in red, for loft microphones, from 80 Hz to 1kHz.

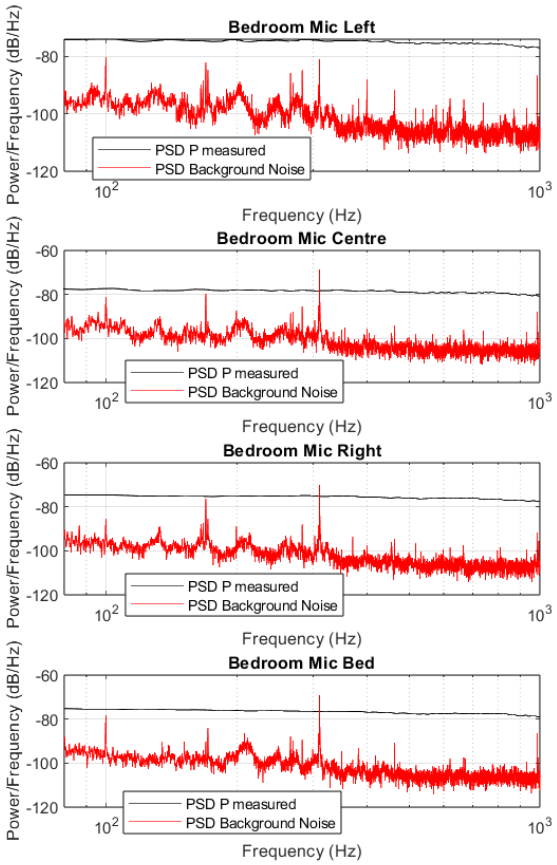

Figure 10. PSD of measured pressure in black, and background noise, in red, for bedroom microphones, from 80 Hz to 1kHz.

Seen in **Figure 10,** there are some erroneous peaks visible in the background noise spectra in three of the bedroom mics, at around 310Hz, which are a higher in magnitude than the measured as seen in **Figure 10**. This could be due to some interfering noise being present during the background noise recording, due to another system in the house such as ventilation, which was outside of operational control during the experiment. The measured signal is out of the noise floor for the remote validation accelerometers and the loft microphones at this frequency range, as seen in **Figure 8** and **Figure 9.**

Using Equations 1&2, predictions at the response positions due to excitation by both shakers are presented here.

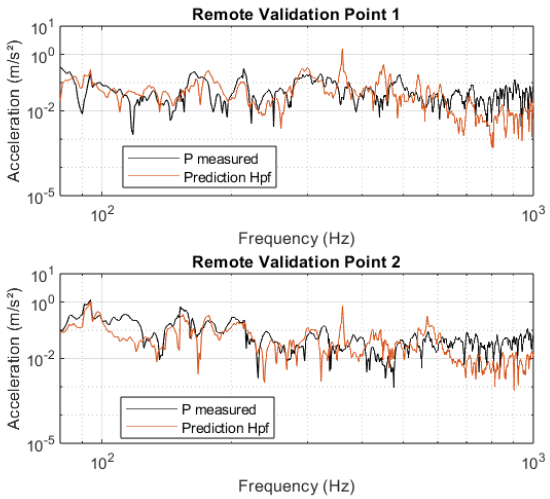

Figure 11. Predicted acceleration at remote validation points using the Hpf transfer function, compared to the measured acceleration, from 80 Hz to 1kHz.

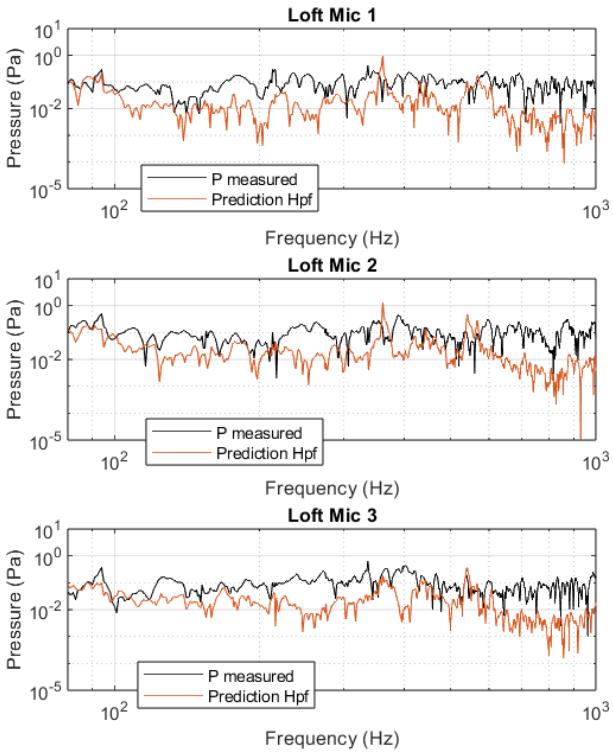

Figure 12. Predicted pressure at loft microphones using the Hpf transfer function, compared to the measured acceleration, from 80 Hz to 1kHz.

At the remote validation accelerometers, which were mounted on wooden roof struts in the loft room, there is relatively close agreement between the measurement and prediction across the measured frequency range, though both positions have an over prediction at around 361 Hz, as shown in **Figure 11.**
There is less overall agreement for the predictions to the loft microphone positions, shown in **Figure 12.** Again, an overprediction is seen at 361 Hz in Loft Mic 1 & 2, as with the remote validation sensors.

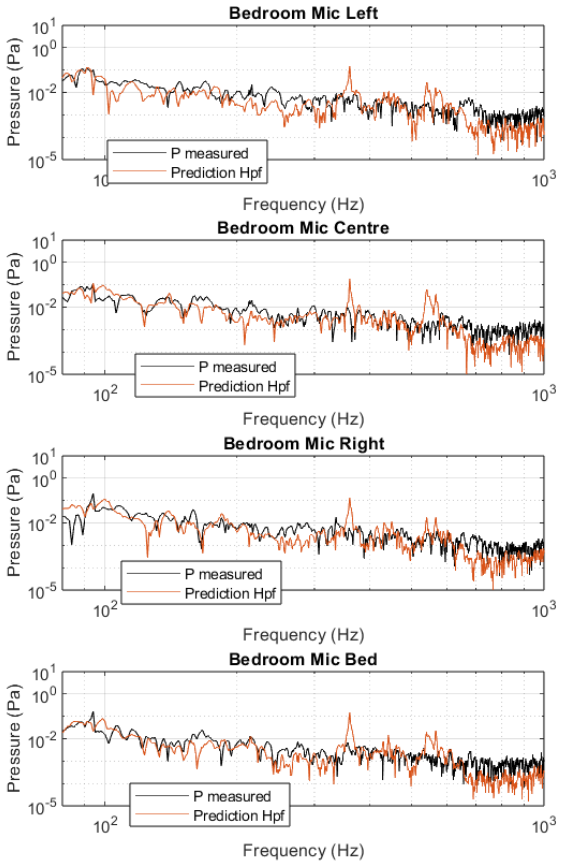

Figure 13. Predicted pressure at bedroom microphone using the Hpf transfer function, compared to the measured pressure, from 80 Hz to 1kHz.

As seen in the remote validation accelerometers and two of the loft microphones, the erroneous peak in the prediction is also present in the bedroom microphone predictions, seen in **Figure 13.**

5. DISCUSSION

The predictions have mixed accuracy. The remote validation accelerometers and the bedroom microphone predictions, both appear to have higher accuracy than the microphones in the loft. This may be due to the different frequency content of airborne and structural excitations within this frequency range. The loft space also has its own acoustic behaviour which may be contributory, and does not have the reassurance lent by laboratory conditions.
The results may be improved by refining the data, using methods such as singular value discarding, to remove noise. Although further analysis is required to be confident of the results, the blocked forces approach can be applied to the measurement of structure- and air-borne noise from a roof mounted ASHP.

6. CONCLUDING REMARKS AND FURTHER WORK

The in-situ TPA approach using blocked forces, which is commonly used in automotive engineering, has been used to evaluate vibroacoustic transfer paths in a home with a roof-mounted ASHP. Following this initial data analysis, there are further steps to be taken. Additional data measured using a volume velocity source will be used to make further blocked forces predictions, treating the entire loft room as the source. This may give clarity to some of the errors in predictions shown in this paper.
If logistics allow, it would be beneficial to repeat the measurement with the ASHP running, to provide verification that the dynamic behaviour and spectral content of the shakers is sufficient to emulate the operational state of the ASHP. Though every care was taken to reduce and mitigate interfering noise from other systems running in the house, any further experiments would take further steps to ensure minimal background noise from processes such as ventilation.
A further condition which may be desirable is to fully instrument around the aperture in which the ASHP hangs, as though the rear quarter of the frame does not appear to be coupled to the ASHP housing, it would be beneficial to ensure this and work towards a more complete interface characterisation.

7. ACKNOWLEDGMENTS

This work was carried out as part of the Future Homes Project, funded by UKRI.

SIMULATION-BASED ANALYSIS OF THE SOUND EMISSIONS OF DECENTRAL AIR-TO-WATER HEAT PUMPS IN RENOVATED MULTI-FAMILY BUILDINGS

William Monteleone[1*] **Fabian Ochs**[1]
[1] Unit for Energy Efficient Building, University of Innsbruck, Austria

ABSTRACT

To decarbonize Europe's building stock by 2050, renovation rates must rise, and fossil-based heating systems must be phased out. Heat pumps (HPs) are central to this effort, but their installation in multi-family buildings presents challenges like space limitations, noise, and invasive infrastructure work. As part of the "PhaseOut" research project, seven multi-family buildings in Vienna will undergo renovations. Each will use a centralized, speed-controlled monobloc air-to-water HP for space heating. The feasibility of decentralized, façade-integrated mini-split air-to-water HPs for domestic hot water will also be explored. To support this, 3D simulation models of a single façade-integrated HP will be created using COMSOL and CadnaA, a commercial acoustic modeling tool. Both platforms will then be used to assess the acoustic impact of multiple HP units installed on façades, highlighting differences in modeling approaches. Simulations in CadnaA will also evaluate the environmental sound pressure levels on the renovation site. Preliminary findings show that sound emissions from decentralized HP units remain within legal limits at the property boundary. However, while tools like CadnaA effectively estimate sound levels across broad areas, they struggle to model near-field acoustics and complex interactions from multiple noise sources with high precision.

1. INTRODUCTION

In nearly-zero energy buildings (nZEBs) a combination of adequate insulation of the building and efficient heat pump (HP) based hydronic systems is required [1,2] to reach the goal of the European Union of a fully decarbonised building stock by 2050 [3]. For existing multi-family buildings, the energy performance of the building envelope can be improved fast and reliably by means of serial prefabricated retrofit solutions [4]. In prefabricated renovation solutions, most of the work can be performed off-site to reduce the installation time and disruption to the building tenants. Moreover, decentral air-source heat pumps can be efficiently integrated in prefabricated façade elements, thereby reducing the amount of disruptive and cost-intensive installation work within the flat, as shown in [5] and [6]. For prefabricated façades with integrated building services, an integral design and analysis approach which unites building physics, thermodynamics and architecture is required [7]. However, one of the main concerns for the extensive acceptance of HPs in residential buildings is noise [8] and the actual legislative framework in Europe does not accurately consider the relationship between HP placement and its operational state [9,10], as frequently the sound power level reported in technical datasheets is not measured at full capacity. Within the Austrian research project PhaseOut [11], seven identical social housing multi-family buildings in Vienna, with each six flats, will be renovated. In two of them, a silent façade-integrated mini-split HP for flatwise domestic hot water (DHW) preparation, installed in a prefabricated timber frame façade, will be installed, while space heating (SH) will be provided by two external monobloc air-to-water HPs. First, the analysis will focus on the comparison between a 3D COMSOL [12] simulation model of the sound propagation around a single façade-integrated

mini-split HP and a 3D simulation model developed within the environment of the commercial software of CadnaA [13]. Then a 3D simulation will be performed in both simulation programs considering the sound emissions of three façade-integrated HPs to evaluate the modelling of interference patterns. Finally, simulations within the software environment will assess the sound propagation on the whole renovation site (i.e. for all seven buildings) and the resulting sound pressure level considering only the decentral DHW HPs will be compared with the limits imposed by the existing regulations. Based on the simulation results, recommendations are made for the creation of a reduced-order simulation model for the pre-design of HP systems.

2. RENOVATION CONCEPT

The mini-split HP concept developed within the research project "PhaseOut" is depicted schematically in Figure 1. The system combines a façade-integrated outdoor unit including the evaporator and four parallel axial fans with an indoor unit housing the compressor, the condenser and the expansion valve. The HP indoor unit is in turn connected hydraulically with a compact 120 Litres hot water storage for the delivery of the DHW demand. The nominal HP heating capacity corresponds to 1.5 kW (A2W55) at an airflow rate of 350 m^3/h. A 2.73 x 2.73 m timber frame test façade was built to measure the HP performance under real operating conditions and installed in a so-called PASSYS test cell [14] at the University of Innsbruck, as shown in Figure 2. The outdoor unit of the mini-split air-to-water HP is integrated in a 120 x 60 x 20 cm niche within the test façade (see lower casing in Figure 2). The back side of the outdoor unit is further insulated towards the inside with a 5 cm aerogel layer (see also Figure 1). A vapour barrier is inserted between the prefabricated façade and the existing wall. Seven three-storey multi-family houses will be renovated in Vienna, Austria. Each building consists of six flats (see also Figure 3), with an average flat size of 55 m^2. SH in the flats is provided currently mainly by decentral gas boilers or electric ovens, while DHW is either supplied by electric boilers or by the same gas-fired boiler used for SH, if existing.

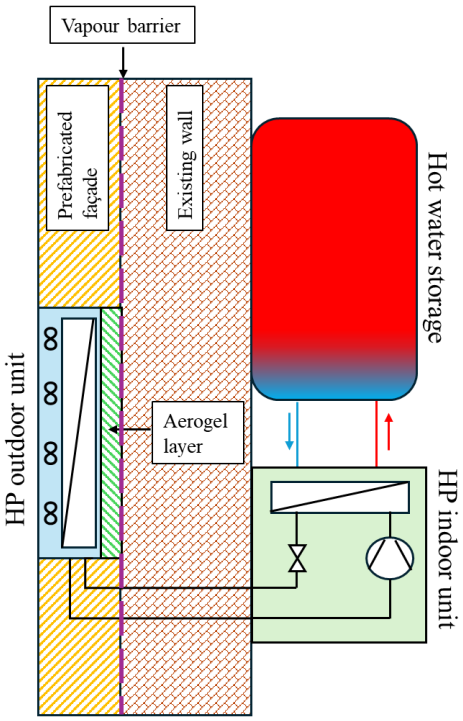

Figure 1. Schematic drawing of the developed façade-integrated air-source mini-split-type HP.

Figure 2. Outdoor unit of a façade-integrated mini split air-to-water heat pump for domestic hot water installed at the University of Innsbruck.

Figure 4 gives an aerial overview of the seven buildings subjected to renovation as well as an indication of the property limit (red dotted line), which is crucial for the evaluation of the sound emissions. Each of the seven buildings will undergo deep renovation to achieve a heating demand of 25 kWh/(m^2 y). Buildings 1 and 4 will be equipped with two centralised speed-controlled air-to-water HPs with a nominal thermal capacity of 5.3 kW each (A2W35) supplying low-temperature water to a water-to-water speed-controlled 7.2 kW (W15W55) booster HP in each flat for SH and DHW preparation. For buildings 2 and 7 the SH demand will be covered by two centralised air-to-water HPs, identical to those in buildings 1 and 4, while DHW preparation will be provided through the developed façade-integrated mini-split air-to-water HP on the south-east façade (see Figure 1, Figure 2 and Figure 3). Buildings 3, 5 and 6 will feature instead a fully centralised system with two monobloc 5.3 kW speed-controlled air-to-water HPs identical to those in the other buildings, one for SH and one for DHW.

Figure 4. Aerial view of all seven buildings on the renovation site located in Vienna with indication of the property limit (dotted red line).

3. REGULATORY FRAMEWORK

In Austria, environmental noise propagation is assessed based on ÖNORM S 5021, ÖAL Guideline No. 6 (Austrian Noise Abatement Association), and relevant Federal Province regulations. ÖNORM S 5021:2017 establishes planning values for noise emissions, considering both location (zone) and time of day.
For urban residential areas, the reference sound pressure levels are:

- 55 dB(A) from 6 a.m. to 7 p.m.
- 50 dB(A) from 7 p.m. to 10 p.m.
- 45 dB(A) from 10 p.m. to 6 a.m.

According to ÖNORM S 5021 and ÖAL Guideline No. 6, a continuously operating system (e.g., heat pumps) is deemed non-intrusive if the sound pressure level at the property boundary remains below the base level. This base level is generally approximated as 10 dB lower than the permitted assessment level [15]. Therefore, in the absence of more detailed in-situ measurements, the critical conditions are expected to occur at night and a maximum sound pressure

level of 35 dB(A) must not be exceeded at the site boundary.

4. METHODOLOGY

For the simulations model in COMSOL, the measured sound power level of the outdoor unit of the mini-split HP shown in Figure 5 (described also in [16]) was used as a base for the definition of the properties of the sound source.

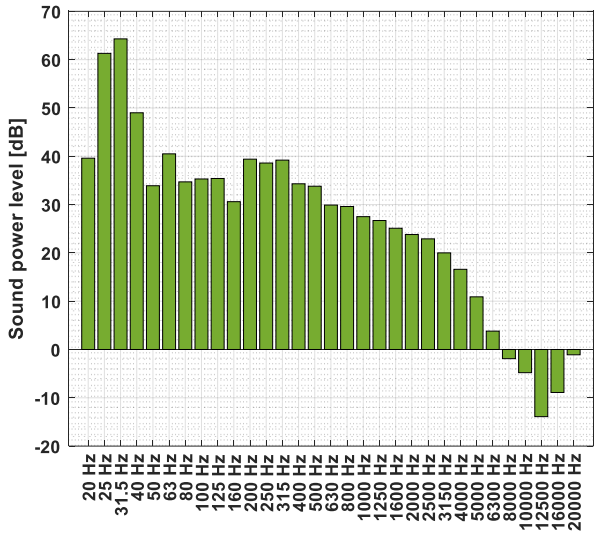

Figure 5. Measured sound power level spectrum of the outdoor unit of the façade-integrated mini-split HP.

The analysis is performed at 125 Hz for sake of manuscript length, but the same methodology can be applied to the remaining frequencies in the spectrum.

A first simulation is performed with a single homogeneous sound source, while a second one is performed for three identical sound sources, with a distance of 3 m between one source and the next one. The sound source is placed at a height of 5 m above ground level and the sound pressure level is evaluated on a horizontal plane orthogonal to the sound source(s).

In the CadnaA simulation model the sound source is modelled as a two-dimensional object with the frontal dimensions of the mini-split HP together with the building façade on which it is installed. The sound pressure level L_r in every point of the domain and for each frequency is calculated according to Eqn. (1):

$$L_r = L_w + L_z + K_0 - 20 \log r - C \ / \ [dB] \quad (1)$$

Where L_w is the sound power level of the sound source, L_z the eventual correction for low-frequency tonalities, K_0 the adjustment value for the position of the HP, r the distance from the sound source and C a constant correlating sound power level and sound pressure level, depending on the sound propagation pattern (e.g. hemispherical or spherical). In Table 1 a summary of the applied boundary conditions (BC) for the CadnaA simulations can be found. For the sake of simplicity, it was decided to discard the influence of low-frequency tonalities for the current analysis. The absorption coefficient of the building façade at 125 Hz $\alpha_{f,125}$ is assumed to be equal to 0.05 and the ground absorption coefficient $\alpha_{g,125}$ corresponds to 0.25.

Table 1. Summary of selected boundary conditions for the CadnaA simulations.

BC	Value
L_z	0 dB
K_0	+ 3 dB (façade installation)
C	8 dB (hemispherical propagation)
$\alpha_{f,125}$	0.05
$\alpha_{g,125}$	0.25 [17]

In the COMSOL simulations, an air volume of 10 m x 10 m x 10 m is defined for the calculation of the sound pressure level (see Figure 6), which includes a fictitious building façade (highlighted in Figure 6) and the ground. The HP is modelled as a cavity in the air volume and a sound pressure is applied to its front surface. The assigned sound pressure is derived by the measurement of the sound power level shown in Figure 5. An impedance boundary condition is assigned to the building façade and to the ground, with absorption coefficients equal to those presented in Table 1. The remaining surfaces are assumed to be open boundaries. The pressure field within the air domain is solved by the software by means of the Helmholtz equation, shown in Eqn. (2), which applies if no monopole or dipole domain sources are assumed. It is also assumed that the background pressure is zero, so the total sound pressure is equal to the scattered pressure.

$$\nabla \cdot \left(-\frac{\nabla p_t}{\rho_a} \right) - \frac{k^2 p_t}{\rho_a} = 0 \qquad (2)$$

Where p_t is the total sound pressure in [Pa], ρ_a the density of air in [kg/m^3] and k the wave number in [1/m]. To minimize the computational effort of the model, a hybrid FEM-BEM (Finite Element Method – Boundary Element Method) approach was used, with all the surfaces except the façade and the ground acting as a BEM-FEM boundary.

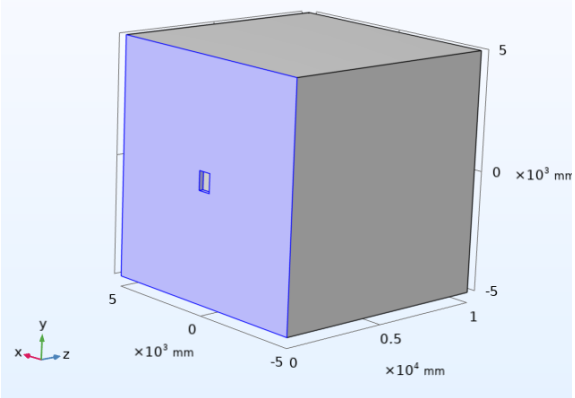

Figure 6. Depiction of the control volume of air assumed in COMSOL. The façade of the building is highlighted, and it is possible to see the HP cavity.

Finally, to calculate the sound emissions due to the DHW HPs around the renovation site, a model in CadnaA was built replicating the location and assuming a total of six façade- integrated heat pumps (e.g. one for each flat) on the east-southeast façade of building 2 and six heat pumps on the east-northeast façade of building 7 (see also Figure 3). To check the compliance with the regulations at night, fictitious receivers have been placed at the property boundary at a height of 2 m. The HPs have been modelled in this a case as one-dimensional sound sources.

5. RESULTS

The sound pressure level on a 2D plane perpendicular to the sound source is depicted in Figure 7 and Figure 8 for the CadnaA and COMSOL simulations respectively. In Figure 7, ideal receivers on the same plane of the sound source can be scene at distances between 0.5 m and 5 m from the sound source. Compared to CadnaA, the COMSOL simulation in Figure 8 is able to represent in a more detailed the sound propagation pattern caused by a two-dimensional sound source, as the sound propagation deviates from a purely hemispherical pattern for distances higher than about 2.5 m. Evaluating the sound pressure level at 125 Hz on a line perpendicular to the sound source yields the diagram in Figure 9. Below 1 m distance from the sound source a similar decay in the sound pressure level can be observed in both CadnaA and COMSOL simulations. Between 1 m and 2.5 m the COMSOL simulations slightly overestimate the sound pressure level compared to CadnaA and for distances higher than 3 m from the sound source, the profiles deviate.

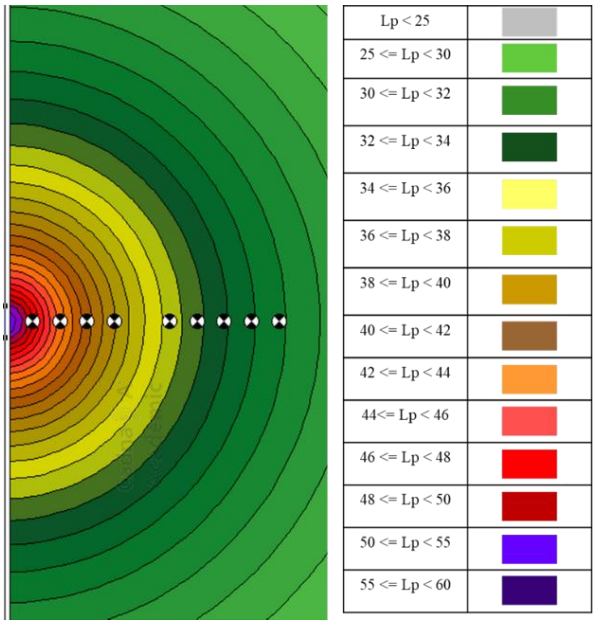

Figure 7. 2D plane of the overall sound pressure level in dB generated by a single HP in CadnaA.

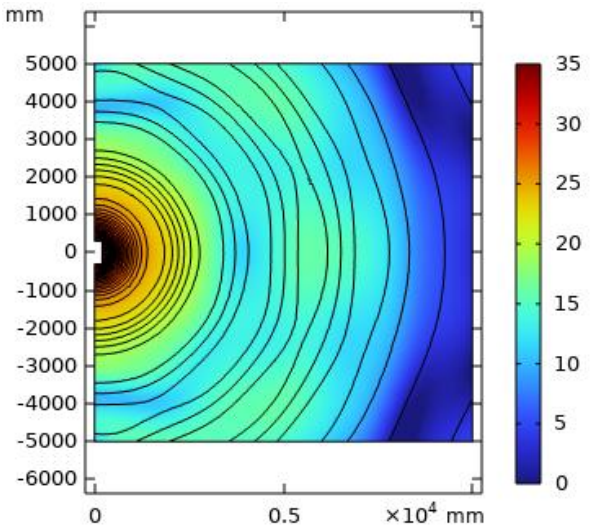

Figure 8. 2D plane of the sound pressure level in dB at 125 Hz generated by a single HP in COMSOL.

The differences between the two simulation tools are more clearly visible if three operating HPs are considered, as shown in Figure 10 and Figure 11. While near (within 1 m of) the sound source the sound pressure levels exhibit similar behaviour, as the distance from the HPs grows, the COMSOL simulation is able to reproduce the constructive and destructive interference patterns caused by the simultaneous sound emission of the three HPs and the reflections from ground a façade, while the sound pressure level in CadnaA assumes a more homogenous behaviour.

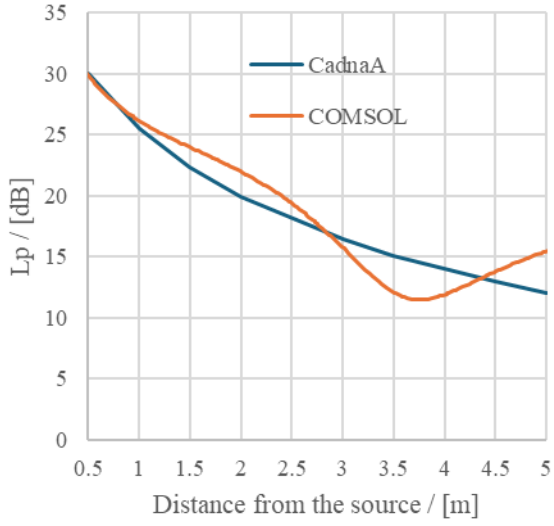

Figure 9. Comparison between CadnaA and COMSOL of the sound pressure level at 125 Hz with a single HP on a line perpendicular to the sound source.

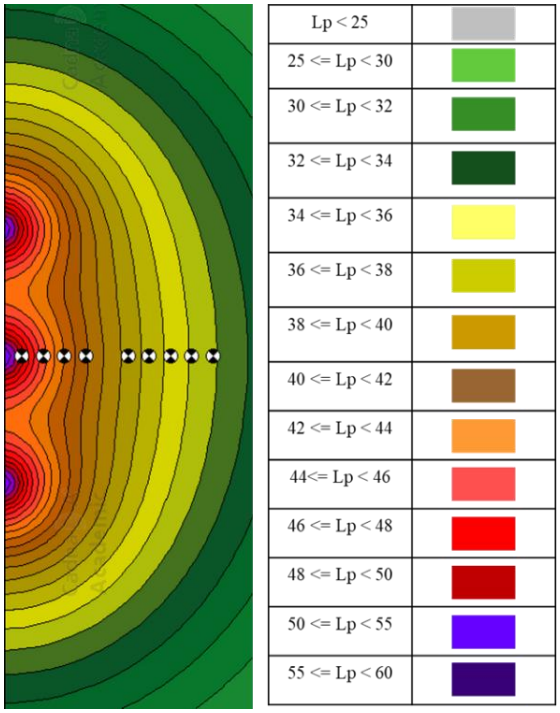

Figure 10. 2D plane of the overall sound pressure level in dB generated by three HPs in CadnaA.

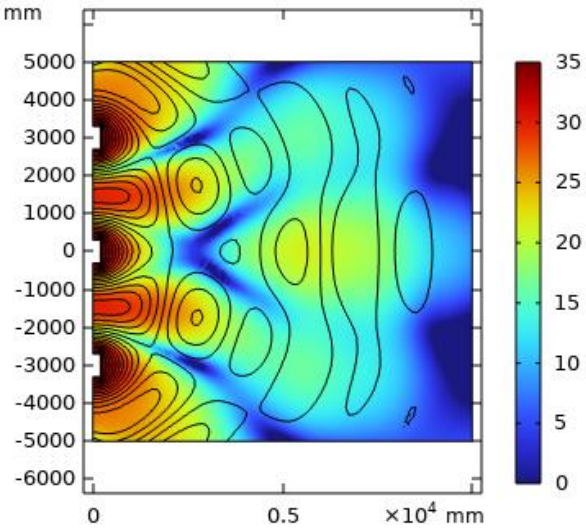

Figure 11. 2D plane of the sound pressure

level in dB at 125 Hz generated by three HPs in COMSOL.

As a result, the sound pressure level on a line perpendicular to the central HP in Figure 12 shows large deviations between the CadnaA and the COMSOL model for normal distances from the sound sources higher than 1 m.
Reflections in the COMSOL model contribute therefore first to a reduction in the sound pressure level from 1 m to 2.5 m, with a minimum around 5 dB and then to an increase from 2.5 m to 5 m.

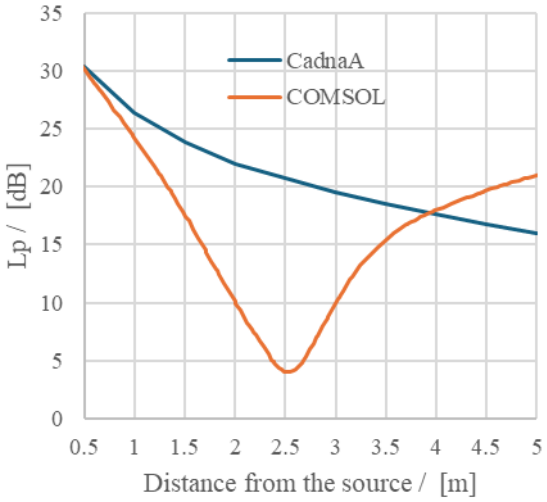

Figure 12. Comparison between CadnaA and COMSOL of the sound pressure level at 125 Hz with three HPs on a line perpendicular to the central HP.

In Figure 13 the simulated sound pressure level at 2 m height on the renovation site described in section 2 is observed considering the simultaneous operation of the twelve DHW HPs, six for building 2 and six for building 7. During night, the most critical property boundaries are therefore for building 2 the points exactly in front of the façade where the HPs are installed and for building 7 also the points southeast of the building. The maximum overall sound pressure level (considering only the DHW HPs) at the property boundaries near building 2 corresponds to 20.4 dB(A), while a maximum value of 29.3 dB(A) is observed near building 7 where the distance between sound sources and property boundary is at its minimum. In both cases, therefore, the regulatory limit is met.

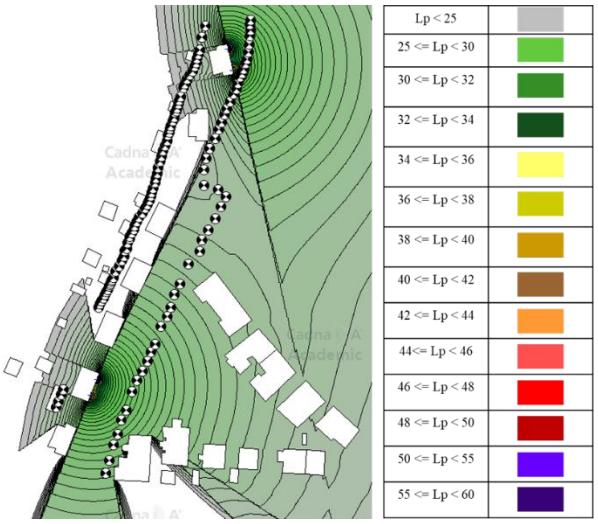

Figure 13. CadnaA simulation of the sound pressure level at the renovation site considering only the decentral DHW HPs. Ideal receivers are placed on the property boundary.

6. CONCLUSIONS

As part of the PhaseOut research project, seven multi-family buildings will undergo deep renovation. In two of these buildings, domestic hot water (DHW) will be supplied using compact, façade-integrated mini-split air-to-water heat pumps (HPs). This study evaluated the sound pressure levels around the renovation sites using the software CadnaA, specifically considering the nighttime operation of the DHW heat pumps alone.
Simulation results show that the sound pressure level at the property boundary remains below regulatory limits (e.g., 35 dB(A)) even at the shortest distance between the HPs and the boundary, where a value of 29.3 dB(A) was observed.
Additionally, the sound propagation characteristics of a single HP and of three HPs were analysed using two simulation models developed in CadnaA and COMSOL. Both models exhibited similar sound pressure level decay within 1 meter of the sound source. However, when simulating three simultaneous sound sources, significant deviations—up to approximately 15 dB—were observed at greater distances. This discrepancy is attributed to COMSOL's more accurate representation of wave phenomena, in contrast to the more uniform sound propagation observed in CadnaA.
These findings suggest that geometric acoustic simulation tools like CadnaA are more suitable for evaluating HP

installations over larger domains. However, for detailed assessment of sound propagation at short distances—especially in scenarios where HPs are installed close to property boundaries—FEM-based physical models like those in COMSOL offer greater precision.
To validate these results, future measurements will be conducted using a mock-up of a prefabricated timber façade integrated with an integrated mini-split HP. Furthermore, the effect of directional sound sources will be incorporated into the simulation models, and the results will be compared with in-situ measurements.

FORUM ACUSTICUM EURONOISE 2025

A RISK-BASED FRAMEWORK FOR ACOUSTIC ASSESSMENT OF ASHPS - FROM DOMESTIC TO COMMERCIAL APPLICATIONS

Jack Harvie-Clark[1*] **James Hill**[1] **Nicholas Dobinson**[1] **Richard Hinton**[1]
[1] Apex Acoustics Ltd, Gateshead, UK

ABSTRACT

Air Source Heat Pumps (ASHPs) are critical for decarbonising building heating across Europe, but their widespread deployment may be hindered by inefficient, inconsistent acoustic assessment methodologies. Through detailed acoustic modelling of realistic scenarios, we demonstrate that the UK's national calculation methodology for permitted development rights (MCS 020) can consistently predict sound levels 5-7 dB higher than calculations to ISO 9613-2. We propose a hierarchical assessment framework where evaluation complexity aligns with installation risk: from simplified MCS-based screening for domestic and commercial installations to more detailed evaluation where necessary. Our analysis addresses both domestic and non-domestic contexts, examining specific challenges around source characterisation, operational patterns, and cumulative impacts. For non-domestic installations, we identify particular issues regarding low-frequency emissions and night-time operation. Critical areas for further research include validation of propagation models, systematic post-installation studies, and standardised approaches to character corrections in the absence of data at the design stage. This framework could significantly reduce barriers to ASHP adoption by making assessments more efficient and consistent while ensuring appropriate acoustic protection as deployment scales up to meet decarbonisation targets.

1. INTRODUCTION

This paper critically examines current acoustic assessment methodologies for Air Source Heat Pumps (ASHPs) in the UK and proposes a risk-based framework to streamline evaluation while maintaining appropriate sound protection. First, we analyse the limitations of existing assessment approaches by comparing predicted sound levels using different methodologies. Then, we propose a hierarchical framework where assessment detail aligns with installation complexity and risk. Finally, we identify key areas requiring further research to support the proposed framework, with the goal of reducing obstacles to wider ASHP adoption while maintaining community sound protection. This approach addresses both domestic and commercial installations, recognising their distinct acoustic challenges while seeking consistent principles for assessment.

1.1 Background

Air source heat pumps (ASHPs) play a crucial role in decarbonising heating across all building sectors. Their successful integration into our built environment necessitates addressing sound emissions, which vary significantly between domestic and commercial installations. While domestic installations typically involve units of 3-16 kW heat output capacity mounted at ground level, commercial installations can be orders of magnitude larger and are often mounted on rooftops or in service yards, presenting distinct acoustic challenges.

1.2 Current planning regime

For domestic units the Microgeneration Certification Scheme 020 standard (MCS 020) [1] provides a simplified assessment framework that enables Permitted Development Rights (PDR), which therefore avoids the planning process. However, PDR do not apply to all domestic installations, and if the proposed installation does not comply with MCS

020 then full planning permission is required. Non-domestic installations typically require planning permission and are usually assessed using BS 4142 [2], though this standard was not specifically developed for heat pump applications, but industrial and commercial sound sources in general.

1.3 Opportunity to simplify the acoustic assessment

Through comprehensive acoustic modelling of realistic scenarios, we have previously demonstrated [3] that the MCS 020 method can consistently predict sound levels 5 -7 dB higher than ISO 9613-2 [4] calculations. This potentially inherent conservatism in the MCS methodology presents an opportunity for streamlining the planning process. For full planning applications, current reliance on BS 4142 introduces specific challenges around background sound level determination and character corrections that cannot be reliably predicted at design stage; in addition, different local planning authorities have different standards for noise impact assessments using BS 4142. These uncertainties introduce additional risk to the acoustic assessment and may also mean inconsistencies between practitioners. Our analysis indicates that a more structured, hierarchical approach to assessment could benefit both sectors.

1.4 More work is needed!

While this paper proposes a framework for determining an appropriate assessment methodology based on risk of adverse outcomes, this would require the consent of planning authorities to become a practical reality. Critical areas for further research are identified, including validation of propagation models and systematic post-installation studies, to inform future standards and ensure a suitable balance between facilitating ASHP adoption and community sound management.

1.5 Considerations for acoustic planning

To undertake the acoustic design for a new sound source, it is necessary to consider three distinct aspects of the sound:

- Source characterisation
- Propagation model
- Impact assessment

These aspects are considered in turn. See section 3 for a description of sound propagation modelling (the differences between those methods used in MCS 020 and typically adopted in BS 4142), and section 4 for a description of sound impact assessment methods.

2. CHARACTERISATION OF THE SOUND SOURCE

2.1 Sound power level

To comply with European Directive 813/2013 [5], ASHPs sold in the UK must declare their rated sound power level. The various EN Standards required to describe how the heat pump should be mounted in the laboratory, the environmental conditions, the water flow and return conditions, are described in [3, 5]. However, the heating load point is described in the EU Directive itself and has some ambiguity within it; manufacturers believe that the sound power test carried out at around 40 % of full load is compliant with the EU Directive, and therefore this is what they do to declare the ErP Sound Power Level, SWL, on the product label.

As there is no other description of the load point, a “full load” test does not have a formal definition and is not standardised. However, in other countries there appears to be data available for both the ErP sound power and “full load” or “maximum” sound power, such as in the German heat pump association’s online calculator [6]. A sample of data from the German website suggests that the maximum sound power may be up to 15 dB more than the ErP sound power, or it may have the same value. The sample data suggests that at sound power levels below 60 dBA the maximum sound power diverges more significantly from the ErP sound power. A discrepancy between the ErP stated sound power and actual maximum sound power introduces uncertainty into the assessment which is impossible to quantify if the data is not available.

For commercial units, source characterisation presents additional challenges. While domestic units must declare their ErP sound power level, commercial units often come with limited acoustic data. Manufacturers may report sound pressure levels at specified distances rather than sound power tests undertaken according to recognised standards.

The operating conditions under which acoustic data is measured may not reflect real-world operation. Literature describing in-situ measurements and comparison with manufacturer’s laboratory test data suggests discrepancies can be significant.

2.2 Tonality

Some countries include a penalty for tonality in the assessment at design stage, as can be seen on the German heat pump association website. The information on the German website indicates a “surcharge” (penalty) for tonality, K_T. The accompanying information notes indicate that a penalty shall be set at 3 or 6 dB, depending on the

degree of conspicuity. The tonal quality of a sound can also be determined by measurement (DIN 45681, draft edition May 1992).
Note that DIN 45681 [7] can only be applied in-situ for the determination of tones. Current practical methods for assessing tonality are hotly debated – three methods are described in BS 4142, with the preferred being the subjective method. This is not possible at the design stage without full auralisation of the sound – which requires directional information of the sound source, and an auralisation of the background sound. Our random sampling of manufacturers and models in the German database has not revealed any units that have a K_T (tonality) penalty.
There is no standardised information available from suppliers in the UK that indicates tonality of ASHP units. It has been mentioned previously [8] that including a characterisation for tonality may facilitate consistency in assessments, but this information is not currently available.
While it is currently not possible to carry out a representative tonality assessment at the design stage, new methods are currently being proposed [9]. Practitioners must often make assumptions about character corrections without having the detailed spectral data that would inform a more nuanced assessment. The MCS 020 procedure does not take account of tonality.

2.3 Low frequency sound

When spectral data is provided, it typically excludes frequencies in and below the 63 Hz octave band, yet low frequency sound can be significant for both small and particularly for larger units. The laboratory standards disregard all sound below the 100 Hz third octave band, as laboratories are typically not big enough to reliably measure at lower frequencies.
Some countries have anomalies, such as the Netherlands; the in-situ standard for ASHPs includes a low frequency criterion, but the information is not available at design stage to assess for this outcome. Where design stage assessment differs from in-situ assessment this introduces a risk for the designers, who respond by taking a prudent approach. This potentially hinders the rollout of ASHPs unnecessarily, as it can entail an unnecessary constraint where there are little or low levels of sound character.

2.4 Directionality

Directional characteristics are also not required to be measured according to the standards. There is only one facility in the UK for measuring the sound power of ASHPs, at BSRIA. Laboratory measurements require a thermo-acoustic chamber, which may be either a reverberation room or a (semi or full) anechoic chamber. Directional sound is only possible to measure in an anechoic chamber, while the facility at BSRIA is a reverberation room.
Many laboratories across Europe are starting to measure the directional characteristics of ASHPs [10]; this necessitates recording both temporal and spatial characteristics of the sound, i.e. the quantity of data recorded is many orders of magnitude greater than for a simple sound power characterisation. Methods to use this data and predict in-situ impacts will also need to be developed, such methods are currently the demise of research institutions and significant project effort.

2.5 Operating conditions and background variations

In operation, the ASHP output is modulated to match the load. The main sources of noise, the compressor and fan, have their speeds and load adjusted, typically to optimise energy efficiency for a given output demand. The background sound level generally varies throughout the nighttime period, typically being lowest in the early hours of the morning. Many manufacturers provide a “low noise mode” for places where there are separate daytime and nighttime noise level limits. While low noise mode operation may reduce the thermal efficiency, its adverse effect is likely to be much less than provision of an acoustic enclosure, for example, or other forms of mitigation.
A “worst case scenario” approach to assessment is typical; under MCS 020 there a single noise level threshold for daytime and nighttime, with no opportunity to use a low noise mode of operation in the nighttime. A more sophisticated assessment under BS 4142 can accommodate different noise emissions in different time periods.

2.6 A common practitioners’ mistake

Practitioners should be wary of manufacturer's data that presents "sound level at 1 m" without accompanying sound power data. While superficially attractive for calculations, such metrics can lead to significant errors. These values typically represent measurements averaged over a control surface 1 m from the unit's dimensions, according to the laboratory test standards such as ISO 3744, ISO 3745, and ISO 3746. This is quite different from the way that practitioners often use this data – assuming a point source of sound, and a simple 20*log(r) to account for attenuation due to distance. Using these data in point-source propagation calculations systematically underestimates the source sound power level, as the total sound energy is

always actually distributed over a larger measurement surface area than assumed in this calculation.
Only declared sound power levels, measured according to recognised standards, provide a reliable basis for acoustic calculations. When manufacturers present sound pressure levels at a stated distance, the unit dimensions and measurement methodology must be clearly stated to enable calculation of sound power level. A variety of reputable manufacturers appear to present data as sound levels at 1 m that encourages acousticians to make this mistake, by using an image with a "measurement location" indicated at a distance of 1 m from the unit.

3. SOUND PROPAGATION MODELS

When calculating the sound propagation and impact from an installation, a variety of models are available to the practitioner. Through systematic comparison of these models, we demonstrate that simpler approaches can provide inherently conservative results that may be sufficient for many scenarios. If a simple calculation demonstrates a robust case for a sufficiently low sound impact, there is no need to expend additional effort on more sophisticated modelling methods. However, simple models have risks in both directions – in simplifying the calculation of sound propagation, simple models need to be used with caution in situations that are beyond the scope of their simplifying assumptions. It can take a greater level of expertise to know when a simpler model is appropriate.

3.1 MCS 020 sound propagation model

As MCS 020 is applied by people with no acoustics expertise, it is based on three simple input data:

- Distance between source and assessment position, rounded down to tabulated integer values
- Number of reflecting planes (one, two or three)
- Barrier attenuation (either 0, 5 or 10 dB)

These data are used to calculate the sound propagation to the receptor location. The approach simplifies the same concepts used in ISO 9613 but treats reflecting surfaces and barriers differently. In MCS 020, each reflecting plane conceptually constrains the sound propagation to half the previously available space (solid angle), adding 3 dB to the calculated level. Our modelling has shown [3] that this in particular can consistently lead to higher predicted levels than the application of ISO 9613-2.

3.2 ISO 9613-2: 2024

A method identified in BS 4142 for calculating sound propagation outdoors is BS ISO 9613-2; this standard is typically applied using specialist software and expertise. The standard accounts for reflecting surfaces by calculating additional sound propagation paths for specular reflections to the receiver location. Our analysis demonstrates that this can result in predicted levels 5 - 7 dB lower than MCS calculations for equivalent scenarios.
While much more comprehensive than the MCS 020 model, ISO 9613 still has limitations when applied to the specific context of ASHP sound assessment. The standard was designed for sound propagation over longer distances and in open environments, rather than the close proximity and complex geometries often encountered around ASHP installations. The standard's assumptions about ground effects and meteorological conditions might also not be entirely suitable for the constrained urban morphologies where ASHPs are typically located.
ISO 9613 does not include wave-based sound propagation effects on tonal content, which can influence the perceived impact. There is a common misconception that ISO 9613 is "3D" modelling, as the model appears to have three dimensions. However, it is described as "2.5 D" [12], as it treats the height dimension differently to the horizontal plane .
For commercial installations, particularly those mounted on rooftops, ISO 9613-2 presents additional challenges. Rooftop installations often involve multiple units in close proximity, making it crucial to accurately model their cumulative impact. The typical lack of information about source directivity means that the manner of modelling the ASHP can become critical for determining barrier heights, for example.

4. SOUND IMPACT ASSESSMENT

The sound impact from a development is considered within the planning regime as part of the assessment of its environmental impact. In England this is guided by the National Planning Policy Framework (NPPF) [13]. The NPPF emphasises the need to avoid noise giving rise to significant adverse impacts on health and quality of life, and minimising any adverse effects. Further government guidance on noise is provided on the Planning Practice Guidance website [14].
The most common way that planning authorities assess noise impacts from building services plant is by applying British Standard BS 4142: 2019, "Methods for rating and assessing industrial and commercial sound." [2]. This

standard provides a method for calculating a rating level that can be compared to background sound levels to determine the likely significance of the impact, depending on the context. Historically, the application of BS 4142 has been subject to varying interpretations. To address this and promote consistency, the Association of Noise Consultants (ANC) published additional guidance in the form of a Technical Note to BS 4142:2014+A1:2019. [15].

If the planning regime fails to sufficiently protect people from noise, there is statutory nuisance legislation that can be invoked under Part III of the Environmental Protection Act 1990 (EPA) [16]. A local authority has a legal obligation to investigate noise nuisance complaints under the EPA. This duty is entirely separate from its function as a planning authority, although in practice, the same environmental health or public protection officers within the local authority often handle both planning applications and nuisance complaints. In addition to complaining to the local authority, aggrieved parties can also take legal action through the courts based on private nuisance.

Under statutory nuisance legislation, there are no fixed noise levels that automatically constitute a nuisance. Instead, the judgement is made based on whether the noise is "unreasonable". Factors considered include the duration, frequency, loudness, and character of the noise, as well as the time of day and local context.

Planning seeks to achieve a high level of amenity for communities; sound impacts should be well below the threshold for a noise to be considered a statutory nuisance. Compliance with BS 4142 is typically used by local planning authorities to not just prevent a statutory nuisance, but in order to protect local amenity and quality of life.

4.1 MCS 020 assessment

The MCS 020 calculation includes a much-simplified sound propagation model, and has a fixed absolute impact limit of 37 dBA based on the declared (ErP) ASHP sound power level. This simple criterion takes no account of sound character such as tonality or low frequency content, and any intermittency during different phases of operation (e.g. during defrosting). The standard was developed specifically for domestic installations under Permitted Development Rights (PDR).

4.2 BS 4142 assessment

BS 4142 describes a process for assessing the impact of industrial or commercial sound at a receptor location – it is not designed to be used for prediction of future sound sources, although this is a common application. It is frequently used for assessment of domestic installations, despite its title "..assessment of industrial or commercial sound", suggesting that a domestic installation would fall outside of its scope.

4.2.1 Background sound levels

For new residential developments, particularly if comprising many dwellings, background levels must be predicted rather than measured. There is little experience within the acoustics industry of predicting background sound levels in new residential developments that may themselves have a significant impact on the background sound environment, for example.

In locations with low background sound levels (e.g. below 30 – 35 dBA), achieving rating levels below background may preclude viable installations, which may not be necessary to preserve quality of life for residents.

According to the National Noise Incidence Study, the percentage of dwellings exposed to background, $L_{A90,\ T}$ levels above 40 dBA is:

- 20 % of dwellings at night ($L_{A90,\ 8\ hr}$)
- 70 % of dwellings during the day ($L_{A90,\ 16\ hr}$)

In Scotland, many local authorities specify absolute limits for plant noise impact, typically adopting thresholds of NR 35 for daytime operation, and NR 25 for nighttime, internally, with open windows. It is standard practice to assume a 10 dB attenuation through the open windows, which means levels of (approximately) NR 45 daytime and NR 35 nighttime externally. NR 35 is likely to be marginally higher than 37 dBA, depending on the frequency content. This approach is not common in England, but can expedite an assessment and reduce its cost burden by omitting the background sound survey. Where the ambient sound environment is louder, and a higher sound impact may be acceptable, a dual approach can enable those assessments that benefit from a more nuanced assessment to proceed without excessive, unnecessary mitigation.

4.2.2 Character corrections

BS 4142 contains detailed guidance on decibel penalties that may be attributed to the character of sound at a receptor location – see section 2, characterisation of the sound source, for discussion of the challenges in predicting character corrections at the design stage.

In practice the background is not stationery in either time or space around a receptor location, which can make assigning character corrections contentious where sounds exist, and a challenging task at the design stage.

4.2.3 Commercial installation considerations

For commercial installation, night-time operation usually drives the acoustic design due to lower environmental background sound levels. Although buildings may only be occupied during daytime hours, frost protection operation or building pre-heating may occur during normally quiet periods of the night. The cumulative impact of multiple units may need appropriate assessment.

4.2.4 Rating level thresholds

Currently local authorities take various approaches to setting sound impact limits relative to background sound levels: some permit rating levels 5 dB above background, while others require the rating level to be 10 dB below background, although meeting the background sound level is more common. The more stringent limits are likely to be a significant obstacle to the roll-out of ASHPs.

5. PRAGMATIC APPLICATION OF ASSESSMENT METHODS

We propose a hierarchical, risk-based framework for assessment that could streamline the planning process while maintaining acoustic protection. A standardised, industry-accepted approach could itself reduce costs and risks associated with proposed installations.

5.1 Step 1: Enable a fixed level threshold for planning

Where an installation requiring planning permission can demonstrate compliance with the 37 dBA threshold from MCS 020, this could be considered sufficient evidence of acceptable acoustic impact. This approach could significantly reduce assessment costs for domestic installations that fall outside permitted development, as well as non-domestic installations that are low-risk due to the low sound level impact. The approach of using fixed threshold levels is proven to be successful across Scotland and much of Europe, where daytime thresholds are generally significantly higher than 37 dBA.

5.2 Step 2: Allow the MCS 020 sound propagation model

To minimise the cost of the acoustic assessment, the simplest assessment of sound transmission is embodied in the MCS 020 sound transmission model. Where an assessment uses the MCS 020 sound transmission model and threshold, it is compliant with PDR requirements. Although there is currently nothing preventing planning authorities from approving this method for planning applications, it could be positively affirmed as being sufficient, given its demonstrated prudence in comparison with more detailing sound propagation modelling.

5.3 Step 3: Permit more detailed sound propagation assessment

Where a simple sound transmission model indicates a marginal failure to comply with the identified criterion, permitting more detailed modelling of sound propagation would be appropriate. However, there are a variety of models, and many model parameters that practitioners may consider to various extents. It is suggested that industry-standard guidelines for modelling ASHP sound propagation with ISO 9613-2 are developed by consensus, to help achieve consistency.
This route could avoid the additional resources associated with a background sound survey while benefiting from more sophisticated treatment of barriers and reflecting surfaces.

5.4 Step 4: Predetermine higher thresholds in higher background sound environments

Where background sound levels are higher, it can be unnecessary to mitigate the sound impact to the threshold level that is considered suitable everywhere – i.e. a higher impact can be acceptable according to BS 4142.
A consensus on rating level margins could expedite assessments and reduce risks and delays with a process of agreeing rating level thresholds compared with background sound levels on a case-by-case basis, as can happen currently.
A BS 4142 assessment also requires an assessment of tonality, intermittency, impulsiveness, and any other features that may attract a rating penalty. In the absence of this information at design stage, a consensus could be developed to agree rating penalties for these features.

5.5 Step 5: Full BS 4142 assessment

Beyond the features of step 4, a full BS 4142 assessment also includes consideration of context, on a case by case basis. Although practitioners regularly carrying out these assessments, there is no assurance of consistency; consultants working for developers and public protection officers may take different views of appropriate penalties between each other as well as amongst themselves. This is the current state for all assessments that fall outside the scope of MCS 020 and PDR.

6. FURTHER OPPORTUNITIES TO FACILITATE ASHP ROLLOUT, AND FURTHER WORK

6.1 Enable further acoustic assessment options under PDR

The first four steps of assessment could be adopted in MCS 020. This could enable some of those properties that currently marginally fail the "noise test" (i.e. just fail to comply with the current scope of MCS 020) to benefit from a more detailed acoustic evaluation, while still avoiding a full planning application. A more detailed assessment would need to be undertaken by a suitably competent person; while MCS 020 is designed to be undertaken by an installer with no specialist acoustics knowledge, a more nuanced a sophisticated assessment would require commensurate accountability, which would be based on a greater level of expertise and experience. It would be prudent to investigate the real-world evidence base discussed below first, to help establish the case for this option.

6.2 Extend PDR

Currently PDR apply to domestic installations only, where there may be a maximum of two units per dwelling. Permitted development rights could be extended to non-domestic properties, with prior approval being required if necessary as a safeguard against potential adverse effects from cumulative impact, for example. This could reduce the planning barriers to ASHP uptake.

6.3 Daytime / Night-time thresholds

The single threshold in the UK that applies at all times of day and night is similar to the nighttime limit in other European countries, where a higher daytime limit is also used. It is standard practice in some European countries to design to different daytime and nighttime sound level thresholds, and to use a reduced sound power mode at night if this is necessary for acoustic compliance.

Discussions with installers during recent research indicated little appetite for this approach, in part amid concerns that residents may adjust the settings on their appliances. Currently installers need not waste time with sites that present challenges, but for wider roll out the more acoustically challenging sites will also need solutions. Enabling higher sound levels during the daytime is one option that could facilitate installations for sites that might otherwise be problematic, and accepting quiet mode operation with associated drop in thermal performance at nighttime.

6.4 Real world evidence base

Currently there appear to be relatively few noise complaints compared with the numbers of installations. However, there is little information about real-world sound impact from installations that are designed with the MCS 020 method. Building further confidence in this approach, and considering potential changes to the threshold levels requires systematic post-installation studies comparing predicted and measured levels, alongside documentation of planning outcomes where MCS compliance has been used as evidence.

Field measurements comparing predicted and actual sound levels are needed to validate both MCS 020 and ISO 9613 predictions. These studies should also examine real installations across different mounting arrangements, particularly investigating the effectiveness of different barriers and the influence of reflecting planes, and the potential effectiveness of sound absorption on nearby surfaces. This also requires a methodology for measuring the sound of an ASHP installation in-situ, which is not a simple task.

This evidence base would help to determine if the current threshold is appropriate, too permissive or too restrictive, and could support a future revision.

6.5 Cumulative impact considerations

Previous research [17] has investigated the potential for cumulative sound impact from multiple domestic ASHPs in high-density residential areas. The study focused on worst-case scenarios in terraced and semi-detached housing, representing the majority of the UK's housing stock. Even under conservative assumptions with all units operating simultaneously at maximum permissible MCS sound levels, the increase in overall sound levels was found to be modest. The cumulative effect typically resulted in increases of up to 2-3 dB at dwelling facades compared to a single unit, with larger increases occurring in garden areas and places where absolute levels remained low.

These findings have important implications for our proposed assessment framework. Where a Step 1 assessment demonstrates compliance for individual installations, cumulative impact is unlikely to be significant even in high-density deployments. Therefore planning conditions requiring the impact to be many decibels below the background, to prevent cumulative impact, are considered unnecessary, and could hinder the roll-out of ASHPs.

7. CONCLUSIONS

The evidence presented strongly supports adopting a proportionate framework for ASHP acoustic assessment. Using MCS 020 as an initial screening tool, with options for detailed modelling in borderline cases, or assessment against a higher background sound level, could significantly reduce obstacles to installation while maintaining appropriate acoustic protection. Success relies on planning authorities agreeing clear guidance on:

- Criteria for selecting appropriate assessment steps
- Documentation requirements proportionate to installation complexity
- Treatment of cumulative impacts
- Standardised approaches to character corrections where detailed data is unavailable

The evidence from the further work proposed would help refine assessment methodologies and support wider adoption of ASHPs whilst maintaining appropriate acoustic protection. This is particularly important as the scale of heat pump deployment increases to meet decarbonisation targets. Implementing this risk-based framework would remove unnecessary barriers to heat pump adoption while ensuring communities remain protected from inappropriate noise impacts.

SCALABILITY OF VENTILATION AND NOISE INSULATION METHODS FOR ASSESSING A FULL-SCALE METAWINDOW

Gioia Fusaro[1*] **Luca Barbaresi**[1] **Massimo Garai**[1]
[1] Department of Industrial Engineering, University of Bologna, Italy

ABSTRACT

Natural ventilation in homes often compromises indoor acoustic comfort by allowing outdoor noise to enter. Recent advancements in acoustic metamaterials (AMMs) have enabled the development of innovative solutions, such as integrating AMMs into windows, to provide effective natural ventilation while maintaining sound insulation. However, European standards for evaluating façade insulation properties primarily focus on closed systems, limiting their applicability to AMM-based windows (AMWs). This study addresses this gap by using the ISO 10140 measurement method to evaluate a full-scale acoustic metawindow (AMW) capable of simultaneous noise insulation and ventilation when open. The sound reduction index (R) was used to measure its noise insulation performance, showing an R in between 13 and 34 dB in the 100-3150 Hz frequency range combined with a more elevated flow rate than the AMW unit. Indeed, additionally, laboratory tests on airflow performance (adapted ISO 9972) across a pressure range of 10-80 Pa demonstrated that the metamaterial acoustic filter does not significantly affect airflow, making this solution versatile and practical. These findings underscore the potential of the AMW for multi-domain comfort with a more sustainable approach and scalable technology.

1. INTRODUCTION

Traditionally, sound insulation and façade ventilation in buildings have been managed separately [1]. Standard windows allow for natural ventilation and an outside view but force users to choose between noise control and airflow, affecting overall Indoor Environmental Quality (IEQ) [2]. Researchers have explored various solutions, such as mechanical ventilation and passive or active noise control systems [3–5]. Passive approaches, like microperforated panels (MPPs) and acoustic metamaterials (AMMs), are particularly advantageous because they require minimal energy and can be integrated into windows, enhancing durability [2].

Acoustic metamaterials used for noise and ventilation management are typically duct-like structures with embedded resonant elements, such as metasurfaces, metamaterial cages, and labyrinthine designs [2]. Originally developed for mechanical applications, such as soundproofing in engines, these structures are now being adapted for building use. However, there are three key challenges in developing metamaterial-based ventilated soundproof windows [2,6]: i) the need for scalable metamaterial modules, ii) a consistent multi-physical analysis approach that aligns both numerical and experimental results, and iii) the absence of standardised methods for assessing sound insulation in open windows.

More details can be found in the comprehensive paper [7].

For these reasons, a numerical and experimental study was run respectively for assessing the acoustic and the ventilation performance of an AMM-based window (AMW) at its full scale (0.8x1.2 m). Previously, an AMW unit was developed and assessed, but its dimensions were relatively small (0.4x0.4 m). This new prototype allows to prove the scalability of the AMM technology towards a more ergonomic and user-friendly design. FEM models were modelled to represent the experimental boundary conditions. ISO 10140 configuration was used to experimentally assess the acoustic performance in a diffuse sound field [6,8–10], while the ISO 9972 [31]) evaluates the ventilation capacity.

2. METHOD

The methodology follows the approach in [3], combining numerical and experimental techniques to assess the Acoustic Metawindow (AMW). First, the Finite Element Method (FEM) is used to simulate measurement configurations and validate the numerical model against laboratory boundary conditions, including source positioning, direction, and edge effects. Then, an experimental method is applied: the ISO 10140 test in a diffuse sound field [6,8–10] to measure the sound reduction index for the prototype (R_w). Additionally, the blower door test (ISO 9972 [31]) evaluates the ventilation capacity while maintaining acoustic insulation.

The AMW prototype measures 0.8 × 1.2 × 0.17 m and integrates an Acoustic Metamaterial (AMM) system within its frame. Key acoustic parameters—specific impedance ($Z_{1,2}$) and refractive index ($n_{1,2}$)—are considered for different regions of the AMW. Variations in the refractive index create an out-of-phase effect on sound waves passing through the AMM unit cell, independent of the angle of incidence. The prototype consists of 5-mm thick laser-cut plexiglass panels for the indoor and outdoor surfaces, with AMM unit cells 3D-printed in polylactic acid (PLA) using fused deposition modeling (FDM). The AMW slides within the wall, allowing two configurations: fully open (duct opening of 0.075 × 0.13 m) and half-open (0.075 × 0.06 m). Before experiments, FEM analysis is performed to optimize the test setup.

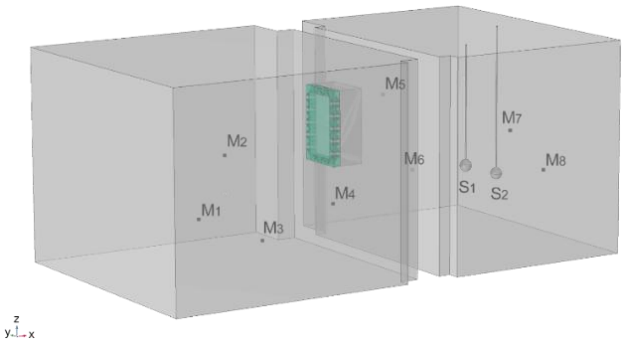

Figure 1. Numerical model of the coupled chambers test setup. S1 and S2 are the two omnidirectional sources, while M1- M8 represent one of the two microphones' positions.

Following ISO 10140, the specimen is installed in a partition between two coupled reverberation rooms to assess airborne sound insulation. ISO 10140-1 [8] defines the test element, while ISO 10140-2 [6] describes the façade opening. A sound source in one room generates noise, and sound pressure levels are recorded in both the source and receiving rooms. Sealant ensures airtightness around the structural window edges.

To address the challenges of having a coherent numerical model, a study was conducted using simulations with the Finite Element Method (FEM). The numerical model is characterised by an air density of 1.215 kg/m³ and a sound speed in air of 343 m/s at 20°C. A 1 Pa sound wave was directed at the test specimen using two omnidirectional sound sources (S1 and S2) across a frequency range of 100-5000 Hz. The simulation replicated two connected reverberation rooms (116 m³ total volume), separated by a 0.4 m partition containing the AMW test sample. The setup involved a coupled room geometrical configuration with a hole in the dividing wall of dimension 0.8x1.2 m. This hole represents the configuration without the AMW, while in the other configuration investigated in this study, the AMW would be placed instead. The receivers of the numerical analysis were placed at multiple points following the indications of to ISO 10140 [6] to calculate sound insertion loss. The sound insulation performance was determined using insertion loss (IL), calculated as:

$$IL_{AMW} = SPL_{noAMW} - SPL_{AMW}\ (dB) \qquad (1)$$

Where SPL_{noAMW} and SPL_{AMW} are respectively the average of SPL measured in the numerical model without and with the AMW unit.

Additionally, a numerical ventilation analysis was conducted using FEM with the k-ε turbulence model to evaluate pressure drop (ΔP) at different airflow velocities (0.5–1.132 m/s). The inlet surface, which represents the outdoor conditions, is used to define the flow, with the maximum wind velocity set according to Asfour and Gadi's criteria [11], based on a height of 20 m above the ground and a room height of 3 m. The model assumed no-slip conditions in a 3D air-filled domain, focusing on natural ventilation at low Mach numbers to reduce noise interference. The outlet pressure was set at 101.325 Pa, with refined meshing in turbulence-prone regions. A stationary solver performed CFD analysis based on pressure and velocity components. The geometric boundaries are the same as the acoustic FEM model, consistent with the 3 m room height assumption in the Asfour and Gadi criteria [11]. For the mesh size in this 3D study, the maximum element size is 0.115 m, and the minimum element size is 0.0144 m, with finer mesh in regions expected to experience turbulence, particularly near corners within the AMW structure. The study is performed using a stationary solver, with the CFD analysis depending on pressure (p) and velocity (u, and velocity components u,

v, and w). To analyse the flow velocity (v) the parameter was assessed as the average throughout the openings on the AMW. The pressure difference defining different flow rates per person was calculated considering the area of the receiving room (20 m²) able to host a maximum of three occupants. The flow rate per person was determined by the Blower Door Test method, which is pre-set by default to a Δp value for three people in the same room, with a gradual gradient from q10 to q80 (ISO 9972) [12].

3. RESULTS

3.1 Acoustic results

The comparison between experimental and numerical IL values in Figure 2 shows a reasonable agreement in the general trend, with both datasets capturing the main characteristics of the AMW's acoustic performance. However, some discrepancies are noticeable, particularly in the frequency range between 200 and 500 Hz. The numerical IL curve underestimates the experimental IL at certain frequencies and overestimates it at others, possibly due to model assumptions. One key factor could be the rigid wall assumption in the numerical model, which does not account for real-world material absorption and edge diffraction effects. Additionally, the sound field conditions in the experimental setup may differ slightly from the idealised conditions assumed in the FEM simulation, contributing to observed deviations. Improving the numerical model by incorporating realistic boundary conditions and absorption properties could enhance accuracy.

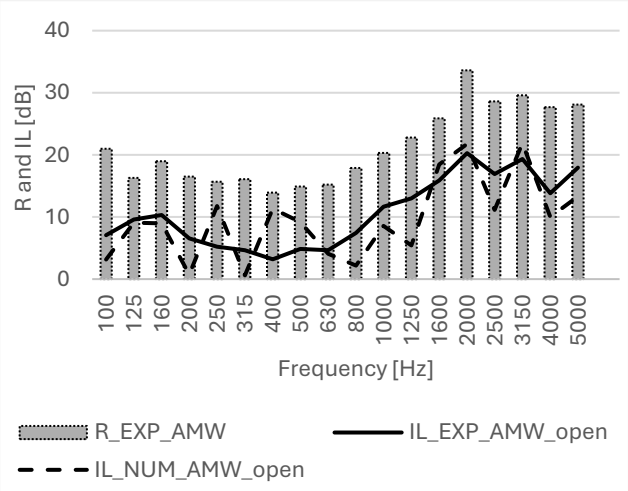

Figure 2. Comparison of the IL in a diffuse sound field calculated experimentally and numerically by subtracting a) the SPL with the fully open AMW from b) the SPL without the AMW in the wall opening.

R values on the other hand, result capturing the noise reduction index in a more realistic indoor acoustic setup.

3.2 CFD results

Building on a previous study [3], numerical analysis in the ventilation domain was carried out using computational fluid dynamics (CFD). The flow velocity and flow rate comparisons between experimental and numerical results in Figure 3 exhibit good agreement, with numerical results generally following the same trend as the experimental data. However, numerical results tend to slightly overpredict airflow velocity and flow rate, particularly at higher flow rates per person (q50 and q80). This discrepancy may be attributed to the k-ε turbulence model's limitations, particularly in capturing near-wall viscous effects and small-scale flow structures. Despite these minor differences, the overall similarity between the experimental and numerical results validates the CFD model's effectiveness in capturing airflow characteristics. Compared to the previous AMW unit model, the flow rate performance of the scaled AMW is higher (see Figure 3) while keeping a perceivable noise attenuation.

While both numerical and experimental analyses show similar trends, refinements in boundary conditions, material properties, and turbulence modeling could improve accuracy, particularly for the IL calculation in the low-frequency range and the airflow simulation at higher velocities. Future work should consider incorporating more complex wall absorption characteristics and refining turbulence models to better represent real-world airflow conditions.

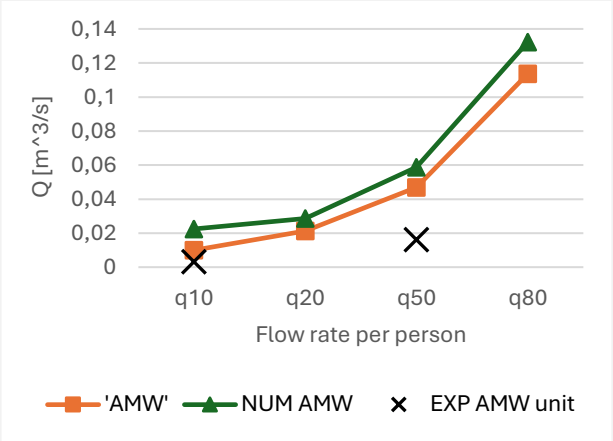

Figure 3. Comparison of different airflow rates of the AMW from Experimental and Numerical analysis.

4. CONCLUSIONS

This study demonstrates the potential of Acoustic Metawindows (AMWs) to provide both effective natural ventilation and significant noise insulation through a scalable technology and a sustainable design. Through a combination of experimental and numerical analyses, the AMW achieved an IL of 23 dB and R of 34 dB in the 100–3150 Hz range. Additionally, airflow testing confirmed that the integrated acoustic metamaterial does not significantly impede ventilation, ensuring a balance between acoustic and indoor environmental comfort. Moreover, the flowrate performance of the scaled-up AMW model is improved compared to unit one.

Numerical simulations using the Finite Element Method (FEM) and Computational Fluid Dynamics (CFD) largely aligned with experimental results, validating the modelling approach. However, minor discrepancies in low-frequency sound insulation and airflow predictions highlight the need for further refinement in boundary conditions, material properties, and turbulence modeling.

The findings underscore the viability of AMWs as a scalable, energy-efficient solution for sustainable building design. Future work should focus on optimizing material properties, refining numerical models, and exploring long-term durability in real-world applications. The integration of standardized testing methods for open-window configurations will be crucial in advancing the adoption of AMW technology in building acoustics and ventilation strategies.

A SILENCER DESIGN FOR A MECHANICAL HEAT RECOVERY UNIT

Darragh Mullally[1*] **John Kennedy**[1]
[1] Department of Mechanical and Manufacturing Engineering, Trinity College Dublin, Ireland

ABSTRACT

Modern homes require energy efficient airtight designs using controlled ventilation systems to retain the heat energy. Mechanical Ventilation Heat Recovery (MVHR) units help to maintain air circulation between the building and the outdoors, while not compromising energy efficiency. A significant challenge to implementation and continuous use of these devices is the noise emission. Noise from MVHRs can cause indoor noise levels to exceed the recommended levels, with respect to the Noise Rating (NR) guidelines. The noise has a frequency content below 500 Hz, which many conventional sound absorbers struggle to attenuate without large space requirements. This research develops a compact silencer suitable for a domestic MVHR unit with a large duct diameter. The design consists of stacked Helmholtz resonators with embedded necks and relatively large cavity volumes. The proposed design achieved >8dB transmission loss for frequencies 250 Hz, 300 Hz and 350 Hz. These were compared with data from an MVHR and the NR guideline and was found to reduce the MVHR SPL to below NR35 for the octave bands 250 Hz and 500 Hz.

Keywords: Transmission Loss, MVHR, Helmholtz Resonators, 3D Printing

1. INTRODUCTION

Mechanical Ventilation and Heat Recovery systems (MVHR) are devices that ventilate rooms and buildings, while recovering heat energy from outgoing air. In modern homes that are highly insulated and airtight, this technology is essential to maintain good indoor air quality [1]. The main challenge to further adoption and continuous use of MVHR are the noise emissions from the fans. It has been reported that a significant portion of MVHR users either rarely or never use their systems and cite noise as the cause [2, 3]. The noise emissions typically exist below 500 Hz [2, 4]. Some manufacturers provide noise emission data on their systems, for example the unit considered in this work is the Air Cycle 1.3+, which has a reported sound power level of 45.4 dB and 46.8 dB at 250 Hz and 500 Hz respectively [5]. Data were taken at the maximum possible flow rate for the unit. With regards to guidelines, the Noise Rating standard for dwellings should be within NR35. Other guidelines suggest a lower SPL for dwellings [6]. In residential buildings, research indicates that due to relatively lower background noise, noise from ventilation systems is more noticeable [2, 3].

There are many ways to address the noise emissions of MVHRs, either at the source (fan blades, DC motor) or applying an acoustic treatment downstream from the source. Suitable designs from literature used to achieve low frequency attenuation in ventilated systems include space-coiled channels [7], singular or double Helmholtz resonators [8, 9] and adaptive resonators [10]. MVHRs available on the market typically have duct diameters >5 inches (127 mm) [5], which is much larger than the experiment setups seen in the cited works. Further more, while research has been done to study the effects of flow on transmission loss [11], no work has been found on application in real MVHR systems.

In this paper, an acoustic treatment for a large circular duct is proposed. The design utilizes Helmholtz resonators with embedded necks, and can be manufactured with a desktop 3D printer at a low cost. The objective is to achieve high attenuate at specific frequencies with minimal resources. Hence, a basic analytical approach is taken for the design rather than a detailed FEM combined with an optimisation scheme.

2. THEORY

The goal of the design is to attenuate the tonal noise of the fan at specified frequencies, which are characteristic of the blade pass frequency. The resonance frequency of a Helmholtz resonator is expressed as:

$$f_0 = \frac{c_0}{2\pi}\sqrt{\frac{S_n}{V(l_n+\delta)}} \tag{1}$$

Where c_0 is the speed of sound in air, S_n is the area of the neck cross section, V is the volume of the cavity, l_n is the neck length and δ is the end correction length. The many different formulations of the δ exist in the literature, mainly for resonators with cylindrical cavities. For a cylindrical neck and cuboid cavity, Catapane *et al* derived an expression for the end correction length [12]. Given in Eq 2 , where $\xi = 2r_n/d_c$, d_c is the cavity width.

$$\delta = (-5.98\xi^3 + 14.8\xi^2 - 9.75\xi + 3.60)l_n\xi \tag{2}$$

Solving Eq 1 for a resonance at 300 Hz and a cavity volume of 125000 mm^3 yields different combinations of r_n and l_n (neck radius and length). The chosen values are list in Table 1. Although there are more sophisticated methods to maximize the magnitude and bandwidth of the transmission loss, the low cost of this design approach may be more relevant for industrial settings. The drawback to this analytical approach is that while target frequencies can be easily attained there, the expected transmission loss is not estimated. A parametric investigation of 3D printed structures allows for empirical refinement of the design at low cost.

3. EXPERIMENTAL SETUP

The transmission loss experiment setup is shown in Fig 1 in accordance with ASTM E2611-09, using the two-load method. The loudspeaker has a frequency range of 10 Hz - 1400 Hz, and is enclosed in a foam filled box. Four GRAS 40PL-10 microphones were used, they have a frequency range of 50 Hz - 5000 Hz (±1.5dB). The microphones were connected to a National Instruments USB-4431 analogue I/O device.

The setup is designed for large samples with an inner radius of 63.5 mm, with mounting screws 106 mm from the centre. This leaves 42.5 mm of width for the acoustic treatment. For every sample and configuration, the tests were performed 3 times to test the repeatability of the results. The frequency resolution of the calculated spectra

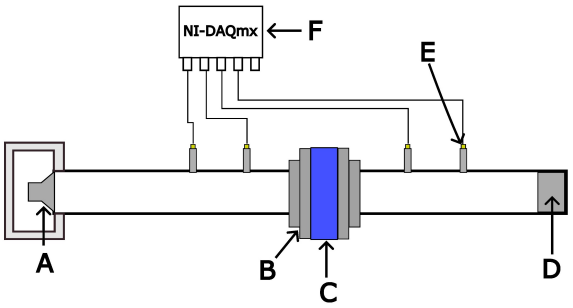

Figure 1. Experiment Setup. (A) Enclosed Loudspeaker, (B) Gaskets, (C) Sample, (D) Anechoic Termination, (E) Microphones, (F) Data Acquisition System

was 2.4 Hz, with a sampling rate of 40 kHz. The measurement duration was 30 seconds, then the termination is changed, and another 30 second measurement was taken. Each of the resonator rings described in Section 4 were tested alone before being stacked together for broadband attenuation.

4. DESIGN AND MANUFACTURING

The goal of the resonator is to attenuate transmission noise while being compact and sub wavelength. Since the operating frequencies are between 250 Hz - 350 Hz, the sub-wavelength constraint is easily satisfied. For compactness, the overall thickness was arbitrarily constrained to 40 mm which was considered representative of a real system. Eq 1 was solved for the specified frequencies, returning a set of radius and length values, given in Table 1. The length L is determined by the volume of the embedded neck in Eq 3, where W is the width of the resonator, S is the arc length and V_n is the volume of the neck, with the wall included. $R_1 = 63.5$mm and $R_2 = 100$mm

$$L = \frac{V_c + V_n}{WS} \tag{3}$$

The Helmholtz Resonator rings were manufactured with a Prusa i3 MK3 printer, using PLA filament and a 0.4 mm nozzle. The printer settings were as follows: 0.2 mm layer height, 205°C and 65°C nozzle and bed temperature respectively. The lower nozzle temperature helped to eliminate stringing while maintaining layer adhesion.

The resonators are asymmetric, this deviation from the model, where the neck and cavity are assumed to be

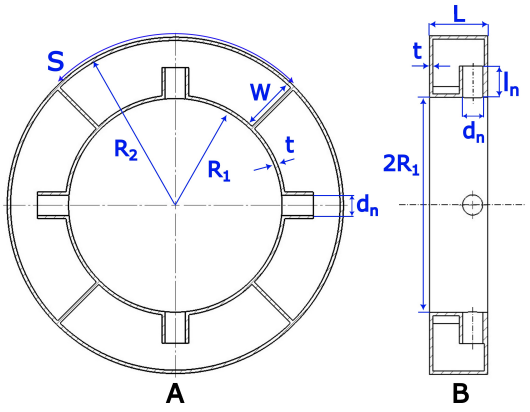

Figure 2. Cross section view of the 300 Hz ring, with dimensions provided in Table 1.

Frequency (Hz)	r_n	l_n	W	L	t
250	5.5	25.5	32.5	36.5	2
300	6	18.8	32.5	35	2
350	5.5	14	32.5	31.5	2

Table 1. Dimensions of resonator rings, dimensions are all in millimeters

concentric, was made to improve the manufacturability. In this configuration, there is no overhang underneath the neck (see Fig 2B), hence no internal supports are required. From the literature, the effect of the asymmetry on the transmission loss should be negligible [11]. The print time for each ring was 14h 30m, using 194 g of PLA, with an estimated cost of €3.8 per unit (estimated cost of PLA is €20/kg).

5. RESULTS AND DISCUSSION

Figure 3 shows the transmission loss of individual resonator rings, and the broadband attenuation when they are all stacked together in the transmission loss tube. The designs achieve transmission loss values at the target frequencies between 8dB and 11 dB. The transmission loss of the stacked configuration provides an increased transmission loss at 358 Hz, from 11 dB to 13 dB. The largest deviation between the calculated and measured resonance frequency is 4%, which is acceptable.

Applying this design to a real MVHR system will be the subject of future work. However the expected performance can be evaluated with a known MVHR and a comparison with the Noise Rating Curves. Provided that the tonal noise emission of the fan aligns with the chosen frequency values this design provides approximately 9 dB attenuation in each of the 250 Hz and 500 Hz octave bands. Figure 4 shows the curve for NR25 and NR35. The data available for the Air Cycle 1.3+ is used to calculate the total sound pressure level, direct plus reverberant, in a domestic bedroom. Reverberation time measurements were made in a domestic bedroom to accurately estimate the sound field in the room for a MVHR unit installed in one wall far from a corner or ceiling. It shows that without acoustic treatment, the SPL in the room would be unacceptable for a private dwelling. The noise reduction from the resonator ring is applied, using the experimentally determined values of 9 dB at 250 Hz and 500 Hz. The SPL reduces from 42 dB to 33 dB at 250 Hz. For 500 Hz, the SPL reduces from 44 dB to 35 dB. This means that the MVHR unit will not exceed the NR35 curve for the bedroom which may be deemed acceptable. The figure also shows that for further improvements additional attenuation will be required for the 1 kHz octave band. It is suggested that acoustic foam could be applied in combination with the designed resonator to provide this attenuation.

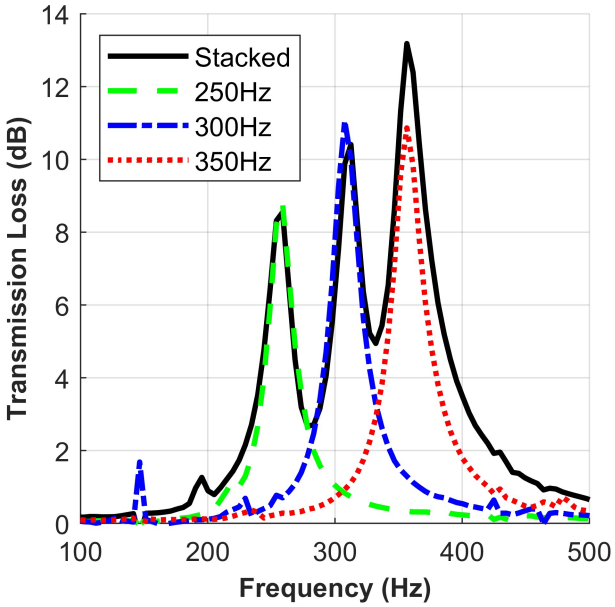

Figure 3. Broadband and tonal transmission loss with 3 resonator rings stacked together. Dashed lines represent individual performance

6. CONCLUSION

In this work, a 3D printed silencer for a circular duct MVHR was designed and tested. The design approach used basic analytical expressions for a Helmholtz resonator, to define the geometries. Three rings with four Helmholtz resonators with embedded necks were manufactured and tested for transmission loss in a 127 mm tube. The individual rings successfully achieved tonal transmission loss ranging from 8 to 13 dB. The maximum error between the target and measured resonance frequency was 4%, which is acceptable for this application. Applying the noise reduction to a MVHR unit in a domestic bedroom room would reduce the SPL below the NR35 curve, which is deemed acceptable. Future work will include applying the design to a real MVHR, by attenuating the measured noise from the system.

EVALUATION OF ACOUSTIC PERFORMANCE IN SMART VENTILATED WINDOWS WITH INTEGRATED HEAT STORAGE

Andrea Gerbotto[1*] **Louena Shtrepi**[1] **Fabio Favoino**[1] **Arianna Astolfi**[1]
[1] Department of Energy, Politecnico di Torino, Italy

ABSTRACT

Windows are essential façade components that balance multiple functions, including daylighting, natural ventilation, and thermal regulation. However, conventional windows often suffer from significant energy losses and inadequate air exchange, even with regular ventilation. To address these challenges, the iclimabuilt project has developed a smart, ventilated window that integrates advanced technologies, including PCM (phase-change material) heat storage, triple glazing with air-filled chambers for enhanced thermal insulation, and 3D-printed components for noise reduction and air purification. These innovations minimise energy losses, improve thermal management, and promote occupant health and well-being.

This study focuses on evaluating the acoustic performance of the three operational modes of the fans integrated into the window of a Living Lab environment. Noise measurements were conducted in accordance with EN ISO 16032:24, both with and without an acoustic filter installed in the PCM box and air filtration unit. Data were collected from three microphone positions: a corner and two reverberant field points. The analysis reveals that the noise levels generated by the fans are in the 35–45 dB range, exceeding standard limits. Moreover, the findings highlight the need to further optimise noise control strategies in smart window design while maintaining their energy efficiency and indoor air quality benefits.

1. INTRODUCTION

The integrated assessment of acoustic conditions, ventilation, and overheating prevention is essential to ensure that residential developments provide a balanced indoor environmental quality (IEQ) [1]. Neglecting any of these aspects may lead to housing that fails to meet occupants' overall comfort and well-being.

Windows and other ventilation openings constitute the primary interfaces between the indoor and outdoor environments and have been the subject of increasing research and development [2]. However, this connection poses a significant challenge for natural ventilation, as it creates a trade-off between fresh air intake and external noise intrusion. This conflict often prevents naturally ventilated buildings from complying with background noise limits established by acoustic standards, building regulations, and rating protocols. In response, extensive research has focused on developing solutions that enable ventilation without compromising façade sound insulation [3, 4].

Over recent decades, double-glazed windows have been enhanced to provide excellent sound insulation when closed. However, they restrict natural ventilation, increasing reliance on mechanical ventilation and leading to higher energy consumption. To address this issue, windows with integrated mechanical ventilation have been introduced. These systems allow for a reduced opening area without diminishing the air exchange rate, significantly improving acoustic comfort and energy efficiency [5]. Despite their advantages, integrated mechanical ventilation systems introduce a continuous noise source within the room. This internal noise must be accurately measured and, if necessary, mitigated to ensure overall acoustic comfort.

2. METHODOLOGY

2.1 Test case

The Test Case is a smart, ventilated heat-harvesting window that consists of a ventilated window with additional functions supporting ventilation, thermal management, and improved air quality in indoor spaces, which sound reduction index has been measured in [6].

Figure 1. The Test Case; PCM-Air exchanger (blue); outer bottom vent (green); Air Filtration Unit (red)

The smart window is composed of the following main sub-components (figure 1):

- Triple-glazed window unit with a ventilated exterior chamber, Air-filled interior chamber, NIR absorbing layer, and omniphobic coating;
- Upper box – PCM-Air exchanger unit which hosts:
  - One axial fans per unit;
  - A stack of five plates filled with Phase Change Material;
  - One 3D printed acoustic absorbers, each consisted of one casing (H130 mm x W130 mm x T100 mm) with nine panels (approx. H120 mm x W120 mm x T3 mm);
- Lower box – Indoor Air Filtration Unit which includes:
  - One 3D printed CO_2 absorber consisted of one casing (H130 mm x W130 mm x T425 mm) with twenty five electro-spun membranes;
  - One 3D printed acoustic absorbers, each consisted of one casing (H130 mm x W130 mm x T100 mm) with nine panels (approx. H120 mm x W120 mm x T3 mm);
  - Ventilator for air circulation.

2.2 Operational modes

The outer cavity of the TGU can be activated using electrical fans, with an airflow path from the outside (with an outer bottom vent integrated into the framing system) to the inside (with an inner top vent integrated into the framing system) to provide the indoor environment with primary ventilation air at a temperature level closer to the indoor required temperature, in heating dominated conditions (Supply Air, SA, operation mode).

In cooling dominated conditions instead the TGU outer cavity ventilation is used with an airflow path from the outside to the outside (with an outer top vent integrated into the framing system), to reduce the g-value (total solar energy transmittance) of the TGU by removing unwanted solar gains absorbed within the glass layers (Outdoor Air Curtain, OAC, operation mode), while a fan-assisted vents provide primary ventilation bypass within the top part of the framing system.

In order to reduce the differences between the air temperature entering the room through the glazing ventilation and the thermal comfort conditions inside the building, the air from the glazing ventilation is conveyed to a PCM to

Air heat exchanger before being delivered to the indoor environment.

Finally, the TGU can also be used as a conventional TGU, in conditions in which solar radiation is not very high and in which ventilation is not needed, by switching off the fans and closing all the vents included in the system (Thermal Buffer, TB, operation mode).

2.2.1 *Supply Air throught the window*

To assess the noise generated by the fan in the bottom box, the system was operated in Supply Air window mode. In this configuration, external forced air enters through the bottom outdoor inlet, flows through the window cavity, and is directed to the PCM-Air heat exchanger by the fan located in the bottom box.

2.2.2 *Supply Air direct*

To evaluate the noise produced by the fan in the PCM box, the system was set to Supply Air direct mode. In this setup, external forced air is drawn in through the top outdoor inlet and directly supplied to the PCM-Air heat exchanger by the fan installed in the PCM box.

In both configurations (figure 2), the fan speed, which can be continuously adjusted with a potentiometer from 0 to 100, was set to either 30% or 100%.

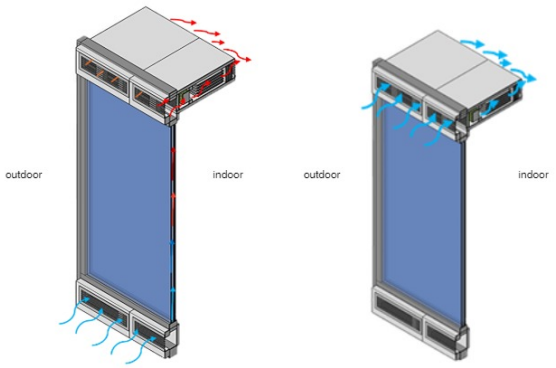

Figure 2. The two considered operational modes

2.2.3 *Air filtration*

For improving indoor air quality and wellbeing, the Test Case features CO_2 capturing filters. The 3D printed component design consists of a Light-Weight PLA-based casing with a customisable number of incisions to integrate

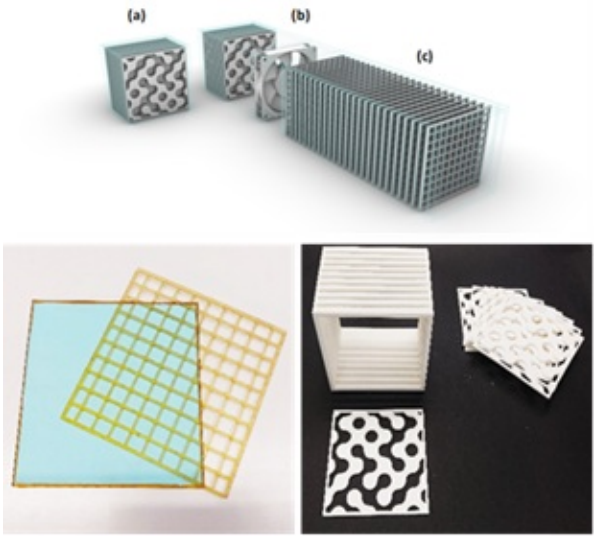

Figure 3. Design of 3D printed air-filtration unit and collateral acoustic components (top); functional panel with CO_2 absorptive properties made of (a) a High HDT photocurable resin-based frame and (b) an electro-spun MOFs/PAN polymer membrane (bottom-left); functional component with acoustic properties based on thermoplastic with foaming agents (bottom-right)

resin-based frames with MOFs/PAN layers of electro-spun CO2 Capturing Membranes and a fan for air circulation. Additionally, an acoustic absorber was integrated in the assembly to reduce the noise of the fan (figure 3).

For all the configurations considered, the air flow rates generated by the fans were measured (table 1).

Table 1. Volumetric flow measurements

Mode	Velocity [%]	Q_{max} $[m^3/h]$
SA_{window}	30	12.68
SA_{window}	100	29.23
SA_{direct}	30	30.53
SA_{direct}	100	35.70
$Air filtration$	100	4.45

Figure 4. Fixed microphone positions

2.3 Test equipment and method

The sound pressure level, L_i, from the service equipment is measured in a fixed position i as the linear (Z weighted) spectrum in one-third-octave-bands during the operation time of the service equipment under test.

For each measurement it is determined the equivalent continuous sound pressure level, $L_{Zeq,i}$, over a period of $t = 30$ seconds. The sound pressure levels taken in the three positions are then used to calculate the average sound pressure levels L_{Aeq} in one-third-octave bands. These average sound pressure levels are then corrected for background noise, measured over $t = 30$ seconds in the same positions before and after the operation time.

The background noise-corrected average sound pressure levels $L_{Aeq,corr}$ in one-third-octave bands are then used to calculate the standardized average sound pressure levels $L_{Aeq,corr,nT}$ to a reference reverberation time as:

$$L_{corr,nT} = L_{corr} - 10\log\left(\frac{T}{T_0}\right) \quad (1)$$

where:

- T is the measured reverberation time in seconds;
- T_0 is the reference reverberation time 0.5 seconds.

2.3.1 Filter

The acoustic performance is evaluated by measuring the insertion loss (IL), calculated by the difference between the sound pressure level (SPL) in the room with and without the filter applied. Therefore, the IL of the filter is calculated as

$$IL_{filter} = SPL_{wout} - SPL_w \quad (2)$$

where:

- SPL_{wout} is the A-weighted SPL measured without the filter, in dB;
- SPL_w is the A-weighted SPL measured with the filter, in dB.

2.4 Measurements

The Test Case was installed on the south-oriented vertical façade in the Living Lab at Politecnico di Torino (Torino, Italy), a single office room of approximately 10 m^2 floor area.

Three different conditions of the test room have been defined, and, for each condition, three measurement positions, one in a selected corner of the room and two positions in the reverberant sound field (figure 4), have been used to characterize the room acoustically, according to EN ISO 16032:2024. For each measurement position, three repetitions were performed. Figure 5 and figure 6 present the equivalent sound pressure levels (L_{Aeq}) of the background noise and the L_{Aeq} for fan speeds of 100% and 30% for the two operational SA modes (through the window and direct), while figure 7 presents that of air filtration box. These curves have been adjusted for background noise and the room's reverberation time (figure 8), measured using the impulse response method in the 100 Hz to 5 kHz one-third-octave bands.

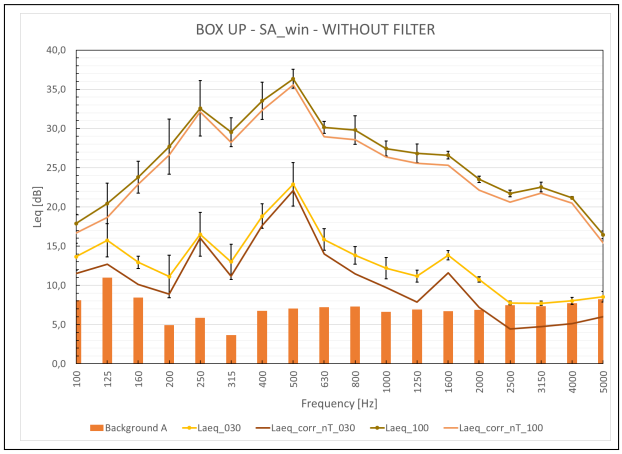

Figure 5. Supply Air window

3. RESULTS AND DISCUSSION

It can be observed that the background noise remains relatively low (< 15 dB for each third octave band) and has a

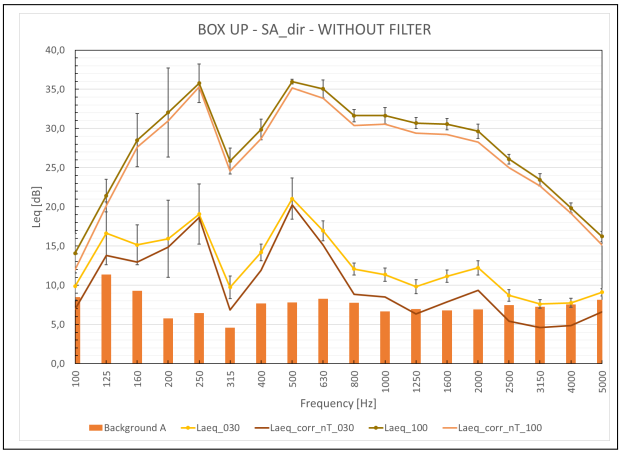

Figure 6. Supply Air direct

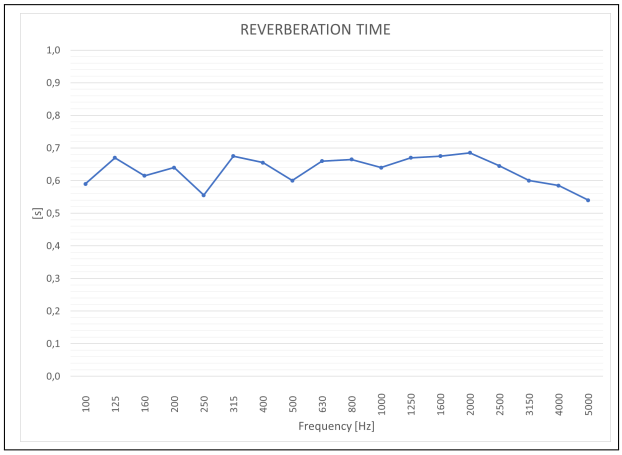

Figure 8. Reverberation Time

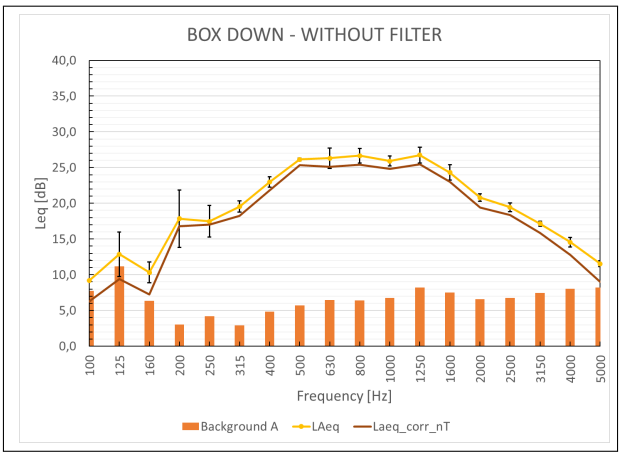

Figure 7. Air filtration

Table 2. Measurements results

Mode	$L_{A,back}$	L_{Aeq}	$L_{Aeq,nT}$
SA_{win} 100 %	20.8 dB	41.6 dB	40.7 dB
SA_{win} 30 %	20.8 dB	27.9 dB	26.3 dB
SA_{dir} 100 %	21.1 dB	43.4 dB	42.4 dB
SA_{dir} 30 %	21.1 dB	27.3 dB	25.7 dB
$Airfil$ 100 %	20.6 dB	35.1 dB	33.9 dB

lot of influence in the low-speed condition. The correction for the background noise and the reverberation time standardisation minimally impacts the results for the condition with the fan speed at 100%, this leads to a limited difference between the two curves, L_{Aeq} and $L_{Aeq,corr,nT}$. Thus the test room could be considered appropriate for evaluating the noise produced only by the fans and the effects of the acoustic filters.

Both the fan in the lower box and the one in the PCM box have two peaks at 250 Hz and 500 Hz, which amplify as the speed increases and which are responsible for exceeding the 30 dB(A) threshold indicated in literature as critical for living spaces, particularly bedrooms [7]. The path through the window in the SA_{win} mode filtered the frequencies above 630 Hz and below the 250 Hz and amplify the range between 315 Hz and 500 Hz, probably due to a resonance in the PCM box, also found in the measurement of the sound reduction index of the test case in [6].

The tested filter, designed as a series of panels with staggered incisions to hinder the transmission of sound with labyrinthine channels to increase the distance sound must travel, enhancing phase cancellation, reveals a frequency-dependent behavior, indicative of a filter optimised for mid-to-high frequency performance. At mid and low frequencies (100–1250 Hz), the insertion loss fluctuates between -1.6 dB and +1.4 dB, with a minimum observed at 1000 Hz. These results suggest limited attenuation capacity in the lower frequency range, likely due to the relatively long wavelengths and reduced interaction with the filter geometry. Above 1250 Hz, the filter demonstrates more attenuation, reaching up to +2.0 dB at 5000 Hz. This indicates enhanced interaction with shorter wavelengths.

Overall, the filter exhibits modest insertion loss across the full spectrum and needs some improvements, as try-

ing to implement helmholtz resonators or using layered impedance transitions to improve energy dissipation.

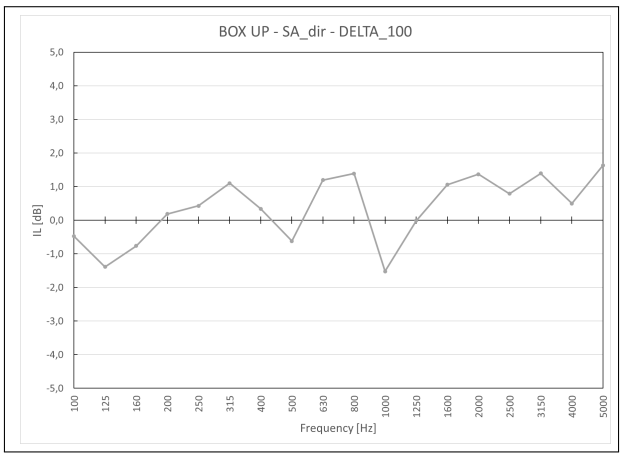

Figure 9. Insertion Loss

4. CONCLUSION

This study presented an experimental evaluation of the acoustic performance of a smart, ventilated window system with integrated phase-change material (PCM) and air purification modules. The results demonstrated that the noise levels generated by the fans in all operational modes exceed recommended indoor background noise limits for residential or office environments, particularly at full-speed operation. While the integrated acoustic treatments provided measurable insertion losses, their effectiveness was not sufficient to reduce fan noise to acceptable levels.

The findings highlight a key challenge in balancing acoustic comfort with advanced functionalities such as heat recovery and indoor air quality control. Future developments should focus on optimising fan design and speed control, improving the acoustic performance of integrated absorptive materials. A holistic design approach is essential to ensure that smart façade components can meet the increasingly stringent performance criteria for indoor environmental quality in low-energy buildings.

5. ACKNOWLEDGMENTS

The experimental activities presented in this paper were carried out as part of the H2020 project "iclimabuilt—Functional and advanced insulating and energy harvesting/storage materials across climate adaptive building envelopes" (Grant Agreement no. 952886). We gratefully acknowledge the support Anna Karatza and Vaia Tsiokou (BIOG3D, Greece) provided for generously sharing detailed design information, which was instrumental in developing this study, Asmaa Ali (Rubitherm GmbH, Germany) and Gianni Cassera (BGTec Sp. z o.o., Poland) for the preparation of the mock-ups.

THE TEACHING OF ACOUSTICS AT THE HIGHER TECHNICAL SCHOOL OF ARCHITECTURE OF MADRID IN 1855

Alexander Díaz-Chyla[1*]
[1] Grupo de Investigación de Acústica Arquitectónica, Universidad Politécnica de Madrid, Spain

ABSTRACT

The Madrid "Escuela Especial Preparatoria de Arquitectura" was created in 1844, with a holistic educational model, which required the reinforcement of technical training to achieve an appropriate balance with the artistic part of the curriculum. In 1848, with the creation of the Preparatory School for Civil Engineers, Mining Engineers and Architects, the scientific-technical training for architectural studies was reinforced. In 1855 a new curriculum was approved for the Architecture degree program, which among its novelties introduced the subject: Notions of acoustics, optics and hygiene applied to architecture. This communication shows the program of this subject, 170 years after the beginning of teaching acoustics in the Higher Technical School of Architecture of Madrid.

Keywords: *History, Architecture, Education in acoustics, Teaching.*

1. INTRODUCTION

The Higher Technical School of Architecture of Madrid is the school of architecture of the Universidad Politécnica de Madrid (Spain) and was created in 1844 under the name of Escuela Especial de Arquitectura de Madrid, being the oldest school of architecture in Spain. Its origins date back to the 18th century.

In Spain, the Royal Academy of the Three Noble Arts (painting, sculpture and architecture) was founded in 1744. In 1752, the Royal Academy of Fine Arts of San Fernando was created. It organized the regulated teaching of architectural studies in that year and its statutes were approved in 1757. Since then, it has been responsible for awarding the title of architect, replacing the old system of guilds [1], [2], [3], [4], [5].

Given the evidence of the lack of technical knowledge of architecture students and their disadvantage compared to engineers, in 1844 the "Escuela Especial Preparatoria de Arquitectura" was created because of the transformation of the teachings of the Royal Academy of Fine Arts of San Fernando, which in 1848 was established as an independent institution understood as a School for the Application of Arts. This Preparatory School was created for the special studies of Architects, Civil Engineers and Mining Engineers, as they all shared a similar scientific background. The duration of studies at the Preparatory School was two years and it was abolished in 1855.

The architecture degree lasted four years and previously required an entrance exam and two years at the Preparatory School. With the Moyano Law of Public Instruction (1857), the School of Architecture came under the university regime as the Higher School of Architecture, dependent on the Central University (currently the Complutense University), and became responsible for awarding the official title of architect.

2. THE NEEDS OF ARCHITECTURE AND THEORETICAL ACOUSTICS IN THE EARLY 19TH CENTURY

Before the 20th century and the development of modern acoustics, there was very little connection between the theoretical knowledge of acoustics and the needs of architects in the design of venues [6]. Architects at that time could not rely on scientific support for their designs.

The evolution of venues design was slow and gradual, with small architectural milestones throughout history. The Roman architect Vitruvius Polion, author of *De Arquitectura* [7], exhaustively described aspects of the design of theatres and their acoustics, one of his aims being to ensure good vision and hearing for the spectators. The architects of the Renaissance and Baroque periods would place the actors on stages elevated above the lower plane of the audience. In 1580 the first permanent theatre designed by Andrea Palladio, the Teatro Olimpico, was built in Vicenza. It is a covered theatre, the stage in the configuration of the ancient Roman theatres and the audience area was in the shape of a semi-ellipse. In 1628 the Farnese theatre was inaugurated in Parma with a U-shaped audience area. The first Italian opera house in the shape of a horseshoe with overlapping boxes on five levels was built in Venice in 1654, initiating a typology that remained unchanged for almost two centuries, being the most common in the design of theatres in the 18th and 19th centuries.

In the 18th century, musical events took place in different venues, such as palaces, masonic lodges, public gardens and ballrooms. Initial venues, sponsored by royalty or nobility were small. As the acoustic power level of the new musical instruments increased and in response to the demand of larger audiences, concert halls dimensions increased. The new need for larger venues in view of the interest in paid music meant that the audience had to be able to see and hear. During the 18th century, the Italian theatrical model became generalized with different floorplan geometries: elliptical, circular, bell-shaped. In central and northern Europe, concert halls evolved from churches and the rectangular floor plans of ballrooms.

During this period, architects continued designing spaces for music, and the first treatises on the topic appeared, specifying technical solutions that had previously worked and were repeated by designers. Two architects who influenced theatre architecture in their countries were the Frenchman Pierre Patte who in 1782 wrote the book Essai sur l'Architecture théatrale [8], and the Englishman George Saunders who in 1790 wrote A Treatise on Theatres, [9]. In 1880, the architect Jean Louis Charles Garnier, designer of the Paris Opera House, [10] expressed his disappointment at not finding any help from the theoretical knowledge of acoustics.

Today, in the subjective ranking of the acoustic quality of opera houses and auditoriums carried out by conductors and acousticians, many of the considered as best halls were built before any scientific knowledge of the behavior of sound in a venue was applied, such as: Teatro La Scala, Milan, 1778; Teatro San Carlo, Naples, 1737; Grosser Musikvereinsaal, Vienna, 1870; Opera Garnier, Paris, 1875; Concertgebouw, Amsterdam,1888; Carnegie Hall, N York, 1891; Teatro Colón, Buenos Aires, 1908, etc.

Throughout the 19th century, the study of acoustics as a science and its dissemination through books and technical journals began. In 1862 Hermann Helmholtz [11] wrote a treaty on acoustics and hearing, and in 1877 Lord Rayleigh (John William Strutt) [12] published The Theory of Sound, considered the beginning of modern acoustic theory. They established acoustics as a science where observation, experimentation and a mathematical basis led to significant advances. Room acoustics as a scientific discipline can be considered to begin with the work of W.C. Sabine at Harvard University at the end of the 19th century with his experimental work on reverberation time in rooms [6].

3. THE 1855 ACADEMIC CURRICULUM

After becoming independent from the Royal Academy of Fine Arts of San Fernando, the new "Escuela Especial Preparatoria de Arquitectura" adopted a holistic educational model, where it was necessary to reinforce the technical background in order to achieve an appropriate balance with the artistic side. With a model similar to that followed in France, the Preparatory School for Civil Engineers, Mining Engineers and Architects was created in 1848, which improved the scientific-technical training for architectural studies with a two-year plan. Table 1 shows the subjects taken at the Preparatory School. Table 2 shows the subjects of the academic curriculum of the Civil Engineering and Architecture courses.

Table 1. Preparatory School subjects

	Subjects
First Year	- Differential and integral calculus. - Geometry. - Graphical constructions. - Physics and chemistry. - Landscape drawing. - Architectural drawing.
Second Year	- Rational mechanics - Applications of descriptive geometry. - Graphical constructions. - Topography and Geodesy. - Topographical drawing. - Architectural drawing.

Table 2. Comparison between the academic curriculum of the degrees of Civil Engineering (1849) and Architecture (1850).

Civil Engineering	Architecture
First year	
Applied mechanics	Industrial mechanics
Stereotomy	Mineralogy and mineral chemistry
Mineralogy	Extension of stereotomy
Graphical and practical exercises	Graphic exercises and architectural drawing
Second year	
Constructions, part one	General construction theory
Machines	Road construction
Geology	Practical resolution of construction problems
Drawing and practice	Architectural drafting
Third year	
Constructions, part two	General theory of art and decoration.
Civil architecture	Use of water.
Administrative law, Part I	Analysis of ancient and modern buildings.
Drawing and practice	Composition exercises.
Fourth year	
Constructions, Part III	Legal architecture
Water supply	Art practice
Administrative law, Part II	Composition
Drawing and practice	Composition exercises

The disappearance of the Preparatory School in 1855 brought another reorganization of teaching at the School of Architecture. In the same year, a new curriculum was approved in which the architecture degree became a six-year course. Among its changes, it introduced the subject: Notions of acoustics, optics and hygiene applied to architecture. In this subject, the teaching of these three subjects, especially hygiene, began. Table 3 shows the subjects of the 1855 curriculum at the "Escuela Especial Preparatoria de Arquitectura".

In order to gain access to architecture studies, students were required to have a certificate of having successfully passed physics and chemistry in an official center or to take an exam in these subjects at the School of Architecture. They then had to pass entrance exams. Classes were held for six hours a day from 15 September to 30 June.

Table 3. 1855 academic curriculum, Escuela Especial Preparatoria de Arquitectura

	Subjects
First Year	- Integral and differential calculus - Topography - Descriptive geometry - Topographical drawing - Architectural drawing
Second Year	- Rational mechanics. - Industrial mechanics. Part I. - Applications of descriptive geometry to shadows - Gnomonic perspective - Mineralogy - Chemistry applied to architectural uses -Analysis, manipulation and manufacture of materials - Architectural drawing
Third year	- Industrial mechanics Part II: Hydraulics; Mechanics applied to construction - Stereotomy, wood and iron; graphic works of this subject - Architectural drawing
Fourth year	- Civil construction - Hydraulics - Staking out and uprights - Acoustics, optics and hygiene applied to architecture - Theory of art and composition - Elements of composition and 3rd order projects
Fifth year	- History of architecture -Analysis of ancient and modern buildings - Composition
Sixth year	- Legal aspects - Composition

4. ACOUSTICS, OPTICS AND HYGIENE APPLIED TO ARCHITECTURE

The following is the curriculum of the subject which was a pioneer in the teaching of acoustics at Spanish universities. The course consisted of sixteen lessons divided into two blocks: Block I (lessons I to XII) on acoustics and optics and Block II (lessons XII to XVI) on hygiene and health applied to civil constructions. The acoustics and optics program follows the book written in 1848 by Theodore Lachèz [13], a 19th-century French architect, known for his contributions in these fields. His influence extended to the educational field, where he wrote about the teaching of architecture and evaluated institutions such as the *École Impériale et Spéciale des Beaux-Arts* and the *École Centrale d'Architecture* [14].

Lesson I	Laws of acoustics and general considerations on some of the phenomena to which it refers.
-Acoustics and music -Sound -Propagation, reflections and modifications -The voice -Air, vehicle and instrument of sound -Echoes, resonance, sonority	
Lesson II	Optics, light and distance
-The intensity of light is inversely proportional to the square of the distance	
Lesson III	Classification of theatres
-Theatres and amphitheaters among the ancients and in modern times -Needs they have to satisfy -Differences which characterize them -Their special purposes -Wise acoustic arrangements -Sound vessels -Velarium	
Lesson IV	Modern Theatres and amphitheaters
-Different purposes -Characteristic differences with ancient monuments	
Lesson V	Defects of theatres and amphitheaters, resulting from the non-observance of the laws of acoustics
-Local or general resonances -Echoes -Suppression of sounds or their destroyed intensity -Denomination of vaults, ceilings, niches, semicircles, coffers -Effects of wooden stands, carpets and upholstery -Harmful air volumes in amphitheaters, auditoriums and concert halls	
Lesson VI	Defects resulting from the non-observance of the best optical considerations
-Light poorly distributed and hurting the eyesight -Absorbed by dark colored walls -Chandeliers, steps and handrails poorly arranged -Inconvenience of direct light coming from the south	
Lesson VII	Favorable acoustic conditions for theatres and amphitheaters according to their use
-Speech and chant -Conditions of their sound propagation -Triangular and parabolic amphitheaters. -Particular inclination of the tiers according to a curve -Harmful vibrations of the tiers -Desired modifications in performance halls -Pulpits -Concert halls	
Lesson VIII	Conditions of optics, light and distance
-Conditions of optics, light and distance -Light distribution -Rooms for scenic effects and meeting rooms -Historical theatres -Congress of Deputies	
Lesson IX	Investigation for the most suitable shape for amphitheaters.
-Circle and half circle; Segment or quarter circle -Point of view or place of the scene -Enclosures proportional to the number of spectators -Special circumstances for amphitheaters -Respective position of audience for viewing objects	
Lesson X	Classification of amphitheaters and public assembly halls into five categories
-Rooms satisfying optical conditions -Rooms satisfying acoustic conditions -Mixed music halls for simultaneous seeing and hearing -Demonstrations and experiments	
Lesson XI	Some observations on the inclination of the stands used today in existing halls and amphitheaters

-Poorly used space -Arbitrary inclination of the tiers. -Parallel visual rays instead of rays converging towards the point of view	
Lesson XII	Research and determination of the curve, according to which the benches or floor of public halls and amphitheaters should be laid
-Point of view or proscenium -Average height of the audience -Abscissae and ordinates of the stands -Width and height of seats -Variable vertical distance between successive rows of listeners	

5. CONCLUSIONS

The political and social changes throughout the convulsive 19th century in Spain had an influence on education and, in particular, on the teaching of architecture. It was necessary to go with its *zeitgeist* in terms of progress, social welfare, economic development and, with criteria of technological development that were more pragmatic than artistic. From 1844 to the present day there have been at least 15 academic curriculums until the most recent one in 2010, adapted to the European Higher Education Plan, and an attempt has been made to seek a balance between artistic and scientific-technical subjects.

The teaching of some notions of acoustics at the Higher Technical School of Architecture of Madrid has been changing according to the different study plans; it has never been taught as an independent subject.

For example: it was taught in the 1855 and 1858 curriculum, but then eliminated in the 1864, 1885 and 1932 ones. In the 1875 and 1896 curriculum, it was included under the subject Applications of the physical-natural sciences to Architecture (together with concepts such as ventilation, heating and building services). In 1914 it was offered in the subject of optics and acoustics, as well as in the 1956 curriculum for electrical engineering and acoustics. It was in 1957 when the subject of Acoustics and building services was created, evolving in the curriculum of 1964, 1975 and 1996 within the subject of Building Physics, where it ended up having a marginal presence. In the current plan, curriculum 2010, a series of fundamentals classes are given within the subjects of Physics and Environmental Conditioning and Habitability, and it's also offered as an elective subject, Experimental Workshop in Architectural Acoustics, with 6 ECTS credits.

At present, scientific-technical subjects in architectural studies in Spain continue to represent an important percentage of the subjects on the academic curriculum (they have a greater weight than in other European countries), as the Spanish architect assumes among his competencies some aspects of civil engineering in relation to buildings, which must be preserved as opposed to the figure of an architect who is merely a designer.

In Spain, the architect has a regulated qualification with professional attributions and the curriculum of this qualification have been adapted to the regulatory body of the country. For this reason, some subjects have been modified over the years and new technical subjects have been introduced according to the new requirements of urban planning, construction and building services. Spanish legislation establishes that buildings, including their services, must meet basic safety (structural, fire, usability and accessibility) and habitability (hygiene, health and environmental protection; noise protection; energy saving and thermal insulation) requirements, with the responsibility lying on the architect.

ACOUSTICS IN MUSIC EDUCATION: EMPOWERING MUSIC TEACHERS AS STEM AMBASSADORS

Montserrat Pàmies-Vilà*
Department of Music Acoustics – Wiener Klangstil
mdw – University of Music and Performing Arts Vienna, Austria

ABSTRACT

Whether formally at music universities or informally in everyday conversations, it is common for acousticians to discuss acoustics-related topics with musicians or music educators. While few University programmes offer joint studies in acoustics and music, many conservatories and music universities require music students to take courses in acoustics and/or organology. At the University of Music and Performing Arts Vienna, for instance, students in both music and music education programmes can enrol in musical acoustics courses. At a time when STEM education (Science, Technology, Engineering, Mathematics – or STEAM when including the Arts) gains increasing importance, music educators have a key role to play at the intersection of music and science. They can make a difference by stimulating their pupils' curiosity about musical instruments and the science of sound, while strengthening critical thinking. To provide music educators with the necessary tools, the acoustics lecture should not only cover essential acoustic concepts, but also include strategies for conveying this knowledge. This paper proposes practical examples and discusses their applicability beyond the acoustics laboratory. This approach not only motivates future teachers while learning acoustics, but also expands their pedagogical resources for introducing STEM concepts into their music classes.

1. INTRODUCTION

Music education and the teaching of musical instruments take place in a variety of contexts and learning and teaching situations. Whether in collective or individual lessons, in schools, institutions and private lessons, or even via online tools, the fundamental aim remains the transmission and development of musical skills and an appreciation of the art of music.

Music educators may be employed in general schools (primary or secondary) or in music schools. In general schools, the music educator teaches general musical concepts to a group of pupils. In music schools, both group lessons and individual instrumental teaching take place. The background of music educators can vary depending on how much they have specialized in one instrument. Some teachers may have studied music education at university, others may have specialized in the performance and/or pedagogy of a particular instrument, and in many cases they may be trained professional musicians who also teach their instrument. At the University of Music and Performing Arts Vienna, for example, bachelor's and master's degree programs are offered for music students who wish to teach at the secondary school level (Lehramtsstudium Musikerziehung), for music students who wish to teach an instrument (or singing) at music schools (Musikpädagogik), and for music students who wish to study instrumental performance (among other programs such as Tonmeister, composition, theatre, film...). For all these study programs, music students —many of whom might become music educators— can take courses on music acoustics at the Department of Music Acoustics – Wiener Klangstil.

In recent years, lots of studies have explored the application of technology-enhanced learning (TEL) in music [1], with examples ranging from computer- or

smartphone-aided gamification tools [2] and sensoric-aided tools [3], to renderings in virtual reality [4,5]. Some studies have also addressed the challenges of preparing music educators for such digital tools [6], and examined the intersection of technology and gender in music education [7]. In parallel, many studies have highlighted the importance of music in STEM (Science, Technology, Engingeering and Mathematics), proposing methods to include music in STEM lessons [8], and proposing ways to give music a place in the 'A' of STEAM (Science, Technology, Engingeering, Arts and Mathemathics) [9, 10]. Yet only a few studies have reflected on the importance of STEM and STEAM in music teacher training [11] or have analyzed the role of acoustics in music education [12, 13].

Musicians and music educators are a very particular audience for a lecture on acoustics. They have a range of prior knowledge, including great practical knowledge of their instrument(s) and great musical skills, but also common misconceptions and beliefs about general acoustics and about the sound production in musical instruments (such as the influence of playing gestures on the produced sound). The acoustics lecture can be seen not only as a place for musicians to learn about the acoustics of their instruments, while reinforcing their critical thinking about their beliefs, but also to learn strategies for transferring acoustical concepts to their pupils. Since acoustics itself is a very interdisciplinary field, the concepts that may arise in the music lecture can be very diverse, ranging from physics and mathematical concepts to electronics, aeroacoustics, psychoacoustics, and more [9]. The current article concentrates on examples that refer to the physics of sound and showcases some exercises that the acoustics educator can use to engage with musicians and future music educators and provide them tools to become STEM ambassadors.

2. TEACHING ACOUSTICS TO (FUTURE) MUSIC EDUCATORS

In a conversation with Gordon Ramsey (Loyola University Chicago), who has recently published on the importance of acoustics and music in STEAM education [9], we shared our views on how to engage students in learning physics through acoustics and music. One of the many pieces of advice he gave me was to always think about the visual memory. "Anything you might say or have written on your slides may not last, but if you show them, it may last", were Ramsey's words. How to activate the (long-term) visual memory could therefore be seen as a motivation for the acoustics educator when preparing a lecture. Ramsey suggested preparing in-class labs and demonstrations and showing examples of the phenomena described. As an acoustics educator in a music university, I agreed and emphasized the importance of using descriptive physics. When preparing a lecture with a focus on descriptive acoustics, one can consider any topic in the field [14], while focusing on the concepts and the relationships between the physical variables, with the goal of introducing certain vocabulary, making connections between concepts, and helping students develop a deeper understanding of how physics principles apply to their instruments.

With these thoughts in mind, I have dedicated this year's lecture preparation to the question "How can I teach acoustics in a way that motivates my students (musicians and music teachers alike) to incorporate acoustics into their teaching?". The first step was to assess the current teaching situation of my students and the age of their pupils. I am currently teaching two courses on music acoustics where I meet musicians of all instruments, some specializing in performance and others in music pedagogy or education. Of the enrolled students, 15 completed a short questionnaire during the first lecture. Most of the students (11/15) are currently teaching an instrument to young pupils in private lessons, and some of them already have experience as music teachers in general secondary schools and/or teaching an instrument in music schools. The ages of their pupils were between 6 and 18 years old, with one student also teaching adults. The rest of the students (4/15) reported that they had no previous or current teaching experience.

Then I rethought the lectures to see how I could add transferable value to the demonstrations I usually show in class. So I would spend more time in class "showing how to show". For example, after we have learned what standing waves look like on a string, and they have identified nodes and anti-nodes in an in-class demonstration of a vibrating string (using a shaker and a tight elastic band), I would say to them, "I know this is some equipment that may not be available in your teaching situation, but let's try to find the similarities on a guitar". Then we would try to relate what they had just learned about standing waves to playing natural harmonics on the guitar (also known as flageolets), a technique most musicians have heard of or played themselves. If there are guitarists or violin-family players in the lecture, I encourage them to demonstrate the technique and explain what they are doing. They would claim that they touch the string lightly in a certain position

to play a given harmonic (Figure 1). Then, the abstraction we do together is to relate the position of the finger with the positions of the nodes of the standing wave. They quickly understand that the finger dampens the standing waves that do not have a node in that position. During this demonstration there is often an aha moment when they see the symmetry of the standing wave, i.e., when they realize that the natural harmonics can be played both near the bridge and near the fingerboard/fretboard. I use this moment to emphasize that they could show this effect to talk about the acoustics of the vibrating string when teaching flageolets (especially for guitar and violin teachers). If they do not teach flageolets, there is usually a guitar available in every general and music school that they can use as non-guitarists to talk about the fundamental frequency and the overtones. Then we look for the positions of the nodes of the standing waves together and find out that many guitars may have fret markers or side dots that show these positions on the fretboard (Figure 1).

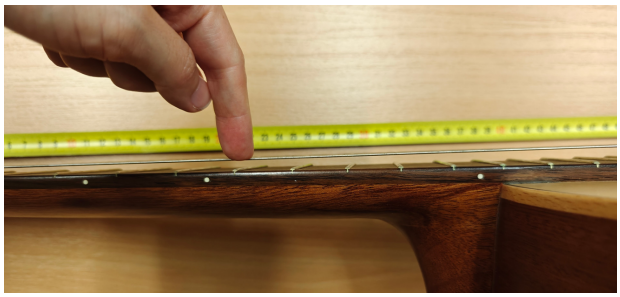

Figure 1. Classical guitar with side dots placed slightly left from the positions of 1/2, 1/3 and 1/4 on the string (from right to left). The finger is placed lightly touching the string on the fret that corresponds to 1/3 of the string.

Finding an equivalent for flageolets in wind instruments is not straightforward. The first association might be the registers: woodwind instruments can play certain notes, and they can be overblown either at an octave above or a quint-above-the-octave above the fundamental frequency that would correspond to the fingered position. Yet, according to my experience with musicians, while flageolets might be introduced very early on in the description of the string motion, standing waves in wind instruments require more careful treatment. It is common to describe the boundary conditions of wind instruments as closed or open [15]. One exercise with accessible materials (instruments) to do with musicians is to play a similar air-column length on two different instruments and discuss about the pitch of the resulting sound. From the acoustics point of view, an easy example is to compare a clarinet and a recorder. I would, first of all, ask them if they know why the recorder plays higher notes than the clarinet. They would usually reply: because the recorder is shorter. After introducing the concepts of open and closed tubes, I would ask two students to play the same length on a B-clarinet and on a soprano recorder. The recorder plays its whole length (C_5) and the clarinet plays a written D_4, sounding C_4. The first open tonehole of the clarinet is marked in red in Figure 2. The students can play the two notes and compare their interval: the flute plays one octave above the clarinet, although a similar air-column length is used. We then talk about the differences in wavelength that result in this difference in frequency. And they can finally complete the correct answer to the question of why the clarinet plays lower notes. Here, again, I would encourage teachers (clarinet teachers or anyone who might have an available clarinet at their school) to demonstrate this phenomenon to their pupils. To support the observations and shared discussions, I would show them a representation of the wavelengths of both instruments (Figure 3). If the group is interested in knowing more, one can also calculate the true length of the instrument for these frequencies according to the wavelength that is given by the frequency and the speed of sound and even introduce more advanced concepts like the end correction.

Figure 2. Comparison of the total length of a soprano recorder (sounding C_5) to the corresponding length on a clarinet (written D_4, sounding C_4). The first open tonehole on the clarinet for this demonstration is marked with an arrow.

Other examples that can be explored in the acoustics lecture while considering the transfer to the demonstration in a music lecture are collected in Table 1. These examples show some of the many useful acoustics demon-

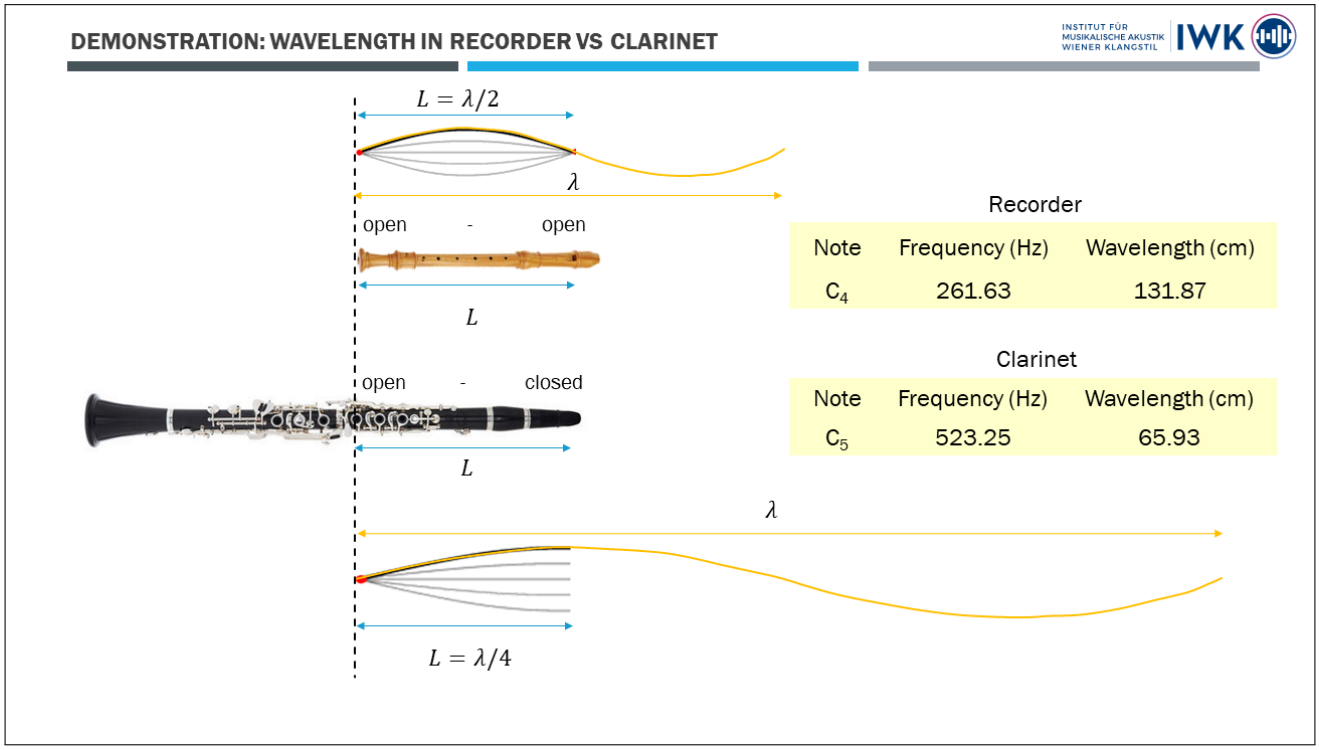

Figure 3. Comparison of the total length of a soprano recorder (sounding C_5) to the corresponding note on a clarinet (written D_4, sounding C_4)

.

strations that can be explored with musicians and music teachers either in a general acoustics lecture, in a lecture on string instruments, or in a lecture on wind instruments (from top to bottom). The paper would be too long if I were to explain the exact procedure in the acoustics lecture for all six examples, as it may be similar to the two demonstrations explained above. In all cases, I would support the use of these demonstrations outside the acoustics lecture by adding sentences like "try this at home" or "try this with your pupils", and I would ask them later if they have tried it (they claim they do!). This collection is by no means complete, but rather an inicial list of examples that the acoustics educator might consider incorporating, while presenting them as transferable demonstrations for a music lecture, and observe if the students engagement in the lecture increases, as well as their willingness to continue talking about acoustics with their pupils.

3. CONCLUSIVE REMARKS

This paper suggests that music educators have an important role to play in promoting STEM-related concepts in their music teaching through acoustics. By integrating acoustics into their teaching practices, music educators increase the interdisciplinarity of their teaching approach, not only to enhance their students' understanding of musical instruments and the science of sound, but also to stimulate curiosity and critical thinking. In doing so, they can inspire their pupils to explore the intersection of arts and sciences, which would contribute to the broader STEAM framework. This interdisciplinary approach not only enriches music education, but also positions the music educator as a valuable contributor to science literacy and as a facilitator of knowledge and awareness of the science of sound.

The examples chosen for this paper demonstrate how practical demonstrations can be made transferable from the acoustics lecture to the music lecture. The paper pro-

Table 1. Proposed use of material that might be accessible or made available in a music school and how to introduce it both in the acoustics lecture (focusing on string and wind instruments) and the music lecture, followed by the related descriptive physics.

Accessible material	Action in the acoustics lecture	Action in the music lecture	Descriptive physics
Slinky spring	Demonstrate pressure disturbance travelling and reflecting	When talking about sound production, use a slinky to represent the particles of air	Sound waves travel when air particles get compressed and decompressed, but the air particles themselves do not move forward
Tuning fork	Press the foot piece of the tuning fork against a table or the sound box of a guitar	When talking about the role of a sound boxes, press the foot piece against a table or a guitar	The table or sound box can make the vibrations of the tuning fork audible. The table or sound box shares more surface with the surrounding air than the tuning fork.
Guitar or violin	Demonstrate natural harmonics (lightly press finger on 1/2, 1/3, 1/4 of string). Demonstrate symmetry. Make standing waves 'visible'.	When teaching about flageolet (natural harmonics) introduce the concept of standing wave and its nodes.	The string vibration is the sum of the modes that are multiples of the fundamental frequency. These frequencies are all present in the string: the finger in the flageolet dampens the frequencies that do not have a node in this position.
Piece of paper	Blow above the paper and see how it raises; discuss Bernoulli principle. Mention plane sustain in air.	When teaching a reed woodwind instrument, introduce the Bernoulli principle to demonstrate the functioning of the reed. The paper mimics the reed.	If the particles of air gain velocity, they have less air pressure. If there are differences in pressure, objects might move (from the part where there is more pressure to the part where there is less pressure).
Clarinet and recorder	Play D in Bb-clarinet (sounding C) and C in soprano recorder, show that although similar air-column length, the clarinet plays one octave below. Discuss about their wavelengths.	Introduce the concept of open-closed and open-open tubes, by demonstrating that the clarinet can reach one octave lower than the flute.	The clarinet has a reed that creates differences in pressure at the beginning of the instrument, while the end of the instrument is open to atmospheric pressure. The flute has an air stream that moves in and out of the tube at almost atmospheric pressure.

poses to use these examples in the acoustics lecture, while including descriptive physics that links the concepts necessary to describe (some aspect of) sound production on string and wind instruments. The aim is to use accessible tools (e.g. instruments found in schools and music schools) to make acoustics engaging and relevant in different teaching contexts.

Further pedagogical development would require a thorough evaluation of the impact of the proposed action, including a follow-up with the music teachers to discuss the challenges they face in introducing acoustic concepts into their teaching practice. In addition, future research could explore other instrument families and acoustic concepts, as well as the relationship between music and other STEM disciplines, such as mathematics or electronics. For example, the mathematical principles underlying musical scales and intervals could be explored and made transferable to the music classroom [9]. Similarly, engineering concepts could be introduced by exploring the role of electronics in sound synthesis and amplification. These interdisciplinary pedagogical approaches would still need to take into account the possibilities of future music teachers in their teaching environment.

One of the main barriers to STEM education in general schools is known to be inadequate teacher preparation and a lack of interdisciplinarity [16]. This paper serves as a call to action for institutions to prioritize acoustics education in music performance and music teacher training programs, ensuring that educators are well equipped to inspire future learners at this unique intersection of STEM and arts disciplines.

4. ACKNOWLEDGMENTS

I would like to thank past and present colleagues at the Department of Music Acoustics - Wiener Klangstil, from whom I have learned about teaching acoustics to musicians and integrating demonstrations into the acoustics lecture (V. Chatziioannou, W. Goebl, A. Hofmann, A. Mayer, W. Kausel, G. Widholm). Thanks to Gordon Ramsey for the discussions on involving music students in the physics lecture. This research was funded in part by the Austrian Science Fund (FWF) [10.55776/T1295].

FROM SOUNDS TO ARCHITECTURAL DESIGN: ACOUSMATIC SPACES

Ayca Sentop Dumen[1*] **Yagdir Celiker-Cenger**[2]
[1] Department of Civil and Environmental Engineering, Norwegian University of Science and Technology, Norway
[2] Department of Architecture, Ozyegin University, Turkey

ABSTRACT

Acousmatic sounds are those that one hears without identifying their origin. Originating from musique concrète of Pierre Schaeffer, acousmatic music detaches the sounds from the individuals, instruments, and visual elements, to focus on the act of 'pure listening'. Implementing this notion on architecture, one can generate acousmatic spaces by detaching sounds from visual references of a space and re-compose them to design an experience.
A 10-day workshop was conducted that questioned the sound environment's potential in design by introducing it as the main element for design ideation while introducing acoustics as a building physics subject. 20 students of Faculty of Architecture in Istanbul Bilgi University participated in this workshop. Through a sequence of listening exercises, soundwalks, seminars and discussions, the students were trained about the main concepts of acoustics, structure-form-sound-perception continuum. A re-design problem was given that started with a blind walk for enabling 'pure listening' and data was collected with soundscape assessment questionnaires and voice recordings. A spatial narrative was created by 'sketching' sounds (sound-editing) and used in the regeneration of the spatial structures. The study showed that introducing systematic steps and experience-based teaching can encourage students to utilize auditory information in design and enable active learning in acoustics.

1. INTRODUCTION

The word "acousmatic" roots back to the ancient Greek word "acousma" which means "the object of hearing" and "akousmatikoi" which described the pupils of Pythagoras who listened the class while a curtain hindered the sound originator to avoid distraction. In 20th century the term "acousmatic" was adopted (initially by Jérôme Peignot and Pierre Schaeffer, later evolved by François Bayle) to describe the sounds that one hears without identifying its origin [1]. The framework for acousmatics comes from "musique concrète" and "reduced listening" pioneered by Pierre Schaeffer - *not to be confused with R. Murray Schafer, known for his contributions to soundscape studies.*

Musique concrète emerged as an experimental composing method using recorded sound "objects" and organizing them by implementing 3 main techniques: (1) transformation of time, (2) transformation of texture and timbre and, (3) spatialisation [2]. Fascinated by the recording technologies, Schaeffer believed that there existed a domain "beyond the sounds" through recording "the noises of things" [2]. This approach emphasized the abstraction of sound, thus enabling its use as a raw material for musical and spatial composition.

Recording technology not just offered the new method of music making but also allowed a new definition of listening. The sounds were disengaged from the origin, striped from indicative and communicative signs and they were no longer a "placeholder for some other thing" which Schaffer theorized as "reduced listening" [3]. By adopting this approach, one could focus on the musical characteristics of a sound or combination of sounds within a composition rather than identifying their source or the action that produced them [4].

Stemming from these fundaments, acousmatic music detaches the sounds from the individuals, instruments, and visual elements, to focus on the act of "pure listening". "Often taken by surprise, sometimes uncertain, we discover that much of what we thought we could hear was in reality merely seen, and explained, by the context." [1; p.66]. Acousmatic sound directs attention to sound characteristics that are typically overlooked when sight is present, as these visual cues tend to emphasize certain elements while masking others [5]. One challenge is that invisibility of the source initially evokes curiosity and intensifies causal listening, although this can be overcome through repetitive hearing [1, 5]. Therefore, acousmatic sounds challenge the listener to shift from conventional listening habits and requires them to focus on the sonic properties rather than their origin or cause.

Inspired by these notions, this study explores application of "acousmatics" in acoustic education as a way to stimulate spatial and soundscape design. In a workshop, students were engaged in a blind walk. They navigated in a building with their eyes closed, took recordings of sounds and defined their perception through a set of questions. This exercise in acousmatic perception aimed to detach the sounds from the space and allow them to reimagine the built environment as a composition of auditory elements rather than predefined spatial functions. The collected sounds were then used to compose new soundscapes, which were later translated into structural and spatial forms—creating a visual entity that emerged from a designed sound experience. In this sense this study aims to introduce a reverse design method to acoustics and spatial design. This paper presents the methodology and the results of this workshop.

2. METHODS

2.1 Preparation and development of the workshop methodology

A 10-days workshop was organized in 2019 summer in Istanbul Bilgi University. The workshop was planned with "learning-by-doing" approach and separated into three parts: (a) novice soundwalk, (b) training and (c) trained (blind) soundwalk.

The initial part of the study benefited from the methods and experiences of a former workshop study which investigated design methods for soundscape interventions [6]. In this previous workshop, students got engaged in a soundwalk, listened the acoustic response of the environment to the spatial sounds as well as self-generated sounds, and analysed their perception through the soundscape assessment forms. The assessment form and reading cards were prepared in line with ISO 12913-2:2018 and ISO 12913-3:2019 [7, 8] and benefited from [9 - 14]. Reading cards were used to evaluate the effect of acoustics during ensemble readings. Acknowledging the role of visual representation in design thinking, the study proposed techniques for audio-visual representation, namely: sound infogram, sound collage with recordings, and abstract sound-model with audio and visual elements. After this representation stage, students were encouraged to work with sound files, as well as sketches, texts and diagram for proposing a design intervention (further explained in [6]).

The current study used the sound evaluation form for the first soundwalk and an adjusted version for the second, i.e. blind walk (Figure 1). A challenge associated with acousmatic sounds was mentioned as the likelihood of the listener's attention shifting to the source due to curiosity. Instead of conflicting with this curiosity, we allowed students to first question the space characteristics through rating items of (a) socio-spatial environment, (b) spatial configuration, and (c) localisation inside the space, before moving to the questions related to soundscape quality.

Audio-visual representation techniques were applied although simplified for the purpose of the current study. An infogram consisting of only the radar chart of studied zone, sound collage with recordings, and sound-model with only visual representation was aimed for the first stage while students were intended to work with sound files, physical models and a videoclip in the second stage.

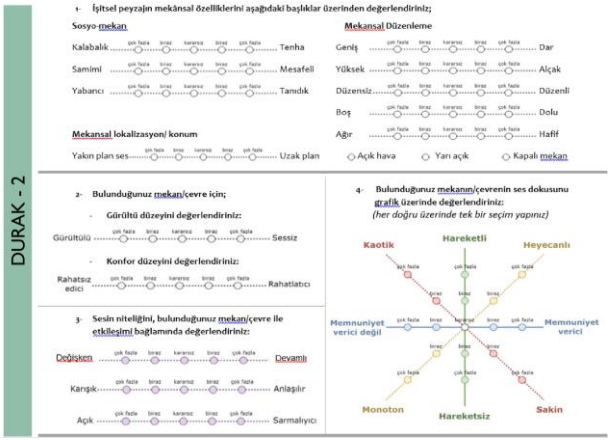

Figure 1. Assessment forms for blind walk

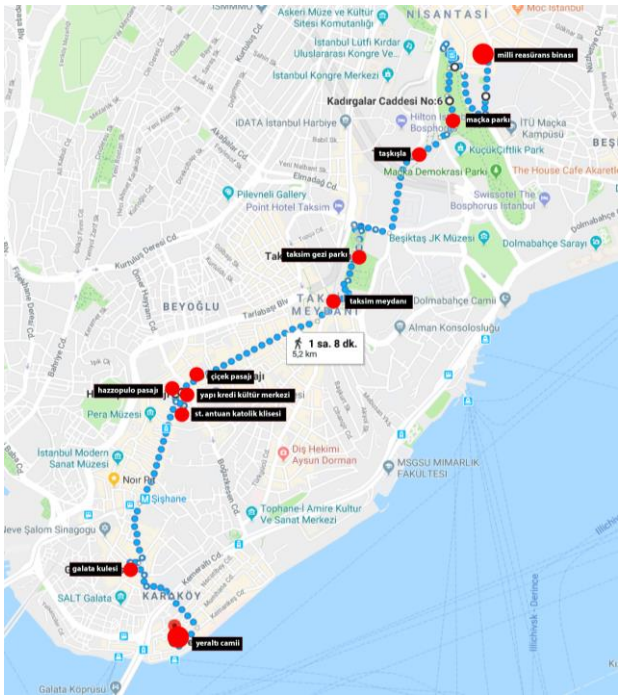
2.2 Workshop process



20 students participated to this workshop (15 female and 5 male). The majority had completed first year and had little or no knowledge on acoustics.

2.2.1 Novice soundwalk

Route: The novice soundwalk route was a central 5,2 km long walking route in Istanbul in the axis of Maçka – Taksim – Karaköy (Figure 2). 11 evaluation stops were predefined which would offer variety in terms of spatial, architectural and sound attributes. 4 open areas included both natural and urban soundscapes (Maçka Park, Gezi Park, Taksim Square, Galata Square). 3 passages constituted narrow urban corridors and courtyards which hosted both transit and leisure (café) activities (Milli Reasürans Passage, Çiçek [Flower] Passage, Hazzapulo Passage). 4 indoor spaces represented different architectural periods and had different spatial ratios (Taşkışla - ITU Architecture Faculty, Yapı Kredi Culture and Arts Centre, Church of St. Anthony of Padua, Yeraltı [Underground] Mosque).

Soundwalk procedure: A group walk was conducted on the route lead by instructors. Students were instructed to listen to the sounds and take recordings. In each stop they listened to their environment for approximately 3 minutes and filled the soundscape evaluation form. To understand the acoustic environment, they were instructed to use self-generated sounds (claps, footsteps) and do ensemble readings (4 students read the given texts while others listened). Afterwards instructors explained the historical background, architectural form and its effect on acoustics.

Audio-visual representation: On the following day, students discussed their experiences and the affective quality responses of all participants were averaged for each stop. Later the students were separated in 4 groups and assigned with one of the stops on the route. They were guided to experiment with the audio-visual representation techniques by preparing (1) a sound collage of maximum 1-minute using Adobe Premiere, (2) a graphical expression (poster) and (3) a physical model of sound-structure interaction. The students had little acoustical knowledge at this point and the aim of this study was to initiate questioning rather than proposing design solutions, while mastering representation techniques and tools. This activity continued for one and a half day.

(a)

(b)

(c)

Figure 2. Novice soundwalk; (a) route map, (b) ensemble reading at Yapi Kredi Culture and Arts Centre, (c) ensemble reading at passage

2.2.2 Training soundwalks and teaching

Theoretical knowledge was developed with seminars on basics of architectural acoustics, spatial design for sounds and interactive structures. An emphasize was given on on-foot learning. Two training soundwalks were conducted with approximately 1 hour duration.

- A soundwalk took place within the Istanbul Bilgi University campus, featuring multiple indoor and outdoor stops. This route encouraged students to perceive their familiar surroundings from a fresh perspective. Along the way, they were introduced to fundamental acoustical concepts and engaged in discussions on the relationship between sound, space, and human interaction.
- The second soundwalk involved a visit to Dialogue in the Dark [15], an exhibition where visually impaired guides lead visitors through a completely dark environment. The experience allowed participants to navigate solely through non-visual senses, deepening their awareness of sound and spatial perception.

2.2.3 Trained soundwalk – blind walk

Route: The trained soundwalk was conducted inside Istanbul Naval Museum in Besiktas (Figure 3). This building consisted of a heritage wing from 1897 and a newly built modern wing from 2013 [16]. Two separate routes were defined in two wings. The route in new wing was characterized by volumetric spaces and ended in a narrower glass bridge that connected the two wings. The route in heritage wing consisted of small- and moderate-size rooms distributed in 3 floors and an installation with water sound. Each route included 4 evaluation stops.

Procedure: Students were separated in groups of two. In each route one completed the walk blind (with eyes-covered) while the other acted as their guide and asked the affective quality assessment questions. They implemented the methods they practiced during the novice soundwalk (self-generated sounds, listening). They simultaneously took recording of the whole route.

Reverse design: Students were given the task of redesigning the route that they walked blindly. They were asked to design an "aural experience" and the form, structure and elements for it.

Students worked individually in this phase. They were encouraged to start with a sound collage of the route by using Adobe Premiere and go through the sound recordings, and their responses to affective quality questions. After familiarization process, they started to "design + compose" the spatial sounds by manipulating the sound texture and adding / subtracting sound elements. These were converted into a physical model where this sonic experience would occur. Students were asked to think about the acoustic principles and sound elements in relation to architectural form and socio-spatial environment.

The method for model making was defined as infilling within a 30x30 wooden frame, and students were free to use multiple frames if needed. For the submission students made a stop-motion video that combined the sound file with the corresponding vistas of their model.

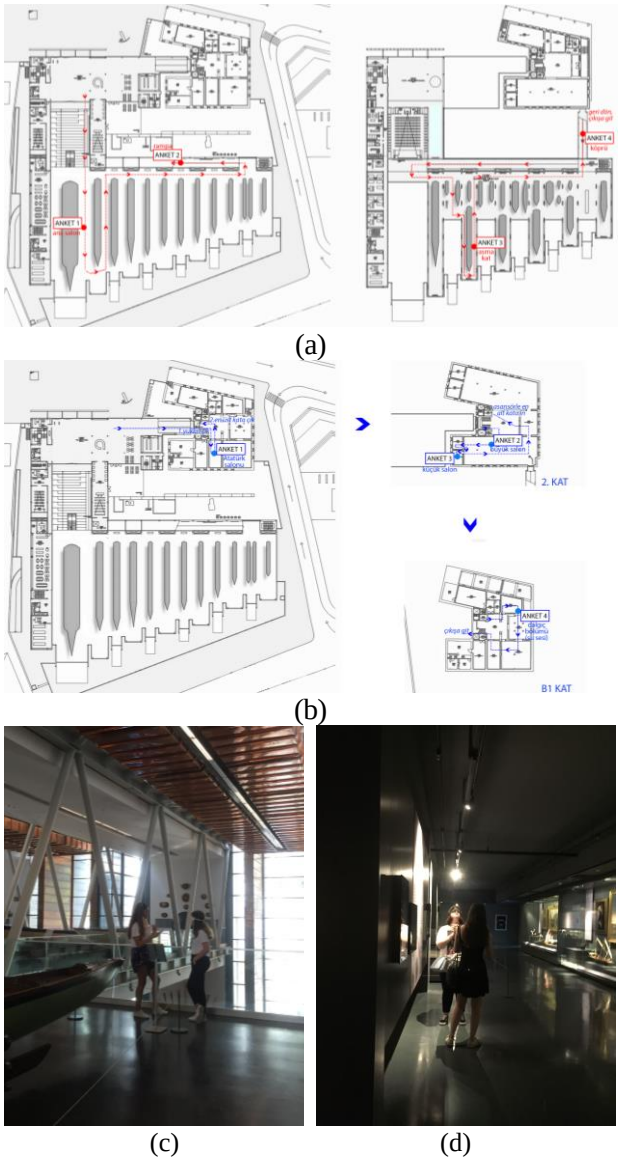


Figure 3. Trained soundwalk; (a,c) route in the new wing, (b,d) route in the heritage wing

3. RESULTS

3.1 Representation of acoustic environments (novice walk)

The first study involved a representation task, and the outcomes included a short sound collage, a poster and a model for four selected spaces.

All four-student-works reflected alterations and contrasts that emerged in the sound environment. When the contrast was not evident, students chose to extend the frame of the study. This was the case for two spaces (2nd and 3rd group) where students included street in addition to the assigned space. Both of them shared similar affective qualities rated as monotonous, uneventful and calm.

1. Çiçek [Flower] Passage
Affective quality: Eventful, exciting, chaotic
Represented elements: The alteration in strength of emotions (colourful spheres), user density (red line), sound level (blue line), reverberation time (green line), location of echo (arrow) (Fig. 4).

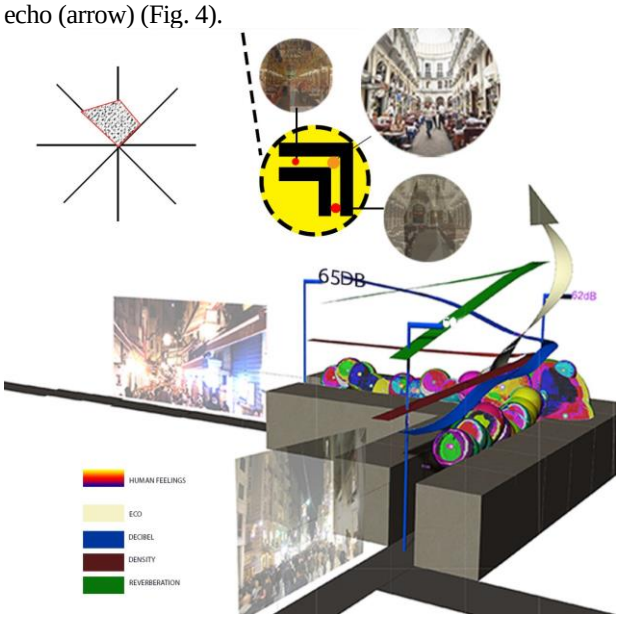

Figure 4. Graphic expression of sound environment in Çiçek [Flower] Passage

This work shows the perception of gradual alteration in sound environment in response to this transition space. The midpoint (corner) corresponds to largest volume which is depicted as climax for emotions along with the reverberation and echo perception (based on hand claps).

2. Church of St. Anthony of Padua
Affective quality: Uneventful, calm, (a little) monotonous
Represented elements: Sound levels (bar heights), variety (colourful vs. blue), envelopment (tangled forms vs. straight forms), transmissibility (forms bending over courtyard boundaries but not over church boundaries) (Fig. 5)

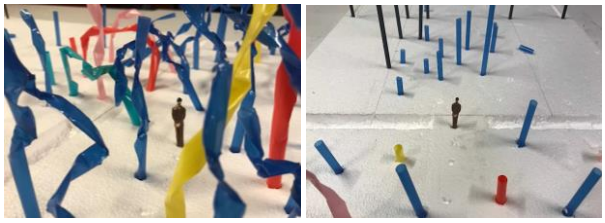

Figure 5. Physical model of sound environment in Church of St. Anthony of Padua

This work shows three different sound zones separated by borders. The two graving on ground shows borders of courtyard (Fig. 5 left) and church (Fig. 5 right). While preparing this work students commented on their observation that although the sound environment was very calm, any single event sounded "bigger" (long reverberation time) and they expressed these events with tall blue bars separated from each other.

3. Yeraltı [Underground] Mosque
Affective quality: Monotonous, uneventful, calm, (a little) pleasant
Represented elements: Temporal and level characteristics (outdoor sounds: rhythmic red line at top vs indoor sounds: continuous beige line at bottom with few movements), sound texture (onomatopoeic words) (Fig. 6)

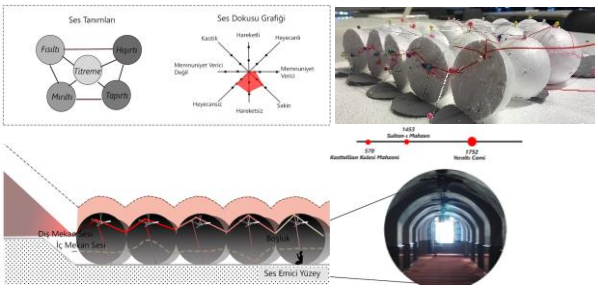

Figure 6. Graphic expression and physical model of sound environment in Yeraltı[Underground] Mosque

Originally built as an underground cellar, this is an unusual space consisting of repetitive domes, low ceiling, massive load bearing columns that create visual and acoustic barrier,

and absorption due to carpet. Students' physical model shows the negative space (void as mass). Their choice of onomatopoeic words (*fısıltı*: whisper, *hışırtı*: rustle, *tapırtı*: tapping, *mırıltı*: murmur) implies perception of soft, subtle and continuous sounds and a non-intrusive environment.

4. Yapı Kredi Culture and Arts Centre
Affective quality: Pleasant, calm, (a little) uneventful
Represented elements: Reflection and absorption of sound by different materials (lines) (Fig. 7)

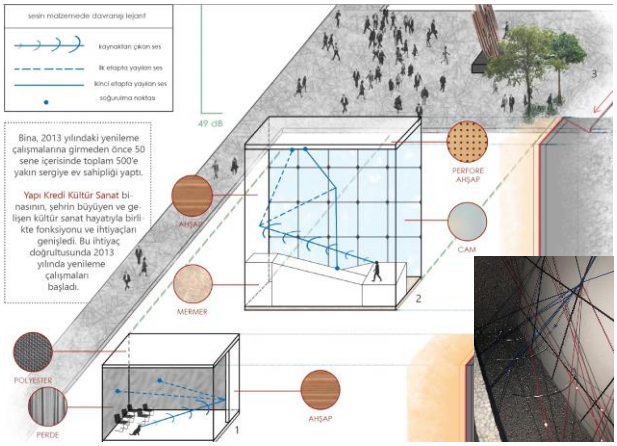

Figure 7. Graphic expression and physical model of sound environment in Yapı Kredi

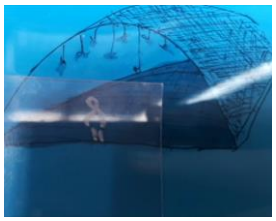
This group focused on sound reflection from surfaces. They compared circulation area which was characterised by its high ceiling, glass and stone surfaces, with the seminar room which contained absorptive surfaces.

3.2 Reverse design (trained / blind walk)

The second study involved a reverse design task, and the outcome was a stop-motion video which combined the sound file and the physical model prepared by the students. 15 of the students submitted their final work. 11 of them were able to complete the final video in time, two students submitted a sound file and a photo of the model, and two students submitted only a sound file.



Students presented their work to the instructors and their peers at the end of the workshop. Due to the absence of students' own verbal descriptions at this stage (contrary to the first study where students' intentions were explicit in posters), the results presented in this chapter include mainly our observations on outcomes and process.

3.2.1 Observations on the design works

Students' instinct of searching for contrasts and comparisons was also evident in the second study (design works) as many of the works offered richness in designed sound experience. Students adjusted the sound characteristics (temporal, frequency, levels), added directivity and spatialization (using left-right channels, dynamic levels, reverb and echo), and through introducing new sounds (spatial, environmental, self-generated, musical and other "effect" sounds). This was reflected in the architectural geometry with changing size, ratio, form and sound elements as well as open / semi-open areas to enable city, and/or nature sounds. This shows that designing "experience" output as a starting point, encourages students to form dynamic spaces (Fig. 8 and 9).

(a)

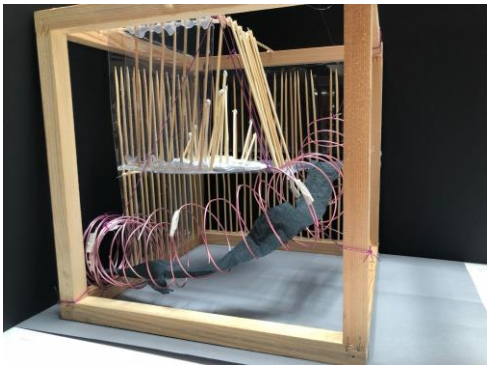
(b)

(c)

Figure 8. Screenshots from one of the videos with a rich space and sound configuration

Figure 9. A study in which a parallel was drawn between the visually reflective tubular form and sounds distorted through delayed repetition

Most designs also included movement at Z axis (stairs / ramps) (Fig. 10). This might be an attempt of creating different "sound vista"s. However, it is also possible that this was induced by the vestibular sense of the movement pattern during the blind walk, or by the model-making method which involved filling in a wooden frame.



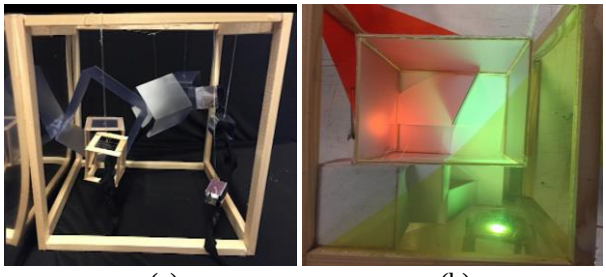


Figure 10. A route where a ramp forms a transition zone between the outdoor sounds and indoor sounds as well as between street level and upper level. The large and reverberant indoor space hosts an inner structure with contrasting sound characteristics

When the studies are analyzed together, a distinction emerges between two approaches to user movement within designed spaces. Some allow for free navigation, enabling users to explore the space openly, while others establish a continuous, predetermined route that guides movement in a specific direction. The intentionality behind these choices needs further examination in future studies (Fig. 11).

(a) (b)

Figure 11. Two approaches to user movement. (a) restricted, (b) free navigation *(the image shows top view)*

There was a clear tendency to include music, even though it was not the main element in most studies. Musical elements can serve as immediate cues for conveying emotion. This should be critically examined in future studies to encourage students to explore alternative means of emotional expression and search spatial sounds.

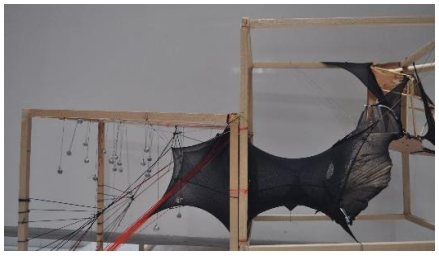

Figure 12. A study where student used spatial sounds very minimally and created a more-deliberately designed sound file composed with sound effects

3.2.2 Observations on the blind walk process

The blind walk received strong interest, and students were generally positive about this experience. The training soundwalk in "Dialogue in the Dark" was helpful for preparing students to navigate in space in the lack of their visual sense (with a guide) and focus on their audio environment. Nevertheless, one student reported being uncomfortable of walking while eyes were covered and that this sense influenced their final work (Fig. 13). This comment and the observed tendency of movement at Z axis (see section 3.2.1) suggest that while blind walk helps to omit visual input, vestibular sense might continue to intervene with the perception.

Figure 13. Student work that reflected discomfort during the blind walk. The sound file included eerie elements such as squeaks and screams, while the spatial model featured vertiginous, torsional surfaces

The implementation of the soundscape assessment forms not only systematized the evaluation but also it directed the

attention to the experience of acousmatic sounds. Furthermore, the voice record of the guide who read the questions on the form and the reading texts was used as a "sound object" in many of the sound collages.

Many students expressed their curiosity about the space. This confirms the challenge associated with acousmatic sounds, as the listener's attention is likely to shift away from the sound upon first contact. Repetitive listening of recordings is found useful for reframing sounds as objects of redesign.

3.2.3 Observations on the design process

The physical model fed from the sound file, demonstrating an example of reverse design, where students first crafted the sound environment and then derived the spatial form from it. This approach highlights the potential of sound as a generative tool in design, encouraging a deeper understanding of the relationship between auditory and spatial experiences. Additionally, it offers a method of acoustic learning where students not only analyse their own perceptions but also design a soundscape and search for forms elements to materialise it.

The two-stage study (novice + trained) helped students to familiarize with listening to spaces, discovering acoustics through self-produced sounds and assessment of soundscape quality as well as representation tools and techniques. This helped the students to focus less on mastering the techniques and more on the activity itself in this second part of the study.

4. CONCLUSION

Inspired by the acousmatic music, this workshop explored its implementation in a design study. Acousmatics suggests renouncing the instrument and traditional musical frameworks, focusing instead on sound itself and its inherent musical "potential" [1]. In this workshop study, students listened to the space without visual cues, stripped the sounds of their origins and spatial context, and explored their potential in designing an aural experience. This provided an alternative way of engaging with sound, moving beyond traditional acoustic design. The designed/composed sound was converted into a spatial form thus exemplifying a reverse design method for architecture and soundscape.

During the 10-day workshop, students were trained in attentive listening and developed a deeper understanding of the acoustic environment. The acoustic training primarily occurred through on-foot experiences and learning-by-doing. This approach fostered an intuitive understanding of how sound interacts with space, offering insights for architectural and acoustic education.

5. ACKNOWLEDGMENTS

This study was conducted in Istanbul Bilgi University.

ABSTRACT

Mangrove ecosystems are critical habitats that provide a diversity of ecological services. Societal and economic sustainability of populations living with mangroves rely on health of those ecosystems, through fishing activities and extraction of firewood, material to build houses, furniture and fishing gear. A knowledge-based support to policy decisions and identification of appropriate interventions for conservation and restoration of ecosystems is needed, including education and training of young generations. We describe the experience of a training course for the installation and management of an observing station for the monitoring of the soundscape. For the first time, a system for monitoring the acoustic field in air, soil, and water has been installed in Inhaca (Mozambique) to provide clues on the mangroves' ecosystems. The potential of operational acoustic measurements, as well as protocols for training and managing observing stations for conservation and protection of the environment, are provided. By integrating acoustic measurements into conservation efforts, the station not only advances ecological monitoring but also acts as a key resource for local communities and schools, fostering environmental education and empowering stakeholders in the protection and sustainable management of mangroves. The experience highlights both the potential and challenges of leveraging soundscape data for environmental stewardship.

1. INTRODUCTION

Mangroves are intertidal habitats, occurring in the sub-tropics along sheltered and shallow-water coastlines [1]. There are important ecosystems that provide goods and services for coastal environments, communities and society as a whole [2-4]. Above the water, the mangrove trees and canopy provide an important habitat for a wide range of species, including birds, insects, mammals and reptiles. Below the water, the mangrove roots are overgrown by epibionts such as tunicates, sponges, algae, and bivalves [1]. Despite being among the most productive ecosystems, mangrove forests have historically been undervalued, and their area has been reduced due to poor management and increasing demand for coastal lands for development [3; 5]. Thus, it has been a high priority for the global community to arrest mangrove loss and restore degraded mangrove ecosystems, and the Knowledge-based approach has been an important support to policy decisions and the identification of appropriate interventions for the conservation and restoration of these ecosystems.

Education and training programs of mangrove ecosystems are held worldwide, to understand all the aspects of the

structure and function of mangroves, as well as their bio-geographical affinities and their conservation and management, which is important to have a considerable knowledge of the species composition and ecology [1-2]. These educational programs are to guide and equip the local communities with the basic technical know-how and skills for conserving, managing and rehabilitating mangroves in their areas.

In Mozambique, the Sapienza - University of Rome, in collaboration with Eduardo Mondlane University, launches an annual Intensive Summer School Course "ManGrowth - Preservation of Ecosystems for Sustainable Development." The course is promoted and funded by the Italian Agency for Development Cooperation, as part of the ManGrowth Project (Preservation of Ecosystems for Sustainable Development – AID 012432/01/2), which focused on the importance of mangrove forests as an essential ecosystem to promote the sustainable development of coastal areas, the mitigation of the effects of climate change and the conservation of animal and plant species that are linked to them by their life cycle.
In this context, as part of the technical training and capacity building for young researchers, two low-cost bioacoustics stations were installed. Sounds from the air, soil, and water were recorded to monitor the soundscape made by the living organisms that occur in the mangrove ecosystems and their behavior due to the floatation of tides and day season into the mangrove. The use of bioacoustics as a biomonitoring tool allows us to understand what the ecosystem's dynamics can tell about the habitat's health, which may aid in monitoring the success or progress of ecosystems restoration and conservation [6-8].

2. THE TRAINING APPROACH

The training course was focused on soundscape ecology. Soundscape ecology is the integration of geophysical, biological and anthropogenic sounds that fill an ecosystem and which vary over space and time [9]. It has recently emerged as an interdisciplinary scientific field that investigates the acoustic field in relation to ecological processes. In this context, the training course tested in mangrove ecosystems an innovative instrumental set-up aimed to use multi-component observing stations of the biosphere for the identification of emergent properties of the status of the ecosystems.
The design and development of the training course was mainly guided by a "learning by doing" approach. Frontal teaching on fundamentals of acoustics, signal treatment, specifications and calibration of instrumentation, concepts of measure, sensitivity and bits were provided. Students were involved from the beginning in a co-decision process for the identification of locations for the observing stations and the adjustment of the parameters of the instrumentation. Students were also divided into sub-groups for the responsibilities of recharging the batteries, inspection of the functioning of the instrumentation, data analysis.

Figure 1. Training session on the field: first concepts of bioacoustics and instrumentation used (Photo by Enrico Nicosia).

Every day, an early morning briefing and a post-dinner reflection meeting were implemented to plan activities and further developments. The duration of the course was a whole week and was included in a one-month summer school (see the acknowledgements for further details), with a final report to be delivered [10], and an extension of 4 more days for the collection of additional data.

3. THE EXPERIENCE IN INHACA

3.1 Study Area

Inhaca Island (Mozambique) is a 40 km² island with diverse ecosystems, including coastal forests, mangroves, and seagrass meadows. Two bioacoustics monitoring stations were set up: one near the Inhaca Marine Biology Station and another at Ponta Rasa. The island experiences a tropical climate with distinct wet and dry seasons. Inhaca has semidiurnal tides, crucial for both ecosystem dynamics and study design. Stations were installed during low tide to ensure accessibility and reduce equipment damage.

3.2 Equipment and Setup

To ensure effective acoustic monitoring that captured the full range of environmental sounds, the recording system was designed with a combination of hydrophones and

microphones, strategically positioned in air, water, soil, and intertidal zones. At the core of the setup was the Zoom P4 PodTrak recorder, powered by reliable power banks to maintain continuous operation in the field [10].

Figure 2. Study area: this is an overview of the second station at Ponta Rasa, which was very close to a channel with continuous water flow from the sea to the internal areas (Photo by Augusto Nhampossa).

Special attention was given to installation to minimize environmental interference. Microphones were shielded to reduce wind noise, while hydrophones were carefully anchored to ensure constant submersion. Additionally, all equipment was securely mounted to prevent accidental disturbances that could affect data quality.

Figure 3. Setup of the acoustic stations: cables needed to be accurately positioned in order to avoid contact with water or movements that could give biased sounds in the recordings (Photo by Enrico Nicosia).

3.3 Data Collection

Recordings were conducted from October 1–8, 2024. Data were collected in segments of 3h22min53sec, and a further selection or shorter time intervals allowed a smooth processing for later analysis [10].

Figure 4. Hydrophone hung on the roots in order to be outside of the water with the low tide and submerged with the high tide (Photo by Enrico Nicosia).

Figure 5. Recorder: as inputs, we used one microphone for air and three hydrophones for water and soil (Photo by Aura Rapino).

3.4 Challenges and Solutions

Several environmental factors posed challenges during the study. The muddy terrain made installation difficult, requiring careful planning and teamwork to position the equipment properly. Ensuring a stable power supply was also crucial, and the use of power banks provided a reliable solution for uninterrupted monitoring and silent generators [10].

Wind interference was another challenge, necessitating adjustments to microphone shielding to reduce background noise. The placement of hydrophones required particular attention as well, as maintaining continuous submersion was essential for accurate data collection. Additionally, managing the large volume of data was a key consideration, with daily recordings reaching approximately 30 GB, making efficient segmentation necessary to facilitate analysis [10].

Figure 6. Microphone hung on a higher branch in order to record air sounds, covered to avoid disturbance from wind and rain (Photo by Enrico Nicosia).

3.5 Recommendations

For future monitoring efforts, conducting a preliminary site assessment can help identify potential challenges and optimize equipment placement. Ensuring secure installations is also essential to minimize environmental and human disturbances. Combining acoustic monitoring with additional sensors, such as anemometers, thermometers and camera traps, can provide a more comprehensive understanding of environmental dynamics. Ultimately, bioacoustics monitoring proves to be a cost-effective and valuable tool for mangrove conservation, offering critical data for assessing ecosystem changes and informing management strategies.

4. CONCLUSIONS

This study highlights the feasibility of monitoring mangrove ecosystems using accessible and cost-effective acoustic techniques. By capturing variations in soundscapes, passive acoustic monitoring provides valuable insights into biodiversity, habitat health, and ecosystem dynamics. However, to fully harness its potential, future research should focus on refining methodologies, expanding monitoring efforts, and establishing standardized protocols for long-term ecosystem assessments.

One key avenue for development is the identification of reliable acoustic indicators that reflect the state of the ecosystem. Distinctive sounds produced by organisms such as crabs, shrimps, fish, and insects, as well as abiotic elements like bubbles and water flow, could serve as bioacoustics markers for assessing habitat quality and ecological changes. Creating archives of reference signals would be instrumental in building a comparative framework, enabling researchers to detect shifts in species composition, human-induced disturbances, or natural seasonal variations.

Mozambique, with its vast coastal and wetland habitats, presents a significant territorial opportunity for expanding acoustic monitoring beyond the initial study site. Establishing a network of monitoring stations across key mangrove regions could provide large-scale, long-term datasets, supporting conservation strategies at both national and regional levels. Scaling these efforts across other African coastal ecosystems could contribute to a continent-wide initiative aimed at protecting critical biodiversity hotspots using non-invasive, technology-driven approaches.

Beyond scientific applications, fostering community engagement is essential for the success and sustainability of bioacoustics monitoring. Training a new generation of “guardians” and citizen scientists—including local fishers, students, and conservationists—can promote widespread participation in data collection and habitat protection. Educational programs, field workshops, and accessible training materials could empower local communities to take an active role in conservation, bridging the gap between research and real-world impact.

The integration of social media and web platforms could further enhance outreach and collaboration. By sharing acoustic recordings and findings through digital platforms, or common devices such as mobile phones, researchers can engage a wider audience, increase public awareness, and facilitate knowledge exchange between scientists, conservationists, and the general public.

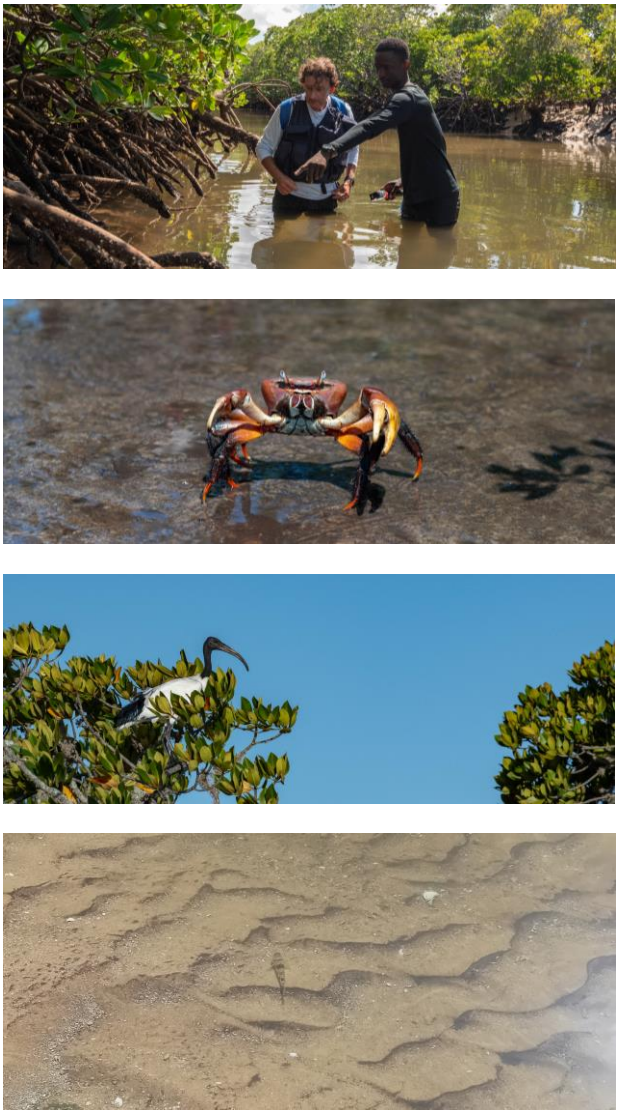

Figure 7. During the field stations, different species where observed in the ecosystem. From top to bottom: crabs, birds, fish (Pictures by Enrico Nicosia and Pier Francesco Moretti).

Open-access databases for bioacoustics data sharing could also help create global repositories of environmental sounds, supporting comparative studies and collaborative research initiatives. Furthermore, the user-friendly, low-cost nature of this system makes it easy to handle and accessible for widespread implementation, ensuring that local communities and researchers can adopt it with minimal technical barriers. Strengthening methodologies, expanding research networks, and engaging local communities will ensure that these efforts contribute to the long-term sustainability of coastal environments. This study serves as a foundation for future bioacoustics monitoring initiatives, demonstrating the potential of soundscape analysis in environmental conservation.

In conclusion, bioacoustics has the potential to become a powerful tool for mangrove conservation, blending science, technology, and community participation. Strengthening methodologies, expanding monitoring networks, and integrating digital tools can significantly enhance our ability to assess and protect these critical ecosystems for future generations.

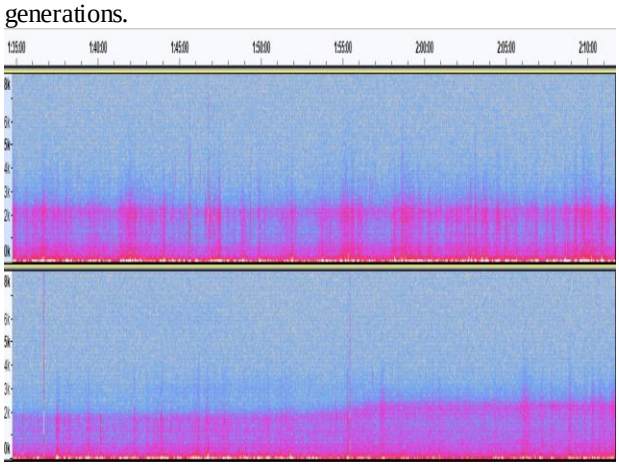

Figure 8. Spectrograms of two selections of approximately 35 minutes of data from the hydrophone hanging on the roots (partially in air and partially in water). Low and high tide cycles are clearly visible, as well as differences in the intensity and variety of sounds, that needs further analysis. Spectrograms are obtained through Audacity® ver. 3.6.4 [11], white and reddish colors refer to more powerful signals.

5. ACKNOWLEDGMENTS

This research was conducted within the framework of the ManGrowth Project (Preservation of Ecosystems for Sustainable Development – AID 012432/01/2), funded by the Italian Agency for Development Cooperation. We extend our gratitude to *Sapienza* University of Rome, Eduardo Mondlane University (UEM), and the National Research Council of Italy (CNR) for their valuable contributions and institutional support.

We also thank Paolo Ramoni as the project coordinator of ManGrowth: without him all of this wouldn't be possible.

MOOCs FOR INTRODUCTORY COURSES IN ACOUSTICS AT THE UNIVERSITY OF LE MANS: ASSESSMENT AND PROSPECTS

Jean-Pierre Dalmont
Laboratoire d'Acoustique LAUM UMR CNRS, Le Mans Université, France

ABSTRACT

The University of Le Mans and its acoustic laboratory have initiated a series of MOOCs in French (Massive Open Online Courses) for an introduction to acoustics. The first, " Les bases de l'acoustique - la voix dans tous ses états ", is aimed primarily at high school students and physics teachers. Open since 2018, it has more than 20,000 registered students and has been used in particular in several speech therapy schools. The second, " Théorie pour un son – l'acoustique au service musicien ", is aimed at musicians and the curious with the aim of creating a generation of acoustically informed musicians. Each chapter begins with a video scenario and offers animations, interactive resources, expert interviews, activities with Audacity and quizzes. Opened in 2024, it has already attracted more than 5,000 registered students. Le Mans University is now working on developing a MOOC on the construction and physics of musical instruments. In collaboration with Itemm (Institut Technologique Européen des Métiers de la Musique), this evolving MOOC, after providing the basics of instrument physics, will detail a certain number of instruments, including the voice. The opening is planned for 2026.

1. INTRODUCTION

MOOCs, i.e. Massive Online Open Courses, are a tool for disseminating knowledge that has become considerably widespread since 2008. The basis of the MOOCs are short videos completed by some written documents. Other resources are usually proposed such as quiz to test knowledge, exercises to put the lessons into practice and discussion forums to interact with the teaching team and other students. Le Mans University made 2 MOOCs which are still available and started to work on third one. These MOOCs are briefly presented below.

2. FIRST MOOC

This MOOC, "Les bases de l'acoustique - la voix dans tous ses états" was and is still dedicated to high school students. It was designed based on the official baccalaureate acoustics program and is proposed on the French MOOC platform "France Université Numérique" (FUN). It contains 5 lessons and the total time investment needed is evaluated to 10 hours. Each lesson starts with a video putting the subject into context and contains experiments and exercises. First lesson is about waves and their speed. It is asked to the student to measure the speed of sound with their phone and give the result on a forum. Second lesson is about sound analysis and signal processing. Using the software Audacity, it is asked to measure the frequency of whistling and vowels. At the end it is asked, using processing tools to transform the vowel [a] into the vowel [i]. Third lesson is about modes of simple resonators such as string and tubes and finally the fourth lesson is devoted to signal digitization.
This MOOC opened first on spring 2018 for 6 weeks. There were important exchanges in the forums and the teaching team was solicited quite a lot. All these exchanges led to important modifications for the second session of winter 2018. Between 2018 and 2021 there were two sessions per year. During the period we observed an important decrease

of the use of the forums and despite a still positive evaluation of the MOOC, the teaching team was no longer in demand. So, we decided to leave it open almost permanently.
Over the years this MOOC had more than 20,000 registrations. However, it didn't it did not completely reach its target since most of high school students in France do not know what is a MOOC. They go much more naturally to platforms such as YouTube. The audience was more teachers, retired people working in the sound domain and curious people. We noticed that the MOOC has been included by some speech therapy schools in their teaching program.

3. SECOND MOOC

The idea for this MOOC entitled "Théorie pour un son – l'acoustique au service musicien" comes from an observation: most of the musicians we met have very little basic knowledge of acoustics. This is a real handicap whether in terms of hearing risk prevention, room acoustics, basics of harmony and the question of temperaments and auditory perception in general. We have therefore designed an introductory MOOC on acoustics for musicians to try to fill these gaps by introducing very little mathematics. This MOOC contains 7 lessons and the total time investment needed is evaluated to 12 hours. As for the previous, each lesson starts with a video putting the subject into context followed by an expert interview. It contains also animations, practical works, exercises, and JAVA applets which can be found independently on JPQ.fr. In the first lesson students are invited to discover the spectrogram with audacity and to make the link with the musical score. Second lesson is about room acoustics and third about decibel scale and the summation of sources and masking. In this lesson is also discussed the question of auditive risks. In the fourth lesson the link between frequency and pitch is explained so that musicians can have an informed use of the tuner. The fifth lesson delves deeper into the subject and addresses the dual perception of pitch: tonal pitch related to frequency and resulting from a counting process and spectral pitch related to the center of gravity of the spectrum and resulting from cochlear tonotopy. Lesson 6, according to Helmholtz, give the physical basis of harmony and discuss the question of tuning and temperament. Finally Lesson 7 addresses the issue of timbre.
This MOOC is open since 2024 and has already been followed by more than 5000 students. As the previous one it has forums but these are almost not used by the users. This is a bit disappointing but this shows that despite a high satisfaction rate, interaction with teachers and other students is not sought.

4. THIRD MOOC

As discussed above, most musicians know very little about acoustics but they also know very little about the making and functioning of their instruments. To try to fill this gap Le Mans Université and the school for instrument making and repair Itemm (Institut Technologique Européen des Métiers de la Musique) join their forces to build a MOOC about making and physics of musical instruments. Firsts lessons will describe the different elements that make up a musical instrument and then the physics of these different elements: exciter, resonator and "radiator". The following courses will deal with specific instruments: piano, voice, guitar, violin and its family, clarinet, flutes, saxophone and oboe, brass, percussions, etc. The MOOC is scheduled to open in 2026, but the different instruments will be covered gradually. For each instrument, the building will be first detailed. Different aspects of their operation will be explained. Our aim is that musicians will find answers about their instruments.
.

5. CONCLUSION

MOOCs are knowledge dissemination tools that can be both rigorous and user-friendly. They allow for the implementation of different learning methods. They are also a way for universities to develop their reputation in their fields of excellence. Our experience at the University of Le Mans, however, has allowed us to identify two limitations to this tool. First, MOOCs are insufficiently known among young people, who are nevertheless the main target audience. We have indeed noted that the very concept of MOOC is unknown to the majority of students, including those in master's programs. Furthermore, one of the advantages of MOOCs is the possibility of having remote interaction with a teaching team, which implies that they can only be open for limited periods. However, our experience has shown that this interaction is not sought by students, which led us to open our MOOCs permanently.

ABSTRACT

Teaching acoustical phenomena, such as the propagation of acoustic waves through different environments, poses many comprehensional challenges for pupils and students due to their abstract nature. Therefore, technical aids play a crucial role in teaching by making acoustics comprehensible and understandable while ensuring learning success. To overcome these difficulties, we present interactive simulation apps that visualize acoustic phenomena and vibrations in essential application areas. These apps enable students to validate the results of hands-on experiments by numerical simulations. The visualization and adaptation of simulation parameters facilitate understanding the underlying physical principles. The interactive apps were initially developed at the Technical University of Munich and employ the numerical software COMSOL MULTIPHYSICS to visualize acoustic phenomena in various fields. During an interdisciplinary cooperation project of the German Acoustical Society (DEGA), students from several universities worked together to create apps related to their respective areas of study, such as noise control, hearing acoustics, room acoustics, and musical acoustics. The apps can be accessed by students and lecturers via the website of the Chair of Vibroacoustics of Vehicles and Machines at the Technical University of Munich (https://apps.vib.ed.tum.de). They are freely available for academic use without license requirements and provide an opportunity to explore acoustical phenomena.

1. INTRODUCTION

The 'junge DEGA' group unites young acousticians in Germany to establish a network and promote professional exchange. As part of this group, a collaborative German university project was initiated to develop interactive acoustics apps for teaching acoustics. The students contributed with the expertise of their supervising institutes, resulting in apps for various sub-areas of acoustics. Based on the existing acoustics apps, which have been developed by the Chair of Vibroacoustic of Vehicles and Machines at the Technical University of Munich [1–4] using the software COMSOL MULTIPHYSICS [5], new apps have been developed to illustrate phenomena in the areas of vibroacoustic, hearing acoustics and musical acoustics. They can be accessed via the website https://apps.vib.ed.tum.de.

2. BACKGROUND INFORMATION

The study of acoustic phenomena, e.g., the knowledge about sound propagation, is associated with some diffi-

culties due to the abstractness of acoustic wave visibility. Certain technical aids help ensure effective knowledge transfer between lecturers and students in the context of school and university teaching. This includes collaborative working and learning in teams, mutual feedback, and the use of active learning methods [6]. The visualization of the phenomena, in combination with practical application, significantly increase understanding of acoustics [7]. The acquisition of expensive measuring instruments and limited access to anechoic chambers restrict the possibility of conducting experiments in teaching. For this reason, interactive learning apps aim to conduct experiments using digital devices. Over time, many different apps were developed to explain acoustic phenomena [8]. The complexity of the problems restricts these tools since they can be resolved only analytically. The multiphysics software COMSOL MULTIPHYSICS allows users to solve problems described by differential equations. Individual geometries and boundary conditions can be modified according to the user's needs. The simulations are calculated on a server and made available to the user via a browser.

3. NEWLY DEVELOPED ACOUSTICS APPS

In the following section, a brief introduction is given to the four apps developed as part of the cooperation project. The interdisciplinary research of the participating institutes resulted in apps dealing with vibroacoustics, musical acoustics, psychoacoustics, and noise reduction.

3.1 Comparison of a Schroeder-diffuser and a meta-surface-based Schröder-diffuser

Mert Dogu, Technical University of Munich

The objective of the app is to compare the Schroeder-diffuser to the meta-surface based Schroeder-diffuser and to illustrate the calculation of the scattering coefficient in the frequency domain. The selected Schroeder-diffuser is based on the primitive root sequence with seven as an odd prime number, which yields a diffuser with six cavities. The study is conducted in two dimensions to reduce the degrees of freedom and, therefore, the computational effort of the simulation. In the case of the Schroeder diffuser, two cases are considered: (1) a single diffuser recessed in an infinite baffle; (2) an array of three adjacent diffusers with a total of 18 cavities recessed in an infinite baffle. For both diffusers, the depths and widths of the indentations can be varied to show the different influences of the geometry. The app offers the possibility to vary the depths and widths of the Schroeder-diffusor and the metasurface-based Schroeder-diffusor to demonstrate different geometrical influences on the sound pressure field. The simulation visualizes the sound pressure and sound pressure level in the room depending on various angles of incidence, varying from $-80°$ to $80°$ per octave band. A visual radiation pattern of the sound pressure displaying the directional characteristic shows the radiation's effect depending on the incidence angle, which can be seen in Figure 1.

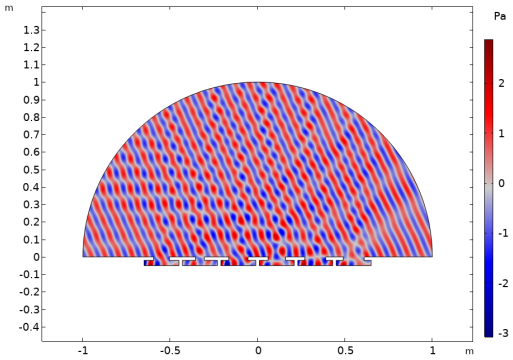

Figure 1. Visualization of the sound pressure field around a meta-surface-based Schroeder-diffuser.

3.2 Simulation of a 'Head-related transfer function'

Mihály Tamás Bárány, RWTH Aachen University

The app calculates the head-related transfer function (HRTF) for a three-dimensional scanned geometry of a human head and torso. Two different simulations are carried out using the Boundary Element Method (BEM), one for the left and one for the right ear so that the differences in sound perception between the two ears can be illustrated. Instead of determining the HRTF by calculating the sound pressure at the entrances of the ear canals for sound sources at certain positions around the head, which would correspond to a measurement setup, the reciprocity principle was applied. In this case, the entrances of the ear canals were each assigned a sound particle velocity in the normal direction, and then the sound pressure was evaluated at positions around the head. This reciprocal approach leads to the same transfer functions as with sources around the head but reduces the number of simulations to only two per frequency. The HRTFs displayed in the app are referenced to the sound pressure measured at the center of the head as if the head is not present. Accordingly, a value of $0\,\mathrm{dB}$ indicates that the body has no influence

on the sound pressure at the ears at a given frequency, while negative dB values indicate shadowing and positive dB values indicate amplification effects, e.g. due to pinna resonances. According to the reciprocity principle, the sound pressure values of the BEM simulation are normalized by the analytically calculated sound pressure of a point source located in the center of the head and whose sound flux corresponds to the sound flux at the ear canal entrances [9].
The app includes three sliders that can be used to adjust the azimuth and elevation angles as well as the distance of the sound source. The selected position is also displayed in a separate window together with the model geometry. In addition to the frequency response, a polar diagram, directivity diagrams and balloon diagrams help to visualize the spatial properties of the HRTF. The polar diagrams show the directivity in the horizontal plane for a given frequency along a circle centered at the center of the head with a radius of one meter.

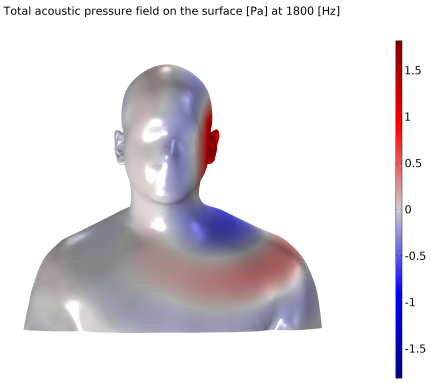

Figure 2. Visualization of the sound pressure field with a sound source in the left ear channel.

3.3 Numcerical simulation of a noise barrier
Tabea Breitkreutz, Louis Heggemann, Hochschule Mittweida, University of Applied Sciences

This app calculates the sound propagation from a sound source along a noise barrier. It shows how sound waves are refracted, absorbed, or reflected at the barrier. The calculation is realized by using the finite element method. A two-dimensional simulation environment was chosen for the display due to the reduced computational effort compared to a three-dimensional calculation domain. The user can change the geometrical properties of the computation domain as well as individually adapt the parameters of temperature and density. The sound absorption coefficient can be entered into the user interface and is incorporated into the model. This app computes numerically the acoustic effectiveness of sound barriers that are used, e.g., to protect neighbors from roadway noise. Analytical approaches calculating noise reduction by noise barriers are delivered by Maekawa [10]. The reference formulas by Kurze [11] and calculation results are displayed in the sidebar. The app shows the cross-section of a sound barrier (see Figure 3), which can be further adjusted in height and thickness using the sliders in a sidebar. Here, the acoustic phenomena of diffraction, refraction, and reflection can be sufficiently well recognized and explained.

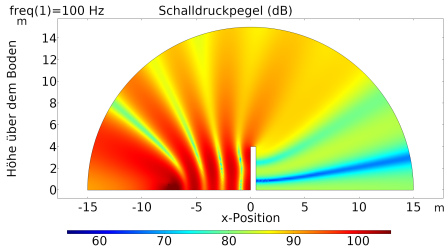

Figure 3. Representation of the sound pressure level at a frequency of 100 Hz, with all sound absorption coefficients set to zero.

3.4 Numerical simulation of the comb filter effect
Luis Enrique Roca Paz, HfM Detmold

The comb filter effect is an acoustic phenomenon that occurs when the same signal arrives at different times at the receiver. This effect is caused by sound reflections from hard surfaces, from multiple sources generating the same tone, or electronically through delay effects and latency. The transfer function between the loudspeakers and the microphones represents the frequency response of the receiver at a specific position and illustrates the effect of comb filtering (see Figure 4). [12]
By using this app, users can explore the influence of various parameters related to the comb filtering effect and observe changes in frequency response in real-time, which helps them to deepen their understanding. The application is also integrated into the learning platform wiki.audio [13, 14]. Wiki.audio is a free online encyclopedia that can be used by pedagogues and audio enthusiasts to easily and intuitively understand various topics in audio technology.

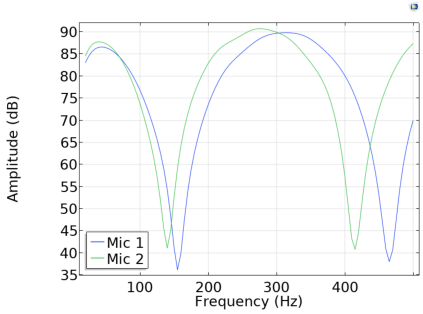

Figure 4. Transfer function of two microphones at a distance of 0.5 meters.

4. OUTLOOK

Students developed acoustic simulation apps using the software COMSOL MULTIPHYSICS during this collaboration project. The apps are related to the research areas of the participating institutes and are intended for use in teaching. For most of the students involved in the project, developing their app was their first experience working with numerical simulation, allowing them to gain many new insights. Through regular meetings and mutual support, they also gained insights into other areas of acoustics.

5. ACKNOWLEDGMENTS

We would like to thank DEGA for financially supporting the project. We would also like to thank the professors from the involved institutes, namely Prof. Dr.-Ing. Steffen Marburg, Prof. Dr. rer. nat. Michael Vorländer, Prof. Dr.-Ing. Janina Fels, Prof. Dr.-Ing. Jörn Hübelt and Prof. Dr.-Ing. Malte Kob, as well as Prof. Stefan Sentpali from the Acoustics Teaching Committee of the DEGA.

ABSTRACT

Many universities offer courses on acoustics and audio signal processing, often with overlapping content. Nevertheless, the lectures and teaching material have typically been developed independently. We present a growing collection of programming exercises in the form of Jupyter notebooks that allow to interactively write and execute code including in-line graphical output such as figures. They can also contain text, equations, and multimedia content. Solutions can optionally be checked automatically using the `nbgrader` package, making notebooks a suitable tool for code-related assignments. Our notebooks are hosted on pyfar.org and are often based on the Python packages for acoustics research (pyfar). Pyfar provides functions for signal processing tasks, as well as for reading, writing, and visualizing audio data. By providing such functionality, it allows the content of the notebooks to focus on core concepts and didactics. Solutions to all exercises will be made available to teachers upon request. We hope that this initiative will foster cross-university collaboration, reduce the workload for educators, improve the quality of assignments through peer review, harmonize the content and didactics of courses across universities, and increase the number of available assignments. We will present sample assignments, the infrastructure behind the collection, and how to contribute.

Keywords: (virtual) acoustics, audio signal processing, open educational resources, python, jupyter notebook

1. INTRODUCTION

Academic teaching is integral to scientific and societal progress because it supports to educate the next generation of researchers and developers for universities and companies. Thus, the quality of education in terms of didactics and content is crucial. However, the conditions for achiev-

*Corresponding author: info@pyfar.org.

ing this goal at the university level are often far from optimal. Depending on the country and the university, newly assigned lecturers frequently must develop their lectures and teaching materials under time pressure due to parallel tasks, such as setting up a new research group and raising funds for future projects. Doctoral students and postdoctoral researchers are also often involved in teaching but face their own challenges—first and foremost the need to complete their scientific work before the end of their mostly fixed-term contracts. In addition, undergraduate students involved in teaching are still in the process of internalizing the concepts and topics being taught and are therefore qualified for limited conceptual contributions.

Cross-university efforts to collaborate on teaching materials could address some of these challenges and potentially improve teaching quality through a collaborative peer review process. Although collaboration and peer review are common in research, we are aware of only a few examples in teaching. One example is the Massive Open Online Course (MOOC) on communication acoustics organized by T9, the nine technical universities in Germany [1,2]. However, this course is not free of charge. A second example is the Acoustics Courseware (acoucou) project [3], which is currently being developed by educational and industrial partners. It aims to provide open educational materials for different levels of expertise. Further, in the field of signal processing and communication acoustics, Spors et al. [4] discussed the open education resources workflow for their courses [1]. Some of these courses are heavily forked. Peer reviews are incorporated, but mostly only within the group of the initial developers. Active outside collaboration is on a very low level, currently.

Integrating programming exercises into lectures is generally advantageous, as it is an important method in engineering or more general in all algorithmic- and data-related tasks. An explicit and dedicated training on this skill will help students to cope with their future challenges in the natural sciences and engineering. Rather than introducing algorithms only in formal notation, actively implementing these often facilitates a deeper understanding of the core concepts behind the particular methods. Hence, solving analytical problems shall be accompanied by solving problems through implementation as this equivalently trains these different skills. Thus, the integration of programming assignments into lectures follows *constructive alignment*, which aims at an "alignment between the intended learning outcomes of the course, the teaching/learning activities and the assessment tasks" [5, p. 95]. At the time of writing, none of the above mentioned projects offers programming assignments in Python that could be integrated into existing or projected lectures. In the following, we propose our initiative to provide such material. By that, we aim at supporting and improving educational collaboration and material.

2. PYFAR OPEN EDUCATIONAL RESOURCES

The pyfar open educational resources, freely available at `pyfar.org`, provide Python-based programming assignments in the form of Jupyter notebooks [2] developed by different institutes from different countries. In the following, we introduce the scope and concepts of the pyfar open educational resources. For detailed technical instructions on how to obtain and contribute assignments, we refer the reader to the open educational resources and contributing section at `pyfar.org`.

2.1 Scope

The pyfar open educational resources are intended to provide programming assignments for acoustics and audio signal processing. At the time of writing, the majority of the assignments focused on virtual acoustics covering topics such as the

- creation of virtual sources using using head-related transfer functions,
- estimation of interaural cues from head-related transfer functions,
- interpolation of head-related transfer functions using local and global interpolation approaches,
- creation of virtual moving sources using vector base amplitude panning,
- creation and rendering of sound scenes using Ambisonics en- and decoding,
- extraction of sound-field parameters (direction of arrival, diffuseness) from microphone array recordings,
- parametric audio rendering such as the spatial decomposition method, and

[2] `https://jupyter.org/`

- room acoustic simulation using image sources and feedback delay networks.

However, we also welcome and encourage submissions from other areas of acoustics including but not limited to audio signal processing, basics of (technical) acoustics, and the measurement of acoustic properties (transfer functions of linear & time-invariant systems, room acoustic parameters, etc.). Many assignments actively use pyfar functionality, but this is not a strict requirement. For assignments focusing on more basic signal processing, such as introducing the Fourier transform or finding the onset of an impulse response, it may be more appropriate to use low-level Python, `numpy`[3] and `scipy`[4] functionality, and pyfar could serve as a reference implementation against which students can compare their own solutions. On the other hand, high-level assignments that aim to introduce more complex algorithms or audio signal processing, such as measuring an impulse response, may benefit from using pyfar functionality directly to hide some complexity in favor of a clearer and shorter presentation of the required processing blocks.

2.2 Concept

Figure 1 illustrates the concept and technical realization of the pyfar open educational resources. The notebooks initially contain the assignments and their solutions. These notebooks are stored in a private (non-public) git repository to prevent an uncontrolled circulation of the solutions. This is important for teachers who grade assignments as part of their course work. Lecturers will be granted access to the private repository, and thereby the solutions, after having proven that they are teaching a course in acoustics or signal processing. The same holds for teachers who want to contribute an assignment (cf. Section 2.3 for details). Solution-free assignments are made available on the open educational resources section at pyfar.org. They can be accessed by students and interested teachers. The `nbgrader`[5] package is utilized to remove the solutions from the notebooks hosted in the private repository before they are published.

2.3 Requirements

Before an assignment is added to the pyfar open educational resources, it is peer reviewed within the pyfar community to ensure that it meets our imposed requirements. First and foremost, the assignment and its solution should be correct, clear, self-contained, and provide at least one scientifically qualified reference for further reading. Apart from that, a few formalities need to be followed to make the assignments more accessible, such as adding author's contact details, stating the required skills, and providing an estimated time in which the assignment shall be completed. Importantly, the notebook must use `nbgrader` to ensure that the solution can be removed automatically. As an additional benefit, `nbgrader` can be used to automatically grade the students' solution, which could further reduce the lecturer's workload. However, this requires well-defined problems suitable for automatic grading and code blocks that test the solutions. Such tests typically require more design effort. Therefore, we leave the use of this functionality up to the lecturer, as it may not be appropriate for all types of assignments. A sample assignment is

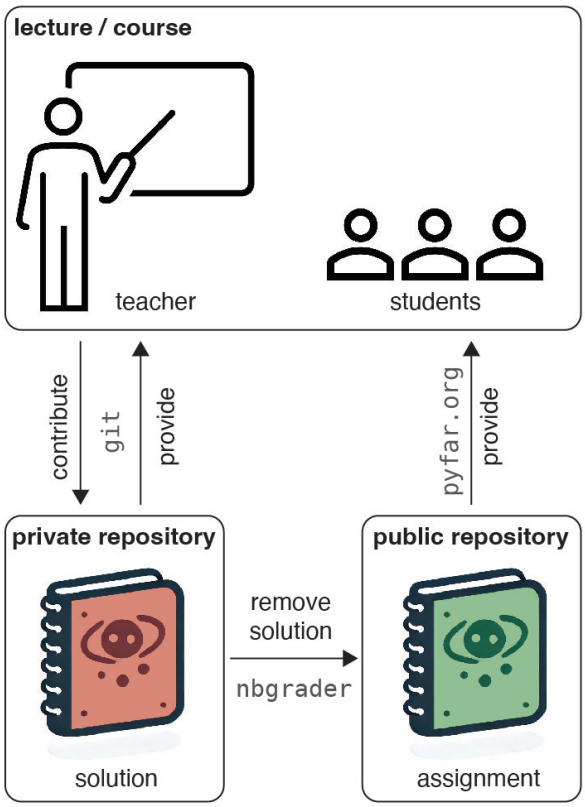

Figure 1. Proposed workflow for providing course materials using the pyfar open educational resources.

[3] `https://numpy.org/`
[4] `https://scipy.org/`
[5] `https://nbgrader.readthedocs.io`

provided to help contributing teachers follow these rules.

2.4 Example

Figure 2 shows a short excerpt from the basic *pyfar challenge* assignment. Like all assignments, it begins with a brief introduction and lists the requirements, the estimated time to complete the task, and the required dependencies. The positions where code has to be added are marked with the comment `#YOUR CODE HERE` and an error will be raised if the block is executed without adding any code. These blocks are automatically generated using `nbgrader` after deleting the solutions.

This specific example might work best as an ungraded assignment at the beginning of a course to familiarize students with Jupyter notebooks, Python, and pyfar. Other assignments could be used in different ways: An assignment could be shown to the class by the lecturer and solved collaboratively during the course. It could also be distributed within a dedicated tutorial to be solved by (groups of) students; or it could be part of the graded course work.

3. CONCLUSION

We introduced the pyfar open educational resources containing programming assignments for teaching (virtual) acoustics and audio signal processing. The assignments are collaboratively developed, maintained, and peer reviewed across different institutes and countries. This may help to improve the quality of teaching and simultaneously reduce the workload of lecturers. The assignments are freely available from `pyfar.org`. At the time of writing, assignments mostly covered topics in virtual acoustics, but we warmly welcome contributions from all other areas of acoustics.

APPLICATION OF ROOM ACOUSTICS SIMULATION SOFTWARE IN UNIVERSITY TEACHING

Lukas Aspöck* **Pascal Palenda** **Janina Fels** **Michael Vorländer**

Institute for Hearing Technology and Acoustics, RWTH Aachen University, Germany

ABSTRACT

Room acoustics simulation software has become an established tool for researchers and consultants. Although such software applications are often regarded as expert tools, they can be effectively integrated into university courses focused on room acoustics and simulation techniques. At RWTH Aachen University, the RAVEN software environment — a C++-based simulation that utilises a hybrid approach that combines the image source model with an efficient ray tracing algorithm — was initiated over 15 years ago. Today, RAVEN is employed in various teaching and research activities and features multiple interfaces, including a MATLAB interface that enables script-based configuration of simulations. Its integration with the 3D modelling software SketchUp creates an interactive environment where students can immediately experience the effects of changes to room designs. This interface allows students to quickly access their first room simulation and auralization, facilitating the incorporation of the software into courses. Currently, it is used in block courses, laboratory sessions, and as a demonstration tool during lectures — not only in Aachen but also at several other universities worldwide. This work summarizes the challenges and opportunities associated with the application of RAVEN in an educational context.

1. INTRODUCTION

As nowadays, most people spend the majority of their time indoors, room acoustics is of particular relevance in many locations, e.g., in classrooms, in workplace environments or in restaurants. For this reason, the traditional field of room acoustics is even today a part of almost every lecture series related to acoustics. It is popular as it contains concepts which are rather easy to grasp (such as specular reflections or the reverberation time), phenomena which are well-defined and understood such as rooms modes, but also less intuitive and more complex aspects such as the spatial perception of sound in rooms or the description of diffuse sound fields, which are also the topic of current research.

In typical environments we experience in our daily lives, the room acoustics can vary substantially. For the sole purpose of demonstrating the role of absorption, volume and reverberation time, the use of simulations and the tool of auralization in the context of acoustics courses is an effective approach to teach students about room acoustics.

While many (commercial) tools for room acoustic modelling exist since the 1990s [1], many of these tools are (understandably) designed for use by experts and do not have interfaces that allow them to be quickly learned and used in courses. This work introduces the room acoustic simulation software RAVEN [2] and how it is applied in university teaching.

2. THE SOFTWARE ENVIRONMENT RAVEN

The RAVEN (Room Acoustics for Virtual ENvironments) software modules were originally initiated by the Institute of Technical Acoustics at RWTH Aachen University by Dirk Schröder and supervised by Michael Vorländer around the year 2005. The main simulation concept

is based on a hybrid model including the image source model for the specular reflections and a ray tracing algorithm for the diffuse and later part of the room impulse responses. The ray tracing algorithm is extended by a diffuse rain model efficiently determining the amount of scattered energy projected to the receiver. The underlying models have already been developed and elaborated in earlier research projects, successively by Vorländer and Heinz under guidance by Heinrich Kuttruff [3–6] and by Schmitz under guidance of Michael Vorländer [7]. The most comprehensive documentation of the main software library is included in Dirk Schröder's PhD thesis [8].
After its initial phase, in which the base functionality for a GA-based room simulation was implemented, the software was extended with various interfaces and integrated in (VR) applications [9, 10]. The efficient implementation of the room simulation and the synthesis of binaural room impulse responses makes it possible to render auralizations in real-time. A MATLAB interface allows script-based configuration and operation of simulations, making it a convenient tool for researchers - a Python-based interface is currently in preparation. At the moment, the software is not an open-source project, but freely available for academic, non-commercial purposes.

2.1 The SketchUp interface

A plug-in for the 3D modelling software *SketchUp* was created with the intention of providing an easy-to-learn user interface to control a room acoustic simulation and efficiently modify the simulated scene (positions, geometry, boundary conditions). The plug-in's interface, integrated into the *SketchUp* environment, is shown in Fig. 1. By transferring all acoustically relevant information from SketchUp to a C++ application, running in the background, room acoustic parameters and reflection paths can be efficient visualised [11] while the user is able to modify the scene within *SketchUp*. Additionally, room impulse responses for defined positions can be exported, or directly applied for auralizations, either for the static situation, or interactively while the receiver position is moving or the scene is modified [12].
This interface, supported by a basic documentation and a tutorial, makes the RAVEN software suitable for application in university courses, also by students without a background in computer science, engineering or acoustics.

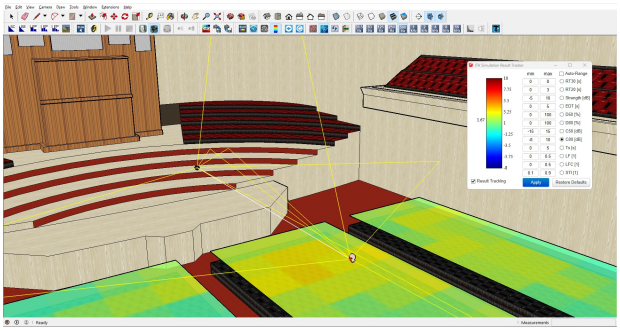

Figure 1. *SketchUp* interface of RAVEN - a simulated concert hall with visualized room acoustic parameters (here: C80) and first order reflection paths.

2.2 Tutorials and examples

Both, for MATLAB as well as for the SketchUp interface of RAVEN, tutorial procedures have been created in English language. The MATLAB tutorial, which is provided in the software's documentation folder, is complemented by various example scripts in the git-repository of the ITA-Toolbox [13] (www.ita-toolbox.org). As the MATLAB interface is mainly intended for researchers, who can be considered as expert users and who typically spend a longer period of time working with the software, the MATLAB interface is rarely used in courses, but frequently applied as a tool in final thesis projects (inside and outside of RWTH Aachen University).
The tutorial document [14] for the SketchUp interface currently includes 17 sections, starting with general information on the involved tools and a very brief introduction of 3D modelling in SketchUp. The main part of the tutorial explains the required steps to start, control a evaluate simulations and auralizations. Completing the tutorial takes around 45 to 120 minutes, depending on the previous experience of the user with SketchUp and room acoustics simulation. The steps of the tutorial also have been recorded and published on *YouTube* [15]. RAVEN's SketchUp tutorial is complemented by a short exercise, which includes the task to run and adjust a simulation of a typical concert hall.

3. APPLICATION IN UNIVERSITY COURSES

Today, RAVEN is used in academic courses related to room acoustics, virtual acoustics and/or auralization at various universities. In these courses, the contents related

to the application of RAVEN range from just demonstrating room simulations and auralizations (by following the tutorial), to specific exercise tasks and project-style group assignments, e.g., the design of a concert hall, theatre or a rehearsal space.

3.1 RAVEN at RWTH Aachen University

For a period of around 10 years, the RAVEN software has regularly been part of two courses at the Institute for Hearing Technology and Acoustics. The first one is a laboratory course on *Acoustic Virtual Reality*, where each semester eight students from electrical engineering learn about the concepts of room acoustic and corresponding geometrical acoustics-based simulation and auralizations. As part of one out of eight experimental session of the course, the students first have to investigate the difference between RAVEN's hybrid simulation model to a previously implemented simplified image-source model [16], before they are asked to investigate the stochastic error of the simulation and its dependence on the number of ray tracing particles. In a final step, the students have to check the impact of an occupied seating area in contrast to an empty concert hall.
The second teaching activity is a one-week block course on room acoustics, which is attended by 30-40 students from architecture, electrical engineering and sound engineering. In this course, students learn about the fundamentals on room acoustics, related regulations as well as measurement and simulation techniques until on the third day. Afterwards they form (if possible) interdisciplinary project groups to design (performance) spaces, where room acoustics are of critical relevance. The project scenarios are usually adapted examples from past editions of the ASA student design competition (Newman Student Award Fund). During the block course, the students are provided with the RAVEN software and can use it to design and improve the acoustics of the designed venue. The application of RAVEN for their projects is complemented by other tools such as equation-based approaches (implemented in spreadsheets) or by web-based applications (e.g., the *amray* Raytracing Sketchpad [17]) which can easily be accessed by the students, supporting their design decisions.
In addition to these courses, the software has also been applied at RWTH Aachen University in seminar work of architecture and electrical engineering students, as a demonstration tool in lectures and laboratory tours, and in numerous final thesis projects (BSc & MSc).

3.2 RAVEN used by other universities

In recent years, RAVEN has been also integrated in or been part of courses in Australia (the University of Sydney), in the UK (University of Edinburgh), in Spain (Universitat Politècnica de Catalunya) and on a regular basis at the Slovak University of Technology in Bratislava. At TU Berlin, HS Düsseldorf and HfM Detmold (all in Germany), the software is also frequently applied in final thesis projects. During the EAA Summer School 2023 (part of Forum Acusticum 2023 in Turino, Italy), the software was integrated in the course on Auralization.
At the Slovak University of Technology in Bratislava, RAVEN is used as a tool in a yearly course for around 15 students from architecture and civil engineering - these students work in larger groups with the task to design rooms in various types of buildings such as music schools, primary schools, university buildings and concert halls. Rooms of these buildings are evaluated with respect to room acoustic parameters required in the corresponding standards and recommendations, and compared to good practice example projects. In some cases, students with a focus on building services or building technology are asked to conduct a parametric study (working in smaller groups) to investigate the influence of various factors on room acoustic parameters, e.g., the influence of volume vs. average sound absorption coefficient and shape, etc.

4. SUMMARY

This work introduced the room acoustic simulation software RAVEN and summarized how it is applied in teaching activities. In general, it is a challenge to implement software, which is not only intended as a research tool, but can also be used in teaching, not only as a tool to demonstrate and explain room acoustics (and its simulation), but also during hands-on exercises in which the students can learn how to run room simulations in a short amount of time and directly use for short studies and projects.
When teaching courses that involve the use of the software, it is essential to ensure that despite a quick and rather short introduction to the software, the students learn how to use the simulation correctly. They need to be made aware of uncertainties, the limits of the simulations and possible errors in the simulation results.
After years of application, based on positive experiences and feedback, the additional effort for specifically creating interfaces and documentation can be considered as worthwhile. However, similarly to other software solutions that

have been in use for many years, the frequently changing staff at the university and dependencies on third party software packages and operating systems are challenges that need to be tackled on an ongoing basis to ensure that the software can continue to be used in teaching.

5. ACKNOWLEDGMENTS

The authors would like thank the developers of RAVEN, especially Dirk Schröder, Sönke Pelzer and Ralf Schallenberg for remarkable efforts during the implementation of the main parts of the RAVEN software and the SketchUp interface. Thanks also to Vojtech Chmelík from the Slovak University of Technology in Bratislava for providing details on the usage of RAVEN in their courses.

AL-ÁNDALUS. SPREADING ACOUSTIC KNOWLEDGE FROM SPAIN TO WESTERN EUROPE

Walter A. Montano Rodríguez[1*]

[1] Acoustics Measurements, Laboratory, ARQUICUST. Gualeguaychú, Argentina

ABSTRACT

During the Early Middle Ages, while in Western Europe science was almost forbidden, in al-Ándalus scientific knowledge flourished, not only for translating Greek philosophers into Arabic, but also for being free to practice art and technology. The first transference from there was the ten digits numeral system adopted in the 11th century, and the milestone is the translation from Arabic to Latin of Euclid's Elements book. In those years the study of sound waves was embedded in music or mathematics, it was not a separate discipline, then to understand their achievements in acoustics a closer look at their writings is needed, of which the few that survived are in the library of *El Escorial*. In al-Ándalus, there were several schools of music, and some of the teachers were craftsmen who made musical instruments, many of them required skills and acoustic knowledge to be designed. The list of scientific contributions made by Moorish Spain to the West is almost endless, and this paper will focus on how they interpreted the translations of the Greeks and their learning and development of the sound wave physics, which became part of the acoustical knowledge.

Keywords: *history of science, al-Ándalus, acoustics, music.*

1. INTRODUCTION

The Iberian Peninsula was militarily occupied by the Muslims in 711, who later introduced, in addition to their religion, the practice and theory of knowledge that the Arabs philosophers had, some of it taken from the writings of the Greek philosophers, whose reading was forbidden in Western Europe. This article only mentions that the study of ancient Greek philosophy was forbidden in Western Europe, it will not go deeper, nor will it comment on the political and/or religious situations that motivated such prohibitions for centuries, a period that until a few years ago was pejoratively called the "Dark Ages," which is now known as the "Early Middle Ages," a historical interval that spans from the fall of the Roman Empire to the 10th century. These occupied territories took the name of al-Ándalus, being Córdoba the city that stood out in the arts and sciences, which sheltered libraries with documents brought from Turkey, Persia, and the rest of the Arab world, among them the translated writings of the Greek philosophers in Arabic.

Regardless of the coexistence between Christianity, Judaism and Islam, which certainly did not have social and/or economic equality in those occupied territories [1], here it will be highlighted those areas in which sound and music were developed in al-Ándalus as a means of cultural expression and human knowledge.

This article is a meta-analysis based on firsthand secondary sources (free available from the Internet), and it is part of a side research started later in 2022, which is conducted by the author who is publishing the history of the acoustics in Spain, in the Acoustics Journal of the *Spanish Acoustical Society*.

2. SOUND AS A PART OF MUSIC INSIDE OF THE QUADRIVIUM

The *Quadrivium* comprised arithmetic, geometry, astronomy and music, and this article is focused on highlighting the scientific contributions that were made in al-Ándalus, in the field of wave phenomena from music, because in the Early Middle Ages physics, and much less acoustics, were not individualized as knowledge since its

theoretical content is embedded in the texts of practical and/or theoretical music written by the Arabs, it is not possible to pinpoint a right place of their theories, and here is shared a summary of what could be unearthed from the main music's treatises known in al-Ándalus, by the most prominent thinkers who subsequently were spread in Western Europe, which ultimately shaped the science that prevailed in the Renaissance and the Enlightenment.

All Arabs books and manuscripts on music include writings which in modern words we could identify as behavior of waves, some translated from Greek texts (and corrected or expanded) and many others elucidated by the Arabs themselves. Those writings were brought mostly from Persia and Turkey to al-Ándalus, as books and treatises written in Arabic were gradually translated into Latin – mostly at Toledo– first spread them from al-Ándalus to Bath and Oxford (in England), and later to France and the rest of medieval Europe.

Certainly, the Arabic thinkers analyzed here, using craft techniques of "trial and error" applied to improve the loudness of musical instruments, accumulated basic knowledge of musical acoustics (in modern words) that is revealed in their writings, i.e., they did not describe a section on physics, but rather the explanation of wave physics is deeply inserted in their musical treatises.

3. MUSIC AND SOUND TREATISES IN AL-ÁNDALUS

One of the firsts books which highlight the Arab legacy on Western culture, was published in 1875 under the title "The intellectual development of Europe," where is discussed the crucial role that Arab scholar played in the preservation and translation of ancient knowledge, protecting many Greeks and Romans texts (mostly at Egyptians, Persians and Turkish libraries) that might have otherwise been lost [2]. This book emphasizes that the Arab world not only preserved those texts but also expanded upon them, making significant contributions to various fields, and discusses the influence of Arab music on European culture.

Also, it highlights how Arab musical traditions and instruments significantly impacted on Western European music, during the Early Middle Ages and beyond. Arab instruments such as the lute ('ud in Arabic), the guitar (qitār), and the rebec (rabāb) were introduced and became integral to European musical development. Besides, it notes that the transmission of these musical elements occurred through cultural exchanges between Iberian Peninsula and other regions which enriched European music, contributing to its diversity and evolution [2].

In the opinion of the author of this article, four are the most important personalities who would be highlighted as the main thinkers of the Arab world in producing philosophical treatises on music and sound (which was used in al-Ándalus), in chronological order they are: Ziryab, al- Kindī, al-Fārābī, and Avicenna.

3.1 Ziryab and the school of music at Córdoba, the first in Europe

Abulhasán Ali ben Nafi (789–857), nicknamed Ziryab, was born in Baghdad. He arrived in al-Ándalus circa 822 and settled in Córdoba city, where he started a revolutionary age of several cultural changes. Among dozens of contributions, he made significant ones in the field of sound physics, particularly musical theory domain and instruments design.

According to the Royal Academy of History of Spain[1], his major contributions were in the art of music: "He made some modifications in the construction technique of the lute, adding a fifth string and reducing its weight with thinner woods with better resonance" [6]. He improved the sound quality of the lute and some other chordophone instruments by using new materials, not only for their frames or bodies, but also for the strings.

He created around 850 in Córdoba, what is considered the first school of music in the world, which was revolutionary both in its time and today, because it was open, did not depend on any religion, and people of both sexes studied.

From some sources [7] [8] [9] it is possible to outline that his direct contributions to acoustics may not be easy to pinpoint, his innovations in designing musical instruments and performance techniques likely had implications for sound production and perception; he concentrated on the theory of composition, chords, rhythms, etc., so that music were pleasant to hear for the human mind.

Regarding musical acoustics, it is credited that Zyrab improved the *nuba* (*nawba*) style, by introducing a structured suite based on modal principles, distinct rhythmic cycles within movements that feature tempo acceleration, and integration of instrumental and vocal elements. Then, these can be understood as a move towards structured musical sequences within a modal framework. Acoustically, the nuba results in a musical form with a defined harmonic color, rhythmic complexity, dynamic contrast, and a rich timbral environment.

His emphasis on the quality of sound and the nuances of musical expression suggests an understanding of basic

[1] In 1738, thanks to the enlightened action of various eighteenth-century personalities, the *Royal Academy of History of Spain* was founded.

acoustic principles; for example, the lengthening of the neck of the lute contributed to the improvement of other stringed instruments, it's likely that Ziryab's modifications were informed by an understanding of acoustic principles, such as string tension, resonance, and sound projection.
While specific details about Ziryab's direct contributions to the field of sound physics and musical notation, may be limited due to historical context, his innovations in musical theory and instrument design had an impact on the understanding and appreciation of waves behavior.

3.2 Works of al-Kindī

According to the Stanford Encyclopedia of Philosophy, *Abu Yusuf Ya'qub ibn Ishaq al-Kindī* (800–873 C.E.) was the first self-identified philosopher in the Arabic tradition (and one of the most prolific writers), and the first to translate Aristotle into Arab. Although he initially borrowed ideas from the Greeks on music and wave physics, he developed, deepened and went beyond what they contributed, improving the theory of sound and its perception.
As it is cited in [3], contrary to the Greeks, he proposed that sound is a form of wave motion "similar to how waves form when you throw a pebble into a pond;" al-Kindī theorized that when an object vibrates, it causes the air around it to also vibrate, and these vibrations spread outwards in a spherical pattern, forming waves of compressed and rarefied air. He recognized that air acts as the medium for these sound waves, transmitting them from the source to our ears. Al-Kindī's theories were remarkably accurate for its time (considering technological limitations), he also theorized that when these sound waves reach our ears, they cause our eardrums to vibrate; then, those vibrations are then translated into signals that our brains interpret as sound [3].
A brief summary of his works on music theory (he wrote at least seven treatises) is presented in [4], where is described how al-Kindī found a scientific approach as well, because one of his aims was "to find a logical explanation of the peculiarities of sound grouping;" he also observed "how harmony is produced by the arrangement of specific notes." Al-Kindī "noticed that each note carries a precise pitch and that those notes with a very high or a very low pitch do not fit in a harmonious manner." Then, he concluded that it is necessary to create an explanation on how to establish a pitch, a revolutionary thought at that time, formalizing the use of the notes by alphabetic names which opened the scientific description of musical instruments by means of the instrumental tablature, the basis of manufacturing instruments, and centuries later this was the most important tool for the tempered system.
Links between music and mathematics are deeply analyzed in [5], where it is explained that al-Kindī reached a blend of scientific observation and mathematical reasoning, when he explored the relationship between the pitch of a sound and the length of the string that produces it. By the available means of his time, he meticulously calculated the precise mathematical ratios that correspond to different musical intervals, developing a system for tuning musical instruments, particularly the 'ud (the lute), being a pioneering acoustical tool, because he came up with his own ideas. It is important to mention that he used for all mathematical reasoning the Hindu numeral system.
Al-Kindī's thoughts on sound physics (music) were accurate for the 9th century, and it laid the foundation for later medieval philosophers to further develop the understanding of acoustics. While he didn't have sophisticated tools that we have today to study sound waves, his logical reasoning and observations led him to a groundbreaking discovery.

3.3 "The great book of music" of al-Fārābī

Perhaps the most relevant and influential treatise on sound and music from the Arab world, was written by *Abū Naṣr Muḥammad ibn al-Faraj al-Fārābī* (870–950 C.E.) titled *Kitāb al-Mūsīqā al-Kabīr* (The great book of music), which the only surviving copy is in custody at *El Escorial* (part of the Spanish National Library–BNE). There are three other musical treatises in other European libraries.
It is important to highlight that al-Fārābī for the Arab world is considered as "The second thinker," being Aristotle the first one. He wrote extensively on music theory, exploring the mathematical and physical principles underlying musical sounds.
According to [10] [11] al-Fārābī writings are being reviewed and revisited, in order to make a distinction among what he borrowed from the Greeks, what he corrected and what are his own contribution to the field of music and sound, because the fact that he gave detailed information about instruments and surpassed the Greeks in the field of sound physics gave him a place in the history of music [11].
Al-Fārābī's work on the physics of sound built upon the knowledge of earlier Greek philosophers like Aristotle, but he is the thinker least influenced by the ideas about music and sound of Pythagoras or Plato [11]. Criticizing the Pythagorean concept of music, he discussed the distinction between practical and theoretical music and emphasized the importance of understanding the physical foundations of sound, because he recognized the significance of sound as a

physical phenomenon; then, he recognized the significance of a sensory foundation for theoretical music.

According to a philosophy of music research on al- Fārābī's work [12], he discusses the relationship between practice and theory of music, and also between the composition and performance of music, and the justification that he gives about that in modern words could be said to belong to psychoacoustics, since "the fact that theories come after sensory experience in the temporal sense does not render reason completely useless or trivial in musical analysis" [12]; then, he expanded on his analysis, including distinctions between sensation, imagination, and reasoning in classical theories of the soul in the study of music (as Greeks did it).

As a music theorist, al-Fārābī conceptualized that music brings together many aural experiences, because tones, melodies, and intervals are indeed dependent on sensation and imagination, meaning that both the inductive method (melody has rational principles), and the deductive method (taking the principles to the individual melodies), both have to be used. This last statement has a deep meaning to human knowledge: It was one of the first times that it was proposed to have the reasoning of the Scientific Method.

While not explicitly focusing on modern physics, his insights into propagation and nature of sound were significant for his time. A few key points on the physics of al-Fārābī's on sound: He realized that sound originates from vibrations, whether produced by the human voice, musical instruments, or natural phenomena. He described how these vibrations travel through the air, creating sound waves. He understood that a medium, such as air or water, is necessary for the transmission of sound, he explained that the denser the medium, the faster sound travels.

While al-Fārābī's contributions to acoustics are significant, it's important to note that his work primarily focused on the theoretical aspects of music rather than practical acoustics or physics of sound. However, his exploration of the nature of sound and its relationship to the human psyche laid the groundwork for future developments.

As a general summary of al-Fārābī's work, he examines the production and perception of sound, contributing to the understanding of the underlying principles of music, writing extensively on music theory, including the physical properties of sound, the mathematical relationships between notes, and the psychological effects of music.

Al-Fārābī left a lasting legacy in the field by moving away from mystical explanations of music and focusing (in modern words) on the physical principles that govern sound.

3.4 Ibn Sina (Avicenna) and his "Book of healing"

Abū 'Alī al-Husayn ibn 'Abd Allāh ibn Sīnā (980–1037 C.E.) or Avicenna, highly influenced by al-Fārābī's, he made significant contributions to the understanding of sound propagation and acoustics, Avicenna works on the nature of sound and its transmission through different mediums helped to lay the foundation for many developments in acoustics. His writings on music theory, such as the *Kitāb al-Shifā'* ("Book of Healing" or "The physics of the healing" for some translators), explored the relationship between music, mathematics, and the natural world [13], and it is a comprehensive encyclopedia which covers a vast range of subjects [14] [15], including medicine, philosophy, astronomy, music and physics.

He discussed the mathematical principles underlying musical scales and intervals, as well as the physiological and psychological effects of music on the human body. It's important to note that Avicenna's primary focus was on music theory and its philosophical implications on human behavior (following the al-Fārābī's work). His insights into sound propagation, including reflection and refraction, were likely integrated within his broader understanding of acoustics and their relation to music and human experience.

Avicenna describes sound as a form of vibration that travels through the air, explaining that sound is produced when an object moves and creates a disturbance in the surrounding medium, typically air, then, sound waves propagate through different media, highlighting that the speed and quality of sound can vary depending on the medium it travels through, such as air, water, or solid materials; all of his explanations were primarily qualitative rather than quantitative.

Avicenna also discusses the phenomena of sound reflection (echoes) and refraction (bending of sound waves), demonstrating his understanding of how sound waves interact with different surfaces and materials, providing a framework to understand that sound as a wave-like disturbance.

Avicenna was interested in movement phenomena and its measurement; he based his analysis on two concepts: rapidity and slowness. As cited in [16] he distinguished between the speed of light and of sound: "Thunder can be seen and heard. Thunder (lightning) is seen at one time, but heard at another, after it (the sound) has moved in the air and gradually reached the hearing." In other words, he established the difference in the speeds of the two forms of movement of matter.

It's important to note that much of Avicenna's work on sound is linked to his philosophical and musical investigations. He explored the relationship between sound, music, and the human soul, considering how music can

evoke emotions and affect the human body (In modern words: a journey between musical acoustics and psychoacoustics), and while his explanations may differ from modern scientific concepts.
Avicenna's work played a significant role in the history of acoustics.

4. EARLIEST WESTERN PHILOSOPHERS WHO USED TRANSLATED ARABIC TEXTS

As cited in [17], the first known translation of philosophical manuscripts from Arab to Latin were made by Adelard of Bath, an English philosopher, during the 12th century introducing ancient Greek texts which had only existed in Arabic form to Western Europe. Among his translations, the most influential work was of Euclid's Elements (text used for eight centuries), and the second is the introduction of the Hindu ten digits numeral system and the zero.
Roger Bacon (1214–1292) is the most prominent philosopher and thinker in disseminating the contributions of the Greeks, which he made known through his great philosophical works with translations into Latin that were made in al-Ándalus, or by translating himself directly from Arabic. Concerning the interpretation of the texts that he translated into Latin, they were not always correct, Bacon himself shared an anecdote about the misinterpretations of the translations: "When I lectured on this in my classes but did not know how to explain it, as was required, my Spanish students derided me. I later learned from them that [the name] was not Arabic, as all the doctors believe, but Spanish, and [the plant] is seed of henbane" [18].
Based on al-Kindī's treatises on Hindu-Arabic numerical notation, Roger Bacon is one of the first to promote its use to leave aside the Roman one (which used letters), saying that it is good for science and academic learning. As cited in [19], Roger Bacon along Robert Grosseteste (1175–1253), based mostly on al-Fārābī's work, they were the first to conceptualize the importance of practice and experimental actions in science, merging the mathematical method with the experimental one, thus beginning the qualitative method in scientific research centuries before Francis Bacon.
Concerning sound physics [20], Bacon applied the term "algorithm"[2] to explain the step-by-step resolution of mathematical problems with algebra (to elucidate sound refraction and other matters), and the result obtained through these procedures he identified as *secundum computistas* (computed afterwards).
Although Greeks wrote about a grammar in music, later improved by Arabs, it was Roger Bacon who gave it a scientific form by incorporating mathematical logic, initiating the idea of meter and rhythm in music in Western Europe, saying that sound is part of music (reinforcing the Quadrivium); at the same time, it can be established that Roger Bacon in the 13th century is the first philosopher who grants the study of sound the entity of a scientific nature.
Among several of his contributions, Roger Bacon formalized the study of sound waves by stating that they do not propagate like a ray because do not have a linear pathway, but he did conceptualize that sound "can be studied as the path of a ray" [20] [21]. *Note*: Roger Bacon use the word "species" to describe rays.

5. DISCUSSION

It is well known that in the Early Middle Ages in Western Europe, the reading of Greek philosophers was forbidden (it was considered as pagan literature), then their writings were completely unknown; the opposite happened in Arab culture. Henry G. Farmer, a renowned researcher on Arabian music, in 1930 stated that the musical treatises of Greeks thinkers were well known among Islamic intellectual circles, and this familiarity was expressed in many of their writings, since Arab thinkers borrowed some ideas from the Greeks, but this does not take away from the originality of their contributions to scientific knowledge, and "al-Fārābī's treatment of physical and physiological principles of sound and music, is certainly an advance on that of Greeks" [22].
The Moorish culture were not mere transmitters of Greek heritage, but rather refiners and creators, who considerably contributed to the foundations of the later Western science, because scholars from European regions went to al-Ándalus (Spain) to study or seek books at Toledo's libraries, then they disseminated to the West the knowledge kept there.
Arabs' theories were accurate in those years and laid the foundation for later thinkers and philosophers of Western Europe (those that emerged in the Renaissance and the Enlightenment) to further develop our understanding of sound waves and acoustics. While they didn't have sophisticated tools that we have today to study sound waves. Their logical reasoning and observations led them to groundbreaking discoveries in the acoustics field. Therefore, it is important to understand that the concept of

[2] Word derived from Al-Khwarizmi, the Arab thinker who introduced the idea of solving arithmetic problems by methodical, step-by-step approach.

waves they had was not understood in the same way then, as it is now.

For some researchers it might seem that many of the contributions made by Ziryab, al-Kindī, al-Fārābī, and Avicenna, they are more focused on musical acoustics than on the physics of waves themselves, but it is important (once more) not to forget that until the Enlightenment sound itself was part of the music, not an individual entity.

All the sources consulted for writing this article agree on one thing: al-Fārābī was the first to give a scientific explanation of sound and to draw up rules for the construction of musical instruments, and "Fārābī made a valuable contribution to physiological acoustics which was not touched by the Greeks" [23]

As mentioned in this article, manuscripts translated from Greek-Arabic and Arabic-Latin are being revisited, not only to better decide how these texts were originally written, but also to find out what contributions were made by Arab philosophers; also, many are being translated directly into English from Arab [24]. Therefore, in the coming years it will be possible to update what is known about the contributions of the Arabs to the science and knowledge.

The way of interpreting the teachings that the Moors had in al-Ándalus had a great impact on the Iberian populations, because when, in the 13th century, the first kingdom of the future Spain could be formed, in order to establish its political power, King Alfonso X *El Sabio* (The Wise) created the first Spanish university in 1254 at Salamanca, which was also the first university that was not dependent on the Catholic Church, like the other three at that time, and also the first to have a Chair of Music [25].

6. CONCLUSION

Unlike the study of medicine, law, astronomy, and other disciplines, that were individualized in the Early Middle Ages, sound and wave physics were not studied separately (acoustics did not even exist as a field of knowledge). Since the study of sound and the behavior of elastic waves were not independent matters during those years, in the texts written by Arabs philosophers these theories are embedded and deeply rooted in their musical treatises, and to a lesser extent in medical ones (those who studied the curative use of music), perhaps for this reason an in-depth study and analysis of those writings is still pending.

Although not strictly "acoustics" in the modern sense, works of these Arabs scholars were an exploration of the physical manifestations of sound, and in essence, advanced the understanding of sound and acoustics by:

- Applying mathematical principles to music theory.
- Exploring the physical and psychological effects of music.
- Systematizing musical knowledge and practice.
- Contributing to the development of musical instruments.

The purpose of this article is to begin this discussion because **ultimately music is part of the creation of sounds**, and also, in a way, to recognize the contributions of those Arab thinkers whose works on music were translated in al-Andalus (from Arab into Latin), and whose ideas spread from Spain to Western Europe through European scholar's sway, leading to the Renaissance and the Enlightenment.

MUSIC STUDIES IN 1254 AT THE UNIVERSITY OF SALAMANCA. AN AL-ÁNDALUS LEGACY

Walter A. Montano Rodríguez[1*]
[1] Acoustics Measurements, Laboratory, ARQUICUST. Gualeguaychú, Argentina

ABSTRACT

The first university in Spain, the fourth in Europe, was founded in Salamanca in 1254, and among the persons mentioned in its Royal Charter to teach, one of them was an "organo teacher" ("maestro en organo") this was a uniqueness because in the 13th century music was taught only in churches and monasteries. Its existence is not a coincidence, because this novel university replicated the way of learning in al-Ándalus, where music was taught and played outside religious life. That fact was worldwide known in 1720 when *The history of Spain* was published and since then, some have debated whether it was a "chair of music" and whether the "organo teacher" taught theory. Considering that in the Quadrivium the physics of sound was not independent, it could be inferred that principles of acoustics was taught there in 1254. In this paper it will be demonstrated that it is not a semantic question of interpreting words, but of interpreting them in the historical context that was written, then it can be assured that it was a professorship, and by the counterfactual in this chair of music was taught the theory of sound/music, just as it was done in al-Ándalus.

Keywords: *history of science, al-Ándalus, acoustics, music, University of Salamanca.*

1. INTRODUCTION

Spain was built with the fusion of kingdoms and crowns that existed in the Iberian Peninsula, and one of them organized in the early 13th century was that of Castile, (*Castle* in English, named for the large number of castles in that region), which, to ensure its linguistic and political identity, King Alfonso X *El Sabio* (The Wise) created in 1254 at Salamanca city the first Spanish university, being the fourth in Europe.

Contrary to the rest of the European kingdoms of that time, authorities, universities, institutions and the Vatican itself, which used Latin as a cultured language for official written and oral communication and also for teaching, Alfonso X "through the work of his *scriptorium* and the dissemination of documents from his chancellery, left this prominent position to Castilian" [1] (Castilian as a language of Castile); hence the use of Castilian language[1] in the first-born University of Salamanca. This decision is evidenced by a copy of the original manuscript of the Royal Charter, which is written entirely in Castilian language.

The first history of the University of Salamanca was written by Pedro Chacon in 1569, which mentions also the "maestro en organo" [2], but according to an in-depth analysis of his manuscript published in 1990 [3], the text was biased and tendentious, perhaps to please the authorities (who were in power in the year this manuscript was written), making it an unreliable source of information. Another book discarded as a source was published in 1855 by Mariano Soriano Fuertes [4], mainly because his investigation relied on *Virgilius Cordobensis* (a.k.a. Virgilio), an apocryphal writer, who supposedly wrote about the creation of the Chair of Music at University of Salamanca, and other issues linked to this matter, as if he had been contemporary [5].

Since it is necessary to increase the importance of this Chair of Music at the University of Salamanca in 1254, the author proposes this discussion, because ultimately music is the creation of sound. This article is a meta-analysis based on

[1] Centuries later "Castilian" language gradually changes its name to "Spanish" language. After the creation of the Royal Spanish Academy (RAE) in 1713, contributes to the standardization and promotion of the term "Spanish" instead of Castilian. The RAE is Spain's official royal institution with a mission to ensure the stability of the Spanish language.

primary sources (old, digitalized manuscripts available on the Internet), and it is part of a side research started later in 2022, which is conducted by the author who is publishing the history of the acoustics in Spain, in the Acoustics Journal of the *Spanish Acoustical Society*.

2. THE HERITAGE OF AL-ÁNDALUS ON THE CREATION OF THE UNIVERSITY OF SALAMANCA

In the 13th century, part of the Iberian Peninsula was still occupied by Moors, where in al-Ándalus they cultivated (among other arts) the music. In Córdoba city was created around 850 what is considered the first school of music in western world, where they taught theory and practice, which was revolutionary both in its time and today, because it was open, did not depend on any religion, and people of both sexes studied [6]. Later, other teaching centers similar to this music school existed in some other cities such as Malaga, Murcia, Seville, and Toledo (the latter had already been reconquered by the Iberians in the 11th century).

It is important to highlight that in al-Ándalus learning and practice of medicine, law, music and other disciplines were open, considering that the knowledge of the Greeks philosophers through Arabs translations were of usual reading. Unlike the rest of Europe, where Greeks writing was banned, in the Iberian Peninsula it was commonly read by the ruling class.

In the 13th century, the city of Toledo was annexed to the Kingdom of Castile, which had a school for translating manuscripts from Arabic to Latin (and probably to Castilian as well), which was of great relevance to the future University of Salamanca. Another city occupied was Murcia where Abu Bakr Muhammad ibn Ahmad al-Raquti (?), a renowned Muslim scholar who born in al-Ándalus, Alfonso X distinguished for his abilities in music, mathematics and other disciplines, so kept him to teach in the schools (Murcia, Sevilla and Salamanca) founded in his kingdom [6].

As for the study and teaching of the physics of waves and sound, in the Middle Ages these were integrated into music as part of the Quadrivium, they did not exist as separate entities. In al-Ándalus, music played a very important role in society, it was seriously studied with the advances introduced by Arab thinkers who improved and deepened the contributions that the Greeks had made in this field. Although not explicitly focused on modern physics, Arab and Moorish scholars explored the physical nature of sound, its propagation, and its relationship to musical intervals.

The contributions of Moorish scholars in al-Andalus to the study of sound waves and music were part of a broader intellectual tradition that extended beyond the Iberian Peninsula. This knowledge, accumulated over four centuries, gradually spread from al-Andalus to the rest of Western Europe. A summary of these historical facts is presented in another article by the author [7].

3. 1254: THE ROYAL CHARTER OF THE SALAMANCA UNIVERSITY AND THE "MAESTRO EN ORGANO" (TEACHER IN MUSIC)

The germ of this university dates back to 1218, which began as *Studium generale* (higher studies), and king Alfonso X El Sabio (The Wise) elevated them to the category of university studies on 1254, through a Decree which is known as "Carta Magna de la fundación de la Universidad de Salamanca" (Royal Charter of the foundation of the University of Salamanca).

The original manuscript of the Royal Charter is lost and the oldest handwritten copy of it is from 1401 and is preserved into the archives of the University of Salamanca [8]. The manuscript is written in square Gothic script (see Fig 1) and vocals has no accent marks (diacritics)[2].

Figure 1. Image extracted from the Royal Charter copy from 1401. Paragraph where "maestro de organo" is mentioned. All rights are reserved, Universidad de Salamanca®

Regarding the people who would teach at this university, they are mentioned as "maestros" ("teachers") [8]:

> *De los maestros mando e tengo por bien que ayan vn maestro en leys […] Otrosi mando que ayan vn maestro en decretos […] Otrosi mando que ayan dos maestros en decretales […] Otrosi tengo por bien que ayan dos maestros en lógica […] Otrosi mando e tengo por bien que ayan dos maestros en lo gramatica […] Otrosi mando e tengo por bien que ayan dos maestros en fisica […]* ***Ot si mando y tengo por bien q' ayan bn maestro en organo y yo q'le enqina m'rs cada Anio***.

Among them, the last one is stated as "maestro en organo" (music teacher). Fig 1 shows the paragraph where the Royal Charter refers to "maestro en organo," and it is written (in

[2] First written Spanish texts using diacritics to indicate the tonic syllable, date from the mid-16th century.

old Castilian language) that: "Another thing I do order, and it is good that there is a teacher of music, and I give him fifty maravedis each year."
It is important to note that the word "organo" was written without an accent on the first letter "o," firstly because the Castilian script (writing) was still developing at the time and the accent on vowels was not yet in use, and secondly (and more importantly) because "maestro en organo" refers to the teaching of music and not to the learning of the organ (to be more precise, "the pipe organ"). This statement will be demonstrated later.
The existence of a chair of music at this university is not a coincidence, and there are two very important reasons that justify that fact: In his youth, Alfonso X received theoretical and practical training in music from the people of al-Ándalus; and throughout his adult life, he distinguished himself as a musician, composer and protector of music [8].
Alfonso X is considered one of the composers who contributed the most songs to the *Cantigas de Santa María* (Songs of Holy Mary), a collection of 420 poems with musical notation –written between 1270 and 1282– that is one of the most important compilations of monodic songs in medieval literature. Of a troubadour and paraliturgical nature, it differs from the openly profane themes of the troubadours of the rest of Western Europe and from the sacred music of the 13th century [9].

4. MISTAKE IN MANY REFERENCES FOR USING THE WORD "ORGANO" ACCENTED

The author of this article considers a mistake to write in Spanish about the history of the University of Salamanca without considering the historical context of the 13th century, and there are countless references where the word "organo" is written with an accent on the first letter "o," resulting in "órgano," being this a mistake.
Writing the word "órgano" (with accent mark) instead of "organo" (without accent) changes the original meaning of the function of the music teacher at the University of Salamanca in 1254, and also because someone who uses this incorrect reference to translate it into another language will unknowingly misinterpret that "it was a teacher who taught how to play the pipe organ."
In section 7, the fact that singing and music were taught as a science in this Chair of Music could be demonstrated by a document from 1256 on the organization of the University of Salamanca.

5. FIRST CHRONICLE IN CASTILIAN ABOUT THE "MAESTRO EN ORGANO"

Although the history of the University of Salamanca was written in 1569, this manuscript was stored away for almost 300 years, and it was around 1840 that it was recovered from an archive in the Vatican.
Although the "maestro en organo" is briefly mentioned by Francisco de Salinas, in a prologue of his Treatise of music published in 1577, the first book which summarizes the creation of the University of Salamanca was published in 1720 by the Jesuit scholar Juan de Ferreras y García, co-founder of the Royal Spanish Academy, refers to the Royal Charter for the foundation of the University of Salamanca in his encyclopedia "The History of Spain," transcribing instead of literally copying the 1401 text as "instituyendo ... una Cathedra de Musica" (establishing … a Chair of Music) [10]. This change introduced in the original text is interesting for two reasons: **(a)** He categorizes the function of "teacher" at the level of a professorship, and **(b)** he assumes that "organo" refers to the teaching of music.

6. EARLY REFERENCES IN OTHER LANGUAGES TO THE "MAESTRO EN ORGANO"

The author of this article, after three years of searching the Internet, has not found any direct or indirect references published before 1720 about this music teacher at the University of Salamanca, in other language than Spanish[3]. Below are the first references available on the Internet to this Chair of Music.

6.1 First reference published in French

"The History of Spain" encyclopedia was translated and published in French in 1751 by Ferreras, so, following the original form written by himself, that phrase was translated as "Chaire de musique" (Chair of music) [11].

6.2 First reference published in German

In 1767, in a book published in German, which summarizes the history of Europe "according to what is reflected in proven news," it does not mention the source of information but surely it is the Ferreras' encyclopedia. The phrase "Cathedra de Musica" was written as "lehrstuhl der musik" (teacher of music) [12], that is, it maintains the semantics of what was written into Spanish in the 1720 encyclopedia following the meaning that music was taught in a chair.

[3] The reader should consider that search engines do not display all documents available on the Internet.

6.3 First reference published in English

As far as an English reference is concerned, of the publications available on the Internet, the first is from 1800, and it is cited in a British encyclopedia as follows: "In Spain, music was early included in the circle of sciences. The professorship of music at Salamanca was founded by Alfonzo the Wise, K. of Castile [13], in which it makes it clear that it was a chair for the teaching of music in a university field of knowledge as a science.

7. IN 1254 MUSIC WAS TAUGHT AS SCIENCE IN THE UNIVERSIT OF SALAMANCA

After the Royal Charter was published, Alfonso X wrote a codex containing laws for this new Kingdom, originally named as *Libro de las Leyes* (Book of Laws) now is identified as *Siete Partidas* (Seven Records), which contain several regulations for the University of Salamanca that reflect the medieval view of education and the importance of this university in that social milieu.

According to a comparative analysis between what is written in the Siete Partidas and the Royal Charter, indicates that they differ since the lexicon in the Siete Partidas "is closer to the Bologna model or reality than Salamanca's" [14]. One of the most reliable transcriptions of the Siete Partidas, is published by the Royal Spanish Academy [15], because this document keeps the original ancient scripts and spelling.

Regarding the legislation on the University of Salamanca, the main content is in *Segunda Partida* (Second Record) under the title "De los estudios en que se aprenden los saberes e de los maestros e de los escolares" (On the studies in which knowledge is learned and of teachers and students), and some other regulations are scattered in the other six Records.

In the following, the number of the page is mentioned where the references to the "maestro" and also to the music and the science in the Siete Partidas can be found in [15], then the sentence in old Castilian, and next its translation in English:

- On page 66: "E otrosy en musica que es saber de los ***sones*** que es menester para los cantos de santa Iglesia." The word "sones" is purposely highlighted, because it is the Latin word "sonus" in Castilian language. "And others, in music, which is the knowledge of sounds that is necessary for the songs of the holy church."
- On page 200: "Ley .x. que los maestros no deuen vender la çiençia por precio." "Law 10. Teachers shall not sell science for money."
- On page 500: "Estudio es ayuntamiento de maestros & de escolares que es fecho en algun logar & con voluntad & con entendimiento de aprender los saberes (…) es a que dizen estudio general en que ay maestros de las artes assi como de gramatica & de la logica & de rretorica & de arismetica & de geometria & de musica & de astrologia." "Study is the conjunction of teachers and scholars that is done in some place and with the will and understanding to learn knowledge (...) general study is in which there are teachers of the arts as well as grammar, logic, rhetoric, arithmetic, geometry, music and astrology."
- On page 905: "& los maestros a los disçipulos a que muestran su çiensçia" "And the teachers to the disciples to whom they show their science."
- On page 947: "mismo dezimos que seria si le diesse en salario a algund su maestro que le mostrasse ciencia" "We say the same thing would happen if a salary were given to a teacher who shows his science."
- On page 983: "& los otros maestros de las çiençias que han salarios çiertos cada año del rey o del comun de alguna çibdad o villa" "and the other teachers of the sciences who have received certain salaries each year from the king or the common people of some city or village."

In the Siete Partidas, instead of referring to the "maestro en organo," it is written as "maestro de música" (music teacher), which is very important since it gives a more direct clue that the function of that teacher in 1254 was to teach music.

Regarding the use of the word "science" to identify the pedagogical functions of teachers in the Siete Partidas, it shall be noted that the meaning it had in the 13th century does not have the same meaning today, since in Latin the word *scientia* means knowledge.

Then, at this point, it urges us to ask a rhetorical question:

Can we say that in 1254 the presence of a "maestro en organo" (teacher of music) was equivalent to a professorship?

It can be observed that there is a lot of information about the "maestro en organo" inside the Siete Partidas: Alfonso X thought music and sound as science. A complete analysis of the university's studies on music in the *Siete Partidas* are in [16] [17].

8. DISCUSSION ABOUT WHAT THE STUDY COULD HAVE INCLUDED IN THIS CHAIR OF MUSIC

As was indicated in the Introduction, it is necessary to increase the importance of this Chair of Music at the University of Salamanca, and because there are no written documents for the first 200 years of this institution, the author will use some additional investigations.

A few researchers have made interdisciplinary studies among Arab philology, musicology, medieval linguistics, and comparative literature [9] [18], that is said about the chair of music are inferences based on documents of that time, such as the Siete Partidas, the Cantigas de Santa María, and other sources of information also from that era. So, in order to put some general context involving the teaching of music in 1254, to find what kinds of topics that would have been involved.

8.1 Organum, the polyphonic chant

Polyphonic chant, also known as *organum*, was a complex musical form that developed in the 12th century, and "by 'maestro en organo' probably organum in the sense of the science of discant was meant" [19]. The word organum was also used to refer to the teaching of this kind of chant, for this reason it is inferred that "organo" could be associated to teach music. Additionally, the Cantigas de Santa María often feature complex polyphonic arrangements, indicating a knowledge of harmony.

8.2 Quadrivium: Music and arithmetic

Cantigas de Santa María offer a way (by the contrafactual) to understand what could be teaching in the chair of music in 1254. They are a collection of secular poems with musical notation, showcasing a sophisticated understanding of music theory. The use of mensural notation, which precisely indicates rhythmic values, suggests an awareness of intricate musical structures, and the knowledge to link the theoretical aspects of arithmetic with musical sounds, meaning the mathematical foundations of sound and its relationships between musical intervals.

8.3 The science of sound

Continuing with the tradition inherited from al-Ándalus, the "maestro en organo" taught the behavior of sound embedded in music [7], because their ideas could have influenced the thinking of music theorists in Salamanca, even if they were not explicitly articulated in the same terms. Then, it could be inferred that this chair of music would include the study of: Sound physics, understanding how sound is produced and transmitted; the theory of musical intervals and consonances; the study of musical notation and the principles of musical composition. It's highly probable that the study of sound (sones) were incorporated, albeit in a more rudimentary form than we understand today.

9. CONCLUSION

We are able to say that in 1254 the University of Salamanca had a chair of music, the first in the world, with a professor called as "maestro en organo." This historical fact is justified by hermeneutics, understood as a general theory of the understanding of texts, with the intention of giving a systematic approach to the translation of ancient texts, consisting in reading the manuscripts as they were intended at the time of their writing and understanding them in their real social context and cultural environment.

It is also clear that in order to understand this historical event of 1254, the "maestro en organo" cannot be analyzed as isolated data, as mentioned in the Royal Charter, but rather it is necessary to refer to the Siete Partidas to better understand his academic role as a professor who could be dedicated to: Teaching music, polyphonic singing, playing instruments.

It's important to remember that medieval music education was very different from modern music education, the focus was on understanding the underlying principles of music, rather than developing performance skills. In essence, the teaching of music by the "maestro en organo" in 1254 at the University of Salamanca would have been a blend of theoretical understanding, arithmetic, and secular/religious music.

In the Middle Ages, when music in Western Europe was taught only in churches and monasteries, the creation of a chair of music with one professorship at the University of Salamanca in 1254 is revolutionary.

The contributions of the Arabs thinkers whose works on music were translated in al-Ándalus (from Arab to Latin), and whose ideas spread from Spain to Western Europe, leading to the Renaissance and the Enlightenment. They played an important role in the creation of this Chair of Music at the University of Salamanca.

Finally, the "maestro en organo" in modern words could be identified like a "chair of musical acoustics," because ultimately music is part of the creation of sounds.

ABSTRACT

The Miguel Hernandez University of Elche (UMH) is a public and young university located in Alicante province, in the southeast of Spain, founded in December 1996 and which started its academic activities in the course 1997/1998. In the earliest beginnings of the UMH, a very small group of researchers of the Mechanical Engineering teaching area had the motivation of creating a working line focused on research on acoustics and vibrations. That fact led, in 2005, to the foundation of the Acoustic Engineering and Vibrations Laboratory of the UMH (LIAV-UMH). Since then, the members of the LIAV-UMH group focus their research lines mainly in the field of sound emissions and vibrations of road traffic and environmental acoustics, which results have naturally led to the knowledge transfer and collaboration with different entities and companies. In the current year, 2025, the LIAV-UMH celebrates its 20 years of research. This is why this paper summarizes the scientific trajectory followed by the group from its creation to the present days, showing the different working lines, developed research projects and knowledge transfer activities.

1. INTRODUCTION

Noise pollution has been perceived throughout the history of civilisations as a nuisance that reduces the quality of life of people exposed to high noise levels. Noise exposure may lead to negative consequences that might vary from difficulties for holding a conversation, to sleep problems and disturbances in the performance of activities that require concentration, or even variations in the nervous system. In the last decades, different policies have been developed to control and reduce environmental noise. In this respect, the European Commission's Green Paper on 'Future Noise Policy' was a first step towards a common noise policy in the European Union [1]. Subsequently, in 2002, the publication of the European Directive 2002/49 on Assessment and Management of Environmental Noise [2], provided the main legislative framework to address noise reduction in Europe. The Directive established a common approach to avoid and prevent exposure to environmental noise through noise mapping and action plans. However, almost two decades after its publication, it was shown that noise from road traffic was still the noise source that affected the largest number of people [3]. This is still the case today, as reported in the European Environment Agency's latest publication [4] on exposure to transport noise in the European Union, which highlights the fact that the number of people exposed to high levels of road traffic noise remains high and is likely to increase in the coming years. Thus, it is estimated that about 113 million people are affected by traffic noise levels of at least 55 dB(A) over extended day-evening-night periods (Lden). This emphasises the need to designate and protect more quiet zones both in cities and in areas outside cities.

The motivation for environmental awareness has always been one of the main concerns of the group of the Acoustic

Engineering and Vibrations Laboratory of the UMH (LIAV-UMH), and what led the team to start research in environmental acoustics and noise and vibration control. In that context, the LIAV-UMH group began its work in 2005. Currently, the group is integrated by a team of seven researchers and several collaborators. All the members of the group are professors and lecturers of the Mechanical Engineering Teaching Area of the Department of Mechanical Engineering and Energy of the UMH, and their lines of work have been oriented towards acoustic engineering and applied vibrations, as well as offering a practical approach to the transfer and provision of services to companies and public and private entities.

The work of the group members is currently framed within the University Institute for Engineering Research of Elche (I3E - https://i3e.umh.es/en/), within the research lines of the Energy and Mechanics Unit. This article mainly describes the research trajectory of the group, focusing on the priority lines of research.

2. FIRST STEPS: TOWARDS STUDYING ROAD TRAFFIC NOISE AND VIBRATION CONTROL

Strategic noise maps are the tool that allows the global assessment of noise exposure of the population in a given area. In this sense, the beginnings of the group coincided with a period when the study of noise mapping was a trending topic.

In this line, one of the first works of the group that received public funding (Generalitat Valenciana, GV05/100, 2005-2006), focused on the development of a prediction model of night-time traffic noise based on the vehicles' sound directivity. The research also allowed the study of the horizontal sound directivity of vehicles travelling at high speed [5] (2009). To this end, work was carried out to establish a methodology capable of providing information on the sound distribution of a noise source in its main plane of emission, based on the proposal of different configurations of microphone arrays [6] -a linear antenna with uniformly distributed microphones (ULA) and a linear antenna with proportionally distributed microphones (PROP)-, in different orientations with respect to the vehicle's driving line. The results of this work yielded very interesting conclusions and led to the registration of a patent for an acoustic speedometer system [7].

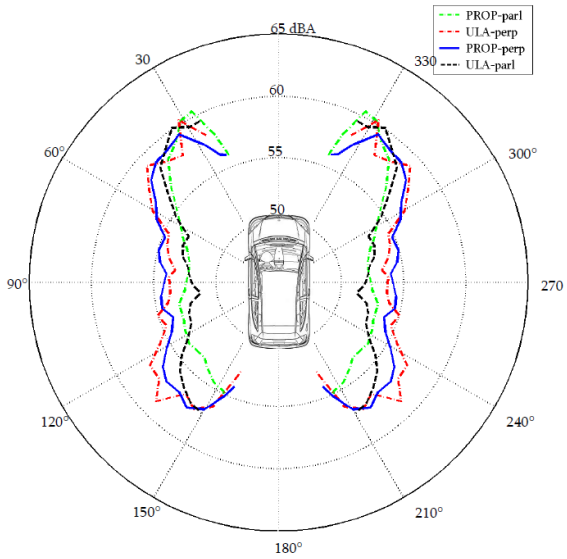

Figure 1. Polar plot of the sound level obtained with each of the proposed antennas [5].

During this first period, members of the group also collaborated in a much larger project (Generalitat Valenciana, GVEMP06/011, 2006), which included other researchers, for the construction of a drum-type tyre testing machine, Fig. 2. The machine allows to perform load/speed tests for new and retreaded passenger car and commercial vehicle tyres according to UNECE regulations 30, 54, 108 and 109, and rolling resistance tests according to ISO 28580.

Figure 2. Tyre testing facility at the UMH.

3. TYRE/ROAD NOISE AS A FOCUS OF ATTENTION IN VEHICLES

The results obtained in that first stage on the sound directivity of vehicles led the group in the subsequent years to open one of its main current lines of work: the study of tyre/road noise. Initially, work was carried out on the development of new measurement methodologies to assess tyre/road noise, the novelty of which laid in the evaluation of sound emission through a standardised engineering method (ISO 3744), to determine the sound power level in the tyre/pavement interaction [8], Fig. 3.

In a first phase, two methodologies were designed for evaluation on track [9] (2013): Alternative Coast-By (A-CB) [10] and Alternative CPX (A-CPX) [11], inspired by the traditional CB and CPX methodologies, but with the result of obtaining the sound power level of the set of sources formed by the four tyres of a vehicle rolling on a pavement (A-CB), and the sound power level of the interaction of a single tyre rolling on the pavement (A-CPX). One of the conclusions drawn from this phase of work was that the tyre/road sound power level of a complete vehicle can be calculated from the energetic sum of the tyre/road sound power level of each individual tyre that comprises a vehicle [12].

At the time when the group had the tyre testing facility in operation, two analogous methodologies were developed for the study of tyre/road noise on a drum testing machine [13] (2018): Alternative Drum methodology (A-DR) [14,15] and Alternative CPX Drum methodology (A-CPX-DR) [16].

4. THE INCORPORATION OF ELECTRIC VEHICLES INTO ROAD TRAFFIC

In parallel to the line related to tyre/road noise, the group also began another of its major fields of work: the study of the effect generated by the inclusion of electric vehicles in noise maps. At this point, in the early years work was carried out on adapting the NMPB-Routes 2008 road traffic noise prediction model to the presence of electric vehicles [17] (2014). The group's work was collected in different publications - some of them of relevant impact [18] - where, among other conclusions, it was possible to gather that the noise emitted by an electric vehicle can be compared with that emitted by an internal combustion vehicle without mechanical noise, when both circulate at speeds above 50km/h.

The study of the NVH (Noise, Vibration and Harshness) of electric vehicles was a very important topic in the early period of the introduction of electric vehicles into vehicle fleets - and it remains so today. That led to the group's participation in the COST Action TU1105 'NVH analysis techniques for design and optimisation of electric vehicles' (European Union, Cost Action TU1105, 2012-2016). As a result of the joint efforts of the members of the Action consortium, a comprehensive catalogue of NVH-related technologies for electric and hybrid vehicles was compiled [19].

5. WARNING SOUNDS: PEDESTRIANS AT POTENTIAL RISK

The experience that the group was acquiring in the NVH of alternative vehicles was focused on the study of their acoustic detectability. In this field, the group had the opportunity to work on different projects. Among them, one of the most noteworthy was the collaboration with ONCE (Spanish National Organisation for the Blind), in a project (Generalitat Valenciana, GV/2017/004, 2017-2019) whose objective was to improve the detection, localisation and identification of the warning sounds of electric vehicles through the perception of blind people. To this end, the emotional response of the test volunteers to different warning sounds was studied, as well as the detectability of these sounds through the analysis of detection times.

More recently, the work carried out in the group has focused mainly on the development of numerical models of mechanical systems that can help to improve the sound detectability of alternative vehicles [20] (2023). In this field, the modelling of the noise generated by a tyre either when it impacts against the ground in free fall or when it impacts against elements external to the vehicle, such as a speed bump or a pothole in the pavement, has been studied. The model developed by the group is solved in two steps: a dynamic analysis of the contact of the tyre with the element against which it impacts, through FEM modelling; and a subsequent BEM analysis of the sound field generated in the environment, based on the vibration of the tyre surface as a sound source.

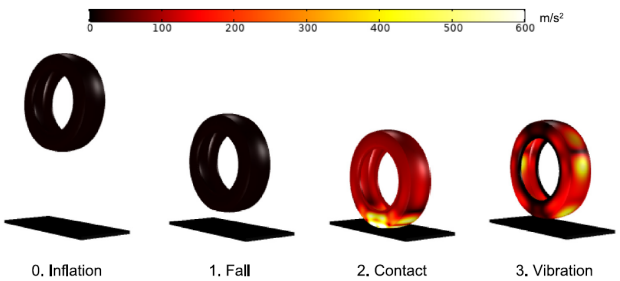

Figure 4. Phases of a transient analysis in a FEM simulation of a tyre impacting a flat, rigid, and reflective surface [20,21].

6. CURRENT RESEARCH IN THE GROUP

The experience accumulated by the group to date has allowed us to identify the need for further research into aspects related to the detectability of electric and hybrid vehicles in particularly sensitive environments in low-speed traffic conditions. To this end, the group is currently exploring the potential that metasurfaces may provide for this solution (Generalitat Valenciana, CIGE/2022/1, 2023-2024). The term 'rolling metasurface' was coined by the team [22] to refer to a surface pavement design modified in its geometry, which confers different properties to those provided by its original textural characteristics (micro, mega and macro texture), and which is capable of generating controlled sound emission and propagation when a tyre circulates on this pavement. Previous work in this line [23], has led the team to continue investigating this proposal.

Finally, the group is also currently exploring the sound directivity capabilities of a low height stepped directional acoustic barrier (SDAB) system. The aim of the design of this barrier is to create an interference to sound propagation in the transverse direction, but at the same time to allow sound transmission at a certain angle in both horizontal and vertical planes [24].

7. CONCLUSIONS

The LIAV-UMH group has focused its work over the last 20 years in the field of applied acoustics and vibrations, especially in the area of vehicle acoustics, with the development of methodologies and characterisation of the sound emission of conventional vehicles, as well as electric and hybrid vehicles; the study of tyre/road noise; environmental acoustics, with the improvement of traffic noise prediction models, development of noise maps and experimental studies of traffic noise emission sources; acoustic studies of sound sources, with special attention to studies on the control of noise measurement installations in MOTs; development of vibration behaviour models for road and rail vehicles; among many others. This article covers only part of the group's work, the most closely related to its research work.

The group's research strategy for the coming years will continue to focus on the search for solutions to improve urban environments in terms of noise emissions. To this end, the group intends to continue collaborating with institutions and entities, both public and private, national and international, with the ultimate aim of achieving results

with a social impact that can be transferred and implemented in practice.

8. ACKNOWLEDGMENTS

The members of the LIAV-UMH research group would like to thank all the people who, in one way or another, have contributed to the development of the group: from students and scholarship holders, members of other UMH research groups, colleagues from other Spanish and international universities with whom they have worked together, and companies and public institutions with which they have collaborated.

PSYCHOACOUSTICS, THE LONG WAY TO BE CONSIDERED INTO INTERNATIONAL STANDARDS

Klaus Genuit[1*]
[1] HEAD-Genuit-Foundation, Herzogenrath, Germany

ABSTRACT

For several decades the A-weighted sound pressure level has been used for the evaluation of sound. But sound character is determined by the spectral composition and the temporal patterns. For this reason, the discipline of psychoacoustics has established itself, which can provide more differentiated analyses describing the sound character. With the help of psychoacoustics parameters such as loudness, sharpness, tonality, roughness, fluctuation and impulsiveness, the auditory impression of sound events can be viewed in a more differentiated way than just with the A-weighted sound pressure level. The first standards were developed for stationary loudness DIN 45632 and ISO 523. In the meantime, we have standards by ECMA-418-2 describing different psychoacoustical parameters based on a hearing model like tonality, roughness and fluctuation strength. The international standard ISO 12913 "Soundscape" describes this relationship of perceived sound quality considering the context.

Keywords: *psychoacoustics, standardization, soundscape*

1. INTRODUCTION

The noise nuisance of the population has increased in recent years, despite numerous measures to reduce the noise emissions of individual noise sources. According to the German Federal Environment Agency (UBA), more than 50% of the population is affected by traffic noise [1]. Although psychoacoustics was introduced by ZWICKER [2] in the middle of the last century, first with the parameter loudness, the A-weighted sound pressure level still dominates all legal regulations with respect to noise measurements. The advantage of the A-weighted SPL is the option to calculate with these data. If you know the level of two sources, a calculation of the superposition is possible. It is not possible to predict the psychoacoustical parameters by superposition of different sound sources, the time signal is necessary. The absence of standardization for a long time was another disadvantage of the introduction. It has been a long way to overcome this handicap.

2. WHAT IS NOISE

Noise is caused by the perception of humans and describes the effect of sounds. Consequently, noise cannot be measured with sound level meters, but sound only becomes noise if it is undesirable for those affected or is likely to affect them psychologically, physically, socially or economically [3]. Noise represents a negatively assessed sound immission, i.e. it does not exist without the perceiving subject. This understanding is also shared by the DEGA (German Acoustical Society) Noise Working Group (ALD) and explains that noise is an evaluative term and therefore cannot be measured with physical devices alone [4]. Consequently, a physically unambiguously describable sound event can certainly lead to different auditory events. The context, the attitude of the exposed person to the source of the noise or to its originators, as well as the experience and expectations of the noise exposure, influence the perception and assessment of sounds. According to this understanding, noise cannot be validly determined based on an A-weighted sound pressure level alone, as is suggested by terms such as "noise measurement" and "noise map". A so-called "noise map" is so far only a map that shows sound pressure levels based on calculated data. A sound pressure level map is certainly necessary for the discussion of noise exposure, but it is not sufficient for the valid determination of nuisance caused by noise, i.e. in the context of noise [5].

3. PSYCHOACOUTSICS

Usually when noise effects are considered with respect to well-being and health, A-weighted sound pressure level indicators are analyzed. However, several decades ago researchers started to use measurement methods to quantify auditory sensations in more detail. Later the soundscape pioneer SCHAFER [6] described acoustics and

psychoacoustics as the cornerstones to understanding the physical properties of sound and the way sound is perceived. This approach emphasized that all aspects of soundscape are related to perception. Psychoacoustic data are considered for a more comprehensive evaluation of acoustic environments that goes beyond the simplified use of sound level indicators. Moreover, a key consideration is that acoustic environments are perceived binaurally by humans. Thus, measurement equipment that collects spatial information about the acoustic environments is increasingly being applied in soundscape investigations and consequently is suggested in soundscape standards. Following the soundscape concept, all measurements and analyses must reflect the way soundscape is perceived by people in the appropriate context. This insight led to an increase in research and applications of psychoacoustic measurements to understand the effects of acoustic environments on humans in more detail. Psychoacoustics deals with the description of the relationship between physical stimuli and the auditory perceptions they evoke. Experimentally observed relationships between stimuli and sensations result in mathematical descriptions and psychoacoustic models. This makes it possible to make statements about the acoustic properties of sounds and their perception. An extended assessment of environmental noise to predict noise pollution can be carried out by considering psychoacoustic characteristics of environmental noise. The most important psychoacoustical parameters are:

3.1 Loudness:

Consideration of distribution of critical bands and masking properties in the hearing, DIN 45631/A1, ISO 532-1. Studies [7] have shown that the 5% percentile loudness (N5) correlates highly with the perceived total loudness valid in cases of unsteady sounds, since the mean value of time varying loudness compared with the subjectively evaluated loudness provides a value, which is too low, the 5% percentile loudness (N5) has to be used with respect to the perceived overall loudness. Experiments have shown that the perception of loudness correlates better with the psychoacoustic parameter loudness than with the A-weighted sound pressure level [7]. Thus, the representative singular value, which considers human cognitive stimulus integration, is based less on a mean value than on the loudness peaks of the function of loudness over time. Basically, loudness depends on the spectral distribution, considers the level-dependent loudness perception of different tones and the duration as well as simultaneous-, pre- and post-masking properties of the human ear.

3.2 Sharpness:

Weighted first moment of distribution of critical band rates of specific loudness, relationship of high-frequency spectral components to total loudness, DIN 45692. The sharpness parameter covers the aspect that sounds with energetic focus in the high frequency range are perceived as sharp, which often leads to increased annoyance independent on level.

3.3 Roughness & Fluctuation:

Time structure of the sound signal, modulation factor and level difference determine roughness & fluctuation, amplitude- and frequency modulation, DIN 38455, ECMA 418-2 [8] (ECMA develops and publishes international standards for the information and communication industry). Roughness or fluctuation, deal with sensations that are evoked in sounds due to special temporal structures caused by modulation of tones or different tones in one frequency group.

3.4 Tonality:

Products emit tonally perceived noises due not only to pure tones but also to narrow noise bands, and to same-vicinity combinations of pure tones and narrow elevated noise bands, ECMA 418-2. The psychoacoustic parameters behave (almost) orthogonally, i.e. one psychoacoustic parameter can vary whereas another parameter remains constant. There is a gain in information compared to the sound pressure level and more differentiated statements about the characteristics and potential reactions of the listener become possible.

4. STANDARDIZATION OF PSYCHOACOUSTIC

Psychoacoustics will be more and more established: automotive field, office and appliance equipment, environmental noise and soundscape. The first standards within psychoacoustics were the loudness standards from stationary sound represented by the recommendation ISO 532-A and ISO 532-B (1966) “Method calculating loudness level”. ISO 532-A is based on octave spectrum in accordance with STEVENS [9], ISO 532-B is based on third octave spectrum in accordance with ZWICKER [10]. These recommendations became an ISO standard in 1975. This early introduction of the loudness standard has had some disadvantages: 1. the calculation was very complicate, 2. two standards instead of one, 3. the discussion that loudness is correct and A-weighted level is wrong has prevented a quick acceptance of this new approach, 4. ISO-

532 was only valid for stationary sounds but in reality around 80% of daily sounds are time-variant. In 1996 the German Institute for Standardization (DIN) initiated a new working group "Psychoacoustical Measurement Technique" to standardize the time-variant loudness, sharpness and binaural measurement system (artificial head). The first result was the DIN 45692 (2009) for "Sharpness" which standardized a modified VON BISMARK sharpness [11] with a different weighting function. Informative was the AURES sharpness [12] mentioned which has a dependence on loudness. One year later the new time variant loudness DIN 45631/A1 was published 2010 based on the ZWICKER method. Parallel the ISO working group WG9 has started in 2007 to review the ISO 532 stationary loudness. In the meantime, another approach was established, the US ANSI S3.4-2007 "Procedure for the computation of steady sounds" in accordance with GLASBERG & MOORE loudness [13] using 40 equivalent rectangular bands instead of the 24 frequency groups by ZWICKER. The ANSI loudness was based on the new ISO 226 from 2003 (Equal Loudness Curves) whereas the ZWICKER loudness was based on the older ISO 226 from 1987. These differences led to a lengthy controversial discussion about which loudness should now be standardized. Unfortunately, the two calculation methods led to different results depending on the signal. It was questioned whether ISO 229 from 2003 is really better or more correct than the old ISO 229 from 1987 or whether it would be better to revise ISO 226 again. Finally, after many years, it was agreed to develop three new standards: ISO 532-1 (2017) according to the ZWICKER method for stationary as well as time-variant noises, ISO 532-2 as stationary loudness according to MOORE & GLASBERG [14] and later in 2023 ISO 532-3 for time-variant signals according to the MOORE & GLASBERG & SCHLITTENLACHER method [15]. In 2008, the first efforts were again made at DIN to standardize roughness. In the meantime, various software solutions were available for calculating roughness, but they yielded extremely different results. While the calculation of the roughness of pure, modulated sine tones was still quite uniform, large differences were revealed for broadband signals. Narrowband signals can cause roughness, but broadband noise cannot. Therefore, the calculation algorithm had to recognize whether the partial roughness occurring in the individual frequency groups correlates with each other or not. Numerous listening experiments with typical everyday noises also showed a large dispersion in terms of the assessment of roughness, even among experts. It was not until 2024 that DIN 38455 Roughness was published. In the field of office equipment manufacturers ECMA, the demand for the calculation of tonality and roughness came earlier, so that psychoacoustic parameters were standardized in parallel with ECMA-418-2 as early as 2022 based on SOTTEK's hearing model [16]. In addition to tonality, roughness has also been defined, and the fluctuation strength will also be standardized 2025.

5. SOUNDSCAPE

Psychoacoustics, sound quality and cognition provide information on how humans perceive and interpret their surrounding world. With psychoacoustics alone it is only possible to describe the sound character. Psychoacoustics can analyze in detail the acoustic composition of a soundscape and the signal properties that elicit specific auditory sensations; however, a comprehensive interpretation of the results requires feedback from the listeners. Whereas the perceived sound quality depends on the context how people experience the sound situation. While the overall noise measured at a specific location can be analyzed in terms of several acoustical parameters, the annoyance or pleasantness level of a complex soundscape composed of several sound sources cannot be determined solely from the values obtained through such analyses. Even if the acoustic contribution of a single sound source to the overall noise does not appear significant in a physical sense, the influence of this sound source on the soundscape can be relevant perceptually [17]. In 2008 a new working group WG54 at ISO started the development of the soundscape standard which was the basis of the first standard ISO 12913. The definition was part of ISO 12913-1 (2014): Soundscape is the acoustic environment as perceived or experienced and/or understood by a person or people, in context. Two major components like pleasantness and eventfulness describe soundscape. This concept allows considering sound quality aspects beyond noise annoyance, a good soundscape quality is not simply identical to the absence of annoyance. Judgments cannot be fully understood by only considering acoustical quantities, since contextual parameters and interactivity are relevant for assessment of a soundscape as well. The ISO/TS 12913-2 (2018) "Data collection and reporting requirements" is the first standard requesting normative the use of binaural measurement as the judgment of acoustical environment is multidimensional, the effects of superposition of several sound sources is not easy to predict and the human hearing is able to select a single sound source among others. Whereas ISO/TS 12913-3 (2019) "Data analysis" recommends the application of psychoacoustical

parameters. The ISO/TS 12913-4 "Design and intervention" is under development.

6. SUMMARY

It is astonishing that for many decades, the complexity of sounds and the perception by humans has only been described with a simple A-weighted sound pressure level measurement. Neither the temporal structures nor the spectral distributions are considered. For over 100 years, scientific investigations have been carried out within psychoacoustics, and for over 60 years there have been efforts to standardize these findings. Difficulties arose due to different scientific approaches, limited practical application and initially technically difficult implementations. In the meantime, standards are available for almost all relevant psychoacoustic parameters, unfortunately within different standardization committees such as ISO, DIN, ANSI, ECMA. However, with the standard for Soundscape ISO 12913, for the first time, the implementation of normative binaural measurement technology and informative use of psychoacoustics has been carried out. A long way! Psychological and cognitive aspects of sound are not physically measurable. The question is: How to measure sound? Very accurate with highest precision using a calibrated A-weighted sound pressure level meter class 1 or correct like the human hearing with consideration of context? A complete overview with respect to soundscape is given in [17].

ABSTRACT

In 1988, Barcelona physicist Higini Arau-Puchades published in international journal *Acustica* an alternative to Sabine's classical formula for reverberation time (T). Arau's formula resulted from a process of reflection that began in 1985, when Arau came into contact with Lothar Cremer during the acoustic renovation of the Palau de la Música Catalana in Barcelona, which architect Oscar Tusquets was restoring. Arau proposed a formula that considered the non-uniform distribution of absorbing material in a concert hall. Consequently, the decay rate of sound was quantified in the three directions X, Y and Z. Of course, Arau went on to use his formula in the auditorium designs that he undertook in the 1990s. He developed it in a second paper published in 1998, while his first paper cut a path in the scientific field. During the 2000s, several articles comparing Arau's work with other known formulae led to his formula being incorporated in the statistical calculation section of some of the most highly regarded computer programs on international acoustic design. We aim to analyse the impact of Arau's proposal in international academic publications to date.

Keywords: *architectural acoustics, reverberation time, non-diffuse field, Higini Arau-Puchades, Lothar Cremer.*

1. REVERBERATION TIME IN ROOMS WITH UNIFORM DISTRIBUTION OF ABSORPTION

1.1 Sabine (1900)

US physicist Wallace C. Sabine (1868-1919) published his studies on reverberation time in seven issues of the periodical *The American Architect and Building News*, between April and June 1900 [1-7]. He had started to research this area in 1895, when Harvard University asked him for advice on how to correct severe acoustic problems in the lecture room of Fogg Art Museum [1, p. 3], which architect Richard Morris Hunt had designed in a semi-circular shape, like old Greek theatres.

In these first articles, which combined experimental measurement of the phenomenon with its physical and mathematical analysis, Sabine formulated a hyperbolic law where the reverberation time in a space would be inversely proportional to its average absorption coefficient [2].

In turn, we owe to US physicist William S. Franklin (1863-1930) the mathematical workings that demonstrated the definitive form of Sabine's equation (1) for calculating reverberation time in 1903 [8]:

$$T = \frac{0.161V}{\sum_i S_i \alpha_i + 4mV} \tag{1}$$

In the framework of statistical theory, the equation (1) provided a global value for the behaviour of sound over time in a particular space that would enable comparisons with other rooms that are known for their acoustics.

1.2 Eyring (1930)

When Sabine had passed away, the publication of his *Collected Papers*, in 1922, spread his legacy worldwide [9]. However, it was soon shown that his equation (1) was suitable for "live" rooms, but not as appropriate for rooms that had a high level of absorption surfaces, such as those of radio stations. US physicist Carl F. Eyring (1889-1951), who worked for Bell Telephone Laboratories, drew up a general theory [10] that could be applied to all types of rooms and was formulated as follows:

$$T = \frac{0.161V}{-S\ln(1-\bar{\alpha}) + 4mV} \tag{2}$$

2. REVERBERATION TIME IN ROOMS WITH NON-UNIFORM DISTRIBUTION OF ABSORPTION: TAKING X, Y, Z INTO ACCOUNT

2.1 Bagenal (1942)

Hope Bagenal (1888-1979), a British architect specialised in acoustics, had grasped back in 1942 the difficulties of assessing reverberation time in rooms when the distribution of absorbent material was not uniform. Without a clear theory, he merely pointed out that: "Another factor also enters into reverberation design. It applies in practice specially to studios and small halls. Reverberation in rectangular rooms really consists of three sets of inter-reflections set up between the three pairs of parallel opposite surfaces. It is important that these three reverberation times should be roughly of equal length and blend into one smooth tone." [11, pp. 113–115].

2.2 Fitzroy (1959)

Shortly afterwards, US acoustic engineer Dariel Fitzroy (1898-1977) noted deviations from the formulae of Sabine (1) and Eyring (2) when they were applied in rooms where the absorption is nonuniformly distributed. Supported by a large number of measurements in rooms of these characteristics, and without seeming to be aware of Bagenal's opinion, he stated that "…the sound field may tend to settle into a pattern of simultaneous oscillation along a rectangular room's three major axes—the vertical, the transverse, and the longitudinal. […] In its simplest case, a rectangular room, we are presented with three sets of parallel boundaries. If the energy oscillates simultaneously between each pair of boundaries—the author is aware that this is highly speculative—the average absorption in each pair would control the sound wave excursions between that specific pair during the 60-db decay period." [12, p. 893]. From his measurements, he inferred an equation (3), without mathematical proof, that brought the estimated reverberation time closer to the measured values in rooms of these characteristics:

$$T = \left(\frac{S_x}{S}\right)\left(\frac{0.161V}{-S\ln(1-\bar{\alpha}_x) + 4mV}\right) + \left(\frac{S_y}{S}\right)\left(\frac{0.161V}{-S\ln(1-\bar{\alpha}_y) + 4mV}\right) + \left(\frac{S_z}{S}\right)\left(\frac{0.161V}{-S\ln(1-\bar{\alpha}_z) + 4mV}\right) \tag{3}$$

2.3 Cremer (1978)

German acoustic consultant Lothar Cremer (1905-1990), in his book *Die wissenschaftlichen Grundlagen der Raumakustik* (1978) with Helmut A. Müller (1930-2015), translated into English as *Principles and applications of room acoustics* (1982), dedicated the chapter "Refinements of the reverberation formulae based on geometric considerations" to reflections on how to assess the impact on reverberation time of a non-uniform distribution of the absorbent material in a room. He recommended dividing "…the total surface area first into several large 'principal surfaces', which can be regarded as encountered by the sound rays one after the other ('in series'); and to subdivide these large surfaces into smaller areas with different absorption, which can be regarded as encountered side by side ('in parallel'). The smaller subdivisions are first averaged arithmetically, to determine the mean absorption coefficients for each of the principal surfaces. Those values are then transformed to the corresponding absorption exponents, and are averaged arithmetically…" [13, p. 235].

2.4 Arau-Puchades (1988)

Thirty years after Fitzroy, Higini Arau-Puchades (b.1946), a Spanish physicist specialised in acoustics, was also concerned about cases of non-diffuse fields. Between 1982 and 1989, when he was director of the Laboratori General d'Assaigs i Investigacions [General Laboratory for Testing and Research], he advised on acoustic improvements for the Palau de la Música Catalana, the most important concert hall in Barcelona, designed by architect Lluís Domènech i Montaner in 1905 [14]. The refurbishment was led by architects Oscar Tusquets and Lluís Clotet. There, Arau-Puchades worked with Lothar Cremer who, from 1973, had collaborated on the design of many concert halls in Spain [15].

Figure 1. From right to left, Higini Arau-Puchades, Lothar Cremer and Oscar Tusquets at the Palau de la Música Catalana of Barcelona. Photo: Pau Barceló (1985), Centre de Documentació de l'Orfeó Català.

The Palau de la Música Catalana was a masterpiece of *Catalan Modernisme* (Art Nouveau). Its ceiling was covered in ceramic tiles, the side walls were formed of a type of glass curtain wall and work could only be done on the absorption of the stalls area. This was a prototypical example of sound propagation in a non-diffuse field, which could not be modified as it was a listed building.

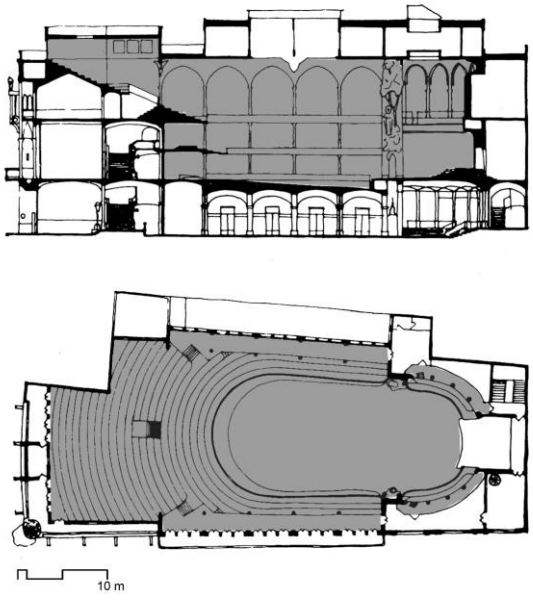

Figure 2. First floor plan and cross-section of the Palau de la Música Catalana (1905-1908).

From conversations between Arau-Puchades and Cremer, Arau-Puchades's dissatisfaction with classic formulae for determining reverberation time in a non-diffuse field began to emerge. As Higini Arau-Puchades explained to a journalist, first he tried an approach to the problem that he showed to Cremer, who "responded to the theory, saying that his calculations were focused on a linear reverberation curve from top to bottom and that in no case did this linearity occur. Stimulated by the problem, Arau averaged the absorption coefficients so that 'now I can calculate all the decays of the reverberation curve'." [16].

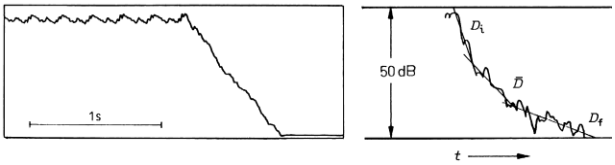

Figure 3. Left, sound decay in a diffuse field, right, sound decay in a non-diffuse field [17, p. 54].

In May 1986, Higini Arau-Puchades presented his theory to the specialised journal *Acustica*. The article was published in the March issue of 1988 under the title "An improved reverberation formula" [18].
Returning to Fitzroy's approach (3), Arau-Puchades proposed that the varying degree of reflectivity of the pairs of walls that make up a room could be broken down using the following convention:

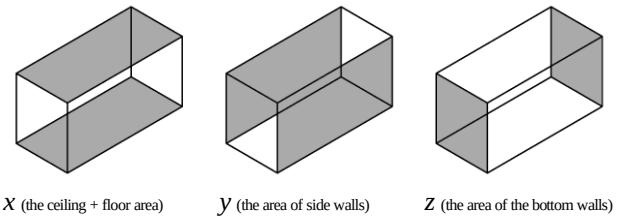

Figure 4. Pairs of parallel surfaces according to Arau-Puchades [18].

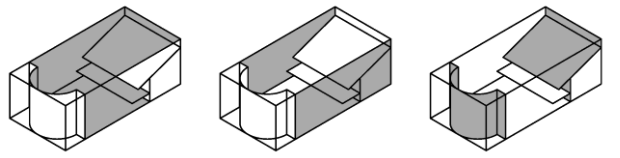

Arau-Puchades considered that the reverberation time of a room with non-uniform absorption would be equal to the area-weighted geometrical mean of the reverberation periods in each one of the directions considered [18, p. 166]. Therefore, in his theory, Arau-Puchades proposed the coexistence of simultaneity (three parallel walls at the same time) and sequentiality (reflections occur on each wall, one after the other).

$$T = \left(\frac{0.161V}{-S\ln(1-\bar{\alpha}_x)+4mV}\right)^{x/S}\left(\frac{0.161V}{-S\ln(1-\bar{\alpha}_y)+4mV}\right)^{y/S} \cdot \left(\frac{0.161V}{-S\ln(1-\bar{\alpha}_z)+4mV}\right)^{z/S} \quad (4)$$

In addition, we know that Lothar Cremer stressed in conversations with Higini Arau-Puchades "that all theories that try to demonstrate the non-diffuse case should be able to calculate the reverberation time T and EDT, the Early Decay Time" [19, p. 4]. In fact, Arau-Puchades's mathematical approach allows this aspect to be obtained using a log-normal distribution [18, pp. 166–170].

In the same article, Arau-Puchades described the application of his formula to various rooms and compared the results with the predictions of Sabine (1) and Eyring (2) and with some real measurements. This was a generalisable theory that was close to the results of Sabine and Eyring in rooms with a uniform distribution of absorption. In addition, to demonstrate its suitability, Arau-Puchades used the experimental data of Koesten [20] and Mehta & Mulholland [21] to support his proposal.

If we go back to the example of the Palau de la Música Catalana, the pairs of walls were broken down according to Figure 5. Table 1 shows the calculation of the absorption coefficient values and Table 2 compares the estimated and measured results.

x (the ceiling + floor area) *y* (the area of side walls) *z* (the area of the bottom walls and upper stalls)

Figure 5. Allocation of surfaces in the study on the Palau de la Música Catalana, Barcelona [18].

Table 1. Dimensional ratios and absorption coefficients of the Palau de la Música Catalana, Barcelona [18, p. 171].

Dimensions	Percentage area	Absorption coefficients		
		$\bar{\alpha}_t$ (energy)	$\bar{\alpha}_i$ (decay)	$\bar{\alpha}_{av}$ (whole energy average)
Ratio: Non rectangular form	$\frac{x}{S} = 0.407$	$\bar{\alpha}_x = 0.250$	$\bar{\alpha}_x = 0.287$	$\bar{\alpha}_{av} = 0.385$
V = 10,352	$\frac{y}{S} = 0.296$	$\bar{\alpha}_y = 0.543$	$\bar{\alpha}_y = 0.784$	
S = 2,438	$\frac{z}{S} = 0.297$	$\bar{\alpha}_z = 0.413$	$\bar{\alpha}_z = 0.532$	

Table 2. Comparison of estimations of reverberation time according to various formulae and the experimental measurements of the Palau de la Música Catalana, Barcelona [18, p. 173].

Eyring (2)	Fitzroy (3)	Arau-Puchades (4)	Experimental
1.37 s	1.57 s	1.44 s	1.47 s

Ten years later, in 1998, Arau-Puchades revisited his article of 1988 with the aim of expanding his results to a general theory of acoustic values of rooms [22]. Its development was based on ideas proposed by Mike Barron, characterised for the case of non-uniform distribution of absorption [23].

3. INTERNATIONAL IMPACT OF ARAU-PUCHADES'S FORMULA

3.1 Use in Arau Acústica for the design of concert halls

The following are notable among the early collaborations of Higini Arau-Puchades, now with his office Arau Acústica and with architects designing concert halls using his method: the Auditori Enric Granados in Lleida (1983-1995) and the Teatre-Auditori de Sant Cugat (1989-1994), both by the firm Artigues & Sanabria; L'Auditori of Barcelona (1987-1999) and Kursaal in San Sebastián (1990-1999), both by architect Rafael Moneo; and the reconstruction of the Gran Teatre del Liceu of Barcelona (1994-1999), with architects Ignasi de Solà-Morales, Lluís Dilmé and Xavier Fabré. These early works catapulted him to consultancy on over 200 auditoriums in Spain and over twenty in other countries, including the refurbishment of the Teatro alla Scala of Milan (2002-2004) and the Tonhalle of St. Gallen, with Bosshard Vaquer Architekten (2009-2010), or the new Filharmonia im. Mieczysława Karłowicza in Szczecin (2007-2014), with Barozzi Veiga [14].

Considering the great demand for collaboration, Higini Arau-Puchades and Lluís Jutglar, a professor at the Universitat de Barcelona, developed their own software for acoustic verification of rooms, which formed part of the firm's unpublished know-how [14].

In addition, Arau-Puchades widely disseminated his equation (4) through his handbook, the *ABC de la acústica arquitectónica* (1999). This is one of the most widespread handbooks on acoustics in Spanish. Beyond the didactic needs of the book, he dedicated 17 pages to showing chronologically the scientific contributions of Sabine's formula to his proposal. He included critical commentaries on the formulae of Sabine, Eyring, Norris, Millington, Sette, Fitzroy, Gomperts, Kosten, Pujolle, Kuttruff and

Wernly, and on computer approaches with ray tracing [24, pp. 227–242].

3.2 Implementation of Arau-Puchades's equation in international professional software

In fact, the publication of Arau-Puchades's equation (4) coincided with the development of the first computer programs that aimed to simulate the behaviour of sound in its three dimensions. Furthermore, Arau-Puchades's formula began to be compared favourably with other statistical methods and the results achieved with these computer simulations. An article published in 2000 by Brazilian engineer Sylvio R. Bistafa and Canadian researcher John S. Bradley [25] was fundamental for the successful dissemination of Arau-Puchades's proposal. Table 3 shows the results of this study, in which seven equations that assessed absorption in a different way were compared with real laboratory measurements. Arau-Puchades's formula had the lowest errors at all frequencies.

Table 3. Overall average relative errors of the analytical predictions of reverberation time for ten sound-absorbing configurations in the simulated classroom, according to Bistafa and Bradley [25, p. 1727].

	Overall average relative error (%)		
	Frequency bands included in the averages		
	1 kHz	500 Hz–2 kHz	125 Hz–4 kHz
Sabine (1)	38.8	31.6	21.5
Eyring (2)	42.6	35.7	24.7
Millington	36.1	30.4	21.1
Cremer	26.7	23.9	17.4
Kuttruff	68.0	63.5	49.3
Fitzroy (3)	92.0	95.8	65.7
Arau-Puchades (4)	22.9	22.7	16.7

The same article compared these statistical results with those obtained from two computer programs, RAYNOISE 3.0 of LMS Numerical Technologies NV (Leuven, Belgium) and ODEON 2.6 of the Department of Acoustic Technology at the Danmarks Tekniske Universitet (Lyngby, Denmark). Reading the article prompted the developers of ODEON software to incorporate Arau-Puchades's formula in their program, probably already in version 5.0 of 2001[1]. Of course, over time, the ray-tracing and wave-based algorithms have improved considerably, but at that time the formula played a notable role in the adjustment of this parameter.

Other researchers have incorporated Arau-Puchades's formula in more specific software such as WINRT60 1.0. This is a program for calculating reverberation time designed by Tor Erik Vigran, professor of the Norges teknisk-naturvitenskapelige universitet (NTNU), in 2006. Using this program, it was possible to calculate the reverberation time of a room using formulae by Sabine (1), Eyring (2) and Arau-Puchades (4) [26]. Likewise, in 2015, STRUTT by Arup incorporated the Arau-Puchades equation in its v5.15.12 [27]. This is a plug-in for MICROSOFT EXCEL that includes a large number of functions for acoustic calculations.

3.3 A proposal with a long history

A simple bibliometric approach shows that the article "An improved reverberation formula" [18] has been cited 40 times in articles indexed in the Web of Science, 64 times in Scopus and 138 times in Google Scholar[2]. The Figure 6 indicates that interest in the model proposed by Arau-Puchades increased notably from the year 2000.

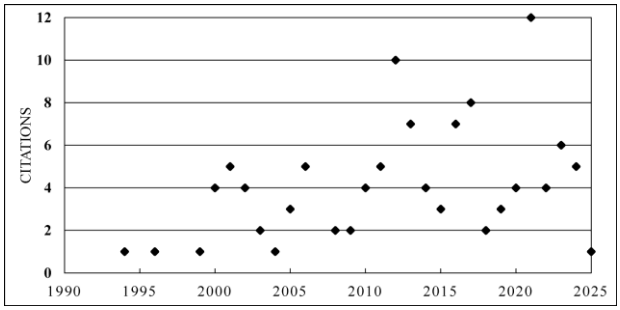

Figure 6. Number of citations per year of "An improved reverberation formula" [18], as recorded in Google Scholar on 23 March 2025.

As noted above, the study by Bistafa and Bradley of 2000 [25] showed that Arau-Puchades's model (4) obtained the lowest relative errors compared to the reverberation time measured in the laboratory. A similar result was obtained by French researchers Joël Ducourneau and Vincent Planeau in 2003. They concluded that, among all the models studied, which included Sabine (1), Eyring (2), Millington, Pujolle, Arau-Puchades (4) and Fitzroy (3), "The Arau-Puchades's model, which is adapted to non-

[1] Claus Lynge Christensen, personal communication (e-mail), December 27, 2024.

[2] Consulted: March 23, 2025.

uniformly distributed absorption, is the closest to the experimental results (maximal relative error <20%)" [28, p. 853].

After these two articles, numerous researchers have shown interest in Arau-Puchades's model, which has been incorporated in some handbooks such as *Sound insulation* by Carl Hopkins (2007) [29, p. 42], *Building acoustics* by Erik Tor Vigran (2008) [30, p. 122], and *Acústica de salas: projeto e modelagem* by Eric Brandão (2018) [31, p. 461].

4. CONCLUSIONS

Finally, we might wonder about the opportunity at the end of the 1980s [32, pp. 390–391] to propose a new model for calculating reverberation time at a time in which new room acoustic parameters were being developed, such as *Deutlichkeit* [D50, definition] (1953), Early Decay Time [EDT] (1970), Clarity [C80] (1974) and G-Strength (1976) [33-35]. However, considering that many of these parameters continue to be governed by reverberation time [36], it makes sense to have as accurate statistical models as possible.

In fact, the model proposed by Higini Arau-Puchades aimed to respond to the need to improve the prediction of reverberation time in a non-diffuse field and took these new parameters into account. The same model enabled determination of the Early Decay Time, as had been suggested by Lothar Cremer.

Nevertheless, it was not an easy model to apply. As we have seen in the case of the Palau de la Música Catalana, the acoustic consultant had to select with criteria the pairs of surfaces that would be assigned to the directions X, Y and Z. For this reason, whoever applies the model must know how the equation works to be able to understand the results that are obtained.

ABSTRACT

In the past decades, noise has gained growing significance. Also in mechanical engineering, increasingly complex mecha(tro)nic systems are emerging which have to perform optimally while satisfying ever more stringent noise regulations and customer expectations. Nowadays, electrification and transition to greener technologies and materials leads to novel noise sources and problems, posing significant engineering challenges.

With increasing computation power over the past decades, also rapid technological evolutions have unfolded in acoustics: from testing to numerical modeling and simulation, from mono- to multi-physical simulation, from offline to real-time online simulations, … Thanks to these evolutions, noise is evolving from an attribute to quantify and control towards an integrated design parameter for the entire lifetime of systems, enabled by reduced order modeling, innovative signal processing techniques, novel emerging vibro-acoustic solutions and optimization. Moreover, combining fast multi-physical models with acoustic measurements has opened the door to a variety of novel developments including auralization, virtual sensing, real-time state/parameter estimation and prognostics.

This paper gives an overview of the dynamics (noise, vibration & motion) research at the KU Leuven Mechanical Engineering Department, in the LMSD research group.

Keywords: *testing, modeling, multi-physics, digital twins*

1. INTRODUCTION

In the past decades, the field of noise, vibration and harshness (NVH) engineering has expanded and evolved. With the growing awareness of the negative impact of noise on human health, the increasingly stringent noise legislation and ever more demanding customer expectations, noise has not only changed from an (unwanted) byproduct to a key product differentiator, but also to a key quantity which is accounted for and exploited at every life phase of a product. At the same time, mechanical engineering systems have evolved to mechatronic systems. These are not only more complex to design, model and analyze, but also create the opportunity for built-in sensorization and continuous data streams between products and virtual counterparts.

Together with this evolution, the LMSD System Dynamics research group at KU Leuven grew from the Noise & Vibrations research group which in its turn started over 5 decades ago as the MOD – Modal analysis research group. The research at LMSD spans a broad spectrum from methodologies, over theoretical foundations, to various application domains: by understanding, monitoring and controlling the dynamics (motion-vibration-acoustics) of mecha(tro)nic systems, LMSD aims at creating added value

during every phase (design, manufacturing, and operations) in their lifetime. Having built out dedicated in-house testing and validation platforms, as well as software toolchains, the research group closely co-innovates together with world-wide research and industry partners and, in doing so, actively cross-fertilizes between applied and industrial research[1][2] [1]. Furthermore, to create scientific as well as societal impact, LMSD regularly brings its latest developments closer to the wide public[3,4].

The rest of this paper presents several recent developments and (industrial) use cases in acoustics research at LMSD. After describing progress in acoustic testing and modeling in Sections 2 and 3, Section 4 discusses advanced techniques for (vibro-)acoustic measurement and analysis. Novel (vibro-)acoustic solutions are the topic of Section 5. Section 6 discusses how models and measurements come together in Digital Twins and add value, and Section 7 provides an outlook on how this digitally connected concept can be elevated to close the loop across all life phases of products. Section 8 summarizes the main conclusions.

2. ACOUSTIC TESTING

With the change from analog to digital, the increase in computing power, and the downscaling of circuits, acoustic measurement devices have become more portable, precise and versatile in the past decades (Fig. 1). Along with that digital (r)evolution, acoustic testing nowadays comprises far more than sound pressure recording, covering a broad spectrum ranging from characterization and (model) updating/validation (Section 3) to condition monitoring (Section 4), sensing and digital twinning (Section 6).

Figure 1. Historical collection of LMSD's vibro-acoustic measurement systems.

[4] https://www.youtube.com/@lmsd-kuleuven

Standard (vibro-)acoustic measurement techniques rely on controlled environments, for which simple analytical models can relate sound pressure measurements to the quantities of interest. However, these idealized environments are often not representative for the final application. Over the years, various non-standard test rigs have been developed to enable the characterization of (vibro-)acoustic properties in more representative environments (Fig. 2), often relying on virtual counterparts (Section 6).

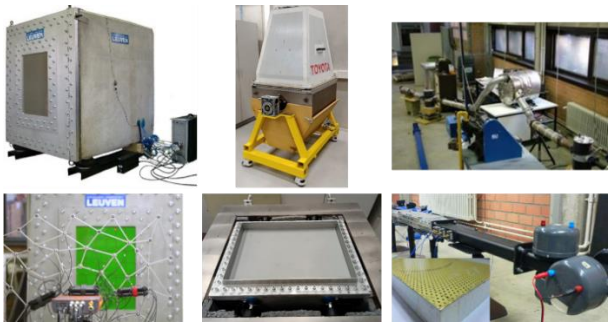

Figure 2. (left, center) Non-standard test-rigs for (vibro-)acoustic transmission, absorption & radiation, (right) modular infrastructure for characterization of (flow-)acoustic properties of duct systems.

These test rigs are augmented with various measurement systems, including sound intensity probes, acoustic arrays, acoustic camera, (scanning) laser doppler vibrometers (SLDV), ... Furthermore, digital counterparts of these test rigs have been created using different modeling strategies (Section 3), which not only enables updating models of tested components, but also allows gaining additional insights via model-measurement combinations (Section 6).

SLDVs have especially gained interest as they enable full-field characterization, not only useful for (source) localization (Fig. 3), but also for analyzing structural wave phenomena in novel materials (Section 5). Recently, also camera-based measurements have gained interest in vibro-acoustics. In contrast to conventional acoustic sensors, cameras allow directly observing the structure-borne noise source. Methods were developed to predict full-field acoustic radiation of vibrating surfaces independently of the acoustic environment (Fig. 4) by leveraging camera measurements with acoustic models (see also Section 6). These techniques especially also hold promise for vibro-acoustic problems involving transient behavior and moving systems.

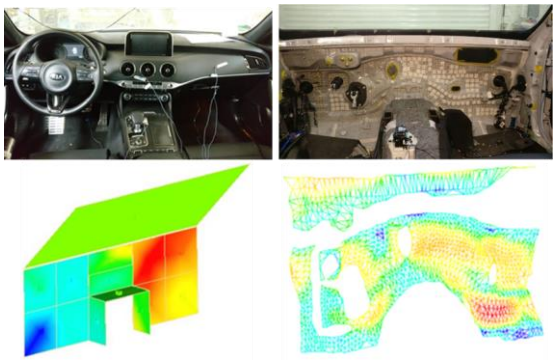

Figure 3. (left) Sound intensity, (right) SLDV-based vibration field measurements of a car firewall [2].

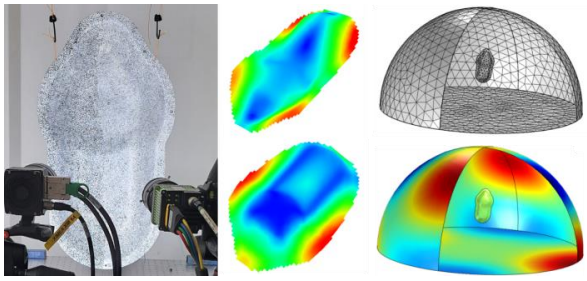

Figure 4. (left & center) Camera-based vibration field measurement, (right) combined measurement-model based acoustic radiation estimation [3].

In particular with the rise of novel emerging materials and structures such as metamaterials (Section 5), which exhibit non-conventional acoustic wave propagation behavior, dedicated acoustic test setups and routines have been developed (Fig. 5) that enable characterizing their performance already early in design process, without need for full 3D simulation, design, manufacturing and testing.

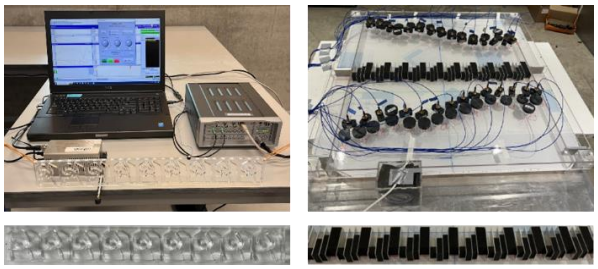

Figure 5. (left) Hammer impact-based method to validate the Sound Transmission Loss (STL) of 2D structures [4], (right) 2D rectangular waveguide for angle-dependent transmission, reflection and absorption coefficient characterization [5].

3. ACOUSTIC MODELING

In the past decades, element-based numerical techniques such as the Finite Element Method (FEM) and Boundary Element Method (BEM) have become industry standard for solving large and complex (vibro)-acoustic problems (Fig. 6a). With increasing frequency, element sizes must decrease, which drives up computation cost of element-based techniques, limiting their application mostly to lower frequencies. Although high-frequency techniques such as Statistical Energy Analysis (SEA) exist, a mid-frequency gap persisted and drove the search for mid-frequency methods[5]. In particular, at LMSD, the Wave Based Method (WBM) for (vibro)acoustics was developed, which is an indirect Trefftz approach. It partitions the (interior/exterior) problem in large convex subdomains, approximating the solution with wave functions, being exact solutions of the governing equation [6]. Although mainly suitable for problems with limited geometrical complexity, WBM was shown to be more efficient than FEM and BEM for said problems. Hybrids with FEM (Fig. 6b), BEM and SEA were developed to combine the best of several worlds. Later, to allow ensuring geometrical exactness - which element based techniques typically lose - isogeometric analysis (IGA)-based FEM and BEM have been proposed [7,8], using Non-Uniform Rational B-splines (NURBS) to represent the geometry and discretize the wave equation (Fig. 6c) instead of polynomials in classical FEM or BEM.

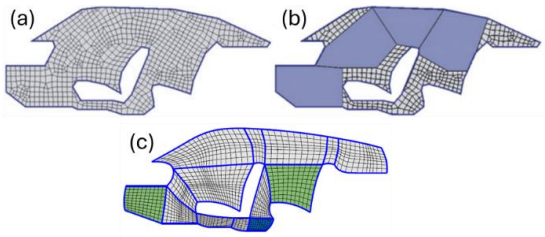

Figure 6. Numerical modeling methods in acoustics: (a) FEM, (b) WBM and hybrid WB-FEM for mid-frequency analysis [6], (c) IGA FEM [7].

Performing a frequency sweep either with FEM or BEM can induce high computation costs (solution time, memory). Such costs can be alleviated, by so-called Model Order Reduction (MOR) techniques, where the structure of the system and the repetitiveness of the procedure are exploited to provide a fast yet accurate solution. Specifically, in case of affine systems (e.g. regular vibro-acoustic FE models), it is possible to split the calculation in an expensive offline part and a cheap online part. In the offline part a reduction

[5] https://www.youtube.com/watch?v=m9OHmurazTA

basis is computed and the system matrices are projected on this basis. The different MOR strategies typically differ in the way the reduction bases are computed. Common techniques are POD, reduced basis method, rational Krylov approximation, … When combined with exterior acoustics, boundary treatments, and time-domain solution procedures, particular attention has gone to preserve stability (Fig. 7) [9]. Compared to FEM, MOR for BEM is more challenging as the frequency is non-affinely involved in the system matrices. To enable the application of MOR, the system needs to be approximated through an affine expression [10].

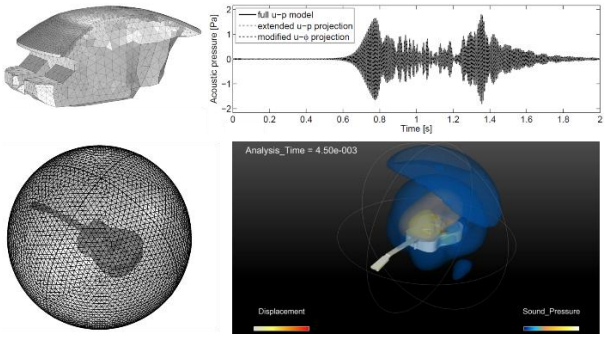

Figure 7. MOR for time stable, efficient FE time-domain simulations for interior/exterior acoustics [9].

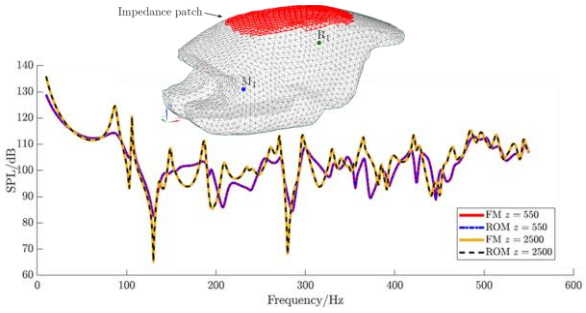

Figure 8. pMOR for acoustic BEM. Interior acoustic treatment modeled with impedance patch [10].

Following the same logic as in conventional MOR for FEM and BEM, it is possible to increase the number of parameters to include e.g. material, source position, shape … which has led to parametric MOR (pMOR) techniques, for instance by sampling information from the parameter space beforehand (Fig. 8) [10]. Doing so, pMOR allows fast transitions among different design configurations, either for design or fast inverse parameter estimation (Section 6). Recently, time-stable MOR routines for vibro-acoustic models including frequency-dependent admittance relations, porous and poro-elastic layers, and PMLs have also been developed [11].

Another avenue on the rise is the use of Machine Learning (ML), not only for MOR, but also to accelerate and improve acoustic model generation. E.g. in absence of CAD data, techniques have been developed to enable creating geometrically accurate acoustic meshes using photo-grammetry (Fig. 9). The latter allows for a high degree of customization of acoustic predictions, but also for improved immersion when considering also the receiver and sound perception in the acoustic problem for e.g. auralization [12].

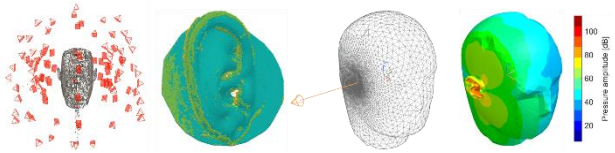

Figure 9. Dummy head ear scans are fed to DNNs trained on point cloud denoising for numerical Head-Related Transfer Function (HRTF) prediction [12].

4. (VIBRO)ACOUSTIC MONITORING AND DETECTION

In many industrial applications including manufacturing, power generation and transportation, rotating machinery plays a pivotal role. As continuously operating drivetrains predisposes their rotating components (e.g. gears, bearings …) to a risk of failure, condition monitoring for accurate and on-time fault detection has grown indispensable.

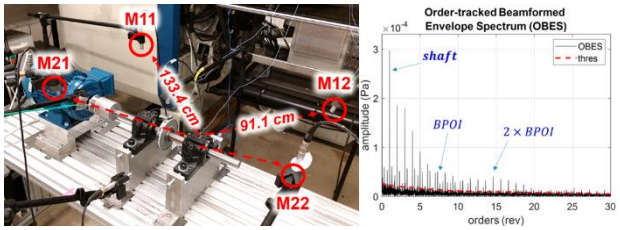

Figure 10. (left) In-house modular drivetrain test setup for bearings & gears diagnostics instrumented with accelerometers and microphones, (right) tracked spectrum of a damaged bearing [13].

While vibration sensors have been historically used for fault detection, recent work has focused on also harnessing the integratory capability of microphones to capture the global, overall acoustic signature of the entire drivetrain with limited and non-contact sensors. Several dedicated setups for drivetrain components have been built and instrumented at LMSD to develop and validate novel advanced signal processing techniques for vibro-acoustics based condition monitoring (Fig. 10) [13].

On the other hand, also nondestructive testing (NDT) has been a topic of extensive research lately with the goal of detecting defects in complex composite parts and assemblies in a limited inspection time. Classical NDT often relies on thermal imaging techniques and ultrasound. At LMSD, the use of vibro-acoustic signals to detect and identify damage is researched (e.g. loose bolt detection with MUSIC[6], Fig. 11). Combining vibro-acoustic information originating from defects with accurate numerical models enables enhancing the detection of such defects (Section 6), while lowering the required number of sensors [14].

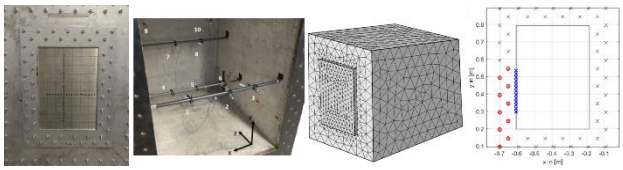

Figure 11. Structural damage (loose bolt) detection of assembly using acoustic measurements (with/ without combination with numerical model) [14].

5. INNOVATIVE VIBRO-ACOUSTIC SOLUTIONS

As classical passive solutions to increase sound insulation and/or absorption rely on adding mass and/or volume, they are less suitable for low frequencies. With the advent of more powerful controllers, active noise control gained a lot of interest in the 90s for low-frequency noise abatement [15]. Two decades later, (vibro-)acoustic metamaterials emerged and have meanwhile shown great potential as lightweight and compact solutions for high noise and vibration attenuation in targeted frequency ranges called “stop bands” [16], enabled by sub-wavelength added resonant inclusions on or in a (flexible)host structure.

To characterize, design and optimize the performance of (vibro-)acoustic metamaterials, a complete toolchain has been developed at LMSD[7] which enables covering all relevant physics, as well as translation from idealized infinite periodic structure theory to more complex, practically realizable solutions (Fig. 12) [17]. Their versatility and effectiveness in treating vibration, acoustic radiation and transmission problems has been proven through a variety of demonstrators, ranging from academic to industrial application (Fig. 13) [16, 18, 19].

Nowadays, metamaterials research at LMSD is expanding towards (mass-)manufacturability (e.g. injection molding) and variability, (topology-optimized [4]) multi-functional metastructures[8] and phase gradient acoustic metamaterials (Fig. 5) [5], as well as active (piezoelectric) metamaterials.

6. VIBRO-ACOUSTIC DIGITAL TWINNING

Leveraging increasingly fast yet accurate (vibro-)acoustic models together with measurement data, enables creating digital twins[12], which are not only continuously updated

[6] https://www.youtube.com/watch?v=H0nFtsJ4HYM
[7] https://www.youtube.com/watch?v=DPbPjo3du5Q
[8] https://www.youtube.com/watch?v=jFNa8gOn-eo
[9] https://www.youtube.com/watch?v=JUi3qK32mf0

[11] https://www.youtube.com/watch?v=MdHVCnvj9x0
[12] https://www.youtube.com/watch?v=_d1oMRVlvMA

with reality, but provide insight in difficult to measure or unmeasurable quantities. Deploying the developed modeling strategies and in-house available test rigs and physical assets at LMSD, in the past years, a Digital Twin Experience Center has been established (Fig. 14).

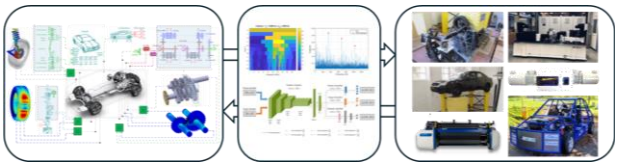

Figure 14. digital twins at LMSD: (left) modeling & simulation platforms for component and system dynamics, (center) estimation, signal processing & ML, (right) full-scale mechatronic systems.

Setting up digital twins for NVH requires digitizing the full chain from source/inputs, over path to receiver. Hence, multi-physical and multi-domain simulation frameworks have been set up, combining e.g. multibody simulation, 1D and 3D simulations, electromagnetic simulations and vibro-acoustic simulations (Fig. 15) [20].

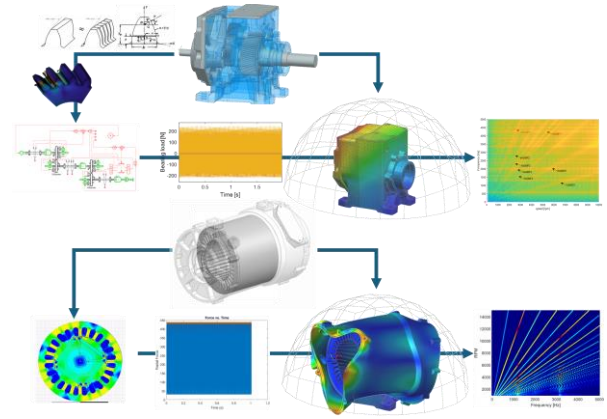

Figure 15. Multi-physical simulation workflow for (top) gearbox and (bottom) e-motor noise [20].

Through combining dedicated test-setups & physics-based (digital) counterparts, these digital twins enable amongst others experimental model-based input and parameter estimation of vibro-acoustic systems[13] as well as optimizing sensor selection and placement: e.g. for operational load estimation (Fig. 16), for source localization in complex environments, for acoustic material identification in reverberant environments [22], for acoustic material characterization under various flow conditions, … In particular acoustic virtual sensing[14], model-based augmented sensing of input forces, acoustic pressure and intensity with numerical models (Fig. 17), but also experimental modal models for e.g. virtual acoustic measurements in exterior vibro-acoustic problems (Fig. 18) have been developed and demonstrated.

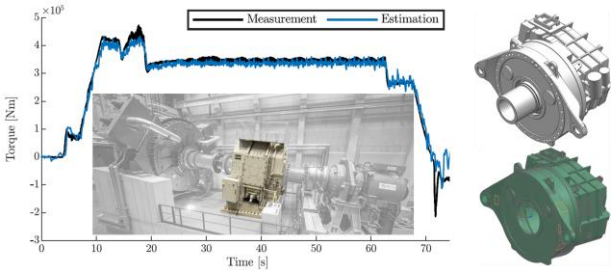

Figure 16. Virtual torque sensing of ZF wind turbine gearbox tested on the 4MW drivetrain testing infrastructure at Center for Wind Power Drives [21].

7. THE FUTURE

Building models and validating products requires accurate data. In the current Industry4.0 era, data is becoming increasingly abundant: during every life phase of a product,

[13] https://www.youtube.com/watch?v=1dW2g6tYsgI

[14] https://www.youtube.com/watch?v=fx6-yIMkN6s

digital information (digitized knowledge, simulation models, test data, production data, etc.) is generated, from early concept design, over detailed design and analysis, virtual and physical prototyping, product validation, commissioning, production and assembly, quality control, to the operational product in-use phase, and even the end-of-life (re-use, re-cycling, re-manufacturing) phases. Digital twins allow collecting and comprehensively managing all digital information linked to a unique product in all its different life phases, and to generate unprecedented added value by digitally connecting these phases in a closed loop, coined by KU Leuven as the "infinity loop" (Fig. 19). As such, the amount of available information and knowledge per product substantially increases, and more optimized and effective decisions can be taken.

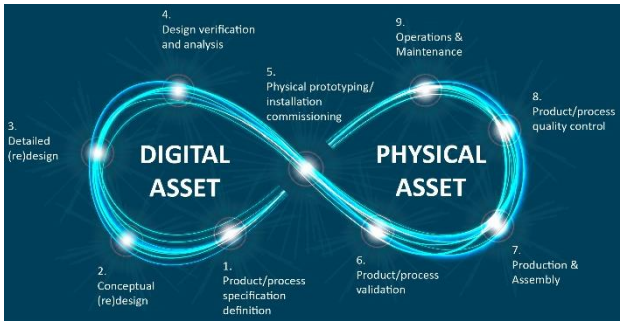

Figure 19. Enabled by digital twins, the infinity loop digitally connects all life phases in a closed loop.

From a vibro-acoustic point of view, this opens the door to various scenarios, such as for example (i) improved product validation since individual variations in part geometry or (mis-)alignment can be propagated to update nominal design models and hence take the effect of off-design into account, (ii) more accurate operational estimation, as these updated vibro-acoustic models allow for better estimates of transfer functions and thus better estimation of loads or states of the mecha(tro)nic system, and (iii) better next-generation designs as operational and end-of-life information can be fed-back to the designers, and many more scenarios.

8. CONCLUSIONS

In line with the increasing importance of quieter living and working environments, acoustic modeling and testing procedures keep improving, and innovative NVH solutions keep getting closer to widespread application. Noise and vibrations are omnipresent, and with the advent of (vibro-acoustic) digital twins, capabilities to both control NVH as well as harness its value at every life phase of the product lifecycle are ever expanding, thereby enabling the development of high-tech products, processes and systems, while at the same time accounting for the health of people and the well-being of society, for a sustainable environment and energy supply, and for safe and comfortable mobility.

ABSTRACT

Exposure to excessive noise is linked to significant adverse effects on human health, including stress, sleep disturbances, and reduced quality of life, particularly in residential areas near commercial or industrial zones. This study focuses on analyzing the noise components emitted by various sources located on the rooftop of a hypermarket. The aim was to measure and identify the noise levels generated by the operating machinery, such as air-conditioning systems, cooling units, rooftop ventilation, transformers and compressors, which could impact the nearby environment, particularly the residential buildings located in front of the examined hypermarket.

Field noise surveys were carried out in the summer period during daytime and night-time to measure noise levels under operational conditions. These measurements were followed by thorough frequency spectra investigations utilizing Fast Fourier Transform (FFT) analysis, which helped identify the most significant noise contributors. While the study provided clear insights into the operational noise impacts during the summer, winter-specific noise sources, such as boilers were excluded due to seasonal constraints.

The findings serve as a foundation for further mitigation measures, including re-evaluation during winter operation to address potential regulatory noise exceedances and noise complaints.

1. INTRODUCTION

Exposure to high noise levels can cause mental and physical adverse health effects [1]. It is linked with long-term risks of cardiovascular illnesses [2], such as heart attacks or hypertension. Moreover, excessive prolonged noise exposure affects work and educational environments, overall cognition, communication, and it weakens our attention [3-4]. Noise from industry increases the probability of residents nearby to suffer from mental illnesses [5]. Therefore, different mitigation measures to reduce the hazard caused by industrial noise were evaluated by many researchers [6]. For instance, sound absorption and insulation enclosures were designed to reduce the noise emissions of transformers [7], noise reduction of around 20 dBA was obtained by building noise barriers around a metallurgical factory [8], and acoustic metamaterials that could be used to increase the sound insulation performance for a better acoustic building design [9]. However, implementing noise reduction measures usually demand significant manpower and financial resources [6]. Therefore, this study utilized the Fast Fourier Transform (FFT) method through environmental noise measurements to analyze the spectral emissions of various equipment. The results were compared with the spectral emissions at the sensitive receptor to identify the most significant noise contributors. The findings are expected to provide a basis for further mitigation measures to reduce noise levels from the major contributors.

2. MATERIALS AND METHODS

2.1 Problem Overview

Residents of a dwelling situated across the street from a hypermarket were disturbed by the noise generated from the machines operating both within the hypermarket, and on its rooftop, despite the presence of a 3-m noise barrier. The study was limited to identifying the most contributing noise sources to the reported annoyance rather than to evaluate compliance with regulatory limits. Figure 1 below illustrates the location of the study area.

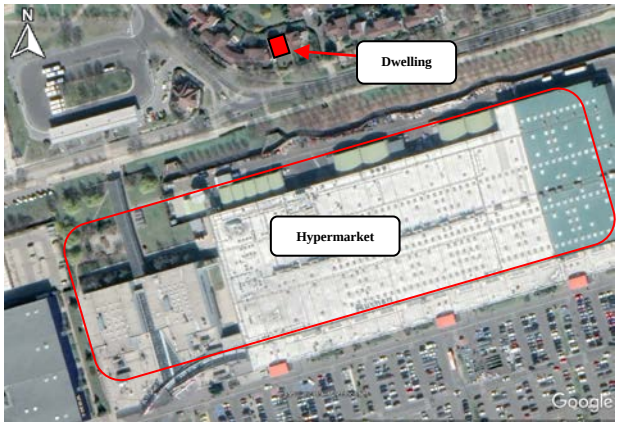

Figure 1. Study Area Overview.

2.2 Methodology

To assess the noise levels and identify the dominant noise sources accurately, two Class 1 Sound Level Meters (SLM) were utilized. One SLM was positioned at 2 meters from the façade of the Dwelling, referred to as Sensitive Receptor (SR) and at a height of 1.5 m from the ground level, according to ISO 1996 series [10-11], to measure the noise levels experienced by the residents, while the second SLM was placed around the machinery operating within the Hypermarket boundary, such as air-conditioning systems, cooling units, rooftop ventilation, transformers and compressors. This simultaneous measurement at both locations was conducted during daytime and nighttime and allowed for direct correlation between the noise contributions of specific machinery and their impact on the residential area. Fast Fourier Transform (FFT) function was enabled during the measurements to provide a full overview of the spectrum at both locations for further analysis.

Additionally, the study took place during the summer period. Therefore, winter-specific noise sources, such as boilers were excluded due to seasonal constraints.
Table 1 summarizes the description of each measurement point depicted in Figure 2 below.

Table 1. Measurement Points Description.

MP ID.	Noise Source Description	Operation (Day/Night)*
R0	Cooling Unit 1	I/I
R1	Transformer 1	C/C

R42/R43	IT Equipment Noise 3	C/C

*C = Continuous, I = Intermittent

Figure 2. Measurement Point Locations.

Then, the results obtained from all measurement points were plotted in charts utilizing FFT analysis and compared with the results obtained at the Sensitive Receptor (SR) during both daytime and nighttime to identify any correlations in the measured spectra. In all charts, the right Y-axis represents the noise levels (dB) of the machinery and the left Y axis represents the noise levels (dB) at SR, while the X-axis accounts for the frequency in Hz.

3. RESULTS AND DISCUSSION

The present section highlights the measurement processing step utilizing FFT analysis. It is to be noted that if no correlation was identified, the measurement point was excluded. Therefore, the following sources were identified as potential contributors:

- Transformers
- Cooling Units (Chillers)
- Pumps
- Air Cooler
- Ice Maker Outdoor Unit

3.1 Transformers

Two transformers were identified in the study area: Transformer 1 (R1), located 170 m from SR, and Transformer 2 (R20/R33), located 85 m from SR, both operating continuously. It was observed that both transformers correlate with the nighttime spectrum measured at SR, with Transformer 2 having a higher contribution due to its closer proximity and higher noise levels. Figure 3 and Figure 4 below illustrates the FFT analysis charts for both transformers.

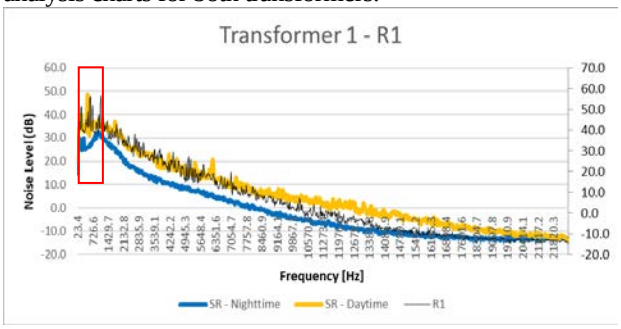

Figure 3. Transformer 1 (R1) FFT Chart.

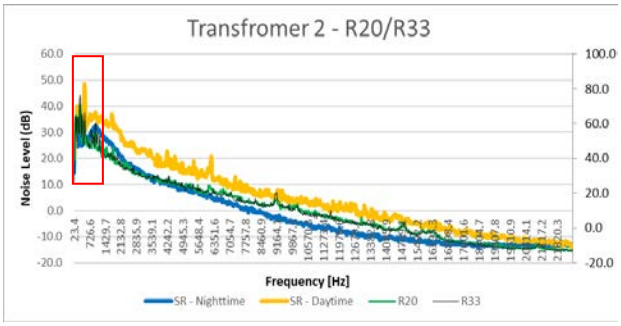

Figure 4. Transformer 2 (R20/R33) FFT Chart.

3.2 Cooling Units (Chillers)

Although five different Chillers were examined, only Cooling Unit 5 (R23), which has intermittent operations during daytime, showed significant correlation with the daytime noise spectrum observed at SR in the low and mid-frequency ranges, due to the following reasons:

a) It is the closest Chiller at 90 m distance from SR.
b) It is positioned on the rooftop of the Hypermarket, above the existing noise barrier.
c) It is oriented perpendicularly to SR.

The FFT analysis showed that in the low and mid-frequency ranges, e.g. 492 Hz, 750 Hz, 1000 Hz, and up to 7200 Hz, the Chiller's spectrum precisely with the peaks identified in the daytime spectrum at SR. However, the peak observed in the high-frequency range (around 15k Hz) in the Chiller's spectrum did not have an impact at SR, due to its rapid attenuation with distance compared to lower frequency. As a result, it was no longer detectable at SR. Figure 5 below depicts the FFT analysis chart for Cooling Unit 5.

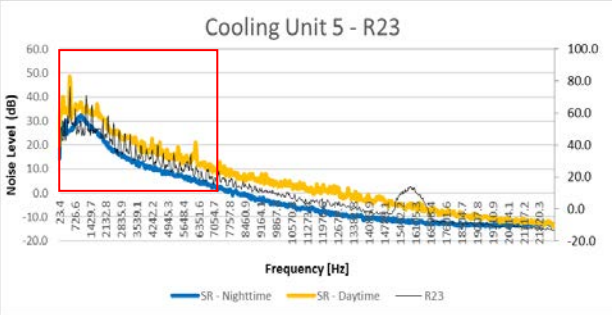

Figure 5. Cooling Unit 5 (R23) FFT Chart.

3.3 Pumps

Two measurements were conducted to analyze the spectrum of the Pumps, R30 and R37, which operate continuously during the day and night. The FFT analysis showed a weak correlation observed during nighttime only at 492 Hz. However, they are located 140 m from SR. Therefore, it was concluded that they are not a main contributor to the annoyance observed at SR. Figure 6 presents the FFT analysis chart for Pumps.

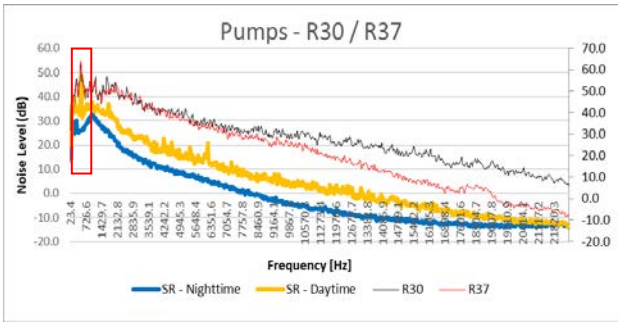

Figure 6. Pumps FFT Chart.

3.4 Air Cooler

Air Cooler, located 112 m from SR, was also evaluated. Two measurement were conducted around the unit, R22 and R34, to analyze its spectrum. Although the Air Cooler's noise was detectable at SR, both measurement indicated weak correlation during its intermittent operations in both daytime and nighttime. Therefore, it did not contribute to the reported annoyance, which can be linked to the characteristics of the noise source, as it lacked tonal or narrowband components. Figure 7 below depicts the FFT analysis chart for the Air Cooler.

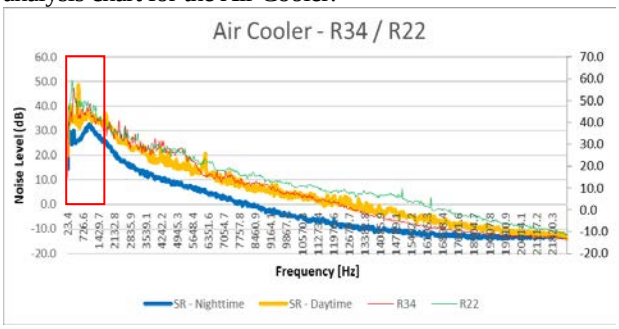

Figure 7. Air Cooler FFT Chart.

3.5 Ice Maker Outdoor Unit

The Ice Maker Outdoor Unit (R19) spectrum showed a weak correlation with the spectrum recorder at SR during nighttime. Despite being 85 m from SR, it was observed that its noise level at 1 m is not high enough to reach SR, especially that it is located behind the noise barrier. Therefore, it can be concluded that the correlation is due to another equipment which has similar characteristics, which in this case is Transformer 2. Figure 8 below depicts the FFT analysis chart for the Ice Maker Outdoor Unit.

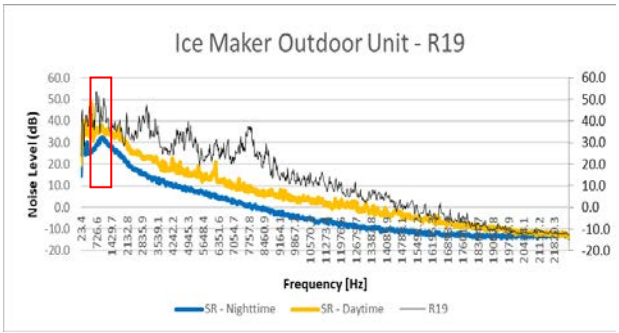

Figure 8. Ice Maker Outdoor Unit FFT Chart.

4. CONCLUSION

This study aimed to analyze the primary noise sources contributing to the disturbance reported by the residents of a dwelling located in front of a Hypermarket. A comprehensive noise measurement campaign was carried out to identify the most significant noise contributors operating within and on the rooftop of the Hypermarket utilizing FFT analysis. The results depicted that during daytime, the most significant contributor is Cooling Unit 5 (Chiller). This conclusion was based on the high correlation between its spectrum and the spectrum recorded at SR, its distance from SR, its high noise levels., and its position on the rooftop above the noise barrier, oriented perpendicularly to SR. However, its operation is intermittent and limited daytime.

During nighttime, it was observed that both Transformer 1 and Transformer 2, correlate with the measured spectrum at SR. Among them, Transformer 2 is more likely to be the primary contributor, due to its higher noise levels being significantly closer to the dwelling.

Other equipment, such as Ice Maker Outdoor Unit, Pumps, and Air Cooler, were also considered as potential contributors. However, the FFT analysis showed a weak correlation with SR. Additionally, site conditions, including their location and distance from SR, indicating that these source are either not detectable or had a negligible effect on the recorded noise levels at SR during both daytime and nighttime.

OBTAINING NOISE LEVELS FROM PROJECTED OVERPRESSURE LEVELS GENERATED BY BLASTING OPERATIONS

Max Glisser[1*] **Betsabé Vásquez**[1]
[1] Gerard Ingeniería Acústica SpA, Villaseca 21 Oficina 1105 - Ñuñoa – Santiago – Chile

ABSTRACT

The overpressure levels generated by blasting generally increase with greater charge mass and decrease with greater distance from the blast site. Scaling methods are often used to determine the relationship between charge mass, distance and peak blast overpressure levels. The overpressure levels were calculated using a cube root scaling equation, taking into account constants that respond to the type of terrain of the blasting site. However, these peak overpressure levels are obtained as a global level in dBL. Therefore, this research gathers background information to provide a more comprehensive understanding of the noise caused by blasting and to advance its analysis. The results can be used for evaluations that require various weightings such as A, C and Z.

Keywords: *noise, blasting, mining*

1. INTRODUCTION

To determine the noise coming from a blasting at a given receiver we use an equation and constants that provide a single value of overpressure level. However, in some cases we need the noise level in different descriptors and/or weightings. For example, when evaluating fauna impact thresholds may be specified in dBA or dBZ. [1]
In Chile, the technical document "Evaluation criteria in the SEIA: Evaluation of noise impacts on native fauna" [1], has brought renewed attention to the assessment of noise effects on native wildlife.

This technical document establishes impact threshold for groups of vertebrate animals, i.e., amphibians, reptiles, birds and mammals, thresholds that are determined based on the species (or group) being evaluated, the type of noise source (continuous, impulsive or intermittent) and the associated adverse effects (physiological and behavioral). The thresholds are weighted using different curves such as A and C.
According to current legislation [2], it is required to study the impact of noise generated by blasting on all objects of protection. In the case of fauna, the object of protection is the relevant habitat for nesting, reproduction, or feeding, which must be located within the project's noise influence area (Guide for the Description of Soil, Flora and Fauna Components of Terrestrial Ecosystems in the SEIA, 2015) [3].
Therefore, this presents the challenge of predicting the noise levels generated by blasting at different weightings and distances in order to determine the impact area and assess compliance with the proposed thresholds.

2. ASSESSMENT OF IMPULSIVE NOISE ON WILDLIFE

For the specific case of impulsive noise, there are thresholds for birds and mammals, which are indicated below:

Table 1. References for the determining of reference thresholds for evaluating the noise impact on terrestrial fauna. Avifauna.

Effect description	Effect Type	Source Type	Threshold	Reference
Increased alertness and vigilance	Behavio-ral	Impulsive (military or blasting)	80 dBA max 63 dBA average	(Shannon et al., 2016) [4] [5] [6]
Direct	Physio-	Single	140 dBA	(Dooling

Effect description	Effect Type	Source Type	Threshold	Reference
hearing damage	logical	impulse (blasting)	max	& Popper, 2007) [7]

Table 2. References for the determining of reference thresholds for evaluating the noise impact on terrestrial fauna. Mammals.

Effect description	Effect Type	Source Type	Threshold	Reference
Increased alertness and vigilance	Behavio-ral/ Physio-logical	Impulsive (military)	85 dBZ average	(Shannon et al., 2016) [4]

In the case of avifauna, the thresholds are presented with the frequency weighting filter A, or dBA. Additionally, "max" refers to the maximum Sound Pressure Level (SPL) recorded during the measurement period, it is sub understood, of the event or blasting, given the short duration that these have, while one of them is indicated not maximum SPL, but average, not indicating the integration time or "averaging".

On the other hand, for mammals a single threshold applies to both behavioral and physiological effects and it based on an unweighted frequency measurement or dBZ and an average value, without specifying the integration time. However, due to the impulsive nature of the source, it can be inferred that the integration time is short.

3. SOUND PROPAGATION EQUATION

The accurate estimation of ground vibration and airblast levels is a complex task. The blasting process is highly non-linear and the variability of most rock types also contributes to the difficulty in accurate predictions of the environmental outcomes. The random character of the blasting outcomes suggests the need for probability distributions to describe strictly the range of possible ground vibration and airblast levels. [8]
In the absence of either field data or the opportunity to conduct blasting trials in the region of interest, it is possible to estimate likely ground vibration and airblast levels using simple charge weight scaling laws. Such laws incorporate the charge weight per delay and the distance from the blast to the monitoring location. Two site parameters are assumed and these influence the peak level and the rate of decay for the levels.
Airblast levels have been commonly estimated using the following cube root scaling formula:

$$P = K_a \left(\frac{R}{Q^{1/3}} \right)^{\alpha} \quad (1)$$

Where:
P = pressure, in kilopascals.
Q = explosives charge mass, in kilograms (charge mass per delay, (MIC)).
R = distance from charge, in meters.
Ka = site constant.
α = site constant.

For unconfined surface charges, in situations that are not affected by meteorological conditions, a good estimate may be obtained by using a site exponent (α) of -1.45, ((which corresponds to an attenuation rate of 8.6 dBL with doubling of distance), and a site constant (Ka) of 516.
For confined blasthole charges, when using a site exponent (α) of -1.45, the site constant (Ka) is commonly in the range 10 to 100.

Airblast is proportional to the cube root of the charge mass. This limits the effectiveness of charge mass reduction as a method of reducing airblast levels; other factors are often more important, especially for confined blasthole charges. In unfavorable meteorological conditions, it is common for airblast levels to be increased by up to 20 dBL due to the combined effects of an increase with altitude of temperature (an inversion) and/or wind velocity (windshear). Effective assessment of meteorological reinforcement requires accurate measurement of temperature, wind speed, and wind direction, generally at heights up to 1000 m above the ground.

4. FREQUENCY SPECTRUM OF BLASTING EVENT

In March 2019 Journal of Vibroengineering article Vibroacoustic measurements and analysis of blasting works by Józef Pyra and Maciej Kłaczyński of AGH University of Science and Technology in Kraków, Poland, sound spectra of measurements made during blasting events are shown. [9]
The investigation was conducted near one of the largest military training camps in Poland within a built-up area.

The study focused on the impact range of explosive charges during detonation, including structural vibrations, overpressure (AB) and acoustic waves (AW). During the measurements, three series of ANFO-type explosive material were detonated, with the following masses: series I - 150 kg, series II - 300 kg and series III - 450 kg. In all cases, the explosive charges were detonated on the surface.
Measurements were taken simultaneously at two points located at the nearest positions in the direction of propagation. At each station, a full set of equipment was used to measure ground vibration intensity, overpressure and noise level (acoustic waves). The distance from the blasting site to measurement point No. 1 (town 1) was approximately 7.5 km, and to measurement point No. 2 (town 2) was approximately 6.5 km.
The following figure shows the spectrum of the maximum unweighted sound pressure level for the explosion event, along with the background noise level at the same location, corresponding to point No. 2.

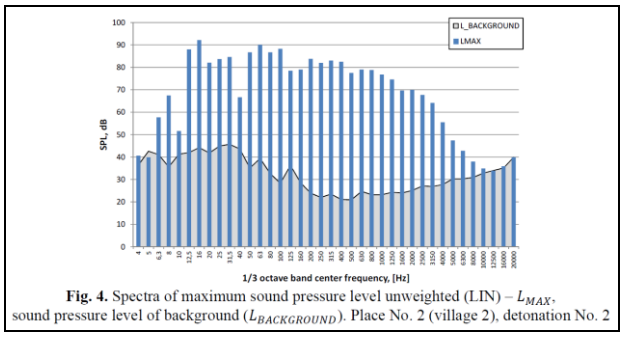

Fig. 4. Spectra of maximum sound pressure level unweighted (LIN) – L_{MAX}, sound pressure level of background ($L_{BACKGROUND}$). Place No. 2 (village 2), detonation No. 2

Figure 1. Spectrum of the maximum sound pressure level of the blasting event and background noise in dBZ.

The following table presents the spectrum in numerical form. Additionally, weighting is applied to obtain values in dBA and dBC.

Table 3. Maximum sound pressure level of the blasting event in spectral weightings Z, A and C.

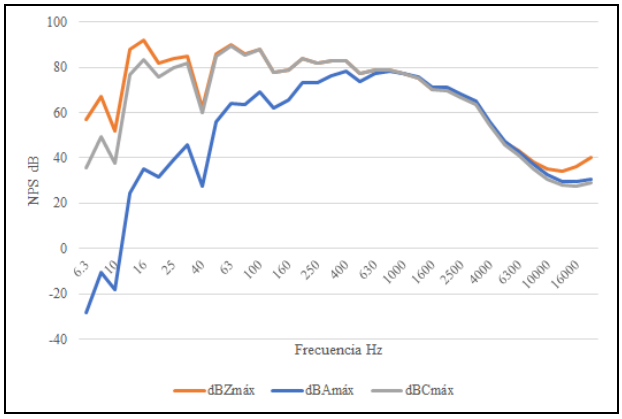

Figure 2. Maximum blasting event sound pressure level spectrum in dBZ, dBA and dBC.

5. ADJUSTMENT FOR OBTAINING NPS, FROM OVERPRESSURE LEVELS IN dBL PEAK

As specified, the results of the projections using the given equation are expressed in terms of overpressure in linear dB, or dBL. In this regard, AS 2187.2-2006 states: "... if a sound level meter measures an airblast level of 115 dBL, the same meter would measure approximately 90 dBA for the same event.

The frequency content of the particular airblast time history will determine the relative levels between the dBL and dBA readings.

This same correlation was found and reported in the document "Prediction and Control of Air overpressure from blasting in Hong Kong". Appendix A, "Analysis of dBA v/s dBL measurements Choi Wan Road and Jordan Valley" records and compares in detail a total of 137 blasting events in dBA and dBL. [10]

In consideration of the above, this correlation is already applied as a factor or correction to obtain the results from the projections. That is, overpressure in dBL is used to estimated sound pressure levels with dBA weighting. Then using a known spectrum from the data above, the levels can be determined at any scale (A, C, Z, etc.), using the following procedure:

(i) Perform the overpressure projection using Equation (1), with the result expressed in dBL peak;

ii) Apply the correction subtracting 25 to the overpressure level result, obtaining the value expressed in dBA;

Considering the blast spectrum presented in chapter 4, this time, between 20 Hz and 20 kHz and applying the A-weighting curve, the results are summarized in the following table:

Table 4. Frequency response of blasting in 1/3 octave bands in dBA.

Frecuency	Lp dBA	Frecuency	Lp dBA
20	31,5	**800**	78,2
25	39,3	**1000**	77,0
31.5	45,6	**1250**	75,6
40	27,4	**1600**	71,0
50	55,8	**2000**	71,2
63	63,8	**2500**	68,3
80	63,5	**3150**	65,2
100	68,9	**4000**	56,0
125	61,9	**5000**	47,5
160	65,6	**6300**	42,9
200	73,1	**8000**	36,9
250	73,4	**10000**	32,5
315	76,4	**12500**	29,7
400	78,2	**16000**	29,4
500	73,8	**20000**	30,7
630	77,1	**Global**	86,4

iii) Express the result in 1/3 octave frequency bands by adjusting the spectrum to the global dBA value obtained in ii). From there, convert it to any other desired weighting.

6. CONCLUSIONS

With the proposed methodology, sound pressure level values can be derived from overpressure levels using any spectral weighting, such as dBZ, dBA and dBC. Therefore, these values can be compared with impact thresholds using different weighting curves.

There is limited information on impact thresholds for blasting noise on reptiles and amphibians. It is important to continue the researching for information maximum acceptable limits for impulsive noise, especially for species where such data are not yet available.

Finally, it would be beneficial to have more noise measurements with spectral information from blasting events and to assess the noise generated in the fauna through empirical results. However, an alternative for

making projections is to follow the steps outlined in this work.

EXPERIMENTAL ASSESSMENT OF OUTDOOR LEISURE NOISE: SAMPLING METHODOLOGY AND ANNOYANCE INDICATORS

Antonio Hidalgo[1*] **Alberto Hernandez**[1]
[1] Centro de Estudio y Control de Ruido SL (CECOR), Valladolid, España

ABSTRACT

Leisure noise is a significant environmental issue across Europe, particularly in Mediterranean countries where outdoor leisure activities are more prevalent and widespread. These regions experience higher levels of outdoor gatherings, music events, and nightlife activities, which contribute substantially to noise pollution in both urban and suburban areas. Although this type of noise is within the scope of Directive 2002/49/EC of the European Parliament and of the Council of 25 June 2002 [1], the directive does not impose specific obligations for controlling leisure noise, leaving a gap in its practical application. Additionally, there are no established standards or universally accepted methodologies for the accurate assessment of this noise type. This lack of regulation creates challenges for policymakers and urban planners attempting to mitigate its impact on communities.

In this paper, a comprehensive guideline is proposed to address these limitations. The guideline focuses on key aspects such as spatial and temporal sampling strategies, the processing of noise measurements, and the selection of appropriate indicators to evaluate noise annoyance effectively. By providing a structured approach, the proposed methodology aims to improve the accuracy and consistency of leisure noise assessments, facilitating better decision-making and promoting healthier, quieter environments.

1. INTRODUCTION

The problem of noise derived from leisure activities in Spain and Europe has specific characteristics and increasing relevance. This noise is closely linked to nighttime and evening leisure activities in bars, terraces, nightclubs, and restaurants, affecting the quality of life of residents by disturbing rest, concentration, and even auditory health.

Leisure noise, particularly in densely populated or tourist areas, causes significant discomfort and an increase in neighborhood complaints. In many Spanish cities (Madrid, Barcelona, Vitoria, Valencia, Málaga, Ibiza, Alicante, Murcia, Logroño, Badajoz, Benidorm, Ciudad Real, etc.), studies based on acoustic measurements have identified notable differences between noise levels during weekdays and weekends, showing an alarming increase during the weekend nighttime period.

European environmental noise legislation, with its main regulation being Directive 2002/49/EC [1], while not excluding leisure noise as an acoustic pollutant, does not explicitly address it as it does with sources such as road, rail, and air traffic, and industry. For example, there is an obligation to carry out Strategic Noise Maps and Action Plans against noise in major cities for the previously mentioned sources, but not for leisure noise. In Spain, strategies such as the designation of Special Acoustic Protection Zones (ZPAE), Acoustically Saturated Zones (ZAS), or Special Acoustic Situations Zones (ZSAE) have been developed. However, leisure noise is not included in the Strategic Noise Maps, and it is often a point of contention whenever a Strategic Noise Map is approved in Spanish cities.

Nighttime leisure noise presents technical challenges for its assessment, such as the absence of valid empirical models for its implementation in acoustic prediction, the difficulty in measuring it representatively, and the impact of factors such as seasonality and tourist density. This article aims to provide a baseline methodology for assessing leisure noise through in situ measurements.

The proposed methodology provides the indicators that best represent the impact of leisure noise, as well as the procedures for the temporal and spatial sampling of measurements. Efforts have been made to draw a parallel with the international standards ISO 1996-1 [2] and 1996-2 [3] (*Acoustics — Description, measurement and assessment of environmental noise*) which provide guidelines for environmental noise measurement, focusing on noise from industry and infrastructure. This article presents the instructions for the experimental assessment of leisure noise.

The recommendations in this work are guidelines; however, the applicable legislation must be taken into account, as it may impose more restrictive conditions in certain aspects.

2. MOTIVATIONS

Leisure noise has many peculiarities and characteristics that differ from other environmental noises such as industrial noise and infrastructure noise. These differences are particularly related to their variability in time and space. There are numerous leisure noise measurements conducted in various studies of cities; however, as mentioned, there is no uniformly accepted methodology.

The behavior over time of leisure noise can be classified as fluctuating sound according to the classification made by ISO 1996-1 [2] (3.4.5). The variation in leisure noise occurs in the short term (in minutes), medium term (different hours of the day with very high variability), and long term (days with high sound emission, such as weekends or differentiated periods like summer and winter). The evaluation method must account for this temporal variation and already indicates that measurement periods should be long, with repeated intervals across the week and over several weeks. Additionally, the selected indicator for measurement should reflect the concentration of emission over short periods of time, especially during the night. Evaluation over periods of several hours (day, evening or night) could attenuate the emission that occurs during shorter periods, typically between 1 and 3 hours.

Regarding spatial variability, it can also be very high, as the typical area for this type of noise is the city center. It is possible to have a high noise level on a street with a high concentration of activities or people, which can decrease drastically just a few meters away on an adjacent street. Since these measurements involve long recording times, it will be necessary to optimize the number of measurement points, as each one will incur high costs.

In conclusion, the high variability of leisure noise over time and space makes it necessary to have a thorough understanding before proposing a spatial or temporary sampling method for its assessment. It may even be necessary to evolve in successive measurement campaigns, expanding points and measurement time based on previous experiences.

The figure below shows the evolution of the 1-hour equivalent level throughout the days of the week in a beachfront leisure area in summertime. The equivalent levels are over 70 dB(A) in the worst night period. There is a clear increase in levels between 1:00 AM and 6:00 AM, with a more pronounced rise on the weekend. The levels during the daytime period are stabilized between 60-65 dB(A).

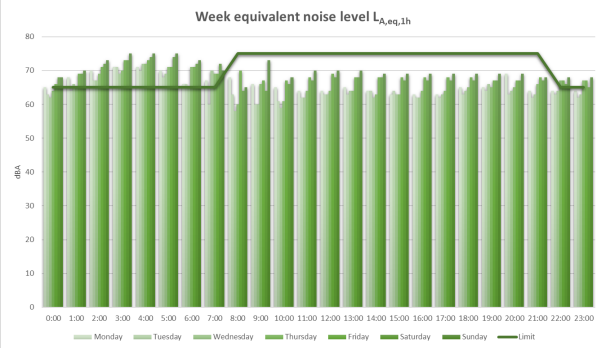

Figure 1. Noise level ($L_{A,eq,1h}$) for one week.

Another special characteristic of leisure noise is that the noise measurements themselves can change the behavior of people or the activities that are intended to be measured. Therefore, measurements with the sonometer at street level over a short period of time should be avoided, as could be done in industrial or infrastructure measurements.

3. ANNOYANCE INDICATORS

3.1 Time-weighted and frequency-weighted sound pressure level

The frequency behavior of leisure noise is broadband, with no low-frequency components or high impulsivity. Therefore, measurements with A-weighting and FAST time weighting are valid.

The appropriate frequency range for the assessment of leisure noise is between 20 Hz and 10,000 Hz. In addition to providing the overall value, it is recommended to perform measurements in third-octave bands or at least in octave bands.

3.2 Noise descriptors

The most appropriate indicator to estimate the annoyance of leisure noise is the equivalent continuous sound pressure level. The reference time interval to process the equivalent noise level is the day, evening, and night reference periods (in dependence of each country), but it is not sufficient. At least during the nighttime period, it should be accompanied by the evaluation of the continuous level over 1 hour. Shorter evaluation periods may not be suitable due to their low representativeness for this type of fluctuating noise. The assessment over a 1-hour period during the night is appropriate for determining the potential sleep disturbance caused by leisure noise.
The maximum level should be recorded in each measurement period ($L_{F,max}$) for each sampling day.
N percent exceedance level, ($L_{N,T}$) are very useful from a technical perspective to determine the behavior of the noise throughout the measurement period, but they are difficult to interpret for non-technical people and are not practical for setting emission limits.

4. MEASUREMENT PROCEDURE

To select appropriate observation and measurement time intervals, it may be necessary to conduct survey measurements over relatively long periods.

4.1 Time intervals, time sampling

About the long-term time interval, leisure noise can exhibit periodic behavior both during the week and throughout the year. During the week, it is common for high noise levels to occur on weekends (from Friday to Sunday). Throughout the year, noise levels typically increase during summer periods, when leisure activities take place outdoors. This is added to the fact that during hot weather, it is more common to have windows open in residences, which increases the noise impact. Therefore, in the long term, measurements should be evaluated as day-week averages, ensuring that high noise level events are repeated for at least three consecutive weeks.

4.2 Spatial sampling

Measurements should preferably be conducted in outdoor spaces, although indoor spaces may be monitored for specific purposes.
At least one measurement point should be placed on each of the streets affected by leisure noise, in the area where the highest impact is expected. For streets longer than 100 meters, a second measurement point should be installed.

4.3 Microphone location

The measurement points should preferably be located at a height of 4 meters. Measurement stations can be placed on balconies, windows (exterior part), or façades, taking into account potential corrections for reflections.
Locations on streetlights or electricity poles may also be acceptable, provided that the anchoring element does not transmit noise or vibrations to the measurement equipment.
In all cases, the equipment should be positioned in such a way that it is not visible from the leisure areas, either by the users or by the staff of the establishments, to avoid altering the behavior of the business owners or users.
In the case of indoor measurements, it must be ensured that the measurement space is not occupied during the measurements. It must also be ensured that the noise coming from the outside is predominant.

4.4 Instrumentation

Depending on the purpose of the measurements, the following types can be established.
Measurements aimed at establishing corrective measures or delineating special action zones by local authorities:
• Class 1 sound level meters according to IEC 61672-1, calibrated before and after each measurement.
• Class 1 acoustic calibrator to verify the proper functioning of the equipment.
Control measurements carried out directly by the local authorities or regulatory bodies may use Class 2 sound level meters according to IEC 61672-1 [4].
For measurements in octave or one-third-octave bands, the class 1 and class 2 instrumentation systems shall meet the requirements of a class 1 or class 2 filter, respectively, specified in IEC 61260:1995.
In all cases, microphones should be protected with windshields and weatherproof kits to prevent wind disturbances and damage from rain.

4.5 Weather conditions

The weather conditions shall be representative of the noise exposure situation under consideration, and it should be registered on the measurement period.

4.6 Other parameters to be controlled.

The noise assessment should include a list of the leisure activities present in the area with at least the following information:

- Name of the activity.
- Type of activity (pub, restaurant...).
- Operating hours.

- Venue capacity.
- Terrace capacity.

Alternatively, other parameters can be monitored, such as the occupancy level of the area being measured. There are person-counting systems supported by Artificial Intelligence that allow the establishment of an occupancy level for terraces or public streets, which can be related to the recorded noise levels.

4.7 Residual sound

The measurements must be corrected for the presence of residual sound (total sound remaining at a given position in a given situation when the specific sounds under consideration are suppressed) with levels similar to those of the leisure activity itself. These levels can be evaluated during the hours of the day when leisure activity decreases, such as in the early hours of the morning. The type of noise may change, with leisure activity being predominant at night, while traffic noise tends to be higher during the day.

5. EVALUATION OF THE MEASUREMENT RESULT

5.1 Correction factors

If the residual sound pressure level is 10 dB or more below the measured sound pressure level, make no corrections.
If the residual sound pressure level is 3 dB or less below the measured sound pressure level, no corrections are allowed. The measurement uncertainty is then large. The results may, however, still be reported and may be useful for determining an upper boundary to the sound pressure level of the source under test.
For cases when the residual sound pressure level is within a range from 3 dB to 10 dB below the measured sound pressure level it should be corrected according to ISO 1996-2 method.
Regarding meteorological corrections, measurements taken in conditions of rain or winds exceeding 5 m/s should be discarded.
Corrections for reflections may be applied in the case of measurements taken near façades, subtracting 3 dB(A) from the average level obtained.

5.2 Noise limits

The competent authorities (usually local authorities) should establish limits for each of the equivalent level parameters for the day, evening, and night periods for leisure activities, as well as for the 1-hour equivalent level parameter for night period.

In the case of equivalent levels, the limits can be the same as the acoustic quality objectives for the designated area. For the 1-hour equivalent level, the limit can be set at 5 dB(A) above the nighttime acoustic quality objective.
Exceedance ranges can be established to determine the types of actions to be taken in each case. For example,

- Exceedances between 0-5 dB(A) may involve implementing zonal plans for the gradual reduction of noise and controlling emissions.
- Exceedances between 10-15 dB(A) may require immediate actions such as time restrictions or limiting terrace areas.
- Exceedances above 15 dB(A) may result in the establishment of Acoustically Saturated Zones with the application of corrective measures, including the closure of establishments.

6. INFORMATION TO BE RECORDED AND REPORTED

For measurements, the following information shall, if relevant, be recorded and reported:
a) time, day and place for measurements.
b) instrumentation and its calibration.
c) measured and, if relevant, corrected sound pressure levels ($L_{A,eqT}$), A-weighted and, optionally, in frequency bands.
d) estimate of the measurement uncertainty together with the coverage probability.
e) information on residual sound pressure levels during the measurements.
f) time intervals for the measurements.
g) thorough description of the measurement site, including ground cover and condition, and locations including height above ground, of microphone.
h) description of the operating conditions, including the list of leisure activities in the area with is main operating description.
i) description of the meteorological conditions, including wind speed, wind direction, cloud cover, temperature, barometric pressure, humidity and presence of precipitation and location of wind and temperature sensors.

7. ACKNOWLEDGMENTS

This work is the result of the intense efforts of CECOR, in collaboration with numerous public administrations, primarily local authorities, in the fight against leisure noise. Special emphasis is placed on the support of CECOR's technicians. Acknowledgements to the University of

Alicante, and in particular to Mr. Jaime Ramis, for his involvement and support in this work.

ABSTRACT

The recent controversy surrounding the cancellation of future concerts at the Santiago Bernabéu Stadium, affecting approximately 250,000 attendees, many of whom came to Madrid from other cities, has generated intense debate. Neighbors in the area claim that "it is a sports stadium, not a space for musical events", and express their complaints regarding the noise generated at these events. With the firm belief that it is possible to address residents' concerns about the development of noise-producing activities in a city, new regulations have been introduced to correct deficiencies in these activities [1]. This project evaluates the impact of these recreational activities on the quality of life of nearby residents and determines whether they follow legally established noise levels. To accomplish this, data collected from in situ measurements will form the basis for simulating the noise affecting residents, verifying the model's accuracy, and suggesting potential solutions.

Keywords: *noise immission, noise modeling, concerts, stadiums*

1. INTRODUCTION

On December 14, 1947, the Santiago Bernabéu Stadium was officially opened with a friendly soccer match as the new Real Madrid Stadium. Today, almost 80 years later, Real Madrid´s president Florentino Pérez claims that "We are in the final phase of meeting the great challenge that Real Madrid set itself five years ago: that the Bernabéu stands as a universal avant-garde icon and an architectural emblem of Madrid. It is the most iconic stadium in world football" [2]. Addressing the impact of the stadium's latest renovations.

In addition to providing a new aesthetic, the renovation also increased the stadium's capacity to 80,000 people and opened the door to new events such as recurring concerts. In 2024 alone, the stadium held more than 15 major concerts, each drawing around 65,000 attendees [3], the maximum allowed for these events. However, it is important to remember that Bernabéu is located in Chamartín District, a predominantly residential area, which is also an environmentally protected zone [4]. These events disturb the lives of local residents because noise affects their well-being and causes significant annoyance.

In the past, sound systems engineering for musical events focused on sound quality in the audience. There has been an increase in these events in stadiums along with complaints from nearby residential neighbors. Some novel and recent methodologies have contributed to addressing this major concern, linking complex loudspeaker systems to outdoor environmental propagation and working with detailed data of sound systems, stadiums, and surroundings for open-air events, as in [5,6]. The current prediction tools do not provide right-away models to fill this gap. Environmental classical noise sources, such as road and train radiation, which are decorrelated, are significantly different from those of sound systems, which

are coherent and highly directional acoustic sources [6]. There is a significant need to plan the environmental impact of these modern scenarios and reach the expected immision noise levels that comply with local regulations [6, 7].

However, some stadiums can be considered semi-closed rooms. Hence, the walls of the stadium do not behave as acoustic barriers, as in open-air events, and there is remarkable acoustic leakage through the walls. Real Madrid's stadium is located in a dwelling area and brings environmental conflict with its dwellers. This leads to a significant lack of relevant data regarding sound systems and building of insights.

This study proposes a practical methodology for modeling noise immision for concerts in semi-closed stadiums with sparse data and moderate resources but with accurate field measurements performed at the neighbors' façades.

The remainder of this paper is organized as follows: Section 2 explains the materials and methods, Section 3 discusses the results, Section 4 suggests mitigation solutions, and Section 5 presents the conclusions.

2. MATERIALS AND METHODS

This paper proposes a practical methodology that can contribute to predicting and finding solutions to highly complex problems. We work on a particular case: Real Madrid's stadium. However, the same approach can be applied to similar stadiums and musical events. Sparse data are a major drawback in these cases because it is common to encounter conflicts with victinity residential buildings and even non-compliant noise radiation according to local regulations. Hence, obtaining insights from stadiums such as loudspeaker setups and construction plans is rare. Our approach consists of the following steps.

1. **Field noise measurements**. We used noise measurements at keypoints/receivers to assess the scenario and obtain valuable data for modeling.

2. **Noise immision modeling**. We modeled the scenario using public data from the stadium and its surroundings, along with sound acoustical assumptions.

3. **Validation of the model**. We made measurements and modeling meet ends and provided a tool to evaluate current and future scenarios.

4. **Analysis of results**. We provided stakeholders with solutions to consider a range of challenges.

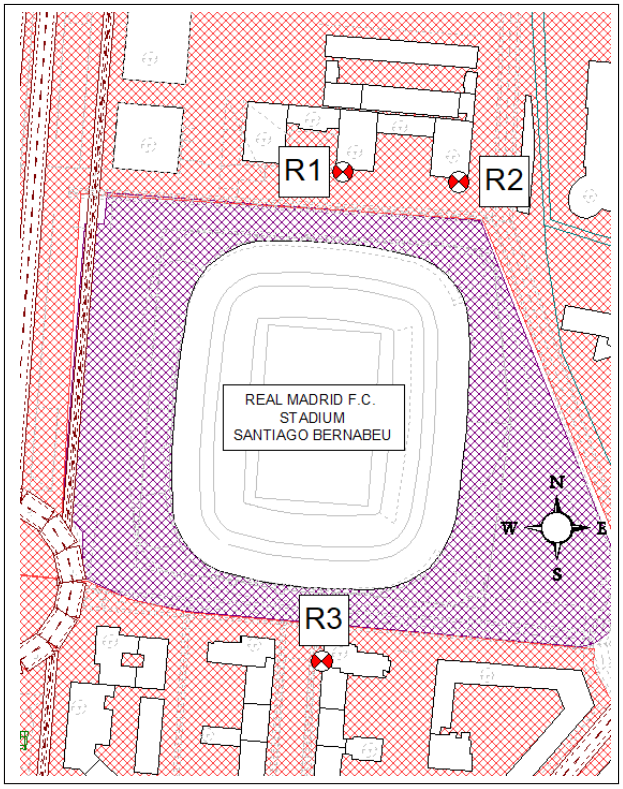

Figure 1. Location of the three receivers situated on the northern and southern sides of the stadium and the areas' land use (The red being residential and purple being recreational).

2.1 Field noise measurements

A noise monitoring campaign was conducted in the outdoor environment on 20th July 2024, the day when Karol G's concert took place. Measurements were taken every 5 s, including the indices required by RD1367/2007 [8] and the local law [1] (L_{Aeq}, L_{Ceq}, L_{AIeq}, and the spectrum in one-third octaves from 20 Hz to 10 kHz). The recordings covered the periods before, during, and after the concerts, allowing for the analysis of noise from activity (music) and noise without activity (no music).

Measurements were performed using 01 dB sound level meters, type SOLO, Class 1 equipped with third-octave filters compliant with the IEC 61672-1 Class 1

Figure 2. View of the microphone on the façade from a house in the vicinity of the stadium.

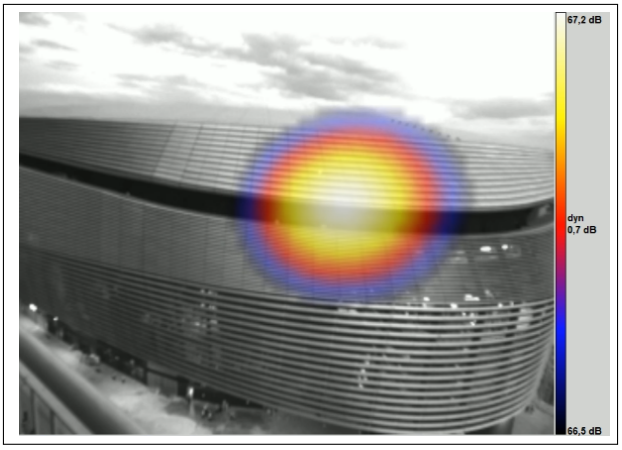

Figure 3. Visualization of the noise radiated from the stadium with an acoustic camera (Soundcam 2 Cae Systems).

standard [9]. A Rion NC74 sound calibrator that meets the IEC 60942 Class 1 standard [10] was used before and after the measurement campaign. All measuring instruments, including sound level meters and acoustic calibrators, have type approval and periodic verification in accordance with the Spanish law (ITC 155/2020 order) [11]. The measurements were performed simultaneously in multiple homes surrounding the Santiago Bernabéu Stadium.

For each sound level meter, the measurement microphone was placed outdoors, 2 m from the façade, using a telescopic pole and microphone extension cable. This positioning minimized the sound reflected by the façade. Each unit was located in one apartment; therefore, we were able to obtain the variability of sound levels at different heights from the street floor. The exact location is not detailed enough to maintain confidentiality and to comply with the Data Protection Act. Fig. 1 shows the locations of all receivers, that is, measurement points, from the stadium; the upper receivers R1 and R2 are on the northern side of the stadium and receiver R3 is located on the southern side.

2.2 Noise inmission modeling

The acoustic modeling was performed with Cadna A (Version 2025, DatakustiK), one of the leading softwares for calculation, presentation, assessment and prediction of environmental noise. Some software configurations worth highlighting: CNOSSOS-EU [12] is the propagation model for estimating L_{Aeq} for the moments of maximum noise impact according to the required limits. The stadium noise was modeled using horizontal surface sources for the ceiling and vertical surface sources for façades. These sources had different assigned values for the northern, southern, eastern, and western sides, and their values were specifically adjusted to those measured with sound level meters. The sound powers of these surface sources were adjusted in the frequency domain at the receivers.

We also incorporated traffic data assigned to each of the surrounding roads, setting up their average daily traffic densities (MDTD). The evaluation of traffic noise is based on the ambient noise scenario in the vicinity of buildings when there are no concerts, thus observing a large difference in levels between the two scenarios: 1) when only traffic noise was present, and 2) when there was only concert music.

Table 1. Model's Validation comparing the measurements results with the prediction value obtained by the model, L_{Aeq} dBA.

	Measurements L_{Aeq} dBA	Model L_{Aeq} dBA	Deviation (dBA)
R1	80	78,2	-1,8
R2	77,6	77,5	-0,1
R3	72,3	72,4	-0,1

2.3 Validation of the model

The validation consisted of comparing the prediction of the outdoor propagation model with the measurements us-

ing the same source and evaluation points. The sound levels of the noise sources involved in the model were conveniently adjusted to fit the measurements. Eventually, the deviations between both L_{Aeq} values were adequate to provide a valuable predictive model (less than 2 dBA), as shown in Tab. 1, thus validating the model. In Fig. 4 and Fig. 5, we observe the spectrum on both the north and south sides of the stadium.

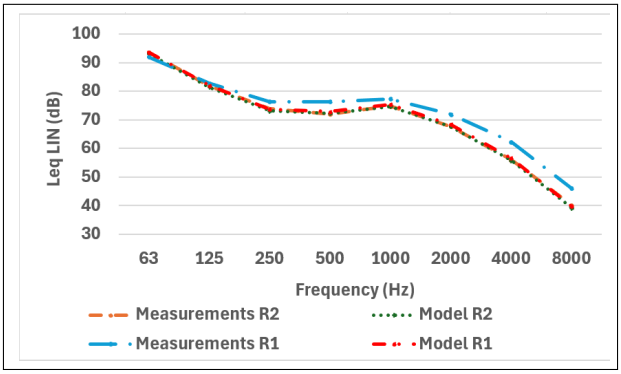

Figure 4. Spectra of measured and simulated levels in the northern side (Reveiver R1 and R2).

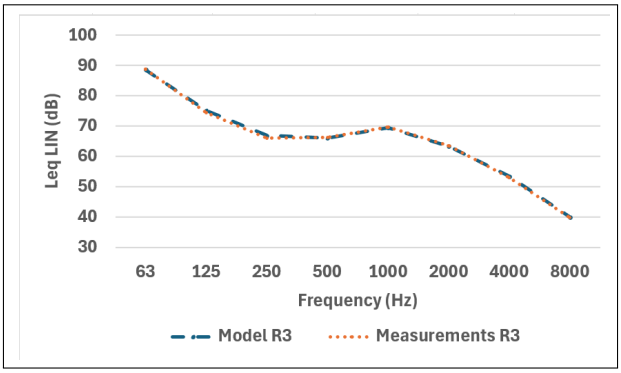

Figure 5. Spectra of measured and simulated levels in the southern side (Receiver R3).

During this project, we faced certain limitations, including a lack of access to the stadium or its construction plans, which restricted our ability to study sound propagation inside and near façade openings where sound leaks. The modeling was performed using surface sources with three validation receivers placed at different heights.

3. RESULTS

To assess compliance with noise regulations during the concert, land use in this area must be considered. Most of the study area is considered residential by the Madrid City Council, except for the area where the stadium is located, which is considered recreational and has its own limits. Fig. 1 shows the purple area, which is the recreational zone, and the red area, which is the residential zone. Since 1997, the stadium's surroundings have been declared an environmental protection area by the Madrid City Council, meaning that the limits should be restricted to 5 dB more than the rest of the acoustic areas [4]. This indicates that it is a noise-sensitive area owing to the amount of activities currently taking place and is considered a noise-saturated area.

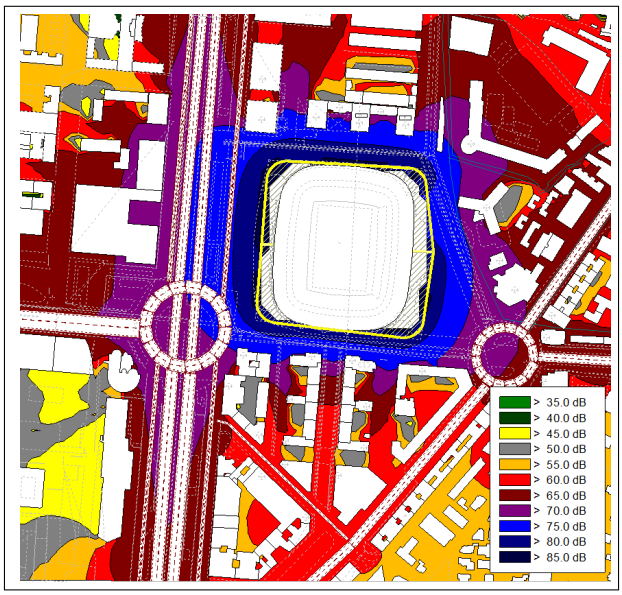

Figure 6. Global horizontal noise map of the area, including traffic and concert noise at 21 m height.

After simulating the noise map of the area shown in Fig. 6 shows how the problem impacts the whole neighborhood, not just the ones closest to the source, putting everyone at risk. Noise limits are exceeded in residential areas, at least within a 500-meter radius of the stadium center in the evening, and at night, they are exceeded at distances greater than 1 km. The "front line" buildings surrounding the stadium are receiving more than 70 dBA or 75 dBA, as seen in purple and blue on the map in Fig. 7. The area shown in red has noise levels higher than 60

dBA, which is the majority of the area whose levels exceed the legal limits established by law.

The simulated value is $L_{Aeq,5s}$, but we must consider 6 dB extra, owing to tonal and low-frequency components (there were no impulsivity components) in accordance with Article 15 of the Madrid ordinance [1], for the evaluation of $L_{Aeq,5s}$, which becomes $L_{Keq,5s}$. This can be observed in Tab. 2, as well as the extent to which the noise levels were exceeded at the receiver points compared with the limits in the evening and at night, when the concert took place. As can be observed, none of the points complies with regulations.It is worth mentioning that the current legislation establishes maximum noise emission limits because it is scientifically proven that exceeding these levels directly affects the health of people exposed to these noises.

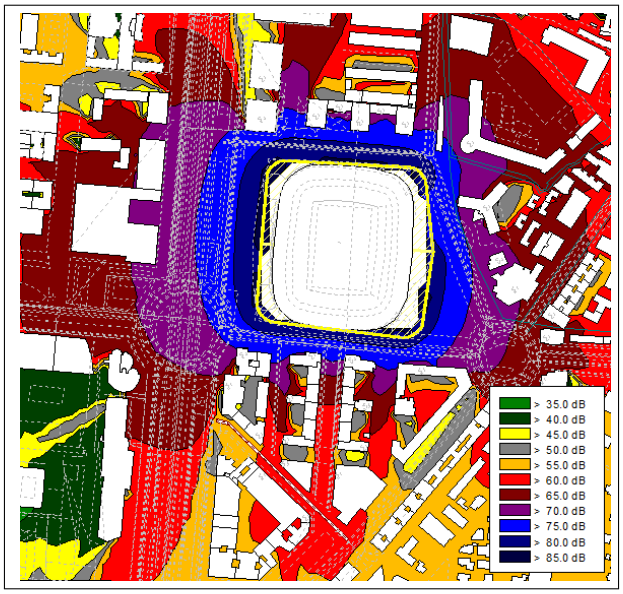

Figure 7. Horizontal noise map: ONLY concert noise at 21 m height.

In addition to modeling the concert, a simulation was conducted only in the area on concert days, considering the traffic of nearby streets. The streets surrounding the stadium, Rafael Salgado and Padre Damian Streets, and Concha Espina Avenue are not simulated, as traffic suffers a cut off during concerts. However, large avenues, such as Paseo de la Castellana, have constant traffic that contributes to global noise levels. As mentioned previously, we simulated roads in the area setting in Cadna A,

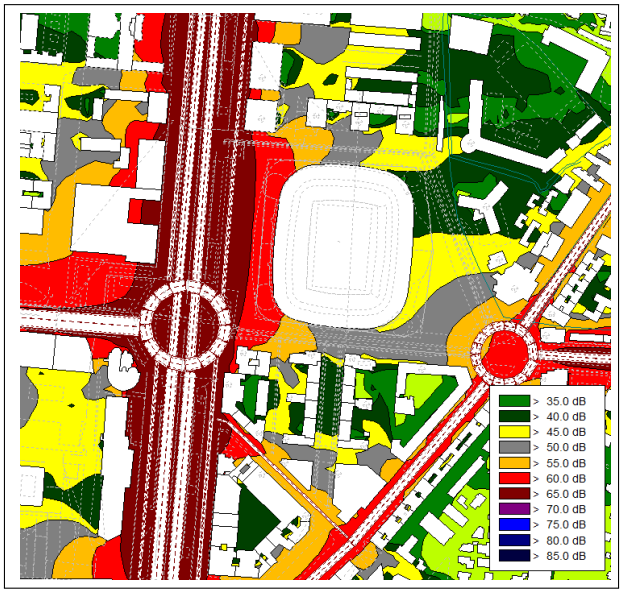

Figure 8. Horizontal noise map: ONLY traffic noise at 21 m height.

each with its traffic limit and MDTD capacity, to obtain the sound levels produced by them. As a result, we observed that Fig. 7 and Fig. 8, where we can clearly see a difference in the noise levels in the area.

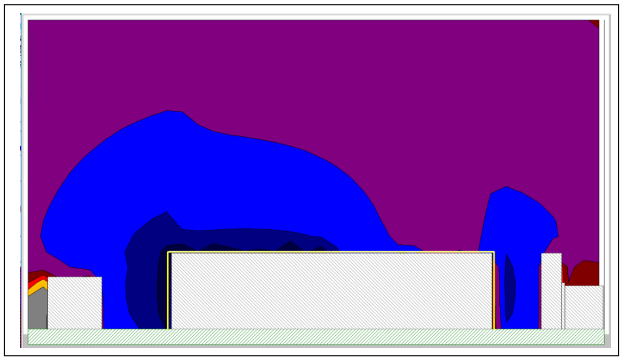

Figure 9. Vertical noise map during the concert.

In Fig. 7 we can observe how the front row of buildings functions as a barrier, reducing the noise observed in the vertical noise map in Fig. 9, which is a longitudinal cut along the z-axis perpendicular to the floor that crosses the stadium from North to South. Noise propagation from the middle of the stadium is shown in the middle of Fig. 9, towards the residential buildings located North and South

Table 2. Comparison of measured levels with legally authorized limits and the degree to which they were exceeded, both in the evening and at night.

Receiver	Measurements L_{KAeq} (dBA)	Limits Evening/Night (dBA)	Exceedance (Evening, dBA)	Exceedance (Night, dBA)	Compliant?
R1	80 + 6 = 86	55 / 45	31	41	No
R2	77,6 + 6 = 84	55 / 45	29	39	No
R3	72,3 + 6 = 78	55 / 45	23	33	No

(right and left sides of the figure). In Fig. 9 we observe that most of the acoustic energy is radiated by the vertical façades and roof of the stadium.

Although we do not know the exact speaker configuration at the concert, we do know that the stage was located near the southern side, facing North. Hence, northern sound sources are more powerful than southern ones. Furthermore, the "front line" buildings act as acoustic barriers for more distant buildings, as shown in Fig. 9 we can see the gray area behind the building on the right, showing lower noise levels. However, horizontal maps have shown that noise from the stadium spreads through the streets perpendicular to the stadium, affecting most of the neighborhood.

In Fig. 8, just modeling with traffic noise, there are many more green areas, indicating noise levels of approximately 35 dBA; however, we can also observe yellow, gray, and orange areas, indicating meaningful noise levels between 45 dBA and 55 dBA. Tab. 3 shows a comparison of the sound levels reaching receivers R1, R2, and R3, modeling concert, and traffic, separately. With no concert, the receivers do not exceed the limits, whereas when simulating a concert, traffic noise barely affects the level received by the receivers.

Table 3. Comparison of traffic noise and concert sound pressure levels, L_{Aeq} dBA, during the concert by the prediction software.

	R1 L_{Aeq} dBA	R2 L_{Aeq} dBA	R3 L_{Aeq} dBA
Concert	78,2	77,5	72,4
Traffic	52,8	45,3	43,1

4. NOISE MITIGATION PROPOSAL

Looking at Fig. 4 and Fig. 5, we can observe that the problem is focused on low frequencies. The 63 Hz and 125 Hz bands have the highest levels, whereas the 8 kHz band has the lowest levels. Low-frequency noise causes vibrations that can cause discomfort among neighbors, thereby increasing their perception of noise (window vibrations).

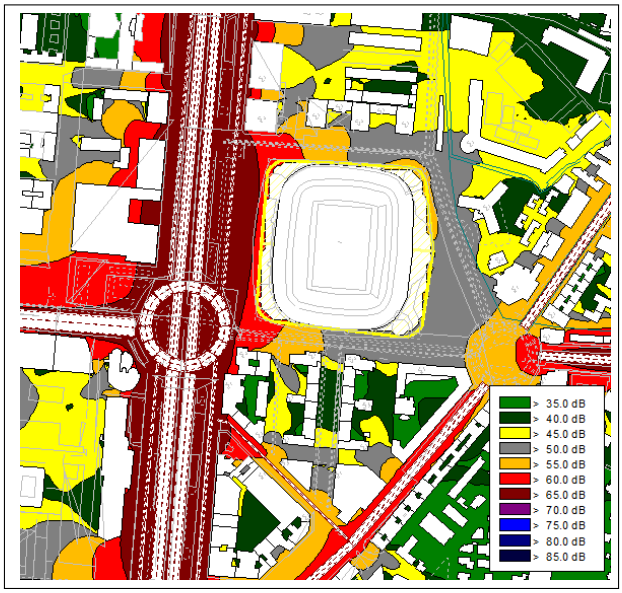

Figure 10. Noise map including corrective measures on the façades of the stadium and roof at 21 m height.

To lower the sound level of the show was first considered. In another concert (Aventura), after months of complaints from neighbors about noise, a test was conducted during the event. It was found that this could not solve the problem; it only frustrated the attendees, who claimed that "they could not hear the music properly." Therefore, it is necessary to provide solutions that reduce the noise

Table 4. Levels at the receivers after the proposed mitigation solutions and its compliance in the evening and at night.

	L_{Aeq} dBA	Evening Compliance	Night Compliance
R1	54,6	Yes	No
R2	51,8	Yes	No
R3	45,8	Yes	No

level approximately by about 30-40 dBA. After modeling several mitigation options, Fig. 10 shows the results of the simulation of an adequate solution. By acting homogeneously on the façades of the stadium, we obtained a decrease of 30 dBA, setting-up 30 dB transmission losses on the vertical surface sources. The same procedure was used on the roof, but the sound power was lowered 10 dB, setting-up 10 dB transmission losses on the horizontal surface sources.

In Tab. 4, the levels obtained at the receivers after applying the aforementioned modifications can be observed. As shown, these levels manage to comply with legal limits in the evening; however, at night, they are still noncompliant. Since it may be difficult to further increase façades' attenuation to comply with the more restrictive nighttime limits, we suggest considering modifying the schedule of the next stadium concerts that will take place during the evening hours.

5. CONCLUSION

In short, the noise levels generated by concerts in the stadium exceed what is permitted and healthy, and it is not a situation that can be sustained. A series of on-site measurements were taken at Karol G's concert, allowing for the creation and validation of a model in which the measurements and predictions match. Noise limits are exceeded in residential areas, at within a 500-meter radius of the stadium center in the evening and even more at night. As a problem that affects both the well-being and the inconvenience in the daily lives of the residents of the area, an improvement in the insulation of façades of the stadium by approximately 30 dB and the consideration of a new concert schedule are proposed to avoid exceeding these levels. This model can be used to directly incorporate the attenuation values obtained from façades and immediately obtain the expected emission values from nearby homes.

We encountered several limitations in accessing detailed information on the stadium's structure, which would be interesting to have more in order to create a simulation that better fits the existing openings and façade, as well as the sound insulation characteristics of the roof. It would also be useful to obtain the information necessary to simulate the transmission of the electroacoustic system during a concert, to consider the diffraction of linear arrays, and to gain a better understanding of how sound is transmitted from the inside of the stadium to the outdoor environment.

ABSTRACT

According to Order PCI/1319/2018, Spain has replaced the interim calculation methods with a common calculation methodology developed by the European Commission through the project "Common noise assessment methods in Europe (CNOSSOS-EU)".

The establishment of the common European calculation method CNOSSOS-EU in noise mapping projects implies the replacement of the previously used calculation methodologies (interim methods) for this new methodology.

It is therefore necessary to compare these calculation methods, in order to evaluate the traceability of the Strategic Noise Maps of different rounds, assess the real effectiveness of the Noise Action Plans and compare simulations carried out using different methodologies.

This paper presents a comparative analysis of the interim calculation methods and the CNOSSOS-EU calculation method. For this purpose, 45 different scenarios were analysed in pairs using both calculation methods, with more than 12 variables studied, for road, railway and industrial noise.

Pairs of sound power level data (when comparable) and mainly pairs of LAeq levels were compared, resulting in more than 1,800 pairs of data analysed.

Keywords: *environmental noise, noise mapping, CNOSSOS-EU, interim methods, comparative study.*

1. INTRODUCTION

According to Directive 2002/49/EC of the European Parliament and of the Council of 25 June 2002, the use of common assessment methods was recommended across all Member States of the European Union. This Directive was transposed into national legislation through Royal Decree 1513/2005 of 16 December, which implements Law 37/2003 of 17 November on Noise, specifically regarding acoustic zoning, quality objectives, and noise emissions.

The common assessment methods outlined in the aforementioned legislation—known as interim calculation methods—include the following, depending on the noise source:

- The French national calculation method, NMPB – Routes – 96 (SETRA-CERTU-LCPC-CSTB), designated as the reference method for road traffic noise.
- The Dutch national calculation method SRM II (Reken- en Meetvoorschrift Railverkeerslawaai'96), designated as the reference method for railway traffic noise.
- The ISO 9613-2 method, designated as the reference method for industrial noise.
- The ECAC.CEAC Doc. 29 method, designated as the reference method for aircraft noise.

In 2008, the European Commission initiated the development of a unified methodological framework for noise assessment through the project Common Noise Assessment Methods in Europe (CNOSSOS-EU), led by the Joint Research Centre (JRC), the scientific service of the European Commission.

As a result of this initiative, Commission Directive (EU) 2015/996 was adopted, establishing common noise assessment methods pursuant to Directive 2002/49/EC.

This Directive replaced Annex II of Directive 2002/49/EC with the updated methodology and was required to be transposed into the legal frameworks of Member States by no later than 31 December 2018.

Spain transposed Directive (EU) 2015/996 through Order PCI/1319/2018 of 7 December, amending Annex II of Royal Decree 1513/2005 of 16 December, which implements Law 37/2003 of 17 November on Noise, in relation to the assessment of environmental noise.

Under this regulation, the previous calculation methods for noise indices were replaced by a unified calculation methodology developed by the European Commission through the CNOSSOS-EU project. The use of this methodology has been mandatory for all Member States since 31 December 2018.

Subsequently, the European Commission conducted a revision of this common calculation methodology, addressing several aspects including new formulations for diffraction in sound propagation and approaches for evaluating population exposure to noise on building façades. These updates were incorporated into Annex II of the Environmental Noise Directive via Commission Delegated Directive (EU) 2021/1226 of 21 December 2020, which amended Directive 2002/49/EC to align with scientific and technical progress. This Directive was transposed into national law through Order PCM/80/2022 of 7 February, which amends Annex II of Royal Decree 1513/2005 of 16 December, concerning the assessment and management of environmental noise.

The establishment of the European CNOSSOS-EU common calculation method for noise mapping tasks marks the replacement of previously used interim methods for this new standardized methodology. Consequently, a comparative analysis between the interim calculation methods and the CNOSSOS-EU method is presented in this study through a comprehensive examination of 45 noise scenarios.

By identifying systematic variations in noise predictions, we seek to provide insights into how the methodological shift affects environmental noise assessments and regulatory compliance.

2. METHODOLOGY

To conduct a robust comparative analysis, a set of 45 noise scenarios was designed, divided into road traffic (17 scenarios), railway (12 scenarios), and industrial noise sources (16 scenarios). Each scenario was modeled using both CNOSSOS-EU and interim models, keeping environmental, topographical, and source parameters consistent with receptor grids placed at varying distances and heights to capture sound propagation effects under different environmental conditions.

2.1 Road Traffic Noise

Several hypotheses have been proposed to assess how sound power and sound pressure levels vary based on the Average Daily Intensity, the percentage of heavy vehicles, and speed.

Different values of Average Daily Intensity were considered: high (which constitute major roadways), medium, and low (which do not constitute major roadways). For each scenario in which the traffic value was set, other variables (percentage of heavy vehicles, speeds, etc.) were varied to assess the variation in both methods.

The percentage distribution of heavy vehicles, as well as the speed, has been varied for probable scenarios and to determine actual ranges of comparable cases.

Free field, urban settings and noise barriers have been included to assess the effects of diffraction and obstacles.

The study considers different road types, traffic compositions, and surface materials. Key parameters analyzed include:

- Traffic volume (light and heavy vehicles).
- Vehicle speeds (urban vs. highway conditions).
- Pavement type (reflective vs. absorbent materials).

2.2 Railway Noise

As in the case of road noise, for railway noise, a series of variables have been established and others varied for each case study to assess their effect on both methods.

The most critical aspect was determining similar rolling stock, as both methods differ significantly in the definition of noise sources and the track parameters considered in each.

Different types of trains have been considered, analyzing not only the sound pressure levels of the receivers, but also evaluating the vertical meshes to compare the different radiation of the source and the propagation between methods.

Noise emissions from railway operations depend on train characteristics and track conditions. The study accounts for:

- Train types (high-speed, freight, regional).
- Track configurations (ballast, slab track).
- Speed variations and train frequency.
- Barrier effects and terrain interactions.

2.3 Industrial Noise

In order to compare methods for industrial noise sources, point, linear, and surface sources were analyzed. Setting the same sound power level (Lw) for each method enabled comparability between methods.

Particular attention was paid to analyzing vertical and horizontal diffraction, for which urban environments with more complex obstacles were modeled to analyze differences in propagation.

Key factors evaluated are:

- Source height and spatial distribution of noise emissions.
- Influence of obstacles (buildings).
- Ground absorption and terrain effects.

2.4 Ground absorption

Finally, different noise sources were analyzed comparing ground absorption (absorbent ground and reflective ground) as a variable.

Results were statistically analyzed to quantify differences in power level estimations and equivalent continuous sound levels (LAeq), as shown in **Table 1.**

Table 1. Summary table of all the cases considered and the pairs of data analyzed.

		Power Data Pairs	Pressure Data Pairs	# Cases
Road Traffic	Free field	18	288	6
	Agglomerations	6	96	4
	Noise barriers	0	96	2
Railway Traffic	Free field	21	336	7
	Agglomerations	12	96	4
	Noise barriers	0	96	2
Industrial Noise	Free field	0	192	4
	Agglomerations	0	144	6
	Noise barriers	0	192	4
Ground Absorption	Various	0	288	6
		57	**1824**	**45**

3. RESULTS AND DISCUSSION

3.1 Road Traffic Noise

3.1.1 Percentage of Heavy Vehicles:

Variation of the percentage of heavy vehicles has a more pronounced effect on the sound power level in the interim method (NMPB – Routes – 96) compared to CNOSSOS-EU.

3.1.2 Vehicle Speed:

Speed variations impact the sound power level more significantly in the CNOSSOS-EU method.

3.1.3 Receiver Height and Distance:

The greatest differences in sound pressure levels are observed at lower heights and distances beyond 25 m from the source, with the interim method producing levels typically over 5 dB(A) higher.

3.1.4 Obstacles (Buildings and Barriers):

Obstacles reduce discrepancies at low heights and shielded positions, though the interim method still results in higher levels.

Summary: Overall, the interim method produces higher road traffic noise levels under the studied variables and conditions.

3.2 Railway Traffic Noise

3.2.1 High-Speed Trains:

The interim method (SRM II) delivers higher sound pressure levels than CNOSSOS-EU, with differences ranging from 4 to over 6 dB(A).

3.2.2 Other Train Types:

For medium-distance, suburban, and freight trains, CNOSSOS-EU estimates levels between 0.1 and 3.5 dB(A) higher than the interim method.

3.2.3 Vertical Propagation:

CNOSSOS-EU shows notable differences in vertical propagation due to its inclusion of directivity effects.

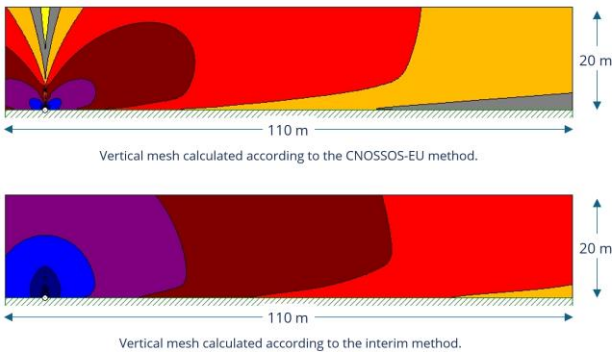

Figure 1. Comparison of vertical propagation for different methods for railway traffic noise.

3.2.4 Obstacles:

The presence of buildings or barriers reduces differences at shielded receivers, although variations persist.

Summary: Generally, the interim method produces higher values. However, direct comparisons are complex due to differing input data and modeling formulations.

3.3 Industrial Noise

3.3.1 Point, Line, and Vertical Surface Sources:

Sound pressure levels estimated using the interim method (ISO 9613-2) are consistently about 1 dB(A) higher across different distances and heights.

3.3.2 Surface Sources:

The interim method again produces higher levels, particularly at low heights and long distances, with differences exceeding 3.5 dB(A).

3.3.3 Noise Barriers:

In shielded scenarios, the interim method estimates sound pressure levels 4–5 dB(A) higher than CNOSSOS-EU.

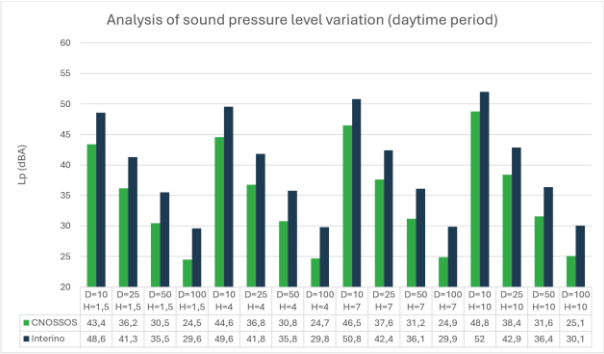

Figure 2. Comparative analysis of sound pressure levels for a point source of industrial noise with an acoustic barrier (*CNOSSOS-EU in green and interim in blue*).

3.3.4 Obstacles and Diffraction:

Without Lateral Diffraction: CNOSSOS-EU predicts higher levels (~6 dB(A)) at shielded positions.

With Lateral Diffraction: The interim method shows higher levels (~5 dB(A)).

With Combined Vertical and Horizontal Diffraction: The interim method estimates levels ~7.5 dB(A) higher.

3.3.5 Vertical Propagation Differences:

CNOSSOS-EU introduces a vertical propagation component for point sources, absent in the interim method.

Summary: Variability in results for industrial noise prevents broad generalization. Nevertheless, significant discrepancies exist, especially in complex propagation scenarios involving multiple obstacles.

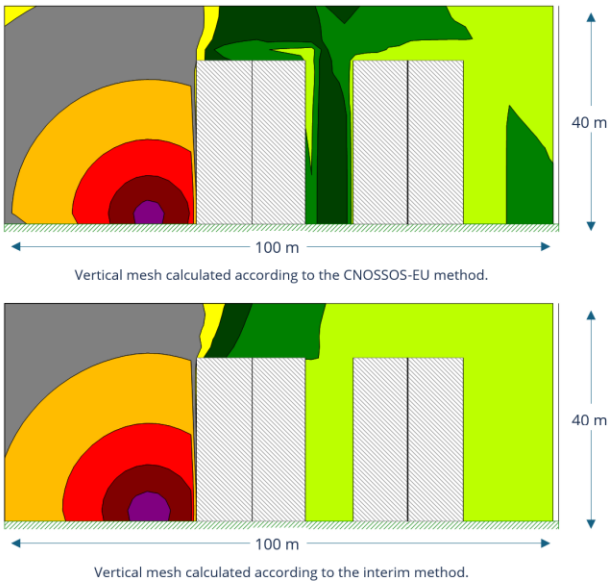

Figure 3. Comparison of the diffraction effect for both methods with industrial noise sources**.**

3.4 Ground Absorption

CNOSSOS-EU is more sensitive to ground absorption variations, leading to greater differences in sound pressure levels. With reflective ground, propagation differences between methods are reduced.

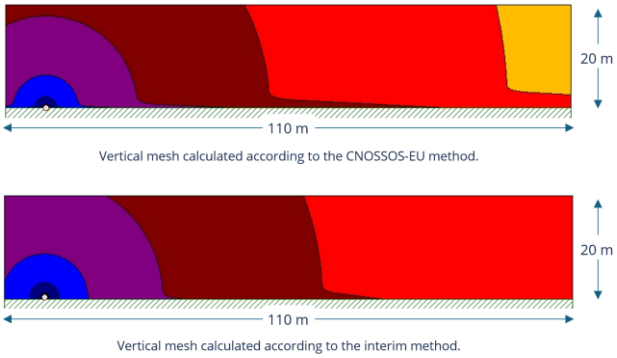

Figure 4. Comparison of methods for road traffic noise in reflective terrain.

4. CONCLUSIONS

This study highlights systematic differences between the CNOSSOS-EU and Interim methods for environmental noise assessment. The main findings are:

- Comparison between methods is not immediate and can be complex since, in addition to differences in the input parameters, the output variables of the parametric equations can also yield different indicators.
- Road traffic noise and industrial noise are more easily comparable, as the power level indices are comparable.
- The comparison is especially sensitive when it is made between railway noise indicators, as there are significant methodological differences between the two methods.
- The Interim method generally predicts higher LAeq values, particularly in road traffic and railway noise scenarios. These differences can be up to 5 dBA.
- The sound pressure level using the interim method may, in general terms, be higher than that used by CNOSSOS for railway noise from high-speed trains. However, for medium-distance trains and freight trains, the opposite may be true.
- Vertical propagation for rail traffic noise is very different between methods.
- Regarding industrial noise, there is large variability when comparing methods. Significant differences are found when comparing scenarios with many obstacles and vertical and horizontal diffraction.
- The transition to CNOSSOS-EU may affect regulatory compliance and noise action plans, requiring careful evaluation of historical and future noise maps.
- The change in ground absorption has a greater impact on the sound pressure levels predicted using the CNOSSOS-EU method. With reflective ground, there is less difference in propagation between the two methods.
- Further research is needed to assess the impact of these differences on long-term noise exposure assessments and public health policies.

This analysis was focused on direct comparisons of comparable pressure levels and power levels across methods; it did not analyze population allocation methodologies or noise-exposed population calculations, which could be the subject of future research.

5. ACKNOWLEDGMENTS

This research was developed within a project funded by the Center for Studies and Experimentation of Public Works (CEDEX) and the Spanish Ministry for Ecological Transition and the Demographic Challenge.

The authors would like to thank ADIF (Spanish railway infrastructure manager) for the consultations carried out to correctly characterize and compare rolling stock across methods.

NEED OF A NATIONAL NOISE STRATEGY IN SPAIN ANDAPPROACH TO DEVELOP IT.

Miguel Ángel González García[1*] **Ignacio Soto Molina**[1]
Carlos Soriano Pastor[1]
[1] Ministerio para la Transición Ecológica y el Reto Demográfico, España

ABSTRACT

The last decade made us awareness of the importance of environmental noise as cause of disease and life quality loss for the population. Since the entry into force of END and Spanish legislation on noise progress has been made, especially in noise evaluation, even with difficulties. Nevertheless, reaching objectives of noise reduction nowadays on the table (ZPAP) seems a difficult goal.

To afford this challenge it is needed a correct overview of noise problems at a macro scale and a strategic approach of what the causes are and the possible ways to work to solve it effectively. This work reviews why this strategical vision is needed, what are the works in course for developing it and which could be, at the State level, the main axes that guide the action of the different administrations to address environmental noise.

1. INTRODUCTION

The impact of noise on health is a key concern for several international bodies. The World Health Organization (WHO) has published guidelines recommending safe noise levels to protect public health, as noise exposure has been linked to sleep disturbances, cardiovascular diseases, and other health problems. Additionally, global institutions like the World Bank and the United Nations Environment Programme (UNEP) have incorporated noise pollution into their sustainable development agendas.

Within the framework of the United Nations Sustainable Development Goals (SDGs), noise pollution is directly related to SDG 3 (Good Health and Well-being) and SDG 11 (Sustainable Cities and Communities). Reducing noise not only minimizes non-communicable diseases but also enhances the overall quality of urban life by creating healthier, more livable environments.

At the European level, Directive 2002/49/EC plays a central role by establishing a common framework for the evaluation and management of environmental noise. This directive requires member states to develop strategic noise maps for urban areas, major transport infrastructures, and densely populated regions, along with comprehensive action plans aimed at reducing noise levels.

In addition to the Directive, the European Green Deal and its Zero Pollution Action Plan integrate noise management into broader sustainability strategies. These initiatives aim to transition the EU towards a sustainable, climate-neutral economy, with noise reduction being a key element in improving both environmental quality and public health.

The European Environment Agency (EEA) plays a pivotal role in tracking and assessing noise pollution across Europe. The report, “Environmental Noise in Europe —

2020," illustrates that noise exposure remains a significant issue, affecting millions of people.

Despite the importance of the problem, we are far from achieving a sound environment aligned with what, according to science, would be adequate for citizens. Some challenges for more progress on this path are:

- A complete picture of the problem is lacking. Based on the best possible technical approach, it would shed light on the true severity of this form of pollution. This work can help administrations and the public better understand the significance of noise pollution for the country's society and economy.
- Despite the existence of long-standing regulations, their application is not always efficient or easy, and there is a significant gap in their implementation.
- This form of pollution has generally been considered a local problem, to be addressed locally. However, this has not led to an improvement in the situation and does not always help address the issue in a coherent and appropriate manner.
- Many times there are no comprehensive policies that are sustained over time.

2. WHY IS A NOISE STRATEGY NECESSARY IN SPAIN?

In Spain, a noise strategy is needed, as the current approach to assessing noise pollution only provides a partial view of its impact on both citizens' quality of life and terrestrial habitats. While strategic noise maps are developed for urban areas with more than 100,000 inhabitants and significant noise sources—such as busy roads, railways, and airports, as defined by the Environmental Noise Directive—this methodology leaves many areas and sources unexamined. For example, while higher noise levels (Lden > 70) are reasonably well represented in current noise maps, initial estimates indicate that, at medium noise levels (Lden 55-70), approximately 50% of the exposed population is not adequately studied. This significant data gap underscores the limitations of the existing framework.

Spain's National Information System on Noise Pollution (SICA) currently only reports data from a limited number of urban agglomerations and infrastructure, including 64 large cities, 21,000 km of main roads, 1,800 km of major railways, and 13 major airports. Consequently, numerous small municipalities and diverse noise sources—from industrial activities, wind farms, and port facilities to local disturbances from leisure activities, neighborhood events, urban services, and construction noise—remain unassessed. This narrow focus means that a large segment of the population and numerous sensitive receptors in the natural environment are not considered in current assessments.

The Environmental Noise Directive's approach, which determines study areas based on noise sources rather than the distribution of affected receptors, results in many affected communities and natural habitats being overlooked. While the European Environment Agency has made efforts to use statistical methods to fill the gaps, these methods can be significantly biased due to a lack of comprehensive data and do not yet identify all areas requiring corrective action.

For these reasons, the Ministry for the Ecological Transition and the Demographic Challenge (MITECO) emphasizes the urgent need for a comprehensive noise strategy. A comprehensive assessment of noise pollution is essential to clearly understand the various problems, analyze the potential impacts on public health and natural environments, and develop synoptic documents that facilitate access to this information for monitoring and evaluating the effectiveness of policies. MITECO is developing global noise models for key sources, especially road traffic, which has the greatest impact on environmental acoustic quality, in addition to promoting assessment methodologies for other noise sources. This strategy would ensure the identification and addressing of all affected areas, thus protecting both the health of the population and the integrity of natural habitats.

3. STRATEGY OBJECTIVES

The National Noise Strategy aims to serve as a benchmark document that not only meets the regulatory requirements set by the European Union but also identifies national priorities and establishes effective measurement indicators to assess progress. This strategy is designed to guide specific policies for mitigating noise across various economic sectors and social environments, ultimately protecting public health, preserving the acoustic quality of natural surroundings, and enhancing the overall well-being of Spanish society. In doing so, it aligns with international commitments and promotes a more livable and healthy environment for current and future generations. The objectives pursued are the following:

- Analyze the information generated, identifying the needs for action to improve current noise pollution levels and reduce its adverse effects on health and the

environment. To this end, the most appropriate tools will be used for this analysis (SWOT).

- Identify those elements with the greatest potential to improve the noise environment but that may still be less developed, such as Quiet Zones, Soundscapes, or Sound Reserves, etc.
- Identify the strategic axes and lines of work that can help gradually improve the noise environment.
- Identify the stakeholders with the greatest responsibility for improving the noise environment to increase the positive impact of the actions that this document may lead to.
- Set achievable objectives for the different strategic axes/lines and define policies and actions that will help the Competent Authorities make progress in reducing noise pollution problems.
- Assess the potential costs and impact of such policies and actions, as well as the best way to implement them.
- Establish formulas to keep the diagnosis of noise pollution in Spain up-to-date, in the simplest and easiest way possible, to evaluate trends and identify potential emerging problems in noise pollution, and to monitor the implementation of the Strategy.

Together, these objectives and guiding principles provide a robust framework for the National Noise Strategy, laying the groundwork for comprehensive actions that protect public health, sustain natural environments, and contribute to the overall quality of life in Spain.

4. METHODOLOGY FOR STRATEGY DEVELOPMENT

4.1 General Methodology

The methodology for developing the National Noise Strategy is structured around a comprehensive index that ensures a thorough analysis of all aspects of environmental noise and its impacts.

The process begins with the justification and objectives of the Strategy. This initial phase examines the nature of environmental noise, its causes, and its effects on both public health and the environment. It also identifies potential for improvement and highlights the need for a strategic approach to noise management.

The Strategy's development is then based on a review of the national, European, and international legal context for noise management. This involves analyzing previous approaches to environmental noise in Spain, examining the international and European frameworks that have influenced current practices, and considering how Spanish national, regional, and local regulations interact with broader environmental policies. This phase also explores the relationship between noise pollution and other environmental issues to identify potential synergies with existing plans and strategies.

The next step is a detailed diagnosis of the current situation. This assessment employs a multifaceted methodological approach that includes both quantitative and qualitative analyses. Quantitative methods involve the collection and processing of noise level data from various sources, the application of standardized noise modeling techniques, such as CNOSSOS-EU, and the use of Geographic Information Systems to assess noise exposure in different population segments and sensitive natural areas.

Complementary semi-quantitative and qualitative approaches help fill data gaps and provide insight into public perception, regulatory compliance, and the effectiveness of existing noise management tools.

Particular attention is paid to assessing significant noise sources—from road traffic, rail, and air transport to industrial activities, port operations, and even local events—allowing for a comprehensive evaluation of both modelable and non-modelable noise sources.

Once the current status has been diagnosed, the synthesis of the findings identifies key needs and challenges that need to be addressed.

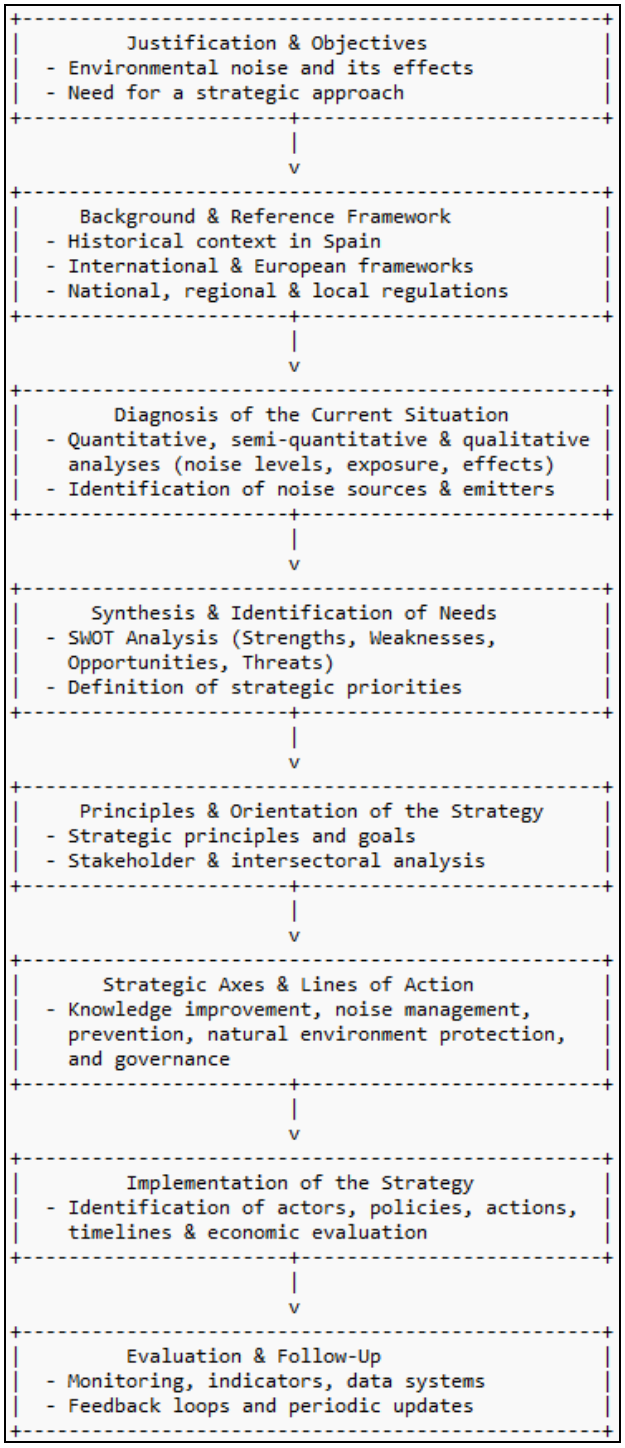

Figure 1. Methodological diagram.

This summary lays the groundwork for defining the Strategy's principles and strategic directions. It includes an analysis of the strengths, weaknesses, opportunities, and threats (SWOT analysis) related to noise management in Spain, as well as an assessment of how various sectors, such as urban planning, environmental protection, and public health, can be integrated into a coherent strategic framework.

The Strategy will define the strategic axes and lines of action. These include improving citizen knowledge and awareness, noise management in different sectors, preventing noise pollution, improving the quality of the acoustic environment, and improving intervention and regulation tools. Each strategic axis is detailed in terms of specific actions, such as capacity building, intersectoral cooperation, and the development of clear policy objectives.

The Strategy's implementation will be planned through a detailed roadmap that identifies key stakeholders, defines specific policies and actions, sets measurable objectives, and includes an economic evaluation of the proposed interventions. This stage also addresses the need for planning, programming, and periodic reviews to ensure the Strategy maintains its effectiveness over time.

Finally, the methodology incorporates an evaluation and monitoring phase. This phase is designed to periodically update the noise pollution assessment, monitor the effectiveness of the implemented measures using defined indicators, and ensure the availability of robust information systems and data sources. This continuous feedback loop is essential for adapting the Strategy to new challenges and technological advances.

Overall, the methodology for developing the National Noise Strategy is an integrated and iterative process. It combines historical analysis, rigorous data collection and modeling, strategic planning, and ongoing evaluation to create a robust framework aimed at significantly reducing noise pollution and its impacts in Spain, while ensuring the necessary participation of all involved authorities and the public through appropriate public consultations and information periods.

4.2 Considered Noise Sources in Diagnosis

To effectively analyze noise pollution within this Strategy and achieve an accurate diagnosis, it is essential to systematically identify and understand the sources responsible for this type of contamination. These noise sources vary greatly in their characteristics, and their contribution to the overall environmental problem differs significantly. Below, the characteristics of some of the most important sources are described.

Road traffic is recognized as the primary source of noise pollution in urban and suburban areas, affecting a large proportion of the population. The noise from road traffic primarily results from the contact between tires and pavement, compounded by engine noise and, to a lesser extent, the use of braking systems. Similarly, rail transport is an important contributor, particularly in urban areas. Trains—especially high-speed ones—generate noise due to the contact between wheels and tracks, as well as aerodynamic noise at high speeds. In urban contexts, the passage of trains at level crossings or in proximity to residential areas can adversely affect quality of life, and noise from freight trains can also cause significant issues in the surrounding environment.

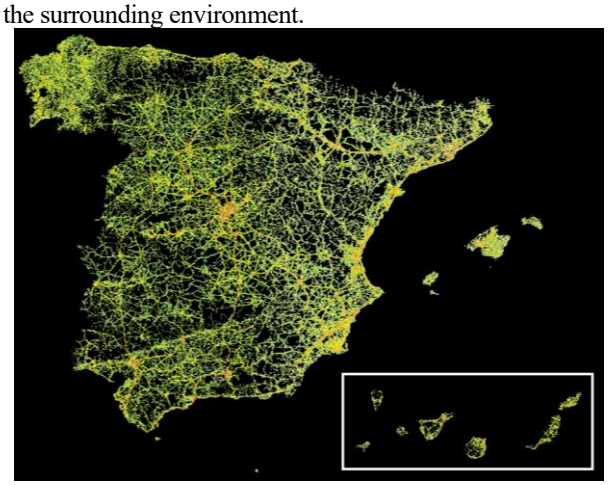

Figure 2. First version of the supra-strategic road map of Spain.

Aviation is another significant source of noise, especially near airports where takeoffs and landings create high noise levels that impact both nearby residents and sensitive natural areas. In a similar vein, maritime transport and port activities are major contributors to noise pollution, even though they are not mandated to conduct noise evaluations and action plans under the Environmental Noise Directive. Operations such as loading and unloading, the movement of heavy machinery, and the vessel traffic within ports generate substantial noise, particularly in port cities.

The industrial sector also plays a key role. Industries contribute to noise not only through manufacturing processes but also via logistics and transportation operations. Noise generated by machinery, material handling, and the movement of vehicles during loading and unloading creates significant issues in industrial areas adjacent to residential zones. Additionally, industrial noise affects rural areas where facilities such as farms, food processing plants, and other agro-industrial activities are located.

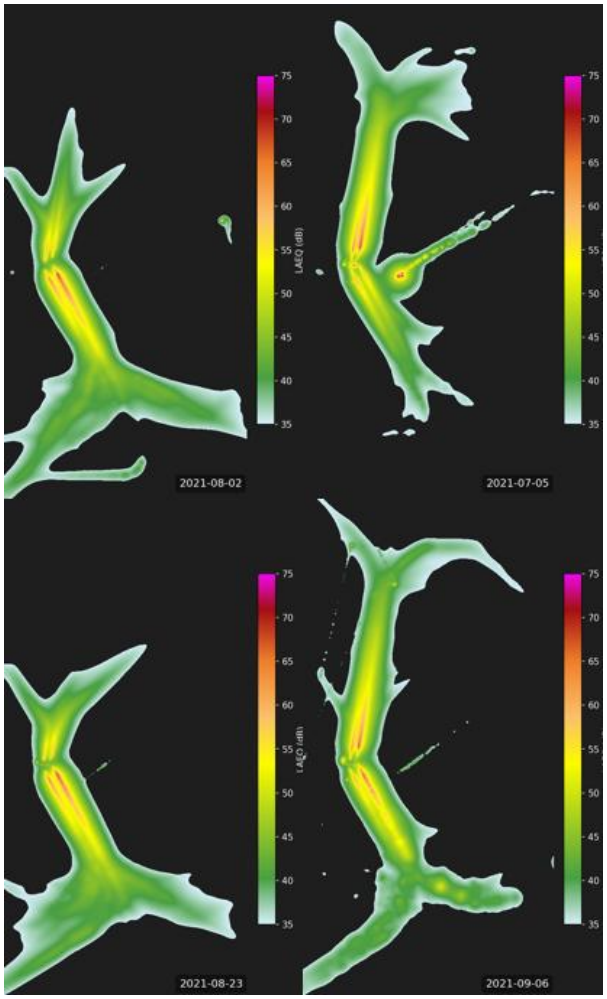

Figure 3. Noise footprints of aeronautical operations on different evaluation days.

The leisure and hospitality sector is a notable source of urban noise, especially in tourist and residential areas with a high density of bars, nightclubs, and restaurants.

Construction, though typically a temporary activity, produces significant noise impact—especially in urban areas where building and renovation projects are continuously underway. These construction activities, which may last for months or even years, can greatly affect residents' quality of life. Moreover, the construction of infrastructures such as roads or rail stations contributes to noise pollution both during the construction phase and in subsequent operational phases.

Other significant noise sources include local festivities and public events like popular celebrations, which generate temporary yet intense increases in noise levels.

Other sources, such as wind turbines—despite being a renewable and sustainable energy source—can emit significant noise in the areas where they are installed, particularly in rural and mountainous regions.

Based on the diagnosis, a framework of noise sources will be established for consideration in the National Noise Strategy. As said before, for each type of emitter, different methodological approaches will be applied to diagnose their importance and significance, depending on the available information and possible work methodologies. These approaches include a quantitative method, a semi-quantitative method, a qualitative approach at the level of territorial administrative entities, a large-scale analysis, and a normative and management analysis, along with a category for those sources not analyzed.

The quantitative approach involves evaluating the noise generated by all identifiable entities from available cartographic data. This process entails identifying the study entities, processing the available information, characterizing the necessary parameters for strategic input into noise calculation software, generating a calculation model using source data and lidar-derived digital terrain models that include building data, and calculating noise levels using base maps from the National Geographic Institute and tools like CEREMA-FR's Noise Modelling based on the CNOSSOS-EU methodology. The results from this approach will later be used to assess noise exposure and its effects.

In contrast, the semi-quantitative approach employs a mixed methodology by calculating noise levels for typical cases and extrapolating the results. This method starts with approximating the territorial distribution of each type of emitter using available cartographic products, classifying groups of similar emitters into synthetic types, and characterizing the noise each type produces. Noise calculations will then be performed for specific cases or by using available data from such cases (e.g., strategic noise maps of urban agglomerations, environmental procedures), potentially utilizing more tailored methods (such as ISO-9613), before extrapolating these analyses to the broader territory using Geographic Information Systems. The outcomes will again be used to evaluate noise exposure and its subsequent effects.

A qualitative approach will also be undertaken at the level of territorial administrative entities, analyzing the significance of each type of source based solely on statistical data and the most disaggregated local or regional data available. This analysis will be extrapolated to the entire set of territorial entities and will include an examination of existing management tools and the need for improvements. Additionally, a large-scale state-level analysis will be conducted to assess the overall importance of these noise sources and evaluate the effectiveness of current management tools, potentially supplemented by expert opinions, communications, or relevant literature.

Finally, a normative and management analysis will examine the current regulatory framework and the possible need for additional instruments, focusing on preserving acoustic quality against the noise generated by these sources. For some types, it may be possible to consider the definition of "tolerable limits" for noise pollution.

It is important to note that the list of noise sources included in this framework is not intended to be an exhaustive catalog of all possible sources of environmental noise in urban, rural, and natural areas. Instead, it aims to provide a sufficiently comprehensive approximation that covers the primary contributors to noise pollution for the current Strategy, grouping them into basic typologies that facilitate systematic analysis and diagnosis.

4.3 Main Lines of Action

To structure the National Noise Strategy in Spain and maximize the effectiveness of interventions on acoustic pollution, the main strategic axes need to be a identified, for instance trough a SWOT analysis.

These axes will serve to orient the Strategy according to both challenges and opportunities, strengthening capabilities in critical areas and improving coordination among administrations and other stakeholders.

Preliminary, with the work already done, the following lines of action can be advanced:

- Improvement of Knowledge, Dissemination, and Awareness, emphasizes the need to expand understanding of noise pollution and its impacts on health. It also focuses on training professionals in the sector and raising public awareness about the importance of this issue.
- Management of Acoustic Pollution, advocates for the effective handling of the main sources of noise. This includes addressing major transport infrastructures, industrial and urban activities, and temporary noise emitters, while also targeting interventions in urban spaces to enhance the overall sound environment.
- Prevention of Pollution and Improvement of the Acoustic Environment, is centered on preserving acoustic quality in areas with low pollution levels and preventing noise in urban settings and new constructions. This axis also encompasses efforts to

improve sound quality in urban areas and in indoor environments, such as residential buildings and workplaces.

- Noise, Biodiversity, and the Natural Environment, underlines the critical importance of preserving biodiversity and natural ecosystems as part of an integrated approach to combating acoustic pollution. It includes managing noise in rural areas, natural settings, and the marine environment to protect vulnerable species and ecosystems.
- Improvement of Management and Intervention Tools, focuses on strengthening the tools necessary for effective governance and compliance. This involves ensuring adherence to regulatory obligations, enhancing the regulatory framework, managing conflicts related to noise, and promoting cross-sector policies that foster synergies and collaboration among various administrations.

Together, these strategic axes will guide the implementation of measures in the areas of management, prevention, knowledge, and regulation of acoustic pollution. They establish a comprehensive framework that contributes to the effective reduction of noise exposure in Spain.

5. EXPECTED RESULTS AND BENEFITS OF THE STRATEGY

The expected results and benefits of the National Noise Strategy are multifaceted, touching on public health, quality of life, environmental protection, and economic gains.

By effectively reducing noise levels, the Strategy is anticipated to lead to significant improvements in public health, lowering the incidence of noise-related issues such as sleep disturbances, cardiovascular problems, and stress. This reduction in noise exposure will enhance urban livability, creating quieter, more harmonious communities that support overall well-being and productivity.

In addition to health benefits, the Strategy aims to preserve and improve the acoustic quality of both natural and urban environments. This will help protect biodiversity and ensure that natural habitats, particularly in rural, coastal, and marine areas, remain less disturbed by excessive noise.

The strengthened regulatory framework and enhanced monitoring tools resulting from the Strategy will facilitate better compliance with European directives and more efficient enforcement of noise standards, leading to a more coordinated and effective noise management system.

Economically, the Strategy is expected to yield benefits by reducing healthcare costs associated with noise-induced conditions and minimizing social costs related to stress and reduced quality of life. Moreover, improved urban planning and intersectoral coordination can lead to increased property values and a boost in tourism, while encouraging innovation in noise reduction technologies that can spur new business opportunities.

Finally, the Strategy's focus on improving knowledge, dissemination, and public engagement will foster greater awareness and participation among citizens and stakeholders, ensuring that noise management becomes a shared responsibility across communities and administrations.

6. CONLUSION

The National Noise Strategy will present a comprehensive framework to address the multiple challenges posed by noise pollution in Spain. Through a systematic and integrative approach, the Strategy will address not only the assessment and monitoring of noise sources, but also the development of effective mitigation measures in various sectors, from urban transport and industrial activities to leisure events and natural habitats.

The analysis underpinning this Strategy highlights the need for a detailed diagnosis that encompasses both modelable and non-modelable noise sources, ensuring that the data-driven approach captures the full magnitude of environmental noise and its impact on public health and biodiversity. By integrating robust methodologies, including quantitative, semi-quantitative, and qualitative assessments, the Strategy lays a solid foundation for informed decision-making and policymaking. The strategic axes, ranging from improving public knowledge and awareness to improving noise management, prevention, and regulatory frameworks, guide the plan toward the creation of a cohesive and adaptive system for noise control.

The emphasis on cross-sector collaboration and inter-administrative coordination further strengthens the potential for achieving tangible improvements in both urban acoustic environments and natural ecosystems. Ultimately, the expected outcomes of implementing the Strategy include policies and tools aimed at achieving significant reductions in noise exposure, improvements in public health and well-being, the preservation of acoustic quality in natural areas, and economic benefits through reduced healthcare costs and improved urban livability.

This Strategy will establishes a forward-looking agenda that supports the goal of ensuring a healthier, more sustainable, and acoustically harmonious environment for present and future generations.

Università degli Studi della Campania "Luigi Vanvitelli", 81031 Aversa, Italy

ABSTRACT

The growing interest in soundscape analysis has highlighted the need for accessible tools capable of capturing and processing audio with high spatial sound fidelity. This study presents a low-cost device designed for binaural recording and soundscape monitoring. The device employs a microphone array to capture sound signals and subsequently applies signal processing techniques to synthesize a binaural output.

A preliminary evaluation was conducted to assess the device's performance in a controlled urban environment characterized by road traffic noise. The evaluation compared recordings obtained with the prototype device against reference recordings captured using in-ear microphones in an artificial head and worn by human. Key metrics, including spatial accuracy, and psychoacoustic parameters, were analyzed to determine the device's suitability for soundscape studies.

Results suggest that the proposed device provides an effective approximation of binaural audio, with certain limitations inherent to its low-cost design. These findings support the potential of the device as a scalable solution for soundscape monitoring, particularly in applications where traditional binaural equipment may be cost-prohibitive. Future work will focus on refining the signal processing algorithms and expanding the evaluation to diverse soundscapes.

1. INTRODUCTION

The study of soundscapes has emerged as a crucial area in acoustic research, particularly in the context of urban planning, environmental monitoring, and public health. Soundscape analysis aims to understand how people perceive and interact with their acoustic environment, providing valuable insights to design more sustainable and livable urban spaces [1, 2]. A fundamental aspect of soundscape studies is the ecological capture of spatial auditory information, which requires high-fidelity binaural recordings. These recordings preserve the spatial cues necessary for human auditory perception, including interaural level and time differences, which are essential for evaluating the subjective experience of sound environments [3].

Traditional binaural recording techniques employ artificial heads, binaural headsets or in-ear binaural microphones worn by human subjects. These devices offer high spatial sound accuracy but are often expensive, equipment and/or human resources, limiting their widespread use in large-scale or long-term soundscape monitoring [4, 5]. Additionally, logistical challenges arise when deploying multiple binaural recording units in diverse environments, further restricting their applicability. To address these limitations, recent advancements in the Internet of Things (IoT) and digital signal processing have facilitated the development of alternative low-cost solutions. Even though low-cost IoT solutions have made significant progress in the soundscape monitoring field, challenges are still open in capturing perceptually accurate data. One approach has focused on integrating low-cost acoustic sensors with

AI-based analysis for urban soundscape research, but the system relies on monaural recording and does not incorporate psychoacoustic parameter extraction [6]. Another initiative has introduced a FIWARE-based wireless acoustic sensor network designed for urban sound classification, utilizing machine learning models; however, it lacks binaural capabilities and the ability to assess perceptual sound attributes [7]. A different solution has explored a multipurpose IoT sensor for biologging and soundscape applications, offering flexibility in data collection but still relying on monaural recording without advanced psychoacoustic analysis [8]. While these efforts contribute to the accessibility and scalability of soundscape monitoring, they also reveal gaps in binaural recording and perceptual sound analysis, highlighting the need for enhanced solutions that improve fidelity and psychoacoustic processing.

In this study, a preliminary evaluation of a low-cost IoT device designed for binaural recording and soundscape monitoring is presented. The proposed system employs a microphone array to capture sound signals and implements signal processing algorithms to synthesize binaural output [9], [10]. A controlled experiment was conducted in an urban environment dominated by road traffic noise to assess the device's performance against a reference system consisting of human-worn binaural headphones. Key performance metrics, including including spatial accuracy, and psychoacoustic parameters, were analyzed to determine the suitability of the proposed device for soundscape research.

The remainder of this paper is structured as follows: Section 2 describes the materials and methods, including the system architecture, experimental setup, and evaluation methodology. Section 3 presents the results and discussion, highlighting the device's performance in comparison with the reference system. Finally, Section 4 concludes the study and outlines potential directions for future work.

2. MATERIALS AND METHODS

The following section provides a comprehensive description of the methodology employed in this study. In the first part, the evaluated device is described in terms of its hardware and software components. Subsequently, the experimental setup is presented, detailing the environment and reference system used for evaluation. The third part outlines the data collection procedure, including the recording protocols and evaluation criteria. Finally, data processing and analysis methods are described, emphasizing the techniques used to assess the performance of the device.

2.1 Description of the Device

The low-cost IoT device was designed to approximate the spatial fidelity of conventional binaural recording systems. The system is structured into two main components: the audio acquisition subsystem and the processing core, which together facilitate real-time data capture, processing, and transmission.

The audio acquisition is based on a Sony PlayStation Eye camera, which features a four-microphone array. This array captures sound with 16-bit depth at a sampling rate of 16 kHz, offering a signal-to-noise ratio of 90 dB. The array configuration is specifically designed to replicate spatial hearing characteristics, with an inter-microphone distance of approximately 62 mm and reversed polarity in the central microphones to enhance spatial audio capture. Calibration procedures were conducted in a semi-anechoic chamber comparing the results with those of a Rion NL-05 sound level meter to ensure reliable and accurate measurements.

The processing core is based on a Raspberry Pi 3 Model B, which serves as the central processing and control unit. This platform is equipped with a 1.2 GHz 64-bit quad-core ARMv8 CPU, 1 GB of RAM, four USB ports, and integrated 802.11n Wireless LAN.

The system captures audio in configurable time-window segments and utilizes a signal processing pipeline to synthesize binaural output. The stages of the pipeline are shown in Fig. 1.

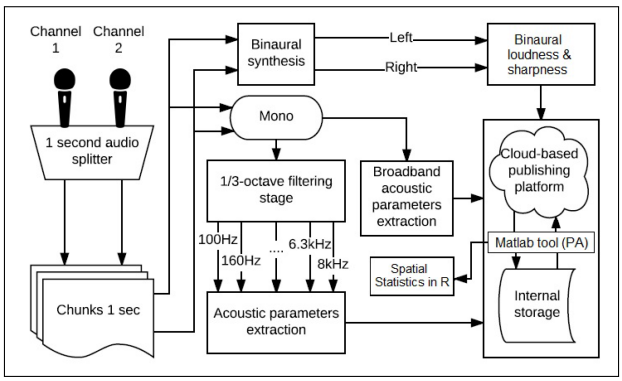

Figure 1. Diagram of the signal processing pipeline to synthesize binaural output. [9]

The system estimates the direction of incoming

sounds using time-frequency domain analysis, employing the Short-Term Fourier Transform and assuming sparsity of audio sources to calculate the Direction-Of-Arrival (DOA). Based on the estimated DOA, the system applies Head-Related Transfer Functions (HRTFs) to synthesize binaural audio. The selected HRTF corresponds to the estimated azimuth, ensuring an accurate spatial representation. The device computes objective psychoacoustic metrics, following Zwicker's and Moore's loudness models. The processed data, including acoustic parameters and raw recordings, are stored locally on the Raspberry Pi and transmitted to a cloud platform for further analysis and archiving.

The entire processing pipeline is implemented in Python, using the Advanced Linux Sound Architecture (ALSA) for audio acquisition. The modular software architecture allows independent operations of each processing stage, enhancing robustness and facilitating updates or modifications. The system periodically uploads processed data to an IoT cloud platform, enabling real-time monitoring and remote data retrieval.

2.2 Experimental Setup

As a preliminary experiment, the performance of the proposed device was evaluated in an indoor environment, specifically an open-plan office of the Universidad Católica de Murcia, Spain. This setting is characterized by stable and consistent acoustic conditions, with predominant noise sources originating from vocal interactions among staff members. The environment was chosen due to its relevance in soundscape studies, as speech-related acoustic fields are common in office and educational settings, making it an ideal scenario to assess the device's performance in capturing binaural audio under realistic indoor conditions. The recording area was situated at the center of the right-hand row of desks within the open-plan office, which is composed of three parallel rows of desks. This positioning was chosen to minimize reflections from nearby furniture and maintain consistency throughout the data collection process.

To assess the accuracy of the proposed device, the recordings were compared against two reference systems. The first reference system consisted of a Roland CS-10EM binaural headphones connected to a Zoom H4n Pro 4-channel digital recorder. The Roland CS-10EM headphones, featuring built-in omnidirectional microphones, were placed in the listener's ear canals. The second reference system consists of the a OKM II Classic Binaural Microphones mounted on a Soundman Dummy Head, also connected to a Zoom H4n Pro. The Zoom H4n Pro recorder provided high-quality audio capture with 24-bit/96 kHz resolution, ensuring accurate documentation of the acoustic environment.

Each recording session lasted 10 minutes, ensuring adequate signal representation for analysis. Both systems were synchronized to ensure simultaneous recording sessions under identical acoustic conditions. Synchronization was achieved using a common time reference and initiating recordings simultaneously to eliminate temporal discrepancies between datasets. Calibration procedures were performed before the experiments to ensure that the signal levels recorded by both systems were comparable, thereby minimizing potential bias due to differences in microphone sensitivity or frequency response.

The experimental setup was designed to allow both the proposed device and the reference system to capture the same acoustic events from identical spatial perspectives. This approach enabled a direct comparison between the binaural outputs of the low-cost device and the reference microphones, focusing on spatial accuracy and perceptual fidelity.

2.3 Data Processing and Analysis

All recorded signals were processed and analyzed using MATLAB. The analysis workflow included signal segmentation, feature extraction, and statistical comparison between the proposed device and the reference system. The 10-minute recording session was segmented into 10-second windows, and for each window, several key performance metrics were calculated, followed by the extraction of statistical descriptors from the entire session.

Spatial accuracy was assessed by comparing the interaural level differences (ILD) in dB, the interaural time differences (ITD) in ms, and the interaural cross-correlation (IACC). Perceptual fidelity was evaluated through an objective analysis of psychoacoustic metrics, including loudness (LO) in sone, sharpness (SH) in acum, roughness (RO) in asper, and fluctuation strength (FS) in vacil, using MATLAB's psychoacoustic modeling tools.

3. RESULTS AND DISCUSSION

This section presents the preliminary results obtained from the evaluation of the proposed low-cost binaural recording device analyzing a single 10-minute recording session, with particular emphasis on a detailed examination of a 10-second window within that session to assess

the suitability of the system. The performance of the device was compared with two reference systems consisting of human-worn binaural microphones and a dummy head equipped with binaural microphones. Moreover, to evaluate the impact of the binaural synthesis algorithm on the recorded signals, the results include the metrics calculated both before (denoted as pre in tables and figures) and after (denoted as post in tables and figures) the signal processing implemented in the device. The results are presented in terms of average values, highlighting the comparative performance of the proposed device relative to the reference system.

Tab. 1 presents the spatial accuracy metrics obtained for the open-plan office environment, including values recorded before and after the signal processing applied in the device.

Table 1. Spatial accuracy analysis metrics for the open-plan office

Capture	ILD (dB)	ITD (ms)	IACC
Device (pre)	-0.18	0.0000	0.97
Device (post)	3.24	-0.5000	0.24
Dummy	0.88	-0.5575	0.50
Human-worn	0.28	-0.5568	0.36

The proposed device demonstrated significant changes in spatial accuracy after the binaural synthesis process. Notably, the ILD increased from -0.18 dB to 3.24 dB, indicating an adjustment in interaural level representation. Similarly, the ITD shifted from 0 ms to -0.5 ms, suggesting an alteration in the interaural time alignment. The IACC also decreased from 0.97 to 0.24, reflecting a reduction in spatial coherence after processing.

When compared with the reference systems, the device's post-processed ITD was closer to the values observed in the dummy and human-worn setups. However, the ILD values remained less consistent, highlighting a limitation in accurately reproducing level-based spatial cues. The reduction in IACC after processing indicates a potential loss of spatial coherence, which could affect the perceptual quality of the binaural output.

These findings suggest that, while the proposed system is capable of approximating spatial cues, improvements in the signal processing algorithm and microphone array configuration are necessary to enhance spatial fidelity, particularly regarding ILD accuracy and spatial coherence.

Tab. 2 presents the perceptual fidelity analysis metrics obtained for the open-plan office environment, including values recorded before and after the signal processing applied in the device.

Table 2. Perceptual fidelity analysis metrics for the open-plan office

Recording	LO (sone)	SH (acum)	RO (asper)	FS (vacil)
Device (pre)	16.32	1.10	0.08	0.16
Device (post)	12.79	1.07	0.10	0.04
Dummy	13.36	1.11	0.10	0.16
Human-worn	8.50	1.15	0.07	0.08

The analysis revealed that the proposed device's loudness decreased from 16.32 sone to 12.79 sone, aligning more closely with the dummy reference, 13.36 sone, but remaining notably higher than the human-worn microphones, 8.50 sone. Sharpness values remained relatively consistent across all setups, with a slight decrease after processing. Moreover, sharpness values around 1 acum show a balanced sound, with a certain brightness, characteristic of a speech signal.

Roughness showed a small increase from 0.08 asper to 0.10 asper, which corresponds with the dummy reference value but is slightly higher than the human-worn system, 0.07 asper. Fluctuation strength exhibited a more pronounced reduction from 0.16 vacil to 0.04 vacil, diverging from both the dummy and human-worn references, which recorded values of 0.16 and 0.08 vacil, respectively.

These results suggest that the proposed device, after binaural synthesis, more accurately replicates loudness and roughness when compared to the dummy reference. However, the reduced fluctuation strength indicates a potential loss in the dynamic variability of the signal, which could impact the perceived naturalness of the soundscape. Adjustments in the signal processing algorithm could help preserve fluctuation cues while maintaining perceptual fidelity.

To further analyze the frequency response of the proposed device and the effect of the binaural synthesis algorithm, the specific loudness versus frequency for a representative 10-second recording is examined. Fig. 2 shows the specific loudness spectra for both the device, before a) and after processing b), and the reference systems, dummy head c) and human-worn binaural microphones d).

In terms of frequency distribution, both device graphs, Fig. 2a and Fig. 2b, display a concentration of loud-

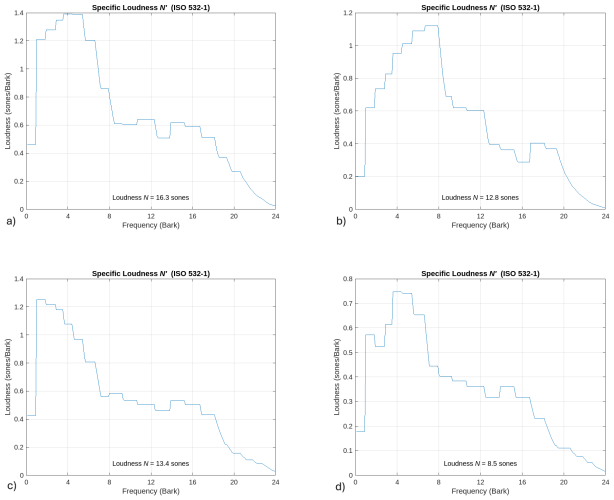

Figure 2. Specific loudness versus frequency for an example of 10 second-recording. a) Device (pre) b) Device (post) c) Dummy d) Human-worn

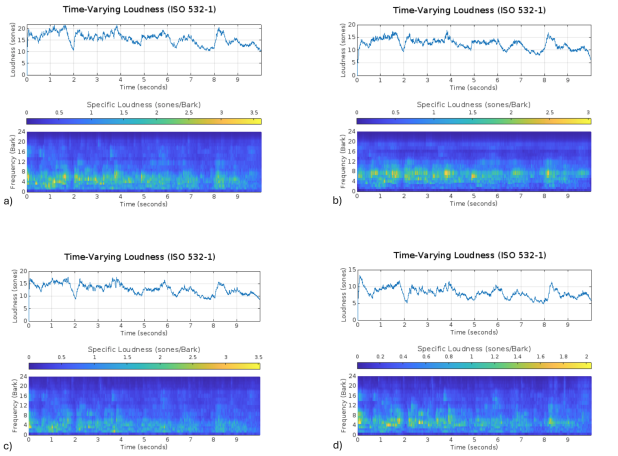

Figure 3. Time-varying loudness for an example of 10 second-recording. a) Device (pre) b) Device (post) c) Dummy d) Human-worn

ness predominantly in the low-to-mid frequency range (0-8 Bark), followed by a gradual decline up to approximately 16 Bark. This pattern is consistent with the human-worn microphone response, Fig. 2d, though with generally lower peak values. In contrast, the dummy head response in Fig. 2c shows a concentration in the lower frequencies, which also exhibits a more uniform distribution across the mid-frequency range, maintaining higher levels up to 16 Bark before decreasing.

Overall, the specific loudness analysis indicates that while the binaural synthesis algorithm can adjust the overall intensity, it does not fully compensate for spectral discrepancies inherent to the device's hardware configuration. Future improvements could include the integration of higher-bandwidth microphones to better capture high-frequency content and enhance perceptual accuracy.

To assess the dynamic behavior of the proposed device, the time-varying loudness for a representative 10-second recording is analyzed. Fig. 3 shows the time-varying loudness (ISO 532-1) for both the device, before and after processing, and the reference systems. The graphs illustrate the variation of loudness over time and its distribution across frequency bands.

Overall, the pattern of level variations, in the time-domain representation in Fig. 3 is similar across the four recordings, indicating that despite differences in loudness values, the temporal dynamics of the sound are consistently captured by both the proposed device and the reference systems. In Fig. 3a, the device's pre-processed signal exhibits noticeable fluctuations in loudness, with values ranging between approximately 10 and 20 sones. After processing, Figure 3b, the device shows a reduction in overall loudness variation, stabilizing around 12 to 18 sones. This decrease suggests that the binaural synthesis algorithm reduces the intensity dynamics, potentially due to signal averaging or noise reduction mechanisms. Comparatively, the dummy head recording, Fig. 3c, presents a loudness range similar to the post-processed device, with values between 10 and 18 sones. On the other hand, the human-worn microphone setup, Fig. 3d, exhibits consistently lower loudness values, ranging from 8 to 15 sones.

The spectrograms in Fig. 3 reveal that the loudness distribution across frequency bands differs notably between the device and both reference systems. Both the pre-processed and post-processed device signals show dominant loudness contributions concentrated in the lower frequency range (below 8 Bark), whereas both reference systems (dummy head and human-worn) exhibit a more evenly distributed loudness profile, particularly across mid-to-high frequencies. This discrepancy can be attributed to the limited frequency response of the PS3 Eye microphones, which do not capture higher frequencies as effectively as the reference binaural microphones. Consequently, the device may not fully replicate the time-varying perceptual attributes of the soundscape, especially

in scenarios with prominent high-frequency components.

In summary, the time-varying loudness analysis indicates that while the binaural synthesis algorithm smooths the loudness profile, it does not fully compensate for the hardware limitations of the proposed device. Further improvements could involve using higher-bandwidth microphones to capture a more accurate representation of dynamic acoustic environments.

4. CONCLUSIONS

This study evaluated a low-cost IoT device for binaural recording and soundscape monitoring in an indoor environment with vocal noise. The device demonstrated reasonable spatial cue approximation, showing potential as a cost-effective alternative for soundscape studies. However, differences in interaural cues and psychoacoustic metrics indicate areas for improvement.

The spatial accuracy analysis showed that after processing, the device achieved interaural time differences similar to reference systems, but interaural level differences remained inconsistent. This suggests limitations in reproducing level-based spatial cues. The reduced interaural cross-correlation after processing indicates a possible loss of spatial coherence, affecting binaural output quality.

After processing, the device's psychoacoustic metrics were closer to the dummy head, especially for sharpness and loudness. However, discrepancies were noted in roughness and fluctuation strength, likely due to the PS3 Eye microphone's limited frequency bandwidth, which may hinder accurate high-frequency representation.

The time-varying loudness analysis showed consistent temporal dynamics across the signals, though the device's processed signal displayed reduced variability, likely due to the synthesis algorithm. The device signals concentrated loudness in lower frequencies, while reference systems had a more even distribution, particularly at higher frequencies.

Despite some limitations, the device demonstrates the potential for affordable binaural recording, useful for soundscape monitoring. Future work should improve spatial accuracy, loudness estimation, and frequency capture, focusing on diverse environments and refining algorithms for better accuracy.

ASSESSING ACOUSTIC DYNAMICS IN ALPINE ECOSYSTEMS: THE NIVOLET PASS CASE STUDY

Giorgia Guagliumi[1*] **Fabio Angelini**[1] **Roberto Benocci**[1]
Giovanni Zambon[1]
[1] Dept. of Earth and Environmental Sciences, Università degli Studi di Milano-Bicocca, Milano

ABSTRACT

Alpine ecosystems, among the most vulnerable to climate change and anthropogenic disturbances, remain underexplored in their acoustic dimensions despite their crucial role in supporting biodiversity and ecological processes. These environments also attract significant human activity, becoming hotspots of interaction between natural and anthropogenic dynamics. This study investigates the acoustic impact of road traffic noise along the SP50 provincial road, from Lake Serrù to Savoia Refuge, in Gran Paradiso National Park (Italy).

Acoustic levels were monitored using class 1 sound level meters, with measurements conducted during periods of both road closure and peak tourist activity. The recorded data were analyzed to assess sound pressure variations in relation to traffic flow and other local sources. Simultaneously, vehicle density was quantified to establish correlations between traffic patterns and acoustic conditions. The findings demonstrate the significant influence of anthropogenic noise on the acoustic environment, highlighting the need for informed noise management strategies.

By situating these results within the European frameworks for noise management and biodiversity conservation, the study underscores the critical role of acoustic monitoring in guiding targeted conservation strategies. This research highlights the importance of integrating noise control measures with ecosystem management to mitigate human impacts and ensure the sustainable preservation of fragile alpine environments.

Keywords: *protected areas, traffic noise, alpine ecosystems, acoustic monitoring, biodiversity conservation.*

1. INTRODUCTION

In recent decades, noise pollution has been recognised as a major environmental stressor with documented effects on a wide range of terrestrial and aquatic ecosystems [1,2]. While anthropogenic noise is typically associated with urban and industrial environments, recent studies have highlighted its increasing impact on protected natural areas, including alpine ecosystems [3,4]. Seasonal road reopening and tourism-related activities in high altitude environments can generate sound pressure levels significantly above natural background levels, altering the soundscape and influencing wildlife behaviour [5].

Alpine ecosystems are characterised by abundant species richness and a remarkable degree of endemism [6]. However, they are particularly vulnerable to anthropogenic pressures, including land-use change [7] and climate change [8]. In the European Alps, climate change is particularly pronounced, leading to increased air temperatures, earlier snowmelt [9], shifts of alpine flora and fauna to higher elevations, and phenological changes in several taxa [10]. In this context, noise management policies have increasingly focused on the protection of ecologically sensitive areas. The European Directive 2002/49/EC on environmental noise management emphasises the need to preserve natural soundscapes [11]. This Directive introduces the concept of quiet areas both within and outside urban agglomerations, recognising their ecological importance. In Italy, Legislative Decree No. 194 of August 19, 2005, Article 4, Paragraph 10-bis [12], defines quiet areas as ecologically valuable locations where minimizing anthropogenic noise is

[*]***Corresponding author***: g.guagliumi@campus.unimib.it.

essential for biodiversity conservation. According to the Ministry of Ecological Transition (MiTE), these areas are situated far from significant anthropogenic sources, maintaining sound pressure levels well below those permitted in urban and residential zones. The natural soundscape of these regions varies significantly, ranging from deep quiet (as low as 25 dBA in remote snowfields during winter) to higher levels (exceeding 70 dBA) near waterfalls in summer. Given this variability, the impact of anthropogenic noise should be assessed on a case-by-case basis, using the site-specific natural ambient sound levels as reference points [13].

At the same time, mountain tourism is an important socio-economic sector, often developing in highly sensitive ecological contexts. Local communities and park authorities face the complex challenge of balancing the promotion of tourism with the preservation of acoustic quality in protected areas. This task is further complicated by the limited availability of empirical data on soundscapes in high-altitude environments subject to seasonal tourist influx.

The Gran Paradiso National Park stands out for its commitment to conservation and environmental protection, particularly in the Nivolet Pass, a high altitude area (~2,500 m) of exceptional ecological value. This plateau, characterised by wetlands and peat bogs, is an important habitat for numerous alpine species. Efforts to mitigate anthropogenic impacts in this area have led to a number of conservation initiatives and public awareness campaigns.

The aim of this study is to assess noise levels on the Nivolet Pass during periods of varying traffic intensity (July, August and September) compared to road closure days, which serve as a reference for natural background noise. The measured noise levels are also compared with existing legal limits and stricter limits proposed for designated “quiet areas”. The results provide critical insights into the effectiveness of current traffic management policies and offer guidance for future interventions aimed at preserving the natural acoustic environment while ensuring sustainable tourism practices within the protected area.

2. MATERIALS AND METHODS

2.1 Study Area

The study area is located in the heart of the Graian Alps, on the border between the Orco Valley (Piedmont) and the Valsavarenche (Aosta Valley), within the Gran Paradiso National Park (PNGP), Italy's first protected area established in 1922.

The site extends around Nivolet Pass, at an altitude of 2,612 m a.s.l., and represents a landscape of significant natural and ecological value. Access to the Pass is provided by Provincial Road SP50, which branches off from State Road SS460 of Ceresole Reale (TO) and extends for approximately 20 km, with an elevation gain of over 1,000 meters. The road runs alongside two artificial reservoirs, Lake Serrù and Lake Agnel, both used for hydroelectric power generation (Fig. 1).

During winter and spring, the road is closed to vehicular traffic due to safety concerns related to snow and ice. The seasonal closure is regulated by an ordinance issued by the Metropolitan City of Turin, prohibiting traffic from October 15 to May 15, subject to extensions due to adverse weather conditions or delays in snow removal operations.

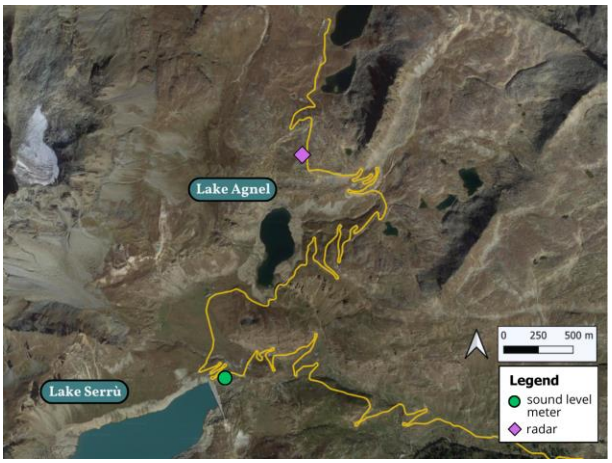

Figure 1. Geographic location of the measurement sites, showing the positions of the sound level and the radar used for monitoring.

2.1.1 Sound sources

The primary contributors to the soundscape in the study area can be categorized as anthropogenic and natural sources. The dominant anthropogenic noise source is road traffic on Provincial Road SP50, which present a peak of vehicular activity during summer, including private cars, motorcycles, heavy vehicles, and shuttle buses operating as seasonal public transport. Other human activities, such as hiking and cycling, also contribute to anthropogenic noise,

particularly in the vicinity of mountain refuges, including Chivasso and Savoia Refuges.

The main natural sources include:

- Geophonies: Wind, which is frequent due to the high altitude and local topography, plays a significant role in shaping the natural acoustic environment.
- Hydrological elements: Flowing water from streams, waterfalls, and alpine lakes contributes to the overall soundscape.
- Wildlife: The presence of species such as chamois, marmots, and various birds, including raptors and passerines, enriches the natural acoustic environment.

2.2 Acoustic Monitoring Plan and Monitoring sites

The acoustic monitoring plan follows national and international regulations on environmental noise management and the protection of ecologically sensitive areas. The study area is part of the Natura 2000 network, including Special Areas of Conservation (SACs) and Special Protection Areas (SPAs), established by Directive 92/43/EEC [14].

Classified as Class I in the Acoustic Classification Plan (PCA), the area is subject to strict noise limits to protect human health and wildlife: I. 50 dB(A) for the day period (06:00-22:00); II. 40 dB(A) for the night period (22:00-06:00). For transport infrastructure, PCA limits do not apply within designated noise buffer zones, as defined by Presidential Decree no. 142/2004 [15]. The SP50, under the jurisdiction of the Metropolitan City of Turin, is a class Cb road with a speed limit of 40 km/h. In the study area, the relevant noise limits are as follows: for Zone A, with a width of 100 meters, the limits are 70 dB during the day and 60 dB at night; for Zone B, with a width of 150 meters, the limits are 65 dB during the day and 55 dB at night.

The monitoring sites were selected to ensure representativeness in terms of major noise sources and proximity to sensitive habitats. A Class 1 sound level meter (Fig. 2a) was placed near the parking area of Lake Serrù, adjacent to the SP50 but outside the parking lot to avoid interference from vehicle movements. The meter was placed next to a small shelter to minimise wind effects and maintain data quality. A traffic radar (Fig. 2b), provided and managed by the PNGP, was installed at Nivolet Pass. This location was chosen because vehicle passages could not be effectively distinguished at the Lake Serrù parking area, where movements within the lot would have compromised data accuracy.

Figure 2. Positioning of the sound level meter (a) and the traffic radar (b).

2.3 Data analysis

The analysis of sound emissions was conducted through a four-month acoustic monitoring campaign, divided into different time blocks based on traffic regulations and seasonal characteristics of the study area. The monitoring periods were defined as follows: during the road open period (July–September), data were analyzed on a monthly basis to capture variations in tourist flows, which significantly influence the acoustic environment. Conversely, during the closing period (October) the collected data served as a reference to determine background noise levels. In this case measurements were taken over three representative days (28–30 October), chosen one week after the road closure to allow the soundscape to stabilise under typical environmental conditions. These days were characterised by favourable meteorological conditions and stable day and night noise levels.

To ensure the reliability and robustness of the results, the dataset underwent a filtering process to exclude periods with hourly precipitation exceeding 0.2 mm, in accordance with the guidelines of D.M. 16/03/98 [16] and UNI EN ISO 1996-1:2017 [17].

For each monitored month, the hourly equivalent noise levels (Leq) were analysed to assess the acoustic impact of road opening. Weekly daytime (06:00–22:00) and nighttime (22:00–06:00) LAeq values were calculated

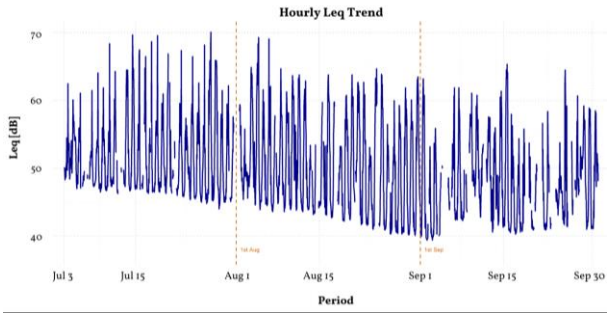
and visualised using histograms to illustrate their temporal variations. These values were compared with the legal limits for secondary extra-urban roads [15] and estimated thresholds for quiet areas [12].

To further investigate noise trends, the average hourly noise levels were calculated for each monitored month, using the acquired hourly data. The results were graphically represented through three different curves, each corresponding to a different month, illustrating the hourly noise trends throughout the day. Each graph included four data series, representing different day types: weekdays, Saturdays, holidays, and a reference trend corresponding to the background noise levels recorded during road closure.

The effect of road opening on sound levels was assessed through a comparative analysis between the noise levels recorded during the period when the road was open and the background noise levels measured when the road was closed. Data were classified by time period (day/night) and day type: weekdays, Saturdays, holidays and special event days when the road was closed for outdoor activities such as cycling, fitwalking and Nordic walking. For each condition, the mean equivalent noise levels were calculated and compared with the background noise to obtain the Leq differences. The results were aggregated on a weekly basis, with averages calculated for each day category, maintaining the distinction between day and night

3. RESULTS

The results provide an overview of the hourly equivalent levels (Leq) recorded during the monitoring period corresponding to the opening of the road (Fig. 3). There are clear differences between months and times of day, with pronounced peaks during the day. The highest Leq values were observed in July, due to the increased presence of tourists, which led to an increase in vehicle activity and consequently high noise levels. In the following months, August and September, the hourly Leq values showed a progressive decrease, coinciding with a reduction in the traffic flow rate. This decrease was accompanied by a more uniform Leq distribution and overall lower mean values, consistent with the decrease in tourist presence and related activities.



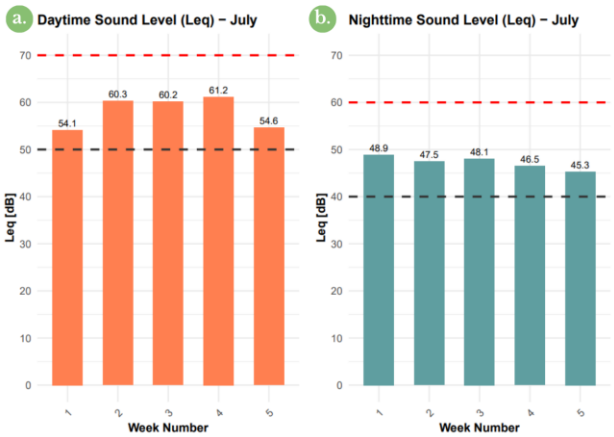


Figure 3. Trend of hourly equivalent levels (Leq) during the opening phase of the SP50, with the transition between consecutive months highlighted in orange.

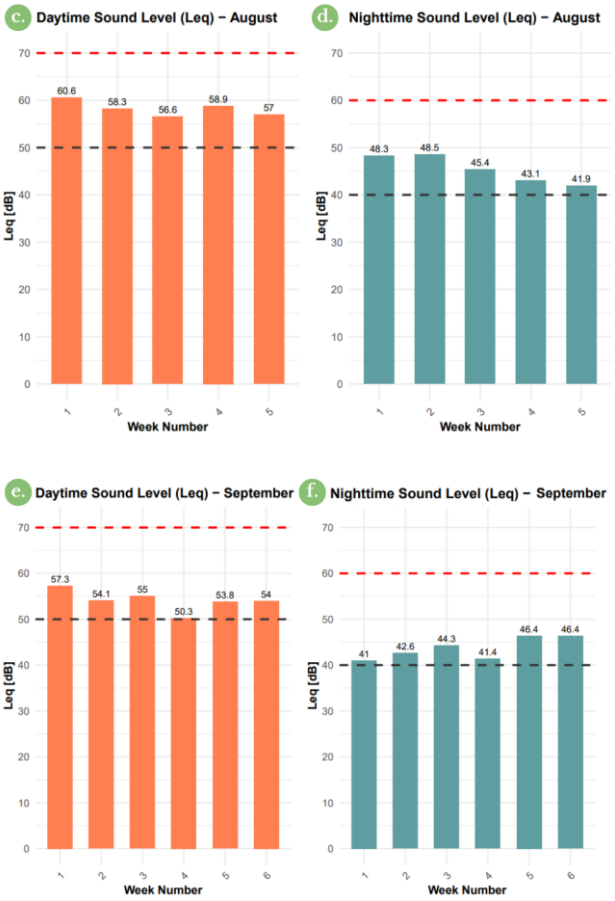
The analysis of the phonometric data collected during the road opening period focused on equivalent noise levels, distinguishing between daytime (LAeq) and nighttime (LAeq) values. The results (Fig. 4) show weekly average LAeq values [dB] for both periods, plotted against the consecutive week numbers within each month. Daytime equivalent noise levels were consistently higher than nighttime values by more than 10 dB, a difference attributable to anthropogenic activities and increased vehicle traffic flow rate. Each histogram contains two dashed reference lines: the red dashed line represents the legal noise exposure limits for secondary extra-urban roads (category Cb) established by [15]; the black dashed line indicates the limits proposed for quiet areas by [12].



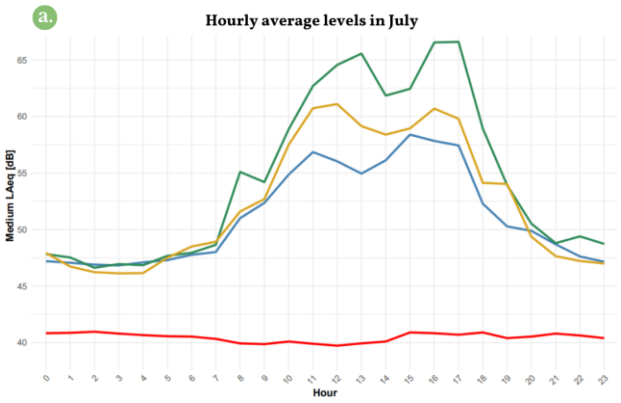


Figure 4. Weekly trend of daytime LAeq levels (in orange) and nighttime LAeq levels (in blue) [dB] for the months of July (a-b), August (c-d), and September (e-f). The red and black dashed lines indicate the regulatory limits and the hypothesized limits for quiet areas, respectively.

A temporal analysis revealed that July recorded the highest LAeq values, reaching 61.2 dB during the daytime and 51.7 dB at night (Fig. 4a-b), in line with the seasonal increase in tourist presence, which generates higher traffic intensity. In August and September, a progressive decrease in LAeq levels was observed, with values reaching 56.6 dB during the daytime and 41.9 dB at night in August, and 50.3 dB during the daytime and 41.0 dB at night in September (Fig. 4c-f), reflecting the reduction in visitor numbers and associated activities. Regarding regulatory limits, LAeq values remained within the thresholds defined for secondary extra-urban roads (70 dB during the daytime and 60 dB at night). However, systematic exceedances of the estimated limits for quiet areas were observed, with values surpassing the proposed thresholds of 50 dB during the daytime and 40 dB at night.

Hourly average levels were calculated for each monitoring month (July, August, September) based on the data collected. In July (Fig. 5a), noise peaks on weekdays were mainly recorded in the late morning (around 11:00, 56.9 dB) and afternoon (15:00, 58.4 dB). On Saturdays, higher noise levels were observed compared to weekdays, with several peaks distributed between 08:00 (55.1 dB) and 17:00 (66.6 dB), indicating more intense and variable traffic. On holidays, noise levels were generally lower, but significant peaks were recorded around 11:00 (60.7 dB) and 16:00 (60.7 dB), followed by a sharp decline in the following hours. In August (Fig. 5b), weekday noise patterns were similar to those in July, but with slightly earlier peaks, particularly between 11:00 (59.3 dB) and 12:00 (60.2 dB), and a gradual decline after 14:00. On Saturdays, peaks were recorded mainly at 11:00 (62.5 dB), 12:00 (62.5 dB) and 15:00 (62.6 dB), with greater variability in the evening hours compared to July, with a notable increase from 22:00 onwards (49.6 dB). On holidays, noise levels increased significantly from 08:00 (49.9 dB), with the highest peak at 14:00 (62.8 dB). In September (Fig. 5c), weekday peaks were concentrated between 12:00 (54.1 dB) and 15:00 (52.5 dB), followed by a slight decrease after 16:00. On Saturdays peaks were recorded at 11:00 (57.8 dB), 13:00 (59.1 dB) and midnight (42.7 dB), suggesting the influence of evening events or specific social activities. On holidays the noise patterns were similar to those in July, with peaks between 11:00 (60 dB) and 15:00 (58.5 dB), followed by a relative stabilisation in the evening hours.

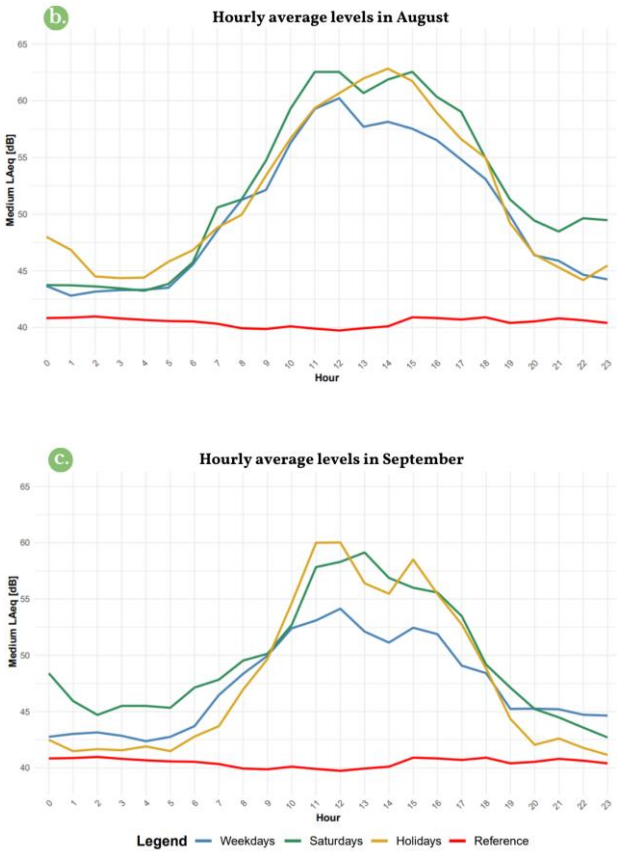

Figure 5. Hourly average Leq trends across different months, categorized by day type, as a function of the time of day: (a) July, (b) August, (c) September.

Finally, the difference (Δ) between the monthly mean levels for each category and the ambient background noise was calculated for both day and night periods to assess the increase in sound levels due to the road opening (Fig. 6). July showed the highest increase in sound pressure for both the daytime (21 dB) and nighttime periods (7.4 dB). On weekdays, daytime levels were highest in July (15.7 dB) and August (16.1 dB), while nighttime levels were highest in July (6.6 dB). Significant increases in daytime noise levels were observed on holidays and Saturdays, with average Δ values of 21 dB and 19.1 dB for Saturdays in July and August, and 18.6 dB and 18.1 dB for holidays in the same months. In sharp contrast, special event days showed a significant reduction in noise levels, with a decrease of 9.4 dB during the day and 3.8 dB at night. These events, marked by road closures to motorised traffic, resulted in a considerable drop in noise emissions.

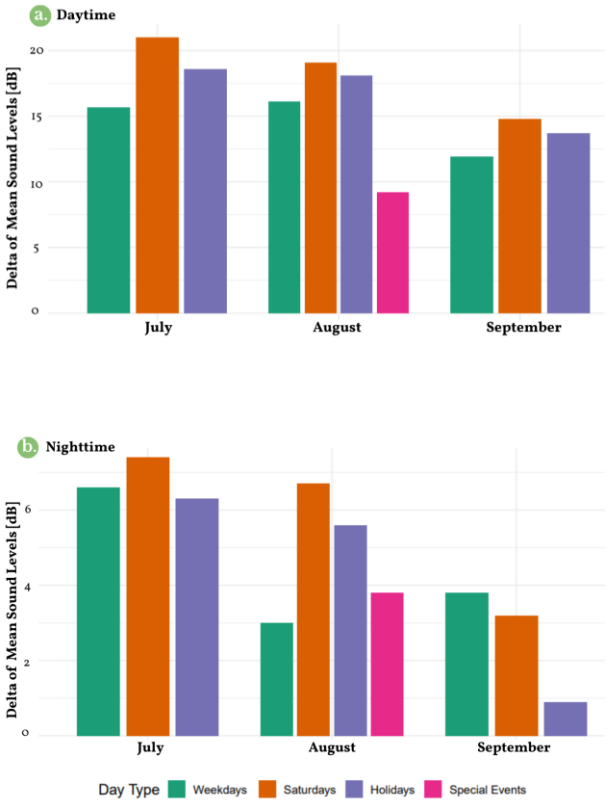

Figure 6. Difference in average daytime (a) and nighttime (b) noise levels (delta), categorized by day type.

4. DISCUSSION

This study provides a preliminary assessment of the acoustic environment at Nivolet Pass during the road opening period, revealing significant temporal variations in noise levels influenced by the seasonal dynamics of tourism and vehicular activity, and by the road closure. Such patterns are characteristic of protected areas with seasonal access [18].

The highest equivalent noise levels (Leq) were recorded in July, coinciding with the peak tourist influx and increase in traffic. This is in line with previous studies showing a direct correlation between road traffic density and environmental noise [19, 20]. The subsequent decline in Leq values in August and September reflects the progressive decrease in visitor numbers, further

highlighting the role of anthropogenic pressure as a primary driver of changes in the soundscape.

Daytime noise levels exceeded nighttime levels by more than 10 dB, a discrepancy attributed to motorised traffic and human activity during the diurnal hours, consistent with observations in other natural and semi-natural areas [21]. While the recorded noise levels were within the legal limits for secondary extra-urban roads (Presidential Decree no. 142/2004), they often exceeded the proposed thresholds for quiet areas (Legislative Decree no. 194/2005). This suggests that, despite legal compliance, the acoustic environment may still be compromised in terms of ecological and recreational expectations.

Temporal analysis of hourly Leq patterns further clarifies the impact of human activity on noise dynamics. In July, peak levels were observed in the late morning and afternoon on weekdays, with values of 56.9 dB at 11:00, 58.4 dB at 15:00, and 57.4 dB at 17:00. On Saturdays, more intense and prolonged noise events were recorded at 11:00 (62.7 dB), 12:00 (64.6 dB), and 16:00 (66.6 dB), due to increased recreational activity. Noise levels on holidays were lower overall, but still showed pronounced peaks around 13:00 (59.2 dB) and at 16:00 (60.7 dB), reinforcing the hypothesis that weekend and holiday tourism has a significant impact on the acoustic environment [13, 22]. A similar trend was observed in August and September, although with reduced intensity, reflecting the seasonal decrease in visitors.

Analysis of the monthly mean sound pressure levels and their deviation from the background noise (Δ) further highlights the influence of road accessibility on the dynamics of the soundscape. July showed the most pronounced Δ values, with marked differences between day and night, especially during Saturdays (21 dB during the day and 7.4 dB at night) and holidays (18.6 dB during the day and 6.3 dB at night). These findings are consistent with previous research showing that increased human presence in protected areas increases ambient noise, potentially disrupting wildlife communication and visitor experience [18]. In particular, during the special event days, when motorised traffic was restricted, noise levels decreased significantly and approached background conditions. This highlights the effectiveness of traffic management strategies in reducing noise pollution and maintaining soundscape quality in protected areas.

5. CONCLUSIONS

The results of this study show how seasonal tourism and vehicular traffic shape the acoustic landscape of Nivolet Pass, with significant differences in noise levels between months and times of day. While the levels recorded are in line with the current legal limits for secondary roads outside urban areas, they often exceed the limits recommendetions for quiet areas. This discrepancy highlights the inadequacy of the current legal limits to take into account the specific environmental context of SP50, which crosses sensitive habitats and is home to species of high conservation value.

A particularly important aspect that emerged from the analysis concerns the special days of experimental mobility management, when the road was closed to motorised traffic and reserved for outdoor activities (such as cycling and Nordic walking). On these days, noise levels were significantly reduced, with a Δ of 9.2 dB during the day and 3.8 dB at night, demonstrating the effectiveness of these initiatives in reducing acoustic impact and improving environmental quality.

The next phase of the project will involve detailed analysis of the data obtained through the expansion of the monitoring network, which has included the installation of additional acoustic detection stations and the introduction of low-cost recording devices for soundscape analysis. This analysis phase will provide a deeper understanding of the ecological impact of anthropogenic noise and help design more targeted noise management strategies for sensitive areas. The results of this analysis will be fundamental in optimising conservation policies, promoting a balance between environmental protection and sustainable access to protected areas.

ABSTRACT

Urban noise exposure has shown significant negative associations with health effects, largely based on outdoor assessments. As most people spend the majority of time indoors, especially at night, assessments should include the attenuation of outdoor noise exposure to estimate indoor noise exposure for developing epidemiological evidence on health-related noise effects. In this study, a prediction modelling framework is defined for estimating the outdoor-to-indoor level differences for three time periods (day, evening, and night) via statistical learning models, employing synchronised and unsupervised outdoor and indoor noise exposure measurements from 49 locations in Greater London, UK. The study evaluates which background noise criteria expressed via percentile indicators (L_{A90}, L_{A95}, and L_{A99}) under two conditions are most effective. In the analysis, stronger correlations between the equivalent outdoor-to-indoor level differences and outdoor levels were obtained after applying the more stringent condition. Particularly, stronger night-time relationships (r = 0.66–0.76) were obtained compared to daytime (r = 0.55–0.63) and evening (r = 0.43–0.55) relationships. Regarding the modelling validation, the lowest RMSE was observed in the night-time models (RMSE = 2.0–2.8dB(A)), followed by the day-time (RMSE = 2.9–3.0dB(A)) and evening (RMSE = 2.5–4.0dB(A)) models. The study's findings support the value of random forest models in estimating outdoor-to-indoor level differences, executing errors mostly below the just perceptible level difference (3dB(A)).

1. INTRODUCTION

The impact of noise exposure on human health has shown significant negative associations with a range of non-auditory health effects effects, including annoyance, sleep disturbance, reduced quality of life, and cardio-metabolic outcomes [1, 2]. The consequences of chronic noise exposure in childhood may manifest in adverse outcomes in later life [2]. Furthermore, the impact of noise exposure,

associated with the indirect accumulation of measurement of noise exposure in human organisms [3], underscores the importance of expressing noise exposure via objective noise indicators for exploring exposure-response relationships [2].

In urban noise exposure studies, outdoor noise exposure levels are usually employed as a basis for analyses in contrast to the utilisation of indoor levels [2]. This suggests the potential for a systematic risk of bias in the identification of exposure-response relationships. This is particularly salient in relation to vulnerable groups whose activities are predominantly confined to indoor environments. Hence, statistical prediction models have been developed with the purpose of estimating outdoor-to-indoor level differences based on outdoor levels as well as parameters related to outdoor environment, indoor environment, and building façade characteristics. This has been done via both supervised [4] and unsupervised [5] measurement approaches. These models allow for a more precise estimation of attenuation levels in comparison to a single-valued attenuation factor (e.g., [4–7]).

Focusing on the incorporation of unsupervised noise measurements in the estimation of outdoor-to-indoor level differences, a recent methodology has been proposed [5]. In this methodology, the L_{A99} percentile indicator has been applied for the estimation of background noise levels, while two defined background noise conditions (6dB(A) and 10dB(A)) verify the incorporation of the proper indoor (and their respective outdoor) noise levels.

The objective of this study was to establish attenuation levels for use in the adjustment of outdoor noise levels to facilitate the prediction of indoor noise exposure levels. First, the impact of indoor background noise levels on the relationship between the outdoor-to-indoor level differences and outdoor levels was investigated via experimental data from 49 dwellings in Greater London, UK. Second, statistical learning models (random forest), were developed for predicting the outdoor-to-indoor attenuation levels with respect to outdoor levels and predictors related to outdoor and indoor environment as well as façde characteristics.

2. METHODOLOGY

In this section, the principal methodologies are presented, corresponding to the dataset processing and the prediction modelling. For a comprehensive overview of the study design, including the detailed procedure of the noise exposure assessment, the reader is directed to [8].

2.1 Data Processing

Following the capturing of outdoor and indoor noise exposure levels [8], the A-weighted equivalent noise indicator was used for the assessment of outdoor ($L_{\text{Aeq,Out}}$), indoor ($L_{\text{Aeq,In}}$), and outdoor-to-indoor noise exposure levels ($L_{\text{Aeq,Out-In}}$) for day-time (07:00-19:00), evening (19:00-23:00), and night-time (23:00−07:00) period based on an integration time of 1-minute and a time-period of 1-hour.

Since noise exposure measurements were conducted via an unsupervised approach, a data processing procedure was employed for capturing the representative outdoor-to-indoor levels. Particularly, noise exposure (i.e. full bandwidth) measurements, where indoor levels exceeded outdoor levels, were excluded. Then, the spectral characteristics of both outdoor and indoor exposure levels were evaluated in 1/3-octave bands (50Hz–5kHz). Consequently, measurements for which the indoor spectral levels were determined to exceed those of the outdoors were excluded. In order to reduce the impact of indoor background noise on the identification of the appropriate outdoor-to-indoor level differences, some percentile noise indicators were selected to express the background noise levels. These correspond to $L_{\text{A99,In}}$, $L_{\text{A95,In}}$, and $L_{\text{A90,In}}$. Finally, two background noise conditions (6dB(A) and 10dB(A)) were defined associated to the minimum level difference between the equivalent indoor levels and the background noise levels (i.e., $L_{\text{Aeq,In}} - L_{\text{AN,In}}$). Differences lower than the two conditional levels indicate a significant effect of the indoor background noise, and therefore they were excluded.

2.2 Prediction Modeling

Initially, the relationship between outdoor levels and outdoor-to-indoor level differences per time-period (day, evening, and night), background noise indicator (L_{A90}, L_{A95}, and L_{A99}) and condition (6dB(A) and 10dB(A)) was verified via a simple regression model, using the R^2 metric and Pearson correlation coefficient (r). For explaining the percentage of unexplained variance in the estimation of the outdoor-to-indoor level difference, random forest (RF) models were developed. Numerical predictors associated to the outdoor noise levels ($L_{\text{Aeq,Out}}$), the room volume (RV), the window size (WS) and the window numbers (WN), as well as to the categorical variables associated to the window type (WT), the room type (RT), the building type (BT), and the site type (ST) were applied. In all the models, the datasets were split into 70% for training and 30% for testing. The random forest models were ap-

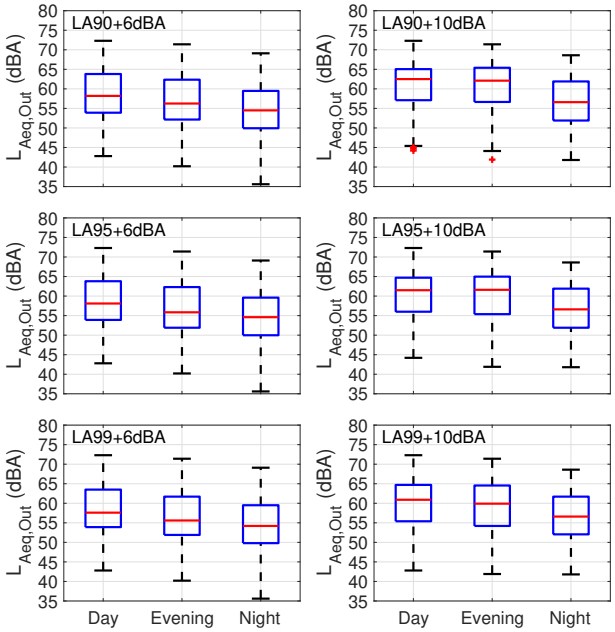

Figure 1. Outdoor levels per time period, background noise indicator and condition.

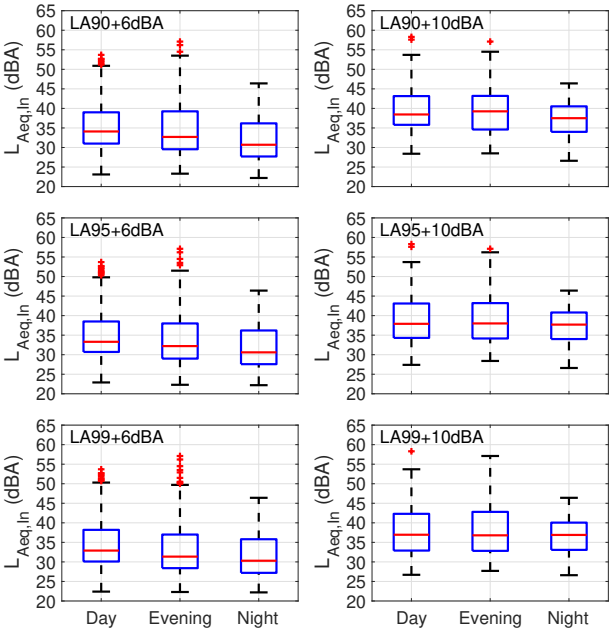

Figure 2. Indoor levels per time period, background noise indicator and condition.

plied via the *ranger* package [9] in RStudio software. All the models were tuned via three (hyper)parameters: the number of trees (n_{tr}), the number of variables (n_{v}) used at each split (m_{tr}), and the complexity of trees (c_{t}). The number of trees was chosen to range from 70 to 1200 trees with a step of 10 trees. The number of split-variables used to tune the models ranged from 2 to 8 variables with a step of 1 variable. Regarding the complexity of tree parameter (tree nodes), the number of nodes ranged from 1 node to 15 nodes with a step of 1 node. Moreover, the (normalized) importance of each predictor per model was evaluated. Finally, the error between predicted and observed $L_{\text{Aeq,Out-In}}$ levels was verified via the root-mean-squared error (RMSE) metric [10].

3. RESULTS

3.1 Assessment of Noise Exposure Levels

First, the outdoor, indoor, and outdoor-to-indoor noise exposure levels were assessed per time period, background noise indicator and condition, and the results are presented in Fig. 1, Fig. 2 and Fig. 3, respectively.

As seen from Fig. 1 and Fig. 2, the median outdoor and indoor exposure levels based on the 6dB(A) background noise condition are lower than the corresponding

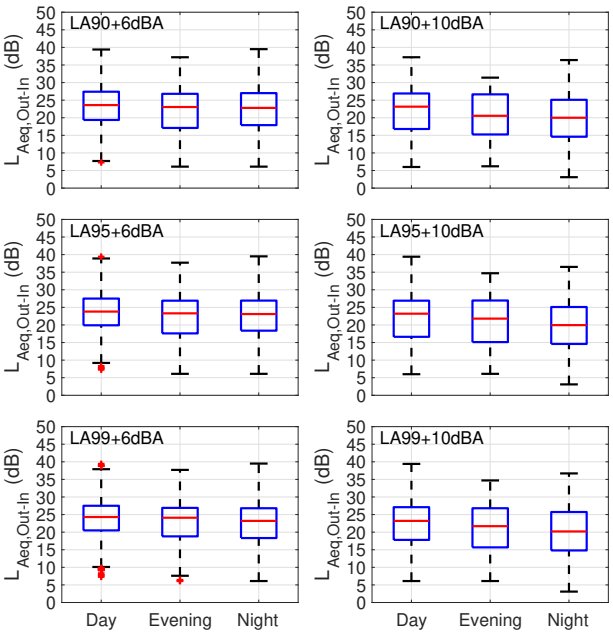

Figure 3. Outdoor-to-indoor levels per time period, background noise indicator and condition.

levels based on the 10dB(A) background noise condition for all time periods and background noise indicators. Fur-

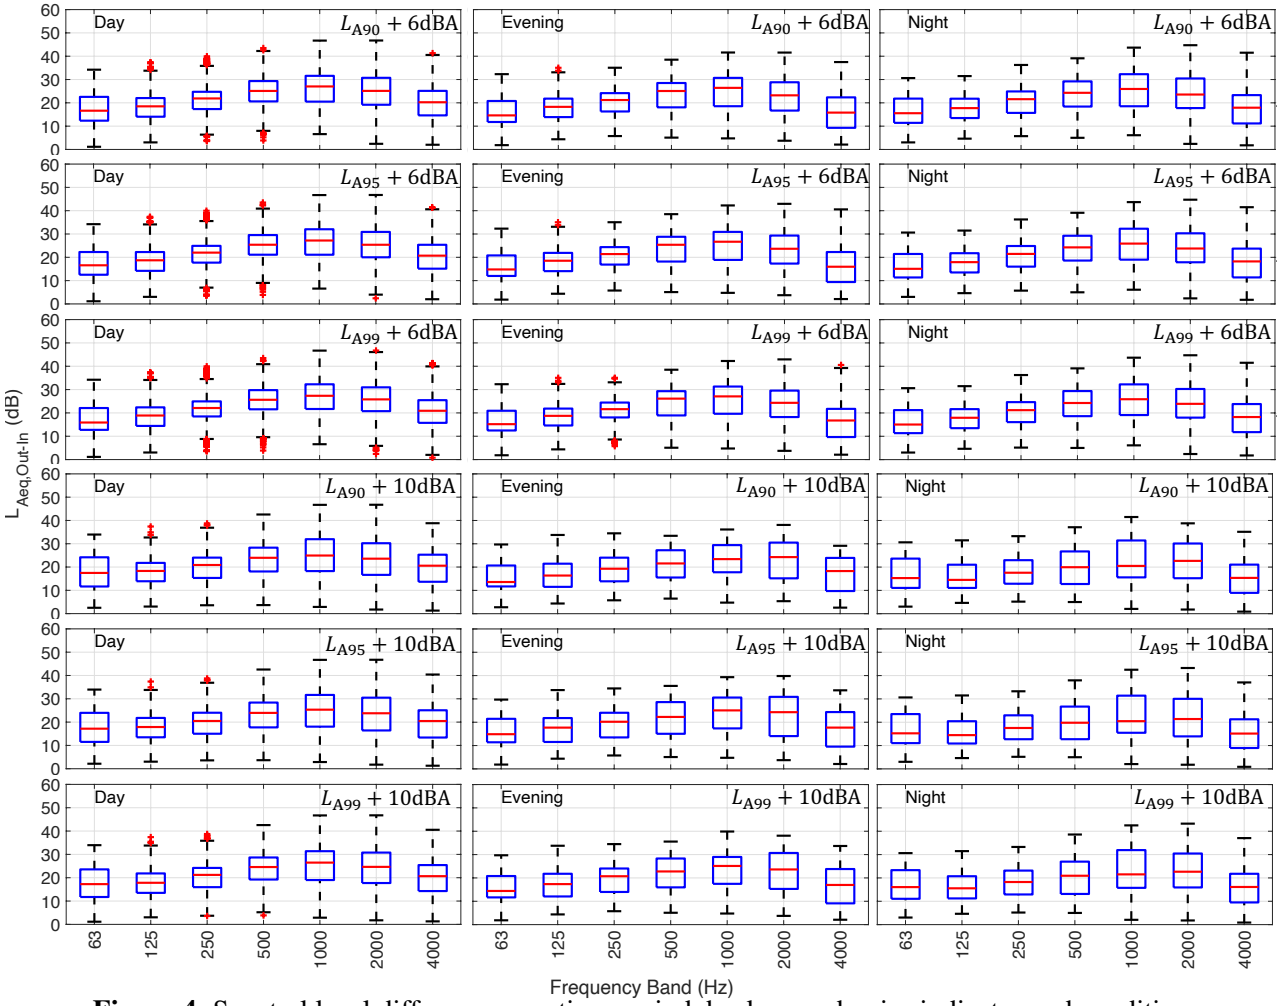

Figure 4. Spectral level differences per time period, background noise indicator and condition.

thermore, the median day-time outdoor and indoor levels are generally higher than evening and night-time levels across the background noise conditions and indicators.

Opposite to Fig. 1 and Fig. 2, the median outdoor-to-indoor levels in Fig. 3 presented a downward trend by increasing the background noise condition across the background noise indicators and exposure periods. The decline in outdoor-to-indoor levels in the transition to stringent background noise conditions is associated with the higher transmission of energy affected less by the indoor background noise. Consequently, the stringent background noise condition is responsible for the presence of broader IQR (interquartile range) across the time periods and background noise indicators.

Focusing on the median average spectral outdoor-to-indoor levels per 1/1-octave bands in Fig. 4, it can be seen that levels based on the 10dB(A) condition present less outliers compared to the levels based on the 6dB(A) condition. Furthermore, the stringent background condition presents broader IQR at most frequency bands across the time periods and background noise indicators.

3.2 Relationship between $L_{Aeq,Out}$ and $L_{Aeq,Out-In}$

For exploring the relationship between outdoor and outdoor-to-indoor levels, simple regression models per background noise indicator and condition were executed. In Fig. 5, the scatter plots between the $L_{Aeq,Out}$ and $L_{Aeq,Out-In}$ are presented, while in Tab. 1, the R^2 and Pearson correlation coefficient (r) are summarized.

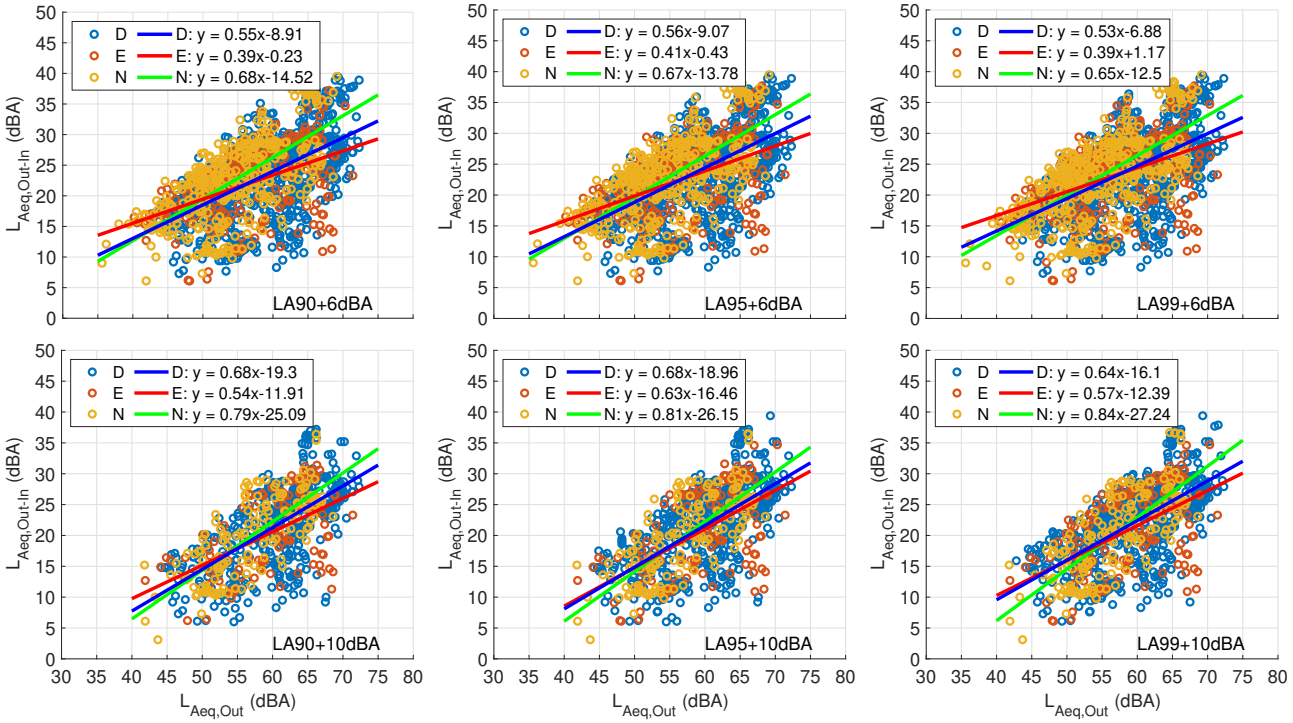

Figure 5. Relationship between outdoor and outdoor-to-indoor levels per time period and setting.

Table 1. Diagnostics per explored relationship.

Model	BGN: 6dB(A)		BGN: 10dB(A)	
	R^2	r	R^2	r
$L_{Aeq,LA90,D}$	0.34	0.58	0.40	0.63
$L_{Aeq,LA95,D}$	0.34	0.58	0.39	0.62
$L_{Aeq,LA99,D}$	0.31	0.55	0.39	0.62
$L_{Aeq,LA90,E}$	0.20	0.44	0.27	0.52
$L_{Aeq,LA95,E}$	0.20	0.45	0.30	0.55
$L_{Aeq,LA99,E}$	0.19	0.43	0.27	0.52
$L_{Aeq,LA90,N}$	0.44	0.66	0.57	0.76
$L_{Aeq,LA95,N}$	0.44	0.66	0.57	0.75
$L_{Aeq,LA99,N}$	0.44	0.66	0.56	0.75

Green cells: Moderate, Blue cells: Strong

As seen from Fig. 5 and focusing on Tab. 1, an increase in background noise from 6dB(A) to 10dB(A) resulted in stronger correlations, indicating the inclusion of less affected indoor background noise levels. In particular, the correlation coefficient exhibited an increase from moderate to strong for day-time exposure. For evening exposure, the correlation coefficient increased, yet it maintained a moderate correlation degree. Regarding night-time exposure, the correlation coefficient exhibited an increase, and therefore it continued to demonstrate a strong degree. As the indoor background levels exhibited less significant variations at night-time stronger correlations were obtained in comparison to the day-time and evening time periods. By comparing r and R^2 with respect to the type of background noise indicator, it can be seen that there were no significant differences among them across the time periods and background noise conditions. Hence, it can be suggested that for a single response relationship, the background noise indicator is less important than the background condition.

3.3 Prediction Modelling

Following the tuned RF models, the importance of each predictor in the estimated response ($L_{\text{Aeq,Out-In}}$) was identified via the normalized importance and the results are presented in Fig. 6.

As seen from Fig. 6, the $L_{\text{Aeq,Out}}$ emerges as the most important predictor across all models, explaining the majority of the variance in the estimation of the outdoor-to-indoor levels. For the 6dB(A)-based models, the RV, WS, and BT predictors mostly accounted for more than 40% of the variance across noise conditions and time periods. In contrast, the ST and WT predictors for the day-time and

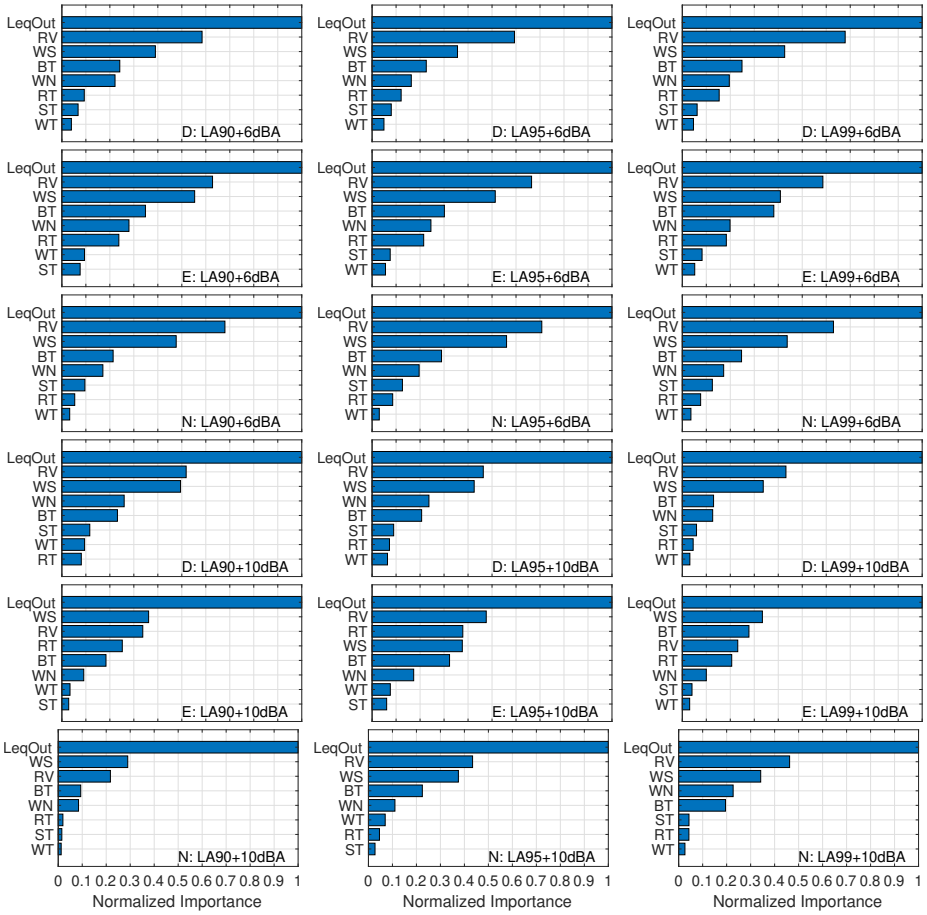

Figure 6. Importance of predictors in models per time period, background noise indicator, and condition.

evening models as well as the RT and WT predictors for the night-time models explained less than the 10% of variance. In the 10dB(A) models, the RV and WS predictors accounted for most of 40% of variance for the day-time models. For evening models, the WS and RV predictors in the L_{A90} model, the WS, RV, BT, and RT predictors in the L_{A95} model, and the WS in the L_{A99} model accounted for more than 30% of variance. For night-time models, the RV and WS predictors primarily accounted for a greater of 30% variance across the background noise indicators. Finally, in all the time period models, the ST and WT predictors explained less than the 10% of variance.

For validating the performance of the developed models, the test datasets were employed and the observed outdoor-to-indoor levels were compared with the estimated levels. The performance of models based on the training and test datasets, is presented in Tab. 2.

Table 2. Modelling performance.

Model	BGN: 6dB(A)				BGN: 10dB(A)			
	Train Dataset		Test Dataset		Train Dataset		Test Dataset	
	RMSE	R^2	RMSE	R^2	RMSE	R^2	RMSE	R^2
$L_{\text{Aeq,LA90,D}}$	3.09	0.76	2.91	0.77	3.12	0.77	2.98	0.79
$L_{\text{Aeq,LA95,D}}$	2.77	0.80	2.97	0.77	3.25	0.77	2.64	0.83
$L_{\text{Aeq,LA99,D}}$	2.75	0.79	2.91	0.78	2.85	0.80	2.99	0.80
$L_{\text{Aeq,LA90,E}}$	3.41	0.71	2.53	0.83	4.08	0.59	4.00	0.61
$L_{\text{Aeq,LA95,E}}$	3.12	0.76	2.74	0.81	3.89	0.77	3.65	0.77
$L_{\text{Aeq,LA99,E}}$	3.36	0.71	2.94	0.76	3.90	0.66	3.42	0.76
$L_{\text{Aeq,LA90,N}}$	2.12	0.90	2.38	0.89	2.99	0.79	2.00	0.90
$L_{\text{Aeq,LA95,N}}$	1.93	0.92	2.28	0.89	2.87	0.82	2.22	0.88
$L_{\text{Aeq,LA99,N}}$	2.26	0.88	2.01	0.92	2.28	0.88	2.83	0.84

Green cells: RMSE≤3dB(A), Blue cells: RMSE>3dB(A)

As illustrated in Tab. 2 and with particular attention to the test dataset, night-time models exhibited the lowest RMSE levels, followed by day-time models across the background noise indicators and conditions. In the

case of the evening models, a greater degree of variation was exhibited, with RMSE levels exceeding 3dB(A) for the more stringent background condition across all background noise indicators. In consideration of the less stringent background condition, RMSE levels lower than 3dB(A) were obtained in the evening models and across the background noise indicators.

3.4 Single-Valued Attenuation Factors

Focusing on the single-valued attenuation factors, the estimated factors were compared to the observed ones and the results are presented in Fig. 7.

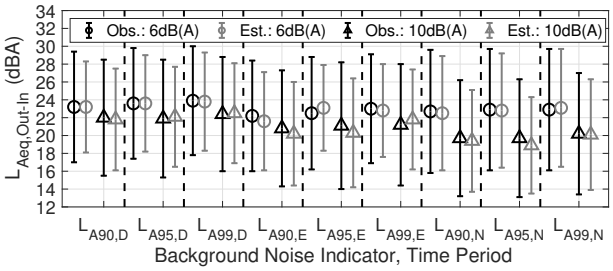

Figure 7. Single-valued attenuation factors per time period, background noise indicator and condition.

As Fig. 7 illustrates, the outdoor-to-indoor attenuation factors for the 6dB-based models are higher than those for 10dB-based models. These differences are more pronounced in the case of night-time noise exposure than of day-time and evening exposure, presenting mean differences up to 4dB(A). Regarding the background noise indicator, mean differences up to 2dB(A) were detected for evening and day-time periods.

4. DISCUSSION

4.1 Noise Assessment

The incorporation of methodologies for the identification of appropriate noise exposure levels, associated with the transmission of noise exposure from outdoors to indoors, could be characterised as important, especially when noise exposure measurements are conducted via an unsupervised approach. The assessment of the relationship between the outdoor and outdoor-to-indoor levels revealed a stronger correlation by increasing the background noise condition from 6dB(A) to 10dB(A) across the time periods and background noise indicators. Consequently, a decrease in the median/mean outdoor-to-indoor levels and an increase in their interquartile ranges across the time periods and background noise indicators was obtained. Consequently, this is associated with the further minimization of noise levels affected by background levels, and therefore with the inclusion of noise levels related to higher transmission of energy. Our results demonstrate analogous trends to those previously depicted in [5]. Focusing on the type of background noise indicator for mitigating indoor background noise levels, it was observed that there were no significant differences in the outdoor-to-indoor levels between the background noise indicators used.

Various outdoor-to-indoor attenuation factors have been reported for closed windows, ranging from 25dB(A) to 32dB(A) [4,6,7,11]. These factors are contingent upon the characteristics of the measurement locations and the measurement methodology employed. In our study, analogous outcomes were obtained, particularly in the context of the 6dB(A) background noise condition, wherein the attenuation factor approximates 23dB(A) across the majority of the background noise indicators and time-periods. However, in the case of the 10dB(A) background noise condition, the outdoor-to-indoor level differences exhibited more pronounced fluctuations in terms of the time period, as opposed to the background noise indicators. Specifically, outdoor-to-indoor level differences of approximately 22dB(A) for day-time, 21dB(A) for evening, and 20dB(A) for night-time were obtained. This indicates the significant impact of the variations in indoor background noise levels and characteristics across the different time periods. Day-time outdoor and indoor levels reach higher levels in relation to the evening and night-time ones from various indoor and outdoor sound sources. Night-time exposure presents less level variations in both environments as well as lower indoor background noise levels, indicating a more representative period for exploring the noise propagation from outdoors to indoors.

4.2 Prediction Modeling

Regarding the performance of the prediction models, almost similar diagnostics were obtained across the different models. In order to gain a deeper understanding of the performance of the prediction models, the RMSE is interpreted by the ability of healthy ear to detect changes in broadband noise [12]. In this context, noise level differences of 3dB(A) and 5dB(A) are associated with just and clearly perceptible differences, respectively [12]. The majority of the day-time and night-time models are subjected to RMSEs that are up to the just perceptible level dif-

ference (3dB(A)), in contrast to the evening-time models where the RMSEs are up to the clearly perceptible level difference (5dB(A)). Regarding the background noise indicators, their performance presented similar diagnostic characteristics with respect to the time period. It is important to note that the number of predictors employed in this study was limited. Incorporating a greater number of measurements and predictors might lead to a more comprehensive dataset based on detailed built environment characteristics.

5. CONCLUSIONS

In this study, a methodology to derive outdoor-to-indoor noise attenuation levels for day, evening, and nigh time exposure was developed, utilising unsupervised outdoor and indoor noise exposure measurements with information related to building characteristics in random forest (regression) modelling. This method minimizes the presence of dominant indoor noise sources and background noise levels, considering the equivalent spectral characteristics of noise measurements. Across the various used background noise indicators, similar results were obtained. Finally, the attenuation factors obtained in the present study have been generated from UK data, reflecting localized noise sources and the characteristics of the built environment.

ABSTRACT

Silencio is a community-driven platform tackling the escalating issue of noise pollution across the world. Through its free application, Silencio aims to become the world's largest citizen science initiative dedicated to combating noise pollution. Users contribute hyper-local noise data and are incentivized with 'noise coins', redeemable for goods, services, and environmental initiatives within the platform. As of April 2025, Silencio has collected 35 billion data points from over 1 million sensors across 180 countries. A key feature allows users to log noise complaints, transforming crowd-sourced data into actionable insights for governments and urban planners. This paper explores the noise complaints dataset, analysing patterns in timing, location, and the types of noise most likely to prompt complaints. We believe this represents the world's largest noise complaint database.

Keywords: Noise**,** complaints, citizen science.

1. INTRODUCTION

Silencio is a community-driven platform tackling urban noise pollution through a free smartphone application (app) that aspires to be the largest citizen science project in the world [1]. By leveraging blockchain technology, it enables users worldwide to contribute real-time noise data by transforming their smartphones into anonymous noise monitoring devices that record decibel levels, creating a detailed global noise map. Users are incentivized through 'noise coins' which can be redeemed for goods, services, and environmental initiatives within the platform, allowing them to generate passive income while improving urban living conditions. By utilizing blockchain technology, the system enables users to maintain full control over their data and receive equitable compensation for their contributions. The economic model incorporates a revenue-sharing mechanism, whereby a substantial fraction of commercialization proceeds are returned to the data-generating community, aiming to establish a sustainable and equitable web3 data economy.

With an innovative tokenomics model, Silencio fosters a sustainable and engaging ecosystem where participants actively combat noise pollution while benefiting from their contributions. By collecting accurate, real-time data, the platform empowers governments, city planners, and industries to make informed decisions, leading to more effective noise control strategies and enhanced quality of life for urban residents.

As of April 2025, there are over 1 million devices on the Silencio Network, across 180 countries. In the month of February 2025 alone, there were 600,000 hours measured across 51.9 million measurement uploads, 400,0000 check-ins and 125,000 new users. Since its inception in 2023, Silencio has become the largest decentralized noise intelligence network in the world.

1.1 Silencio App

1.1.1 Street Level Explorer

Silencio uses a data pipeline to continuously stream information from their database for user interaction. This

[*] ***Corresponding author***: *eoin.king@universityofgalway.ie*

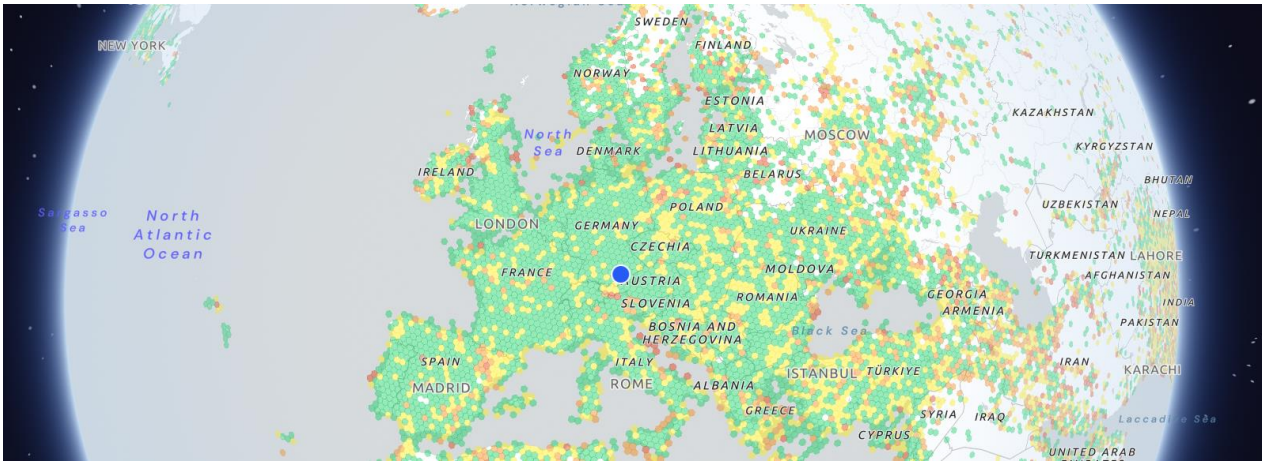

Figure 1. The Silencio Steet Level Explorer

pipeline systematically processes hexagons at multiple resolutions, ranging from 3 - 13, depending on geographic location. It then recalculates and updates the average noise levels in each hexagon. Overall results are displayed on a map that users can explore from a broad overview (Figure 1) to the street level (for examples a street level map for the city of Malaga is displayed in Figure 2). These maps are developed from real noise measurement data, uploaded by users of the Silencio App.

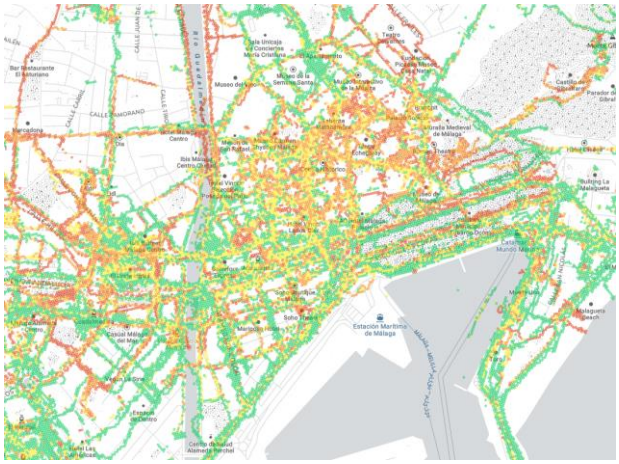

Figure 2. Results from Malaga, Spain

1.1.2 Venue Check in Explorer

Silencio also lets users check in at venues and measure and report noise levels in real-time using their mobile devices. The app verifies the user's location to ensure noise levels are accurately associated with the corresponding venue. The app first records a 15 second noise measurement. After that, users answer a series of questions about their environment, such as whether they are indoors or outdoors, how easy it is to have a conversation, and how crowded the venue is. These measurements are then aggregated and displayed on a map for easy visualization. Users can view the number of check-ins and the average noise level at each venue, all of which are displayed on the map for easy reference.

1.1.3 Noise Complaints

The app also allows users to log noise complaints when they encounter excessive noise in their area. Complaints can be reported at any location or venue, making it easy for users to highlight problematic areas. Each complaint is recorded and displayed on the map, with clusters indicating areas with higher noise levels based on the zoom level. This visual representation helps users and city officials quickly identify noise hotspots. By collecting and analyzing this data, cities can gain valuable insights into noise pollution trends, enabling them to implement better urban planning strategies and public health initiatives to create quieter, more livable spaces.

1.1.4 Noise Coins

Silencio harnesses blockchain technology to build a global community of users contributing to a real-time noise map. By turning their smartphones into anonymous noise monitoring devices, users help collect decibel measurements, creating a detailed worldwide picture of noise levels. In return for their contributions, users can earn passive income while also helping to improve urban soundscapes. With an innovative tokenomics model, Silencio fosters a sustainable and engaging ecosystem where participants are rewarded for their efforts in reducing noise pollution and enhancing overall quality of life.

Central to the Silencio ecosystem is the $SLC token, powered by the Blocksound Foundation, which is used for rewarding contributors, transactions, staking, and governance across the network. The network allows contributors to earn $SLC tokens as a reward for their data contributions, ensuring that every user is a stakeholder in the network's success.

2. NOISE COMPLAINT DATABASE

For this paper we focus on the noise complaint database acquired through the Silencio App. As of March 2025, Silencio users have logged over 150,000 noise complaints all across the world. Complaints are logged for over 180 countries.

Table 1 presents the top 10 countries by noise complaint logged on the Silencio App.

Table 1. Top 10 countries by noise complaint logged.

Country	Number of Complaints
Nigeria	50,400
Philippines	16,509
India	10,553
Bangladesh	9,994
Indonesia	9,759
Pakistan	7,028
United States	6,362
Brazil	3,922
Turkey	2,421
Vietnam	1,922

Figure 3 presents the geographical spread of noise complaints over Europe, while Figure 4 presents results from Nigeria.

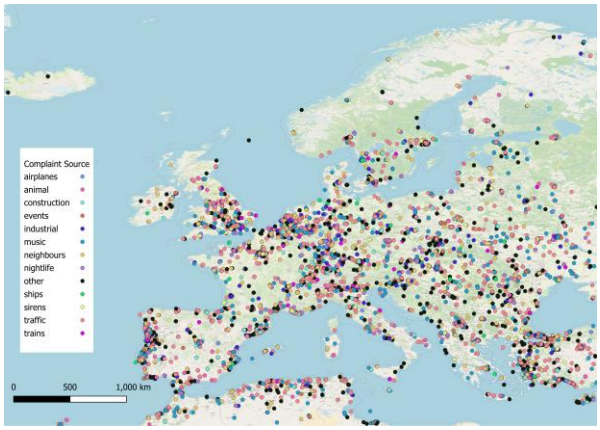

Figure 3. Noise complaints from the European Region.

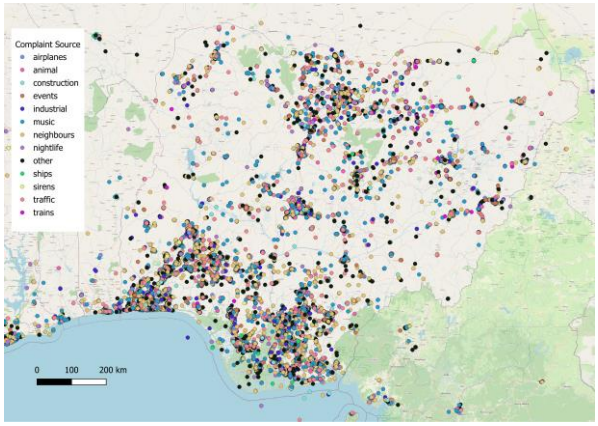

Figure 4. Noise complaints from Nigeria

2.1 Results Analysis

Figure 5 presents the source of noise by category logged. It is evident that road traffic noise is the number one source of noise complaints logged, contributing to over 35,000 noise complaints.

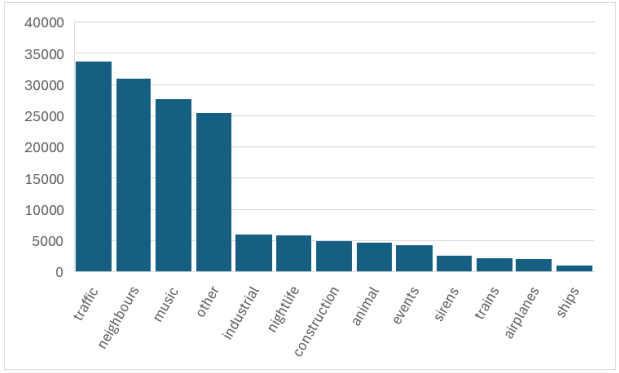

Figure 5. Number of complaints by source type.

Users are also asked to describe how the noise affecting them is impacting their well-being. They can choose from various options, including "uncomfortable," "annoyed," "disruption of relaxation," "anxious," "difficulty sleeping," "increased stress," or "angry." The results, shown in Figure 5, reveal that the most common response fell under the "other" category, suggesting a range of additional disturbances not explicitly listed. The second most frequently reported impact was feeling "uncomfortable," followed closely by "annoyed."

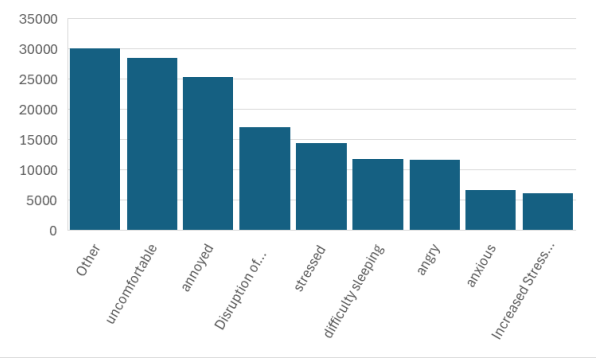

Figure 5. Number of complaints by effect induced.

3. DISCUSION

The Silencio noise complaint database builds on previous research [2-4] that explored the use of smartphones as noise meters, offering valuable insights into global noise pollution and its effects. With over 150,000 complaints across 180 countries, the data highlights the widespread nature of noise disturbances and the need for targeted mitigation strategies.

A key finding is the concentration of complaints in specific regions, with Nigeria reporting the highest number. The dominance of road traffic noise aligns with global urban trends, emphasizing the impact of transportation infrastructure on acoustic environments. Beyond identifying noise sources, the reported effects, such as discomfort, annoyance, difficulty sleeping, and increased stress, underscore the serious implications of noise pollution on well-being and public health.

Silencio's blockchain-based model enables large-scale, community-driven data collection, providing valuable insights for urban planners, policymakers, and researchers.

As this database continues to grow, its potential to drive meaningful changes becomes even greater. By refining data collection methods and integrating advanced analytics, we can uncover deeper patterns in noise pollution and its long-term effects on public health. Future efforts could involve collaborations with city governments, environmental agencies, and urban developers to create smarter noise management policies and real-time response systems. Additionally, integrating Silencio's data with other environmental datasets, such as air quality and traffic patterns, could provide a more holistic view of urban livability. For example, previous research has considered combining air and noise into one index to assist with urban planning [5]. Ultimately, this expanding database has the potential to become a powerful tool for shaping quieter, healthier, and more sustainable cities worldwide.

4. ACKNOWLEDGMENTS

The authors gratefully acknowledge the Silencio team for sharing noise complaint data.

ASSESSMENT AND ANALYSIS OF VIBRATION IMPACTS FROM UNDERGROUND RAILWAY TUNNELLING AND EXCAVATION IN SYDNEY, AUSTRALIA

Aaron Miller[1] **Jeffrey Parnell**[2,3*] **Vyshakh Ajith Menon**[1] **David Hanson**[1]

ABSTRACT

The NSW Government is building, operating and maintaining a network of four metro rail lines, 46 stations and 113km of new metro rail in Sydney, Australia. Whilst there have been geographical challenges with the new alignments, Sydney's high strength sandstone bedrock has provided a very stable substrate in which to tunnel. This has meant that measurable and perceptible levels of vibration can be propagated to significant distances. Contemporary understanding of tunnelling impacts is mostly underpinned by overseas experiences with respect to peak particle velocity (PPV). Moreover, this is generally limited to the relatively short setback distances applicable to structural damage concerns. This study presents PPVs, A-weighted ground-borne RMS vibration levels and one-third octave band spectra from tunnel boring and cross-passage excavation activities at various offset distances out to 300m that may be applicable to ground-borne noise or sensitive equipment concerns. This data will likely inform future predictions of tunnelling projects in Sydney and may be applicable to other regions both domestically and internationally. It also highlights uncertainties in predictions, ground conditions and the practicalities of contemporary tunnelling processes.

1. INTRODUCTION

Sydney is the largest city in Australia and is the capital of the State of New South Wales with a population of over 5.6 million (2025). Being a harbour city, it has geographical constraints that have historically resulted in the city expanding parabolically westward from the coastline. Whilst this is not an unusual configuration, it has occurred in a short space of time with Sydney only being declared a city in 1842. The delivery of large infrastructure brings significant challenges of whether this can be accommodated on the surface, or needs to be underground, and as is common in most international cities, the preference is for underground public transport, particularly in high density CBD environments.

1.1 Project Description

Sydney Metro is building, operating and maintaining a network of four metro rail lines, 46 stations and 113km of new metro rail, some of which is underground. The metro program includes the operational M1 Metro North West & Bankstown Line, and three projects under construction: Sydney Metro Southwest (upgrade of the existing rail line between Sydenham and Bankstown to metro standard), Sydney Metro West (24km of new twin tunnels between Westmead and the Sydney CBD) and Sydney Metro - Western Sydney Airport (23km, including 9.8km of twin tunnel between St Marys and Bradfield City Centre).
Geologically, Sydney sits on a large sedimentary feature known as the Sydney Basin. The metro rail corridors are dominated by Triassic-Age Hawkesbury Sandstone and Ashfield Shale. There are some instances of Quaternary Age alluvial/fluvial sediments comprising sand, silt and clay, but these are minor in the tunnel sections. Of most interest is the Hawkesbury Sandstone which is a very high

strength medium to coarse grained quartz sandstone. Its high compressive strength is characteristic of Sydney's large vertical coastal cliffs, and it was used extensively in the 19th and early 20th Century in the building of significant Government buildings and churches. It is therefore an excellent material in which to tunnel and is very stable. However, this also makes it quite efficient at transmitting vibration energy. The Ashfield Shale which comprises claystone, mudstone, siltstone, laminites, and fine-grained lithic sandstone has a much lower compressive strength and is more prone to weathering. Consequently, it is not as efficient in the propagation of vibration energy.

1.2 Impact Assessment

Following initial geotechnical and civil engineering concept designs, but prior to any infrastructure project being approved, a number of studies are undertaken to confirm the project viability and to assess likely environmental impacts from construction and operation. This includes noise exposure to surrounding residents, and potential building damage from tunnelling. Where Planning Approvals are granted, they will be subject to meeting certain noise and vibration objectives. In NSW, Australia these objectives are articulated in various policies, guidelines and Standards including BS7385.2 [2] which provides guidance on building damage from vibration, DIN 4150.3 [3] which makes recommendations for protection of structurally unsound heritage buildings, BS6472 [4] which discusses the impact of vibration on humans and is referenced in the NSW Environment Protection Authority's (EPA) Assessing Vibration: A Technical Guideline [5] and the Vibration Criterion (VC) Curves [6] which provide guidance for sensitive equipment. In regard to Ground Borne Noise (GBN) impacts, the NSW EPA's Interim Construction Noise Guideline [7] provides guidance.

1.3 Excavation Considerations

Excavation of an underground railway is primarily undertaken through three separate activities:

- Excavating the fixed diameter mainline tunnel using tunnel boring machines.
- Mining of irregular shaped underground infrastructure such as station and crossover caverns using road headers.
- Use of percussive methods to excavate the cross passages between the twin mainline tunnels, and for some minor cavern excavation works.

These tunnelling works can generate significant amounts of vibration that can propagate through the ground and into nearby buildings. This vibration has the potential to impact sensitive receivers in two ways:

1. Higher frequency vibrations (approximately 20 Hz to 250 Hz) will propagate through the ground, and into buildings. These will result in building elements vibrating and acting like loudspeakers, creating an audible rumble. This is known as 'ground-borne noise'.
2. Lower frequency vibrations (typically <20 Hz) can also induce cosmetic damage into buildings at high amplitudes, be felt (rather than heard) by building occupants to the extent that they disturb or annoy at moderate-to-low amplitudes, or interfere with the operations of sensitive equipment at very low amplitudes.

Tunnel depth will vary along an alignment being largely a function of changing surface topography as shown in the example given in Figure 1 where it varies from around 10m depth down to more than 90m below ground level. The intervening material along with coverage and specifically the slant distance from a tunnel to the foundations of a sensitive receiver are also important factors in the propagation of vibration.

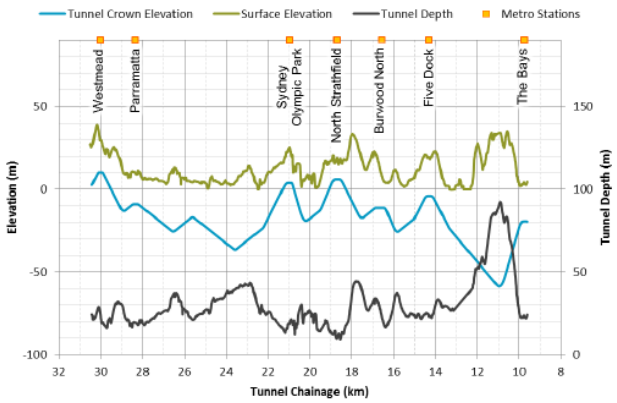

Figure 1. Tunnel depths and existing ground elevation on Sydney Metro West. [1]

1.4 Tunnel Excavating Techniques and Equipment

There are three main excavation techniques associated with rail tunnelling and one ancillary technique that can result in significant vibration. Firstly, is the use of a Tunnel Boring Machine (TBM) that effectively drills through the substrate to provide the mainline rail tunnel. Secondly, is the use of road headers (typically associated with larger diameter road tunnels) to excavate larger irregular shaped caverns for crossovers and underground stations, and for pedestrian and ventilation adits. Thirdly, there is the use of hydraulic rock

hammering often used to provide interconnecting cross passages between twin rail tunnels. Lastly, and ancillary to the three other excavating techniques is the need to insert rock bolts in unsupported spaces to improve stability. A brief discussion of these techniques and equipment is provided below.

1.4.1 Tunnel Boring Machines

TBMs are designed to excavate through sandstone and shale and are in the order of 1250 tonnes and 165m long. The operations include:

1. The cutterhead at the front of the TBM spins and as it does, high-steel alloy steel discs extend out to the rock surface and crush the material in its path.
2. Crushed rock is scooped into the machine's head and onto a conveyor belt.
3. The conveyor moves rock through the machine and out of the tunnel behind it.
4. Concrete ring segments are delivered to the ring building area.
5. Concrete ring segments are fixed onto the tunnel wall carved out by the TBM using a vacuum lifting device.
6. When completed, the ring is connected to the previously built ring.
7. The gap between the concrete ring and the rock is filled with grout – this helps keep water out of the tunnel.

A total of six concrete segments make up one concrete tunnel ring. Once the TBM finishes building the fully lined tunnel, it breaks through a rock wall to arrive at its destination where it is then retrieved.

1.4.2 Road Headers

Road Headers used on Sydney Metro projects are typically in the order of 120 tonnes. They are used for a large range of excavation work such as for the new Pyrmont Metro Station where they will excavate a future station cavern. This will eventually measure 18m high, 24 m wide and 170m long, requiring the removal of 151,000 tonnes of material from the site over a 2 year period. Unlike the TBMs which move along the alignment at a steady rate in one direction, road headers can work in specific areas for long periods of time, increasing the exposure time and fatigue of affected residents and buildings.

1.4.3 Rock Hammering

Hydraulic hammering refers to the highly percussive impact excavation methods that are sometime used underground to excavate or remove small areas of rock.

1.4.4 Rock Bolting

The drilling and subsequent installation of anchors or rock bolts into excavated caverns and passages can result in a more intermittent vibration pattern that can be perceived on the surface.

1.5 Approvals and Operating Constraints

Planning approvals usually allow tunnelling activities to occur 24 hours per day, seven days per week, primarily in order to reduce project timelines, noting that TBMs and road headers are expected to excavate approximately 200m per week and 20-40m per week, respectively. In practice, however, TBMs and road headers produce vibration approximately 50% of the time (as the other 50% of the time is spent erecting tunnel lining and support structures) and will have breaks of days or weeks to undertake maintenance.

TBMs and road headers cannot be replaced with alternative, less vibration-intensive equipment, and there are no reasonable and feasible path or receiver controls that will reduce the vibration levels. Consequently, assessments of ground-borne noise and vibration impacts from these activities are limited to ensuring that vibration will be below structural damage thresholds, and then quantifying the ground-borne noise and vibration levels that the surrounding community / sensitive equipment will be exposed to, as well as the duration (which is usually in the order of days rather than weeks or months). These impacts and their duration then determine the extent to which community consultation is undertaken, and in extreme cases, the extent to which temporary alternative accommodation will be provided.

Other excavation activities using hydraulic hammers, like cross passage excavation and minor cavern works, do not necessarily need to occur 24 hours per day, seven days per week, and can therefore be restricted to standard construction hours as a means of mitigating their impacts.

Whilst potential building damage is rarely a concern, perception of vibration or ground-borne noise is usually expected as a TBM both approaches and then departs. Figure 2 provides an example showing that a residential receiver with a 20m slant distance from the nearest tunnel alignment will likely experience internal ground-borne noise levels greater than the 35 dB(A) night-time ground-borne noise management level (NML) objective [7] for around five days if the TBM is transiting at 20m/day. The maximum ground-borne noise level is expected to peak at around 50 dB(A).

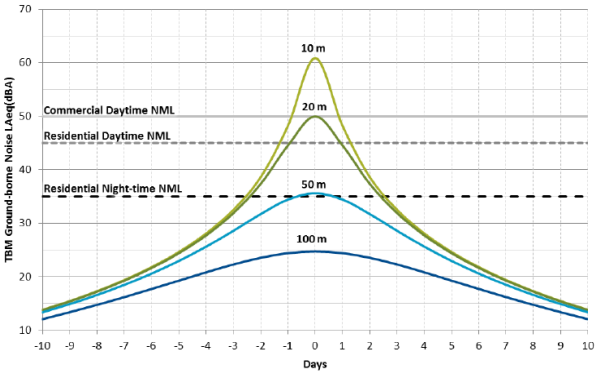

Figure 2. Example of TBM Ground Borne Noise levels (where progress ~ 20m/day). [1]

2. CURRENT PREDICTION METHODOLOGIES

The assessments for recent projects in Sydney typically use similar approaches to predict the ground-borne noise and vibration impacts as summarised below:

- PPVs and A-weighted ground-borne noise levels are presented as single curves with respect to distance. These appear to be based on the datasets provided in Speakman and Lyons, Hiller and Karantonis [8-10] as well as unpublished internal databases. These are usually based on Hawkesbury Sandstone.
- Human comfort is assessed in one of two ways:
  - The PPVs are used as a screening assessment, or
  - Estimated Vibration Dose Values (eVDVs) are predicted based on the PPV vs distance curves, incorporating assumptions regarding crest factors, dominant frequencies and how often the equipment is used within a daytime or night-time period.
- The duration of these impacts is assessed based on a combination of the PPV and ground-borne noise vs distance curves, and typical progress rates per day.
- Parameters like coupling loss, internal amplification and floor-to-floor attenuation are conservatively assumed and generically applied across every building included in the assessment.

2.1 Limitations of Current Methodologies

The current prediction methodologies tend to be generic in nature, mostly as a consequence of there being insufficient data available in the literature to perform any kind of detailed assessment. Moreover, there is currently no mechanism for assessing vibration impacts against the VC curves. For example, this would be limited to assuming a crest factor to convert a PPV at a specific distance to a maximum one-third octave band velocity level. This generic approach tends towards conservatism, which can lead to the over-specification of community consultation measures and the provision of temporary respite accommodation. This can be problematic, particularly with multi-storey buildings with large footprints. In such a scenario, a generic assessment might indicate that all occupants of such a building require temporary alternative accommodation due to excessive annoyance. In reality, only the lower floor apartments might require this level of respite because this building may have a much higher coupling loss than the assessment assumed, which would result in a much lower impact to the upper floors and other ends of the building.

Capturing one-third octave band spectra and associated waveforms at various offset distances would allow for more detailed assessments to be undertaken when necessary because:

- It provides a mechanism to assess vibrations against VC curves.
- It can be used in conjunction with other parameters such as coupling loss, internal amplification, floor-to-floor attenuation and vibration to noise transfer functions that are published in terms of one-third octave bands in sources such as the Federal Transit Administration manual [13], RIVAS Project [12] and Transit Cooperative Research Program [13] or data sourced locally, such as Karantonis et al. [14].
- Calculations of eVDVs can be improved by validating the assumptions around crest factors and dominant frequencies or going further and calculating weighted RMS or weighted RMQ accelerations at various distances directly.

There are also additional opportunities for improving generic assessments. Hiller [9] notes that "*in general terms, the vibration increases as the strength of the ground through which the tunnel is bored increases*", this is also demonstrated in Rallu et al. [15]. ITA [16] also suggests that reducing thrust may also reduce vibrations. This presents two opportunities:

- Capturing data covering different rock types may allow for less conservative predictions on rock types that are softer than Hawkesbury Sandstone.
- Capturing different thrust conditions and quantifying their differences may allow for specific thrust conditions to be specified as mitigation measures.

Finally, capturing long-term monitoring data allows for the impacts and durations to be quantified based on actual

progress rates, rather than the typical progress rates used in these generic assessments.

3. STUDY OBJECTIVE AND SCOPE

This paper provides a small sample of the results of monitoring that has been undertaken to address these shortfalls identified in Section 2.1. Monitoring is ongoing, but the possibilities of quantifying and presenting this are practically endless. This paper focuses on the opportunities to improve the generic assessments, and provides one-third octave band spectra from two sites, at which very robust datasets were able to be collected.

3.1 Methodology

Attended monitoring has been undertaken across the Sydney basin using a consistent approach using 10 V/g or 1V/g accelerometers (Wilcoxon 731-207 and PCB 393A03, respectively). External monitoring utilised small ferrous stakes driven into the earth, and magnetically mounting the accelerometers to these stakes. At most locations, vibration has only been measured in the vertical direction. Rallu et al. [15] notes that vibrations at the surface are similar in all three spatial directions, which has been confirmed in our monitoring at the small number of locations at which triaxial vibrations were measured. Vibration on or inside buildings has been undertaken by mounting the accelerometers using beeswax.

The attended monitoring has typically involved setting up one location to continuously monitor vibration, and then measuring at numerous other locations to triangulate the location of the TBM from the surface. The continuous monitor is able to capture changes in vibration emissions due to (what is believed to be) changes in thrust.

Data have been recorded using National Instruments cDAQ units incorporating sampling rates of 2048 Hz, with anti-aliasing filters providing unfiltered data up to 800 Hz. The waveforms have been processed to calculate LZeq and LZSmax one-third octave band spectra, overall LZeq, LAeq, LZSmax and LASmax levels, PPVs, Wb and Wg weighted RMS and RMQ levels, and crest factors (PPV / LZeq) all at 1s intervals.

3.2 Location Details

The geographic spread of locations across the Sydney basin at which monitoring, and the subsequent analysis has been completed (at the time of writing) is shown in Figure 3. Details about the monitoring are provided in Table 1, rock types are based on those described by Willan [17].

Figure 3. Aerial View of Measurement Locations.

Table 1. Locations, rock types, and activities measured at each location.

Location	Rock Type	Activity
Luddenham	Sandstone, shale and thin coal seams	TBM
St Marys	Silt and clay	TBM
Sydney Olympic Park	Silt and clay	TBM
North Strathfield	Clay shale and sandy shale	TBM
Five Dock	Hawkesbury Sandstone	TBM, Cross-passage hammering
Leichhardt	Hawkesbury Sandstone	TBM, Cross-passage hammering

4. RESULTS

The measurement results are presented in terms of PPVs in Figures 4a/4b, and ground-borne vibration levels in Figures 5a/5b. Figures 4a/4b and Figures 5a/5b also include typical curves (shown in black solid, dashed and dotted lines) that have been used at EIS and construction vibration management plan stage on Sydney projects and are based on Hawkesbury Sandstone. The curves on Figures 5a/5b are ground-borne noise curves to which 27 dB has been added (based on the formula from Kurzweil, [18].

The maximum one-third octave band levels and corresponding dominant frequencies for three of these datasets are provided in Figures 6a/6b. Figures 7 and 8 are effectively a summary of the velocity spectra measured for TBMs at St. Marys and Five Dock West respectively, whilst Figure 9 graphically presents Cross Passage hammering in Five Dock. The VC curves (from IEST) [19], which have evolved from those described in [6] as described in Miller [20] are overlaid on these spectra as black dashed lines.

5. DISCUSSION

It can be observed from Figures 4a and 5a that the TBM PPV's and A-weighted ground-borne vibration levels can, in practice, be significantly lower than those typically predicted. There are two possible explanations for this:

- Changing the thrust of the TBM appears to be able to significantly reduce vibration levels, particularly at shorter slant distances. This is evident when comparing the 'increased thrust' and 'reduced thrust' values at Five Dock East. This was also very clearly evident when reviewing the spectra versus time at individual locations where 'continuous' monitoring was undertaken at Five Dock East.
- Operating the TBM in different rock types appears to significantly influence the vibration levels as evidenced by comparison of vibration levels measured at St. Marys, in silt and clay, compared to levels measured at Five Dock West, in Hawkesbury Sandstone.

It is not clear which of these is the dominant contributing factor. At Five Dock East, it may not have been a change in thrust that changed the vibration levels, but rather the TBM may have temporarily encountered different rock. Conversely, the TBM at St. Marys may have been operating at reduced thrust settings in comparison to the TBM at Five Dock West. More information is needed from the tunnelling contractors to understand this.

The measured vibration levels for cross-passage hammering shown in Figures 4b and 5b are generally significantly lower than the prediction curves with some variation in the intensity of hammering also observed, particularly at high frequencies. Whilst this did not increase the PPVs significantly, it did produce large increases in A-weighted ground-borne vibration levels. Again, it is unclear if the lower levels or variations in intensity are due to a different rock type, different hammer, or hammering technique. Understanding this might allow for ground-borne noise mitigation measures, in the form of restricting how hammers are used, to be implemented where tunnelling works occur near noise-sensitive receivers. More cross passage hammering data is needed in different rock types.

6. FUTURE WORK

The authors intend to continue building and subsequently publishing this dataset for widespread use. This will include calculations of weighted RMS and weighted RMQ at various offset distances to assist with human comfort calculations.

7. CONCLUSIONS

Vibration monitoring that uses sensitive accelerometers to capture one-third octave spectra and waveforms has been undertaken at multiple locations, covering a cross-section of the bedrock found in the Sydney basin. The purpose of the monitoring is to construct a database that can be referred to by those undertaking ground-borne noise and vibration predictions of tunnelling activities, to improve the current prediction methods. The dataset presented in this paper will facilitate vibration predictions with respect to sensitive equipment (VC curves). Monitoring is ongoing, and the dataset will continue to improve. Collaboration with the tunnelling contractors will be essential in understanding the large variations in measured levels.

IMMISSION DIRECTIVITY IN THE FREQUENCY DOMAIN

Jure Murovec[1*] **Luka Čurović**[1] **Anže Železnik**[1] **Jurij Prezelj**[1]
[1] Laboratory for Pumps, Compressors and Technical Acoustics LEDSTA, Faculty of Mechanical Engineering, University of Ljubljana, Slovenia

ABSTRACT

The spatial domain has proven to be a crucial element in the measurement of environmental noise and allows for better identification and classification of noise sources. This paper presents spectral immission directivity, an extension of the concept of immission directivity into the frequency domain, which improves the spatial representation of noise at different frequencies. The proposed methodology combines spectral and spatial insights and provides a comprehensive view of the acoustic environment. Theoretical simulations were performed and validated by measurements in an anechoic chamber, confirming the reliability and precision of the approach. The integration of spectral immission directivity into existing noise measurement systems is seamless and requires no significant changes, and it improves their ability to localize and characterize noise sources. This advance reduces reliance on complex post-processing algorithms and promotes more efficient, accurate and cost-effective noise monitoring strategies. By enriching environmental noise assessments with spectral-spatial data, this research paves the way for innovative approaches to noise assessment and management.

1. INTRODUCTION

Noise pollution in urban areas is a significant but often overlooked environmental problem, largely due to inadequate measurement methods and impact assessments. Noise is defined as unwanted or disturbing sound and is constantly perceived by the auditory system, making it inherently intrusive. Urban areas, with their dense population and industrial activity, face particular challenges in managing noise levels. Apart from the effects on human health - which are associated with sleep disturbance, cardiovascular disease and cognitive impairment, noise pollution also has economic costs, such as healthcare expenditure, property devaluation and lost productivity. In addition, it disrupts ecosystems and affects biodiversity on land and in the sea [1-3]. Tackling noise pollution presents significant technical challenges, with the most effective strategy being to reduce noise pollution at the source itself. However, many noise sources, such as industrial plants, ports, railways, airports and construction sites, are constantly in operation and cannot be easily mitigated. The simultaneous activity of multiple sources makes accurate assessment difficult, as environmental noise is inherently dynamic and varies in time, frequency and space. Effective assessment requires sophisticated measurement and modeling techniques [4-6].

Noise propagation modeling, combined with sound power assessments, helps estimate individual contributions to overall noise levels. However, these models depend on extensive input data, including operating times, source geometries, and terrain characteristics, and are subject to uncertainties from variations in software tools and standards. Consequently, noise modeling primarily serves to extrapolate data from limited measurement points (MPs) to broader areas, a method supported by numerous studies [7-9]. Long-term measurements are crucial for accurate assessments, allowing the identification of dominant noise sources and enabling targeted reduction strategies.

However, manual post-processing, such as listening to recordings, is time-consuming and costly.

Recent advances in noise research have led to the development of the immission directivity (ID), a concept that can be seamlessly integrated into existing legally compliant noise measurement methods. By combining ID with standardized approaches, noise monitoring technologies can be further improved. ID is compatible with calibrated Type 1 noise level meters, ensuring traceability to SI units and enabling accurate assessments of environmental noise [10-12].

Using a small microphone array, ID identifies the most dominant noise source at each measurement integration time based on its location and direction relative to the MP. The inclusion of this spatial dimension in equivalent sound pressure level measurements has proven valuable in analyzing acoustic environments and distinguishing individual noise sources. Since traditional noise source identification is based on frequency analysis, combining spatial and spectral data is a logical next step. This paper presents Spectral Immission Directivity (SID), a novel approach that has emerged from our recent research and improves the analysis of environmental noise by incorporating spatial and frequency data. By mapping the directional distribution of different frequency components around the MP, SID improves the identification and classification of noise sources, especially in complex environments with multiple overlapping sources [13].

In addition to human-generated noise from traffic, industry and construction, SID can also be used to analyze biological sounds such as bird calls, insect activity and wildlife vocalizations, making it valuable for both urban and ecological studies. Its applications extend to urban planning, building design, traffic noise studies, public health research and biodiversity monitoring, supporting targeted noise mitigation strategies. In addition, SID can be seamlessly integrated into existing regulatory compliant methodologies and can serve as a key component in classification models and smart city monitoring networks.

To validate this approach, 16 hours of in-situ pilot measurements were conducted in a multi-source noise environment, demonstrating the ability of the SID's to distinguish and identify different noise sources and their contribution to the overall noise level. This study aims to use SID to transform the assessment of environmental noise, making it more accurate and effective.

2. METHODOLOGY

In this study, we performed in-situ measurements as a case study to evaluate the SID approach and analyze its performance in a real-world environment. We used a dedicated microphone array and the Delay, Subtract, and Sum (DSS) algorithm [12] to determine the direction of arrival (DOA) and spectral characteristics of the noise sources. Using SID, we identified the number of individual noise sources, analyzed their contribution to the overall noise level, examined their frequency characteristics, and determined the times at which they were present.

2.1 Equipment

The experimental setup for this research included specialized measuring devices and software tools for data acquisition. The Behringer UMC404HD ADC USB audio interface, which operates at a high sampling frequency of 192 kHz, was used to capture audio signals. A horizontal microphone array consisting of four Behringer ECM8000 measurement microphones arranged in a circle with a diameter of 27 mm was used. The DSS method was applied to the signals from the array. This configuration provided a computationally efficient system capable of capturing DOA over the frequency range of most environmental noise sources (100 Hz to 6300 Hz, in 1/3 octave bands) and operating with an integration time of 125 ms. The user interfaces and data acquisition programs were developed using LabVIEW 2023, while the processing of the measurement data and the generation of the figures was performed in MATLAB R2024a. This combination of hardware and software ensures accurate data acquisition and analysis.

2.2 Spectral immission directivity

ID, first introduced in 2018, is a ground-breaking concept in environmental acoustics that aims to address the challenges of understanding and quantifying the contributions of different noise sources to the overall noise level at a given MP. It captures both the spatial and temporal dynamics of noise and provides a detailed representation of how sound energy from different directions affects an acoustic environment. By incorporating both the direction of arrival (DOA) and the sound pressure level (SPL) of noise sources, ID serves as a valuable tool for analyzing complex soundscapes found in urban or industrial environments.

Building on the foundational principles of ID, a derived concept known as SID was developed. SID extends ID by

integrating a 1/3-octave frequency analysis alongside the spatial distribution of noise sources around the MP. This extension enables a more comprehensive understanding of the acoustic environment and provides deeper insights into the frequency-specific contributions of the different noise sources. By combining spectral and spatial data, SID is a powerful tool for the assessment of environmental noise and contributes to the development of more effective noise mitigation strategies and the design of the urban soundscape.

To simplify the SID pattern, it can be reduced to a two-dimensional spatial problem by disregarding the elevation angle. This approach is feasible because environmental noise sources such as traffic, industrial plants and wind turbines are usually located at a certain distance from the MP, so that the propagating sound waves can be approximated as parallel to the ground. As a result, the A-weighted equivalent sound pressure level $L_{A,eq,T,fi}$ at a specific frequency can be defined by Eq. (1).

$$L_{A,eq,T,f_i} = 10 * \log\left[\frac{1}{T}\int_0^T\int_0^{2\pi} 10^{\frac{L_{p,A}(t,f_i,\varphi)}{10}} d\varphi dt\right] \quad (1)$$

Where $L_{p,A}(t,f_i,\varphi)$ stands for A-weighted instantaneous sound pressure level for the frequency f_i as a function of time t and direction φ. $L_{A,eq,T,fi}$ can be defined as the sum of a specific frequency of all noise sources that are present in the vicinity of the MP in the time interval T (from directions between 0 to 2π). To obtain the total A-weighted equivalent sound pressure level, we use the logarithmic summation of all $L_{A,eq,T,fi}$ for I number of frequency bands described with Eq. (2).

$$L_{A,eq,T} = 10 * \log\int_0^{f_I} 10^{\frac{L_{A,eq,T,f_i}}{10}} \quad (2)$$

At each point in time, the levels of the individual frequencies are assigned to a single direction — the most dominant — as the DSS algorithm only identifies the strongest source. By extending the measurement duration and sequentially activating different noise sources, unique ID patterns are generated for each frequency. The aggregation of these patterns forms the SID. As shown in the results section, analyzing the ID on a frequency basis helps significantly to identify the main noise sources, understand their contribution to the overall noise level and determine their spectral characteristics.

The frequency resolution can be chosen according to need. However, in this study, a 1/3-octave spectral analysis was chosen in line with standard practice to limit the amount of data and improve conceptual clarity. Regardless of whether a narrowband frequency analysis is used, the underlying method for calculating the SID remains unchanged.

In discrete form, Eq. (1) and Eq. (2) can be rewritten as Eq. (3) and Eq. (4), where N represents the measurement duration in terms of integration time count. I corresponds to the number of frequency bands, which was set to 19 in this study. The spatial resolution for DOA determination at the immission point was fixed at 6° on the horizontal plane, resulting in $M = 60$ observed angles.

$$L_{A,eq,T_N,f_i} = 10 * \log\left[\frac{1}{T_N}\sum_{n=1}^{N}\sum_{m=1}^{M} 10^{\frac{L_{p,A}(t_n,f_i,\varphi_m)}{10}}\right] \quad (3)$$

$$L_{A,eq,T_N} = 10 * \log\sum_{i=1}^{I} 10^{\frac{L_{A,eq,T_N,f_i}}{10}} \quad (4)$$

2.3 Measurement location

The MP was placed near a large cement plant, its stone quarry and an industrial area. The location of the main sources of noise can be seen in Fig. 1. Otherwise, there are several small villages in the vicinity of the MP where agriculture is practised.

Figure 1. MP and surrounding noise sources.

3. RESULTS

The in-situ measurements were carried out on a working day from 15:00 to 7:00. Fig. 2 shows the recorded data and the dynamics of the acoustic scene during the measurement. It can be clearly seen that the dominant direction (Fig. 2.b) was quite stationary during the night when the overall sound pressure level (Fig. 2.a) was lower. Spectrogram and spectrum (Fig. 2.c and Fig. 2.d) are also shown, which is a typical representation of noise measurement data. Even with only 16 hours of data, no direct conclusions about the noise sources can be drawn from Fig. 2. The data must be condensed to a level that is easier to interpret and clearer.

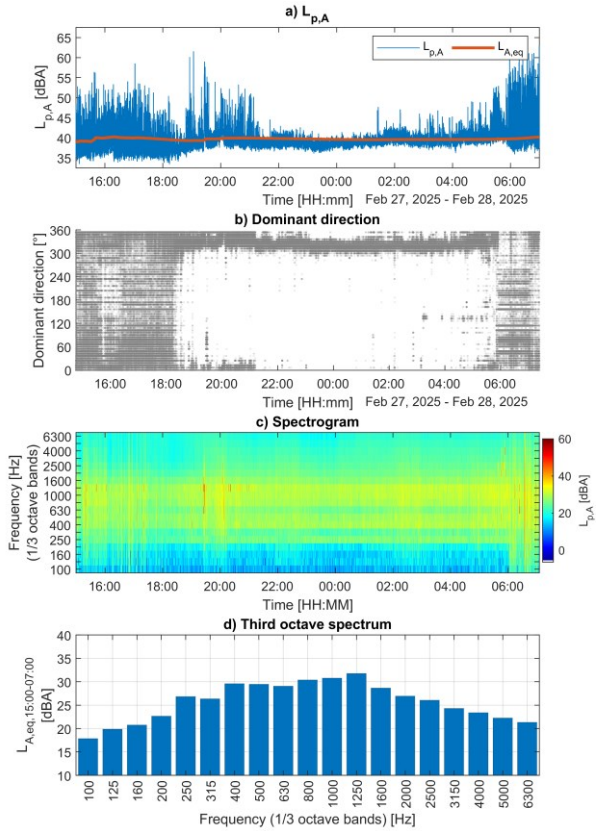

Figure 2. Noise measurement data.

To get a clearer picture of the contribution of the different noise sources around the MP, we use the ID pattern as shown in Fig. 3. The polar diagram shows how $L_{A,eq}$ is spatially distributed. We can notice that most of the sound energy comes from the southeast direction, but some other directions are also notable.

To get a better understanding of the different noise sources, Fig. 4 shows the comparison of the dominant direction distribution and the ID. It can be seen that the noise source in the southeast direction (approx. 330°) had a lower SPL at the MP than the noise sources in the directions 6°-30°, 72°-90°, 102°, 114° and 156°, as the contribution of the noise source in the southeast direction to the total $L_{A,eq}$ was not much higher compared to the other sources, although it was the most dominant noise source for most of the measurement.

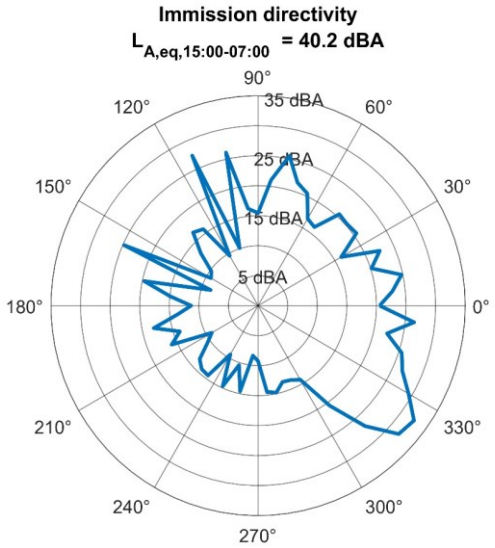

Figure 3. Imission directivity.

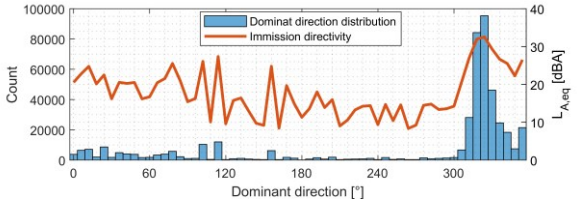

Figure 4. Dominant direction distribution around the MP.

Fig. 5 shows the SID of the measurement performed. The approximate spectrum and the dominant frequency bands of the main noise source are clearly recognisable. The sources in the directions 102°, 114° and 156° show a rather broadband spectrum, while the sources in the directions 72°-90° and 6°-30° show peaks in certain frequency bands.

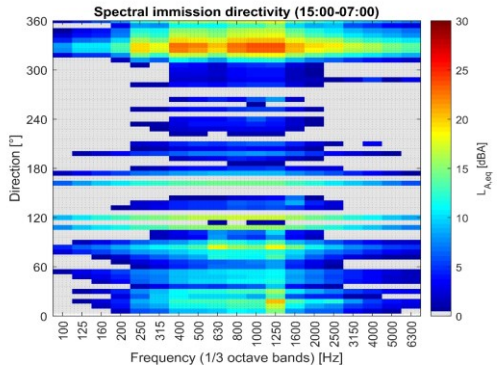

Figure 5. Spectral immission directivity.

To better represent the spatial-temporal dynamics of the acquired noise data, IDs for 1-hour intervals were calculated and can be seen in Fig. 6. A shift from a multiple noise source operation to a single noise source operation can clearly be observed as IDs between 15:00 and 19:00 display a more spatially even distribution of $L_{A,eq}$ around the MP and then a transition at 19:00 , when a noise source at 78° starts to dominate alongside the noise sources east of the MP. While some sources at 342°-24° are still present between 21:00 and 23:00, they completely stop operating thoughout the night. The dominance of this noise source ends at 5:00 when noise sources from other directions start to appear and by 7:00 they start to dominate.

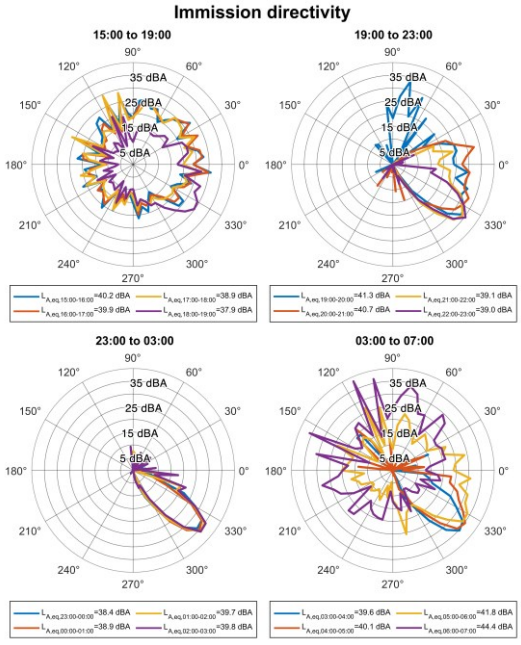

Figure 6. Hourly imission directivity.

SID allows us to examine 1-hour data in more detail by analysing the spatial-frequency content of the measurement. In Fig. 7, we can observe a noise source at 18° with a prominent peak at 1250 Hz in the frequency band from 15:00 to 17:00.

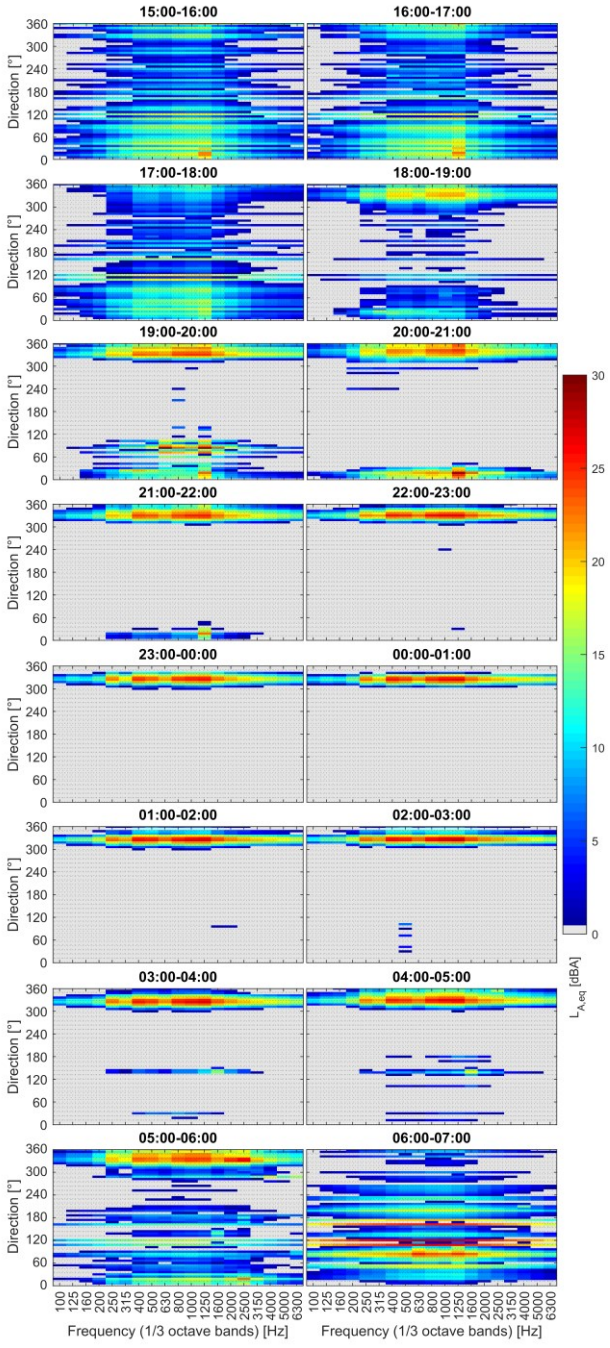

Figure 7. Hourly spectral imission directivity.

It is obvious that the operation of the source stopped between 17:00 and 19:00 and then continued until 22:00. Another noise source occurred between 19:00 and 20:00 with peaks at 630 Hz and 1250 Hz in a direction of about 78°. Looking at the data in the morning, especially between 6:00 and 7:00, noise with broadband frequency content and higher amplitudes can be observed in the directions of 102°, 114° and 156°.

If we filter the data spatially, we can calculate $L_{A,eq}$ of the 1/3-octave spectra for specific noise sources (their direction/location relative to the MP). Fig. 8 shows the results for six noise sources together with the total $L_{A,eq}$ (from 0° to 360°). It can be seen that the main noise source contributing the most to the total noise level is between 312° and 360°. The sources at 102°, 114° and 156° have broadband frequency components (influenced by the A-weighting) that could belong to an impulse noise source. The source at 6° - 30° had a peak in the frequency band of 1250 Hz, while the source at 72° - 90° had an additional peak in the frequency band of 630 Hz.

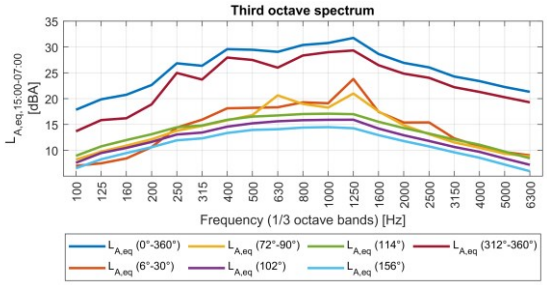

Figure 7. 1/3-octave spectrums of selected directions.

4. DISCUSSION

Pilot measurements were carried out on site to validate and evaluate the usability of the SID. Several noise sources were identified during the analysis, one of which accounts for the largest share of the total noise level. As shown in the ID polar diagram (Fig. 3), the industrial area proved to be the main noise source. A further analysis with the SID (Fig. 7) showed that the noise emissions from the industrial area have a broadband frequency spectrum that is most pronounced in the evening and at night (19:00–06:00).

In certain cases, certain frequency components can cause greater disturbance, especially when people are at home. This effect is more pronounced at lower frequencies, which are better able to penetrate into people's homes. In addition, it is widely recognized that tonal noise is a significant contributor to noise annoyance. The use of SID facilitates the rapid identification of such noise sources and increases the efficiency of noise monitoring and mitigation efforts.

One such noise source, presumably a heat exchanger, was detected between 19:00 and 20:00 at an angle of 78°. This source showed clear peaks at 630 Hz and 1250 Hz within the 1/3-octave frequency bands (Fig. 7). Another conspicuous noise source associated with stone quarry activities was detected in an 18° direction and occurred from 15:00 to 17:00 and again from 19:00 to 22:00. This source had strong tonal characteristics, as shown in Fig. 7.

In addition, three separate noise sources with broadband spectral characteristics were identified in the morning hours (06:00-07:00) in the directions 102°, 114° and 156°. These sources also appeared between 15:00 and 19:00. As these directions coincide with residential areas in nearby villages, it is plausible that these noise sources originate from human activities and may represent impulsive noise events.

These results highlight the effectiveness of SID in accurately identifying and characterizing complex noise environments, thereby supporting more targeted noise mitigation strategies.

5. CONCLUSION

The results of this study show the usefulness and efficiency of the SID for the measurement of environmental noise. A key advantage of SID is its ability to provide a comprehensive overview of the acoustic environment at a glance, allowing for quick identification of dominant noise sources without the need for extensive post-processing. In addition, SID offers flexibility in data analysis as measurements can be analyzed in real time or retrospectively, providing valuable insights for both immediate assessments and in-depth post-measurement evaluations. This capability significantly increases the efficiency of environmental noise assessments and facilitates targeted noise mitigation measures.

To further validate and extend the applicability of SID, future work will focus on conducting longer measurement campaigns in more diverse acoustic environments. This will include the investigation of biological sounds, which will provide additional insights into the effects of natural and anthropogenic noise sources. In addition, efforts will be made to expand the frequency range of the microphone

array's frequency range will be extended to capture and analyze a wider range of noise sources. These planned improvements will increase the versatility of SID and make it a more robust tool for environmental and industrial noise monitoring.

ABSTRACT

Green roofs provide a distinct acoustic environment with reduced sound pressure levels (SPL) compared to conventional roofs. These levels arise from a combination of direct sound, diffraction, reflection, and absorption effects—strongly influenced by measurement height. Simultaneous SPL measurements at eight heights were carried out to examine how roof geometry and materials affect SPL through absorption and diffraction. Results show that SPL decreases with decreasing measurement height, particularly when greenery covers wall parapets, highlighting the role of vertical surfaces in shaping rooftop soundscapes.

Keywords: *green roofs, sound absorption, soundscape, height dependency of SPL, sound diffraction* .

1. INTRODUCTION

Urban noise pollution is a widespread source of discomfort, with potential medical implications [1]. Among other benefits, urban greenery contributes to noise reduction and improves acoustic comfort [2]. To achieve these effects, densely built cities with limited space for ground vegetation, such as Barcelona, must integrate greenery into the architectural envelope. This study examines the acoustic effects of a semi-intensive green roof comprising $350\,\mathrm{m}^2$ of horizontal vegetation and $200\,\mathrm{m}^2$ of vertical greenery, located primarily along the walls of the roof parapet; and of a conventional roof with no vegetation. The conventional roof refers to a typical Mediterranean solution with ceramic tiles.

A preliminary study at the same location [3] explored differences in soundscape between the two aforementioned roofs. That study, along with subsequent field observations, led to the hypothesis that noise reduction exhibited a marked dependence on height, meriting further investigation. Subjective experience suggested a substantial change in perceived sound when standing versus sitting: from an open, noisy soundscape—where multiple urban sources were clearly identifiable—to a rooftop soundscape characterised by significantly lower sound levels. This contrast, though still present, was less pronounced on the conventional roof.

The soundscape of green roofs has been the subject of numerous studies [4]. In addition, the acoustic absorption properties of green roofs and green walls have been analysed both in laboratory [5] and in situ [6], confirming the expected good sound absorption behaviour due to both, substrate and vegetation.

The experienced sound field results from a combination of direct, diffracted, and reflected components.

While previous models describe insertion loss behind sound barriers due to diffraction [7] [8], the geometric and absorptive particularities of the green roof—such as the highly absorbent wall parapet/barrier walls and substrate—warrant specific analysis. This experimental study investigates the dependence of SPL on both height and distance to the parapet, with a focus on the diffracted field within the acoustic shadow cast by the roof's parapet walls.

2. MATERIALS AND METHODS

2.1 Roofs under analysis

The selected roofs are located in a peripheral district, with a sparse population, approximately 500 m from an extensive green zone along the Besòs river. The immediate environment consists of a noisy, heavily motorised industrial park. The green and conventional roofs are separated by about 100 m and are part of the same industrial complex. The green roof, beneath its soil, water-proofing and drainage layers, features a thin roof system, while the conventional roof has a standard roofing solution. The dimensions of the green roof are $37 \times 13\,\mathrm{m}^2$ with a height 20 m, while the conventional roof measures $27 \times 6\,\mathrm{m}^2$ with a height of 12 m.

Figure 1 shows the floor plans of the two roofs, indicating the locations of the microphone arrays and their respective planes. Figure 2 shows a photo collage featuring five key scenes from the study.

2.2 In-situ sound absorption coefficient

Acoustic absorption measurements were conducted in situ using an impedance gun from Microflown Technologies [9–11]. This device consists of a spherical loudspeaker and a PU probe that simultaneously detects acoustic pressure and particle velocity. White noise is generated by the loudspeaker, placed 23 cm from the probe. The probe is positioned near the surface to be measured, as shown in the bottom-right image of Figure 2. The absorption coefficient is obtained from the impedance, that is, the complex ratio between acoustic pressure and particle velocity. The frequency range analysed spans from 200 Hz to 8000 Hz, and the results are presented in third-octave bands.

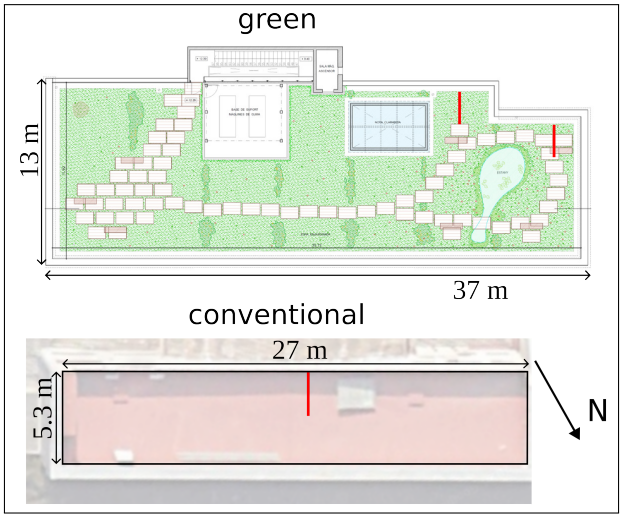

Figure 1: Floor plans of the green (top) and conventional (bottom) roofs. The red stripes indicate the locations and planes of the microphone arrays.

2.3 8-Microphone Array

A special arrangement of eight microphones was used to simultaneously measure sound variation at different heights and distances from the wall, as the background noise was highly variable. The microphone configuration was employed both vertically, with a fixed distance to the wall, and horizontally, with a fixed distance to the floor. These configurations are shown in the diagram of Figure 3. The measurements were recorded using 8 free-field Roga MI-17 microphones and a Rion DA-40 8-channel data recorder, and processed with the Rion AS-70 waveform analysis software.

3. RESULTS AND DISCUSSION

3.1 Acoustic absorption

The acoustic absorption coefficient is determined following the procedure described in Section 2.2, in different areas of the green roof. The results obtained for two representative areas of the roof are shown in Figure 4. The results are presented in third-octave bands between 200 Hz and 8000 Hz. In both cases, relatively high absorption coefficients are observed, with values approaching 1 for frequencies above 2500 Hz in the area with the most vegeta-

Figure 2: Photo collage of five key scenes. Left: vertical array of microphones in front of a conventional wall parapet. Middle top: vertical array of microphones in front of a photovoltaic glass of width 0.02 m. Middle bottom: horizontal array of microphones along a vegetated zone. Right top: acoustic camera facing a conventional wall parapet. Right bottom: impedance gun measuring absorption of a vegetated surface.

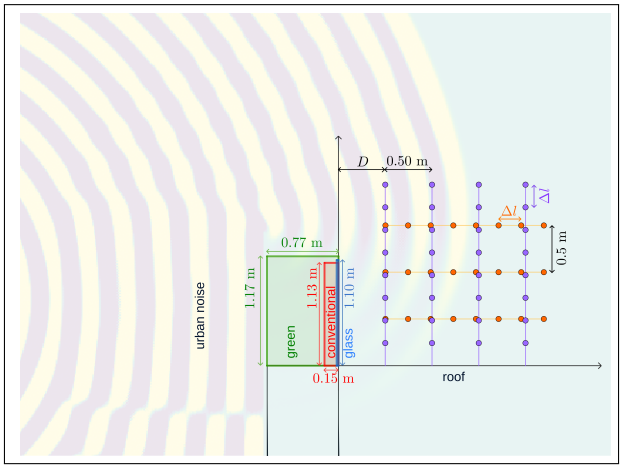

Figure 3: Diagram of wall parapets and microphone array positions (arrays are dots connected by lines). Two types of parapets are shown on the green roof: one wide and vegetated (green in the figure), and another thin, made of photovoltaic glass (blue in the figure). The wall parapet of the conventional roof is shown in red. Vertical microphone array positions are indicated in violet, while horizontal arrays are shown in red. The spacing between microphones in each array is Δl =24.2 cm, with recordings within a given array being simultaneous. The background wavefront represents sound propagation, depicted artistically from a 2D sound-wave simulation using Python Matplotlib. The distance D between the wall parapet and the first microphone of a horizontal array is 50.2 cm for the green roof and 54.2 cm for the conventional roof. For vertical arrays, the first microphone is located 50.0 cm from the parapet.

tion (right image).

3.2 Acoustic camera

We use an acoustic camera to localise the sources of noise in order to characterise the incident sound field. The equipment used was the SevenBel Sound Scanner with the P132 sensor, capable of measuring down to 250 Hz. Figure 5 shows three images of the three wall parapets.

3.3 Sound pressure levels

Figure 6 shows the results for three different fixed heights, where in each case the sound is recorded simultaneously by the eight microphones located at 8 distances from the barrier. The sound levels remain approximately constant with height while changing the distance. Figure 7 displays the A-weighted equivalent continuous sound level for measurements taken at three different positions, with simultaneous measurements from eight microphones at varying heights above the ground. The three graphs correspond to the three barriers analysed. For a fixed distance, the difference in sound level with height exhibits different behaviour in each case. The difference between the maximum height, h =1.94 m, and the lowest height, h =0.25 m, is 10 dB(A) in the green roof-green wall configuration, 6 dB(A) in the green roof-glass wall configuration, and 2 dB (A) in the conventional roof-brick wall configuration.

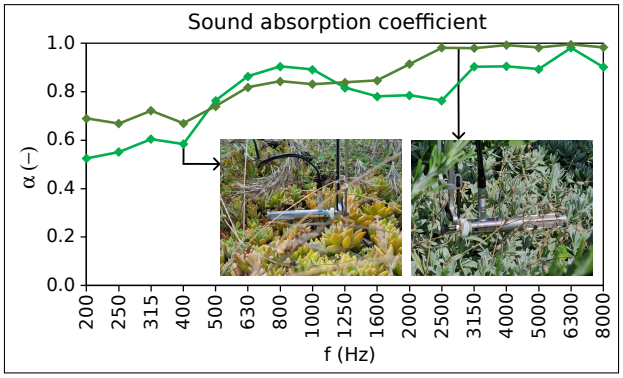

Figure 4: Acoustic absorption coefficients as a function of frequency measured with the impedance gun. Light green represents absorption coefficients for low vegetation, such as Sedum, and dark green for intermediate vegetation, such as leaf plants.

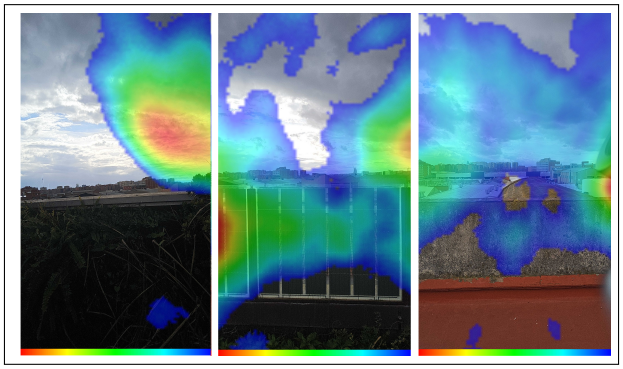

Figure 5: Acoustic camera measurements. From left to right: green roof with green barrier; green roof with glass barrier; conventional wall with brick barrier. The optical image is overlaid with a sound level map, where blue and red represent lower and higher sound levels, respectively. The dynamic range is 3dB. In the left image the sound source is perceived to be slightly higher than the noise source. In the centre image, the two original noise sources are perceived but are out of the frame. The same happens at the conventional wall

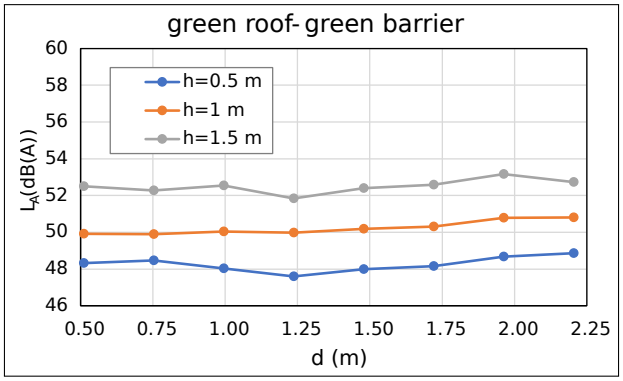
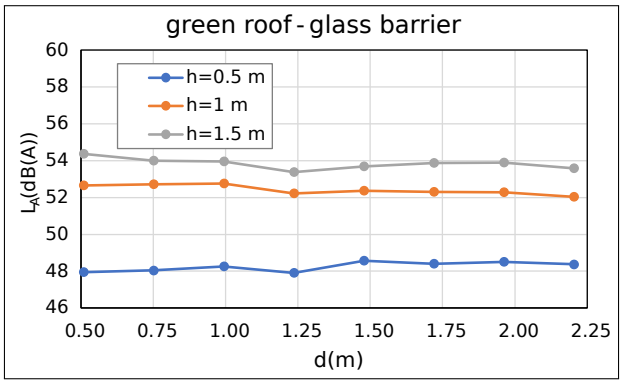
3.4 Noise level dependency on the frequency



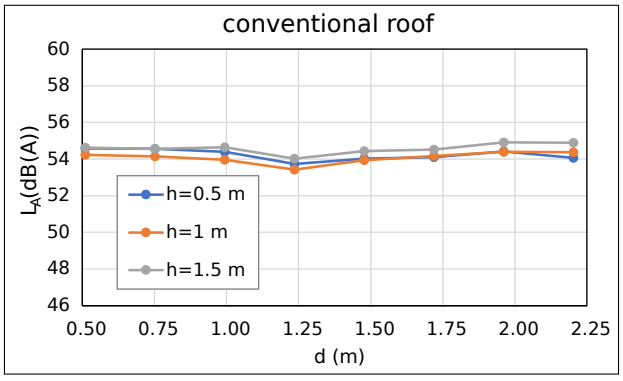
To understand which frequency bands contribute to the overall decrease in sound level, sound levels in third-octave bands between 50 Hz and 10.000 Hz are analysed for eight different heights at a distance of d=1.0 m from the wall in the three roof-barrier configurations (Figure 8). Additionally, for each configuration, the variation in noise levels in some selected third-octave bands with respect to height is plotted in Figure 9.

The spectrum of the conventional roof (Figure 8 c) does not depend on the height of the receiver, and the noise level decreases monotonically with frequency. The green-green case (Figure 8 a) exhibits a behaviour similar to the conventional one at low frequencies, while at medium and high frequencies the curves diverge, clearly decreasing the sound level. Low frequencies at different heights appear to have similar values of L_p, but as the frequency increases, so does the difference between the sound levels at difference heights. The green-glass roof (Figure 8 b) displays intermediate behaviour between the two previous ones. To illustrate this, a closer look at the variations in different third-octave frequency bands for a selected position, as a function of height, is provided in Figure 9. At low frequencies, the level decreases slightly with height across all three configurations. In contrast, at higher frequencies (from 500 Hz onward), the level increases with height. This increase is greater for the green-green roof and modest for the conventional one.



The difference in sound levels for eight different heights in the 125 Hz and 1000 Hz third-octave bands, for two selected distances d=1 m and d=2 m, is shown in Figure 10. For each position, the difference in level of each microphone is determined in relation to the highest microphone, which is taken as the reference level.

In all three cases, the 125 Hz band increases at lower heights, contrary to expectations based on diffraction models. This behaviour could be explained by the low absorption at low frequencies in both the green roof and conventional configurations, allowing the sound to reflect off the barrier walls and the floor at these heights. In the case of the 1000 Hz band, which behaves similarly to the 500 Hz, 2000 Hz, and 4000 Hz bands, the difference between roof-barrier configurations is much clearer.



The difference between the reference level (highest microphone) and the lowest microphones ranges from 14 – 16 dB in the green roof-green barrier configuration. The same measurement on the glass barrier shows a difference of 10 – 12 dB between the extremes. In both

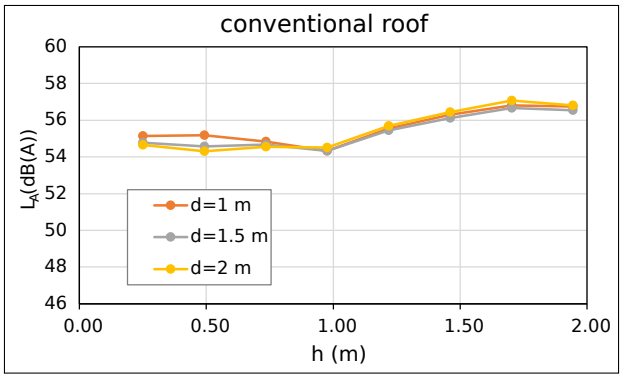

Figure 6: L_A vs d. Panels (a), (b), and (c) show the A-weighted sound pressure level, L_A, as a function of distance to the wall, for three different fixed heights h. The measurements are performed at the green roof-green barrier case (a), the green roof-glass barrier case (b), and the conventional roof (c).

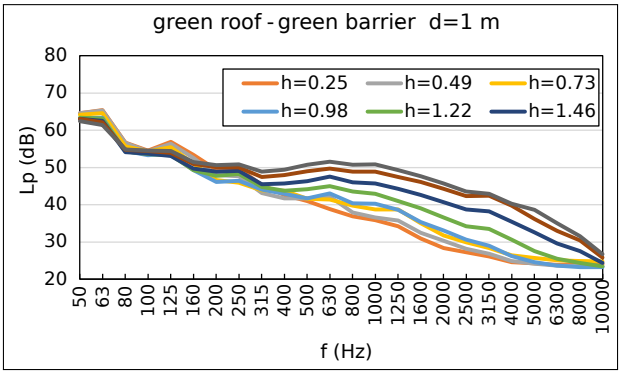
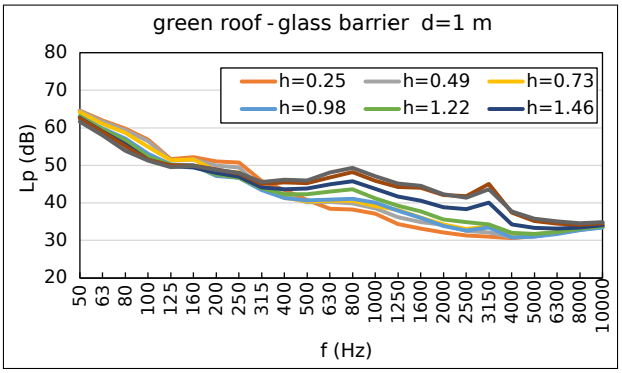
(a)



(b)



(c)

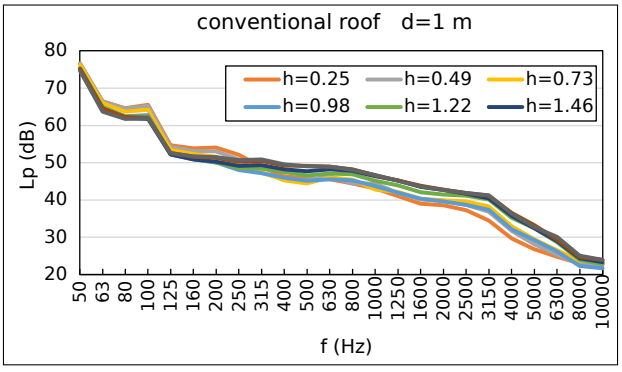


Figure 7: L_A vs h. Panels (a), (b), and (c) show the A-weighted sound pressure level, L_A, as a function of height, for three different fixed distances d from the wall. The measurements are performed at the green roof-green barrier case (a), the green roof-glass barrier case (b), and the conventional roof (c).

(a)

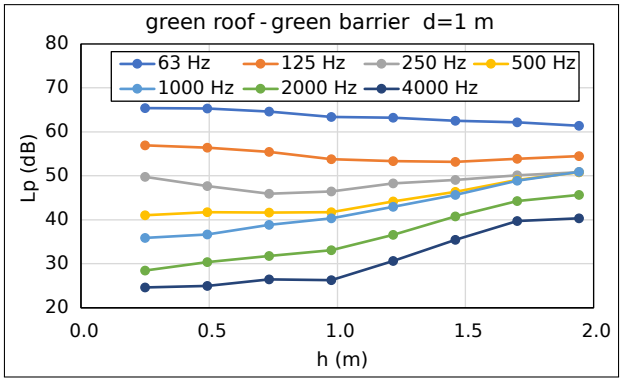
(b)

(c)

Figure 8: Panels (a), (b), and (c) show the sound pressure level, L_p, in third-octave bands as a function of frequency, for a fixed distance d=1 m from the wall. The measurements are taken at different heights for the green roof-green barrier case (a), the green roof-glass barrier case (b), and the conventional roof (c).

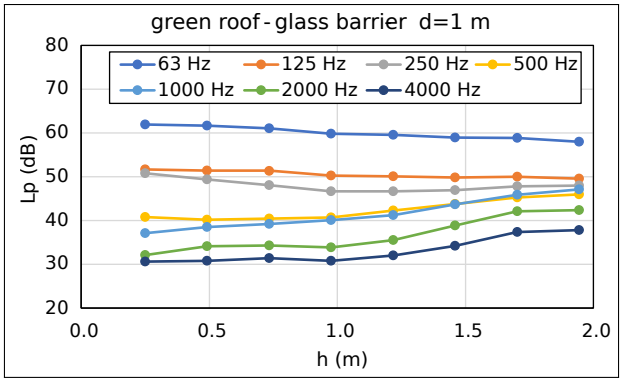
cases, the trend is relatively linear. Finally, the conventional roof-brick wall configuration shows differences of $4-5$ dB between the highest and lowest microphones.

From these measurements, it can be inferred that the L_A level differences presented in Section 3.2 are mainly driven by medium and high frequencies, from 500 Hz to 4000 Hz, as also evident from the graphs in Figure 8.



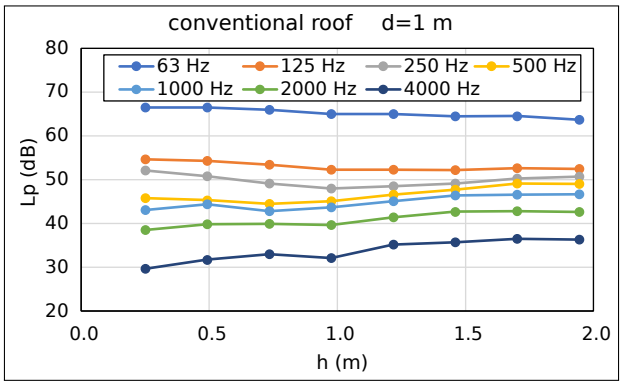
4. CONCLUSIONS

Three different cases were analysed: a green roof with a green wall parapet, a green roof with a glass barrier, and a conventional roof with a brick parapet. The green roof with a green barrier exhibited the largest difference in sound levels between the highest measurement point and the lowest, with level differences of up to 15 dB in medium to high frequencies, from the 500 Hz band up to 4000 Hz. The glass barrier showed a similar behaviour but with smaller differences, up to 10 dB. The conventional roof showed a maximum difference of 5 dB. This comparison is shown in Figure 10 (b).



This contrasting behaviour was also observed when measuring the A-weighted global sound levels. In this case, the green roof with a green wall parapet exhibited differences of 10 dB(A), the green roof with a glass barrier 6 dB(A), and the conventional roof with a brick parapet 2 dB(A).

Much smaller variations between roofs were observed at low frequencies ($125-250$ Hz), as shown in Figure 10 (a). The three configurations show similar behaviour, reaching 4 dB as the measurement height decreases. Therefore, the trend is reversed at higher frequencies. The effect of internal sound reflections inside the roof is hypothesised, as there is low absorption coefficients of the walls and plants at low frequencies, along with the possibility of additional inter-reflections of sound inside the roof walls.



The hypothesis is confirmed: greenery on the roof, particularly when covering wall parapets, results in a reduction of overall sound levels with decreasing measurement height. Future work will involve numerical modelling of diffraction, absorption and reflection to better understand and predict the mechanisms shaping rooftop soundscapes.

REDUCING THE TRAFFIC INDUCED ANNOYANCE BY PUBLIC PARTICIPATION; INTERACTION BETWEEN QUESTIONNAIRES, MODEL CALCULATIONS, AND MEASUREMENTS

Wim van Keulen[1*]
[1] VANKEULEN advies, Schijndel, the Netherlands

ABSTRACT

Commissioned by a major province in the Netherlands, VANKEULEN advies conducted a study into the annoyance aspects of a main 2-laned road. In 2019, a study was conducted into the complaints and the possible solution(s). Due to its complexity, a step-by-step approach was chosen at the time to quantify the problem based on the path: source - transfer – receiver.
To this end, the first 'subjective' and 'objective' measurements were carried out in 2019. The subjective measurements consisted of a survey among residents, the objective of several measurements on the existing road surface and expansion joints. In addition, noise calculations were carried out. After the application of noise reduction measures (noise barrier, low-noise joints and asphalt), the survey and measurements were repeated in 2022. In this way, the partial effects and the total effect (subjective and objective) of the measures could be determined.
The total noise reduction amounted to 12 – 15 dB(A). The overall nuisance decreased by approximately 50%. At the same time, a significant majority indicated that the overall environmental quality improved. However, the overall appreciation for the high impact of the two measures is surprisingly low.

1. INTRODUCTION

On behalf of the Province of South Holland, VANKEULEN Advies conducted a study on noise annoyance associated with the N210 near Rotterdam a road section where numerous complaints were reported to road management authorities in recent years. Significant noise disturbance was documented among residents living along the N210.
In 2019, a global study was initiated to analyse complaints and investigate potential mitigation strategies. Due to the complexity of the issue, a phased approach was adopted, adhering to the framework of **source–transmission–receiver**. Both subjective and objective measurements were conducted in 2019 and repeated in 2022. The subjective assessment involved a survey of residents on both sides of the roadway, while the objective evaluation comprised various assessments of the existing road surface and expansion joints.
Additionally, noise modelling calculations were performed to determine the optimal height for a potential noise barrier and assess its effectiveness. Subsequently, the following noise-reduction measures were implemented:

- 2021: Installation of a noise barrier close to the road, measuring 1.40 meters in height, consisting of a concrete barrier topped with noise-absorbing panels.
- 2022: Application of a noise-reducing thin surface layer.

The follow-up study replicated the pre-measurement assessments to evaluate the individual and cumulative effects (both subjective and objective) of the implemented measures. The total noise reduction at the façades of adjacent residences (relevant for regulatory compliance) and the net noise reduction (relevant for nuisance reduction) were systematically assessed.

2. QUESTIONAIRE

2.1 Questionnaire Design

The questionnaire in 2022 was largely based on the initial survey conducted in 2019. However, in 2022, the primary objective shifted from determining the extent of annoyance to evaluating the reduction of annoyance. The questionnaire was conducted among residents of two sides of the road during September 19 and 22, 2022, concurrently with the noise level measurements. A total of 47 valid replies were collected, of which 24 completed electronically and 23 via postal mail. Statistical analysis indicated no significant differences between the response methods. For comparative analysis, the results were categorised by roadside (south and north) and expressed as percentages.

2.4 Indoor Noise Perception

Tab. 1 presents the results for noise barriers under conditions of closed and open windows.

Table 1. Improvement in Indoor Traffic Noise Due to Noise Barriers [%].

	Closed Windows	Open Windows
High	20	4
Moderate	43	46

Approximately half of the respondents experienced an improvement due to the new noise barrier. Tab. 2 presents the results for quieter asphalt under conditions of closed and open windows.

Table 2. Improvement in Indoor Traffic Noise Due to Quieter Asphalt [%].

	Closed Windows	Open Windows
High	15	7
Moderate	43	48

More than half of the respondents reported improvements due to this measure. Furthermore, the results suggest that the perceived positive effect of quieter asphalt was slightly greater than that of the noise barrier.

2.5 Outdoor Noise Perception

Tab. 3 presents the results for the noise barrier and quieter asphalt in outdoor environments, respectively. The findings indicate a relatively limited impact of the measures in outdoor spaces, except on the north side of the roadway, where the noise barrier had a more pronounced effect.

Table 3. Improvement in Outdoor Traffic Noise [%].

	Noise Barrier	Quieter Asphalt
High	4	9
Moderate	24	39

The quieter asphalt was generally perceived as more effective than the noise barrier.

2.6 Perceived Traffic Noise Annoyance

Tab. 4 presents the results regarding the reduction in traffic noise annoyance due to the noise barrier and quieter asphalt, respectively.

Table 4. Reduction in Traffic Noise Annoyance [%].

	Noise Barrier	Quieter Asphalt
High	9	11
Moderate	37	53

The noise annoyance was reduced by 46% due to the noise barriers, whereas quieter asphalt led to a 64% reduction. Again, the positive effect of quieter asphalt on reducing annoyance was larger.

2.7 Changes in Traffic Noise Characteristics

Tab. 5 presents the results regarding improvements in the perceptual characteristics ("colour") of traffic noise.

Table 5. Improvement in Traffic Noise Perception [%].

	Noise Barrier	Quieter Asphalt
much	13	28
Moderate	49	47

These findings indicate a greater perceived improvement in noise characteristics than the reduction in noise annoyance presented in Tab. 4.

2.8 Overall Improvement

Tab. 6 presents the average improvement in traffic noise perception across different environments.
The average reported improvement in noise perception was 2.3. In summary, while annoyance levels decreased slightly due to the implemented measures, the overall acoustic environment improved for most respondents. However, overall appreciation for the two measures remained relatively low.

Table 6. Average Improvement in Traffic Noise Perception [sca1e 1–5].

Inside	Outside	Area	Total
2.6	2.2	2.1	2.3

3. MONITORING

3.1 Immisions

Monitoring stations were installed at two residential locations, one at the north side and one at the south side. During September 19–22, 2022, concurrent with the survey, noise levels at the two locations were continuously recorded over the course of a workweek. The monitoring results were categorised into daytime, evening, and nighttime periods. These measurements provide insight into the variation of the equivalent continuous sound level (L_{Aeq}) over different short time periods (every 5 minutes). Microphones were positioned at the façades of the residences at both side of the road: northside: 2 m high and southside: 5 m high. These measurement heights correspond to the upper floors where noise-sensitive rooms are located. The monitoring results were compared with those from 2019 to identify relevant differences and potential causes.

3.2 Results

During monitoring, construction activities were ongoing in the vicinity of a patrol station. These activities significantly impacted some measurements (>10 dB(A)); however, these intervals were readily identifiable and accounted for in the analysis. Additionally, the central bus lane had not yet been opened, which led to a slight increase in the influence of bus traffic. However, this effect was found to be minimal. Fig. 1 illustrates the monitoring data obtained from the two locations.

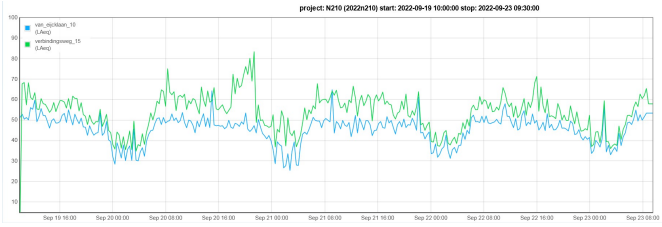

Figure 1. Results of the full monitoring at the two locations.

Tab. 7 provides an overview of the average noise levels for each period. The data have been rounded to the nearest whole number and adjusted for prescribed façade reflection (-3 dB(A)).

Table 7. Average Noise Levels per Time Period [dB(A)].

Location	Day	Evening	Night
North	47	43	34
South	55	49	38

The measured values at south side were higher than those on the north side, primarily due to its closer proximity to the road.

4. NEW ROAD PAVEMENT

4.1 Noise Measurement

A SPB measurement [1] was conducted on September 22, 2022. Tab. 8 presents the measured SPB values for light motor vehicles, along with the strict Dutch reference values.

Table 8. Measured SPB-levels [dB(A)].

Speed	SPB level	reference
50 km/h	63.6	71.0

The noise reduction at the SPB measurement point is approximately 7 dB(A). CPX measurements [2] were conducted on September 11, 2022. Tab. 9 presents the measured CPX values for light motor vehicles.

Table 9. Measured CPX-levels [dB(A)].

Direction	CPX level
East	87.8
West	86.9

By using the calibration relationship between the SPB and CPX measurements conducted in this study, the CPX values were converted into an average SPB level of the entire section as presented in Tab. 10.

Table 10. Average Noise Reductions of the new pavement [dB(A)].

Direction	Noise Reduction
East	7.4
West	8.3

The average initial noise reduction for light motor vehicles travelling at 50 km/h is approximately 8 dB(A). The new expansion joints are not audible and, therefore, not measurable.

5. COMPARISON WITH THE 2019 SITUATION

5.1 Representativeness for the Considered Area

Considering the relatively simple acoustic environment and the symmetry around the road, the results obtained for the two monitoring locations can be generalised to all residences in the vicinity of the road except for a small number of houses located directly behind the petrol station. In this specific area, the full benefit of the quieter road surface is observed, but the influence of the newly constructed noise barrier is minimal.

5.5 Reduction of the immission

Tab 11. shows the average noise immission levels as measured in 2019 and 2022, respectively.

Table 11. Average Noise Immission Levels [dB(A)].

Location	2019	2022	Reduction
North	62	47	14 ± 3
South	68	55	12 ± 3

5.2 Effect of Road Pavement

By comparing noise emissions before and after repaving, the net effect of the new pavement has been quantified (see Tab. 12).

Table 12. Average Noise Reductions before and after Repaving [dB(A)].

Situation	Noise Reduction
Before Reconstruction	1.1
After Reconstruction	7.8

The new pavement results in an approximate noise reduction of 7 dB(A) compared to the previous pavement, which is acoustically equivalent to a fourfold reduction in traffic volume.

5.3 Effect of Noise Barriers

The absolute shielding effect of noise barriers is not easily quantifiable, as it depends on the relative position of the receiver, the noise source, and the barrier. This is because noise barriers primarily attenuate sound via diffraction rather than absorption. When the receiver is located within the acoustic shadow of the barrier, noise attenuation is maximal. However, when the road is directly visible from the receiver's position, the noise attenuation is minimal. The absorptive panels installed on the noise barriers are designed exclusively to prevent reflections that may affect positions on the opposite side of the road. The effect of a noise barrier can be accurately calculated using the Dutch Noise Calculation Method. This method was applied to the two measurement locations based on the actual geometry and placement of the implemented noise barriers (see Tab. 13).

Table 13. Average Noise Reductions before and after Construction of the Barriers [dB(A)].

Situation	Noise Reduction
North	8.5
South	5.5

5.4 Net Subjective and Objective Effect of the Measures

From the data presented in Tab. 12 and Tab. 13 it is evident that the overall noise reduction due to the implemented measures ranged from 12 to 15 dB(A). Notably, the results exhibit a high degree of similarity to those presented in Tab. 11 and in this section. However, as can be seen in Tab. 6, despite the substantial improvements in noise levels and environmental quality, the perceived appreciation of these measures is relatively low.

6. CONCLUSIONS

Based on the findings derived from the questionnaire responses, as well as the noise emission and immission measurements, it can be concluded that, despite achieving a substantial overall noise reduction (>10 dB(A)), the subjective evaluations provided by the residents were only moderately favourable. Furthermore, the research indicates that the level of public participation did not meet anticipated expectations.

ABSTRACT*

Long-term exposure to noise is linked to various adverse effects on human health. Growing evidence suggests that residential green spaces can positively influence a wide range of health outcomes. Noise annoyance is a key factor examined in the literature in this context. We present findings from two large-scale studies conducted in Switzerland (combined n = 3,340 participants), one in the city of Zurich and one nationwide. Road traffic noise annoyance data was collected and regressed on exposure to (a) road traffic noise and (b) residential green around participants' home location. Higher exposure-response curves were found for the nationwide sample compared to the Zurich sample. Importantly, more residential green was associated with lower annoyance at comparable road traffic noise exposure. These findings highlight the positive, mitigating influence of natural green on negative noise-induced outcomes.

Keywords: *noise, annoyance, residential green, NDVI, exposure–response curve*

1. INTRODUCTION

Noise has demonstrable detrimental effects on human health. Long-term exposure to transportation noise from road traffic, as one of the most prominent noise sources, has been associated with noise annoyance, sleep disturbance, increased risk of cardio-vascular diseases, hypertension, and depression [1-2]. As a countermeasure to the negative impact of noise, the beneficial role of nature on human health has come into focus in recent years. Access to nature has shown to reduce noise annoyance, perceived stress, blood pressure, and stress hormone concentration short-term [3-5]. Long-term effects of living in green neighborhoods have also been shown, protective effects on mental and physical health [6-7].

The Swiss project RESTORE (www.restore-project.ch) investigated the positive influence of green spaces in conjunction with the negative influence of noise on stress

restoration. The present contribution reports data from two RESTORE surveys: one conducted in the city of Zurich and one nationwide across Switzerland. Road traffic noise (RTN) annoyance is analyzed in dependence of RTN exposure (L_{den}) as well as residential green (normalized difference vegetation index NDVI) to gauge if and by how much natural environments may mitigate the negative impact of noise.

2. METHOD

The two surveys were conducted between the years 2021–2022 in Switzerland. The Zurich (ZH) survey collected data only from residents of the city of Zurich, while the Swiss (CH) survey was conducted nationwide. Both surveys followed a stratified sampling approach to cover an ample range of RTN exposure and degree of residential green. Areas with increased exposure to aircraft and railway noise were excluded to avoid mixing different noise sources that may disparately impact health outcomes [8]. RTN annoyance data was collected using the ICBEN 11-point numerical scale (annoyance ratings from 0–10) [9].

2.1 Participants & Exposure Data

Annoyance data from 1,111 (ZH) plus 2,229 (CH) respondents were analyzed (combined n = 3,340). Gender was balanced in both samples, and the mean age was 51.4 (SD±16.1) years. For each respondent, individual RTN exposure (L_{den}, modelled in sonBASE 2015 [10]) and NDVI (300 m Euclidean buffer, years 2019-2021 [11]) were linked to the annoyance response via a residential unit identifier.

2.2 Statistical Analysis

Annoyance data were transformed into 'highly annoyed' (HA) by setting all ratings ≥ 8 to 1 and all others to 0. The binary HA data then served as the dependent variable for a generalized linear model using a logit link function to predict pHA (probability 'highly annoyed'), in which L_{den} and NDVI were included as predictors, see Eqn. (1).

$$\text{logit}(p\text{HA}) = \beta_0 + \beta_1 \cdot L_{den} + \beta_2 \cdot NDVI \qquad (1)$$

Two separate regression models were fitted following Eqn. (1), one with the CH survey data ('CH model') and one with the ZH survey data ('ZH model').

3. RESULTS

Model coefficients for the CH model and the ZH model are given in Tab. 1. Both models revealed L_{den} to be significantly associated with pHA (p < .001), with ORs of 1.15, meaning for every 1 dB increase in L_{den} the odds of a HA response increase by 15%.

Table 1. Log-odds coefficients (coef.), odds ratios (OR) with their 95% confidence interval (CI), and p-values for the CH and ZH models following Eqn. (1).

Parameter	Coef.	OR	CI OR	p
CH Model				
Intercept	-8.3008	-	-	**< .001**
L_{den}	0.1368	1.15	[1.13; 1.16]	**< .001**
NDVI	-1.3611	0.26	[0.10; 0.67]	**.006**
ZH Model				
Intercept	-9.7014	0.00	[0.00; 0.00]	**< .001**
L_{den}	0.1431	1.15	[1.12; 1.19]	**< .001**
NDVI	-0.8904	0.41	[0.07; 2.33]	.314

Fig. 1 displays the relationship of noise exposure and residential green with the outcome of pHA to RTN for both samples. The ZH exposure-response curves are shifted downwards on the y-axis compared to CH (also visible with the lower intercept in the CH Model). Given that the slopes (β_1) for L_{den} are very similar for both models, this shift signifies that, at comparable L_{den} values, the overall pHA is lower in ZH than in CH.

Concerning NDVI, the negative log-odds coefficient β_2 indicates a protective effect of residential green against RTN annoyance. This association is statistically significant in the CH model with an OR of 0.26 (i.e., 74% decreased odds of a HA response per 1-unit increase in NDVI). In the ZH model, the confidence interval around the OR for NDVI is large and not statistically significant.

To gauge the size of the protective effect of NDVI, the equivalent sound pressure level change (ΔL) between the 5th and 95th percentile NDVI (i.e., for areas with little vs. much green) can be calculated as the shift along the x-axis between the two curves. Inserting the respective model coefficients and solving Eqn. (1) for L_{den} results in a ΔL of ca. 4 dB for CH, and ca. 3 dB for ZH in terms of magnitude of a protective effect of residential green against RTN annoyance.

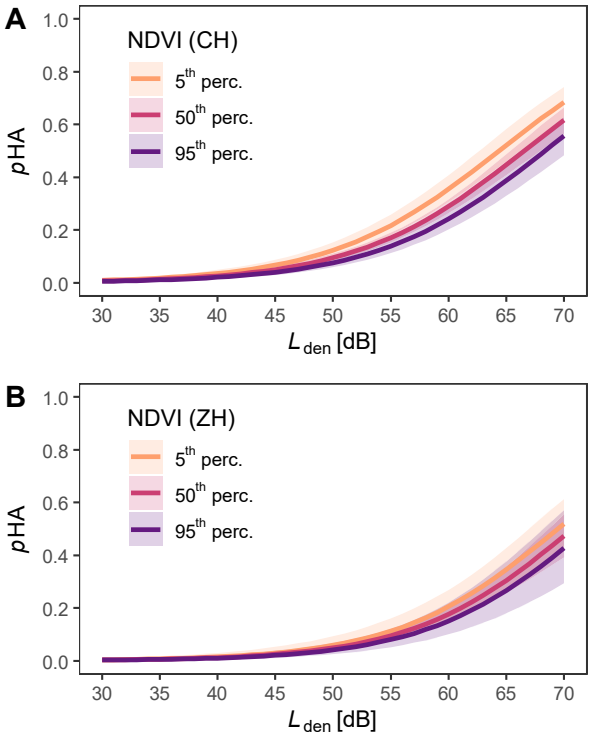

Figure 1. Exposure-response curves after Eqn. (1) for the CH sample (A) and the ZH sample (B).

4. DISCUSSION

The data reported here, collected in two stratified Swiss surveys, contribute evidence towards the mitigating effect of residential green on RTN annoyance. For the nationwide sample, an increase in residential green (as measured by NDVI) was associated with decreased probabilities of being 'highly annoyed' by RTN. Comparing residents in areas with little (5th percentile) versus much green (95th percentile) in the CH sample, an equivalent level reduction of RTN of 4 dB was found. This also indicates that, at the same RTN exposure, 'highly annoyed' reactions are less likely when the neighborhood is greener. While the results for the ZH sample go in the same direction, the protective effect of residential green was smaller and not significant ($\Delta L \approx 3$ dB).

The finding that the Zurich sample, covering the most populated city in Switzerland, showed a smaller protective effect for NDVI compared to the nationwide sample could indicate that there might be some differences in other qualities of residential green (e.g., biodiversity, openness) between the metropolitan ZH area and the heterogeneous CH area that NDVI alone cannot entirely explain.

In general, the magnitude of the protective effect of residential green on noise annoyance found here, while corroborative, falls short of those reported in the literature, with reported values of 6 dB [12] and 10 dB [13]. Possible reasons for this discrepancy might relate to the green metric used, which differs between studies in this research field, as well as other manifold methodological differences (e.g., different NDVI buffer sizes, context of the questions, etc.).

In conclusion, our results demonstrate that natural green in residential areas can help to decrease the negative impact of road traffic noise on the population.

CLUSTERING INDIVIDUALS BASED ON PERFORMANCE IN AUDIO-VISUAL TESTING

Timothy Van Renterghem
Ghent University, Department of Information Technology, WAVES research group, Technologiepark 126, Gent-Zwijnaarde B 9052, Belgium

ABSTRACT

Audio-visual interactions play a crucial role in shaping individuals' perception of their surroundings and have been proposed as an effective strategy for improving environmental noise perception. However, the relative influence of visual and auditory inputs, as well as the degree of audio-visual integration, will vary across individuals. To investigate these influences, a dataset of 196 valid participations in an audio-visual performance test was collected under controlled laboratory conditions. Using Uniform Manifold Approximation and Projection (UMAP) for dimensionality reduction and k-means clustering, three distinct participant groups were identified based on six relative performance indicators. These clusters were categorized as *visual-first responders* (cluster A), *balanced integrators* (cluster B) and *visually dominated* individuals (cluster C). Visual-first responders and the visually dominated group show hardly any audio-visual integration in the audio-visual acuity test, while the balanced integrators clearly do. Notably, clusters A and C, accounting for 68% of the test population, are expected to benefit most from noise annoyance mitigation strategies that incorporate green window views.

Keywords: *environmental noise perception, psycho-acoustics, audio-visual integration.*

1. INTRODUCTION

The concept of enhancing environmental noise perception through audio-visual interactions is gaining increasing attention. A key example is the ability of visual vegetation in a window view to mitigate noise annoyance, a phenomenon convincingly demonstrated by multiple studies [1-5]. In these, contrasting vegetation views are typically compared at fixed sound exposure levels to ensure fair comparisons. While much of the focus has been on the quantity of greenery, recent controlled virtual reality research [5] suggests that the aesthetic quality of urban vegetation is a key factor in noise annoyance mitigation. Specifically, visually appealing greenery may encourage prolonged viewing, which in turn enhances cognitive restoration and stress reduction—two critical mechanisms counteracting the negative effects of environmental noise exposure.

Beyond exposure levels and green-related (or potentially non-green) contextual factors, individual characteristics also play a role. People process auditory and visual information differently, and the extent to which these inputs are integrated can vary widely. Research indicates that differences in audio-visual processing are shaped by cognitive abilities, personality traits, attentional capacities, and neural processing styles [6]. While green window views have shown a broad, positive effect across large-scale studies, it is crucial to investigate for whom these effects are most pronounced and whether certain subpopulations benefit less. This study takes an initial step in that direction by analyzing data from an audio-visual acuity test.

2. AUDIO-VISUAL PERFORMANCE TEST

The audio-visual dominance/acuity test used in this work is based on an object recognition task proposed in Ref. [7] and implemented in Ref. [8]. In front of a computer screen with headphones, participants were randomly presented with two

Corresponding author: timothy.vanrenterghem@ugent.be

objects, indicated as A and B (see Fig. 1), and were asked to correctly classify these objects as fast as possible by pressing the left or down arrow key, corresponding to object A and B, respectively.
Objects were defined by visual features alone, auditory features alone or in combination. The visual part of the object consisted of a circle deforming into an ellipse, either horizontally (object A) or vertically (object B). The auditory part was of a pure tone of 540Hz (object A) or 560Hz (object B).

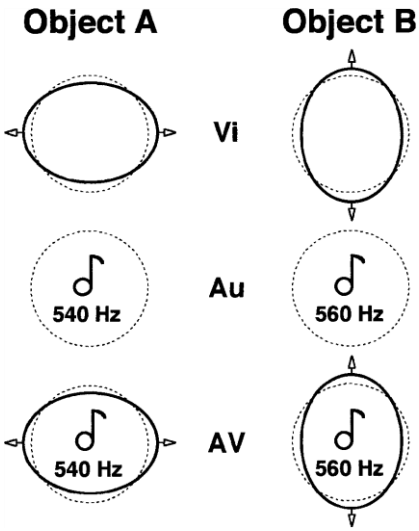

Figure 1. Illustration of the audio-visual objects used in the acuity test.

After each trial, the accuracy of the response was recorded. If correct, the reaction time was also saved. After initial practice trials, each participant completed 72 trials, consisting of 6 repetitions of audio-only (Au), visual only (Vi), and the audio-visual (AV) representations for both objects A and B. This enabled calculating the average accuracy and reaction times for audio-only, video-only, and audio-visual cues, finally leading to 6 parameters describing the audio-visual acuity of the test persons.

3. RESULTS

3.1 Data set

The performance test was held as a part of other audio-visual experiments [5][9], operated in 3 batches. In total, 218 valid audio-visual acuity tests were taken. As an additional criterion, participants with accuracies of less than 33% on both the Au, Vi and AV challenges were removed as these participants might not have understood the task well or might have pressed the keys randomly. In total, 196 datapoints were finally retained for further analysis.
The age of the participants was inclined towards younger people and students, but not restricted to this group. The average ages were 32.9 years (SD=standard deviation=13.9), 27.6 years (SD=12.9) and 29.6 years (SD=11.9) over the 3 batches. Overall, there were slightly more female than male participants (56%, 61% and 45% in each of the batches, respectively). In Table 1, the overall performance on the acuity test is summarized.

Table 1. Overall performance of the test panel with relation to the audio-visual acuity test.

	Mean	SD
N	196	
Acuity test : Correctness Audio only (%)	74%	24%
Acuity test : Correctness Audio-Visual (%)	87%	18%
Acuity test : Correctness Visual only (%)	86%	17%
Acuity test : Reaction time Audio only (ms)	810	150
Acuity test : Reaction time Audio-Visual (ms)	680	140
Acuity test : Reaction time Visual only (ms)	710	130

3.2 Cluster analysis

3.2.1 Relative acuity indicators

In order to identify distinct groups based on the 6-dimensional parameter space, clustering analysis was performed. To rule out the fact that some persons will generally perform better in the tests, regardless of the presentation modality, both the correctness scores ("corr") and reaction times ("rt") are considered in a relative way per test person. Following parameters were therefore defined for subsequent analysis: "corr_AV-A", "corr_AV-V", "rt_A-AV", "rt_V-AV", "corr_V-A", and "rt_A-V". Based on the average responses, positive values are expected for these relative parameters.

3.2.2 Optimized clustering

Uniform Manifold Approximation and Projection (UMAP) [10] was applied for dimensionality reduction, preserving both local and global structure, followed by k-means clustering to identify patterns in the data. Key UMAP parameters, such as the number of neighbors and minimal distance, were tuned for optimal embedding.
The 2D representation obtained via UMAP (see Fig. 2) was clustered using k-means, with the optimal number of clusters determined iteratively through the elbow method and silhouette analysis. The best clustering performance was achieved with 3 clusters, yielding the highest silhouette score (0.68) and the lowest Davies-Bouldin Index (0.69). In

theory, silhouette scores range from -1 (poor clustering) to 1 (perfect clustering), while a Davies-Bouldin Index of 0 indicates ideal, well-separated clusters, with values above 1 suggesting poor clustering. Visual inspection of Fig. 2 already suggested the presence of 3 clusters. Without using UMAP, the silhouette score was 0.42, while the Davies-Bouldin Index increased to 1.20, highlighting UMAP's effectiveness in enhancing pattern discovery while reducing noise and redundancy, finally leading to a better clustering performance.

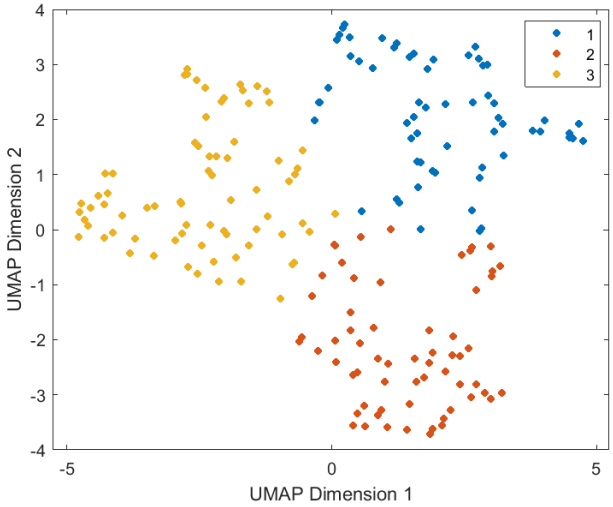

Figure 2. Clustering results in a 2-dimensional UMAP space, the latter being a reduction from a 6-dimensional parameter space.

3.2.3 Cluster centroids

Table 2 shows the cluster centroids after transforming back to the original 6-parameter space. This table should be jointly analyzed with Table 3, indicating which cluster centroids give rise to statistically significantly different means of the relative acuity parameters.

The clustering resulted in groups of roughly equal size, reinforcing the robustness of the classification. Combined with strong clustering performance metrics (see Section 3.2.2), statistically significant differences were observed across the six indicators, further supporting the existence of three distinct groups in how people process audio-visual information.

Table 2. Average values for the relative parameters in the identified clusters.

	cluster A	cluster B	cluster C
n	61	62	73
corr_AV-A (%)	4.1%	3.3%	28.5%
corr_AV-V (%)	3.0%	0.7%	-0.1%
rt_A-AV (ms)	173	63	174
rt_V-AV (ms)	9	97	15
corr_V-A (%)	1.1%	2.6%	28.6%
rt_A-V (ms)	164	-34	159

Table 3. p-values of two-sample t-tests analyzing the means between each cluster pair for the relative performance parameters. "*" means statistically significant at the 5% level, "**" at the 1% level, and "***" at the 0.1% level.

	cluster A-B	cluster A-C	cluster B-C
corr_AV-A (%)	0.483	<1E-10 ***	<1E-10 ***
corr_AV-V (%)	0.030 *	0.017 *	0.522
rt_A-AV (ms)	<1E-10 ***	0.965	<1E-10 ***
rt_V-AV (ms)	<1E-10 ***	0.487	<1E-10 ***
corr_V-A (%)	0.302	<1E-10 ***	<1E-10 ***
rt_A-V (ms)	<1E-10 ***	0.724	<1E-10 ***

4. DISCUSSION

4.1 Single modality analysis

Clusters A and C process visual information much faster than cluster B. In Cluster C, in contrast to cluster A, this also leads to a strong accuracy gain. Notably, Cluster B even leads to faster reaction times for audio only relative to visual only, but also here, similar to cluster A, accuracy gains are very minor.

Persons belonging to cluster C can be called *visually dominated*, as the correctness is much higher (29%) and responses are much faster (159 ms) for visual only compared to audio only inputs. Cluster B could be called the *balanced cluster*. Unimodal audio-input even leads to slightly faster reactions (-34 ms) to the challenges in the performance test but with nearly no accuracy gains (3%). So both modalities have a similar reliability and reaction time. When comparing to the other clusters, this group seems better in processing audio information and its description might tend towards audio dominance. However, audio dominance is clearly not reached, as the speeding up in case of audio only inputs is very limited, while visual

input is still slightly more accurate. So this means that he visual dimension is still important.
Cluster A positions somewhere in between clusters B and C. Similar to cluster C, reactions to audio only are much faster (164 ms), and similar to cluster A, unimodal audio and visual inputs lead to more or less the same correctness (1%). This group is therefore called *visual-first responders*.

4.2 Audio-visual integration analysis

In cluster A and C, audio-visual integration is limited. Audio-visual inputs, relative to visual only, hardly lead to a decrease in reaction time (only 9 ms and 15 ms difference on average), while correctness gains are very limited or non-existent (3% and -0.1%, respectively). Although the correctness gain is limited, in cluster A it is nevertheless statistically significantly different from the other clusters. These characteristics align with the concept of modality appropriateness [11], which posits that the dominant modality (in this case, visual information) becomes the primary source of information for decision making.
Note that for cluster A, visual information only increases processing speed but not accuracy relative to audio only. In cluster C, both speeding up and a strong increase in accuracy is obtained when comparing unimodal cues, leading to true visual dominance. Regarding audio-visual integration, both seem to follow the race model [12] but with a very weak redundant multi-sensory gain.
In cluster B there is a significant reaction time decrease for combined audio-visual cues relative to visual only information, but without accuracy gains. Audio-visual exposure significantly enhances visual processing. This can be explained since both audio and visual information are reliable inputs, with audio slightly faster and visually slightly more accurate. But also relative to audio-only, reaction to the audio-visual stimulus is significantly faster. Strong audio-visual integration is thus observed in this cluster, suggesting co-activation [13].

4.3 Relation to environmental noise perception

The cluster descriptions allow hypothesizing how audio-visual interactions influence environmental noise perception, particularly in relation to the green window view concept discussed in the Introduction.
Since vision dominates environmental processing in Clusters A and C, individuals in these groups are likely to benefit most from an attractive visual element, such as vegetation, which shifts auditory cues—and their associated disturbance—into the background. Auditory information integration remains minimal when both auditory and visual inputs are present. In Cluster C, the visually dominated group, the strongest effects could be expected, as visual input not only enhances the speed of scene evaluation but also contributes to a more accurate mental representation of the surroundings.
Together, Clusters A and C account for 68% of the test population in this work, aligning with the findings in Refs. [1-5], which demonstrated that the positive effects of green window view holds overall for the populations surveyed.
In contrast, the balanced audio-visual integration group (Cluster B) is expected to benefit less from an attractive window view. Here, environmental sounds are likely to carry equal weight to the visual scene and may even elicit faster responses. As a result, auditory information is less likely to be suppressed in favor of appealing visuals, leading to a weaker mitigation effect on noise annoyance.

5. CONCLUSIONS

Performance indicators from an audio-visual acuity test suggest that individual responses to green window views as a noise annoyance mitigation strategy are likely to be influenced by personal characteristics, forming three distinct clusters. It is hypothesized that the *visually dominated* group (Cluster C) and the *visual-first* responders (Cluster A) - together comprising 68% of the test population - stand to gain the most from this strategy. In contrast, Cluster B, consisting of more proficient listeners who integrate both auditory and visual information to a similar extent (the *balanced* group), may experience less benefits, if any.

6. ACKNOWLEDGMENTS

The author is grateful to master thesis students Elin Vermandere, Maarten Lauwereys and Amber Lippens for guiding the test panels through the audio-visual acuity tests that complemented other audio-visual perception experiments.

EXPLORING SOUNDSCAPE PERCEPTION THROUGH THE ITALIAN LANGUAGE: A STUDY ON DESCRIPTIVE WORDS FOR NOISE AND SOUND

Melissa Ferretti[1*] **Davide Chiarella**[1] **Alessandra Cinini**[1] **Paola Cutugno**[1]

[1] Istituto di Linguistica Computazionale "Antonio Zampolli", Consiglio Nazionale delle Ricerche, Italy

ABSTRACT

This study investigates the linguistic description of soundscapes in seven port and hinterland areas in Italy, focusing on the perceptual aspects of remembered or heard sounds. Adjectives associated with the Italian nouns "rumore" (*noise*) and "suono" (*sound*) were extracted from large linguistic corpora and presented in a linguistic-acoustic questionnaire, allowing participants to select those most descriptive of the sounds they perceived.

Through the analysis of responses, a four-point scale was constructed, ranging from "silenzioso" (*silent*) to "molto rumoroso" (*very noisy*), with significant adjectives identified for each level. This scale offers a structured framework to interpret and classify soundscapes, linking linguistic descriptors to specific acoustic environments and sound sources.

The findings highlight the importance of integrating linguistic and perceptual approaches to capture the subjective and cultural dimensions of soundscapes. By offering a language-specific perspective, this research aims to support a deeper understanding of auditory perceptions and inform urban and environmental planning in culturally sensitive ways.

Keywords: *sound perception, linguistic analysis, subjective survey, port noise, sound characterisation*

1. INTRODUCTION

Sound perception is a multidisciplinary field encompassing medicine, ecology, and architecture. Traditional quantitative methods, such as equivalent sound levels (Leq, LAeq), often fail to capture the emotional and subjective responses elicited by sounds [1]. Psychoacoustics highlights that noise perception is shaped not only by the physical intensity of sound but also by individual interpretations and psychological factors, thus underscoring the importance of adopting a qualitative approach to the study of sound [2].

Language plays a critical role in this process, providing a framework through which sensory experiences are articulated and understood [3]. The words we use to describe sound shape our perceptions of it, reflecting both cultural norms and personal experiences. This understanding is essential for addressing broader issues related to well-being, health, and the environment, particularly in urban areas, where the interplay of these factors significantly impacts the quality of life.

The European Landscape Convention (2000) [4] marked a pivotal moment in recognizing how collective perception shapes the identity of a place. Well before the Convention, attention to environmental perception had already extended beyond the visual to include the auditory dimension. In the 1960s, Michael Southworth and R. Murray Schafer [5, 6] introduced the concept of soundscape, emphasizing that sounds, like visual elements, play a fundamental role in defining spatial experiences.

Despite the growing recognition of the importance of auditory perception, there remains a gap in systematic studies focused on the language used to describe sound.

Understanding the semantics of sound-related terms can provide deeper insights into how we interpret our acoustic environment. This need is particularly evident in multicultural research contexts, where translating sound

perception terms requires sensitivity to cultural nuances for accurate conceptual understanding.

For example, the translation of *quiet areas* into Italian as *zone silenziose* led to restrictive interpretations of noise regulations, distorting the original intent of European legislation. Our study examined linguistic and cultural variations in sound perception through Italian and French corpora, identifying adjectives linked to "rumore" (*noise*) and "suono" (*sound*) in Italian and "bruit" and "son" in French. This analysis revealed how cultural differences shape perceptions of the soundscape.

By analyzing terms within their linguistic context, we gain a more nuanced understanding of sound experiences, helping to avoid misinterpretations and fostering respect for cultural diversity. This study underscores the importance of a culturally informed approach in international research, ensuring that sound perception is represented accurately across different languages and contexts.

Despite advances in sound perception research [7, 8, 9], there is still much to explore regarding the language used to describe sound environments. Our study focused on adjectives associated with noisy and quiet spaces, aiming to provide insights into the terminology that characterizes these environments.

2. METHODOLOGY

This study, part of a cross-border cooperation project between Italy and France [10], aims to enhance the sustainability of commercial ports and their logistics platforms, addressing high noise pollution levels in areas between ports and logistics hubs. These zones, often marked by intense freight and vehicle traffic, present significant acoustic challenges affecting the environment and local quality of life.

The project's primary goal was to create a joint strategy to reduce noise pollution by optimizing traffic flows and minimizing the acoustic impact of logistics activities. Efficient traffic management not only promotes environmental sustainability but also improves livability for nearby communities.

Beyond logistics, the project also focused on the perceptual dimension of the soundscape. Understanding how local populations perceive port and logistics sounds is crucial for supporting policymakers in planning and balancing economic development with community well-being.

Language plays a key role in this context. It reflects the experiences and cultures of communities, shaping perceptions of the soundscape. This study investigates noise perception in port and hinterland areas, combining subjective questionnaire data with objective sound recordings.

The research involved multiple phases: identifying areas of interest, recording characteristic sounds, selecting descriptive adjectives for the questionnaire, and administering it across seven pilot areas.

2.1 Study areas

The study areas include seven locations in different pilot territories: Livorno and Lucca in Tuscany (Italy), Sassari and Porto Torres in Sardinia (Italy), Genoa in Liguria (Italy) and Toulon and La Seyne-sur-Mer in the Var region (France). Each area within the port or retro-port contexts represents a distinct environment shaped by social, economic and natural activities, ranging from industrial sounds to rural noises and port-specific acoustics. The study also includes areas further away from the port, such as Lucca and Sassari. Although these areas are geographically distant, they are significantly affected by port activities, as they serve as key hubs for the traffic and processing of goods. For example, the paper mill districts on the outskirts of Lucca and the industrial area of Sassari highlight how these regions remain closely connected to Livorno and Porto Torres, respectively, contributing to the distinctive soundscape of each territory.

2.2 Recordings

The noise associated with port and hinterland infrastructures is a complex form of acoustic pollution. The noise includes typical port sounds, such as ships and machinery, and noises from surrounding areas, like cranes and road and rail traffic. To capture this complexity, the sounds characteristic of the locations were recorded on-site, and locations that best represented the acoustic profile of each area were carefully selected. For example, we recorded road traffic in Lucca and Toulon to capture the distinct soundscapes of each location.

Up to four sound level meters were used to measure psychoacoustic parameters, while two digital recorders captured 16-bit audio at 44,100 Hz. The recordings were brief, typically lasting a few minutes for constant noises and up to several dozen minutes for more variable sounds. The data analysis involved creating spectrograms and extracting key acoustic events, from which we selected 10-second normalized sound samples. These samples, consisting of sounds like seagulls, crickets, cranes, boarding and disembarking operations, chainsaws, forklifts, level crossings, ship sirens, vehicle traffic, and rail traffic, were later included in the questionnaire.

2.3 Adjectives

This study adopted an approach based on large textual corpora to explore the cultural and linguistic nuances of Italian and French. The primary objective was to collect many authentic examples, an essential condition for developing reliable statistical models that accurately reflect the linguistic peculiarities of both languages. The use of large-scale corpora, as suggested by Sinclair [11], enables a more accurate analysis of lexical distribution and grammatical structures within a given context.

In particular, several linguistic web corpora were used: vast digital archives consisting of texts extracted from various online sources, including journalistic articles, literary works, social media posts, blogs, and other written content. The use of these corpora allowed for an examination of how the language is effectively used by speakers, thus providing a solid empirical basis for linguistic analysis. The methodology adopted aligns with the perspective of Biber et al. [12], who argue that corpora represent a fundamental resource for quantitative linguistic analysis.

The corpora employed underwent a tokenization process, which involves dividing the text into basic linguistic units (words or sentences), followed by lemmatization to normalize each term to its base form (for example, the verb "went" became "go"). Additionally, grammatical annotation assigned each term its corresponding morphosyntactic category, such as verb, noun, or adjective. These operations are essential to ensuring a high-level linguistic analysis, as highlighted by McEnery and Hardie [13].

Incorporating morphosyntactic information into the corpora enabled the extraction of a targeted sample of adjectives and nouns linked to the lemmas "suono"-"son" (*sound*) and "rumore"-"bruit" (*noise)*. Further statistical and linguistic analyses explored these terms, focusing on the most frequent collocations and examining how the two lemmas behave in different usage contexts. This approach follows the perspective of Stubbs [14], who emphasizes the importance of collocations in lexical meaning analysis.

The statistical investigations focused mainly on the data extracted from various linguistic corpora. The analysis of these corpora included absolute frequency, relative frequency, and lemma dispersion. We examined the adjectives from the corpora to determine usage trends and discrepancies. We subsequently applied a reduction process based on linguistic and statistical criteria to streamline the initial set of adjectives. The process included eliminating adjectives with low co-occurrence, normalizing through synonymy and polysemy, and filtering out less relevant elements using linguistic rules. This approach is consistent with the methodologies commonly used in computational linguistics, as highlighted by Kilgarriff and Grefenstette [16].

For Italian, the analysis also included a comparison with data from a preliminary questionnaire administered to a group of students at the University of Pavia [15]. This questionnaire provided additional insights into adjective usage, subsequently compared with the corpus data to examine possible discrepancies and trends specific to the Italian language.

2.4 Questionnaire

The online questionnaire explored participants' acoustic perceptions through three sections. The first collected demographic data, including gender, age, origin, and hearing ability, and allowed participants to select a relevant investigation area, which determined the audio recordings they would hear later.

In the second section, participants described a street in their chosen area, providing personal impressions of its soundscape by selecting adjectives from a predefined set.

The third section involved listening to recordings from pilot locations, identifying the dominant sound source, and selecting adjectives from the same linguistic sets categorized into Evaluation, Strength/Type, and Space/Time, requiring at least one choice per group.

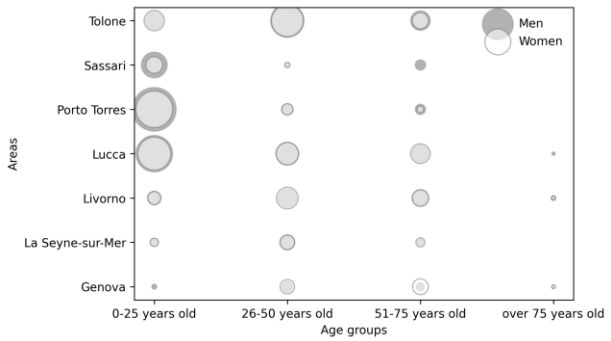

Figure 1. Age groups and areas with gender distinction

The respondent sample, shown in Figure 1, represented the areas under study and ensured demographic diversity. The sample included 46% women and 54% men, with 50% under 25, 32% between 26 and 50, and 18% over 50. Regarding education, 35% had completed high school, 31% secondary school, 9% held a bachelor's degree, and 12% had a master's or higher. A combined 13% had a doctoral degree, vocational training, or only primary school education. Regarding hearing ability, 52% rated their

hearing as excellent, 37% as good, and 11% reported a lower level of hearing, with 1% of this group using a hearing aid. This diversity provided a representative group for sound perception experiences.

3. RESULTS

This study was conducted on both Italian and French. So far, we have discussed findings related to both languages; however, in the following section, we will focus specifically on the results obtained for Italian.

3.1 Initial observations and analysis

In the first section of the survey, participants rated the soundscape of a street of their choice, using a five-point scale ranging from *very quiet* to *very noisy*. They then identified the most relevant sound source from categories including vehicular traffic, railway, airport, port activities, industrial noise, neighbourhood sounds, human activity (daytime or nighttime), and natural or atmospheric elements.

After classifying the street according to these scales, participants selected at least one adjective from a predefined list.

We initially decided to create word sets based on these classifications. As a result, five documents were compiled for noise, one for each noise level and, in the same way, ten for sound sources. A TF-IDF (Term Frequency-Inverse Document Frequency) analysis was conducted, followed by NMF decomposition.

Regarding the first question, we divided the data into five topics, aligning with the five response options. The analysis revealed a clear association between each topic and a specific noise level, identifying distinctive linguistic patterns for each category. We selected only the words with the highest weights, which represented 50% of the total weight, to highlight key descriptors for each noise level.

For *quiet* or *very quiet* places, adjectives like “naturale” (*natural*), “rilassante” (*relaxing*), “sopportabile” (*bearable*), and “innocuo” (*harmless*) suggest a positive and reassuring perception, often linked to natural or domestic settings. In *very quiet* places, words like “soffuso” (*soft*) and “leggero” (*light*) indicate subtle, almost imperceptible sounds that contribute to a peaceful sense of isolation. In *quiet* places, terms like “gradito” (*pleasant*) and “avvolgente” (*enveloping*) reflect a contained and comfortable soundscape.

Conversely, *noisy* and *very noisy* places are associated with adjectives like “eccessivo” (*excessive*), “fastidioso” (*annoying*), and “insopportabile” (*unbearable*), highlighting a persistent disturbance that negatively affects well-being. Terms like “artificiale” (*artificial*), “urbano” (*urban*), and “motore” (*engine*) emphasize a human-made soundscape, often linked to traffic and industry, distancing it from nature. In *very noisy* places, words such as “nocivo” (*harmful*) and “insostenibile” (*unsustainable*) suggest potential health risks.

Overall, these adjectives show that quieter places are perceived as spaces of relaxation and well-being, whereas noisier ones evoke artificiality and discomfort.

We also analyzed the responses regarding the dominant sound source to see if there were correlations between the adjectives used and the identified sources. The results show that each topic aligns with one of the response options, demonstrating a strong correspondence between specific sound sources - such as vehicular traffic, industrial activity, or natural elements - and the adjectives used to describe them.

To better understand the impact of traffic, we analyzed adjectives associated with categories like vehicular, railway, aircraft, and port traffic, identifying distinguishing features for each type of traffic. This analysis highlights variations in perceived noise intensity and the distinctive acoustic traits of different traffic types.

For airport traffic, adjectives such as “crescente” (*rising*), “potente” (*powerful*), “ritmico” (*rhythmic*), “insopportabile” (*unbearable*), and “assordante” (*deafening*) emphasize not only its high volume but also its disruptive and cyclical nature, evoking tension and discomfort.

“Ferroviario” (*railway*) and “ferroso” (*ferrous*) define railway traffic, along with “rumoroso” (*noisy*), “costante” (*constant*), and “artificiale” (*artificial*). These suggest a recognizable but less distinct identity, blending with other urban sounds like vehicular traffic.

Vehicular traffic is associated with a broad range of terms, from “caotico” (*chaotic*), “fastidioso” (*annoying*), and “persistente” (*persistent*) to “quotidiano” (*daily*), “continuo” (*continuous*), and “cittadino” (*urban*). This reflects its omnipresence in city life - both integrated into routines and perceived as intrusive.

Port traffic presents a complex soundscape, combining industrial and natural elements. Adjectives like “marittimo” (*maritime*), “profondo” (*deep*), “chiassoso” (*boisterous*), and “minaccioso” (*threatening*) suggest an intense yet variable acoustic environment.

We then considered the responses identifying natural and atmospheric elements, daytime or nighttime human activity, and the neighbourhood as the primary sources of the evaluated area. Common adjectives, such as “ambientale” (*environmental*), “vivo” (*lively*), “acceptable” (*acceptable*), and “allegro” (*cheerful*), indicate an impact perceived as

predominantly positive or tolerable, suggesting a sense of belonging to the daily context. However, the adjectives associated with each source provide insight into how listeners experience these sources in distinct ways.

Natural and atmospheric elements are described by terms like "naturale" (*natural*), "rilassante" (*relaxing*), and "piacevole" (*pleasant*), evoking a harmonious and calming atmosphere, in stark contrast to urban sources. Words like "avvolgente" (*enveloping*) and "magnetico" (*magnetic*) suggest that these sounds are not only pleasant but also engaging.

For human activity, adjectives such as "notturno" (*night*), "lavorativo" (*working*), and "caotico" (*chaotic*) paint a lively yet ambivalent picture, where some sounds are perceived as intrusive, while others like "colorato" (*colourful*), "divertente" (*fun*), and "festoso" (*festive*) contribute to an enriching social dimension.

Finally, the neighbourhood is associated with adjectives like "domestico" (*domestic*), "tollerabile" (*tolerable*), and "quotidiano" (*everyday*), indicating that neighbourhood sounds are part of daily life, perceived as manageable and non-invasive, creating a sense of familiarity and intimacy.

Overall, the analysis highlighted how each sound source contributes to creating a unique *acoustic footprint*, reflecting the complex interaction between sound, environment, and human perception.

3.2 Creating a vocabulary associated with the value scale: very quiet - very noisy

The previous analysis identified key adjectives for each noise type, focusing on those with the most significant weight in their respective classes.

Next, we aimed to create a vocabulary linked to the scale from *very quiet* to *very noisy*. We focused on identifying adjectives that specifically characterize each noise class. To do this, we analyzed the distribution of adjectives, concentrating on those not overly spread out across multiple groups. We regarded adjectives as specific if they appeared in at most two contiguous classes, reflecting a stronger association with the noise type.

3.2.1 Analysis for identifying significant adjectives by noise class

In 824 Italian questionnaires, participants provided 3,337 adjectives describing the overall soundscape of a road they had selected. On average, participants provided four adjectives for location, with a standard deviation of 6.3 and a mode of 1. The data showed that, generally, participants used only one adjective to describe the sound characteristics, with more adjectives used when the area was considered *very noisy*. Interestingly, only 3% of respondents labelled the area as *very quiet*, and just 3% of adjectives were assigned to this category, making it impossible to identify representative adjectives for *very quiet*. Thus, the analysis focused on identifying significant adjectives for four of the five noise classes.

Out of the 312 adjectives initially proposed, participants selected 261 at least once. After excluding 40 adjectives with infrequent usage, we retained 221 adjectives for further analysis.

Table 1. List of adjectives identified for noise classes

Classes	Adjectives
Silenzioso[1]	Delicato, rilassante, simpatico, tranquillo, usuale
Né silenzioso, né rumoroso[2]	Allegro, banale, bianco, breve, casalingo, casuale, ciclico, discreto, distante, distinto, elettrico, familiare, lento, lieve, limitato, magnetico, marittimo, melodico, meraviglioso, monotono, noioso, normale, occasionale, percettibile, perenne, periodico, potente, sintetico, statico, tenue, tollerabile, udibile
Rumoroso[3]	ansioso, continuo, eccessivo, elettromagnetico, frustrante, inaccettabile, incessante, innaturale, logorante, martellante, metropolitano, percepibile, prolungato, rumoroso, snervante
Molto rumoroso[4]	assordante, insostenibile, roboante

For each adjective, we calculated its relative frequency in each class. We then used these frequencies to compute a

[1] Quiet: gentle, relaxing, sympathetic, peaceful, usual

[2] Neither quiet nor noisy: cheerful, dull, white, brief, homely, casual, cyclical, discrete, distant, distinct, electric, familiar, slow, slight, limited, magnetic, maritime, melodic, wonderful, monotonous, boring, normal, occasional, perceptible, perennial, periodic, powerful, synthetic, static, tenuous, tolerable, audible

[3] Noisy: anxious, continuous, excessive, electromagnetic, frustrating, unacceptable, incessant, unnatural, wearing out, pounding, metropolitan, perceptible, prolonged, noisy, unnerving

[4] Very noisy: deafening, unsustainable, bombastic

weighted average noise index, reflecting the adjective association with different noise levels.
The index is calculated by multiplying the relative frequency of each adjective in a class by the corresponding noise level of that class and then summing these values. This method allows adjectives to be assigned a noise value between 1 (very quiet) and 5 (very noisy) based on how they appear across the different classes. A standard deviation threshold of 0.7, validated by TF-IDF analysis, ensured the selection of the most significant adjectives for each class. The final list includes 55 adjectives, mostly with positive connotations for quiet environments and negative ones for noisy areas. The *neither quiet nor noisy* class was more complex, containing positive and negative adjectives, demonstrating how sound perception depends on noise intensity, context, personal expectations, and emotional experiences. For instance, environments in this category could be described as dull or cheerful, showing that emotional and contextual factors shape sound perception beyond simple decibel measurements.

3.2.2 Analysis of the sounds presented based on the noise scale

In the second part of the questionnaire, participants listened to audio recordings and matched them with adjectives from the first part. We then compared the adjectives assigned to vehicular traffic, railway traffic, and natural elements in the first part with those selected for recorded sounds of traffic, trains, crickets, and seagulls.
The first set of adjectives describes a remembered soundscape with a known source, while the second refers to listened audio recordings with unspecified sources. This distinction reveals how different conditions influence descriptions. Adjectives for remembered soundscapes tend to be broader and influenced by visual elements or personal memories, "gioioso" (*joyful*), "soave" (*sweet*), "magnetico" (*magnetic*), "lento" (*slow*), "atmosferico" (*atmospheric*), "leggero" (*light*), "piacevole" (*pleasant*), for natural elements which integrate an overall mental vision of the soundscape. In contrast, adjectives for heard sounds are more specific, focusing on the perceived characteristics; for example, "breve" (*brief*), "contenuto" (*contained*), "crescente" (*increasing*), "inconfondibile" (*unmistakable*) for crickets and seagulls, indicate how the participants tried to describe concrete and observable properties.
The memory of railway traffic emphasizes general and constant aspects, such as "costante" (*continuous*) and "artificiale" (*artificial*). Terms like "ferroviario" (*railway*) and "ferroso" (*metallic*) highlight its mechanical and metallic nature, while "rumoroso" (*noisy*) reflects a more generic negative perception. In contrast, direct listening elicits a broader and more detailed range of descriptions "breve" (*brief*) and "contenuto" (*contained*), "crescente" (*increasing*), "cigolante" (*squeaky*), "secco" (*dry*), and "brusco" (*abrupt*)). Spatial and temporal terms like "vicino" (*near*), "distante" (*distant*), "circostante" (*surrounding*), and "diurno" (*daytime*) demonstrate how listening engages multiple perceptual dimensions.
A similar trend appears for road traffic. Heard traffic sounds are associated with intensity and spatiality, with adjectives like "atmosferico" (*atmospheric*), "avvolgente" (*enveloping*), "basso" (*low*), and "circostante" (*surrounding*) emphasizing their immersive quality. In contrast, remembered traffic is more influenced by prior knowledge, leading to adjectives such as "nocivo" (*harmful*), "indesiderato" (*undesirable*), "confusionario" (*confusing*), "lavorativo" (*working*), "persistente" (*persistent*), and "innaturale" (*unnatural*), reflecting a broader consideration of its impact beyond sound. Notably, 43% of participants misattributed the vehicular sound to natural or animal sources, influencing their lexical choices and leading to terms such as "naturale" (*natural*), "atmosferico" (*atmospheric*), "avvolgente" (*enveloping*), and "soffuso" (*muffled*), which evoke a sense of tranquility. When, however, the source "traffic" is known, the adjectives become predominantly negative, such as "nocivo" (*harmful*), "dannoso" (*damaging*) and "fastidioso" (*annoying*). That suggests that the perception of sound and the language used to describe it depend not only on the acoustic experience but also on expectations and knowledge of the source.
Subsequently, we applied the classification obtained to position the sounds along a scale ranging from *quiet* to *very noisy*.
Before conducting the analysis, several preprocessing steps were applied. First, since the number of adjectives associated with the different noise classes was uneven, a normalization of the classes was performed, assigning each a weight proportional to the reciprocal of the number of adjectives present, then normalized relative to the total sum of the reciprocals. Second, the adjectives, divided into three distinct groups (Evaluation, Strength/Type, and Space/Time), were weighted to account for differences in size: smaller groups received lower weights, while larger groups were assigned greater weights. Finally, we halved the weight of adjectives belonging to multiple groups to prevent overestimation.
This classification placed seagulls and crickets in the *quiet* category, traffic and railway crossings as *neutral*, and industrial sounds (e.g., crane, chainsaw, ship siren) in the *noisy* category.

A deeper analysis shows that while seagulls and crickets evoke calm, some participants perceive them as "assordante" (*deafening*) in specific contexts. Traffic sometimes appears "rilassante" (*relaxing*) due to misidentification with natural sounds. Noisy sounds, such as trains and cranes, are described as "assordante" (*deafening*) and "incessante" (*incessant*), while workplace sounds like forklifts seem more tolerable.

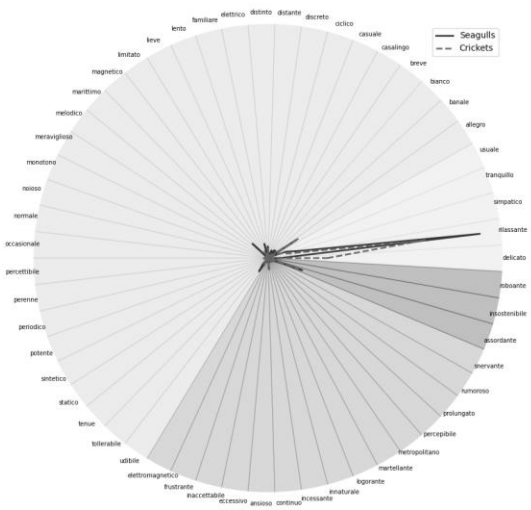

Figure 2. Sounds classified as *quiet* based on adjectives from the *quiet*-to-*very noisy* scale.

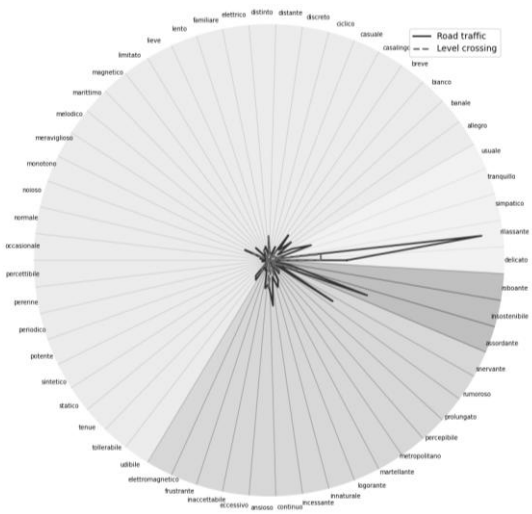

Figure 3. Sounds classified as *neither quiet nor noisy* based on adjectives from the *quiet*-to-*very noisy* scale.

The ship siren and loading/unloading sounds are strongly associated with "marittimo" (*maritime*), reflecting their port context.

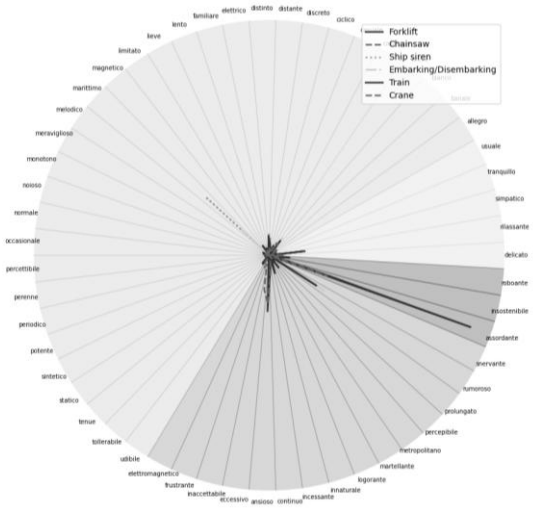

Figure 4. Sounds classified *noisy* based on adjectives from the *quiet*-to-*very noisy* scale.

4. CONCLUSIONS

The study addressed the issue of sound perception in port and hinterland environments, with particular attention to the linguistic description of soundscapes perceived as noisy or quiet. The research stemmed from the need to understand how describing the acoustic characteristics of specific areas requires measurable data, such as decibel levels and qualitative impressions that emerge exclusively through linguistic descriptors. The study adopted a methodological approach that combined questionnaires, linguistic analyses, and audio recordings.

When interpreting the results, it becomes clear that the linguistic descriptors used by participants offer a rich and nuanced representation of sound perception, emphasizing both the degree of noisiness and the emotional and contextual qualities associated with sounds. This variety of adjectives reflects a complex interaction between the physical characteristics of sound and the environmental and social contexts of the analyzed areas.

These observations find a theoretical framework in the concept of soundscape [5, 6], which emphasizes how the sounds of a place, much like visual elements, play a role in defining our experience of space, creating a multisensory dimension that influences both perception and the meaning attributed to landscapes.

A critical aspect that emerged is the role of source awareness: when participants were aware of the sound source, their descriptions often included evaluative and contextual elements, whereas when the source was unknown, they focused more on purely acoustic characteristics. This result reinforces the idea that sound perception is a complex process influenced both by direct experience and by the mental construction of context.
Previous research, such as Raimbault [17], has shown that knowledge of a sound source influences its perceived quality, supporting these findings.
Future research could further explore the role of familiarity and cultural context in the perception and description of the soundscape.
The relevance of this study to the fields lies in its methodological and applicative implications. The main conclusion is that combining qualitative and quantitative approaches offers a more complete understanding of the soundscape, addressing the limitations of relying solely on physical noise measurements. These findings can contribute to developing more perceptually and emotionally sensitive acoustic policies, emphasizing language as a key tool for capturing the complexity of sound perception.

KEY ASPECTS FOR SURVEY DATA PROCESSING AND STATISTICAL ANALYSIS WHEN MODELLING EXPOSURE-ANNOYANCE RELATIONSHIPS

Mark Brink[1*] Beat Schäffer[1] Dirk Schreckenberg[2]

ABSTRACT

In the context of (classical) noise annoyance surveys, the main product of interest is usually exposure-response relationships to inform health risk assessments or policy makers. Surveys conducted for this purpose are becoming increasingly complex, raising the question of what the key aspects in terms of data processing and statistical analysis are, that allow valid and representative exposure-response functions to be derived from the data collected. In this talk we will look at relevant decisions at different stages of analysis and illustrate their impact, in parts using data from the NORAH and SiRENE noise annoyance surveys as examples. The focus is on the necessary data processing and statistical considerations when aiming at statistically sound predictions of the percentage of 'highly annoyed' (%HA) as a function of noise exposure, alongside potential further predictors. The paper touches on the issues of (a) the explanatory or predictive approach related to variable selection and modelling, (b) the use of survey weights or not, (c) the proper handling of cases with low or missing exposure values in survey samples, (d) population-averaged vs. subject-specific responses and (e) the treatment of non-focal predictors when plotting exposure-response curves.

Keywords: noise annoyance, exposure-response relationship, statistical modelling

1. STARTING POINT

Annoyance is one of the most widespread immediate and long-term effects of transportation noise exposure, and this outcome has always played a pivotal role in informing policy, carrying out environmental impact assessments, or setting noise limits. All these goals require solid and valid exposure-response functions, which are derived from the data of so-called socioacoustic surveys. Most common statistical techniques to derive these functions are generalized linear (mixed) models. Corresponding model parameters are used to predict the outcome (mostly, the percentage highly annoyed, %HA) for a given level of noise exposure, which can be visualized in exposure-response curves (i.e., graphical representations of the exposure-effect relationship). Even though statistical analyses are *the* crucial part in the processing of data from socio-acoustic studies to derive exposure-response relationships, the steps to arrive there are usually hardly questioned out of habit – although there are various important decisions to be made regarding how to proceed in each particular case. While the things that are usually decided during the planning/conceptualization phase of a survey, such as sampling strategy, stratification, the way the questionnaires are presented, survey mode, response scales used etc., are of course crucial factors for the final result (cf. for example [1, 2]), the focus of this conference talk is basically on what happens *after* data collection. The talk covers the following points:

(1) The decision for an either explanatory or predictive approach related to variable selection and modelling

(2) Whether to use survey weights in the data prior to inferential statistical modelling
(3) The proper handling of low and missing exposure values in survey samples (censoring vs. truncation)
(4) The choice of modelling population-averaged or subject-specific exposure-response relationships (in the case of longitudinal surveys)
(5) The treatment of non-focal predictor variables when plotting exposure-response curves.

The present short paper is a brief preview of the conference talk. Our thoughts on the above topics will be consolidated in a journal paper containing a more extensive discussion and detailed recommendations.

2. BRIEF ROUNDUP OF COVERED POINTS

2.1 Aspect #1: Purpose of an annoyance survey: Explanation versus prediction

We argue that the distinction between predictive and explanatory approach is key when analysing data from socioacoustic surveys. Is the goal of the study to obtain, from amongst a large collection of variables, a set which best predicts the outcome variable? Or is the goal to estimate the association between a risk factor (i.e., exposure or treatment variable) and the outcome? Indeed, this principal decision should be taken even before designing a survey as it affects every aspect of model construction and evaluation thereafter. Just look back at your own career: you will find introductory texts from term papers to theses to maybe even the first peer-reviewed articles later on, where your research goals were rather vaguely described, perhaps in the sense of "by this research we aim at a *better understanding* of the association between x and y" or "this research wants to *examine* the factors that influence x"... things of that sort (by the way, we are no exception). A very basic question that should be answered before the set-up of any noise study (and even more so before the analysis begins) is whether the research pursues a *descriptive* goal (summarizing characteristics), a *predictive* goal (forecast effects [of noise, and maybe additional variables]), or, whether the goal is *explanatory* (unravel causal mechanisms). Various statisticians have pointed out the importance of this distinction [e.g. 3]. When it comes to environmental impact assessments, the explanatory ("risk factor") approach is perhaps the least cumbersome because it leads to more easily interpretable exposure-effect curves.

2.2 Aspect #2: Should one use survey weights?

In response to a request from a colleague, we deal with the question of whether case weighting may have an advantage in socio-acoustic surveys or not. For purely descriptive purposes, where the aim is to achieve the highest possible representativeness for the population, the weighting of sample data is widely accepted. For analytical conclusions about model parameters, however, there is a wide range of opinions about the role of sample weights among statisticians. We concluded that it is better to avoid weighting and stick to the original data when inferential statistical questions are in the foreground. The disadvantage of weighting is that it moves the data away from what has actually been empirically observed. And experience shows that the more data have been processed, the more difficult it becomes to understand what they represent. Also, results based on a weighted data set can be more difficult to interpret or communicate to stakeholders, especially if the weighting factors are complex or not well known.

2.3 Aspect #3: How to handle cases with low and missing exposure values?

Standard uncertainties in noise exposure assessments are larger at lower exposure levels than in the vicinity of infrastructure (roads, railways, airports) where the respective noise levels are higher. For some of the receiver points in a sample, the noise levels may even fall outside the calculation grid and thus are completely missing. This is often the case in socio-acoustic surveys, in which several noise sources are examined simultaneously in the same sample, but where not all noise sources are present at each receiver. Further, modelled exposure values may be so low that they may not actually be perceptible in "real life" with other ambient sound sources [4]. This raises the question of how low the bottom of an exposure-response function should be for a particular noise source and whether cases with very low or missing exposure values should be a) included in the analysis, b) replaced by a specified value (censoring), or c) excluded from the analysis altogether (truncation). In the talk, we discuss these alternatives and come to a fairly clear judgment, namely, that the inclusion of essentially unexposed cases has the potential to bias the resulting exposure-response curve. We therefore recommend that, given the weaknesses in exposure estimation at low exposure levels, cases with exposure levels below some 30 to 40 dB (L_{den} or L_{Day}) should be excluded from the analysis. This may limit the number

of cases available, but will lead to better, i.e. more representative %HA predictions, especially at higher exposure levels.

2.4 Aspect #4: GEE vs GLMM modelling

The primary product one usually has in mind when carrying out socio-acoustic surveys are noise exposure-response relationships which are important for predicting the effects of noise on individuals and populations. In the case of %HA-research, such relationships can be derived from independent (this means: non-nested and non-hierarchical) or, – admittedly – less often, repeated binary observations ("repeated measures"; e.g. in laboratory listening studies/experiments). As long as the binary observations are independent, a "standard" logistic regression analysis is applied, which yields so-called population-averaged exposure-response relationships that are directly applicable in risk assessment on the population level. However, if data from repeated binary observations are collected, one needs to account for the correlation of the data within individuals. Possible approaches to do so are generalized linear mixed models (GLMM) [5] or generalized estimating equations (GEE), [6]. We thoroughly discuss the two options of deriving exposure-response relationships in longitudinal or repeated measures studies, namely, the population average versus subject-specific prediction, that can be achieved with the GEE and GLMM modelling approaches, respectively.

2.5 Aspect # 5: Treatment of non-focal predictor variables when plotting exposure-response curves

For most use cases, socioacoustic surveys are carried out to describe or indeed, predict the association between some amount of noise exposure and a corresponding health effect. The minimum set of variables that is needed for this is an exposure variable, here L_{den}, and an effect variable, here HA. However, most survey designs are more complex, and modelling involves additional variables such as level-2 variables in hierarchical (multilevel) designs and/or additional covariates and/or confounders. Regardless of the number of predictors in the model, one can just use two dimensions to describe the relationship between exposure and effect in a graphically simple (two-dimensional) exposure-response plot with the so-called *focal term* (e.g. L_{den}) on the x-axis and the outcome on the y-axis. This requires all *non-focal terms* (non-focal predictors in the model) to be fixed (kept constant) at a certain value. For continuous predictors, this is often (but not necessarily) the sample mean. If categorical variables with multiple levels are involved, e.g. "gender", or "school", it is not immediately evident how to "average" over them, especially when the group sizes are different. We show in detail which methods of marginalization of non-focal predictors are possible when it comes to draw exposure-response curves for %HA (or similar outcomes). We will particularly shed light on *empirical average* and *estimated marginal means* prediction.

Of course, we cannot – for all the aspects mentioned above – give an unequivocal recommendation in every case for or against a specific way of action. However, we believe it is important that our peers from the field of noise effects research are aware of the issues and pitfalls we raise in the talk, and that they can overcome them by making well-informed decisions. We hope that our soon to be published full paper on the topic will prove to be a useful resource for this decision-making process.

EXPLORING THE ACOUSTIC ENVIRONMENTS OF BARCELONA'S SUPERBLOCKS: PERCEPTIONS FROM SOUNDWALKS

Aline Ramos Esperidião[2],[1*] **Andrea Potenza**[3] **Ester Vidaña-Vila**[1] **Marc Freixes**[1]

ABSTRACT

The Superblock proposal in Barcelona is a strategy for urban intervention that aims to promote lower traffic density, increased green spaces and quiet areas, thereby improving the health and well-being of citizens. Consequently, it can serve as a valuable case study for testing tools for soundscape assessment, as it provides a unique acoustic environment. To evaluate it, soundwalks were conducted in the Poblenou, Sant Gervasi, and Sant Antoni Superblocks. This study examined the similarities among these three locations in terms of how people perceive the quietness and sounds in each area. Subjective data were obtained through questionnaires with a 5-point Likert scale and multiple-choice questions. The results showed that Sant Gervasi and Sant Antoni Superblocks were not considered quiet areas by the participants, although birds and vegetation contributed positively to the sense of quietness in the first location. In Poblenou, the quietest point is related to the promotion of social interaction. The findings of this study can be used to plan new superblocks and analyze their effectiveness in promoting a better acoustic environment in the city.

1. INTRODUCTION

Proposals to rethink urban environments based on enhancing proximity relations have been extensively discussed across various fields of study. Notably, global cities such as Paris, Milan, and Barcelona are striving to place citizens at the center of urban planning [1]. Furthermore, it not only aims to alleviate the negative impacts of urban congestion but also seeks to foster a healthier environment for residents.

These cities are promoting active mobility and reducing reliance on private vehicles through measures aimed at mitigating air and noise pollution. This approach aligns with the implementation of the "proximity city" concept, which seeks to create more accessible and sustainable urban spaces put all citizens at the centre [2].

In Barcelona, the Superblock proposal represents a comprehensive urban intervention strategy designed to reduce traffic density, enhance green spaces, and create quieter zones [3, 4]. The superblock is a spatial unit consisting of nine blocks, forming a square of (400x400) m, delineated by a network of primary roads that connect various origins and destinations throughout the city. When this unit is replicated within the urban framework, its dimensions are adapted to accommodate the morphological and functional characteristics of the existing city [5].

This approach maximizes the availability of public space, which is currently dominated by vehicular traffic, while simultaneously ensuring the system's functionality and organization. By prioritizing pedestrian accessibility and promoting active forms of mobility, the Superblock approach encourages community engagement and social

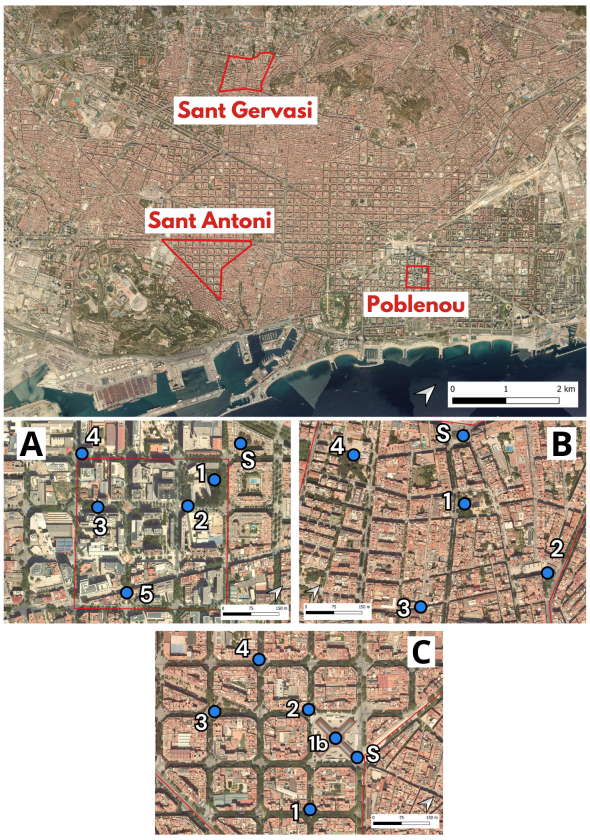

Figure 1. Three Superblocks analyzed (above) and the three soundwalks stops: A) Poblenou B) Sant Gervasi C) Sant Antoni.

interaction [3, 4]. The boundaries of the Superblock are defined by the primary roads, where through and connecting traffic is permitted to travel at a maximum speed of 50 km/h. In contrast, the interior roads (intervias) of the superblock form a local network with speed limits of 10 or 20 km/h, facilitating shared urban uses [4, 5].

The initial three superblocks were implemented between 2016 and 2019 in the neighbourhoods of Poblenou, Sant Antoni, and Horta. These interventions yielded benefits such as improved opportunities for rest, reduced noise levels, and decreased air pollution [4]. Consequently, these areas became quieter, fostering enhanced interactions among residents [3]. Over the years, other superblocks have been implemented in neighborhoods such as Sant Gervasi, Hostafrancs and Sagrada Familia [4]. This strategy is intended to enhance the overall well-being of citizens, contributing to health benefits [3,6] and a more sustainable and livable urban landscape [7].

In this context, the proposal of superblocks aligns with the necessity to enhance soundscapes through an understanding of the perceived acoustic environment. The purpose of quiet areas is to safeguard human health against noise annoyance and sleep disturbances—psychological factors that cannot be quantified using physical measuring instruments [8]. Only an assessment of how people perceive a quiet area can provide these insights. Considering that, superblocks may be a valuable source of information for the assessment of the sound environment, as they foster a distinct acoustic setting within the city.

For this purpose, were performed soundwalks, a conventional method for data collection in soundscape research, which offers a qualitative overview of typical methodological approaches in this field [9]. Therefore, the aim of this study is to examine the similarities among Poblenou, Sant Gervasi and Sant Antoni Superblocks in

Figure 2. Three Soundwalks (from left to right): A) Poblenou - participants listening to the soundwalk instructions at Ada Byron Square (point S); B) Sant Gervasi - acoustic measurements being taken at *Jardins de Vil·la Florida* (point 1); C) Sant Antoni - intersection of Parlament and Comte Borrell Streets, both pedestrianized (point 1).

terms of how people perceive the quietness and sounds in each area.

2. METHODOLOGY

To evaluate each location, one soundwalk was conducted in each Superblock: Poblenou, Sant Gervasi and Sant Antoni (Figures 1 and 2). The structure of the soundwalks was detailed in each starting point (S), with an introduction to the activity in the field and a description of its purpose. Each soundwalk was designed to cover a length of 1.3 to 1.7 km. Each route was predefined incorporating 4 to 5 quiet areas. Participants were guided along the designated route, making stops at the identified quiet areas. At these locations, they were encouraged to engage in active listening to the surrounding environment for a duration of 1 to 3 minutes in silence. After listening, the soundwalk participants were requested to assess their experiences using a questionnaire that included open entry, multiple choice and 5-point Likert scale questions, to measure different aspects of the acoustic environment.

In total, a sample of 21 participants voluntarily participated in three soundwalks: 12 at Poblenou, 7 at Sant Gervasi and 2 at Sant Antoni. The participants were asked to evaluate the soundscape and express their perceptions using Hush City App [10]. Respondents answered questions concerning about what people were doing around, and evaluated the overall quality, cleanliness, maintenance, security and accessibility of each point. Related to acoustic environment, respondents answered the questions shown in Table 1 and L_{eq} values were collected at each stop via smartphone through the App. The subjective data collected were analyzed through descriptive statistical analyzes and qualitative data analyzes.

2.1 Poblenou Superblock

The first soundwalk was conducted in the Poblenou neighborhood, which has undergone significant transformation in recent decades, evolving from an industrial zone into a residential and commercial district, while still retaining several areas of undeveloped land [11]. In September 2016, the Poblenou Superblock was established within the perimeter formed by Badajoz, Pallars, Llacuna, and Tànger streets [4]. The soundwalk was conducted in the fall of 2019 (27 September) at 3:00 pm.

The proposal involves a guided walk through the Poblenou Superblock, with stops at five listening points, beginning at Ada Byron Square (point S), a quiet area situated near the first street of the Superblock.

Point 1 is located within the Superblock, in a green space between the Can Framis Museum and a roadway. Point 2 is positioned between this museum and the Flor de Maig School. This street has been pedestrianized, converting it into a public space for community use.

Point 3 is situated in an office area where enhancements have been made, including resurfacing the ground and installing benches and tables, attracting office workers during lunch breaks. Point 4 is found in the border of the Superblock, adjacent to a busy road where traffic noise dominates the soundscape. Finally, point 5 is near one of the access points to the Superblock, where road traffic noise remains a significant presence.

Table 1. Variables and questions used in this research.

Variables	Questions
Participant emotional status	What prompted you to record this sound?
Quietness of the soundscape	Rate how quiet the soundscape is in this location
Sense of quietness	Sounds that contribute positively to your sense of quietness
Social interaction	Do the sounds promote social interaction?
Conversations	Do the sounds encourage you to have conversations here?

2.2 Sant Gervasi Superblock

Sant Gervasi is a residential neighborhood known for its green spaces, such as *Parc de la Tamarita* and *Jardins de Vil·la Florida*. The soundwalk was conducted in the spring of 2021 (29 April) at 4:00 pm. The starting point (S) is located at the center of Bonanova Square, where Sant Gervasi de Cassoles Street begins, characterized as a semi-pedestrianized thoroughfare. Point 1 is situated in the park between Muntaner Street and Sant Gervasi de Cassoles Street, known as *Jardins de Vil·la Florida*.

Point 2 is positioned at the center of the square adjacent to the Mercat de Sant Gervasi, specifically in Frederic Soler Square. Point 3 is located at the intersection of Sant Marius Street (semi-pedestrianized) and Muntaner Street.

The path to point 4 extends outside the Superblock, traversing primarily through usual streets, such as Mandri Street. Point 4 is found in a highly regarded tranquil area of the neighborhood, known as Can Altimira Gardens.

2.3 Sant Antoni Superblock

Sant Antoni is a neighborhood of the Eixample district, close to the old city centre, and famous for its market which has recently been renovated [5]. The work carried out in this Superblock is the result of a dialogue process with local residents, merchants, and community organizations that began in February 2017 [4]. The soundwalk was conducted in the fall, on 17 November 2020 at 4:30 pm.

The starting point (S) is located in the final section of Ronda Sant Antoni, near the Sant Antoni Market, one of the largest markets in the city. Point 1 is situated at the intersection of Parlament Street (pedestrianized) and Comte Borrell Street (also pedestrianized). Point 1b is inside of Sant Antoni Market.

Point 2 is positioned in the center of the Superblock, at the crossing of Tamarit St. and Comte Borrell St. Point 3 is in a pedestrianized area, yet close to a road with traffic, located at the intersection of Tamarit St. and Calabria St., marking one of the borders of the Superblock.

The route to point 4 extends outside the Superblock, passing through "normal" streets; however, point 4 is back within the Superblock, at the intersection of Viladomat Street and Floridablanca Street.

3. RESULTS

3.1 Poblenou Superblock

Participants were asked what activities the other people present at the location were doing, with the majority of responses indicating "passing through" or "talking", and, in point 1, "relaxing" was highlighted.

In Poblenou Superblock (PB), when asked what prompted them to record the sound (Table 2), points 1, 2, and 3 were primarily characterized by the participants as associated with "comfort", "calm" and "interest". In contrast, point 4 was predominantly characterized by "disgust", "irritation", and "distraction", while point 5 was identified with "distraction", "disgust" and "interest".

Therefore, points 1 and 2, identified as the quietest, were more closely associated with promoting social interaction and encouraging conversations (Figure 3). Conversely, points 4 and 5, which were less quiet, showed a weaker correlation with these factors.

Regarding sounds that positively contribute to a sense of quietness (Figure 4), "bird songs" at point 2, "leaves moved by wind" at points 1, 3, and 5, and "speech" at points 4 and 5 were particularly notable, although the latter were considered the least quiet among them.

Furthermore, participants evaluated how quiet each point was on a scale from 1 to 5, where 5 represents "very quiet". It was observed that points 1 and 2 exhibited the highest average scores (3.5 and 4.2, respectively), whereas point 4 was the least quiet, with an average score of 2, as confirmed by L_{eq} smartphone measurements (Figure 5).

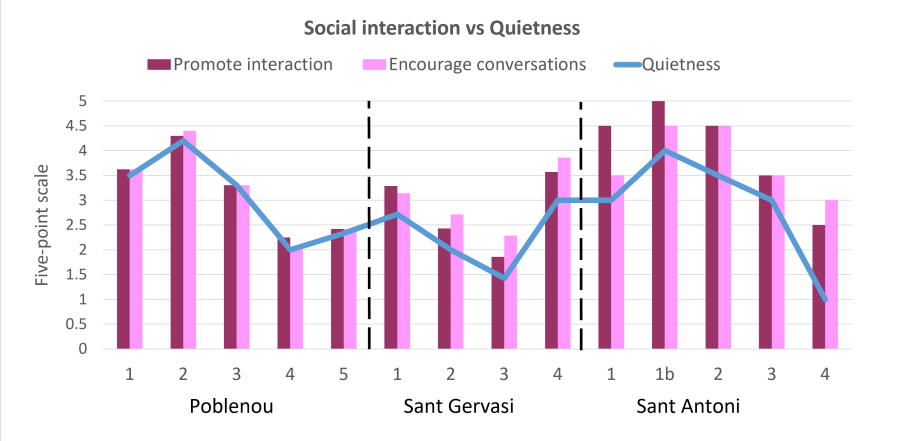

Figure 3. Answers to: To what extent do the sounds in this location promote social interaction and encourage conversations? - graph counting answer occurrance and plotted to get a 100 percentage on each bar.

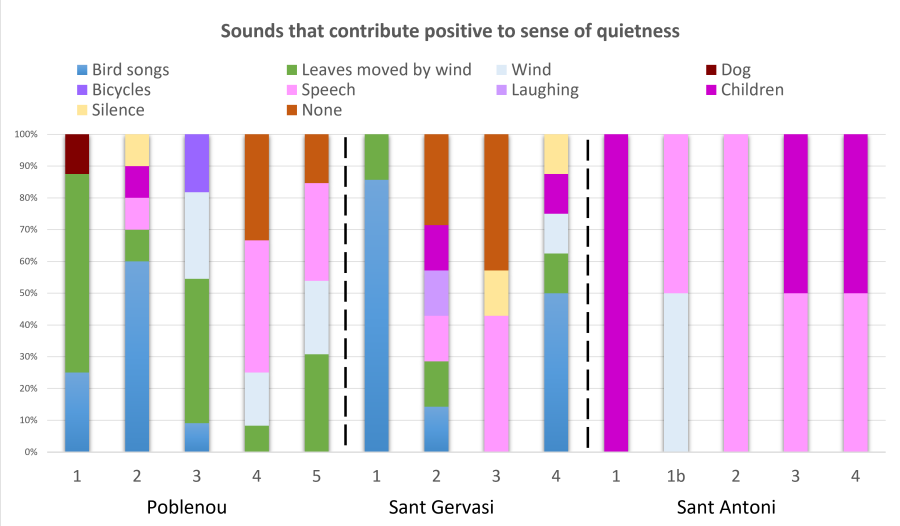

Figure 4. Answers to: Sounds that contribute positively to the sense of quietness - graph counting answer occurrence and plotted to get a 100 percentage on each bar.

Therefore, it was observed that in Poblenou Superblock, the sense of quietness is associated with green spaces (such as point 1), and pedestrianization of the street (point 2) has also contributed to a quieter environment, encouraging social interaction. However, points 4 and 5, characterized by higher traffic noise, caused feelings of irritation and disgust among the participants.

3.2 Sant Gervasi Superblock

In Sant Gervasi (SG), responses indicated that individuals were passing through, talking, and relaxing, but other activities also emerged, such as recreation, playing, and reading. When asked what prompted them to record the sound (Table 2), point 1 was characterized by feelings of distraction, comfort, and calm. Point 1 is located in *Jardins de Vil·la Florida*, recognized as one of the more

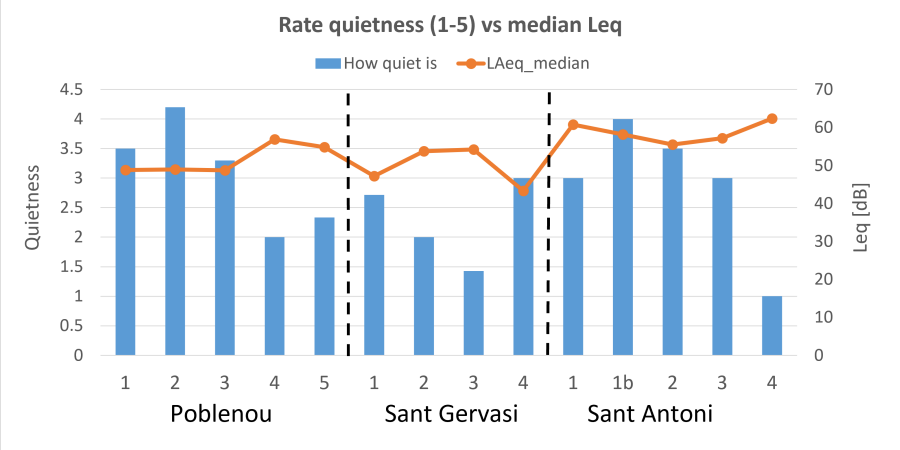

Figure 5. Answers to: mean Rate the quietness (1-5) vs median L_{eq} measured by smartphones.

tranquil areas in the neighborhood.

Point 2 also revealed distraction, along with irritation, which is interesting since this stop is located in a small square with a small park with a children's playground, adjacent to a market (Frederic Soler Square).

Point 3 was associated with irritation, anxiety, and distraction. This point marks the intersection of "quiet" area with a broader street that features ample pedestrian walkways. This segment of the Superblock has seen fewer interventions compared to others, but is home to several stores, bars, and restaurants. Point 4, a green space characterized by silence and tall trees, featuring a small bridge for crossing and recreational activities (Can Altimira Gardens), was primarily linked to distraction and enjoyment.

Participants evaluated the quietness of each point (Figure 5) on a scale from 1 to 5, with the highest score being 3 at point 4 and the lowest score of 1.43 at point 3, indicating that this area was not considered quiet by the participants.

Regarding the promotion of social interaction and encouragement of conversations (Figure 3), point 4 stood out compared to the others.

Finally, bird songs positively contributed to the sense of quietness (Figure 4) at points 1 and 4, while the sound of leaves moving in the wind was noted at points 1, 2, and 4. Speech was particularly prominent at point 3, and children were also mentioned at points 2 and 4.

Therefore, in Sant Gervasi Superblock the sense of quietness is associated with green spaces (point 1 and 4). However, points 2 and 3, characterized by closed proximity to trafficked roads caused feelings of distraction and disgust among the participants. On the other hand, bird songs and moved vegetation produces positive sensation to people.

3.3 Sant Antoni Superblock

In Sant Antoni (SA), responses also indicated that individuals were passing through, talking, or relaxing. The Sant Antoni Superblock is situated in a highly commercial area of Barcelona (Eixample) and encompasses one of the largest markets in the city. When asked what prompted them to record the sound (Table 2), point 1 was associated with feelings of comfort, pleasure, surprise, and fun. Point 1b was characterized by calmness, nostalgia, and comfort, probably related to the market. Point 2 elicited feelings of comfort, calm, distraction, and pleasure. This area features a spacious environment adjacent to the market, while still accommodating local residents in terms of traffic flow.

Point 3 was associated with pleasure, irritation, and calm. This point is designated as a pedestrianized zone; however, it remains in close proximity to a roadway with vehicular traffic. While point 4 was primarily associated with disgust, distraction, and irritation, which involves interventions on two of the four surrounding streets to improve accessibility for pedestrians. Although Calabria Street continues to experience traffic and is not pedestrianized, this area has been adapted for urban life in a calming manner. It predominantly hosts conventional retail outlets and features a large square for public use.

The participants evaluated how quiet each point was

(Figure 5) on a scale from 1 to 5. Points 1 and 3 had an average score of 3, with point 1b recording the highest average score of 4, followed by point 2 with an average of 3.5. The lowest value was observed at point 4, with an average score of 1, indicating that the area was not quiet. Furthermore, it was observed that points 1, 1b and 2 were more closely associated with promoting social interaction, while points 1b and 2 were related to encouraging conversations (Figure 3).

Table 2. Participants' results to the question: What prompted you to record this sound?

Location	Stop	Emotional status
PB	1	Calm (5), Comfort (4), Interest (2)
PB	2	Comfort (6), Calm (6), Interest (3)
PB	3	Comfort (4), Calm (3), Interest (3), Disgust (2)
PB	4	Disgust (5), Distraction (4)
PB	5	Distraction (5), Interest (2), Disgust (2)
SG	1	Comfort (3), Distraction (3), Calm (2)
SG	2	Distraction (4), Disgust (1)
SG	3	Distraction (2), Disgust (1)
SG	4	Calm (4), Distraction (3), Comfort (2)
SA	1	Comfort (1)
SA	1b	Calm (2), Comfort (1)
SA	2	Comfort (2), Calm (1), Distraction (1)
SA	3	Calm (1)
SA	4	Disgust (2), Distraction (1)

Regarding sounds that positively contribute to a sense of quietness, children were notably present at points 1, 2, and 3, while speech (people talking) was significant at points 1b, 2, and 3 (Figure 4).

Although numerous streets are pedestrianized, the Superblock does not conform to the traditional shape associated with such developments and is primarily concentrated around Comte Borrell Street and the Sant Antoni Market.

3.4 Discussion

Although the L_{eq} values are similar between the Superblocks (with Sant Antoni's being slightly higher), it is observed that Sant Gervasi was perceived as the least quiet by the participants, although birds and the sound of leaves moving in the wind contributed positively to the sense of quietness. This result was unexpected, considering that two of the four points are located in green areas, which are generally presumed to be quieter. However, this result could be partially explained by the presence of an adjoining road to the park at point 2 that may have caused "distraction" and "disgust" feelings. This relation is also evident in the fourth points of Poblenou and Sant Gervasi which are located at the edge of the Superblock and are exposed to traffic. This relation is observed in [12] where a significant relationship is reported between L_{eq} and the perceived annoyance of traffic noise.

However, there are some cases where, even if the L_{eq} values were similar to those points or slightly inferior, the soundscape of the stop was perceived as positive using adjectives such as "comfort", "calm" and "interest"; it is the case of points 1 to 3 of Poblenou, 1 in Sant Gervasi and 1 to 3 in Sant Antoni. This relation was also found by [13], underlying the differences between objective measure and people's perceptions and the role played by other sound sources (birds and leaves) and visual pleasantness.

In the case of Sant Antoni Superblock, no biophonies or geophonies were assessed as positive contributors to the sense of quietness. This may be due to the absence of parks in the area, but also to the low number of participants; for this reason, another soundwalk will take place in Sant Antoni to better assess its soundscape. It was also observed that the quieter points were more conducive to promoting social interaction and encouraging conversations. Furthermore, the presence of people talking did not negatively influence the sense of quietness.

4. CONCLUSIONS

This study examined the similarities among these three locations in terms of how people perceive the quietness and sounds in each area. The findings of this study can be used to plan new superblocks and analyze their effectiveness in promoting a better acoustic environment in the city.

The results underscore the importance of understanding the perceptions of individuals of acoustic environments, providing essential information for planning new superblocks and promoting improved acoustic conditions within the city. Assessment while participants were still at the specific location allowed them to better express their perceptions of the acoustic environment. Furthermore, understanding citizens' perceptions of the soundscape allows for a more accurate comprehension of the acoustic environment.

As a limitation of the research, there were few participants in the soundwalk conducted in Sant Antoni Superblock, once it was a pilot study of the route. Nevertheless, the validity of the data is corroborated by the acoustic measurements collected. Further studies could reapply soundwalks in the Superblocks to conduct comparative analyzes over time.

5. ACKNOWLEDGMENTS

The authors would like to thank the Departament de Recerca i Universitats (Generalitat de Catalunya) under Grant Ref. 2021-SGR-01396 for the funding of HER (Human-Environment Research) research group. Also, this study was financed in part by the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior - Brasil (CAPES) - Finance Code 001.

ABSTRACT

The growing demand for offshore wind energy has driven a rapid increase in wind turbine size and the development of large-scale wind farms, often comprising more than 100 turbines. However, the environmental impact of underwater noise emissions remains largely unaddressed. The Off-coustic project (ERC Consolidator Grant Ref. 101086075) develops numerical methods and experiments by integrating wind turbine noise prediction techniques to predict the wind turbine acoustic footprint.

Here, we present an approach to calculating the transmission of aerodynamic noise into underwater acoustics, taking into account the air-water impedance and the penetration angle (governed by Snell's law). Our calculations show that aerodynamic noise from offshore wind farms may affect marine life. In addition, we present the capabilities of our solver, HORSES3D, to simulate wind turbines in offshore environments. This solver will soon be capable of simulating acoustics in offshore environments.

1. INTRODUCTION

The rapid expansion of offshore wind energy has led to large-scale wind farms with more than 150 turbines (1). Although turbine designs prioritise power output (2; 3; 4), their acoustic emissions remain largely unexamined. Aerodynamic noise from the blade trailing edge and blade-turbulence interactions is well studied for onshore turbines, but remains unexplored offshore. Aerodynamic noise scales with rotor diameter (D^5) and aggregates between turbines ($\sim 20\log_{10}(N)$) (5; 6). Although prior research focused on mechanical noise (7; 8; 9; 10; 11; 12), the transmission of aerodynamic noise in water is still poorly understood. Governed by Snell's law, only sound waves within $\sim 13°$ of normal refract into water, with further attenuation due to impedance differences. However, offshore wind farms can generate detectable underwater noise, raising concerns for marine species dependent on sound (13; 14; 15; 16).

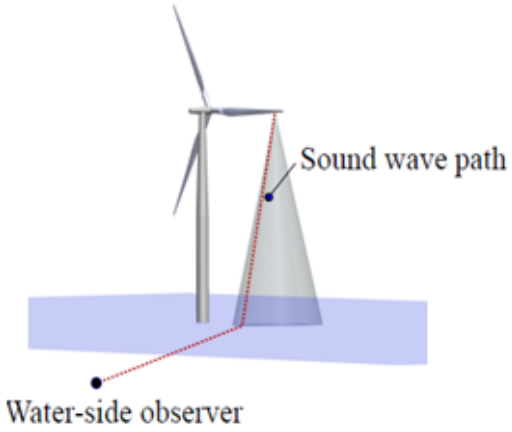
In response to this emerging environmental challenge, the *Off-coustic* project introduces a novel methodology that merges advanced aerodynamic noise prediction techniques. This framework enables estimation of the underwater noise levels generated by large offshore turbines and their assemblies. By quantifying the acoustic footprint and comparing it with the auditory thresholds of diverse marine species, our approach offers insights into the environmental impacts of offshore wind energy and paves the way for noise-mitigating design strategies.

2. ACOUSTIC UNDERWATER FOOTPRINT OF AEROACOUSTIC NOISE

2.1 Acoustic analysis

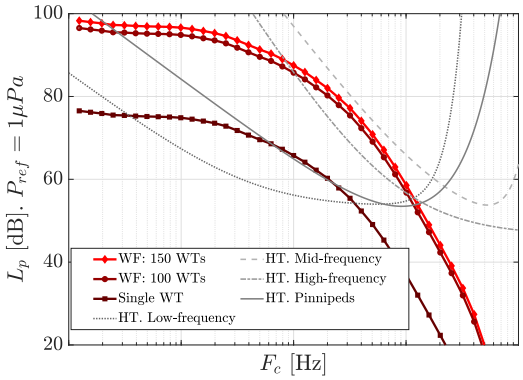
Aerodynamic noise is the dominant noise source in modern wind turbines, generated by the turbulent interaction of flow with blades (17). This noise comprises two main components: leading edge noise (LE) from the impingement of atmospheric turbulence on the blade front and trailing edge noise (TE) from the interaction of the turbulent boundary layer with the finite trailing edge. Due to the wide range of turbulent scales—from hundreds of metres in the atmosphere to millimetres along the blade—this noise exhibits a broadband spectrum that can affect marine species with different hearing thresholds.

The turbine blade is divided into n segments, each modelled as a two-dimensional airfoil. For each segment, LE and TE noise are computed as uncorrelated sources using Amiet theory (18; 19) (with corrections for finite chord effects (20)). The overall blade noise is obtained by summing the contributions from all segments and applying a Doppler correction to account for the motion relative to the observer. The transmission of sound from air to water is governed by Snell's law, which confines the effective propagation to a narrow cone (approximately 13°relative to normal); see figure 1a. In addition, we account for the transmission loss across the air-water interface (due to the change in media), which is 29.5 dB. Underwater propagation is modelled via cylindrical spreading, while atmospheric attenuation (21; 22). Finally, for a wind farm consisting of N turbines, the overall noise level scales as $10\log_{10}(N)$ when each turbine is considered an uncorrelated noise source. This framework provides a concise method for predicting aerodynamic noise emissions and their potential impact on marine life.



We consider the IEA 22 MW (5). The IEA 22 MW offshore wind turbine represents a significant advancement in turbine design for large-scale energy production. It features a hub height of 170 m and a massive rotor diameter of 284 m, which enables it to capture more wind energy even at relatively low wind speeds. The turbine is designed to operate at a nominal wind velocity of 11.78 m/s, with a rotor angular velocity of 7.1 rpm. This results in a high blade tip speed of 102.0 m/s, ensuring efficient aerodynamic performance. In addition, the turbine employs a blade pitch of 6.6°, which is crucial for optimising power output and reducing aerodynamic loads.

Figure 1 shows the far-field aerodynamic noise spectra generated by a single wind turbine and groups of 100 and 150 wind turbines for each case, compared to the hearing thresholds of various functional hearing groups, i.e., low-, mid-, and high-frequency cetaceans and pinnipeds (14; 23; 24). The figure shows that aerodynamic noise from the three wind turbines affects the low-frequency hearing group even when considering only a single wind turbine. When considering farms, the figure shows that a group of 100 turbines causes a general increase in the amplitude of aerodynamic noise spectra, with a footprint underwater of 25 dB louder than the hearing threshold of some marine animals, for the 22 MW wind turbine. In these cases, the aerodynamic noise of offshore farms is much larger than the hearing threshold of several groups of marine species, which can potentially mask the natural sound present in the environment. Further details of the methodology and analysis of other turbines can be found in our paper (25).



2.2 Simulations using the high order solver HORSES3D

Having identified a potential problem, our aim is to develop accurate tools that allow deeper studies. We are currently developing the open source solution HORSES3D (26; 27; 28) at the ETSIAE-UPM School of Aeronautics in Madrid, and available on Github (`https://github.com/loganoz/horses3d`). This solver is a high-order discontinuous Galerkin (DG) tool capable of addressing a wide array of flow applications. These applications encompass compressible flows, incompressible flows, multiphase flows, and aeroacoustics, see Figure 2. Furthermore, HORSES3D is equipped to manage body-fitted, immersed boundaries, and actuator lines.

One of the main advantages of DG methods is their ability to accurately capture high-order spatial and temporal variations of the solution, which makes them particularly suitable for simulating flows with sharp gradients and complex flow phenomena. DG methods also exhibit good numerical stability and conservation properties because of the local nature of the approximation and the use of fluxes at the interfaces of the elements. In HORSES3D, rotating turbine blades can be modelled using either actuator line methods or sliding meshes, while the air-water interface is captured using a robust Cahn-Hilliard formulation; see figure 3. Additional components, such as tower, nacelle, and platform, can be incorporated through immersed boundary techniques(29; 30; 31; 32; 33), offering exceptional flexibility. We include a robust local p-adaptation based on reinforcement learning to enhance ac-

WT: wind turbine; WF: wind farm with 100 and 150 WTs; HT: hearing threshold. Color scales from 20-100 dB in figure (d).

Figure 1: Acoustic analysis to quantify the underwater acoustic footprint of offshore wind turbines.

curacy at an affordable cost. Finally, we demonstrate the solver's capabilities through large eddy simulations of offshore wind turbines to soon provide a characterisation of their noise emissions and underwater footprint.

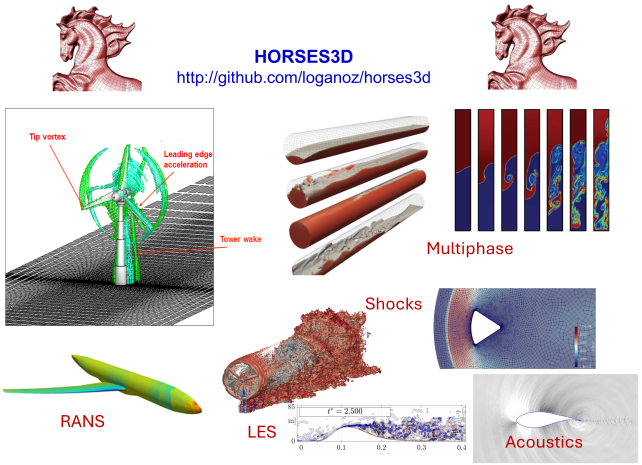

Figure 2: Summary of HORSES3D features (Ferrer et al. 2023).

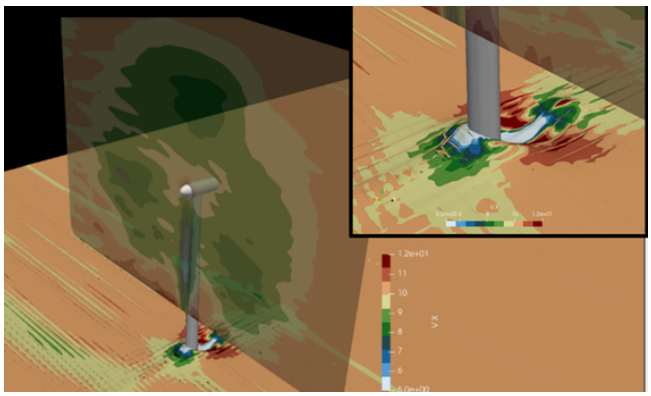

Figure 3: Example of offshore wind turbine simulated with actuator lines and free-surface using a Cahn-Hilliard formulation.

3. CONCLUSIONS

Achieving sustainable offshore energy means addressing environmental impacts, particularly the underwater noise of wind turbines, which can harm marine life. Traditional designs often focus on energy output while overlooking aerodynamic noise transmission into water.

We introduce a methodology that integrates noise models, offering manufacturers and policy makers a versatile tool for predicting underwater noise in both low- and high-fidelity scenarios. For the first time, we quantify the acoustic footprint of a 22 MW turbine and scale emissions to wind farms of 100–150 turbines, confirming that

aerodynamic noise—especially from trailing edges—is a significant environmental challenge.

Furthermore, our ongoing development of the HORSES3D solver will advance underwater acoustic predictions for offshore wind turbines, filling a current gap in capabilities.

ABSTRACT

Recently European Court of Auditors (ECA) recommended introducing EU noise-reduction targets and noise limits in the Environmental Noise Directive. The ECA approach would be aligning the noise exposure reporting thresholds, as closely as possible, with the guideline levels in the 2022 update report by the World Health Organization (WHO) in urban areas. WHO Guidelines provide guideline L_{den} and L_{night} levels for specific noise sources. For wind turbines, they provide a guideline level of 45 dB L_{den} with no L_{night} guideline determined. For long term assessment relevant factors must be defined, as the calculation method for yearly L_{den} may be affected by different meteorological conditions, operational states of the turbines, relative position of the source and receptor, background noise and masking levels or applicable daily night-time and short time limits. The determination of how to determine compliance with an L_{den} will be explored.

The present work's aim is the identification of the environmental parameters necessary for sound propagation and the reasonable evaluation time for long term wind farm noise assessment. A detailed knowledge and understanding of the emission and propagation characteristics can allow an optimised noise levels and energy yield, which can be achieved by adapting the operation of the turbine.

1. INTRODUCTION

European Union Directive 2002/49/EC (END) [1] was published to define a common approach intended to avoid, prevent or reduce on a prioritised basis the harmful effects, including annoyance, owing to exposure to environmental noise. Noise indicators L_{den} and L_{night} were selected for the preparation and revision of strategic noise mapping. Day-evening-night level L_{den} in decibels (dB) is defined by the A-weighted long-term average sound level as defined in ISO 1996-2:1987 [2] and the updated to ISO 1996-2:2017 [3]. The equation for the day-evening-night weighted sound pressure level, L_{den}, for the equivalent continuous sound pressure level for day-time, L_{day}, evening-time, $L_{evening}$, and night-time, L_{night}, with the weightings of 0 dB, 5 dB and 10 dB, respectively, is shown in the equation below [4]. The time, in hours, for the day-time, t_{day}, evening-time, $t_{evening}$, and night-time, t_{night}, are normally 12, 4 and 8 hours, respectively. These times may vary for different countries[1].

$$L_{den} = 10\,log_{10}\left[\frac{t_{day}10^{0.1L_{day}} + t_{evening}10^{0.1(5+L_{evening})} + t_{night}10^{0.1(10+L_{night})}}{24}\right] \quad (1)$$

European Environment Agency collects official noise data reported every five years by EEA member countries under the Environmental Noise Directive (END) with last available noise country fact sheets of 2021, including road, rail, aviation and industry sound sources.

The WHO Regional Office for Europe developed environmental noise guidelines for the European Region in 2018 [5], proposing an updated set of public health recommendations on exposure to environmental noise. The

[1] The typical values are day-time of 0700 to 1900, evening time of 1900 to 2300 and night-time 2300 to 0700.

guidelines presented recommendations on reducing noise levels for road, railway, aircraft, wind turbine and leisure noise sources.

A compendium of WHO and other UN guidance on health and environment update of 2022 refers to L_{den} and L_{night} indicators for noise monitoring and exposure assessment adding $L_{Aeq,T}$ for measuring leisure noise exposure. For average noise exposure, sound pressure levels <45 dB L_{den} for wind turbine noise are recommended. There is not any reference for night noise exposure or $L_{Aeq,T}$ for wind turbine noise.

Recently, the European Court of Auditors (ECA) [6], published a special report about Urban pollution in the EU, giving the recommendation of prioritising actions against noise pollution to The European Commission, to assess the feasibility of introducing EU noise-reduction targets in the Environmental Noise Directive and aligning the noise exposure reporting thresholds as closely as possible with those recommended by the World Health Organization with a target implementation date of 2029. The referred indicators are L_{den} and L_{night} without any reference to $L_{Aeq,T}$ levels. The noise sources are focused on road, aircraft and railway noise.

1.1 World Health Organisation 2018

World Health Organisation (WHO): Regional Office for Europe (ROE) provided Environmental Guidelines for the European Region for the following noise sources: Road Traffic, Railway, Aircraft, Wind Turbines and Leisure Activities. The recommended level for wind turbine noise is an L_{den} value of 45 dB. This latest report works in conjunction with WHO 1999 [7] and WHO 2009 [8] where those guidelines levels also apply, in particular 45 $L_{Aeq,8hour}$ outside a bedroom with a wind open, and 40 dB $L_{night,outside}$, respectively.

The wind turbine guideline level was given a **conditional** recommendation and would require substantial debate amongst stakeholders, since the quality of the evidence used to derive the rating was **low quality.** It was marked as **low quality** owing to heterogeneity, inconsistency and imprecision. No guidelines for L_{night} were produced since the evidence consisted of study limitations, inconsistent results and imprecision.

The WHO themselves state that the L_{den} and L_{night} is a poor acoustic measure for wind turbines in section 3.4.2.3, an excerpt is quoted below:

"*Even though correlations between noise indicators tend to be high (especially between L_{Aeq}-like indicators) and conversions between indicators do not normally influence the correlations between the noise indicator and a particular health effect, important assumptions remain when exposure to wind turbine noise in L_{den} is converted from original sound pressure level values. The conversion requires, as variable, the statistical distribution of annual wind speed at a particular height, which depends on the type of wind turbine and meteorological conditions at a particular geographical location. Such input variables may not be directly applicable for use in other sites. They are sometimes used without specific validation for a particular area, however, because of practical limitations or lack of data and resources. This can lead to increased uncertainty in the assessment of the relationship between wind turbine noise exposure and health outcomes.*".

"*Based on all these factors, it may be concluded that the acoustical description of **wind turbine noise by means of L_{den} or L_{night} may be a poor characterization of wind turbine noise** and may limit the ability to observe associations between wind turbine noise and health outcomes.*"

It is important to note that the WHO does not provide methodology, procedure or detailed information on how to predict, measure and assess an L_{den} for wind turbines.

1.2 Compendium of WHO and other UN guidance on Health and Environment 2022 update

The compendium of WHO and other UN guidance on Health and Environment report, Chapter 11, provides a short summary of the guideline levels to achieve for a range of sources such as: road traffic noise, railway noise, aircraft, wind turbine, leisure sources [9]. The compendium states an average level of less than 45 dB L_{den} is recommended. There is no other guidance or other information provided for wind turbines in the compendium document.

1.3 Special report 02/2025

The European Court of Auditors (ECA) provides a review of the European Green Deal and the Zero Pollution Action Plan to reduce air and excessive noise on human health with respect to the END [6]. The special report found that there are no EU limit values or reduction targets for noise, and provides recommendations for limits for road, rail and aircraft. There is no mention of wind turbines in the report; however, the ECA special report should assess the feasibility of aligning the reporting thresholds as closely as

possible with those recommended by the WHO by 2029. Therefore, wind turbine levels could be passed through without careful consideration.

2. REGULATION ON LONG-TERM ASSESSMENT

The application of the calculation and enforcement of short-term and long-term sound levels from wind turbines varies from country to country owing to noise prediction, noise modelling, legislative frameworks and evidence at the time of the law and/or supplementary guidance creation. Countries such as Spain, Lithuania and Poland may have stated annual limit, but have short-term $L_{Aeq,T}$ levels that are more stringent. . Therefore, in practice, the annual levels are not generally calculated or assessed.

2.1 Netherlands

The Netherlands had a law to assess the annual levels for 47 dB L_{den} and 41 dB L_{night} [10]. The Law seta out the source level for which measurements should be done according to the method in the law or NEN-EN-IEC 61400-11 (2002). These methods determine the sound power level of the wind turbine per wind speed bin at hub height from cut-in to rated power. For sound power levels at wind speeds greater than the rated power, then the sound power level at the rated power can be used for these higher wind speeds.

The wind speed distribution for day, evening and night from a long-term wind statistics should be obtained from KNMI[2]. The annual average sound power level per octave band is calculated for each period of day. The predicted immission level is then determined from subtracting following attenuation terms: geometric divergence, atmospheric attenuation[3], reflecting objects, screening, vegetation, industrial, ground, housing and meteorological corrections. It should be noted that though the propagation methods and parameters are similar to ISO 9613-2:1996 [11] and ISO 9613-2:2024 [12], but the ground attenuation is less in the Netherlands Law. The immission level is then modified for each turbine-receptor based on the relative bearing, owing to the long-term meteorological effects. However, this only comes into effect at a distance 10 times the combined receptor and source heights. Once the immission has been calculated for each period, it is combined into the L_{den}. The receptor height is 5 m.

Compliance with the limits is determined by a sound power level measurement, since it is not possible to measure an annual level at a receptor location. This is owing to the influence of the dominant background noise on measurements at receptors [10].

The ruling on Dutch wind farms means that law cannot be applied, but a temporary bridging scheme is in place until new rules are in place [13]. The publication of the new draft law and consultation period were in October 2023 to November 2023, whilst the new law will come into force in 2025 or 2026 [13].

2.2 Norway

The guideline for noise is specified in T-1442/2021 as an L_{den} of 45 dB [14]. The prediction of the immission level is according to NORD2000, assuming that the turbines are operating 100 per cent of the time, and the sound power level at wind speed of 8 m/s, at 10 m standardised height, shall be used. There are no set parameters for NORD2000 calculations and it is dependent on the experience of the practitioner; however, the following parameters are typically used:

- Receptor height of 4 m,
- Ground is a uniform class D [4],
- Temperature of 10 degrees Celsius and relative humidity of 70 per cent, and
- Wind speeds at 10 m standardized height.

3. FACTORS AFFECTING LONG-TERM ASSESSMENTS

3.1 Source Sound Power Levels

The sound power level of a turbine should be determined using the IEC 61400-11:2012+AMD1:2018 CSV [15], where the sound power level is determined with respect to hub height wind speeds and third octave frequency. The wind speed bins are centred on the integer and half integer. The sound level index should be expressed as an $L_{Aeq,T}$. Depending on the regulatory context, further treatment of the measured sound power levels should be used, or the warranted levels - usually issued by the manufacturer - or declared sound power levels using IEC TS 61400-14:2005 [16]. A comparison of different representations of sound power levels are shown in Institute of Acoustics (IOA)

[2] www.windenergie.nl

[3] 10 degrees Celsius and 80 per cent relative humidity

[4] 2000 kPas/m2 - Normal uncompacted ground (forest floors, pasture field)

Good Practice Guide (GPG) Supplementary Guidance Note (SGN) 3 [17].

The sound power level should be declared between cut-in to cut-out wind speeds. If the sound power level is not declared for wind speeds above the rated power wind speed, then the rated power sound power level should be used. If the sound power level is unknown for wind speeds between cut-in and the 68 per cent of the rated capacity[5], then care should be taken in extrapolating these data. An example is given in Figure 1. Any omission of sound power levels, at wind speeds where the turbine can generate, will reduce the calculated annual average sound power level.

A larger rotor size for the same rated power would increase the swept area, energy yield and capacity factor[6]. Increasing the energy yield would typically involve shifting the power curve, and sound power level curve, to lower wind speeds. This would increase the L_{den} and L_{night} values, but maximum sound power level, L_{WA}, would remain the same. Increasing the rotor size does not necessarily increase the sound power level, owing to the tip speed being the limiting speed.

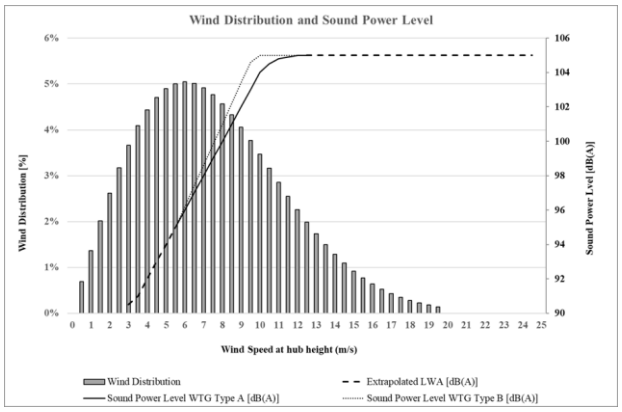

Figure 1. showing an example of sound power level (right y-axis), for Turbine Type A, with respect to hub height wind speed (x-axis) showing the solid black line as the declared sound power level and the dashed black line is the extrapolated level. Turbine Type B is shown as dotted lines. The wind distribution percentage of occurrence (left y-axis) at hub height wind speeds. The maximum sound power level for Turbine Type A and B is 105 dB(A), whilst the average sound power level is 100.8 dB(A) and 101.3 dB(A), respectively. If the wind speed distribution is the same for day, evening and night, then the Lden value would be 107.2 dB and 107.7 dB for turbines Type A and B, respectively.

[5] 0.8 times the 85 per cent of the maximum power as per section 5 in IEC 61400-11.

[6] Capacity factor is the actual or predicted energy yield divided by the maximum potential energy yield.

3.2 Wind Speed

The wind speed for calculating the annual average should be measured at the same resolution as the sound power level measurements. The introduction of binning data to a lower resolution or interpolating to a higher resolution, will introduce systematic errors and additional uncertainty. The wind speed should be measured at hub height or at points above and below the proposed hub height. Therefore, care should be taken to ensure that the correct wind speeds are used with the correct hub heights for all turbines. Typically, wind turbines with a lower hub height will see lower wind speeds compared to turbines with a higher hub height. When converting wind speeds from one height to another, wind shear must be taken into account, guidance is provided within IEC 61400-11 [15], IEC 61400-11-2 [18] and the IOA GPG [19] and the IOA GPG SGN 4 [20]. When using wind speed measurements with lower anemometers on a mast, care should be taken to account for the mast wind shadow. When using a LiDAR, data quality and signal to noise must be considered, either by filtering, infilling or omitting some data.

Each site will have its own wind speed and wind direction distributions. In the case of wind measurements, a metrological mast and/or LiDAR should follow to the IEC 61400-50 series, and a robust long-term wind catalogue can be used. Wind speed measurements conducted on the development site may be limited to 1 or 2 years. These "shorter" measurements could be correlated with longer-term wind measurements from a national or international wind catalogue. Wind speed distribution will vary year by year; therefore, the annual average sound power level of the turbine will vary year by year. The wind speed distribution can be approximated to a Weibull distribution. The wind speed distributions and power curves are used to calculate representative wind energy yield(s). The calculated energy yield should be considered as the greatest values. In real-life power output is likely to be slightly below these values due to downtimes: maintenance, grid outages, sector managements and others (see section 3.4).

Wind speed distribution should be grouped for the day-time, evening-time and night-time periods. These time periods may vary for different countries or regions, and that

the hour change to and from summer-time should also be taken into account. Therefore, the average sound power level, for a period of day, per octave band, $L_{W,period,j}$, Eqn (2), is the logarithmic sum between cut-in and cut-out wind winds speeds for the frequency of occurrence of the wind speed bin, V_i, for the corresponding sound power level per octave and wind speed bin, $L_{W,i,j}$,

$$L_{W,period,j} = 10\log_{10}\left[\sum_{i=v_{cut-in}}^{v_{cut-out}} V_i 10^{(0.1L_{W,i,j})}\right] \quad (2)$$

The sum of V_i may not equal 1 owing to wind speeds outside of the cut-in and cut-out region.

For simple flat sites it may be appropriate to use a single point for the entire wind farm, but for larger wind farms or those with complex terrain, multiple wind speed measurement locations may be needed. In addition, when a wind turbine is downwind of another turbine, the wind speed may be lower. Determining the "mean" sound power level from the arithmetic mean wind speed is an incorrect method this is owing to 1) the wind speed distribution follows a Weibull distribution rather than a Gaussian distribution, and 2) the annual average is based on weighted logarithmic average.

3.3 Wind Direction

Wind direction will have an effect at the receptor location owing to the shadow zone for the upwind and close to cross wind positions [19 and references within]. The prevailing wind direction may change owing to the season and time of day, in particular for regions in coastal or areas close to large bodies of water. Treatment of the effect of wind direction on the sound propagation is discussed further in ISO 9613-2:2024 Annex C [12] and the IOA GPG section 4.4 [19].

The distribution of wind directions is important for the siting of wind turbines in a wind farm. A wind rose shows probability of a wind from a certain sector. In addition, the wind speed distributions can be different for these wind direction sectors.

Higher wind speeds may be associated with the prevailing wind directions, whilst lower wind speeds in for non-prevailing wind directions. The wind direction may vary across the site, especial for site with complex terrain and inter- and intra-wind farm turbulence.

When assessing the directional effects, it is prudent to create an attenuation matrix of wind speed, wind direction and period for each receptor turbine pair.

According to the IEC TS 61400-14, the apparent sound power level shall be declared by combining the mean sound power level and the confidence level. Aerodynamic sound theories and experiments have demonstrated that the sound pressure levels in the crosswind direction are lower than those in the up- or downwind direction [21] [22]. There is no definition of emission directivity in the manufacturer's sound power declaration.

3.4 Turbine Operation

The operation of the turbines on a wind farm will affect the annual average owing to, but not limited to, the following:

- Availability of the turbine, where turbines are subject to maintenance, expected levels of stoppages owing to faults and grid outages. The availability of a wind farm will not be 100 per cent but expected to be greater than 95 per cent.
- The wind farm may be constrained by the grid restriction based on capacity load, where the wind farm may have to run a reduced power mode or shutdown owing to oversupply or other restrictions by the grid operator.
- Individual turbines operate in curtailed modes or shut down at specified wind speeds, wind directions and time of day owing to turbine wakes, turbulence from the terrain, noise mitigation, bat and bird protection, shadow flicker, intra-wind farm grid constraint, loading, etc.

These operational constraints may be known for the development under assessment but may be unknown for neighbouring wind farms that are not under the operator's control. Assuming that the wind farm will be operational 100 per cent of the time would often lead to an over estimation of the annual average.

3.5 Propagation

The depending on the propagation model (NORD2000, ISO 9613-2 etc) some of the attenuation parameters may vary over the year. The predicted levels according to ISO 9613-2 is for downwind conditions under a moderate ground-based temperature inversion, such as commonly occur on clear and calm nights.

Geometric divergence should be the same irrespective of the time and date. However, the parameters for atmospheric absorption and ground attenuation will vary. Ambient temperature, temperature gradient, relative humidity and atmospheric pressure will change throughout the day and through each season. Wind farms coexist with agricultural activities and the ground factor may change over the course of the year depending on the land use. For example, there may be crops in the summer, bare ground in winter and spring, frozen, snow or flooded during the winter. Therefore, full evaluation of temperature, relative humidity and ground conditions should be used; however, a pragmatic approach could be to use the average values.

If turbine rotors are obscured by landforms relative to the receptor location, the screening attenuation for that turbine at the receptor, is limited to 3 dB according to ISO 9613-2:2024 Annex D or 2 dB according to the IOA GPG Section 3[7] . Where there is a concave ground occurs between the source and the receptor, then an additional 3 dB can be added to the contribution of that turbine at that receptor according to ISO 9613-2:2024 and IOA GPG Section 3. However, it should be noted that the calculation of the mean propagation height and the trigger criteria are different in ISO 9613-2 and the IOA GPG.

3.6 Receptor locations

The receptor location for the predicted levels should be carefully selected. Country specific requirements such as prediction on the façade closest to the wind farm or in free field conditions should be used. Care also needs to be taken, as national legislation could mandate the precise location for measurements, such as in Germany, where the immission level should be measured 0.5 m in front of the open window, outside, of the most affected room in need of protection, such as bedrooms [23].

4. MEASUREMENT AND ENFORCEMENT

Measurement of an annual average at receptor locations will be impracticable owing to the effect of background noise, road, rail, aircraft, industry or other anthropogenic sources. Therefore, it may be impracticable to determine the specific sound level of the wind farm or wind turbine at receptor locations, owing to the unknown contribution of the other sounds. Also, the presence of measurement equipment in at receptor locations, may have a disruptive effect on inhabitants of the dwelling and affect their subjective response to the source of noise.

To implement long-term (annual) immission measurements at several receptor positions around a wind farm, during the development and operation, would increase the cost of energy production and the security of supply, owing to the number and complexity of the measurements and precision instrumentation needed for the task. In addition, a clear description of uncertainties in any methodology should be calculated and stated.

In shorter term measurements, assessed against L_{Aeq}, L_{A50}, L_{A90} indices, it is a proper approach to perform shutdowns and logarithmically subtract the shutdown levels from the total levels, to give the specific sound pressure level owing to the source [18] [24]. However, it is impracticable to have regular shutdowns, over a year, for the wind farm, since this will impede the generation of electricity. In addition, neighbouring wind farms that were stopped for various reasons throughout the year would provide an incorrect picture of the cumulative noise exposure.

The Netherlands and Norway, where the L_{den} index is used, state that measurements at receptor locations are impracticable. They sate that compliance is assessed with sound power level measurements with a prediction of immission levels at receptor locations [10] [14]. Therefore, given the multiple meteorological effects on propagation it is more logical to use receptor measurements to compare to L_{Aeq}, L_{A50}, L_{A90} or other similar indices for sound level limits, rather than attempt to measure an annual average.

The annual average sound level indicators may not reflect the neighbours experience of sound at their dwelling. For example, the character or level of the sound that may occur under specific conditions that may cause a complaint. Would a complaint be resolved if the annual average was compiled with?

There are some challenges with showing compliance with the annual limit under the following circumstances:

- The nature of the annual average implies that the short-term immission level would be greater than the annual average limit. Therefore, if a

[7] If the landform is close to the receptor, then a reduction of 10 dB can be used.

limit was X dB L_{night}, then the source could remain at X+3 dB $L_{Aeq,T}$ for 50 per cent of the year, and then shutdown for the rest of the year and meet the limit.

- If the annual average is calculated from the operational data , would the wind turbine(s) or wind farm have to cease operating, or the operator would be subject to penalties, if they reach the annual limit before the 12 months? Would it be a fixed 12 months or a rolling 12 months?

5. SUMMARY

The EU Directive 2002/49/EC aims to mitigate harmful effects of environmental noise using indicators like L_{den} and L_{night} for strategic noise mapping. The WHO European Region issued noise guidelines in 2018, recommending guideline levels for various noise sources including wind turbines. However, the WHO guidelines levels in 1999 and 2009 are still extant. The WHO guidelines level was given a **conditional** recommendation and still requires substantial debate, since the quality of evidence used to derive this guideline level was **low quality**. In addition, the WHO 2018 report states that the L_{den} and L_{night} is a poor acoustic measure for wind turbines.

A 2022 guidance update references L_{den} and L_{night} for noise monitoring, recommending L_{den} < 45 dB for wind turbine noise, with no L_{night} or $L_{Aeq,T}$ reference for wind turbines. The ECA recommended prioritising noise pollution actions and assessing EU noise-reduction targets within the END. These targets should align with WHO recommendations by 2029, focusing on indicators L_{den} and L_{night} for road, aircraft, and railway noise.

The Netherlands has set annual sound limits at 47 dB L_{den} and 41 dB L_{night}, assessing turbine sound power levels with NEN-EN-IEC 61400-11 and KNMI wind statistics for immission predictions. Currently, a temporary bridging scheme is active whilst the Netherland's wind farm laws are under review, with new regulations anticipated by 2025 or 2026. Norwegian guideline T-1442/2021 sets a 45 dB L_{den} limit for noise prediction using NORD2000, with turbines assumed to operate continuously. Sound power level is based on 8 m/s wind speed at 10 m height. Norway and Netherlands calculate the L_{den} in different ways and therefore a direct comparison is not advised. Both countries do not recommend receptor measurements for the determination of the annual levels, but a sound power level measurement with a prediction to the receptor is required to determine compliance.

Sound power levels must be declared from cut-in to cut-out wind speeds, using rated levels if not specified above rated speeds. Extrapolation outside of measured levels requires caution to avoid reducing the annual average sound power level. The resolution of wind speed measurements for calculating annual averages shall be the same as the sound power levels, avoiding errors from binning or interpolating. Measurement of wind speeds should be at hub height or appropriate heights, considering wind shear to convert between heights, guided by IEC standards and good practice guides.

Wind direction affects the immission at receptor locations, especially in shadow zones, with variations owing to season and time, notably near coasts and large water bodies. Wind direction distribution, illustrated by wind roses, is crucial for turbine siting in farms, with differing wind speed distributions across these sectors.

Prediction of annual levels at the receptor will have to take account the wind statistics, meteorological conditions, operational conditions and variations in the propagation attenuation over the year and lifetime of the wind farm. Assuming the turbines are operating at full rated capacity would be an overestimation of the annual averages. Annual average sound levels may not reflect the neighbours' experience, as long-term averages often miss short-term variations, character and specific disruptive conditions.

Measuring annual average sound levels at receptor locations are impactable owing to background noise and the presence of measurement equipment, which may disrupt inhabitants and affect their response to wind farm noise. Long-term immission measurements around a wind farm increase costs and complexity, requiring precision and clear methodology, whilst trying to minimise uncertainties in the result.

Challenges in meeting annual sound limits include potentially exceeding short-term immission levels and needing shutdowns to comply. Questions arise about operations ceasing and penalties if limits are reached, whether on a fixed or rolling 12-month basis.

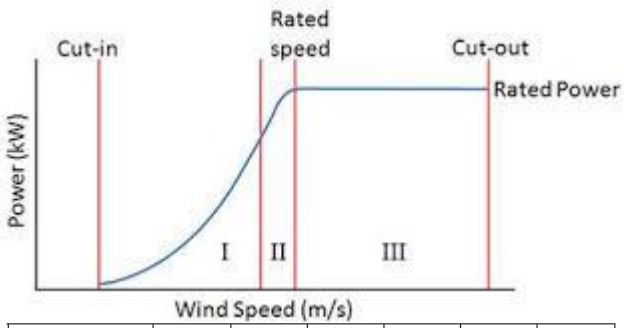
OPTIMIZING ELECTRICITY PRODUCTION IN WIND FARMS WITH NOISE MITIGATION STRATEGIES

Álvaro Grilo[1*]
[1] INERCO Acústica, S.L., Tomas Alba Edison, 2, 41092 Sevilla, Spain

ABSTRACT



Wind power will be key to achieve the European Renewable Energy targets and making the EU carbon-neutral by 2050. Wind farms can cover several square kilometers of land and the permitting processes must consider the legitimate concerns of citizens regarding the environmental noise impact. In order to increase local acceptance of wind farm projects, a noise mitigation strategy should be available in cases where the noise standards are exceeded. A validated noise prediction model with monitored data will permit to verity the compliance of the noise regulations with best precision and limit the production of the wind turbines only when it is strictly required. This paper shows a methodology for the optimization of the electricity production of a wind farm, considering different noise calculation standards during the design of noise mitigation strategies.

Keywords: *wind farm, noise mitigation, low noise operation, CNOSSOS, ISO9613*

1. INTRODUCTION

Wind energy production constitutes a fundamental pillar of the energy sector, compensating for the energy deficit of the system through the development of alternative renewable energies, which have rapidly developed worldwide in recent decades. In Europe, wind farm capacity exceeds 270 GW, covering the wind energy almost a quarter of the demand in Spain [1].

From an acoustical point of view, wind turbines are a noisy source whose sound power level increases with their electrical power and depends on wind speed. When the wind turbine starts operating (usually at wind speeds between 4 and 30 meters at hub height), the sound power increases gradually until it reaches a stationary level as can be seen in Figure 1.

U_s m/s	4	5	6	7	8	9
Lw dB(A)	97.9	100.9	104.2	106.1	107.0	106.9

Figure 1. Evolution of electrical production and example of associated acoustic power (Lw) for a 3 MW wind turbine, according to wind speed [2][3]

Given these particular emission characteristics, the evaluation of the acoustic impact of wind farms requires a specific methodology regarding the development of prediction models and acoustic monitoring. Some countries, such as Australia or New Zealand, have developed methodological guidelines for the acoustic study of wind farms. Additionally, there are different studies and recommendations that refer to the need to adapt acoustic prediction models that were not designed for elevated sources:

- Studies [4] have demonstrated the deviations derived from the use of the ISO 9613-2 standard, so the selection of the calculation standard and input parameters must be carefully analyzed.
- The Institute of Acoustics [6] already established correction factors associated with visibility criteria

or average height calculated independently for each receiver.

- Other authors [7] recommend the validation of the prediction models to ensure their suitability for the evaluation of wind farms, with the value of ground absorption (G) being one of the key parameters that determines the representativeness of noise predictions.

In the present study, an update of the validation of a noise prediction model under different calculation standards and different values of acoustic impedance has been carried out for a case study, in order to maximize the precision of the model and the optimization of the electrical production.

2. METHODOLOGY

The present study has developed the workflow described in to verify the effectiveness of the mitigation plan for an operating wind farm:

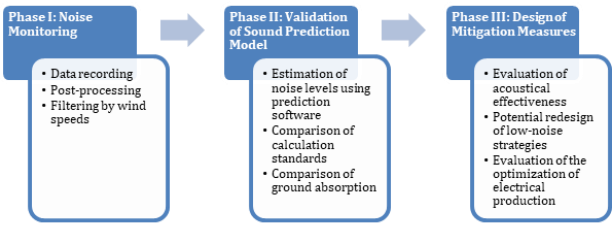

Figure 2. Workflow of the present study

In the phase of monitoring the noise of the wind farm, an in-situ acoustic testing campaign was carried out in accordance with ISO 1996-2 (under favorable conditions), with the aim of obtaining sufficient and representative sound records of the wind farm's operation at different wind speeds. The noise campaign was conducted over more than seven (7) days for a total of 368 hours of measurement and a database with more than 20,000 noise-meteorology-operation records of the park. The variation of sound levels with the wind speed was represented was obtained using the binned method, as described at in the Ontario Wind Farm Acoustic Measurement and Evaluation Guide [11], for each measurement position and period (day/night).

The acoustic testing campaign was carried out in two buildings (see Figure 3) located in the vicinity of the eastern area of the wind farm, with dominant westerly winds (predominant in the area).

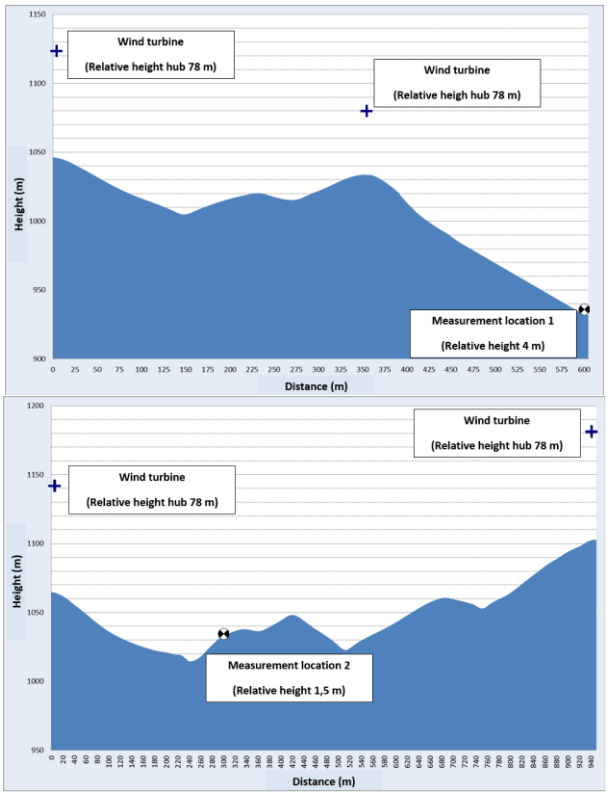

Figure 3. Elevation Profiles of Measurement Positions (Position 1 – up, Position 2 – down)

The noise prediction models were developed using the CadnaA acoustic software from Datakustik, for simulating the noise levels at the monitoring points according to the following calculation standards:

- ISO 9613-2:2024 "Acoustics — Attenuation of sound during propagation outdoors Part 2: Engineering method for the prediction of sound pressure levels outdoors" [12].
- CONCAWE-report 4/81, "The propagation of noise from petroleum and petro-chemical complexes to neighboring communities" [13]
- The Nordic sound prediction model NORD2000 [14]
- Common Noise Assessment Methods (CNOSSOS-EU) [15].

The ground absorption parameter has been configured for different scenarios including hard (G=0) and mixed ground (0,5) according to various European recommendations [16] as well as considering an absorption map based on land uses or covers established in the EAA Corine Land Cover (CLC) database [18]. The G absorption coefficient was established based on the different land use categories established in CORINE and following recommendations from previous studies [19], resulting an average G value for the study area of 0.71. More technical details about the developed noise campaign and prediction models can be found in [21] .

3. STUDY CASE

The wind farm under study is located in an extensive area situated between small towns, in a region with a marked rural-natural character dominated by crops, as well as scattered groves and scrubland. Especially during the nighttime period, human influence is practically nonexistent, and sound levels are mainly influenced by natural noise and the operation of the wind turbines.

The wind farm has more than 50 wind turbines and an installed capacity of over 100 MW. The wind turbine model under study develops an electrical power of 2 MW and has a rotor diameter of 90 meters and a total hub height of 78 meters. The wind turbines under study have a sound emission power provided by the manufacturer in accordance with IEC 61400-11, reaching a maximum power (106 dBA) at wind speeds above 6 m/s. This model can operate under low-noise configurations that can be used as corrective measures in the management of the wind farm to avoid exceeding the limit levels established by current regulations (45 dBA). Table 1 specifies the noise attenuation of the available low-noise modes for a hub height of 78 meters, in accordance with IEC 61400-14, with a reduction range of 1,4-4,8 dBA. Since noise attenuation relies on reducing the blade speed, implementing low-noise modes results in decreased electrical production from the wind turbine

Wind Speed W10 (m/s)	Noise Attenuation of Low-Noise Modes				
	NRS01	NRS02	NRS03	NRS04	NRS 05
5	0,5	0	0	0	0
6	4,4	3,9	3,2	2,4	1,4
7 – 10	4,8	4,3	3,6	2,8	1,8
dBA					

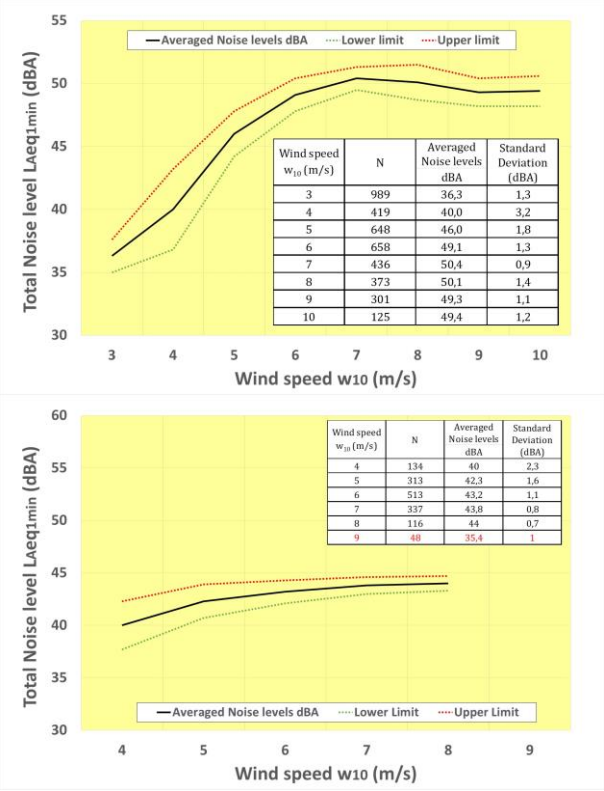
Table 1. Reduction of sound power level of low-noise mode compared to the normal operation (Source: Wind turbine manufacturer)

In the wind farm under study, low-noise operating modes were implemented, designed using a sound prediction model based on the CONCAWE standard with an absorption value of G=0.5 (developed prior to this study and validated with discrete noise records) to not exceed a sound level of 45 dBA during nighttime. This strategy is implemented exclusively during nighttime, from 5 m/s at measurement point 1 and from 6 m/s at measurement point 2.

4. RESULTS AND DISCUSION

4.1 Noise monitoring

Figure 4 below presents the wind bin analysis derived from the noise campaign data, after filtering and post-processing for the two measurement positions. The central line indicates the arithmetic mean of the sample records, and the upper (red) and lower (green) lines show the result of adding or subtracting the standard deviation value, respectively. In addition, tables with the arithmetic mean of the total noise (expressed as $L_Aeq_{1\ min}$) and the standard deviation for each analyzed wind window are included.



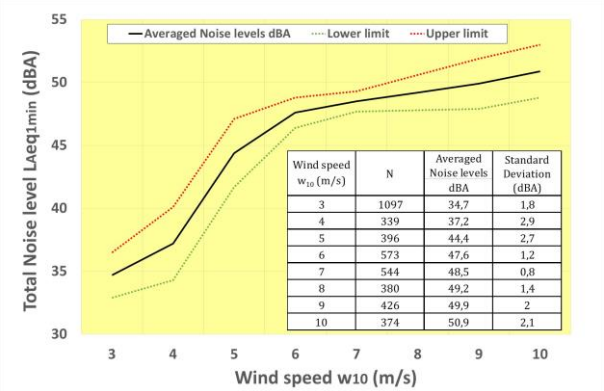


Figure 4. Monitored noise levels at measurement position 1 (Day – up, Night – down)

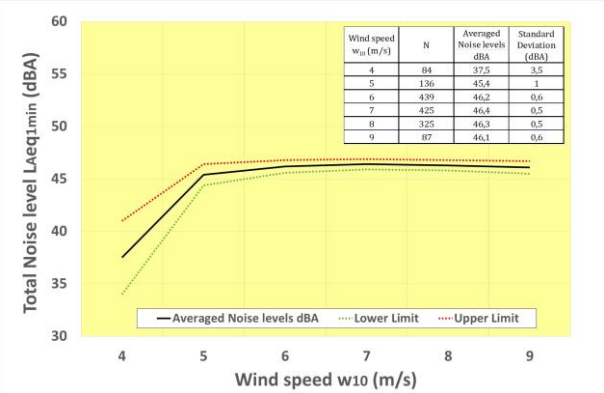

Figure 5. Monitored noise levels at measurement position 2 (Day – up, Night – down)

This analysis provides highly valuable information about the most probable average value, as well as the dispersion of samples within that interval. Generally, the variation of arithmetic averages increases with wind speed during the daytime period. During the nighttime period, the moment when mitigation measures come into operation is more clearly identified to achieve the regulatory compliance of 45 dBA: for measurement point 1 at 5 m/s (42.3 dBA) and for measurement point 2 at 6 m/s (46.2 dBA).

4.2 Noise predictions

Table 2 shows the average deviations (simulated value minus measured noise levels) for each calculation standards considering the different G values considered. The analysis of the results has revealed the following for the case study:

- All calculation standards predict conservative estimations (around 3 dBA) for hard ground, with CONCAWE showing significantly higher deviations of up to 7 dBA.

Table 2. Average deviation of noise calculations according to ground absorption for all studied cases

Calculation Standard	Average Deviation (dBA) (Predicted – Monitored)		
	Absorption G=0	Absorption G=0.5	Absorption G=CLC (0,71)
CONCAWE	6,9	2,7	2,7
NORD2000	2,6	1,9	1,5
ISO9613	2,8	-0,1	-1,2
CNOSSOS	2,7	1,0	0,3

- As the ground absorption value increases, the prediction models reduce deviations from monitored levels, without underestimations except in the case of the ISO 9613 standard (-1,2 dBA deviation). These results are in line with the recommendation not to use values above 0.5 with this standard, confirming the recommendation of the Institute of Acoustics [6] and other references [12].
- CONCAWE and NORD2000 overestimate monitored sound levels for all considered scenarios, although in the case of the NORD2000 standard, the smallest deviations are obtained with porous absorption values (deviations of 1.5 dBA for G values of 0.71).
- For the case study, the ISO9613 and CNOSSOS standards are the most accurate (below 0.5 dBA) for absorption values of 0.5 and 0.7 respectively. In the case of the CNOSSOS method, there are no underestimations in any studied scenarios.
- The results obtained for the ISO9613-2 standard are explained by other authors [22] considering the topography and the distance of the receivers vary. The ISO 9613-2 model with hard terrain has been used in other studies as a conservative model [24] with deviations ranging between 1.5 and 2.7 dBA depending on the degree of terrain irregularity. These data are in line with the deviations found of 2,8 dBA for hard terrain in the case study. The consideration of mixed terrain (0.5 or CLC) results in slight underestimations (0.1 dBA in the case of G=0.5) and -1.2 dBA in the case of absorption based on land uses.

Additionally, it is relevant to identify how the G absorption value affects the range of average deviations found for each calculation model. The CONCAWE model presents the

greatest range of variation (4.2 dBA) followed by the ISO9613 model (4.0 dBA) and CNOSSOS (2.4 dBA). The NORD2000 model is confirmed as the standard with the least variations regarding terrain attenuation (1.1 dBA). It is observed that the CNOSSOS-EU model has a lower tendency to underestimation compared to the ISO9613 model as the acoustic impedance of the terrain increases, in line with previous studies in which CNOSSOS-EU predicts higher levels than ISO 9613 [28]. These results differ from other previous studies for this case study [21], although such deviations might be explained by the different versions of the standards used and their implementation in the simulation software itself.

The NORD2000 model presents overestimations of the monitored level in the range of 1.5-2.6 dBA, being the most accurate model that uses land use covers based on CLC, making this database relevant for absorption evaluation with this standard, in line with Kokowski et al. [29] .

Finally, it is noteworthy that the CONCAWE model obtains predictions with overestimations of monitored levels, especially considering hard terrain (6.9 dBA), and in the case study, it should only be used from a conservative point of view with porous terrain absorption values and/or prior validation through acoustic tests.

The following Figure 6 graphically represent the deviation of each noise prediction model based on the G value.

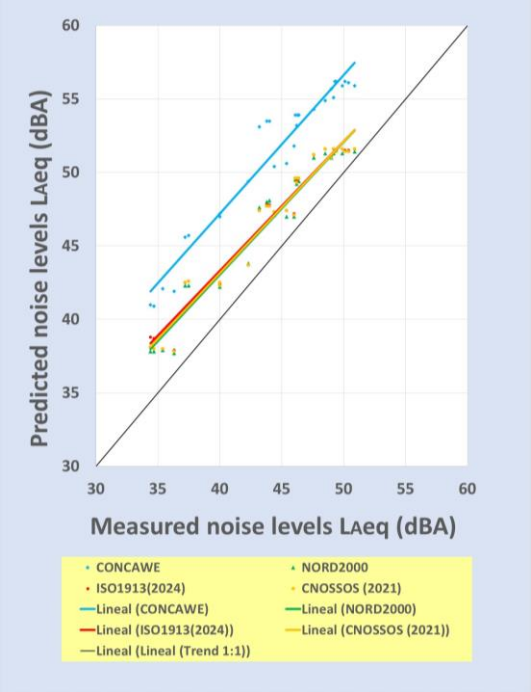

Figure 6. Comparative Analysis Between Monitoring and Sound Prediction for hard ground (G=0)

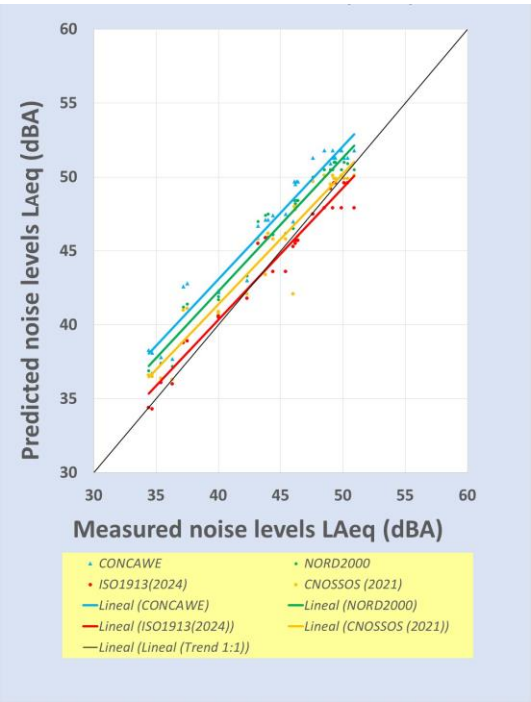

Figure 7. Comparative Analysis Between Monitoring and Sound Prediction for mixed ground (G=0,5)

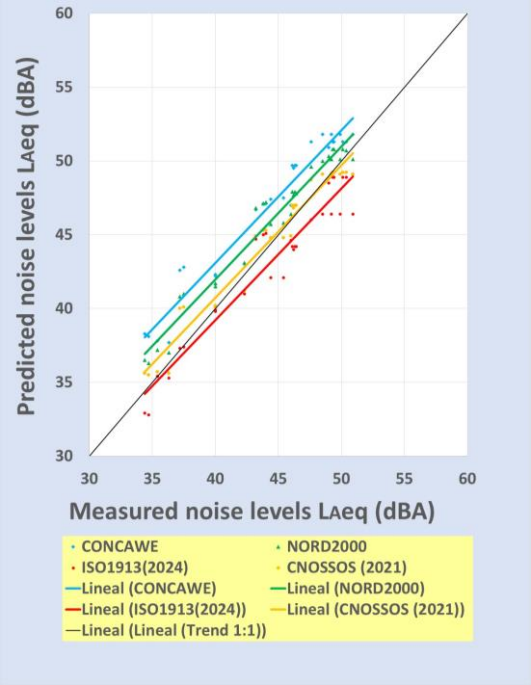

Figure 8. Comparative Analysis Between Monitoring and Sound Prediction for porous ground (G=0,71 - CLC)

4.3 Noise reduction of Mitigation Plan

Figure 9 compares the total noise with and without the implementation of low-noise modes in order to evaluate the effectiveness of the Noise Mitigation Plan strategy.

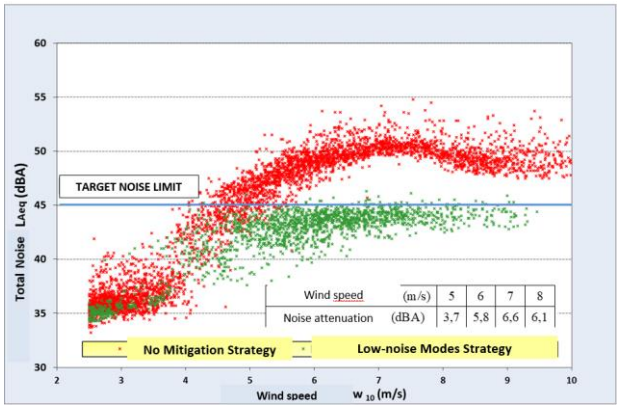

Figure 9. Total noise ($L_A$eq) during the night period and target sound level with the application of low-noise strategies at measurement position 1

The results demonstrate the effectiveness of the proposed corrective measures for reducing sound levels, especially at measurement point 1, where the average reduction is 6.2 dBA for the maximum emission of the wind turbine. At measurement point 2, the average acoustic attenuation is around 2.9 dBA and deviates by about 2 dBA from the expected sound levels. These deviations could be explained by insufficient model validation or could be associated with the implementation of low-noise strategies and the deviations found when they come into operation [30] .

Once the noise attenuation of the low-noise is confirmed, the next step is to consider the impact of the precision of the noise prediction in the design of the mitigation plan, especially during the early permitting phase when all studies are based on simulations. For this purpose, new noise reduction strategies were designed using the most accurate models (ISO9613 for G=0.5 and CNOSSOS for G=0.7) and compared against the original reduction strategy at measurement position 2. The following graph shows the accumulated electrical power as a function of wind speed for the four wind turbines with the highest contribution at that location.

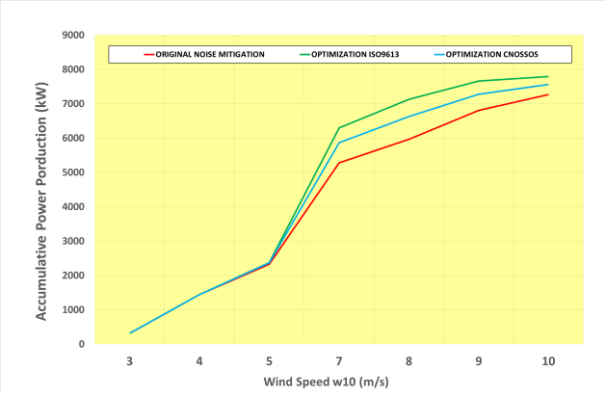

Figure 10. Accumulated electrical power (kW) for the four wind turbines with the highest contribution according to different prediction models

The results show that more accurate prediction models could lead to improvements in the electrical production of these wind turbines by up to 12% in the case of the ISO9613 standard and up to 7% in the case of the CNOSSOS model for these four wind turbines and for that wind direction. The real optimization of electrical production will evidently depend on each case study, including the frequency and distribution of wind speeds and directions, but undoubtedly, the use of more accurate sound

prediction models validated with in-situ monitoring data will potentially allow designing a noise reduction strategy that optimizes the installation's production.

5. CONCLUSIONS

This study has developed a specific system for assessing the acoustic impact of wind farms, using a prediction and acoustic monitoring method, which has been validated in a practical case with complex topography. According to the results obtained for the case under study, the following can be confirmed:

- The prediction model according to CNOSSOS-EU with a ground absorption value G equal to 0,7 and the ISO9613 standard G=0,5 are the calculation standards with the least deviations from the monitored values.
- The results of the monitoring campaigns have shown that the design of low-noise strategies with prediction models is effective for managing the noise generated by wind turbines.
- The use of more accurate and validated prediction models potentially allows for the selective optimization of wind turbine electrical production, ensuring regulatory compliance.

The application of this methodology has allowed to estimate the noise immission level of the wind farm under study with a high degree of precision (average deviation less than 0,5 dBA) and would allow optimizing the electrical production of the four wind turbines with the highest contribution in a range of between 7 and 12%.

In the future, it is recommended to compare the conclusions derived from this study by expanding the validation cases under different variables (topography, distances, height and power of wind turbines, and land uses) as well as verifying the real optimization of production of a wind farm by evaluating long-term averages that consider different wind speeds and directions.

ABSTRACT

Wind turbines are a valid alternative to produce electricity in place of hydrocarbons, in this way it is possible to achieve the objectives set by the energy transition and limit the effects of greenhouse gas emissions. One of the problems that limit the spread of wind turbines are the effects of the impact on the environment. The problems identified are those of flicker shadow, noise and visual impact. The biggest problem is that due to noise. In fact, people who live near wind turbines complain about the negative effects of noise. This paper reports noise measurements carried out in proximity to wind turbines in different wind speed conditions.

Keywords: *wind turbines, acoustic measurements, wind speed, noise, annoyance.*

1. INTRODUCTION

Wind energy contributes significantly to reducing the use of fossil fuels in electricity production and is a valid contribution to the reduction of greenhouse gas emissions. Today, wind energy is spreading to achieve the goals of the energy transition. The first windmills were built in the Middle East around 600 AD and later spread to the countries of Northern Europe. The first wind towers for the transformation of wind energy into electricity were built in the United States in the 1950s and then spread in the 1970s, following the oil crisis. The areas with the greatest presence of wind farms are Asia (China and India), Northern Europe and the United States. In Italy the first wind towers were installed in 1990, but only from 1996 onwards has there been a significant number of plants connected to the electricity grid. In fact, in Italy in 2001 there were only 81 wind farms installed, with a total power of 664 MW (3% of the electricity produced from renewable sources). In 2015 there were 2,734 plants, with a power of approximately 10,000 MW (18% of the electricity produced from renewable sources). In Italy, due to the morphology, the areas with the greatest presence of towers are those in the south, where the average wind speed during the year exceeds 5 m/s. Many wind farms have been built near homes, creating problems for people living in those areas. Compared to other sources of noise (for example, airplanes, railways, etc.), the degree of annoyance of the noise emitted by wind turbines is the one that generates the greatest disturbance in the population. The noise due to the operation of wind turbines is potentially capable of causing sleep disturbances and other pathologies. The reason for these disturbances is due to the particular noise emitted that modulates over time, the type of noise concentrated in the medium - low frequencies and the fact that the towers are over 100 meters high, and the sight of these objects is not accepted by the populations living near the wind farms.

Usually, the noise emitted by a wind turbine is broadband and concentrated in the frequency range between 300 Hz and 2,000 Hz, in the range in which the human ear is most sensitive and therefore the individual feels greater discomfort [1-2]. The types of noise produced are aerodynamic noise due to the rotation of the blades and mechanical noise inside the nacelle, due to the electromechanical components (generator, gear multiplier, cooling systems and other components) [3-4]. Aerodynamic noise is a very complex phenomenon and is due to the turbulence of the air generated by the rotation of the blades and the compression effect of the air on the tubular tower. Another possible discomfort that can be generated is that of the "flicker shadow", or the intermittent effect of the shadow, which occurs when the wind tower is placed between the sun and the observer. The effect of the intermittence of the shadow caused by the rotation of the blades is visible to the observer for over 300 meters from the tower. This phenomenon does not occur when the blades do not rotate. Furthermore, one of the problems that arises in the design phase of wind farms is the theoretical estimate of the acoustic impact generated by the operation of the towers [5-8]. The estimate of the noise produced is performed in accordance with the ISO 9613:2-20024 standard, but in the verification phase the numerical model underestimates the measured value of the sound pressure level [9]. Wind turbines, even if they are complex systems, are considered point sources of sound, since the source-receiver distance is considered sufficiently large compared to the dimensions of the towers. For the determination of environmental noise levels, the ISO 9613-2:2024 standard provides a theoretical method to evaluate the sound attenuation, with the source-receiver distance, in propagation in open-air. The standard provides for the calculation of the equivalent noise level “filtered A”, assuming meteorological conditions favorable to the propagation of sound, through the application of the following simplified relationship:

$$Lp = Lw - 20\,Log\,(d) - 11$$

Where d, is the distance in meters between the sound source (tower) and the receiver as the distance increases the sound pressure level Lp decreases. Furthermore, over time the rotating parts of the towers wear out with a consequent increase in the sound level emitted compared to the initial conditions. This condition has not yet been fully examined, but the effects of mechanical wear and the consequent increase in noise are a problem that needs to be analyzed.

2. ACOUSTIC MEASUREMENTS

The acoustic measurements were carried out with a sound level meter configured to acquire the equivalent sound level of the linear sound, A-weighted, of the statistical levels with a Fast constant time. The sound level meter was installed at a height of 1.70 m from the ground and more than 1.0 m from any vertical surfaces [10]. The wind turbines subject to acoustic measurements have a nominal power of 3 and 4 MW, with a total tower height equal to 100 m and a blade length equal to 60 m. The acoustic measurements were taken with the wind turbines are on (ambiental noise) and off (background noise), to evaluate, with the same wind speed, the noise contribution caused by the operating wind towers. in the condition in which the sound levels were acquired inside an house with open windows. The measured sound levels are reported as a function of time and a table indicating the value of the equivalent sound level LeqA in dBA, the statical sound level L95 in dBA and the wind speed in the condition in which the wind farms are in operation or are turned off. For wind speeds of about 9 m/s, when the towers are in operation compared to when they are turned off it is possible to notice a difference in the measured sound levels. This difference denotes that for this wind speed the towers in operation generate annoyance in the populations living in the vicinity of the wind farms. Table 1 shows the acoustic measurements when the wind speed is below 9 m/s. While Figure 1 shows the time history of the measured sound level (dBA) inside home when the wind speed is below 9 m/s.

Table 1. Acoustic measurements when the wind speed is below 9 m/s

Activities	Leq (dBA)	L95 (dBA)	Average wind speed (m/s)
Towers on Measurements 1	38.5	37.0	9.0
Towers off Measurements 2	25.0	21.5	9.0
Towers on Measurements 3	37.0	35.5	8.8

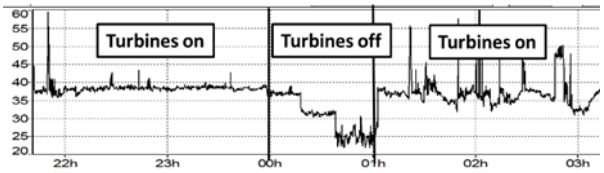

Figure 1. Time history of the measured equivalent sound level (dBA) inside home when the wind speed is below 9 m/s.

Table 2 and Figure 2 instead show the sound levels when the wind speed exceeds 12 m/s. It is noted that for the tower in operation or when it is turned off no differences in the sound level are detected. For these wind speeds the towers in operation do not generate annoyance. The wind's noise covers the noise emitted by the towers.

Table 2 Acoustic measurements when the wind speed between 12 m/s and 25 m/s.

Activities	LeqA dBA	L95 dBA	Average wind speed, m/s
Towers on measurement 1	40.5	37.0	12.0
Towers off measurement 2	40.5	36.0	15.0
Towers on measurement 3	39.0	36.5	14.2
Towers on measurement 4	45.0	37.5	14.4
Towers on measurement 5	51.0	47.0	21.3
Towers off measurement 6	54.0	47.5	23.1
Towers off measurement 7	52.5	48.5	24.4

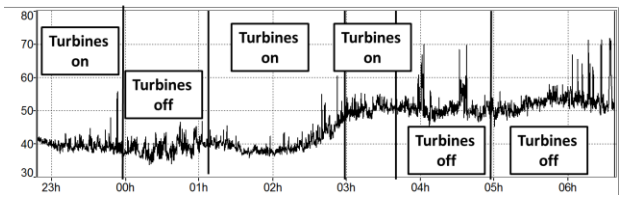

Figure 2. Time history of the measured equivalent sound level (dBA) inside home when wind speed is in the range between 12 m/s and 25 m/s.

The following are the results of measurements of noise generated by wind towers and the relative wind speed near the microphone, carried out outside a house. The distance from tower to home is 200 meters; the wind tower is 70 m height; the nominal power is 200 kW. The measurements are performed with a sound level meter and the equivalent sound levels have been grouped in function of the wind speed range (from 1 m/s to 5 m/s). The values of the ambient noise level (active source) are shown in solid line, while the background noise (source off) are shown in dashed line. Figure 3 shows the sound trends in the daytime period; Figure 4 shows the sound trends in the night period. The wind speed varies between 1 m/s to 5 m/s. For wind speed values above 5 m/s the measured sound level values are meaningless.

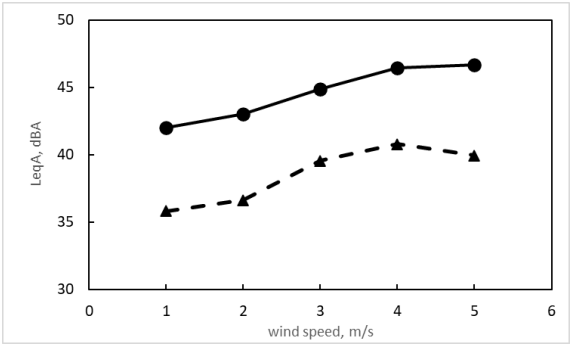

Figure 3. Sound level trends in the daytime period.

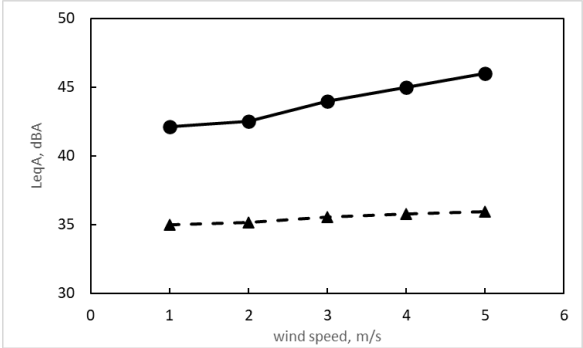

Figure 4. Sound level trends in the night period

The background noise during the day is higher than the night one due to the presence of human activities. While the environmental noise (tower in operation) increased with the increase of the wind speed as expected. It should be noted that the noise levels when the source is active do not change between the night and day periods. The noise of the wind tower is a stationary sound source, for each interval of the wind speed considered.

3. CONCLUSIONS

This paper reports the results of acoustic measurements performed near wind towers. The effects of wind on phonometric measurements have been analyzed. For measurements inside houses, it has been noted that the effects of noise disturbance are due to wind speeds up to 9 m/s. For higher wind speeds, the wind noise covers the noise emitted by the wind towers. Furthermore, the values of acoustic measurements performed outside a house are reported for different wind speeds both when the wind tower is in operation and when it is off. It is possible to note that as the wind speed increases, the effect of the wind tower emission increases.

WIND TURBINE DIRECTIONAL TONALITY

Mikel Amatriain[1*] **Miguel Arana**[2]

ABSTRACT

Knowledge of the emission patterns (directivity) of modern wind turbines improves the prediction of noise levels at receptors over medium and long distance. Tonality is usually attributed as a penalty or character correction factor in most regulations. In some of them, the penalty, up to 6 dB, is equivalent to quadrupling the power of the wind turbine. To predict the impact caused to residents near wind farms, it is desirable to know precisely both the directivity of the wind turbines and the potential tonality.

The present work shows the results of the tonality around a wind turbine and not only for the downwind conditions of the IEC standard. It was carried out for different wind speeds. The aim of this work is to contribute to the improvement of the prediction of wind farm nuisance.

Keywords: *Directivity, Tonality, Wind, Turbine*

1. INTRODUCTION

Part 11 of the IEC 61400 standard [1] outlines a structured methodology designed to ensure consistent and precise measurement and analysis of acoustic emissions from wind turbines. This section of the standard offers procedures for characterizing the noise emissions of a wind turbine by considering it as a point source situated at the rotor center.
Standard measurements are typically conducted at a designated reference location to determine the turbine's acoustic profile. However, to gain further insight into the directional tonality of emissions, supplementary measurement positions can be used. These additional measurement locations, while not commonly applied in traditional IEC testing protocols, provide valuable data concerning the directional characteristics of wind turbine noise.
By incorporating a greater number of measurement positions, this paper seeks to explore the tonal directivity of a wind turbine, offering a comprehensive analysis that extends beyond standard practices.

2. METHODOLOGY

The reference position for the measurements is specified as the downwind location, situated at a distance equal to the hub height plus rotor radius from the rotor center. As optional measurement locations, positions at upwind and downwind angles of ±60° are also considered at the same distance.

In both the downwind and upwind positions, similar sound pressure levels are anticipated, whereas greater variations are expected at the crosswind positions, as suggested by aerodynamic sound theories and empirical studies [2-5]. The directionality of the predominant aerodynamic sound source is primarily attributed to trailing edge noise; however, variations in mechanical and electrical noise can arise depending on the wind turbine's cooling system configuration or whether the power electronics are housed inside or outside the tower. Some setups may also include additional cooling systems. To evaluate the impact of these components, supplementary measurement locations may be necessary [6].

This setup aims to provide a comprehensive array of measurement points to capture a detailed acoustic profile of the wind turbine from multiple directional perspectives. By

using these positions, both aerodynamic and mechanical noise characteristics can be thoroughly analyzed.

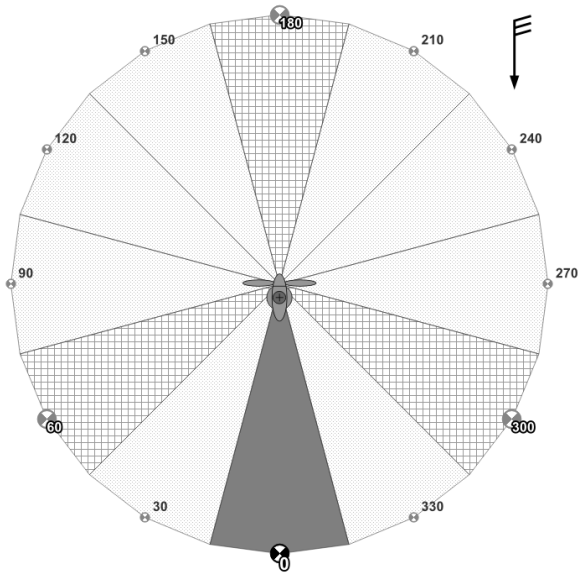

Figure 1. Plan Standard pattern for microphone measurement positions (plan view). Measurement positions for reference (0º), optional locations (60º, 180º and 300º) and complementary locations in 30º sectors.

3. TONAL AUDIBILITY

The IEC 61400-11 standard provides clear definitions and descriptions for terms related to the tonality and tonal audibility of the noise generated by wind turbines. Specifically, Section 9.5 of the standard outlines the procedure for assessing tonality across varying wind speeds through narrowband analysis.

According to this procedure, the tonality should be represented for each wind speed bin, using increments of 0.5 m/s. This approach ensures a detailed examination of tonal characteristics over a spectrum of operating conditions, thereby providing a comprehensive understanding of the noise emissions from wind turbines.

3.1 Fixed positions with board positioned on the ground

Measurements are conducted using a microphone positioned on a measurement board placed at ground level. This setup is designed to reduce wind noise impacting the microphone and minimize the influence of varying ground types on acoustic data. All measurements are synchronized with data from both the turbine and mast anemometers to ensure accurate correlation. The reference wind speed for analysis is derived from the turbine's electrical power output.

For each wind speed bin, ten measurements were selected for analysis. In this study, a sampling frequency of 25,600 samples per second was employed, resulting in data matrices with dimensions of 256,000 x 10 cells for each set of conditions. Although the wind speeds varied from 6 to 13 m/s, the results presented will focus specifically on the wind speed bins of 6 and 11 m/s.

The algorithm outlined by the standard is straightforward, though it allows flexibility in narrowband spectral resolution, accepting values between 1 and 2 Hz. The results obtained using both resolutions are practically identical [7]. In the analysis, ten measurement records each lasting 10 seconds are utilized for a given wind speed. The overall tonal audibility is confirmed if at least six out of ten narrowband spectra exhibit an identified tone originating from the same source. Tones identified in different spectra are considered to have the same origin if they fall within an interval of ±25% of the critical band centered at their frequency. Tones of the same origin are treated and reported as one tone.

Tables 1 to 19 detail the methodology employed by the implemented program in Matlab [8] for tone detection and audibility analysis. Utilizing the Fast Fourier Transform (FFT) of the ten input signals, the program computes sound levels, energy, and bandwidth for resolutions of 1 and 2 Hz. It identifies local maxima of the signals but selects only those whose levels surpass the critical band average by more than 6 dB (excluding the maximum line and its two adjacent ones) as potential tones. The *findTones()* function then locates these tones.

The signal lines are categorized as 'masking,' 'tones,' or 'neither' using the L_{70} and L_{pn} criteria (sound pressure level of masking noise within a critical band). The process concludes with the determination of tonality (the difference between the tone level and the masking noise level) and audibility, which includes a frequency-dependent correction to account for the human ear's response to tones at varying frequencies.

At this wind speed, 11 m/s, only one audible tone is identified at a frequency of 113 Hz (or 114 Hz when using a 2 Hz resolution). Reporting these frequencies is justified, as they correspond to the maximum number of records with a tone present at that frequency, totaling five for both scenarios.

Furthermore, a secondary tonal presence at 227 Hz aligns with the frequency of 2 * f_c, suggesting a mechanical origin, likely related to the slow axis of the nacelle.

The tonal noise identified in the high-frequency range is attributed to background noise from bird songs and is not considered a tonal component originating from the wind turbine. To accurately assess this background noise, narrowband spectra should be utilized to isolate and analyze these frequencies.

Table 13. Tone identification for 60° position and wind speed of 6 m/s with 2 Hz resolution.

f_c, Hz	Identification of spectra with a tone at this line

250	**2,29**	**4,36**	**9**	**6**	**Y**

The highest average audibility for low wind, 6 m/s at hub height, is found at f_c=250 Hz with $\Delta L_{a,6}$ =4.36 dB, similar to the audibility of $\Delta L_{a,11}$=4.76 dB resulted at 11 m/s for the same position but at different central frequency f_c=114 Hz.

3.2 Short time complementary positions

Short-time measurements were conducted around the wind turbine. All measurements were performed using a tripod set at a height of 1.5 meters. Events not associated with the wind turbine source under investigation are excluded from the analysis.

Measurements are carried out with an emphasis on minimizing wind noise at the microphone. A temporary mast-mounted anemometer serves as a reference to ensure accuracy, with measurements discarded if wind speeds exceed 5 m/s at 3 meters above ground level. Consistent with the IEC standard, the reference wind speed is derived from the turbine's electrical power output.

In parallel with the IEC methodology test, additional logs were obtained using a moving tripod, maintaining a distance of hub height plus rotor radius. The testing was extended up to the 180-degree position (upwind) in 30-degree increments relative to the yaw orientation, ranging from 0 degrees (downwind) to 180 degrees (upwind). These measurements incorporated A-weighted spectra, including FFT analysis with a sound level meter integrated at a 1.465 Hz resolution, alongside third-octave band recordings. These positions were synchronized with recordings from the fixed ground-mounted board and turbine data to ensure comprehensive analysis.

The reference condition for measurements is established during middle-range turbine operation, which corresponds to 30% to 60% of the rated power. This operational range represents wind speeds at hub height between 6 and 11 m/s, effectively minimizing background noise levels and wind-induced distortion. All measurements are conducted under conditions where wind speeds remain below 5 m/s, as monitored by a temporary meteorological pole synchronized with the system.

Short-time complementary measurement positions focus on the frequency range of 20 Hz to 1500 Hz. These efforts aim to minimize background noise effects while identifying frequencies detectable from standard positions.

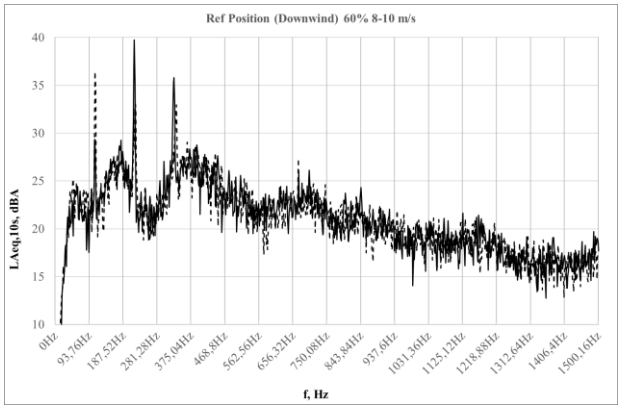

Figure 2. A-weighted FFT-spectra for reference position at 60% of capacity.

The FFT-spectra analysis reveals similar tonal components to those identified in the board-positioned measurements, specifically at frequencies of 110 Hz, 218 Hz, and 328 Hz. These complementary positions are strategically employed to corroborate findings from automated audio extraction analysis, ensuring consistency and accuracy in the detection and characterization of tonal components.

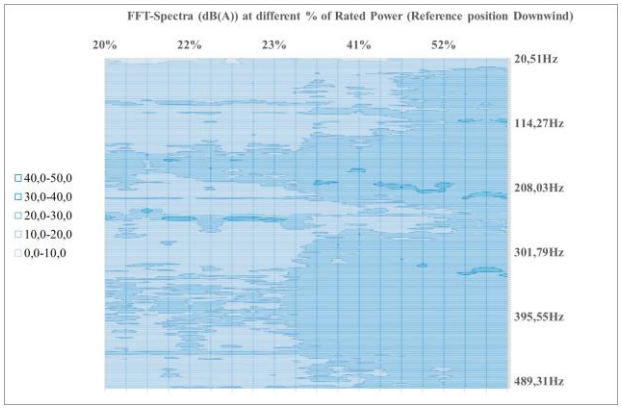

Figure 3. FFT-spectra change at different operational conditions 20 to 60% of active power output at downwind reference position.

Selected spectra from the same location are grouped and organized according to output power and derived wind speed. In Figure 4, the tones identified per the IEC standard exhibit a frequency shift from f_c = 83 Hz to 114 Hz, emerging at higher power ratings. Additionally, this shift reveals three harmonics at frequencies of 2 * f_c and 3 * f_c.

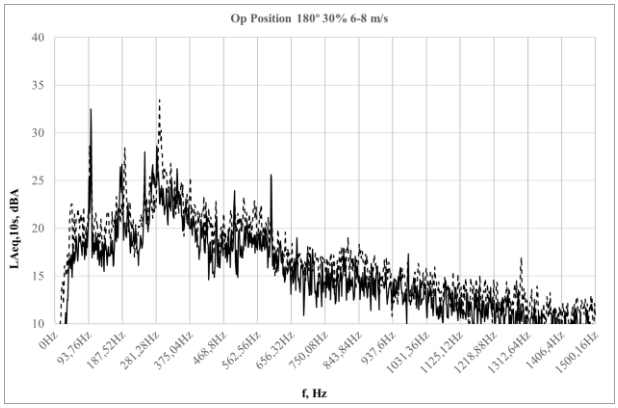

Figure 4. A-weighted spectra for upwind position at 30% of capacity.

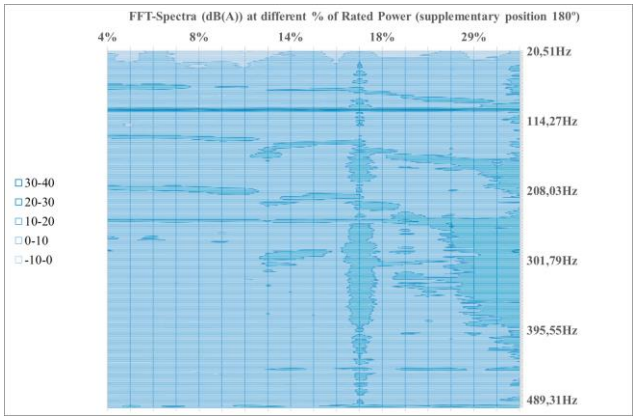

Figure 5. FFT-spectra change at different operational conditions 5 to 30% of active power output at 180 position (upwind).

The results from the upwind position indicate an increase in the tonal component at 100 Hz. The origin of this tone is electrical and aligns with the behavior typically observed in transformers. The tonality at 100 Hz remains stable across all operational rates, whereas the predominant tone at 113 Hz, identified at the IEC-positioned measurements, varies according to the wind turbine's rotary speed.

The sources and locations of the two tonal components are distinct. However, under specific operational conditions, they can converge at the same frequency, leading to enhanced audibility and perception of the tones.

4. CONCLUSIONS

The IEC 61400-11 standard specifies the measurement position to be in the downwind condition. It assumes an apparent sound power level from a point source located at the rotor center, with emissions in the downwind direction analogous to those of the wind turbine.

Experimental noise measurements around a modern wind turbine have been carried out to explore the tonal directivity associated with the turbine.

The primary noise source of a modern wind turbine is attributed to the blades. Specifically, it is recognized that the main emissions originate from the last third of the blade. Additionally, the trailing edge noise exhibits a non-omnidirectional directivity, varying with different wind speeds, rotor speeds, and pitch angles.

Mechanical and electrical components can contribute to the tonal characteristics of a wind turbine. These components tend to be more audible at lower wind speeds, as emissions from the rotor decrease and background noise is minimal.

The noise emitted by the wind turbine was measured in the absence of other external sources such as other wind turbines, industrial noise, or traffic noise. Some bird songs have been identified in the recordings, contributing primarily in the 4-5 kHz range. These contributions do not affect the results, which focus on the frequency range of 20 to 1500 Hz.

The automated audio analysis from fixed positions (with board positioned on the ground) shows good correlation with the short term moving positions (tripod at 1.5 meter).

Ideally, reference measurements and all complementary measurements should be performed simultaneously, adhering to the methodology outlined in the IEC standard. Utilizing synchronized parallel measurements conducted over short periods at 1.5 meters above ground level demonstrates excellent correlation, particularly when the maximum wind speed is controlled and limited. The ground effect, in general, must be considered and corrected to ensure measurement accuracy.

This technique offers increased flexibility while maintaining reference positions downwind, enabling the investigation of tonal components whose origins may not be readily apparent from a fixed position.

Certain components of wind turbines can contribute to overall sound levels and, particularly, to tonal components, which may not originate from the hub height. These components may have directivity characteristics that might alter test results, as they deviate from the assumption that emissions are centered at the rotor location.

When noise sources are situated close to ground level, the topography of the terrain significantly influences sound propagation. The selection of test conditions, including the IEC-specified downwind positions, can alter results, especially concerning components close to ground level.

The use of optional and complementary measurement positions reveals significant differences in audibility assessments. These variations can even alter the dominant tonal frequency observed in the analysis.

Further investigations should involve additional measurements across different turbine types. Measurements at higher wind speeds are preferable, with devices positioned on the ground, and simultaneous assessments conducted in various optional or complementary locations. The variability in wind direction presents a challenge for these tests. Effective synchronization of non-acoustic data aids in filtering results when necessary. However, ideally, stable conditions are preferred, allowing measurements to cover different wind speeds within a shorter period of time and enabling precise repositioning.

GUIDELINES FOR AN INSTITUTIONAL PROPOSAL FOR THE CREATION OF A NOISE AND VIBRATION OBSERVATORY IN URUGUAY

Luis Marisquirena[1*] **Elizabeth González**[2] **Pablo Gianoli**[3]
[1 2 3] Facultad de Ingeniería, UDELAR, Uruguay

ABSTRACT

Concern about noise pollution and the consequences of exposure to noise and vibration is of worldwide relevance. Organizations such as the World Health Organization have dedicated spaces to visualize these problems of exposure to noise and vibration. So much so that they describe noise pollution as the first environmental nuisance in developed countries and as a threat to public health. In Europe, noise pollution is the second most harmful environmental factor. There are multiple studies where it is demonstrated the link of diseases with exposure to noise and vibration, such as heart disease, emotional pathologies, digestive disorders, among others.

Keywords: *Observatory, Noise, Vibrations*

1. INTRODUCTION

What is a Noise and Vibration Observatory?
The Noise and Vibration Observatory operates as a tool that, from the processing of environmental information on noise and vibration, generates knowledge and guidelines for action so that, jointly, the population and the authorities become aware and act to mitigate the effects on the welfare and public health of exposure to noise pollution caused by noise and vibration. It will supervise, together with the Government and the University, the operation of an equipment calibration laboratory.

The information processed will be used to develop communications of interest to the population as well as to support actions in defense of citizens and to seek changes in legislation to improve their welfare and health conditions.

2. GENERAL OBJECTIVE OF THE NOISE AND VIBRATION OBSERVATORY

To manage the environmental information on Noise and Vibrations, making it available for actions for the benefit of the population.
This Observatory is aimed to carry out actions such as:
- Working together with the Institutions that already carry out some of the tasks related to environmental noise pollution, for the collection of information on Noise and Vibrations. The compilation will include records of measurements, reports related to the subject, description of actions developed from detected problems related to noise and vibrations, etc.
- The development of local information through the promotion of inter-institutional and intra-institutional research related to the consequences of noise and vibration exposure. Developing local databases with historical and new information obtained. Processing information with inter-institutional data cross-checking.
- The analysis of current regulations, proceeding to their assessment, the follow-up of policies related to noise and vibration, and their evaluation with respect to international regulations and environmental agreements entered into by Uruguay. Reviewing the regulations, particularly those related to construction (buildings, traffic routes) regarding

[*] ***Corresponding author***: luismarisquirena@gmail.com

noise and vibration. Updating the regulations in response to environmental commitments acquired. Proposing adjustments for its updating and seeking consensus to unify noise and vibration regulations in the country.
- Registering and analyzing the social problems associated with noise and vibrations (Noise Pollution).
- Proposing a noise and vibration monitoring network with fixed and mobile stations. Registering and processing data. Elaboration of reports. Generation of proposals for noise attenuation solutions. Elaboration of the "MAP OF NOISE AND VIBRATION ALERTS". Analyzing the information to be made public on noise and vibration. Maintaining public information channels and managing their operation. Evaluating the realization of mass participatory mapping for noise and vibration. Maintenance of technical and information processing equipment. Maintenance of an operational Noise and Vibration Control Center where the Noise and Vibration Alerts Map is displayed centrally in addition to being able to visualize specific selected points. Developing noise and vibration simulation models.
- Giving general guidelines for the installation in the country of a certification laboratory for noise and vibration measurement equipment. This laboratory will depend on public institutions with competences for this task.
- Supporting the actions of the municipalities in their competence as environmental police. Reviewing specific regulations and evaluation of problems. Generating actions and designing a system, with specific equipment and resources, for the automatic control of deviations from the regulations and subsequent derivation of the information to the offices with competence to apply sanctions.
- Analyzing specific noise pollution problems and proposing possible solutions.
- Systematizing information related to noise and vibration from the register of complaints. Statistical treatment of information.
- Promoting the relationship with other organisms related to noise and vibration problems. Facilitating the generation of agreements for the exchange of information and homogenization of information to be made public.
- Promote the formation of a National Noise and Vibration Honorary Advisory Council (CCOHNARVI) that will function as a consultative body. The National Noise and Vibration Honorary Advisory Council should have the participation of at least three national referents in noise and vibration issues and in parallel maintain communication with the main actors linked to the subject such as the Ministry of Environment, the Congress of Mayors, the UDELAR (Faculty of Engineering, Faculty of Architecture, Faculty of Social Sciences, Faculty of Information and Communication, etc.), the Neighborhood Ombudsman, Social and Business Organizations.
- To carry out the management for the realization of training and communication instances such as Congresses, Forums, Informative Talks, etc. to spread and raise awareness about the noise and vibration problems and to elaborate possible actions to mitigate the impacts of these problems.
- It will supervise, together with the National Government and the University, the operation of a calibration laboratory for equipment related to noise and vibration measurements.

3. SPECIFIC LINES OF WORK

- Centralizing information on noise and vibration.
- Managing the network of noise and vibration records.
- Processing available information and information generated from new records.
- Updating available tools (acoustic map, regulations). Definition of homogeneous noise and vibration zones. Strategic map. Support environmental police tasks. Noise and vibration laboratory.
- Raising awareness of noise and vibration problems. Periodic reporting. Preparing information for public disclosure. Developing the concept of co-responsibility.
- Evaluating the development of collaborative noise and vibration maps adjusting them with the records of fixed and mobile networks.
- Developing noise and vibration simulation models.
- Coordinating the supervision of the equipment calibration laboratory.

4. INSTITUTIONAL INTEGRATION

General aspects of the integration of the observatory in an Institution are shown:
- Dependency relationship: 2nd or 3rd institutional level.
- Unit modality with allocation of resources

4.1 MINIMUM HUMAN RESOURCES:

- 1 engineer specialized in Acoustics and Vibrations.
- 2 assistant engineers
- 1 electronics technician with knowledge in telecommunications.
- Transversal supports from institutional dependencies linked to noise and vibrations.

4.2 EQUIPMENT:

- Sound level meter network reviewing and complementing other existing networks and adapting mobile recording equipment.
- Seismograph network to be considered and vibration equipment to be acquired.
- Data transmission and reception at headquarters. Maintenance and operation of recording networks. Noise and Vibration Control Center.
- Processing software and appropriate hardware. Data backup units.
- Availability of transportation for recording, maintenance and supervision of the networks.

5. ENVIRONMENTAL POLICE

To the extent that it falls within the purview of the Institution that hosts the Observatory, support the environmental police tasks that will continue to be carried out as before. The observatory will support these offices.

6. INFORMATION TO BE COLLECTED AND ORGANIZED ON NOISE AND VIBRATIONS

- Compilation of information within public institutions: City Halls, Faculty of Sciences, Faculty of Engineering, Neighborhood Ombudsman, etc.
- Information on noise and vibration regulations: National norms and departmental norms. Compilation.
- Records of the existing sound level meter network in Uruguay.
- Compilation of data on complaints or inspections related to noise and vibration.
- Acoustic map of Montevideo. Departmental acoustic maps.
- Proposals for updating regulations. Feasibility of unification of regulations.
- Compilation of other available information
- Experiences from Uruguay
- Experiences outside Uruguay
- International regulations. Agreements and commitments.
- Equipment certification. Certification laboratory.

7. EQUIPMENT FOR NOISE AND VIBRATION RECORDING NETWORKS TO BE INSTALLED

7.1 Recording networks with sound level meters.

The Municipality of Montevideo has a network of fixed sound level meters that should be updated and maintained. Verify the existence of other networks in the country. Implement the installation of equipment to develop a recording network with sound level meters. It is proposed, based on this existing network, to acquire equipment for fixed installations and mobile noise recording to complement the existing network and meet the specific needs of the Observatory. Analyze the network, adapting it to obtain data of homogeneous quality in the fixed network compared to the mobile equipment.

7.2 Seismograph recording networks

There is a network of seismographs operated by the Faculty of Sciences. It is proposed to acquire equipment for fixed installations and mobile vibration recordings to complement the existing network and meet specific needs of the Observatory.

7.3 Recording networks oriented to monitoring.

Evaluate international experiences of recording and monitoring networks for noise, especially associated with construction and traffic. The facilities have noise recording equipment and cameras to identify noise sources.

7.4 Network complements to be installed.

- Hardware and software for network data storage and transmission.
- Implement the noise and vibration monitoring network based on the knowledge generated in the development of other data recording and transmission networks.

8. MINIMUM SOFTWARE AND HARDWARE FOR THE NOISE AND VIBRATION OBSERVATORY.

- The use of free software is suggested as far as possible.
- Mapping in the existing geographic systems of Ministries and Municipalities. Implement the warning map. Improvements to be proposed in the existing systems.

Linkage for the reception of information from mobile telephone equipment.
- Use for dissemination the existing channels already established for environmental issues in both the Ministries and the Intendancies. Improve and expand communication channels.
- Two fixed equipment and one laptop for information management.
- All the equipment will have the software installed.
- They will have features that will allow storing and processing all available information and making adequate backups.
- One of the fixed equipment will be the main equipment and will receive the information from the sound level meter and seismograph networks. The other equipment will function as a backup. All the information is backed up in the institutional servers.

9. NOISE AND VIBRATION HONORARY ADVISORY COUNCIL

- The Noise and Vibration Observatory, together with other institutions, shall promote the creation of an Honorary Advisory Council on Noise and Vibration, which shall have at least three members, who are referents in Uruguay on noise and vibration issues. It will act in consultation with the rest of the actors linked to noise and vibration issues: Ministry of Environment, Congress of Mayors, UDELAR (Faculties of Medicine, Engineering, Social Sciences, Psychology, Architecture, Information and Communication), Neighborhood Ombudsman, associations of transport companies, events (discos, parties, music, dances, ...).
- Functioning as a forum to raise and discuss general issues of social scope related to noise and vibrations.
- Resolutions of an orientation nature that may or may not be taken later at a normative level.
- Contribute to raising awareness on noise and vibration issues and the generation of strategies to address this problem with general consensus.

10. EXPERIENCES IN URUGUAY TO BE TAKEN INTO ACCOUNT BY THE NOISE AND VIBRATION OBSERVATORY

OAN: National Environmental Observatory. It depends on the Ministry of Environment. Among the environmental issues it could integrate noise and vibrations.

MOVES PROJECT: Noise studies were carried out as part of this project.
NOISE MONITORING: Municipality of Montevideo (Grafana) There is a fixed network of sound level meters that theoretically measure 24/7 but have some updating problems. There is historical information that should be evaluated.
NEIGHBORHOOD OMBUDSMAN: Compilation of complaints related to noise and vibrations.
ELECTRICAL AND MECHANICAL INSTALLATIONS SERVICE: Municipality of Montevideo. History of noise nuisance complaints. History of seismograph measurements in tasks related to construction using explosives.
FACULTY OF SCIENCES: Geophysical Observatory of Uruguay.
NATIONAL EMERGENCY SYSTEM: Record of earthquakes in Uruguay.

11. NOISE AND VIBRATION OBSERVATORY. EXPERIENCES OUTSIDE URUGUAY.

There are similar experiences in the world. In some cases, they are already implemented and in development; in other cases, only some aspects of the proposal have been implemented.
As examples we have the City Grenoble with Accoucite [1] of Paris with Bruitparif [2] , , in Cordoba (Argentina) the Noise Observatory of Cordoba [3], in Australia the Australian Observatory of Acoustics [4], Ecodes in Barcelona [5] , and experiences in some cities of Colombia [6] and in Santiago de Chile [7].

12. RELEVANT ROLE FOR DEVELOPMENT IN LATIN AMERICA

Some experiences have been reported, mainly in Europe, of noise observatories. In the case of Latin America, being able to set up a noise and vibration observatory such as the one proposed will be a milestone to support the development of those partial experiences already underway and to encourage the installation of other observatories in Latin American countries.
The possibility of having local noise and vibration measurements makes it possible to develop policies to improve the quality of life of the inhabitants of Latin America. The possibility of having own indicators for Latin America favors a more effective measurement of development projects that include improvements in noise and vibration impacts. It also makes possible, to the extent

that it is possible to maintain continuity, the existence of time series of values to weigh improvements due to implemented policies.

13. ASPECTS OF NOISE POLICY.

In the case of Uruguay, regulations originate from different agencies at the two higher levels of government. The initiative may come from these levels of government or from other agencies. There are laws, decrees, regulatory decrees that cover the whole country. There are local regulations that originate from departmental governments.
At the national level, through the Ministries of the Environment, Labor and Social Security and the Ministry of Health, there are regulations and the authority to oversee the regulations. At the departmental government level, there are regulations and the authority to oversee them.
The regulations also include the international conventions signed by Uruguay at the ILO or the WHO that are related to noise and vibration control.
A review of the existing regulations shows that in many cases they are outdated, the values are difficult to adequately control and there are differences between the requirements of the departmental governments.

14. URUGUAYAN REGULATIONS

In the case of Uruguay there are national and departmental regulations.

14.1 NATIONAL REGULATIONS

Law No. 17852. Prevention, surveillance and correction of noise pollution.
Decree N° 143/012
Noise and vibration regulations are included in the regulatory compendium on occupational health and safety. [8]

14.2 DEPARTMENTAL GOVERNMENT REGULATIONS

Each departmental government has its own regulations in addition to the national regulations they must comply with. [9] .

15. RECOMMENDATIONS.

It is advisable to set up a Noise and Vibration Observatory in Uruguay to centralize existing and new information generated from field work on noise and vibration.

This Observatory will become a national reference point on this subject, making the information available for its use with different scopes, from the elaboration of regulations to the dissemination for educational purposes.

The existence of a reference center of this type in the country will serve as a bridge to establish exchange agreements with other similar centers around the world.

ABSTRACT

Literature provides strong evidence that nature can potentially alleviate negative mental as well as physiological health effects of excessive traffic noise exposure. As green spaces (GSs) not only help mitigating negative noise impact, but also improve public health in general, GS planning has become an important task for cities. We conducted a field study in the city of Zurich, Switzerland, to investigate which characteristics of GSs determine their attractiveness. In three waves in the summer periods of 2022 and 2023, 1,129 participants filled out an online questionnaire that included a participatory geographical information system approach to specify and characterize their most visited GS. Interestingly, while the distance to the nearest GS was important for how frequently residents visited GSs spaces, 64% of the participants still did not indicate their closest GS as their most visited one. We found that large GSs, which in general exhibit lower traffic noise exposure, attract more visitors than small ones. Water bodies were also identified as attractive. Our study highlights the relevance of these features for city planners and urbanists when planning, designing and/or maintaining urban GSs.

1. INTRODUCTION

Urban areas are continuously expanding. As urbanization increases, permanent noise-related activities within these areas also rise. In Europe, a large proportion of the population in urban areas is currently exposed to harmful environmental noise, particularly from road traffic [1]. With rising demand of mobility, exposure of the population and corresponding undesirable health outcomes are likely to aggravate. Environmental resources, specifically green spaces (GSs), have been identified as potential elements to alleviate the adverse noise-induced health impacts. However, urban densification not only entails an increase in noise pollution, but usually also a loss of GSs.

One of the goals of the RESTORE project (Restorative potential of green spaces in noise polluted environments; www.restore-project.ch) was to determine how frequently GSs are used and what features make them attractive.

2. METHODS

The concept and methodology of the survey (i.e., noise and green exposure assessment, stratification to identify study areas, participant selection and inclusion/exclusion criteria, recruitment, etc.) follows the study protocol by Dopico et al. [2]. In the following, we give a short methodological overview of this cross-sectional study.

The survey was conducted in a stratified population sample across the municipality of the city of Zurich, Switzerland, according to varying levels of road traffic noise exposure and the degree of access to GSs at home.

The city of Zurich has 139 publicly accessible GSs. All GSs were characterized by size, modelled road traffic noise exposure, type (i.e., bathing area, botanic garden, cemetery, meadow, miscellaneous, playground, sports complex, urban forest and urban park) and the presence of natural water bodies (stream, river or lake: with vs. without). In addition, 156 audio and video recordings of five minutes length were taken in 48 GSs close to the sampling areas, to characterize landscape and soundscape in more detail.

A total of 7,368 potential participants were randomly selected within the stratified sample and contacted with an invitation letter, followed by a reminder letter in case of no response by the specified deadline, in three waves in the summer periods of 2022 and 2023.

The participants filled in an online survey in German covering, among others, questions about noise annoyance and leisure time activities, where participants were asked about the main reason for GS visits. In addition, they were asked to pinpoint a location in their most visited GS on a map. The participants were also presented the ISO 12913-2 soundscape assessment scale [3], to retrospectively describe the soundscape in their most visited GS. The soundscape variables Pleasantness and Eventfulness were derived according to ISO 12913-3 [4].

Each participant was assigned an anonymized identification number, and a building code was linked to each identification number, enabling the merging of survey and geospatial data, which were extracted from public sources. Data from public sources comprised (i) modelled road traffic noise exposure data (L_{den}) across the city of Zurich for façade points of all buildings for the year 2020 to quantify the noise situation at home, (ii) road traffic noise exposure data for the day (L_{day}) from sonBASE, the Swiss-wide noise data base, for the year 2015 to quantify the noise exposure of the GSs, (iii) location (as polygons) and properties of public GSs, and (iv), quantification of greenness around participant's dwellings (within a 300 m euclidean buffer) with the mean value of the satellite-derived Normalized Difference Vegetation Index (NDVI).

A total of 1,129 participants across Zurich took part in the online survey (response rate of 15.3%). From those, 282 participants were excluded due to wrong or missing indication of their preferred GSs location or due to missing data (either L_{den} or questionnaire data). The final sample comprised 847 participants. Figure 1 shows a density heat map of the home locations of the study participants, as well as the locations of publicly accessible GSs and water bodies.

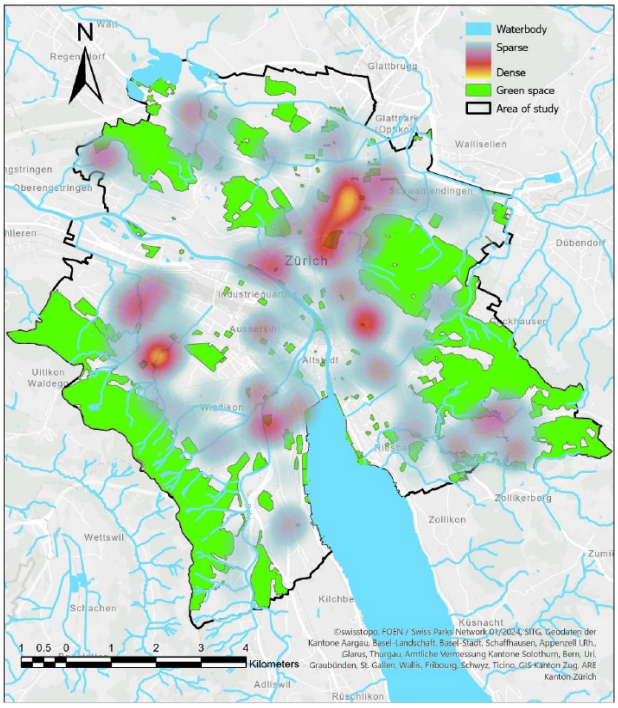

Figure 1. Density heat map of the city of Zurich showing the home locations of the study participants.

Two outcome variables were explored by means of negative binomial regression models analysis:

a) The **frequency of visits**, which reflects the individual perspective and is based on the question how often participants visit their most frequented GS.
b) The **number of visitors of a specific GS**, which serves as an indicator of attractiveness by reflecting the number of visits a GS generates.

As predictor variables, the characteristics of the home environment (L_{den}, NDVI, gardens), individual factors (noise annoyance, perceived free time) as well as GS characteristics (L_{day}, size, water bodies, soundscape variables Eventfulness and Pleasantness) were explored.

3. RESULTS

A share of 68% of the participants reported to visit their most frequented GS at least once a week, confirming the importance of public GSs in their daily routine. Urban forests and parks as well as GSs close to water bodies were visited very frequently and seem to be specifically attractive. Interestingly, 64% of the participants did not indicate their closest GS as their most visited one. In total, 91 GSs were selected by the participants, while 48 GSs remained unvisited in this study. An explorative analysis comparing the properties of visited vs. non-visited GSs showed that visited GSs tended to be substantially larger than the non-visited ones. In addition, visited GSs had considerably lower noise exposure, with a median L_{day} of 44 dBA and of 57 dBA for visited compared to non-visited GSs, respectively. This raises the question which factor is more relevant for people to visit a GS; low noise exposure or the size of the GS.

The statistical analysis revealed the following associations:

The individuals' frequency of visits to GSs significantly increased with (i) increasing greenness (NDVI) at home, (ii) increasing road traffic noise annoyance at home (particularly for females), (iii) increasing perceived free time (particularly for males), (iv) decreasing distance from home to the most visited GSs, and (v) increasing individually perceived eventfulness of the GS's soundscape.

The finding about the soundscape variables should be interpreted with caution. All GSs exhibited neutral to pleasant and medium eventful soundscapes. The fact that pleasantness did not show any significant associations might be attributable to the small variability of pleasantness scores in the dataset. On the other hand, the positive association with eventfulness could be a coincidence, as the sound recordings revealed that positively connoted events like bird song or human voices were present in some locations, while in others negatively connoted events like individual vehicle pass-bys dominated.

The attractiveness of urban GSs, as measured by the number of visitors (our study sample only), was found to increase with (i) increasing size, and (ii) when water bodies are present. Here, one should note that size and noise exposure were negatively correlated, i.e., the importance of (large) size indicates also the importance of (low) road traffic noise exposure.

4. CONCLUSION

This cross-sectional study investigated the determinants for the frequency of GS visits in an urban environment in the municipality of Zurich, Switzerland. It also assessed the attractiveness of GS by the number of visitors they received from the study sample. The size of GSs and the presence of water bodies emerged as the main attributes to attract visitors. The visited GSs were generally also rather quiet.

Our study highlights the relevance of these features for city planners and urbanists when planning, designing and/or maintaining urban GSs.

NECESSARY STEPS TO ADVANCE RESEARCH ON HEALTHY URBAN SOUND PLANNING

Timo Haselhoff[1*] **Susanne Moebus**[1]
[1] Institute for Urban Public Health, University Hospital Essen, Essen, Germany

ABSTRACT

The acoustic environment (AE) matters for human health and well-being. Decades of research revealed noise pollution to be a major disease burden. Well-established mitigation strategies like speed limits or noise barriers exist. Beyond noise, field and laboratory studies suggest salutogenic properties of the AE. However, for a more comprehensive understanding of the relationship between human health and the AE beyond noise, i.a., population-based epidemiological studies are necessary.
However comprehensive studies are missing, and robust strategies for health-promoting urban sound planning are scarce. Currently, several factors limit research in this area. A major factor is the difficulty in quantifying acoustic properties that may reflect the salutogenic properties of AEs on a population-level. This is particularly important, as such studies are needed to investigate health issues of defined populations in real-life settings. While various methods (e.g. the soundscape approach by DIN ISO 12913) aim to assess the "acoustic quality" of an AE and provide valuable insights, they do not provide the spatially high-resolution exposure data needed. Here, we outline requirements necessary to advance research at the population-level. We discuss and demonstrate approaches in AE research that show promise in meeting these requirements and could guide urban planning towards healthier AEs.

1. INTRODUCTION

In recent decades, significant efforts were undertaken to investigate the link between the urban acoustic environment (AE) and human health. Among other definitions, the AE can be defined as “the sound from all sound sources as modified by the environment” [1]. While the link between environmental noise exposure and adverse health effects (e.g. cardiovascular disease or mental health) is well established [2], an increasing number of studies focusses on the potential beneficial effects that high quality AEs may provide [3]. For example, using laboratory settings, studies found that uneventful and more pleasant sounds were linked to a greater reduction in heart rate [4], that stress recovery was facilitated by sounds from nature [5] or that biophonic AEs have a favourable impact on the functional connectivity of the human brain [6]. In addition to laboratory studies, several field studies investigated the impact of natural sounds on different human health dimensions and found, e.g., associations with decreased pain, lower stress or enhanced cognitive performance [7]. However, so far, studies are missing that take into account a broad spectrum of urban neighbourhoods as well as population based studies. The lack of population based studies highlights a substantial research gap. These studies are essential to investigate patterns, causes and effects of health issues of defined population (groups) in real-life settings [8]. By addressing this gap, we can better identify which acoustic properties benefit human health and well-being in order to develop robust measures for health-promoting urban sound planning. Currently, a significant challenge in this area of research is obtaining the high-resolution spatial exposure data required for population based studies. Below, we will discuss reasons behind this challenge. We will focus on issues regarding definitions, operationalisations and measurements of exposure, as well as the difficulty of linking findings to urban planning.

2. THE CONCEPT OF EXPOSURE

In general, prerequisites to plan healthy urban AEs are insights into how the AE and human health are related. Here, the embedding into the framework of epidemiology is appealing, as it is concerned with the distribution, patterns and determinants of health and disease [8]. Following epidemiological basics, the determination of exposure and outcome is fundamental to gain such insights. Since the measurement of health outcomes on a population-level is a well-established research field, we will not address the challenges associated with defining and measuring outcomes here. Rather we want to focus on the challenges in defining and measuring the exposure (e.g. natural sounds) on a high spatial resolution, and how this complicates population based studies at the time.

2.1 Defining the exposure

One criterion to define the exposure is that it is derived from a research question, which reasonably connects it to a health outcome [8]. While the question of a reasonable connection is rather philosophical [8], there are multiple theories and studies on the relations between the AE and human health that can legitimize an investigation (e.g. stress reduction through biophonic sounds). Furthermore, the construct of the exposure needs to be clearly defined. Regarding the example above, questions such as whether biophonic sounds include human sounds, dog barks, or leaves rustling in the wind need to be answered. However, other constructs such as "(high) acoustic/sound-(scape) quality" or "fidelity" are frequently used but often only vaguely defined or have varying definitions. Acoustic and sound-(scape) quality are often used interchangeably, but lack a uniform definition. Kang and Schulte-Fortkamp [9] define "environments of high acoustic quality [as those] where one can postulate that type 1 restorative effects could occur", while soundscape quality may be defined as "warm-hearted, lively and peaceful, therefore noisy but enjoyable" [10] or solely by survey responses [11]. In addition to the latter being problematic from a measurement theory point of view, because the construct is not defined a priori [12], vague definitions of constructs complicate their operationalisation, and thus a valid measurement [12]. For example, biophonic sounds are often operationalized by the amplitude of a recording between 2 and 8 kHz, also allowing other sound sources in this frequency range to be considered biophonic. Besides physical-acoustic measures, constructs derived from the AE are also often operationalised by sound source classes or questionnaires.

Regarding the literature, there are also differences on which level the AE is operationalized as exposure. Hypotheses concern settings (e.g. urban vs. rural AEs), complex mixtures (e.g. pleasant sounds) as well as single agents (e.g. birdsongs) of exposures [8]. Neither of which are generally weaker approaches to assess exposures, but it underlines that there are most likely multiple relevant exposures that need to be considered, if we want to assess the relation between the AE and human health.

In summary, many theories in the field of AE have gathered sufficient evidence to warrant further investigation on population-level. However, the definitions and operationalisations of some constructs from the AE are often too vague, which can hinder interpretation, comparability and generisability of results.

2.2 Measuring the exposure

When it comes to measuring the operationalized constructs of the AE (e.g. urban soundscapes, pleasant sounds, biophonic sounds), the most widely used approaches include the use of acoustic indices and surveys using questionnaires. In the following, we will shortly describe each approach, followed by an evaluation of their respective challenges to assess the exposure on a high-resolution spatial level.

2.2.1 Acoustic indices

We refer to acoustic indices as those, which represent physical-acoustic properties of an AE. An elaborate example to illustrate the construct, operationalization and measurement of an exposure through an acoustic index is environmental noise. Among other definitions, the one from the European Directive 2002/49/EC is probably the most widely used. Here, environmental noise is defined as "unwanted or harmful outdoor sound created by human activities, including noise emitted by means of transport, road traffic, rail traffic, air traffic, and from sites of industrial activity". The operationalisation is the A-weighted long-term average sound level and the exposure measures are derived from strategic noise maps, which model the a-weighted sound pressure level (SPL).

Beyond SPL, there is a plethora of acoustic indices that are designed to measure constructs in relation to, e.g., human perception of acoustic phenomena (e.g. from psychoacoustics) or specific sound sources (e.g. from ecoacoustics). Some examples are measures for psychoacoustic annoyance (as a combination of loudness, sharpness, roughness and fluctuation strength) [13] or biophonic activity (measured e.g. by the normalized difference soundscape index) [14].

However, unlike to SPLs, methods to derive exposure levels for these indices on a population-level are not established to this date. Acoustic measurements could provide the necessary exposure data, but are complex and costly, especially on a larger scale. In contrast to strategic noise maps, no models are yet established from which high-resolution exposure data could be derived. In addition, research into the performance of certain acoustic indices and their relations with exposure constructs (e.g. natural sounds) in the urban environment is a relatively new field of study. Still, there are significant developments in recent years that explore the relation between acoustic indices and, e.g., human perception in the urban environment [15, 16].
Drawing from the example of strategic noise maps, which utilise traffic estimates and the built environment to predict SPL, similar information could be used to create sound maps for additional acoustic indices (see Fig. 1), as their relations to the built environment are getting increasingly more evident. Additionally, these relationships provide insights necessary for urban sound planning.

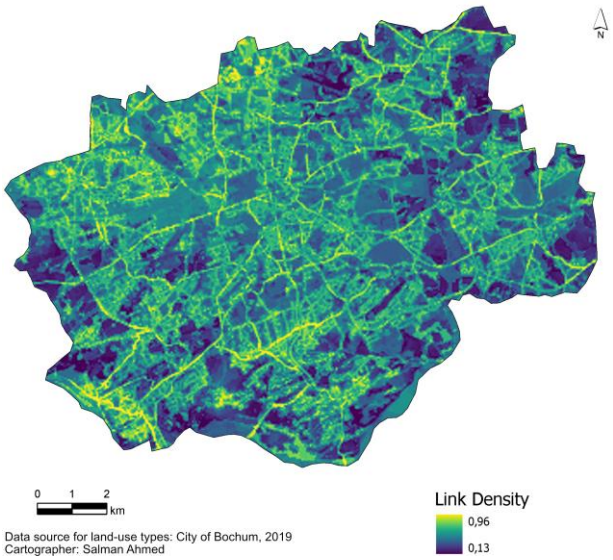

Figure 1. Exemplary presentation of preliminary results for exposure assessment of an acoustic index. Here, acoustic dominance, operationalised by the acoustic index link density, is shown using a prediction model based on land use types. The area depicted is Bochum, Germany.

2.2.2 Questionnaires

In recent years, the use of questionnaires has emerged as a popular method to investigate the urban AE. Among the various questionnaires deployed, one of the most frequently applied is from the DIN ISO 12913 [1]. Here, e.g., the construct of perceived acoustic pleasantness, operationalised as a combination of multiple human answers on a 5-point Likert scale, is investigated. In addition, the context (e.g. the built environment, socioeconomic factors) plays a crucial role here, as it influences the rating of the respondents and should always be considered[1].
Regarding the exposure measurement on population-level, the application of questionnaires on the AE represents a highly feasible approach, as questionnaires are an established method for population surveys. Such surveys could also gather additional person-related variables, offering insights into the contextual factors influencing AE perception or even individuals' health. However, this approach is not without challenges. Existing questionnaires are primarily designed for in-situ applications, which poses difficulties when adapting them for population surveys[2]. Here, the reliance on context also raises the question of whether people can be effectively queried about their responses to hypothetical or memorized acoustic scenarios (e.g. the perception of the AE at home for the last month). Currently, the research field lacks widely established questionnaires for population surveys [18].
In addition, the insights required for healthy urban sound planning regarding the interplay between the built environment and the perceived AE would need to be gathered through additional surveys or similar methods.

2.2.3 Additional considerations

In addition to the method specific challenges, there are general factors that need to be considered in exposure assessment, namely the intensity duration, and timing [9]. For example, the mitigating effects of being indoors might be important for the intensity of the exposure to the outside AE. This might also be important for the duration of exposure if we expect an isolation from the outdoor AE. Furthermore, the place of stay needs to be considered, as the exposure may vary from being at home, being outside or at work. Even the place at home might matter, if the exposure

[1] An issue that arises here concerns whether the operationalization measures the acoustic pleasantness of the AE specifically, or rather the overall pleasantness of the investigated place, as recent research suggests [17], but this question remains open to future debate.
[2] Due to its high expenditure on time and personnel we do not consider in-situ measurements (e.g. soundwalks) a feasible option for assessing exposure on a population-level.

differs across rooms. Also the timing might be important. For instance, the recommendations for SPLs are lower at night than at daytime.

3. CONCLUSION

There remain multiple challenges that need to be addressed to assess exposure to the AE on a population-level. For acoustic indices, their functionality and effectiveness in reflecting relevant constructs in the urban environment in relation to humans needs to be further investigated. For example, it is necessary to investigate whether and which indices could represent biophonic sounds in the urban environment. In addition, models need to be developed to predict relevant indices at high spatial resolution.
For the questionnaire approach, instruments need to be developed that measure perceived constructs of the AE for non in-situ situations. Furthermore, the challenges of context dependency need to be addressed and methods to relate results to the built environment need to be established.

DEVELOPMENT OF A TOOL FOR NOISE MANAGEMENT IN LEZs

José Ignacio Riesco[1*] **Saray Herrero** [1] **Lidia García** [1]
Ramón Díez [1] **Ruth Paredes** [1] **Ana Esther Espinel** [1] **Marco Lora** [1]
Audiotec Ingeniería Acústica S.A., 4 JuaneloTorriano St., 47151, Boecillo (Valladolid), Spain

ABSTRACT

Audiotec is part of a consortium that is carrying out an R&D project with the overall objective of developing a comprehensive and accessible prototype to assist decision-makers in the fight against climate change and air pollution in the task of defining and assessing the economic, social and environmental impact of Low Emission Zones (LEZs) in urban areas.

Audiotec's role in the project is the development of a non-standardized tool for environmental noise prediction in LEZs using geographic information systems (GIS).

The developed tool, which is easy to use, allows to quickly predict the evolution of acoustic indices and health indicators in LEZs, as well as to analyze the acoustic impact in these areas in different alternative scenarios, varying the mobility parameters.

The developed prototype presented here allows municipal technicians to manage LEZs through the use of commonly used free software, with the consequent saving of resources.

Keywords: Low Emission Zones, acoustic module, noise map.

1. INTRODUCTION

The Spanish Law on Climate Change and Energy Transition defines a LEZ as 'an area delimited by a public administration, in the exercise of its powers, within its territory, of a continuous nature, and in which restrictions on access, circulation and parking of vehicles are applied to improve air quality and mitigate greenhouse gas emissions, according to the classification of vehicles by their level of emissions in accordance with the provisions of the General Vehicle Regulations in force'.

Low Emission Zones are a mobility management tool that helps to promote a modal shift in cities towards more sustainable modes of transport, as well as the adoption of low-emission alternative vehicles, such as electric cars.

Spanish municipalities are currently in the process of implementing LEZs, and there is a need for public administrations to have tools that facilitate the definition of their boundaries and perimeter, the analysis of emission reductions, and access to information on public health, as well as economic and social aspects.

In this context, in 2024, an R&D project was proposed in collaboration with several companies, with the overall objective of developing a comprehensive and accessible prototype that would assist decision-makers in the fight against climate change and air pollution by facilitating the task of defining and evaluating the economic, social, and environmental impacts of Low Emission Zones (LEZs) in urban areas. The aim was to promote more effective and sustainable management of urban mobility, in line with the objectives of reducing pollutant emissions and improving air quality, as established in regulatory frameworks at all levels (local, regional, national, and European). At the same time, it aimed to provide additional benefits for the locality and its citizens, such as reducing noise pollution, improving health and quality of life, promoting alternative forms of mobility (sustainable mobility), and creating healthier and more livable urban spaces; see Fig. 1.

- To analyze and diagnose the starting point by calculating the current balance of carbon and pollutant emissions in the municipality through the integration of data from public and private sources. Among other sources of information, noise maps are used to

***Corresponding author**: idi@audiotec.es*

identify not only sources of noise pollution but also atmospheric pollution, as these often overlap.

- Design the LEZ by defining its area, extension and perimeter, as well as the number of LEZs in the city being studied.
- Evaluate and visualize the potential impacts and changes that the LEZ causes in the carbon balance and pollutant emissions in the municipality (CO, NO, NO2, O3, PM10, PM2.5, SO2).
- Quantify other impacts and benefits (economic, social and environmental) that the defined LEZ could potentially produce.
- Evaluate the different options (scenarios) by calculating indicators that enable quantitative comparison and support informed decision-making.
- Export the results for the scenario identified as optimal.

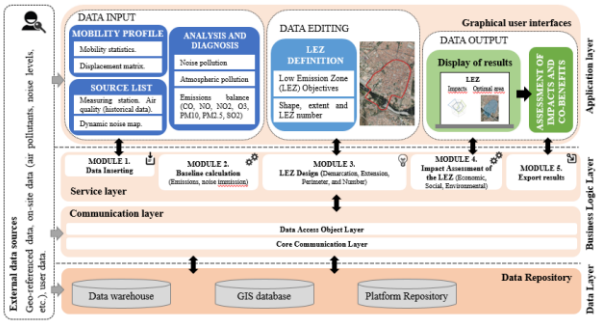

Figure 1. Conceptual framework and functional modules of the platform prototype

Audiotec's role in this R&D project has focused on the development of the acoustic module of the platform.

2. NEED FOR THE DEVELOPED TOOL

Currently, municipalities with more than 100.000 inhabitants are required to update and approve the strategic noise maps for their territory, along with the corresponding action plans.

Strategic noise maps are a valuable tool for assessing the acoustic environment of a municipality with respect to environmental noise and for developing, based on the graphical and statistical results they provide, well-founded action plans to address noise pollution. However, updating these maps requires considerable effort and the use of specialized software for environmental noise prediction, which makes it challenging for government technicians to perform frequent updates.

In this context, Audiotec has developed a module for the acoustic assessment of LEZs with the following objectives:

- To thoroughly research and analyze the specific characteristics and needs of the city regarding the implementation and management of Low Emission Zones (LEZ), considering environmental noise as a key factor.
- Design and develop an automated, intuitive, and easily accessible prototype that enables decision-makers (consultants, urban planners, politicians, etc.) to visualize and analyze the 'noise' variable when defining the area and impact of the LEZ.
- Develop algorithms and models to assess the potential impact of implementing or expanding of an LEZ in terms of noise reduction.
- Integrate Geographic Information Systems (GIS) based calculation capabilities, up-to-date databases and public information sources on noise and mobility to ensure the accuracy and reliability of the data used in developing of the acoustic module.
- Conduct a pilot test to validate the results in collaboration with local authorities and other relevant stakeholders to ensure the practical utility, acceptability, and adaptability of the acoustic module in various urban contexts.

3. DESCRIPTION OF ACOUSTIC MODULE

This is a prototype developed to assess and compare the acoustic impact of various traffic management measures in Low Emission Zones (LEZ). The tool allows users to edit and update the parameters related to traffic in the different streets within the LEZ. Using an intuitive interface in QGIS, users can select a specific road by name and modify key data such as traffic volume, speed, and road surface type. These changes are applied to a new layer that duplicates the original, ensuring that the previous data is preserved and enabling direct comparisons.

Additionally, the tool includes a feature that allows for the calculation of noise levels that receptors will experience after the implementation of the new conditions. As a result, a new receptor layer is generated with the updated values, facilitating the analysis of the acoustic impact of the introduced changes; see Fig. 2.

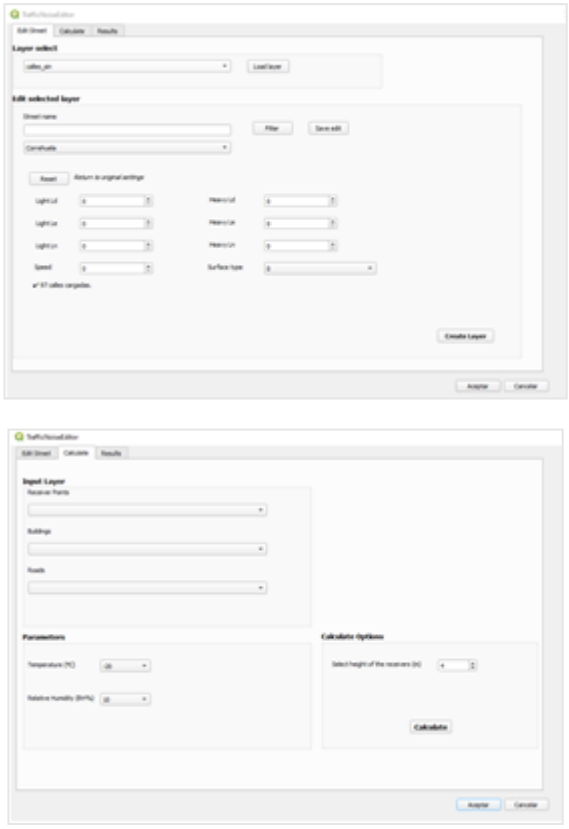

Figure 2. Prototype Model.

It should be noted that these calculations do not account for factors such as the topography of the terrain or the acoustic absorption properties of various urban elements. Furthermore, the search radius for assigning values to receptors is limited to 50 meters. However, in the context of Low Emission Zones, where the analysis focuses on small areas, this approach is sufficiently valid to support decision-making. These simplifications enable faster processing times and dynamic visualization of the effects of the proposed measures, facilitating a quick and effective assessment of their impact on urban noise pollution.

In addition, the tool has been designed with an adaptive approach that allows it to be adapted to the specific characteristics of each city. This enables it to be configured to accommodate different types of road infrastructure, analysis criteria, and local regulations, offering a flexible solution for planning noise mitigation strategies in LEZ environments.

As a prototype, the tool is in the initial development phase and can be refined and adapted in the future based on emerging needs and methodological advancements.

Being developed in QGIS environment, this tool leverages the full range of benefits offered by this open-source software, including its visualization and geospatial analysis capabilities. Users can overlay multiple layers of information, perform spatial queries, and combine results with other environmental or urban data available within the project. This enables a more comprehensive interpretation of the impact of the measures implemented and facilitates the integration of acoustic variables into urban planning processes. Furthermore, as part of the QGIS ecosystem, the tool is compatible with a wide variety of data formats and can be easily adapted to meet the specific needs of each city, ensuring its applicability across diverse urban contexts.

One of the key advantages of this tool is its accessibility for users who are not familiar with the QGIS environment. Thanks to its intuitive interface, no advanced knowledge of geospatial editing methods is required to modify traffic parameters. Users can quickly make adjustments through the integrated questionnaire, enabling them to incorporate changes such as traffic volume, speed, or pavement type with ease. This ease of use broadens the tool's accessibility to a wider audience, including urban planners, local authorities, and other non-technical users, empowering them to make informed decisions without the need for specialized GIS expertise.

4. PROTOTYPE VALIDATION PILOT TEST.

In 2023, Audiotec was responsible for updating the fourth-phase of the strategic noise map and action plan in the city of Salamanca, a municipality in Castilla y León (Spain) with a population of over 140,000 inhabitants.

During the duration of the Noise Action Plans, the Low Emission Zone is expected to be implemented.

The Low Emission Zone, expected to have a highly beneficial impact on environmental noise, is designed as a ring system, given that Salamanca is a radial city with its epicenter at Plaza Mayor, the city's geographic and cultural hub.

The first of the rings encompasses an area of approximately 600 000 m², which is being fully pedestrianized. It merges

areas that previously contained intermediate corridors and adds new streets and squares that were once designated for unrestricted motor vehicle movement. All access points to this area will be monitored by cameras equipped with license plate recognition.

Figure 3. Pedestrian area.

The second perimeter shares its northern boundary with the first and spans approximately 1 500 000 m²; it encompasses the entire first ring road of the city, along with both banks of the River Tormes. This area includes all the monuments that contributed to Salamanca being designated a UNESCO World Heritage City, making it essential to protect the health of its inhabitants.

Figure 4. Low Emission Zone (ZLE) area.

The Low Emission Zone (LEZ) of Salamanca has been selected to test and validate the developed acoustic module. This decision is based on the availability of sufficient cartographic and demographic data to feed the model, as well as the existence of previous results obtained using the commercial software CadnaA. A comparison was then made between the model generated with CadnaA and the prototype acoustic tool developed.

The analyzed area of the LEZ has a population of 14 665 inhabitants. The evaluation enables the analysis of differences in the estimation of environmental noise impact and health indicators for the population, as well as the verification of the prototype's usefulness in the acoustic management of these areas. It is important to note that the prototype is not intended to be standardized software, but rather an analytical tool whose results should be interpreted relatively, rather than absolutely. Its goal is to provide an accessible tool for municipal technicians responsible for managing Low Emission Zones (LEZ), enabling them to evaluate alternative scenarios using free and commonly available software.

4.1 Analysis of acoustic receivers in façades

When comparing the estimated values at the receptors on the façades of both models for a typical building in the LEZ, it can be observed that the model generated with CadnaA presents slightly higher noise levels on certain façades, particularly in areas with greater exposure to traffic.

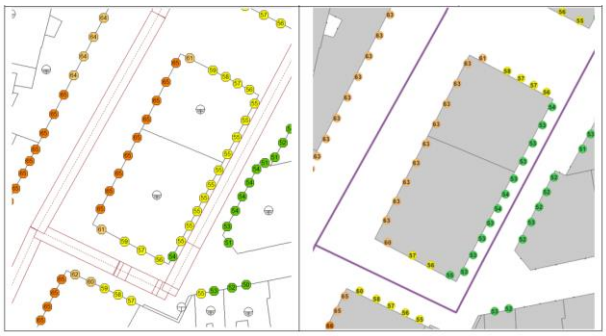

Figure 5. Noise levels in facade. CadnaA model on the left and GIS model on the right.

The maximum difference between the two models is approximately 2 dBA.

The following graphs display the distribution of the percentage of receivers as a function of the acoustic index value within the range of 55 to 69 dBA for three time periods (day, evening, and night) in the analyzed LEZ. Each graph compares the values obtained using the

commercial software CadnaA with those from the developed acoustic prototype, see Fig.6.

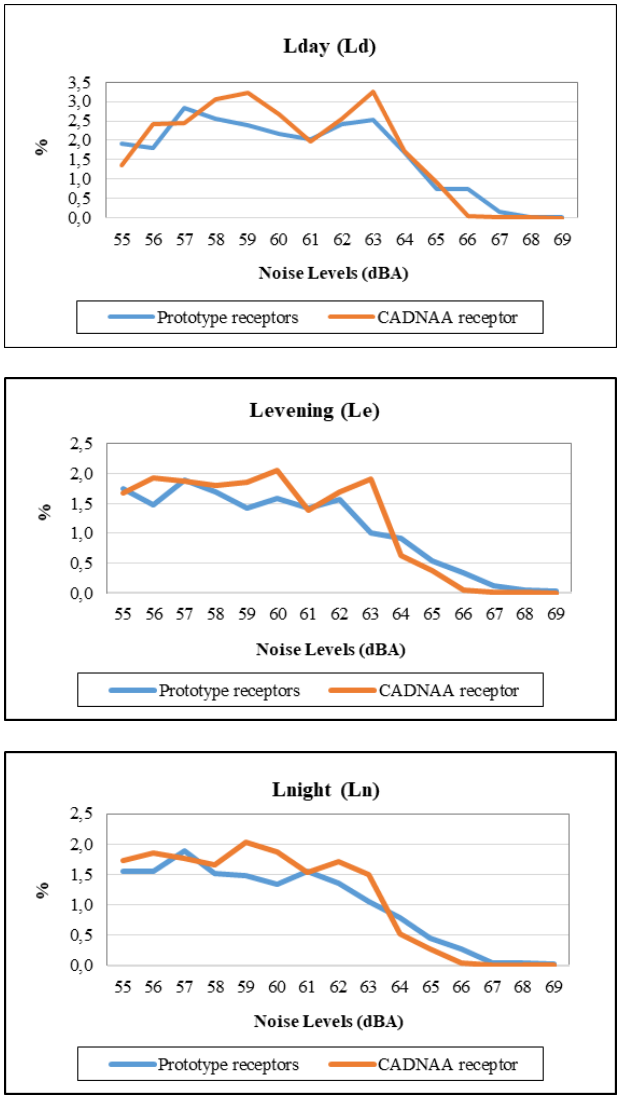

Figure 6. Distribution of the percentage of receptors across three time periods (day, evening, and night) in the analyzed Low Emission Zone (LEZ).

In all three time periods, the distribution of the percentage of receptors is similar in both models.
It is observed that the maximum number of receptors occurs at intermediate values, followed by a gradual decrease as the noise level increases.

The developed acoustic prototype shows significant agreement with the results obtained using CadnaA, with differences falling within an acceptable range for decision-making in the management of the LEZ.

4.2 Analysis of the population impacted by environmental noise

In the evaluated Low Emission Zone (LEZ), the results for the number of people and the percentage of the population exposed to noise, as estimated by both methods, have been compared across the different acoustic indicators, see Table 1:

Table 1. Population exposed to noise.

Acoustic Indicator	CadnaA		Prototype	
	Number of people	% population	Number of people	% population
Ld > 65 dBA	215	1.47%	374	2.56%
Le > 65 dBA	229	1.57%	371	2.53%
Ln > 55 dBA	2596	17.70%	2538	17.31%

The results indicate that, although the values estimated by both methods are similar, the prototype estimates a higher number of people affected during the daytime (Ld) and evening (Le) periods compared to the CadnaA software, while the differences are smaller during the nighttime (Ln) periods.

The Ln indicator has been chosen as the reference to study the distribution of people by ranks and the percentages of the population exposed to noise. The results obtained are as follows, see Table 2:

Table 2. Population exposed to noise based on the Ln indicator.

Nighttime noise level range (Ln, dBA)	CadnaA		Prototype	
	Number of people	% population	Number of people	% population
50 < Ln ≤ 55	2897	19.75%	2550	17.39%
55 < Ln ≤ 60	2433	16.60%	2238	15.26%
60 < Ln ≤ 65	163	1.10%	300	2.05%
Ln > 65	0	0%	0	0%

It is observed that both models provide similar estimates; however, the acoustic tool prototype, compared to CadnaA, predicts lower impairment in the 50-55 dBA

and 55-60 dBA ranges, but higher impairment in the 60-65 dBA range.

4.3 Analysis of health indicators related to environmental noise

In addition to acoustic information, the prototype enables the calculation of health indicators related to noise exposure. The results obtained are presented below, see Table 3:

Table 3. Population exposed to noise according to health indicator.

Health Indicator	CadnaA		Prototype	
	Number of people	% population	Number of people	% population
Nxy_ECI	180	0.82%	180	0.82%
Nxy_MI	1385	6.28%	1341	6.08%
Nxy_AGS	287	1.30%	275	1.25%

The estimated values of the health indicators obtained using the prototype are very similar to those obtained using CadnaA.

5. CONCLUSIONS

As part of an R&D project aimed at developing a comprehensive and accessible prototype to assist decision-makers in defining and assessing the economic, social, and environmental impacts of Low Emission Zones (LEZs) in urban areas, Audiotec has developed a module that enables the assessment of environmental noise in LEZs.

The acoustic module has been developed based on the Common Noise Assessment Methods in Europe (CNOSSOS-EU) for road traffic noise, although certain simplifications have been made to the methodology to enhance its agility and operational efficiency, as well as to expand its use to operators working with open-source software.

A pilot test has been conducted to validate the module in the LEZ of the city of Salamanca by comparing the results obtained from the acoustic module with those estimated in the municipality's strategic noise map. The differences between the two methods are not significant, and it can be concluded that the developed acoustic module provides reliable information.

The acoustic module offers several advantages over standard commercial programs for environmental noise prediction, including reduced processing times, ease of use, strong dynamic visualization capabilities for the effects of proposed measures, and quick, effective evaluation of noise-related health indicators and the impact of noise pollution in LEZ.

ABSTRACT

With the increasing attention to soundscape concepts in noise policy discussions and the recent integration into legislation in some regions, there is a growing need for objective measures to assess soundscape quality. In a project funded by the Swiss Federal Office for the Environment, various acoustical, room-acoustical, and psychoacoustical parameters identified through acoustic literature, as well as preliminary research and measurements, were used to evaluate soundscape quality. These parameters include, among others, L_{Aeq}, RT60, STIPA, sharpness, loudness, tonality, and fluctuation strength. Additionally, environmental factors such as nearby noise sources, greenery, and spatial morphology were documented. Measurements were conducted in four residential outdoor spaces in Switzerland and compared to subjective evaluations obtained from a small group of participants at the same locations. This paper presents the measurement results and subjective evaluations, along with a statistical analysis comparing the two datasets. Based on the findings, a method for the objective assessment of soundscapes is proposed, and recommendations for improving soundscape quality are discussed.

1. INTRODUCTION

According to the ISO 12913-1 standard, a soundscape is an ”acoustic environment as perceived or experienced and/or understood by a person or people, in context” [1]. This definition entails the inclusion of holistic principles and subjective views of the people experiencing the soundscape [2, 3]. For legislative purposes, objective, simple and reproducible methods to assess the quality of soundscapes are needed, however. Different researchers have thus proposed objective evaluation methods, a review of which can be found in [4]. The ISO/TS 12913-2 and 12913-3 standards [5, 6] propose a number of methods for the collection and analysis of soundscape studies, investigations and applications. Different, more recent efforts aim for a simplification of soundscape evaluation by providing single number indices [7, 8].

The Swiss Federal Council proposed an amendment to the Environmental Protection Act (EPA), according to which, among other things, the planning of additional residential housing in noise-polluted areas should also include the provision of open spaces/quiet areas for recreation and measures to ensure an acoustically appropriate quality of living. These requirements need to be specified and objectified. As part of a study for the Swiss Federal Office for the Environment FOEN, the physical and perceived soundscape qualities of urban residential courtyards at four locations in Switzerland were investigated by the authors. The goal of the study is to provide insights for the as of yet not clearly defined minimum requirements and guideline values in the context of soundscape design in view of aforementioned changes to the Environmental Protection Act. This interdisciplinary project aimed to de-

velop an objective evaluation method for soundscape assessment and classification. Both acoustic measurement methods and qualitative survey methods of soundscape perception were tested and compiled into suitable sets of methods. These were tested on four case studies - different residential courtyards in four Swiss cities. Subsequently, the acoustic and qualitative results were checked for consistency and initial findings were derived.

2. METHODS

2.1 Selection of objects

The aim of the object selection was to achieve heterogeneity in the survey of the soundscape quality of different recreational spaces in housing areas. The main parameters for the selection were their noise situation, proportion of greenery, and character as a publicly used space. All objects are surrounded by residential buildings. The soundscapes are located in four different cities in Switzerland (see Tab. 1).

Table 1: Selection of soundscapes

No.	Object	City
1	Erlenmatt Ost	Basel
2	Park Humboldtstrasse	Bern
3	Himmelrich 3	Luzern
4	Zwicky-Areal	Zürich

2.2 Acoustical measurements

Measurement variables were chosen according to results found in the scientific and normative literature, linking them to subjectively perceived soundscape quality [4, 5, 9, 10]. The main data acquisition methods included the measurement of sound pressure level (*SPL*), reverberation time (*RT60*), speech transmission index (*STI*) and room impulse responses (RIR). Binaural audio recordings were made and used for the extraction of psychoacoustic metrics. Additional metrics were extracted from the RIRs and audio files, recorded by the sound level measurement device. Measurement methods were adapted according to the findings of a preliminary study [11]. This includes the measurement of sound pressure level during different times of the day, a high number of measurement repetitions for reverberation time measurements and the possible division of the soundscape into sub-spaces with different acoustical characteristics. A complete list of the measured and calculated variables can be found in Tab. 2.

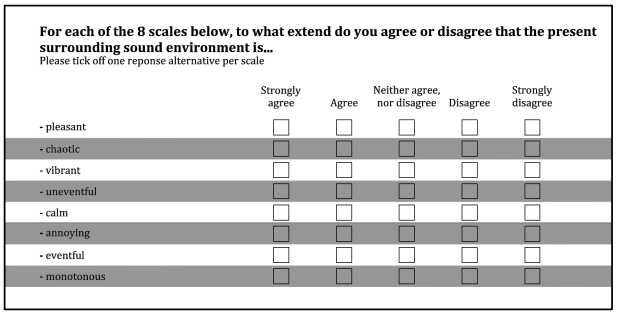

Figure 1: Questionnaire related to the perceived soundscape quality according to ISO/TS 12913-2 [5]

2.3 Subjective Survey

Soundscapes are inextricably linked to their uses and users. However, a mere description of uses and users is not sufficient for describing how soundscapes are perceived. It is the meaning which respondents (users) attribute to uses and other users that provides clues to how the soundscape is perceived.

Based on results of previous research ([25] and ISO/TS 12913-2 [5]), the following procedure was designed for the survey in the four soundscapes.

1. Questionnaire survey on the perception of the soundscape with the following questions:
   - Opening question: what do you hear? (Please indicate in descending order of clarity) the various sound sources that you can identify (e.g., “children,” “airplane,” “birds,” ... maximum of 8).
   - Three statements regarding the perception of sounds and soundscape, rated on a 5-point scale: It’s loud here / it’s acoustically pleasant here / the sounds fit the surroundings.
   - How do you perceive the soundscape? (ISO/TS 12913-2 dimensions [5]; see Fig. 1).
2. On-site focus group discussion on perception of the soundscape, guided by the following questions:
   - What do you like about this place? Why?
   - What is the quality of stay of this place? What defines it?
   - How would you rate the ”room acoustics” of this courtyard?

Table 2: Acoustical measurement variables with measurement/calculation method

Variable	Method	Ref.
SPL with different time and frequency-weightings, as well as percentiles	4 measurements of 15 minutes between 08:00 and 18:30 hours per area	[12]
RT60 (T30)	1 measurement with 10-12 repetitions per area	[13]
STI	1 measurement distances 1m/4m 8 repetitions per measurement	[14]
RIR	1 measurement distances 1m/4m	[15]
Sharpness	Evaluation of 4 binaural audio recordings of 15 minutes between 08:00 and 18:30 hours	[16] [17]
Loudness	See *Sharpness*	[18]
Harshness	See *Sharpness*	[19]
Tonality	See *Sharpness*	[20]
Mel Frequency Cepstral Coefficients (*MFCC*)	Evaluation of the audio recordings from the *SPL* measurements	[21]
Spectral Slope	See (*MFCC*)	[22]
Time Frequency Second Derivative (*TFSD*)	See (*MFCC*)	[4]
Echo criterion	Evaluation with RIR-measurements	[23]
Percentage of green/blue	Calculation of green/blue from views of typical seating locations	[24]

- What sounds/soundscape would you typically expect in this place?
- Would you want to live here? Why/why not?

3. Questions regarding additional assessment positions:

   - What has changed in the sounds/soundscape compared to the center of the courtyard?

Note: Evaluating audio recordings without direct spatial reference at other times of day has not proven effective. For spaces characterized by different areas, this survey should be conducted separately for each area.

3. RESULTS

3.1 Acoustical measurements

Tab. 3 shows average values across all measurements, positions and measurement repetitions of the four soundscapes. The averaged L_{Aeq} values are significantly lower in Basel and Bern, while the *RT60* measurement shows similar values across objects. The median values of the *STI* measurements at a distance of 1 meter are above limit A (high speech intelligibility, complex messages, unfamiliar words) for 3 objects. Depending on the room and measurement position, the values fluctuate between the F (Good quality PA systems, complex messages, familiar context) and A ratings (see Fig.2). At a distance of 4 meters, the median value in Basel remains at level D, while the values of the other objects drop to level H (normal lower limit for VA systems, simple messages, familiar context).

Table 3: Averaged results of the measurements

Parameter	Basel	Bern	Luzern	Zürich
L_{Aeq} [dB]	50.02	53.39	61.90	58.51
RT60 [s]	1.29	1.44	1.35	1.24
STI 1m	0.88	0.77	0.73	0.71
STI 4m	0.65	0.47	0.51	0.45
Percentage of Green	21.9%	64.9%	14.6%	15.8%

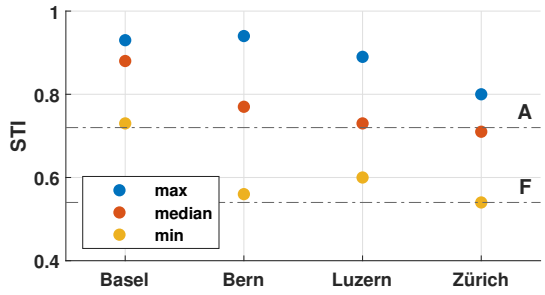

Figure 2: Measured *STI* values at 1 m distance

3.2 Subjective Survey

Mean ratings of the ISO items are shown in Fig. 3 for the four locations investigated in this study.

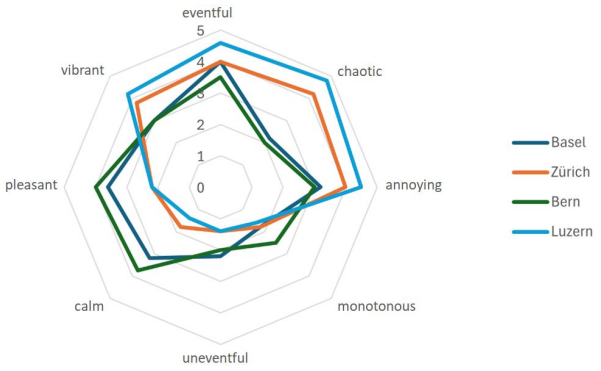

Figure 3: Survey results of soundscape perception according to ISO/TS 12913-2.

The following indications for the planning of soundscapes can be derived from the case studies:

- Greenery and proximity to nature (also sounds of nature) is associated with a more positive perception of the soundscape.
- Attractive utilization options and high-quality design can improve the quality of stay.
- The above positive criteria can only partially compensate for high-level noise pollution.
- A variety of possible uses and the presence of other people play a decisive role in whether people feel comfortable or not.
- Identification with the space, its uses, and people present fosters a positive soundscape perception.

3.3 Comparison of acoustical and subjective data

A post hoc correlational analysis was conducted to investigate the extent of the association between quantifiable subjective perception indications and objective data. A few examples are shown in the following.

3.3.1 Percentage of green

Tab. 4 shows correlations between *Percentage of green* and the subjective quantitative items (translated from German). Strong associations are observable: courtyards with more greenery were perceived as more pleasant, calming, and less noisy or annoying. A saturation of the positive greenery effect can be observed in Fig. 4.

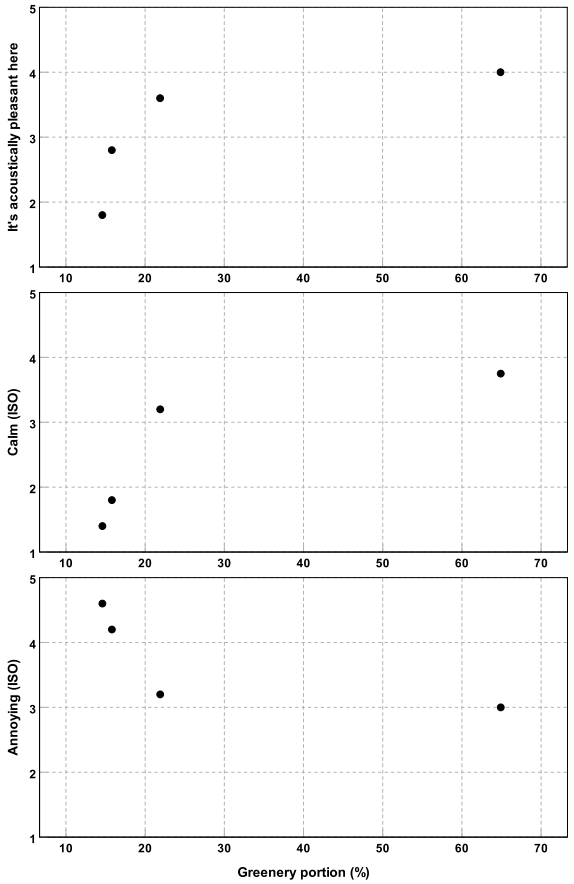

Figure 4: Mean subjective ratings for the items *It's acoustically pleasant here*, *Calm (ISO)*, and *Annoying (ISO)* as a function of *Percentage of green*.

Table 4: Correlations between *Percentage of green* and *STI* and the subjective ratings. Significant ($p < 0.05$) and highly significant correlations ($p < 0.01$) are marked with * and **, respectively.

	Green (%)		*STI*	
	r	p	r	p
It's loud here	-.585**	.008	-.863**	.000
It's acoustically pleasent here	.555*	.014	.741**	.000
The sounds fit the surroundings	.253	.295	.090	.714
eventful (ISO)	-.303	.208	-.578**	.010
chaotic (ISO)	-.626**	.004	-.884**	.000
annoying (ISO)	-.575**	.010	-.786**	.000
monotonous (ISO)	.495*	.031	.420	.074
uneventful (ISO)	.233	.338	.409	.082
calm (ISO)	.611**	.005	.772**	.000
pleasent (ISO)	.522*	.022	.660**	.002
vibrant (ISO)	-.335	.162	-.503*	.028

3.3.2 STI

Correlations between the *STI* and the subjective quantitative items are presented in Tab. 4. Courtyards with high *STI* values (at 1 m) were rated more positively (see also Fig. 5). This was also the case for *STI* values measured at a distance of 4 m (not shown here).

3.3.3 RT60

The potential correlation between *RT60* and the subjective ratings was examined, but no such relationship was observed in the cases investigated in this study. Instead, the subjective evaluations appeared to be more strongly influenced by the *Percentage of green*, *STI*, and *SPL* than by *RT60*. This finding warrants further investigation, as it contrasts with previous results and recommendations reported in the literature [7, 10, 11].

3.3.4 Subjective methods

It was investigated whether the first three quantitative items (*It's loud here*, *It's acoustically pleasant here*, and *The sounds fit the surroundings*) are correlated with the ISO items. Tab. 5 shows that most items were significantly correlated, and in a reasonable and interpretable direction. Several items exhibited significant and strong correlations. Notably, this was not the case for the item *The sounds fit the surroundings*. The authors suggest that this item may represent a distinct dimension in soundscape assessment or may capture a novel factor in the context of factor analysis.

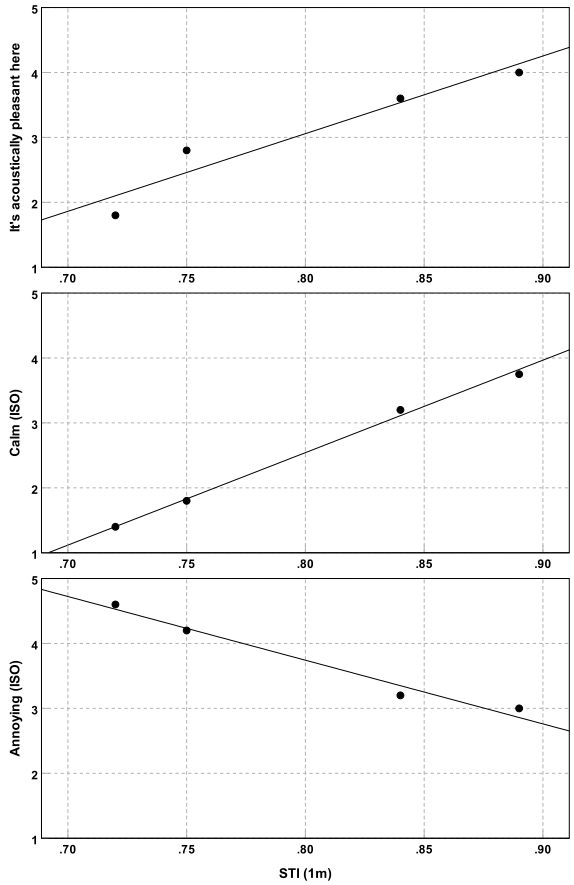

Figure 5: Mean subjective ratings for the items *It's acoustically pleasant here*, *Calm (ISO)*, and *Annoying (ISO)* as a function of *STI*.

Table 5: Correlations between the subjective items *It's loud here*, *It's acoustically pleasant here*, and *The sounds fit the surroundings*, and the ISO items. Significant ($p < 0.05$) and highly significant correlations ($p < 0.01$) are marked with * and **, respectively.

	It's loud		Acoustically pleasant		Sounds fit	
	r	p	r	p	r	p
It's loud here	1					
It's acoustically pleasant here	-.737**	.000	1			
The sounds fit the surrounding	-.011	.965	.323	.177	1	
eventful (ISO)	.658**	.002	-.663**	.002	-.158	.519
chaotic (ISO)	.803**	.000	-.763**	.000	-.208	.392
annoying (ISO)	.735**	.000	-.823**	.000	-.414	.078
monotonous (ISO)	-.230	.344	.153	.532	-.043	.862
uneventful (ISO)	-.420	.073	.374	.114	.171	.484
calm (ISO)	-.720**	.001	.875**	.000	.312	.193
pleasent (ISO)	-.696**	.001	.821**	.000	.402	.088
vibrant (ISO)	.588**	.008	-.394	.095	-.037	.881

4. DISCUSSION

4.1 Proposal for new evaluation method

Research into the perception of soundscapes requires the human perspective. The survey by a selected group of test subjects, who adopted the perspective of users, has provided results that, together with the measurement results, provide comprehensible interpretations. In particular, the separation into individual perception of the sound situation and a dialogue-based consideration in the group led to differentiated results and the integration of different perspectives. A strong agreement was observed between the objective measurement results and the subjective quantitative ratings across the different methods and items.

4.2 Limitations and further research

The sample size of objects (4) and participants (a maximum of 5 per room) in this study's subjective survey is limited. A larger sample size would enable more reliable statistical analyses, allowing the tendencies observed in this study to be verified.

5. CONCLUSIONS

This study investigated a combination of objective (acoustical) measurement methods and a subjective evaluation (including qualitative and quantitative items and focus group discussion) to assess soundscape quality in the vicinity of residential housing complexes. Four objects were investigated in this case study, representing various courtyards. The results emphasize the need for both objective and subjective evaluations. Acoustical data (e.g. *SPL*, *STI*) combined with non-acoustical parameters (e.g. *percentage of green*, natural elements) and qualitative descriptions (e.g., usage, design) were shown to provide provide a multi-disciplinary description of soundscapes, enabling evaluation. The quantitative survey data showed statistical correlations with the acoustical data to some degree. It was not possible to further simplify the evaluation using e.g. a point-based or traffic light system. Developing such a system would require a systematic investigation of all relevant factors, based on a substantially larger dataset and analysis using multi-factorial models. Furthermore, it remains uncertain whether an objective evaluation of soundscapes is achievable, as subjective, holistic and descriptive factors appear essential for a comprehensive assessment.

6. ACKNOWLEDGMENTS

This study was funded by the Swiss Federal Office for the Environment (FOEN) and authors' employer, The Lucerne University of Applied Sciences and Arts. The authors are grateful to the test subjects for their valuable contributions. Furthermore, the authors would like to thank Silvio Emmenegger, Mario Rölli, Mauro Ronchetti, Nadja Hutmacher, and Sandra Hollenstein for their contributions in the project.

A SPATIAL PROCESSING FRAMEWORK FOR MAPPING AREAS BENEFITING FROM URBAN MORPHOLOGY AND BUILDING DESIGN IN AIRPORT REGIONS

Gustaf Wuite[1,2*] **Martijn Lugten**[1,2] **Rodrigo Vassallo**[1,2]
Arjan van Timmeren[1]
[1] Department of Urbanism, TU Delft, Netherlands
[2] AMS Institute for Advanced Metropolitan Solutions, Amsterdam

ABSTRACT

In many places, ongoing urban expansion, in conjunction with higher traffic volumes, have reduced or dissolved the separation between environmental noise zones. This is specifically the case near airports, with conflicting land-use demands for housing and flight operations. Apart from zoning, aircraft noise plays no role in urban design and form studies. Serving as tall noise barriers, recent studies in a designated test street demonstrated the potential of buildings as noise barriers for reducing aircraft noise in urban contexts. Correlating sound shielding levels with the elevation angle of passing aircraft, results from the test street environment were used for mapping shielding potential areas on a regional scale. This study introduces a spatial framework combining aircraft trajectory, and land-use, geo-data to determine such areas using a geo-spatial processing methodology in QGIS. It is applied the Amsterdam Schiphol airport region as case study.The methodology determines areas affected by noise from passing aircraft at elevation angles identified as most indicative for leveraging optimal shielding by buildings. The subsequent map layers can aid urban planners in decision-making processes for further exploring the potential of urban design for mitigating aircraft noise in urban airport regions, serving further tool development for livable and healthier neighborhood design.

1. INTRODUCTION

Prolonged exposure to aircraft noise is associated with various health risks, both physical and psychological. For example, communities close to airports report higher cardiovascular hospital admission rates [1], and worse sleep quality [2], and have an increased risk of high blood pressure [3]. Compared to other traffic noise sources, aircraft noise is perceived as more annoying, at similar L_{DEN} noise levels. To mitigate and minimize aircraft noise effects, land use planning and management constitutes a priority of the International Civil Aviation Organization's "Balanced Approach" for noise reduction around airports [4]. A consequence of this approach is a strict regulation of housing developments through environmental zoning in the proximity to flight paths, depending on air traffic movements. The boundary conditions for land use and planning are defined by noise contours, generated computationally based on standardized methods, such as Doc29, INM (Integrated Noise Model), or national equivalents such as NRM (Netherlands Regional Model) in the Netherlands. For the case of Schiphol International Airport in the Netherlands, this amounts to a total area of 203 km^2 in which new housing projects and urban area (transformation) development is mostly prohibited (LIB 4), and or, an even greater surface of 384 km^2 where area development and housing expansion is strictly regulated (LIB 5) (See Fig. 1) [5]. This has resulted in so-called 'noise landscapes' around many airports, referring to land-use patterns and spatial typologies unique for airport regions. To

compromise computational overhead and model complexity, aircraft noise prediction methods rely on various assumptions for describing source, atmospheric and surface conditions. One of these assumptions is that the ground below a receiver position comprises flat surfaces, thus omitting the reflections and diffraction of sound waves in the built environment [6]. Although this approach seems acceptable valid under flat-field conditions based on annual aggregations, this is not the case for urban contexts.

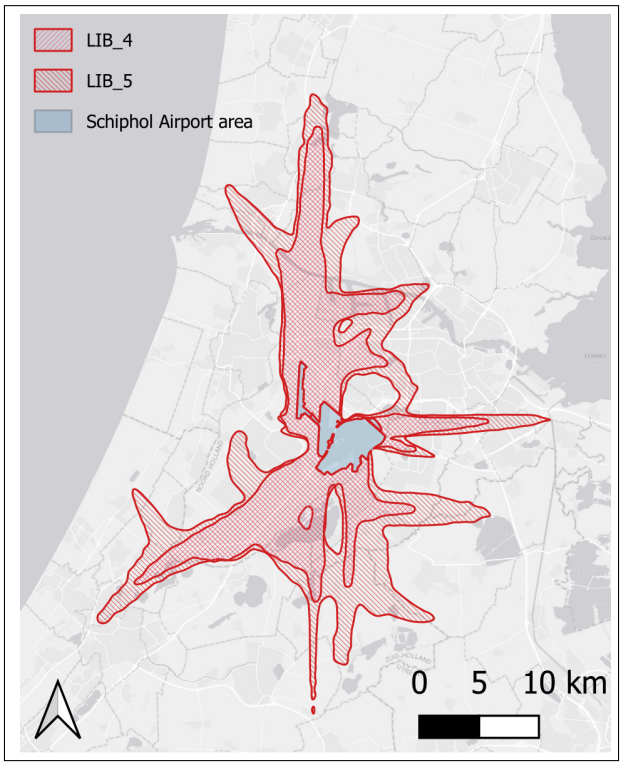

Figure 1. Areas of noise sensitive building restrictions and consideration between noise and external safety around Schiphol airport, Netherlands

Buildings, when placed parallel along flight paths, can function as noise barriers, reducing noise levels on the facade shielded from direct incident noise. This effect was investigated at the Urban Comfort Lab (abbr. UCLab) from 2022-2024, with a full-scale measurement facility consisting of 120 shipping containers arranged to recreate the urban form of three different courtyard configurations. Long-term measurements were conducted, and recorded a mean A-weighted sound exposure level (abbr. ASEL) reduction of 8.1 dB(A) between exposed and shielded building sides for two-story courtyards [7]. The addition of a slanted roof on the exposed side to reduce courtyard noise reflection effects, and a building inset on the shielded side to reduce diffraction levels, further increased the mean ASEL difference to 11.6 dB(A). These ASEL differences were measured for flights passing the facility at a mean elevation angle at closest point of passing of 37 degrees (abbr. °), with a standard deviation of $\pm 7°$.

While these findings demonstrate the potential of the use of buildings to reduce local sound levels, the integration of these effects into land use management and planning is lacking. Despite demonstrating the potential of low-rise urban canyons for aircraft noise reduction for a single test site consisting of three canyons, the potential of the UCLab results at regional scale largely remain unclear. Also, such cross-scale extrapolation at full scale of airport operations would allow for further examination of the impact of this approach, compared to the existing spatial zoning regime and described aircraft noise prediction methods. Assuming similar noise reductions for the range of elevation angles passing the UCLab, this study proposes a first assessment entailing the integration of the built environment into the strategic noise planning in airport regions.

This study presents a methodology for mapping the number of daily flyovers at elevation angles recorded in the UCLab for regions around airports using QGIS and historical ADS-B aircraft positional data as input. The methodology is then applied to a test case of Schiphol airport, for flights departing and arriving in January 2023. Finally, an exploration into the integration of the generated maps in land use planning is conducted.

The objectives of this study are defined as follows:

1. Design of a methodology that maps aircraft flyovers at defined elevation angles for airport regions.
2. Application of the methodology to aircraft arriving and departing from Schiphol airport in January 2023.
3. Examining the spatial consequences of the method in comparison with e.g. existing noise zoning and land-side aircraft noise mitigation schemes.

2. METHODOLOGY

Based on the study conducted by Lugten et al. [7], one can expect courtyard ASEL shielding effects between 8.1

dB(A) and 11.6 dB(A) for flights passing at a mean elevation angle of 37° at closest point of passing , with a standard deviation of ±7°. Within this elevation angle range, it is assumed urban canyon morphologies similar to UCLab can yield equivalent noise reduction levels between exposed and shielded building facades. This elevation angle range of 30° and 44° can be extrapolated along flight paths. The measured ASEL differences are assumed independent of ground distance [8]. Results depend accordingly on the altitude of the aircraft (see Fig 2), leading to ground areas parallel to the flight path. The areas increase in width and in distance from the ground flight path with increasing aircraft altitude. Within these two boundaries, the method presented in this paper assumes that the urban geometry akin the UCLab design is applicable and will yield comparable noise shielding effects.

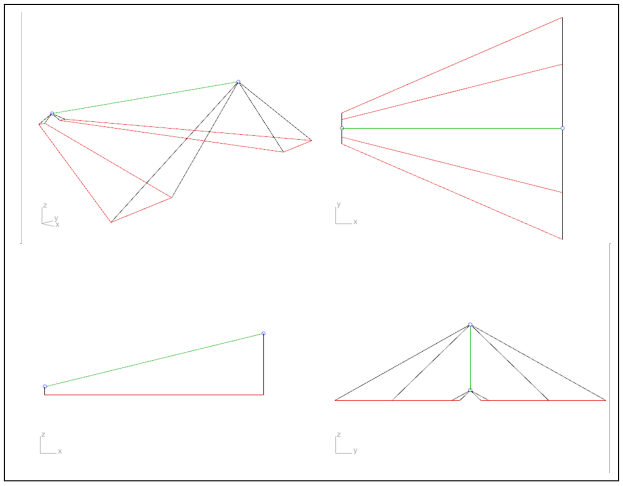

Figure 2. Flight path following a straight ascent (green) and applicable areas for noise-adaptive building (red) in perspective view (top left), top view (top right), side view (bottom right), and under flight path (bottom right)

For spatial mapping purposes, the open-source geospatial software QGIS (version 3.34) was used to create the processing framework. The methodology is generated in the graphical modeler environment, using native processing algorithms and processing scripts created using the QGIS Python Console. A graphical overview of the input, processing steps, relevant parameters, and output is shown in Figure 3. The input data is of format line .shp data. The line data contain z (altitude) variables of all vertices of each flight. The line data are fed into the model and split up into vertices. Vertices with an altitude between 50 and 1500 meters are extracted. 50 meters as a lower threshold is defined to remove flight points on the runways. The higher threshold is set to reduce computational overhead, under the assumption that aircraft passing at an altitude of 1500 m and higher do not lead to high noise exposure. Subsequently, variable width buffers are calculated for maximum and minimum elevation angles, with the width defined as altitude/tan(elevation angle). Differences between the lower and upper boundary elevation angle buffers are generated per feature and intersected with a flat end buffer., leading to ground areas parallel to the flight paths in which the aircraft passes at an elevation angle between 30° and 44°. The resulting area for a single flight is displayed in Fig. 4

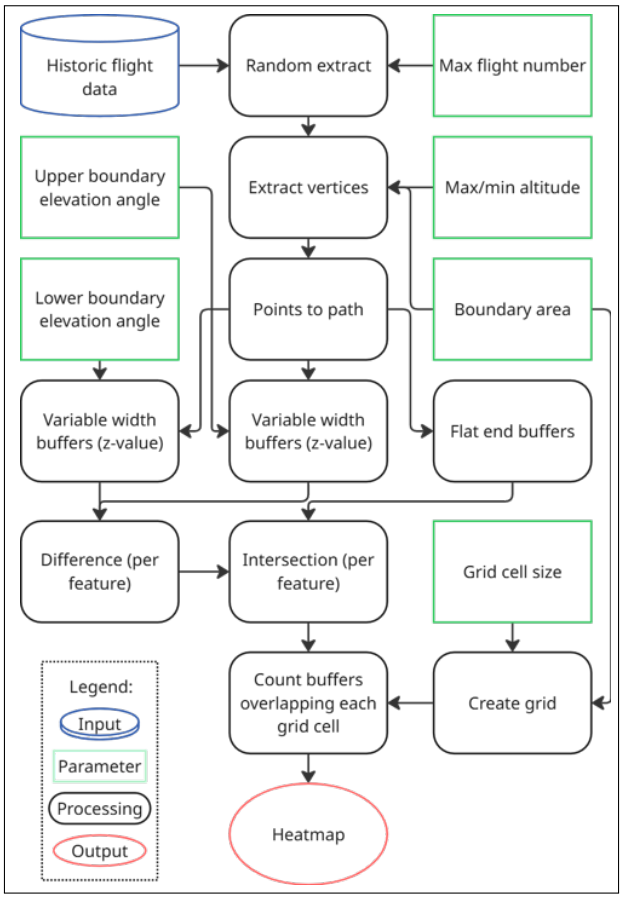

Figure 3. Geo-processing flowchart of the developed spatial framework

To map the number of flights passing locations on the

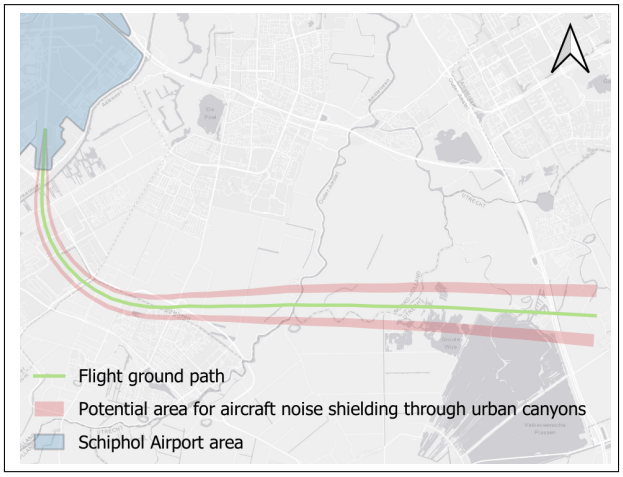

Figure 4. Flight path (green) of Flight KLM831 departing from Schiphol Airport (blue) to an altitude of 1500m on Jan 1st 2023 and altitude-dependent potential area (red)

Figure 5. Grid cell map layer displaying the number of flights passing at an elevation angle range between 30° - 44 °

ground at the defined elevation angles, a hexgrid of 200m x 200m is generated within a predefined boundary area around Schiphol airport, based on the extent of the LIB 5 layer. For each grid cell, the amount of buffers overlapping the cell are counted, creating an index of the total flights passing at an angle between 30° and 44° at closest ground distance between flight path and grid cell. The index is divided by the amount of days of the period of analysis, yielding the number of flights per day to identify areas with high daily flyover rates at elevation angles suitable for noise shielding through urban canyons. Fig 5 shows an example output of the processing methodology. Grid cells recording less than 4 flights per day are removed from the dataset for legibility.

3. AMSTERDAM SCHIPHOL AIRPORT

To test the methodology's applicability, the processing framework was applied to the region surrounding Amsterdam Schiphol airport, in the Netherlands. The line input data consist of all flights departing and arriving from Schiphol airport during January 2023, based on ADS-B radar data retrieved from Casper flight data portal, provided by the airport authority. For processing capacity reasons, for the case study presented in this paper a only half of the data was used, based on randomized selection, resulting in a total of 15545 flights. For data processing a laptop computer was used (11th Gen Intel(R) Core(TM) i7-1185G7 @ 3.00GHz with 16GB RAM), requiring a runtime of 13 hours. Figure 6 shows the resulting grid layer for the area surrounding Schiphol airport. The main arrival and departure routes are visible. Arrivals can be distinguished from departures, characterized by straighter and narrower surface boundaries due to fixed arrival trajectories. In contrast, climb rates are steeper for departures compared to arrivals, resulting in 'shorter' areas per flight path, which are also more curved and less fixed.

4. GEO-SPATIAL AND LAND-USE ANALYSES

Apart from the area plots, the density maps presented in the previous section can be combined with other spatial datasets, e.g. related to the spatial distribution of complaints, building stock and facade insulation data, and/or planned location for housing development or urban retrofitting.

For example, Figure 7 combines the density grid with residential land use and planned residential areas layers and with Dutch Spatial Legislation for Airport Land-side Management layers LIB 4 and LIB 5 [**?**]. Within LIB 4, housing projects and urban area (transformation) development is mostly prohibited. In LIB 5, area development and housing expansion is strictly regulated. These maps indicate which areas might benefit from the findings as introduced in this article. One such (illustrative) exam-

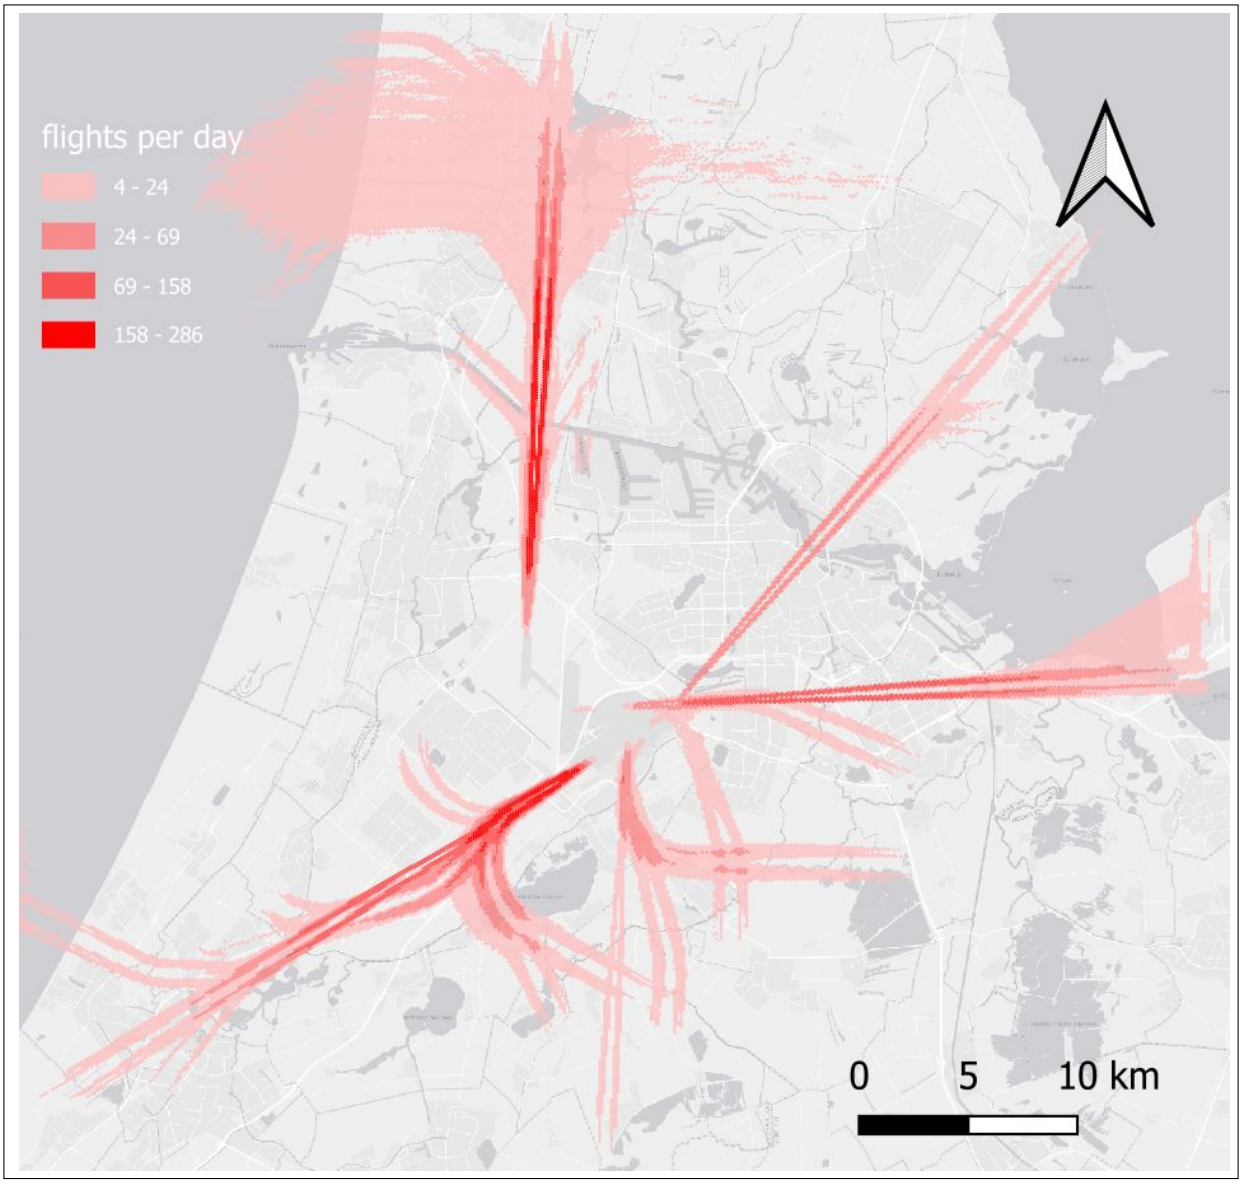

Figure 6. Number of flights passing at an elevation angle range between 30° and 44° per grid cell for flights to and from Schiphol airport in January 2023

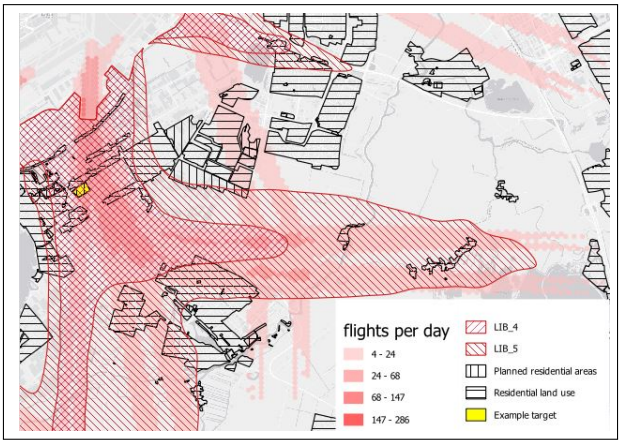

Figure 7. Overlay of spatial processing output, LIB 4 and LIB 5 zones, (planned) residential land use and spatial processing output, with high potential example target

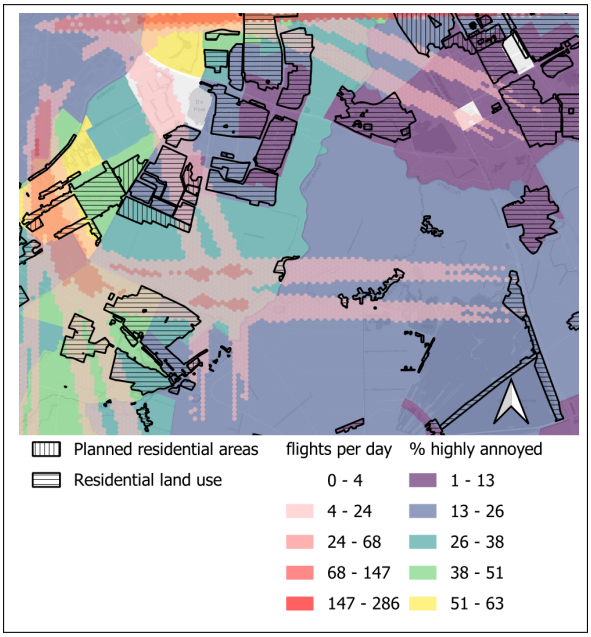

Figure 8. Overlay of spatial processing output, (planned) residential land use areas, and percentage of inhabitants highly annoyed by aircraft noise per neighborhood

ple area is highlighted in Figure 7, indicating a planned residential development in the LIB 4 zone, with a high frequency of flyovers within the elevation range allowing the use of urban form for noise shielding. Thereby these maps could aid spatial planners, urban designers - but also airport and governmental authorities - in determining for which locations additional 'urban and architectural form' oriented measured could be investigated and considered. To further pinpoint areas of heightened interest, grid density maps can be combined with noise annoyance data. Figure 8 shows flight paths and the percentage of highly annoyed inhabitants by aircraft noise per neighborhood. Neighborhood shape files are sourced from the Dutch national Geo-registry [9], the noise annoyance per neighborhood is sourced from the RIVM open StatLine data portal [10] . Although higher noise levels largely coincide with higher noise annoyance, it is advisable to take into account both where data allows.

5. CONCLUSIONS

In this article a spatial analysis framework is presented, aimed at identifying areas in which building and urban design interventions may contribute to aircraft noise attenuation in urban contexts. Using aircraft flight data, the framework generates a grid overlay to extrapolate small-scale findings to the mesoscale airport regions. The method calculates the number of aircraft passing at elevation angles fitting the conditions for building-induced shielding effects between 8.1 dB(A) and 11.6 dB(A) derived from in-situ measurements in a test canyon for each grid cell. This added layer of spatial information presents areas which meet similar conditions, based on cross-scalar spatial extrapolation of measurement results. The outcomes are useful for e.g. identifying where urban design might be of further interest for aircraft noise mitigation in existing and planned housing and area developments around airports. The method takes into account e.g. aforementioned elevation angles, derived from flight data obtained for a test location in which extensive measurements were carried out. Factors including variations of atmospheric refraction over longer distances were omitted for this method. Sound shielding variances arising from weather variables could be studied as part of future research. While this methodology delivers robust results for the analyzed area and time-frame, extended aggregation for the time period of a full representative year is envisioned. This time-frame will allow for more accurate representation of the flight distribution arriving to, and departing, from Schiphol airport.

ABSTRACT

This study examines the role of urban free surfaces—parks, trees, water bodies and open squares—in mitigating road traffic noise in adjacent buildings. Case studies focused on built-up areas near roads with defined traffic levels, including aligned frontages, widened streets and urban courtyards with corner buildings.

Free surfaces were analyzed using parameters such as the green-to-paved surface ratio, grass-to-tree vegetation ratio, tree height, and percentages of green areas, paved areas and water bodies. Noise level measurements (LAeq), were taken at different times of the day and under various weather conditions, to understand the acoustic contributions of these surfaces. Qualitative data and measurements enabled the verification of parameter distributions (e.g., green-to-paved surface ratio, grass-to-tree ratio, vegetation height) in relation to LAeq, considering seasonal features and surrounding building heights. Multivariate regression identified linear relationships between factors. Finally, an average dynamic absorption coefficient was estimated for open spaces, treating them as equivalent absorbing areas. This coefficient, influenced by seasonal and meteorological variations, allows modeling of open spaces as acoustically active surfaces. It also provides a basis for designing optimal configurations, offering practical recommendations for urban planners and policymakers to improve acoustic comfort in urban environments.

Keywords: *road traffic noise, urban design, acoustic measurement, acoustic absorption, multivariate regression model, optimization algorithm*

1. INTRODUCTION

Acoustic absorption in urban spaces is a crucial topic for improving the quality of life in densely populated cities. With the increase in urban noise, mainly due to traffic and other human activities, it is essential to develop effective strategies to reduce noise pollution and enhance the acoustic environment. The importance of developing quiet areas within urban environments is addressed at the European directive level by the European Directive 2002/49/EC "European Directive relating to the assessment and management of environmental noise".

In this context, urban design should not be limited to considering noise indicators, but must also integrate human perception into the definition of the acoustic landscape. Aspects such as acoustic quality, the type of predominant sounds, and acoustic contrast with the surrounding environment are indeed decisive, as well as thermal and visual comfort [1].Greenery, in city landscape or building envelopes, helps mitigate the

urban heat island [2], with trees and hedges reducing peak temperatures by up to 7 K and green roofs by up to 3 K. Alongside thermal control, greenery components and water bodies contribute to citizens' mental balance and noise mitigation. Water bodies like lakes and rivers can cool urban areas by evaporation: 1 kg of water can lower the temperature of 2000 m³ of air by 1 K. Water surfaces are generally cooler than built environments, reducing air temperature through convection. Passive systems such as pools and fountains are commonly used in public spaces for both decoration and climate regulation [3, 4]. There is growing interest in the relationships between acoustics and urban planning, particularly in how factors such as urban density, morphology, land use, street distribution, the surrounding street environment and green spaces influence sound dynamics [5, 6]. [7,8] developed models to characterize urban sound environments, focusing on selecting key variables that aid in decision-making for the effective characterization of environmental urban noise. Some studies have shown that sound fields in urban squares surrounded by reflective façades present a uniform reverberation time (RT), while the initial decay time (EDT) is low in the near field and increases rapidly with distance, approaching the RT. Sound pressure level (SPL) attenuation is generally smaller with geometric boundaries compared to diffuse ones, unless the height/width ratio is high [9, 10]. Adding absorptive materials to façades or the ground can increase sound attenuation by 2-4 dB. Reducing building height or creating spaces between buildings can further provide sound attenuation [10]. Directives promoting urban acoustic design face the challenge of integrating acoustic planning with urban design. This process requires the support of specialized technicians and adequate time for accurate calculations, which are often difficult to manage during the preliminary design phases. For detailed analyses, the UNI 9613-2 standard is used to calculate the ground effect attenuation (Agr) for a specific octave band. Agr is determined by summing the attenuations of the three regions involved in the sound path—source (As), receiver (Ar), and intermediate (Am)—based on the ground factors of the corresponding terrain (Gs, Gr, Gm) and the source (hs) and receiver (hr) heights. Ground factors range from G = 0 for reflective surfaces (pavement, concrete, water) to G = 1 for highly absorptive surfaces (agricultural soil, sand, earth), while for mixed terrain, $0 < G < 1$, depending on the fraction of porous ground.

This work purposes a data-driven optimization framework, implemented in Python, developed to determine the optimal distribution of urban surfaces (green areas, paved areas and water bodies) to achieve a target equivalent sound absorption coefficient (α_eff) for a given available area. The workflow is based on Leq measurements conducted in urban spaces with different geometric configurations and various horizontal surface treatments, and consists of three key steps: data preprocessing, regression modeling, and constrained optimization.

2. METHODOLOGY

2.1 Selection of Study Sites

Three urban configurations were chosen for consideration: Aligned Frontages, Widened Streets, and Courtyards (Fig. 1). For each of these, 15 study sites were identified across the neighborhoods of Rome's EUR and Parioli districts (Fig.2). This selection ensured that the buildings were from the same construction period, and therefore had similar construction techniques and materials. The buildings facing the chosen open spaces are also of comparable height, ranging from 5 to 6 stories. the focus of this phase is to account for and compare the effects of the planimetric configuration of the buildings on the open spaces between them, rather than different aspect ratios. The selected sites are also similar in terms of building density, typology and traffic volumes.

2.2 Measurement Campaign

The case study employed Brüel & Kjær 2250 sound level meter to measure and collect data on the environmental SPL of selec ted urban areas. SPL was measured on working days in February 2025. To ensure consistent traffic conditions, measurements were carried out during three time intervals: 8:00–10:00, 12:00–14:00, and 16:00–18:00. Sound pressure levels were recorded at a height of 1.5 meters, corresponding to the average ear level of a standing person. At each measurement point, 15-minute recordings were performed. The weather during the measurement was stable, sunny, with a temperature of 15-20°C and a wind speed of 3 m/s.

2.3 Data Collection and Processing

The sound pressure levels measured at each receiver point were normalized with respect to the same traffic volumes to obtain comparable results. The actual Lw was adjusted to 74 dB, which corresponds, according to

the ROUTES NMPB 96 model, to 86 light vehicles and 8 heavy vehicles passing at a speed of 50 km/h. This reference Lw′ was chosen since it reflects average traffic volumes across the dataset, and ensures a balanced comparison without biasing results toward high or low traffic intensity scenarios. To adjust Lp accordingly, the general relationship between sound power level and free-field sound pressure level was used.

$$Lp=Lw-10\log(S)+DI-A \quad (1)$$

where S is the area over which the sound energy is distributed, DI is the directivity, and A is the attenuation in the propagation path from source to receiver, which accounts for atmospheric absorption, ground effect, presence of barriers, and additional types of attenuation such as vegetation, industrial sites and densely built-up areas.

Figure 1. (a) Widened Street-Tipo1, (b) Aligned Frontages-Tipo2, (c) Courtyards-Tipo 3.

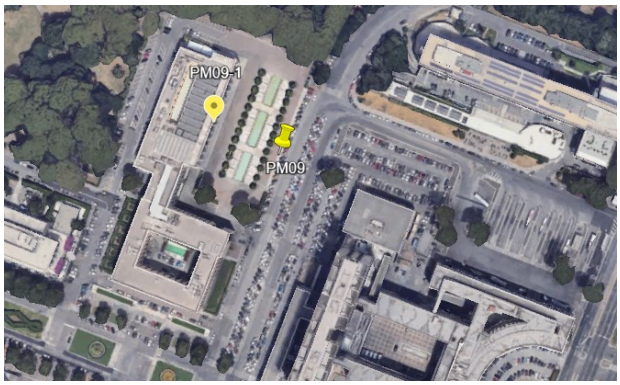

Figure 2. Measurement points in EUR

If the propagation type, the distance of the measurement point from the source, the directivity, and the environment remain constant, we can assume:

$$Lp'=Lp+(Lw'-Lw) \quad (2)$$

Where Lw'=74 dB (3)

Having identified paved area, green area and water body area as predictive variables, it was necessary to recognize and assess the extent of these surfaces in each urban space examined. The spaces were analyzed by defining the study area as the space bounded by the streets (5.5 m width for each traffic flow direction) and the fronts of the buildings facing it (Fig 1). To determine the area occupied by trees, an average was considered for each tree between the area of the trunk and the area of the canopy.

3. RESULTS: ACOUSTIC ANALYSIS OF FREE SURFACES

3.1 Influence of Urban Configuration and Surface Composition on Noise Levels

Figures 3, 4, and 5 demonstrate the effect of green, paved, and water surface treatments on the frequency distribution of noise for the selected urban configurations. In Widened Streets, all surface types showed similar performance at frequencies up to 63 Hz, but differences emerged at higher frequencies. Green areas performed poorly at lower frequencies, while paved surfaces began to outperform green ones around 630 Hz.

Water bodies provided the best acoustic benefits starting at 160 Hz. In Aligned Frontages, green spaces improved acoustic performance from 63 Hz to 1000 Hz due to the sound-absorbing properties of vegetation, but water bodies had mixed effects. They offered some benefits at lower frequencies but worsened at higher frequencies, likely due to reflection and scattering. In Courtyards, paved surfaces performed better than green areas, with a 6.45 dB higher Leq in paved areas, likely due to the reflective properties of paved surfaces that help distribute sound evenly. In general, a trend can be observed in the influence of surface treatments on

acoustic performance of various urban settings: green areas offer sound absorption, water bodies excel at mid-to-high frequencies but can cause issues at lower and higher ones, and paved surfaces provide stable acoustic performance, particularly in courtyard environments. Urban designers should consider these factors when planning for desired acoustic outcomes.In the analysis of urban spaces, sound level fluctuations, evaluated between L90 and L5 (Table 1), varied depending on the surface type and traffic volumes. The smallest fluctuations were observed in Type 1 areas with water, while the highest occurred in Type 1 areas with green surfaces and pavement. These differences may be linked to the urban space configuration, as traffic volumes were similar, indicating the layout's influence on acoustics. For Type 2 areas, water features caused the least fluctuation, followed by pavement and green surfaces. However, the result is less reliable due to the traffic volume being double in the water scenario compared to the others. In Type 3 areas, fluctuations remained stable regardless of traffic volume. Notably, fluctuations in pavement areas with 300 vehicles were slightly lower than in green areas with 150 vehicles, suggesting that surface type is more influential than traffic volume on acoustic variation.

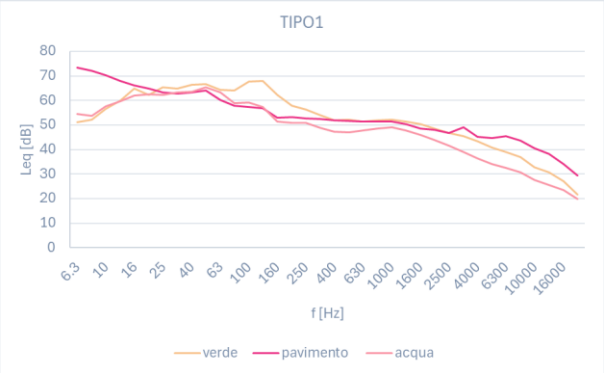

Figure 3. Widened Street.

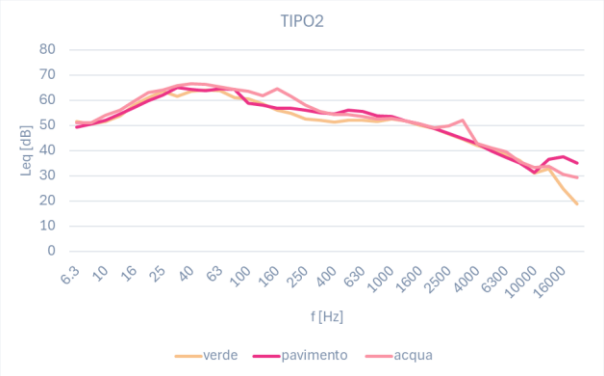

Figure 4. Aligned Frontages.

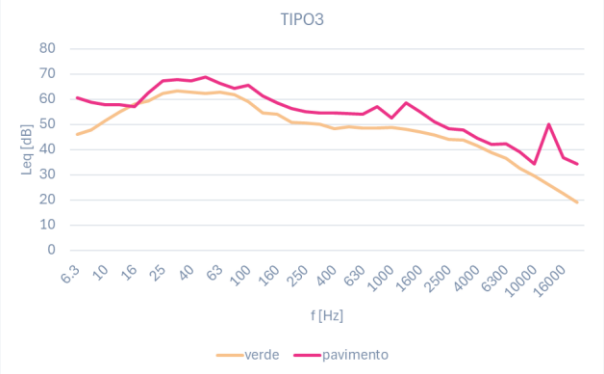

Figure 5. Courtyards.

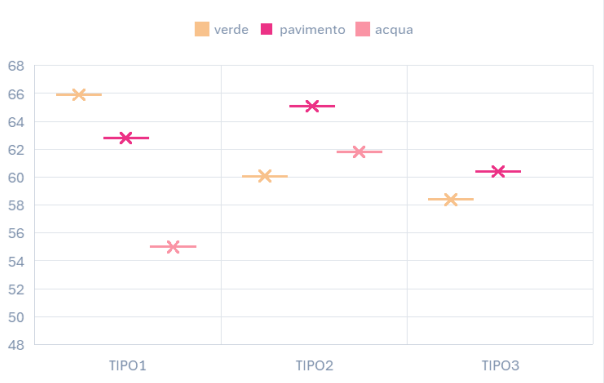

Figure 6. Treatments and urban layouts influence on Leq.

The analysis of global noise levels (Leq) in identical urban configurations with varying surface treatments

(Fig. 6) revealed that in Widened Streets, water was the most effective treatment, followed by pavement and green surfaces. For Alignments, green surfaces performed best, with pavement and water following. In Courtyards, green surfaces also provided the best noise reduction, with pavement in second place. As a whole, water proved more effective in type 1 configurations than in type 2, suggesting that water sources contribute to better noise management. Pavement in type 1 yielded the best results, followed by type 2 and type 3, indicating that the materials used in type 1 are more efficient in reducing noise. Greenery performed best in type 3, with a decline in effectiveness in types 2 and 1. The ideal configuration was type 1 with water, while type 3 with pavement was the least favorable, possibly due to high traffic volume, which requires further normalization specified below.

3.2 Estimation of the Absorption Coefficient: Multivariate Regression and Linear Relationships

Having conducted several measurements in urban spaces containing open areas of various sizes, and having Leq data for comparable traffic volumes, it is possible to estimate an average absorption coefficient for an open space by treating it as an equivalent absorbing area. This approach is useful for modeling open spaces as acoustically active surfaces with a simplified overall behavior. Acoustic and surface data are loaded in Python from a CSV file, containing measured sound pressure levels (L_p_meas), source power levels (L_W), and surface percentages. The effective absorption coefficient (α_eff) is computed as:

$$\alpha\text{eff} = S\text{eq}/(\%A\text{green} + \%A\text{paved} + \%A\text{water}) \quad (4)$$

where Seq represents the equivalent absorbing surface area derived from acoustic measurements

$$S\text{eq} = 10\text{^}((LW - Lp,\text{meas})/10) \quad (5)$$

A first-order polynomial regression (Ordinary Least Squares, OLS) is fitted to correlate α_eff with the three surface types. The model includes an intercept term to ensure physical interpretability, as there is always a contribution from the geometry of the surrounding environment and atmospheric conditions. The models obtained for the Widened Streets, Aligned Frontages and Courtyards configurations are reported in Eq. (6), Eq. (7), and Eq. (8), respectively, where GA = Green Area, PA = Paved Area, and WA = Water Body Area. Table 3 provides the distribution of surface treatments, the absorption coefficients calculated using Eq. (4) and Eq. (5), and those obtained by applying the models developed for Widened Streets.

$$\alpha\text{eff} = 0.000455 * 1 + 0.001461 * \text{GA (\%)} + -0.000654 * \text{PA (\%)} + 0.044671 * \text{WA (\%)} \quad (6)$$

$$\alpha\text{eff} = 0.000050 * 1 + 0.002657 * \text{GA (\%)} + 0.000626 * \text{PA (\%)} + 0.001747 * \text{WA (\%)} \quad (7)$$

$$\alpha\text{eff} = 0.000032 * 1 + 0.003972 * \text{GA (\%)} + 0.002599 * \text{PA (\%)} + -0.003357 * \text{WA (\%)} \quad (8)$$

Table 3. Comparison between α_eff calculated by acoustic equation and polynomial regression for Widened Streets (TIPO1).

11	35	55	10	0.52	0.46
12	10	85	5	0.10	0.18
13	40	50	10	0.35	0.47
14	5	90	5	0.08	0.17

Model significance is verified via summary statistics such as R-squared, p-value, correlation matrices and Variance Inflation Factor (VIF) (Tab.4, Tab.5).
The model for Typology 1 (Eq. 6) demonstrates a good explanatory capacity ($R^2 = 0.722$), with variable x_3 significantly contributing to sound absorption ($\beta = 0.0447$, $p < 0.001$). However, the presence of multicollinearity (Cond. No. = 6.94×10^{18}) suggests caution in interpreting the coefficients of x_1 and x_2, which are not statistically

significant. The multicollinearity analysis revealed a strong inverse correlation between green areas and paved surfaces ($r = -0.87$), further confirmed by VIF values > 10.
The model for Typology 2 (Eq. 7) shows an excellent fit to the data and is statistically significant overall. The p-values indicate that all variables are significant.
The model for Typology 3 (Eq. 8) explains 65.8% of the variability in α_eff and is globally significant ($R^2 = 0.658$, $p = 0.0005$), with x_1 and x_2 positively influencing α_eff ($p < 0.001$). However, the presence of multicollinearity (Cond. No. = 2.34×10^{18}) and non-normal residuals suggests caution in interpretation and highlights the need for improvements, such as handling multicollinearity through Ridge Regression techniques and increasing the sample size.

3.3 Constrained optimization tool

A nonlinear optimization problem is solved to find the surface distribution that, given the total available area (A1) and a desired target value of *α_eff,* minimizes the squared error between predicted and target *α_eff*:

$$\text{minimize}(\alpha\text{pred} - \alpha\text{target})$$

subject to constraints:

$$A\text{green} + A\text{paved} + A\text{water} = A\text{total}$$

Bounds ensure each surface percentage lies within [0,Atotal]. The solver uses an initial guess of equal distribution (33% per surface).
The algorithm returns the optimal surface percentages (e.g., 45% green, 30% paved, 25% water) or reports convergence failure. The results of TYPE 2 appear to be evenly distributed among the treatment types (Tab. 6). Keeping the study area unchanged but imposing α_eff = 0.6, the optimization yields 64.4% Green Area and 35.6% Water Body.

4. CONCLUSIONS

The analysis was automated through a Python script that combines regression modeling and constrained optimization. Acoustic data were processed to compute an effective absorption coefficient (α_eff) for each studied area, which was then correlated with surface compositions using first-order polynomial regression (OLS), providing a characteristic polynomial for each urban configuration. An optimization routine was implemented to determine the optimal surface distribution to achieve a target α_eff under area constraints, offering a scalable tool for urban noise mitigation design to mitigate the impact of urban noise on receivers, in terms of sound pressure levels at building façades.

Table 6. Example of optimization algorithm application.

	Green Area (%)	**Paved Area (%)**	**Water Body (%)**
	A1=100, α=0.3		
TIPO1	46	48	5.9
TIPO2	33.3	33.3	33.3
TIPO3	51.7	43	5.3

Summary of findings

- Configuration-specific α_eff integrates empirical acoustic measurements with surface composition.
- First-order polynomial terms prevent overfitting while effectively capturing linear relationships.
- The developed design tool provides practical, actionable recommendations and implications for urban planning.

Limitations and future research directions

- Besides area extension in widened streets and courtyards, aspect ratio and maximum source distance should also be considered.
- The linearity between α_eff and surface ratios is likely due to the limited number of samples; a greater number of experimental Lp will allow for extensions to higher-order terms, capturing nonlinear effects.
- The simplified method for α_eff proved valid for fixed-distance data; for greater flexibility with variable distances, the full physical approach including source geometry and directivity will be implemented.
- Increasing the sample size and refining the regression model will improve statistical robustness; future developments will include frequency-domain analysis and economic constraints in optimization.

ABSTRACT

The use of city-scale big data in urban planning practices has grown significantly over the past few decades, revolutionizing the way cities are designed and managed. This trend holds the promise of creating urban environments that better account for the perceptions, needs, and complex interactions of people with the built environment. However, despite these advancements, there remains a lack of comprehensive frameworks for incorporating the auralization of urban soundscapes into city-scale big data systems. The integration of soundscape auralization is critical, as it offers the potential to address the acoustic dimension of urban life, enabling more informed and human-centered urban sound planning. In this regard, soundscape auralization frameworks are expected to play a pivotal role in facilitating data-driven decision-making processes that enhance the auditory quality of urban spaces. This contribution aims to address the challenges associated with achieving such integration, outlining a structured workflow for creating soundscape digital twins—virtual representations of urban acoustic environments. The contribution will also highlight that these digital twins could serve as powerful tools for simulating and evaluating soundscapes, ultimately supporting urban planners in designing cities that are not only functional but also acoustically pleasant.

1. INTRODUCTION AND SIMULATION WORKFLOW

As urban challenges become more complex, innovation alone is insufficient; strong partners are needed for comprehensive support and diverse perspectives. The Fraunhofer Institute for Building Physics in Stuttgart has established the Urban and Architectural Acoustics research group (UAA) to accelerate innovation in urban acoustic challenges. By uniting research institutions and demonstration environments under one partner, it aims to improve solutions for society's sound and noise issues.
Noise mapping is a well-established practice in acoustic urban planning, calculating noise levels based on sound source models, propagation effects, and receiver positions. However, this method is limited to frequency band levels, lacking temporal and spectral information, which affects qualitative sound properties evaluated through psychoacoustic parameters. Auralization and physically-based simulation can enhance urban soundscape analysis beyond classical noise mapping. By integrating auralization technology with visual representations of urban spaces, a plausible virtual environment can be created. In this chapter we present the simulation workflow used by the UAA group and in chapter 2 we discuss several challenges and opportunities of soundscape auralizations in urban planning.

1.1 Auralization signal chain

An auralization usually consists of separated simulation models for sources, propagation, and receivers [1]. Virtual Acoustics (VA) is a physics-based auralization framework developed at the Institute for Hearing Technology and Acoustics (IHTA) at the RWTH Aachen university [2] and is intended to be used by the UAA group.

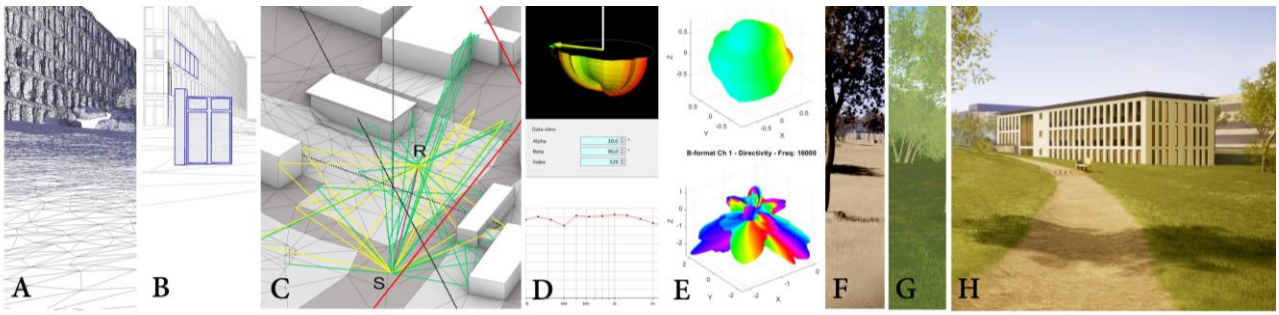

Figure 1. Soundscape auralization workflow example: A) photogrammetry; B) visual geometry; C) acoustic geometry and sound propagation paths; D) sound source directivity characterization; E) 1st HOA receiver characterization; F) light sources and shadows calculation; G) visual materials definition; H) Final audio-visual model of IHTApark [5].

In general, VA allows the acoustic rendering of virtual scenes purely based on synthesized data using physics-based models. It follows a server-client architecture with bindings to various technologies like Matlab (The MathWorks, Portola Valley, CA), Python (Python Software Foundation, Wilmington, DE), Unity (Unity Technologies, San Francisco, CA), or Unreal Engine (UE). Using a purpose-built plugin, UE connects to an instance of VA. During execution, all sound source information is forwarded. VA then handles the auralization including propagation effects according to the selected renderers, as well as the reproduction via an audio interface (Figure 1).

The sound propagation model applies effects to the raw input signal from the source model. For outdoor auralization, it involves two steps: simulating geometric sound paths connecting source and receiver, and deriving acoustic parameters for each path, including spreading loss, propagation delay, and air attenuation. These parameters, called auralization parameters, control digital signal processing during auralization. The consideration of propagation effects and sound path simulation depends on the detail level needed for the scenario. For a car pass-by in an open field, considering solely direct sound and ground reflection may suffice, while urban scenarios require additional effects like reflections and scattering, especially in dynamic situations where movement can occlude direct sound.

1.2 Visualization framework

The basic paradigm of visual simulation of architectural and urban scenes includes four interconnected prerequisites: geometry, materials, light sources and viewers. The approach to construct the model is highly modular. The modular setup allows for the independent modification of each module under certain variables, independent from the rest of the modules, which makes the models versatile. The visualization includes the following elements: geometry, or ways to represent and process surfaces; an imaging or processing acquisition, ways to reproduce the visual—or material—characteristics of objects; rendering, algorithms to reproduce light rays; and animation, ways to represent and manipulate motion, as described by Foley et al. [4]. Further details on the visualization workflow can be found under Llorca-Bofí et al [5].

1.3 Digital twin scenario for validation

To test and develop the simulation workflow, an immersive environment was created over the last years. The IHTApark digital twin, an accurate virtual recreation of the small park behind IHTA in RWTH Aachen, was chosen for this purpose. Combined with VA and the UE VA plugin, the IHTApark project serves as a template for complex audiovisual environments [5]. The park was monitored with audio recordings across multiple weather conditions and visually recreated in Unreal Engine (UE) for presentation on monitors and in VR. The templates made use of VA for auralization and simulated sound propagation in IHTApark with a simplified acoustic model. Further validation of these urban digital twins is planned by the UAA group soon.

2. SELECTED CHALLENGES AND OPPORTUNITIES

2.1 Weather changes

One major problem in auralizing complex urban scenarios is creating ambience - the diffuse background representing the sound floor for the acoustic scene. Omitting realistic ambience leads to a sterile impression. A hybrid approach with spatially recorded background sounds appears promising. Llorca-Bofí et al. [6] explored the influence of weather changes on psychoacoustic parameters (Figure 2). To address improving spatial diffusivity and accounting for weather-dependent variations in outdoor auralizations, we collected and characterized background sounds from the urban scenario IHTApark regarding acoustic parameters and weather conditions. Results indicate that sharpness and roughness correlate highly with relative humidity and cloudiness, while tonality relates to surface wetness. In contrast, loudness correlates with fewer and weaker weather indicators. Thus, it is important to use background sounds in virtual soundscapes, given that the temporal and spectral content affect the soundscape evaluation as well.

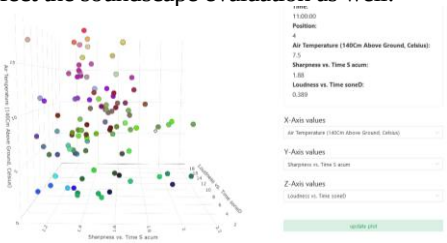

Figure 2. A web application to explore a dataset of ambient noise recordings made at IHTA Park. It can be interactively explored here: https://paad-group.github.io/IHTApark-ambient-recordings/

2.2 Auralization for citizen science

The use of such digital twins in citizen science is a promising field. They can be used to collect assessments of urban design variations across questionnaires to citizens using streaming technologies. In [2] the authors validated the plausibility of such tests comparing virtual reality and web-based listening experiments. For such noise perception experiments, the results are promising, showing minimal differences in questionnaire ratings between VR and streaming reproduction. Visual quality ratings suffered mildly in the consumer setup, but auralization quality was rated similarly positive in both cases. Even for lower feeling of presence in the consumer setup, the subjects' attention remained similarly high despite having lower sense of presence in the consumer setup. Finally, accessibility and quality ratings indicate equally promising results.

2.3 Neural networks training of urban soundscapes

Recent advances in machine learning (ML) and artificial intelligence (AI) have enabled predictive models that capture nonlinear interactions between environmental parameters and psychoacoustic features. Specifically, neural networks are powerful tools for modeling these complex relationships. The authors explored the performance of Back-Propagation networks in predicting psychoacoustic features from urban meteorological inputs using a soundscape database as training data (Figure 3) [7]. The networks' predictive potential suggests that synthetic soundscapes could be generated for various urban situations. These synthetic soundscapes could preserve the physical and psychoacoustic properties from the training data while streamlining the time-consuming modeling process of soundscape environments.

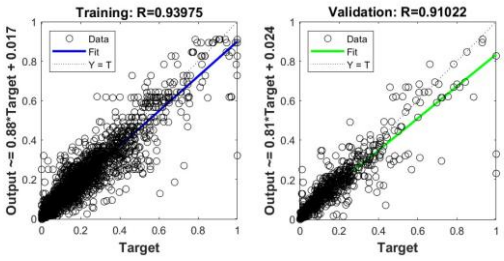

Figure 3. Back-propagation network performance prediction of psychoacoustic indicators based on weather indicators. The dataset is part of the urban background soundscapes dataset, using 80 % as training data and the resting 20% as validation dataset.

2.4 Integrating sustainability measures with noise simulations in urban planning

Towns and cities have to strike a balance between the needs of society and individuals, which tend to clash and coincide with one another. Acoustic urban design has to deal with an unrestrained demand for mobility, increasing urban density and many other factors, together with all other sustainable challenges that cities face. For this reason, today it is even more important to look at the future of acoustic urban design integrated to sustainability measures. The integration of acoustic data together with sustainability data in urban planning simulation is key to tackle those challenges. Available acoustic measurements, air pollution reduction index, resilience to climate change and other data for green

facades at the Fraunhofer-IBP makes the urban planning simulations and optimizations possible (Figure 4).

Figure 4. Measurements of the integrated database of acoustic and other sustainability indicators, available at https://imcom2.hoki.ibp.fraunhofer.de/attribute/index.php

2.5 Soundscape planning at the micro, meso and macro levels

Figure 5. Urban planning concept fort he „Gräselberg – Auf den Eichen“ urbanization area, in Germany, by Reicher-Haase Assoziierte.

The use of auralization techniques might be implemented at different scales in the urban design process, this is for example, to check the impact of the U-shaped buildings as sound barriers for the highway noise, or to assess the impact of the façade manterials to reduce noise on the inner courtyards (See Figure 5). However, since auralization techniques aim to render the soundscape at the receiver position, it is important to mention that the renderings will be perceived from the human point of view, this is, as a pedestrian or dwelling inhabitant. In order to assess the impact of the near sounds as well as the far-away ones, the physically-based auralization techniques previously presented are necessary.

3. DISCUSSION AND CONCLUSION

In this manuscript a workflow to integrate soundscape auralization in urban planning was presented and selected challenges were discussed, in particular, the effects of varying weather conditions, the opportunities of urban soundscape auralization for citizen science, the use of neural networks to agilize the simulation processes, and the integration of sustainable data of facades and buildings, into the acoustic simulations to achieve a multidisciplinary urban planning. Further work at the UAA group will be published in future steps.

ABSTRACT

In this paper an overview of the LIFE SILENT Project and its preliminary results is presented. The project aims to develop and implement sustainable solutions for mitigating noise in complex urban scenarios affected by the coexistence of multiple and diverse noise sources, typically from road and railway traffic, in proximity to densely populated areas. In such contexts, conventional noise mitigation solutions, such as noise barriers, are often unsuitable due to their impact on nearby receivers. However, high noise barriers can reduce visibility, hinder air circulation, and alter the microclimate, potentially leading to social opposition.
To address these challenges, at-source solutions are recommended. For roads, low-noise pavements are proposed, while railways are encouraged to adopt measures such as dampers, rail grinding, and silent brakes. However, these solutions are often limited by issues such as durability and high implementation and installation costs. The LIFE SILENT Project seeks to overcome these challenges by developing and testing innovative solutions, including low-noise pavements and low-height noise barriers incorporating metamaterials, designed to deliver enhanced environmental performance and improved durability.
Finally, to facilitate the coordinated implementation of these solutions by infrastructure owners and managers, the project aims to define a dedicated management procedure.

Keywords: *low-noise pavements, low-height noise barriers, metamaterials, innovative mitigation measures, management procedures.*

1. INTRODUCTION

Urban areas are frequently affected by noise pollution stemming from various simultaneous sources, predominantly road and railway infrastructures. Commonly adopted solutions, such as noise barriers or extensive structural installations, can significantly impact the local environment. These intrusive methods often disrupt visibility, impede airflow, alter microclimates, and negatively influence the overall urban aesthetics, consequently leading to dissatisfaction and opposition among local communities.
In response to such issues, more effective strategies aim to mitigate noise directly at the source. Approaches like low-noise pavements and vibration dampers, rail grinding, and silent braking systems for railways, are

promising but can face challenges related to durability or substantial implementation costs.
Consequently, it is essential to explore sustainable and less intrusive noise-mitigation techniques that balance effectiveness with minimal environmental and social impact. To this end, the LIFE SILENT project aims to develop and test advanced, durable, and environmentally friendly solutions, and to provide comprehensive guidelines to transport infrastructure owners for managing noise mitigation measures in a synergistic way.

2. THE LIFE SILENT PROJECT

The LIFE SILENT project [1] specifically aims to address three key areas:

- sustainable Low-Noise Pavements (LNP);
- compact Low-Height Noise Barriers (LHNBs);
- and coordinated implementation strategies.

The idea of developing and exploring these three areas stems from the following considerations.

Low-noise pavements. Despite the effectiveness of traditional low-noise pavements in reducing noise (approximately 3-5 dB), existing solutions often face durability and sustainability issues. Projects like PERSUADE, LIFE NEREIDE [2][3], LIFE C-LOW-N, LIFE E-VIA, LIFE SNEAK, and IASNAF [4] have advanced research in this area. Particularly notable is the project IASNAF, demonstrating the effectiveness of functionalized cellulose fibres in enhancing pavement durability. However, most studies remain limited to laboratory conditions. LIFE SILENT aims to overcome these limitations by validating durable, sustainable pavements using recycled and eco-friendly materials in real-world settings, improving durability, reducing CO2 emissions, costs, and health impacts, while maintaining optimal acoustic performance.

Low-height noise barriers. Low-Height Noise Barriers have gained popularity as cost-effective solutions, providing noise reductions between 5 and 10 dB [5][6][7]. Typically installed directly onto rail infrastructure, LHNBs eliminate the need for costly foundations, making them economically advantageous and visually appealing. Studies, including numerical simulations and scale-model tests, have demonstrated the effectiveness of LHNBs through optimized designs developed using boundary element methods (BEM) [6]. However, real-world trials have reported noise attenuation ranging from 1.5 to 5 dB(A) [8][9][10][11], primarily limited by multiple sound reflections between LHNB surfaces and train bodies. The LIFE SILENT project aims to address this limitation by integrating metamaterials to enhance LHNBs' sound-absorbing properties, thereby reducing multiple reflections and providing improved durability over time.

Figure 1. LHNB built by Kraiburg STRAIL in San Cugat (Spain).

Noise mitigation synergistic procedures. Effective noise management in complex urban environments, impacted by multiple noise sources, needs coordinated actions among diverse infrastructure stakeholders, as mandated by European and Italian regulations (DPCM 29/11/2000, Directive 2002/49/CE [7], Legislative Decree 42/2017). However, the absence of detailed operational guidelines has hindered effective implementation. LIFE SILENT addresses this gap by developing practical methodologies to facilitate integrated, collaborative solutions across different transportation entities, ensuring sustainable, comprehensive, and regulatory-compliant noise mitigation strategies.

2.1 Project's objectives

Following the previous considerations, the LIFE SILENT project sets out three main goals aimed at innovative noise mitigation strategies.
Firstly, it seeks to enhance road pavement durability and resistance while reducing costs by integrating cellulose fibres derived from recycled waste materials like textiles, paper, and cardboard into bitumen mixtures. This

approach aims to improve fatigue performance, extending pavement lifespan.

Secondly, the project aims to design and implement advanced Low-Height Noise Barriers (LHNB) by using metamaterial technology and a significant proportion (approximately 85%) of recycled materials. These materials will be specifically designed to maximize acoustic absorption and durability, overcoming the limitations of traditional fibrous components, which degrade rapidly. Particular attention will be given to sustainability, ease of maintenance, and structural integrity.

Lastly, LIFE SILENT will establish comprehensive guidelines and procedures for the management and implementation of noise mitigation measures, especially in complex and environmentally sensitive contexts. This will ensure efficient implementation and consistent performance of noise solutions in different scenarios.

3. METHODOLOGY

The methodology adopted by the LIFE SILENT project involves a systematic, multi-phase approach structured into five sequential stages (Figure 2). Initially, the innovative solutions are conceptualized and developed. Then, these solutions are designed and implemented in a dedicated pilot area. Following installation, rigorous impact monitoring and performance evaluation are conducted. The sustainability of the proposed interventions is then thoroughly assessed. Finally, the developed prototypes undergo a formal certification process to confirm their compliance with relevant standards and their effectiveness in real-world conditions [1].

3.1 Development of innovative solutions

The initial phase of the LIFE SILENT project is structured around three core activities:

- Defining procedures and guidelines to support the synergistic implementation of noise mitigation measures.
- Development and design of the innovative LNP:
- Development and design of the LHNB.

The first core activity involves identifying methodologies and preparing guidelines to implement synergistic noise mitigation measures in challenging environmental contexts. This entails the analysis of complex scenarios and existing conditions to ensure effective integration of noise mitigation solutions.

The design and characterization of the innovative low-noise pavements is based on previous findings from the IASNAF project. This approach involves developing a sustainable asphalt mixture incorporating cellulose fibres obtained from recycled textiles, paper, and cardboard. Through iterative laboratory tests and subsequent real-world trials, the project aims to optimize pavement formulations, enhancing durability by approximately 20% compared to current state-of-the-art options, without compromising acoustic and safety performance. This strategy is expected to reduce long-term costs and significantly lower environmental impacts by decreasing reliance on virgin materials and minimizing landfill waste.

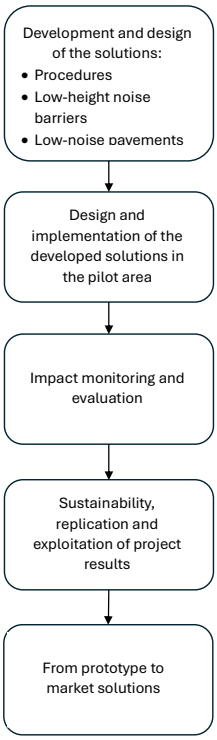

Figure 2. Flow-chart of the main steps of the project.

Lastly, the LIFE SILENT project targets the development and characterization of advanced Low-Height Noise Barriers. Insights from prior research, particularly the experiences from the Kraiburg STRAIL prototype, guide the selection of suitable recycled materials evaluated against EN 15804 standards. Additionally, metamaterials will be employed to significantly improve acoustic absorption characteristics, surpassing traditional fibrous materials in

both performance and durability. Ensuring structural integrity, safety, and ease of maintenance is also a critical component of this barrier design phase, supplemented by fatigue testing and innovative acoustic performance assessment methodologies.

3.2 Implementation of the developed solutions in the pilot area

The innovative solutions developed and tested through initial laboratory testing will subsequently be implemented at a real-world pilot site located in a densely populated urban area (Muratella, Rome, Italy), characterized by proximity to both road and railway infrastructures (see Figure 3). Specifically situated within Rome's XI District, the selected area is crossed by the Rome-Fiumicino Airport railway line and the A91 motorway. This predominantly residential zone includes buildings typically comprising three to four floors, primarily positioned on the northern side of the roadway. Approximately 170 buildings, housing a population of nearly 19,769 residents, students, hospital personnel, and patients, are exposed to noise levels exceeding 55 dB(A) Lden.

Figure 3. View of the pilot area (Muratella, Rome) crossed by the A91 Motorway and the railway line Rome – Fiumicino Airport.

Prior to the full-scale implementation, comprehensive baseline measurements will be conducted to accurately assess subsequent improvements resulting from the new low-noise pavement and low-height noise barrier. This assessment will involve a detailed measurement campaign designed to calibrate the noise propagation model and refine strategies for effective noise mitigation.

The campaign includes five distinct measurement procedures:

- Road vehicle noise emissions measured following ISO standard 11819, with both Close Proximity and Statistical Pass-By methods, including the backing board approach, to assess the influence of pavement characteristics on noise generation.
- Noise level recordings at sensitive receiver locations based on the Italian decree DM 16/03/1998, essential for validating the acoustic propagation model.
- Ex-ante evaluation of the effectiveness of LHNBs using the methodology specifically developed within the project.
- Assessment of pavement surface texture and mechanical impedance following standards UNI CEN 13036-1 and UNI EN ISO 7626-5.
- Preliminary evaluations of community noise annoyance through psychoacoustic methodologies and social surveys aligned with guidelines established in the LIFE NEREiDE project.

The collected data are then used to calibrate an acoustic model that simulates various acoustic scenarios, offering insights into total noise exposure and identifying individual noise source contributions. The measurement results will guide the project's design phase, integrating newly established management procedures to harmonize and optimize noise mitigation efforts by road and rail infrastructure authorities.

To mitigate noise impact, a 200-meter LHNB will be installed adjacent to the railway tracks, primarily targeting sensitive areas on the southern side. The barrier's design prioritizes easy maintenance and structural stability while minimizing visual disruption and preserving views for residents and train passengers.

Additionally, a 1.9 km section of newly formulated low-noise pavement will be implemented on the A91 motorway. Its design will consider urban-specific factors such as road safety, geometric layout, and logistical considerations related to asphalt production and application processes.

The design phase will focus on optimizing asphalt mixtures, refining material compositions and proportions, improving supply chain efficiency, and implementing rigorous quality control measures. Environmental protection will also be a

key priority, achieved through reduced toxic emissions, and strict adherence to safety standards.

3.3 Performance assessment of the implemented solutions

A comprehensive monitoring campaign will be conducted to assess the acoustic effectiveness and long-term performance of the implemented noise mitigation solutions. Specifically, the acoustic durability of the new low-noise pavement will be evaluated through four measurement sessions scheduled at intervals of 3, 6, 12, and 18 months after the laying of the new mixtures. To accurately characterize the pavement durability, data on rolling noise emissions, traffic volume, and weather conditions will be collected even beyond the project's duration of 60 months. The performance assessment for the pavement will also include Statistical Pass-By noise measurements, Close Proximity evaluations, and non-acoustic indicators such as surface texture, frictional properties, and mechanical impedance. These combined data sets will feed fatigue test validation and provide essential inputs for Life Cycle Assessment (LCA) and Life Cycle Cost (LCC) analyses.
The effectiveness of the installed low-height noise barriers will similarly be evaluated through targeted acoustic measurements conducted according to the methodology developed specifically within this project. Additionally, regular visual inspections and periodic testing of the barriers will be performed to monitor structural integrity and material durability.
Further impact assessments will involve detailed measurements of noise levels at sensitive receiver locations, according to the Italian decree DM 16/03/1998. Additionally, psychoacoustic studies and structured social surveys will measure public perception and evaluate community acceptance and response to the implemented noise mitigation strategies.
Finally, the established procedures for managing noise mitigation actions will be continuously evaluated to monitor their effectiveness and efficiency, from the initial strategy formulation to the practical implementation phase. This evaluation will systematically identify potential challenges, recommend corrective actions, and refine the methodology based on feedback from citizens, stakeholders, and public institutions involved in the process.

3.4 Sustainability analysis of the newly developed solutions

The sustainability of the LIFE SILENT approach will be assessed with a focus on the solutions implemented in the pilot area, ensuring a comprehensive analysis of their long-term effectiveness. In addition to the traditional environmental, social, and economic dimensions, the assessment will also consider technical aspects.
The technical evaluation will be performed using standardized methodologies and protocols. Specifically, EN 1794-1/2 will be employed to assess the non-acoustic performance of road traffic noise-reducing devices, while EN 14389 will be used to evaluate their long-term non-acoustic performance. In the railway sector, the non-acoustic performance of noise barriers and related devices will be analysed according to EN 16727-1/2/3.
The assessment of environmental, social, and economic impacts across the life cycle of each technology will be conducted using the Life Cycle Sustainability Assessment (LCSA) framework. This integrated approach combines Life Cycle Assessment (LCA), Social Life Cycle Assessment (S-LCA), and Life Cycle Costing (LCC), in alignment with ISO EN 14040/14044, EN 15804, and the UNEP/SETAC Guidelines for Social Life Cycle Assessment of Products.
The LCSA methodology follows a structured four-stage process: (i) definition of objectives and scope; (ii) inventory compilation; (iii) impact assessment; and (iv) interpretation of results. Additionally, public perception of both conventional and the newly developed noise mitigation technologies will be analysed through a mixed-methods approach, incorporating qualitative and quantitative data collection techniques, such as structured surveys and in-depth interviews.
By integrating technical, environmental, social, and economic considerations, this comprehensive approach ensures a robust sustainability evaluation of the project's solutions. A Multi-Criteria Decision Making (MCDM) framework will be applied to compare the LIFE SILENT noise reduction solutions against an Optimal Hypothetical Ideal Solution (OHIS), which will serve as a reference benchmark. The final assessment will generate an Overall Sustainability Index (OSI), ranging from 0 to 1, quantifying the proximity of the LIFE SILENT solutions to the OHIS.

3.5 Prototypes certification

To ensure the validation of the developed technologies and enhance their market potential, both the newly designed low-noise pavement and the low-height noise barriers will undergo Environmental Product Declaration (EPD) certification. This certification process aims to support the deployment of environmentally sustainable technologies by providing technology developers, manufacturers, and investors with independent third-party verification of their

environmental performance. Achieving EPD certification will attest the reliability of the LIFE SILENT solutions, fostering greater confidence among potential stakeholders and accelerating their adoption and large-scale implementation.

4. EXPECTED OUTCOMES AND IMPACTS

The expected outcomes and impacts of the project are classified into three main domains: low-noise pavements, low-height noise barriers, and advanced methodologies for the management and implementation of noise mitigation measures in complex environmental settings.

4.1 Low-noise pavements

The adoption of low-noise pavement technologies is expected to bring substantial environmental and functional improvements to road infrastructure. One of the main advantages is a projected 4 dB reduction in noise levels, achieved through modifications in surface texture, optimized aggregate gradation, and the incorporation of crumb rubber. This is designed to meet EU Green Public Procurement Criteria, ensuring CPX noise levels around 86±1 dB(A) at 50 km/h.

Beyond noise reduction, the durability of these pavements is anticipated to improve by 20% compared to conventional solutions, thanks to the integration of functionalized cellulose fibres. This enhancement not only extends the pavement's lifespan but also contributes to sustainability by lowering the carbon footprint by 17%, which translates to an annual reduction of approximately 420 tons of CO_2 per kilometre. Additionally, the use of 16 tons of recycled materials per kilometre aligns with circular economy principles.

The implementation of these mixture is also expected to reduce volatile organic compounds (VOC) and polycyclic aromatic hydrocarbons (PAH) emissions, leading to better air quality in road-adjacent areas. From an economic perspective, the extended lifespan of the pavement is projected to result in a 14% cost reduction, reinforcing the technology's role in promoting sustainable and cost-efficient road infrastructure.

4.2 Low-height noise barriers

The Low-Height Noise Barrier represents an innovative solution that integrates environmental sustainability, social acceptance, acoustic efficiency, durability, and cost-effectiveness into a novel design paradigm. Composed of 85% recycled rubber, the LHNB is strategically developed to enhance the circular economy, significantly reducing the environmental impact associated with traditional noise barriers. Due to its low-profile design (0.5 meters in height), it is anticipated to achieve twice the level of public acceptance compared to conventional barriers, primarily due to its minimal visual intrusion into the surrounding landscape.

Despite its compact dimensions, the LHNB employs metamaterial technology to enhance sound absorption and an estimated noise reduction of 5 dB. Engineered for a service life exceeding 15 years, the barrier is also linked to the development of a novel acoustic testing methodology, currently under refinement, with the potential to serve as a future standardization framework.

From a structural perspective, the LHNB is designed for ease of installation and maintenance, benefiting from its lightweight composition and modular assembly. To ensure long-term reliability, the barrier will be subjected to comprehensive fatigue resistance testing, assessing its ability to withstand mechanical stress and environmental degradation.

Economically, the LHNB is projected to deliver a 30% improvement in the benefit-cost ratio compared to conventional barriers, positioning it as a pioneering solution in noise mitigation that effectively addresses spatial, aesthetic, and economic constraints while maintaining superior performance standards.

4.3 Advanced methodologies for the management and implementation of noise mitigation measures

The LIFE SILENT project is also dedicated to developing a systematic methodology for the coordination and implementation of diverse noise mitigation strategies, including low-noise pavements and low-height noise barriers, to optimize their effectiveness. This approach is designed to facilitate collaboration among key stakeholders, such as public transport operators and infrastructure managers, ensuring that their interventions align with broader urban planning frameworks. By fostering coherent and integrated action plans, the initiative aims to enhance noise reduction in urban and suburban environments, contributing to a more sustainable acoustic landscape.

A key component of the project is the development of guidelines to facilitate compliance with legislative requirements, particularly those related to the formulation of Action Plans under European Directive 2002/49/EC. These guidelines are expected to benefit all designated agglomerations covered by the Directive, as well as other European cities seeking to implement more effective noise mitigation strategies.

For infrastructure owners, the project provides clear and structured implementation frameworks, facilitating cost-effective planning, construction, and maintenance of noise-reducing devices. It is estimated that this methodology could lead to a 50% reduction in costs for adjacent infrastructure development, significantly improving the economic feasibility of noise control interventions.

In the pilot area of Muratella (Italy), the project seeks to substantially reduce noise exposure for approximately 19,769 residents, including vulnerable groups in hospitals and schools. This will be achieved through the deployment of 1.9 km of low-noise pavement and a 200-meter low-height noise barrier, with the objective of reducing the annoyed population by 12%, equivalent to 2,464 individuals.

Furthermore, the project emphasizes community engagement and social acceptance, incorporating co-design methodologies that actively involve residents in the planning and design of mitigation measures. By fostering public participation, the initiative enhances community support for noise reduction solutions, ensuring their long-term success and integration into the urban landscape.

5. CONCLUSIONS

The LIFE SILENT project represents a significant step forward in the development and implementation of innovative noise mitigation strategies that address both environmental and societal challenges associated with urban noise pollution. By integrating low-noise pavements, low-height noise barriers, and a coordinated management approach, the project provides a comprehensive and sustainable framework for reducing noise exposure in complex urban environments.

The project's findings demonstrate that low-noise pavements, incorporating recycled and eco-friendly materials, can effectively reduce noise emissions while enhancing durability and sustainability. Similarly, the low-height noise barriers, using metamaterial technology, have shown promising noise attenuation capabilities while maintaining a low visual and spatial footprint, ensuring higher public acceptance. Additionally, the development of standardized methodologies for noise mitigation planning and implementation will facilitate more effective collaboration among stakeholders, enhancing the feasibility of large-scale adoption.

The pilot implementation in Muratella, Italy, highlights the potential impact of these solutions, with an expected 12% reduction in noise-exposed people and significant cost savings for infrastructure owners. The systematic evaluation process, including acoustic performance assessments, environmental impact analyses, and stakeholder engagement strategies, further ensures the long-term viability and replicability of these interventions across various urban settings.

Moving forward, the project's methodological approach and technological advancements will provide a blueprint for future noise reduction policies and urban planning strategies. The integration of sustainable materials, advanced acoustic engineering, and participatory design principles sets a new benchmark for noise mitigation efforts, fostering greener, more liveable urban environments.

By bridging scientific innovation, regulatory compliance, and public engagement, the LIFE SILENT project offers a scalable and transferable model for tackling urban noise pollution, reinforcing its potential as a pioneering initiative in sustainable infrastructure development.

ABSTRACT

This paper discusses the challenges encountered during the LIFE SILENT project in producing innovative asphalt mixtures designed to develop low-noise, sustainable, and eco-friendly pavements for urban environments. The project's aim to integrate recycled materials and innovative additives into asphalt production revealed several technical and operational issues that required careful consideration and adaptation of traditional processes.

Key challenges included ensuring the proper integration of unconventional materials into the mixture, managing their physical characteristics to prevent compaction issues, and adjusting production parameters, such as the order of ingredient introduction, mixing time, and temperature.

This study provides an overview of the lessons learned during the experimental phase, focusing on the technical adjustments and pre-treatments required to overcome production obstacles. By addressing these challenges, the research offers valuable insights into the potential for scaling up the production of innovative low-noise pavements that combine environmental sustainability with improved performance.

Keywords: *Asphalt Plant, Waste Reuse, Low Noise Pavement.*

1. INTRODUCTION

The LIFE SILENT project represents a significant endeavor to advance the development of sustainable, low-noise pavements for urban environments. This research focuses on the integration of recycled materials and innovative additives into asphalt mixtures, aiming at both addressing environmental concerns and enhancing pavement performance. The experimental project revealed a series of technical and operational challenges in adapting traditional asphalt production processes to accommodate these novel materials. Specifically, the introduction of crumb rubber and other additives needs a thorough re-evaluation of mixture design and production parameters. This paper outlines the key challenges encountered during the production processes of asphalts, including material handling, mixture homogeneity, and environmental compliance, and discusses the innovative solutions developed to overcome these obstacles. Ultimately, the insights gained from this project contribute to the broader goal of fostering sustainable urban infrastructure through the adoption of advanced asphalt technologies. This paper is divided into three sections: the first section (Section 2) provides a literature

review related to the plants' structure and the obstacles that emerge during the production phase of the asphalts. The second one (Section 3) provides a critical review of the problems encountered with the use of innovative materials. In the last section (Section 4), some conclusions are drawn.

2. LITERATURE REVIEW

One of the goals of the LIFE SILENT project is to design, manufacture, and test new asphalt mixtures. This new mix formulation includes bitumen, coarse aggregate, filler, and additives, such as crumb rubber and fibers. The production of such a mixture is associated with a few potential risks that can occur at any stage of the production process, including the mixing stage within the production facility, which could significantly compromise the expected performance of the mixture. For this reason, it is essential for designers and producers to be aware of the critical issues that may arise in asphalt plants so that they can address them effectively, not only to prevent performance decline but also to avoid project delays and increases in production costs.

An asphalt plant is a facility designed to produce asphalt mixtures and it typically consists of a dryer drum, conveyor belts, cold feed bins, a hot elevator, storage silos (for filler and powder additives), tanks for storing hot bitumen and liquid additives, pumps, pneumatic and screw conveyors, and control systems. The operational process of each asphalt plant necessitates input materials, such as aggregates (e.g., crushed stones, gravel, sand, and filler), bitumen, and other raw materials that are transformed into asphalt concrete at the end of the production process [1].

The coarse aggregates in various sizes and types are previously stored in the hoppers. Filler, additives and bitumen are stored in tanks and silos.

In any Asphalt Plant, based on the recipe, the control system selects the hoppers, and aggregates are properly dried in the Dryer Drum.

There are two main types of asphalt plants: batch or discontinuous and continuous. A batch plant, whose schematic representation is shown in Figure 1, produces asphalt mixtures in discrete batches, making it suitable for small and medium-sized projects. In contrast, a continuous plant, as shown in Figure 2, produces asphalt mixtures without interruption. The key difference between continuous and batch plants lies in their production method. Batch plants produce asphalt in discrete batches, where materials are loaded, and the binder is injected directly into the mixer. This type of machinery offers high control over the mixture quality and allows for frequent changes in the asphalt recipe.

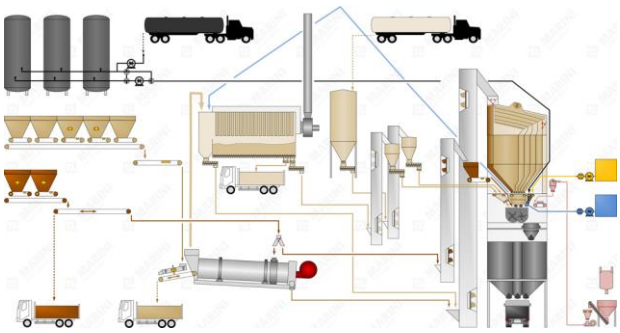

Figure 1. Schematic representation of a Discontinuous Plant (source: Schema di un impianto discontinuo per asfalto - Marini Makina A.Ş.).

In contrast, continuous plants produce asphalt continuously at high rates, without interruption, as the materials are processed within the dryer drum.

The coarse aggregates, bitumen, filler and other aggregates are mixed in the last part of the Dryer Drum.

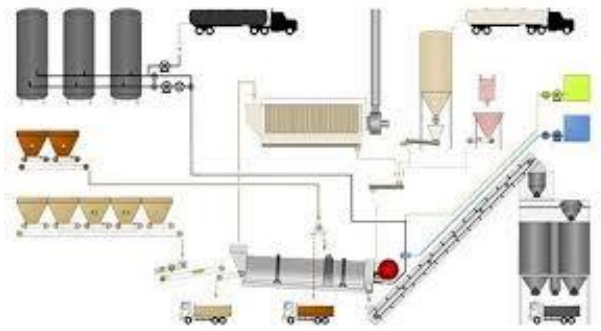

Figure 2. Schematic representation of a Continuous Plant (source: Schema di un impianto discontinuo per asfalto - Marini Makina A.Ş.).

The control systems used in modern facilities are very important because they play an important role in the efficiency of the entire production process: controlling and monitoring the final temperature of the coarse aggregates and asphalt, ensuring the accurate proportioning of materials, controlling the production

rate, and ensuring the safety of the process. The Emission Control Systems (filters, scrubbers, dust collectors) collect and capture dust and any type of emission.

In recent years, to improve the performance of asphalt mixtures, crumb rubber has been added to hot mix asphalt [2]. Crumb rubber, recycled from end-of-life tires (ELTs), has a powder-like consistency and can be incorporated into the mixture using different technologies, including the wet and dry methods. In the wet method, the rubber is added directly to the bitumen, modifying the base binder and resulting in a more resistant and durable asphalt mixture [3].

On the other hand, with the dry method, crumb rubber is added directly to the asphalt mixture during production at the asphalt plant.

One of the main goals of the LIFE SILENT project is to develop a new sustainable, eco-friendly bituminous conglomerate and to improve its durability by preventing fractures and increasing load distribution, mechanical properties and shear resistance. A key part of this project is the design and testing of a new asphalt formulation incorporating fibers derived from waste materials, such as recycled cardboard. These materials are properly treated. The chemical treatment of the fibers makes them suitable for mixing with bitumen to produce the bituminous conglomerate and enables the formation of strong bonds between the fibers [4]. Furthermore, to reduce energy consumption and improve environmental performance, special chemical additives will be used to help maintain the fluidity of bitumen at lower temperatures [5][6][7][8][9].

3. PROBLEMS ENCOUNTERED

Any commercial asphalt plant utilizing innovative materials such as crumb rubber and fibers is facing adjustment challenges. Some of the difficulties related to the use of ELTs, fibers, and additives were addressed within the LIFE SILENT project. This project developed a mixture containing these elements, in addition to the standard asphalt constituents, to be produced using the dry method at a traditional discontinuous asphalt plant.

The introduction of rubber powder and other innovative components into the mixer represents a significant challenge, as traditional plants were not specifically designed for these materials. This is due to the following characteristics of these materials:

- Crumb rubber and fibers are low-density ($<<1 g/cm^3$), are made of low-cost waste materials, and have a powder-like consistency.
- There is a number of liquid additives that were used.

During the production of asphalt, additives and fibers must be inserted into the mixer at different times to prevent them from reacting exclusively with each other. Different methods were investigated for liquid additives, including 1) the use of a dedicated line composed of tank, pipeline, and pump. 2) the use of the existing bitumen line, combining additives and bitumen.

As mentioned above, ELTs and treated fibers, characterized by a powdery consistency, could create problems in the asphalt plant.

The problems that could arise include the following:

- The materials could compact inside their respective feed pipes and create blockages that would reduce or block their regular flow.
- Given their consistency, they might not flow when discharged from the special weighing device into the mixer.

One solution that could be applied for addressing these issues is to form the powder materials into pellets. The palletization process, although offering advantages in terms of handling and dosing powdery materials such as ELTs and fibers, can present several disadvantages from the economic and chemical points of view, implying a new experimental campaign in the laboratory. The traditional palletization process often involves moistening the material to facilitate pellet formation; however, this process could be incompatible with the characteristics of fibers. Consequently, a palletization method for fibers that does not require the addition of moisture could be investigated. Collaboration with the plant owner is crucial to ensure that the developed solutions are practical and applicable to the real-world context, with the aim of overcoming the limitations of palletization methods, which can involve additional costs and operational complexities. The introduction of powder-like materials, using manual or automated feeding systems without compressed air, represents a potential solution, for example, using biodegradable bags.

Another important, eco-friendly and cost-effective advantage of the LIFE SILENT mixture could be linked to lower mixing temperatures (WMA). Lowering the

mixture temperature involves lowering the heating temperature of coarse aggregates, one of the most energy-intensive steps in asphalt production (cf. ANAS RUFAS project) and results in a reduction of emissions from the asphalt plant's chimney and a decrease in perceived bad odors.
The last parameter that requires control is the mixing time, owing to the quantity of components in the bitumen conglomerate mixture, to achieve homogeneous asphalt. Mixing time is defined as the duration needed to thoroughly blend the heated aggregates, bitumen, and any added additives within the asphalt plant's mixer.
The mixing time must be appropriate for the specific asphalt mix being prepared. An insufficient mixing time will result in a non-homogeneous final product, while excessive mixing can lead to asphalt overheating and significantly reduced product quality.
The WMA developed in the LIFE SILENT project, as previously detailed, incorporates rubber powder and fibers in addition to hot aggregates, filler, and modified bitumen. Achieving a uniform distribution of these various elements within the mixture has fundamental importance. The rubber powder must not clump or concentrate in localized areas, and the fibers must be distributed homogeneously, as they are essential for enhancing the mechanical properties of the asphalt.

4. CONCLUSION AND OUTLOOKS

The LIFE SILENT project has the aim of demonstrating the feasibility and potential of producing innovative, low-noise asphalt mixtures utilizing recycled materials and advanced additives. However, the experimental phase highlighted several critical challenges that must be addressed for successful large-scale implementation. The need for precise material handling, particularly with powder-like substances and reactive chemicals necessitates the development of tailored production methodologies. Furthermore, optimizing mixing parameters, such as temperature and time, is essential to ensure mixture homogeneity and environmental compliance.
The exploration of alternative palletization techniques and manual feeding systems, as well as the adoption of warm mix asphalt (WMA) technologies, has shown promise in mitigating these challenges. By documenting these findings and the solutions developed, this research provides valuable guidance for future projects aiming to integrate sustainable practices into asphalt production. The successful application of these technologies holds the potential to significantly reduce the environmental impact of urban pavements while enhancing their performance and longevity.

HOW SUSTAINABLE ARE INNOVATIVE NOISE MITIGATION ROAD PAVEMENTS? AN LCA APPROACH

Alessandra Altobello[1] **Francesco Valerio Catania**[1] **Martina Busti**[1]
Chiara Ravagnan[1] **Almona Tani**[1*]
[1] Italferr SpA – Gruppo Ferrovie dello Stato Italiane, via V. G. Galati 71 - 00155 Rome (Italy)

ABSTRACT

The use of innovative materials is being experimented in asphalt mixtures to improve acoustic performance of road pavements with the aim of mitigating noise as one of the impacts generated by road infrastructures. However, further investigation is required to evaluate their sustainability.
To this end, as part of the LIFE SILENT project- aimed at developing innovative and sustainable solutions for mitigating road and railway noise- a comparative Life Cycle Assessment (LCA) has been conducted to assess the environmental impacts of asphalt mixtures incorporating recycled and innovative components.
The LCA has considered multiple processes involved in the application of asphalt mixtures, from raw material extraction and transportation to manufacturing and laying, as each of these contributes to the overall impact. The study compares 8 alternatives of asphalt mixtures, that differ from each other for the presence of traditional or innovative materials, such as crumb rubber. The latter enhances the acoustic performance of the paved surface and could provide environmental benefits, being a secondary raw material.
This approach enables standardized assessments at system level, offering the opportunity to compare the impacts of either different flows within the same process or different product alternatives, to identify and promote more sustainable practices.

1. INTRODUCTION

Asphalt mixtures are essential materials in modern infrastructures, widely used in the construction of roads and other surfaces. These mixtures are composed of a variety of materials, including aggregates, bitumen, and, increasingly, recycled and innovative components, such as the ones used for the road pavements developed in the LIFE SILENT project that are the focus of this paper.
The production and application of asphalt mixtures involves multiple and various processes, from raw material extraction and transportation to manufacturing and construction. Each of these stages contributes to the overall impact of asphalt, making its environmental life cycle assessment (LCA) a highly complex task.
A comprehensive LCA is based on extensive and detailed data collection and analysis and often requires the definition of assumptions for calculations; therefore, changes in material composition and processes for asphalt mixture production involve significant variability in LCA outcomes. Therefore, a life cycle thinking (LCT) method represents a powerful tool to compare product alternatives and have a detailed understanding of generated impacts.

2. THEORETICAL FRAMEWORK AND RESEARCH GOAL

Sustainability assessment methodologies in road infrastructure design and construction have been extensively addressed and rated by the scientific literature [1-3], highlighting their capacity to innovate existing procedures and approaches. While the importance of sustainability is nowadays recognized in all aspects of life [4], the significant weight of road infrastructures in destabilizing the environment has stimulated strategic and proactive approaches towards the adoption of low-emissions and energy saving

solutions starting from the phases of infrastructures design [5-7]. In particular, the application of a life cycle assessment (LCA) to road pavement industry has been receiving considerable attention by practitioners and policy makers for the recognised ability of this methodology to assess the performance of materials and products throughout their life cycle [8-10], considering both their technical and environmental characteristics.
In this context, this work contributes to the existing studies focused on the potential of innovative materials in asphalt mixtures to help alleviating the environmental burden of road pavements [11-13]. The comparison of multiple additives through the LCA approach has been helpful to assess the consequences and to highlight the hotspots of incorporating innovative solutions into asphalt mix production, contributing in particular to the assessment of the use of crumb rubber in asphalt mixtures [14-18].
Crumb rubber is a recycled material obtained from end-of-life tires (ELT) through mechanical shredding and grinding processes. It can be used as an additive in asphalt mixtures to enhance performance characteristics such as durability, flexibility, and above all noise reduction. By incorporating crumb rubber into asphalt, the material, besides improving the mechanical properties of road surfaces, contributes to the overall asphalt's sustainability, by reducing tire waste and minimizing the demand for virgin raw materials. The LCA approach inquires further in the environmental impacts of its production, including the energy-intensive chipping process, to fully assess its benefits.
Against this framework, the goal of the paper is to assess the sustainability of innovative and low-noise road solutions developed in the LIFE SILENT project through an LCA study. In particular, the paper aims to contribute to the assessment of environmental impacts, paying attention to the analysis of hotspots generated by incorporating innovative solutions into asphalt mix production.

3. METHODOLOGICAL APPROACH

For the purposes of this study, the LCA work breakdown structure of the analysis conducted, aligned with international sectorial standards, consists in the following steps:

A) Scope definition;
B) Base assumption and Inventory analysis (LCI);
C) Selection of impact categories and Impact assessment for the selected impacts (LCIA);
D) Results interpretation.

A) SCOPE

Comparative LCA analysis constitutes a useful and adaptable tool for identifying and promoting more sustainable practices; this applies also to asphalt mixture design and production as required by CAM Strade - the ministerial decree nr. 279/2024 indicating the Minimum Environmental Criteria for the design, construction, and maintenance of road infrastructures. The scope of the LCA analysis reported in this paper is to present and compare LCA results for 8 alternatives of closed asphalt mixtures, which are listed and described in the table below.

Table 1. Description of the 8 asphalt mixture alternatives.

Type	Description
A	This traditional asphalt type, developed by ANAS and used as a reference scenario in the LIFE SILENT project, includes bitumen and stone aggregates. Its composition contains a slightly higher percentage of bitumen and a lower percentage of aggregates in comparison to type B.
B	This traditional asphalt type, developed according to regulatory standards in the LIFE SILENT project, includes bitumen and stone aggregates, and is used as a reference scenario together with type A.
2	This new asphalt type, developed within the LIFE SILENT project, includes bitumen, stone aggregates, crumb rubber, warm mix asphalt additives, and treated cellulose fibre. Its composition contains the highest percentage of warm mix asphalt additives, compared to all other new types.
4	This new asphalt type, developed within the LIFE SILENT project, includes bitumen, stone aggregates, crumb rubber, additives for warm mix asphalt and cellulose fibre. Its composition contains the same percentage of additives for warm mix asphalt as types 5 and 6, and lower percentage compared to types 2, 7 and 8.

5	This new asphalt type, developed within the LIFE SILENT project, includes bitumen, stone aggregates, crumb rubber and additives for warm mix asphalt. Its composition contains the same percentage of additives for warm mix asphalt as types 4 and 6, and a lower percentage compared to types 2, 7 and 8.
6	This new asphalt type, developed in the LIFE SILENT project, includes bitumen, stone aggregates, crumb rubber, hot asphalt additives and treated cellulose fibre. Its composition contains the same percentage of additives for warm mix asphalt as types 4 and 5, and a lower percentage compared to types 2, 7 and 8.
7	This new asphalt type, developed in the LIFE SILENT project, includes bitumen, stone aggregates, crumb rubber, hot asphalt additives and treated cellulose fibre. Its composition contains a higher percentage of hot asphalt additives compared to types 4, 5 and 6, but a lower percentage compared to type 2. Also, the amount of treated cellulose fibre is lower than in mixtures 2 and 6.
8	This new asphalt type, developed in the LIFE SILENT project, includes bitumen, stone aggregates, crumb rubber, hot asphalt additives and treated cellulose fibre. Its composition contains a higher percentage of hot asphalt additives compared to types 4, 5 and 6, but a lower percentage compared to type 2. In addition, the amount of treated cellulose fibre is lower than in types 2 and 6. It differs from all other new types by the lower amount of crumb rubber.

B) BASE ASSUMPTION AND INVENTORY ANALYSIS

Determining raw material inputs, energy requirements, and other fundamental data is a critical step in conducting comprehensive and close-to-reality LCA studies.
The baseline assumptions and the inventory analysis are described in the following:
The *declared unit* is one square meter of pavement.

The *system boundary* is *"Cradle-to-Gate"* with declared modules of life stages A1 to A5 (see table below). The setting of calculation follows the Allocation Cut Off System model in line with regulatory standards [19-21] and PCRs [22-23], and meets the requirements set by EN 15804+A2:2019 in compliance with the end-of-waste criteria [24].

Table 2. Life cycle stages [22].

Product Stage			Construction process stage		Use Stage	End of life Stage	Benefits and loads beyond the system boundary
A1	A2	A3	A4	A5	B1-B7	C1-C4	D
Raw materials supply	Transport	Manufacturing	Transport	Construction-Installation	Modules not declared		

Geographical aspects were considered those as representative as possible of the life cycle processes of the mixtures analysed.
Data Quality is assured using the most recent available datasets and internationally recognized database. The software employed for the assessment is OpenLCA, which allows for a detailed evaluation of the environmental impacts associated with asphalt mixture production and installation through the use of Ecoinvent 3.10 and other specifically selected datasets.
Necessary data from the production, transportation and installation processes are collected using the best available datasets, including both primary and secondary data collection, such as:

- consultations and data exchange with industry specialists: for material and other input selection and *quantity estimation*;
- sectorial scientific literature: utilized when direct access to experts' data was not available;
- official database "Ecoinvent 3.10 – 15804 Unit process Cut-off", and publicly available LCA studies: for supplementary data and validation.

Besides, the baseline assumptions on material inputs are established for LCA calculations. While specific input

quantities are not detailed in this paragraph, the association of calculation inputs with relevant environmental datasets is provided to introduce the assumptions of the analysis.
The following table summarizes the inputs considered in the model along with their corresponding data sources used later for the impact assessment.

Table 3. Datasets used for each life cycle stage.

Life Cycle Stage	Data source
A1	LCI by Eurobitume, 2012 [25] LCI by Ortega et al., 2023 [26] Ecoinvent 3.10 [27]
A2	Ecoinvent 3.10 [27]
A3	
A4	
A5	

Additionally, assumptions regarding energy consumption and transportation distances are made based on the best available data sources. The energy consumption associated with the manufacturing of asphalt mixture production process is derived from technical plant sheets provided by LIFE SILENT partners.
Similarly, transportation distances for materials and finished products were estimated based on discussions with sector experts, aiming to the most realistic representation of logistics and supply and transport chain.

C) SELECTION OF IMPACT CATEGORIES AND IMPACT ASSESSMENT

The methodology adopted for identifying the environmental Impact Categories, and relative KPIs, consists of a literature review carried out as a joint work of the project partners and consolidated in specific meetings. For the literature review were considered, among others, European and international standards, scientific journals and research projects' reports, as well as FS Group internal documents. The initial list of KPIs resulted from the literature review was further refined through desk analysis and validated in a workshop held with the project partners, in order to cover all the life cycle phases of the solutions developed in the project. This process has been critical to confirm the reliability of the methodology and refine its reproducibility.
Impact Categories and indicators used for this LCA study are listed in the following table. The choice of KPIs started from the EN 15804+A2 (EF v3.1) standard, which has a high relevance being among the main standards of the LCA and found to be recurring as a source also in other documents of the literature reviewed.
In addition to the 14 indicators of the most known 7 Environmental Impact Categories, the table lists also:
• 6 indicators for the 5 additional Environmental Categories;
• 5 indicators for the category Outgoing Flows;
• 10 indicators for the category Consumption of Resources;
• 3 indicators for the Waste category.
This makes a total of 15 impact categories and 38 indicators used for the LCA of the LIFE SILENT project asphalt mixtures.

Table 4. Impact Categories and KPIs used for LCA.

Impact category	Indicator (Acronym)	Unit of measure
Environmental		
Abiotic depletion potential	ADP - fossil resources (ADPF)	MJ
	ADP - non-fossil resources (mineral and metal) (ADPE)	kg Sb eq.
Acidification Potential	AP, Accumulated Exceedance (AP)	Mol H+ eq
Ozone depletion Potential	Depletion potential of the stratospheric ozone layer (ODP)	kg CFC 11 eq.
Eutrophication potential	EP – freshwater	kg P eq.
	EP - marine	kg N eq.
	EP - terrestrial	mol N eq.
Global Warming Potential	GWP - biogenic	kg CO2 eq.
	GWP - fossil fuels	kg CO2 eq.
	GWP - land use and land use change	kg CO2 eq.
	GWP - total	kg CO2 eq.
	GWP except emissions and uptake of biogenic carbon (GWP-GHG)	kg CO2 eq.
Photochemical Ozone Creation Potential	POCP	kg NMVOC eq.
Water Depletion potential	Water (user) deprivation potential (WDP)	m3 world eq. deprived
Ecosystem Potential Toxicity	Potential Comparative Toxic Unit for ecosystems (freshwater) (ETP-fw)	CTUe
Additional environmental impacts		
Human Toxicity Potential	Potential Comparative Toxic Unit for humans - cancer effects (HTP-c)	CTUh
	Potential Comparative Toxic Unit for humans - non-cancer effects (HTP-nc)	CTUh
Ionizing radiation	Potential Human exposure efficiency relative to U235 (IRP)	kBq U235 eq.
Particulate Matter emissions	Potential incidence of disease due to PM emissions (PM)	Disease Incidence
Soil Quality Potential	Potential Soil quality index (SQP)	Adimensional
Outgoing flow (energy and other materials)		
Outgoing Flows	Components for re-use (CRU)	kg

	Exported electrical energy (EEE)	MJ
	Exported thermal energy (EET)	MJ
	Materials for energy recovery (MER)	kg
	Materials for recycling (MFR)	kg
Consumption of resources		
Consumption of Resources	Total use of non-renewable primary energy resources (PENRT)	MJ
	Total use of renewable primary energy resources 8 PERT)	MJ
	Use of net fresh water (FW)	m3
	Use of non renewable primary energy resources used as energy carrier (PENRE)	MJ
	Use of non renewable primary energy resources used as raw materials (PENRM)	MJ
	Use of non renewable secondary fuels (NRSF)	MJ
	Use of renewable primary energy resources used as energy carrier (PERE)	MJ
	Use of renewable primary energy resources used as raw materials (PERM)	MJ
	Use of renewable secondary fuels (RSF)	MJ
	Use of secondary materials (SM)	kg
Waste		
Waste	Hazardous waste disposed (HWD)	kg
	Non hazardous waste disposed (NHWD)	kg
	Radioactive waste disposed (RWD)	kg

D) RESULTS INTERPRETATION

This paragraph summarizes the results of the comparative LCA of innovative and complex asphalt mixtures, evaluating their environmental performances against standard ones. Due to the extensive amount of data reported for each mixture, the complete set of results of the LCA study conducted with OpenLCA are available from the authors upon reasonable request.
A specific focus on Global Warming Potential (GWP-total) is provided here for a clearer understanding of the carbon footprint associated with the different alternatives. GWP is one of the most significant impact categories since all the indicators show similar trends, therefore it can be used as a key indicator for assessing the overall sustainability of asphalt mixtures.

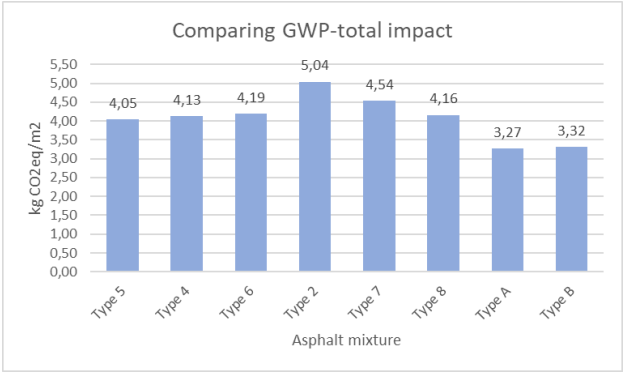

Figure 1. GWP-total for the 8 asphalt mixture alternatives.

The above graph shows the impact in terms of GWP-total. It highlights that the innovative LIFE SILENT mixtures could have higher carbon impact compared to traditional ones, with type 5 and 8 mixtures having the lower impact and type 2 the highest.
The higher impact of these mixtures may be attributed to the greater variety of materials and processes which leads to a higher number of assumptions, also increasing the level of uncertainty. It is worth noting that when the LCA for preliminary assessment was conducted, project data was not fully available therefore secondary data has been used as well [13].
Furthermore, the below graph illustrates the contribution of each life cycle phase to the total impact across the A1-A5 life stages, using average data. The results show consistent trends among all the mixtures.

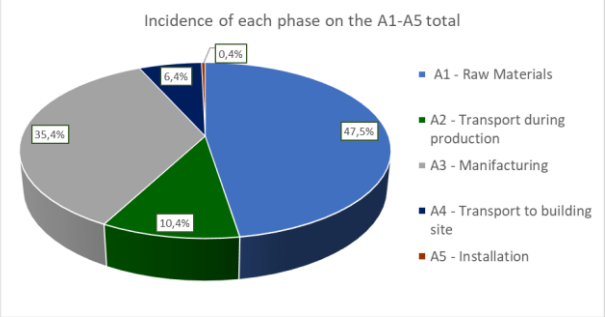

Figure 2. Contribution of each life cycle phase to the total impact.

4. CONCLUSIONS AND WAY FORWARD

The findings provide valuable insights into key impact areas and highlight opportunities for further improvements of the sustainability of the asphalt mixtures proposed within the LIFE SILENT project.
The incorporation of recycled materials, such as crumb rubber and cellulose fibres from recycled cardboard offers notable environmental and economic benefits, which adds to the aim of improved acoustic performance. By replacing virgin aggregates with the right amount of recycled materials, the demand for raw material extraction is reduced, leading to lower environmental impacts. Additionally, recycling minimizes waste generation and landfill disposal, contributing to a more circular and sustainable approach to asphalt production.
To improve the accuracy and reliability of LCA studies on the LIFE SILENT asphalt mixtures, future research should focus on refining critical parameters and assumptions, particularly by collecting more detailed and reliable data on:

- production temperature and its corresponding energy consumption;
- raw material transportation and packaging;
- Crumb rubber and cellulose fibres production, assessing its processing and potential optimizations;
- proportion of primary and secondary materials, including the presence and typology of chemical additives.

Along with the abovementioned points, a scenario comparison is presented to evaluate the potential impact of the LIFE SILENT mixtures production choices, again in terms of GWP-total.
The following graph illustrates how GHG emissions vary when reducing packaging (i.e., avoiding the use of big bags) and cutting off waste impact from the crumb rubber production. According to the LCA results this can lower GHG emission of about 10 % on average.

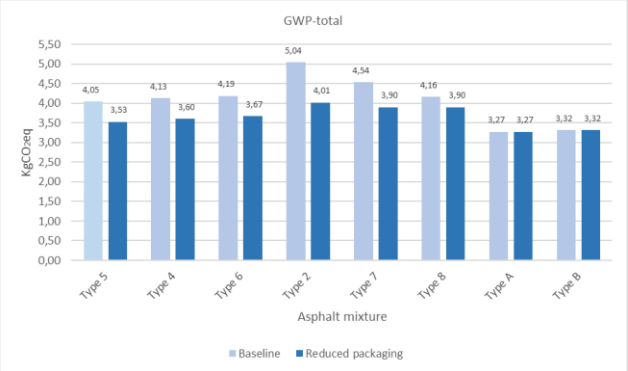

Figure 3. GWP-total in the scenario comparison.

Another graph shows the potential benefit of using higher amounts of crumb rubber by replacing virgin aggregates. The results illustrated in the graph below show that variations in crumb rubber content can improve the mixtures' impacts.

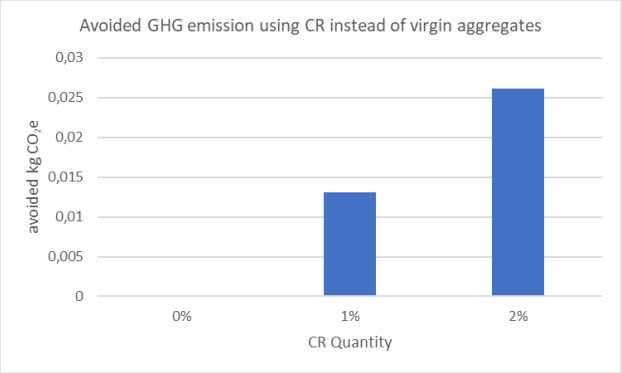

Figure 4. Avoided GHG emissions for different crumb rubber contents.

Additional sensitivity analyses can be conducted on materials' selection. For instance, bitumen, which represents another significant environmental impact, can be the subject of further analysis. While this study assumes the use of virgin bitumen (with SBS), incorporating recycled bitumen could significantly reduce resource depletion and environmental impacts, further contributing to the sustainability of the LIFE SILENT asphalt mixtures.
Together with bitumen, chemical additives also contribute to the overall impact of LIFE SILENT mixtures, despite being used to reduce production temperatures. In future studies, it will be crucial to assess

the benefits of lower temperatures against the environmental impact of these chemical products.
Although the improvement opportunities identified in an LCA study can be numerous, the participation of other academia, industry and design experts is essential to identify additional optimization scenarios and to validate the abovementioned ones.

5. ACKNOWLEDGMENTS

The research has been developed as part of the LIFE SILENT project (Sustainable Innovations for Long-life Environmental Noise Technologies), funded by the European Climate, Infrastructure and Environment Executive Agency under the LIFE Project Grants (LIFE22-ENV-IT-LIFE SILENT).

EUROPEAN PROJECTS FOR NOISE QUALITY IN FLORENCE

First author Arnaldo Melloni[1] **Second author** Gessica Pecchioni[1], **Third author** Raffaella Bellomini[2]

[1] Municipality of Florence
[2]Vie en.ro.se.Ingegneria srl, Florence Italy

ABSTRACT

The city of Florence has promoted and participated in numerous European projects (LIFE and HORIZON 2020) on the topic of environmental noise in cities. Over the last 10 years, the topics of quiet areas, sound-absorbing asphalt, noise produced by tramways and roadside noise control methods have been addressed. The presentation will illustrate the main results obtained and the practical applications in urban areas.

Keywords: European projects, cities, environmental noise

1. INTRODUCTION

The municipality of Florence programs and plans activities for the control of environmental noise using the tools provided for by European directives: strategic noise map and action plan. The main activities are concentrated on the reorganization of city mobility, with the creation of a tram system spread throughout the urban area. The reorganization of private and public mobility is being developed around the tram system, favoring cycle and pedestrian mobility. The goal is to make the city more sustainable, reducing air and noise pollution. The European projects that the municipality of Florence uses to experiment with innovative and replicable activities in the field of sustainability fit into this general framework. Below are presented the results of some European projects on the topic of environmental noise containment and the positive effects on the territory of our city.

2. LIFE HUSH

The H.U.S.H. project moves from the evidence that harmonization of noise action planning methods is needed, not only in Italy but also in all the European countries where a former Legislation about noise planning was present at the moment of END Directive adoption. Among particular project's objectives, one is to define a new development system (procedures and database) for action planning, by testing it in two pilot cases, in the city of Florence. In each selected area a qualitative analysis phase besides a quantitative standard analysis phase is carried out, by means of surveys on sensitive areas, hotspots and quiet areas, as well as through inquiries about people's opinion regarding the disturb perception. In this paper methodological approach for the collection of non-acoustic data, procedures adopted for sample selection, methods for building up and analysis of questionnaires, in the frame of a participatory planning approach, are described. The results of non-acoustic surveys already carried out on a significant sample of people are reported. Expected outcomes are a collection of information that can be used to plan the actions and the community involvements.

3. LIFE QUADMAP

Quadmap Project has met the challenge of defining a methodology to select, analyse and manage QuieTUrban Areas (QUAs) which has been tested in 10 Pilot Areas located in Florence (6 schoolyards), Bilbao (a square and a green corridor) and Rotterdam (2 public parks). The methodology is thoroughly illustrated in the Guidelines which can be considered one of the Project's main final. The methodology proposed by the QUADMAP Project is based on a new definition of QUA. END definition: "quiet area in an agglomeration" shall mean an area, delimited by the competent authority, for instance, which is not exposed to a value of Lden or of another appropriate noise indicator greater than a certain value set by the Member State, from any noise source. QUADMAP definition: a QUA is an

urban area whose current or future use and function require a specific acoustic environment, which contributes to the well-being of the population. The QUADMAP project focused on the problem of noise in urban areas, not only considering the legal limits on noise pollution and taking into account that noise is one (and not the only one) of the sources of pollution that cause discomfort. The main objective of the QUADMAP project was to develop a harmonized methodology for the selection, evaluation (combining quantitative and qualitative parameters) and management (noise attenuation, increase in usability of the areas and user satisfaction) of the Areas Urbane Quiete (QUA), with the aim of overcoming the regulatory and procedural impasse. These objectives were achieved, leaving each responsible entity free to produce its own Action Plan, evaluating and addressing both territorial specificities and political priorities. The validated results of the project facilitated urban planners to apply standard procedures for the identification, delimitation and prioritization of QUAs. A significant part of the project was dedicated to the development and testing of methods for determining the relative weight of concomitant sources of discomfort, considering various factors and acoustic indicators. • Another important topic was the systematic use of soundscape analysis in qualitative acoustic analysis and in the general collection of stakeholders' opinions on the present and desired characteristics of the selected QUA.

4. LIFE E-VIA

Reduce noise on the streets of highly populated urban areas through the implementation of a mitigation measure aimed at optimizing road surfaces and electric vehicle tyres. Three road surfaces (and one test area), at least 5 different electricvehicles (including tires specially designed for electric vehicles) will be tested; The holistic soundscape approach will be used to evaluate the performance of EV vs ICEV in the new scenario (also qualitative evaluation). Awareness campaign: 20,000 people reached. The estimate was based on the experience of previous LIFE projects and on the various initiatives that are expected to be organized during the project. Noise level reduction: noise level reduction Lden and Lnight -5dB (A). The estimate of noise exposure is made taking as reference the side of the road of the receptors. 5 dB (A) reduction compared to the current situation. Improvement of the soundscape: acoustic perception and comfort of an optimized asphalt compared to the standard one. The estimate of the improvement in perception will be verified based on the questionnaires that will be collected. Number of people benefited from noise reduction: 2000 people. The estimate is based on the evaluation of the number of residents in a buffer of 50 m from the road axis.

5. LIFE SNEAK

The general objective is to reduce noise from roads in densely populated urban areas, where noise and vibrations from trams and road traffic overlap, using low noise/vibration surfaces and retrofitting solutions with life cycle costs comparable to those of standard surfaces. The following solutions will be tested in the pilot area: Sound- absorbing asphalt, sound-absorbing panels, miniskirts and mixture of water and oil on the tram to reduce squeel noise when cornering. Furthermore, the psychoacoustic parameters will be evaluated to evaluate the annoyance of citizens before and after the interventions. A contribution will be made to Directive 996/2015/EC regarding the noise assessment method (CNOSSOS).

6. HORIZON NEMO PROJECT

NEMO aims to create a complete (and therefore replicable) solution through which new systems are integrated into existing infrastructures to empirically measure the emissions and noise emitted by individual vehicles. The new measurement systems, together with the implementation of new mitigation solutions, form a comprehensive and modular approach to improve air quality and reduce noise impact in EU cities. Thanks to standardization, the systems will represent a tool for applying limitations to polluting media in low-emission zones and other sensitive areas. The first dimension of the project includes a new and advanced autonomous remote sensing system that identifies noisy and polluting vehicles in existing traffic and makes this information available for possible tolling or access systems. The system can be fully integrated into the road/rail infrastructure and will have the tools to communicate with the existing data structure of both vehicle/train operators and road/rail authorities. The second dimension develops a holistic solution to mitigate noise and emissions from passing vehicles. This integral approach involves the optimization of road structures, green barriers, photocatalytic materials and

the collection of microplastics in the pores of the asphalt layer.

7. CONCLUSION

The description of the activities and results obtained thanks to the European project aims to provide an example of how the experimental and replicable activities carried out thanks to this funding can offer innovative and effective operational tools for the planning and programming activities of the Local societies. In particular, they can contribute to the drafting of Noise Mappings and Action Plans within which medium and long-term strategies for the containment of environmental noise are defined - even punctually.

FORUM ACUSTICUM EURONOISE 2025

MANAGING ENVIRONMENTAL NOISE BY BRINGING TOGETHER CONTINUOUS MONITORING AND SIMULATION MODELS

Luis Conde Santos[1*] **André Carvalho**[2] **Jorge Preto**[1]
Paulo Valério[1] **Cristina Leão**[1] **Guilherme Covas**[2]
[1] dBwave.i - Acoustic Engineering, SA, Oeiras, Portugal
[2] Instituto de Soldadura e Qualidade, Oeiras, Portugal

ABSTRACT

Assessment of environmental noise is commonly done by either performing measurements, long or short-term, or by calculating noise by means of acoustic models. These methods, although satisfactory for long-term planning or for noise limit compliance assessment, may not be suitable as a basis for an environmental noise management and control system, especially if one wants to be able to act upon the noise sources almost in real time. This paper addresses the implementation of environmental noise management systems based on continuous monitoring together with simulation models, which seek to combine real-time information from monitoring stations, installed close to the noisy activity, with information from an acoustic model that allows to predict sound levels at a distance, typically near sensitive receivers. Monitoring data is processed and made available by a digital platform, with the capacity to detect and classify noises, and that can generate alarms in quasi-real time, making it possible to take immediate action to reduce noise emission. The monitoring data is fed into the acoustic model to adjust noise sources emission for a best-fit with the measured levels. Examples of application are presented, namely the case of a racetrack and the case of a construction site.

1. INTRODUCTION

A common method for assessing environmental noise generated by a noisy activity is to carry out noise measurements near potentially affected sensitive receptors, which can be carried out by sampling or continuously over several days (e.g. 48 hours). Another method is by developing an acoustic model of the noisy activity (e.g. a factory) and its surroundings and use it to calculate noise levels at the sensitive receptors and, in a more comprehensive way, noise maps throughout the surroundings. These methods, although applicable in many cases, have some limitations as a basis for an environmental noise management and control system, and are even totally inadequate in situations where there is great variability or unpredictability in the noise emitted by the activity and/or where there is a need for real-time monitoring of the noise of the activity.

In fact, in the context of rapid changes in society and the technologies at its disposal, the methods and technologies used in the assessment and management of environmental noise have evolved slowly, failing to keep up with the real paradigm shifts that have been occurring around them. dBwave, an acoustic engineering company of the ISQ Group, seeking to address this type of issues, has developed and has been applying continuous noise monitoring methodologies, for more or less extended periods (from 48 hours to several weeks), with manual analysis of the recordings in post-processing, methodologies that are currently insufficient, consuming a lot of time, not allowing remote access to the data during monitoring, nor any real-time control of the activity or noisy source that is being monitored and that are only identified a posteriori.

2. MIRA – AN INTELLIGENT PLATFORM FOR ENVIRONMENTAL NOISE MONITORING

To respond to the afore-mentioned challenges, dBwave and ISQ joined efforts to develop an innovative solution, named MIRA, which focuses on continuous, unaccompanied noise monitoring, by means of type 1 sound level meters which communicate with an integrated digital platform with automations to identify specific sounds or noises, as well as the generation of alerts and daily reports of measurements made. MIRA aggregates different modules, all interconnected by a robust architecture, which allows the integration and centralization of several existing technologies, as well as new ones developed with innovative and differentiating characteristics. It thus seeks to respond to the needs identified in the market, in sectors such as industry, construction, transport infrastructures, municipalities and musical and sports performances [1].

MIRA platform is designed to allow flexibility, performance, scalability and ease of use, with the main focus on the ability to scale depending on the traffic that is occurring at the time. For this purpose, a cloud service is used that allows flexibility of the contracted computing capacities according to the need of the moment. This aspect is critical because it allows us to guarantee great security in the quality and responsiveness of the service, but also control the associated costs, since these are directly related to the number of equipment/work to be carried out at any given time.
Figure 1 illustrates the various existing modules and how they communicate with each other.

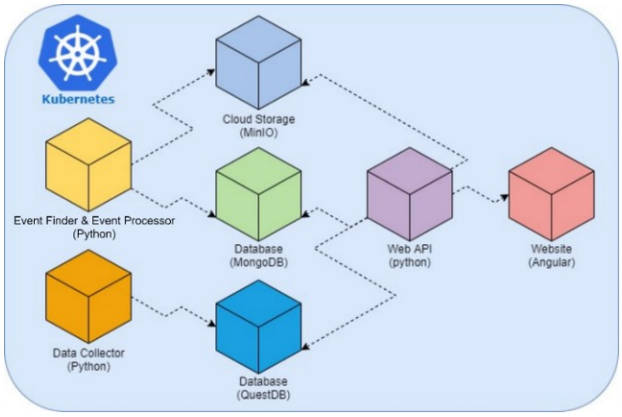

Figure 1. MIRA Architecture Schematic.

3. NOISE MANAGEMENT WITH PERMANENT MONITORING AND SIMULATION MODELS

As far as we know, the first time the approach to environmental noise management with the integration of noise mapping and monitoring techniques was proposed, goes back to 1999 [2]. Since than substantial developments have taken place, such as the technique of Dynamic Noise Mapping, extensively addressed in the European project LIFE DYNAMAP [3].

One of the areas in which permanent monitoring and noise simulation models have long been combined is that of noise management and monitoring systems around airports [4]. For example, in Portugal, Noise Monitoring Systems (in continuous operation) are installed with the aim of monitoring and controlling noise levels, with a special focus on those generated by aircraft, at Humberto Delgado, Francisco Sá Carneiro, Faro and Madeira airports. Simulations/forecasts are also carried out, through the regular preparation of Noise Maps, which are integral elements of the noise monitoring reports of these airports. Real data associated with aircraft movements in the reference periods (flight tracking technology) are used, allowing greater accuracy of the results obtained.

This paper addresses environmental noise management systems based on permanent monitoring and simulation models, in which it is sought to combine real-time information from monitoring stations, installed near the noisy activity, with information from an acoustic model that allows predicting sound levels at a distance, typically near sensitive receivers. The monitoring data is processed and made available by a digital platform, with the capacity to detect and classify noise, feeding the acoustic model for assigning sound power to the noise sources present.

4. EXAMPLES OF APPLICATION

4.1 Environmental noise management of a Racetrack

4.1.1 Background

In the specific case of motorsport tracks, as in other situations (airports, industries) the problem generally arises that, although the objective is to control and limit noise near sensitive receptors, in practice it is not possible to control the noise generated by the racetrack based on monitoring near these receptors. In fact, there are almost always other sources of noise present, such as road, air, rail traffic, animal noise, etc., and it is not possible to attribute the

noises monitored at these points to the specific noise of the racetrack alone. On the other hand, the high number of sensitive receivers to be analyzed could make it unfeasible to install permanent monitoring equipment in all of them.

In this context, many automotive circuits have implemented Noise Management Plans, often based on the imposition of limits on the noise emission of vehicles and their control, either through static tests (at 50 cm and 45º from the exhaust), or drive-by tests (20 m from the track) [5], as well as monitoring systems, such as the Circuit de Spa-Francorchamps, in Belgium[1], using one or more trackside monitoring points and others near potentially more affected sensitive receivers, then seeking to correlate the noise recordings near the sensitive receivers with the trackside recordings, thus seeking to rule out noise that does not originate from circuit activity. In other cases, the approach is to monitor the noise inside the circuit, near the track, and calculate the relationship between the sound level near the source and the sound level near the sensitive receivers, which in practice can be done with an acoustic model of the circuit and its surroundings [6].

Some noise indicators have been developed for automobile circuits such as the Lap Equivalent Level (LEL) and the Race Equivalent Level (REL), the first defined as the L_{Aeq} of the noise received at a given point due to a lap of the track by a single vehicle, and the second as the L_{Aeq} of the noise received at a given point due to the set of vehicles during a race [7].

4.1.2 The Estoril Racetrack

Inaugurated on June 16, 1972, the Estoril Circuit has had some layout changes throughout its history, and the track currently has the following main technical characteristics:

- Runway length (centerline): 4,182.7 m
- Ideal Length of the Route: 4,140.4 m
- Runway Width: between 10 and 18 m
- Total turns: 13
- Longest Straight (Finish Line): 985.7 m

Figure 2. Example of preliminary noise measurements for the development of the acoustic model, during a classics race.

4.1.3 Elements of the noise management system

This case study refers to the environmental noise management and control system implemented at the Estoril Circuit. The system is intended to control the noise emission of all private and corporate events (i.e., other than official sports competitions and respective training), and is essentially based on the following elements:

Event planning and emission control procedures:

- Pre-setting the maximum noise emission levels of vehicles for each event, as well as the maximum number of vehicles that may circulate simultaneously on the track, and previously inform the organizers of these events;
- Systematic pass/fail inspection of all vehicles, before the start of the event, according to a standard procedure (noise level measured at 50 cm and 45 º from the exhaust pipe outlet, at 3/4 of the maximum engine speed);
- Planning of the events for each month in such a way as to avoid concentration of noisiest events in the same month and try to mix them with less noisy events (e.g. alternating track days for motorcycles and for electric cars).

Environmental noise monitoring network, consisting of:

- 3 permanent continuous monitoring stations for ambient noise, weatherproof, consisting of type 1 sound level meters, duly approved in Portugal and subject to annual metrological control, installed within the limits of the circuit, strategically placed to determine the noise emission of the various sections of the circuit;
- Integrated digital platform, MIRA, which receives, stores, and processes the data transmitted by the monitoring stations, namely relevant noise indicators for environmental noise assessment (L_{Aeq}, L_d, L_{den} and

others, including analyses in 1/3 octave), with capacity to generate reports, make information available via the web to those responsible for the circuit, as well as detect specific characteristics of the noise, such as exceeding pre-programmed thresholds and generating alarms for the user.

Acoustic simulation model of the circuit and the surrounding area, developed based on 3D cartographic information, including the digital terrain model, buildings and other obstacles, as well as the layout of the track, which constitutes the specific noise source, divided into a number of segments according to their characteristic sound emission levels. The model allows relating the following variables, involved in the activity of the circuit:

- Maximum permitted noise levels within 0,5 m of vehicle exhaust, taking into account the number of simultaneous vehicles on the track;
- Noise emitted by each segment of the runway, based on the developed acoustic simulation model;
- Noise levels measured at the 3 permanent monitoring stations;
- Specific and background noise levels in the most critical sensitive receivers, to verify the noise nuisance criterion of the Portuguese Noise Regulations.

The environmental noise management and control system includes the preparation of monthly reports with the results of permanent monitoring at the 3 points, respective detailed analysis, identification and individualized calculation of the noise generated in private and corporate events, estimation of the acoustic impact at sensitive receivers, with evaluation of the applicable legal criteria (maximum exposure and nuisance) for a monthly evaluation period. Also, an annual report is produced, synthesizing and systematizing the information from the monthly reports, and making an annual assessment of noise emissions, control and monitoring measures implemented, and evaluation of the applicable criteria.

4.1.4 Noise monitoring network

Monitoring stations have been installed at the following points:

- PM1: "Airton Senna Parabolic" Curve
- PM2: Finish line (Stand B)
- PM3: “Chicane” Curve

Location and example of results are depicted in the next figures.

Figure 3. Location of the monitoring points.

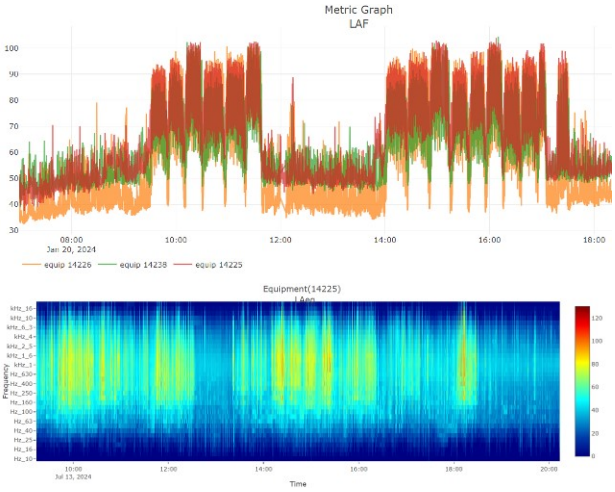

Figure 4. Examples of records on MIRA platform.

4.1.5 Acoustic Model

The acoustic model developed for the Estoril Circuit and surrounding area is shown in the following figure. The model was developed using CadnaA software and is used to calculate the specific noise of the events recorded each month, next to the defined sensitive receptors. For this purpose, the sound power emitted by each segment of the track is optimized for a best-fit between measured and calculated sound levels at the receivers, thus obtaining a model which is calibrated by continuous monitoring.

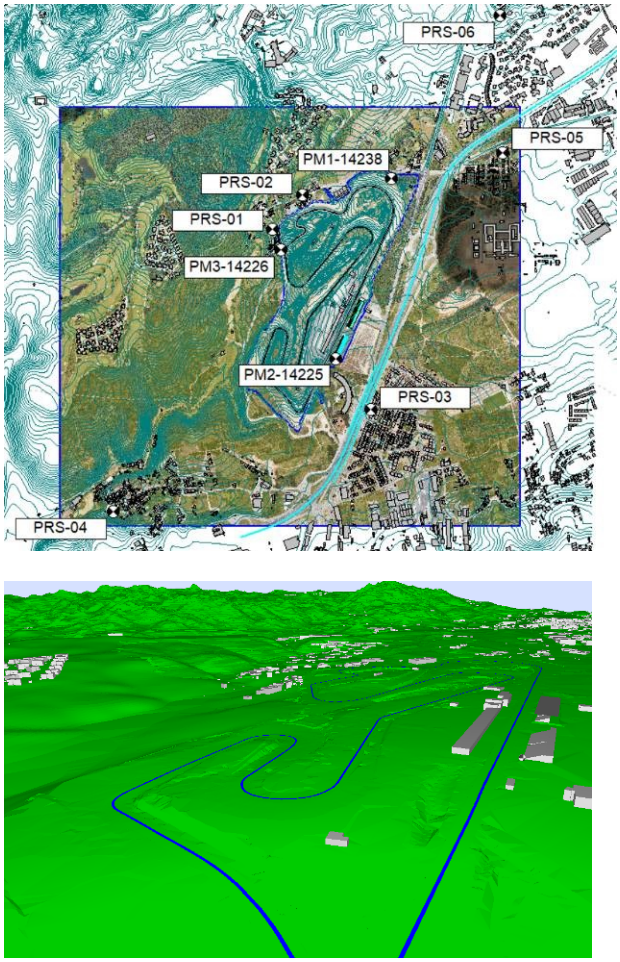

Figure 5. Images of the acoustic model, seen in plan (above) and in 3D view (below).

4.1.6 Evaluation procedure

Taking into account the assumptions of the circuit noise management system, the following compliance assessment procedure has been defined:

- Monitoring of L_d values (L_{Aeq} of the daytime period) for the days with private/corporate events that occurred in the month and calculation of the respective logarithmic average;
- Monitoring of L_d values on days with no activity in the circuit, as a reference for residual noise, and calculation of the respective logarithmic average;
- Extrapolation of the residual noise values obtained above to the closest sensitive receptors or with sound environment characteristics similar to the monitoring points (the so called "image points" according to Procedure 2 of Note 8 of the Practical Guide for Environmental Noise Measurements, published by the Portuguese Environment Agency (APA));
- Calibration of the model to adjust, at the monitoring points, with the values of the logarithmic mean of the L_d values recorded during the private/corporate events;
- Calculation of the specific noise by the model, at points representative of the areas with sensitive use in the circuit envelope;
- Definition of the limits to be applied to the differential of the nuisance criterion, taking into account the quotient between the number of days in the month with private events and the total number of days in the month (for example, in a given month in which there are private events in 9 out of 30 days, the regulatory quotient q = 30% is calculated, so correction regarding the duration of the activity will be D = 2, the regulatory limit to be considered is then 5+2 = 7 dB(A), in the daytime);
- Analysis of the results to verify the criteria of nuisance and of maximum exposure.

4.1.7 Noise control procedures

Within the scope of the noise management system, control procedures have been implemented for private/corporate events which, since its entry into operation in January 2024, have been adjusted according to the results obtained with monitoring. The main procedures currently in force are the following:

Prior Inspection of Vehicles:

All vehicles participating in private events are subject to systematic inspection prior to the start of the event, by

measuring 50 cm from the exhaust, at 3/4 of the maximum engine speed and with the sound measured at a 45-degree angle to the tailpipe outlet. Purely electric vehicles (which do not have exhaust) are excluded.

The emission limit set for most private events has been 100 dB(A), and any vehicle that fails this inspection is prohibited from entering the track. The limits are announced in advance to the promoters of the events, and in the future there may be greater or lesser restrictions on emission levels, as is the case in other international circuits [5], taking into account aspects such as:

- Maximum number of vehicles on the track at the same time;
- Number of events scheduled for the month (in a month with many scheduled events, it may be necessary to restrict emissions further, at least in some of them);
- Event schedules;
- Vehicle and event type in question.

The results of all emission measurements are presented as an annex to the monthly report.

Generation of automatic alarms for the motorsport marshals:

Taking into account the experience of several months of monitoring, and the identification of some of the most critical points, an alarm was programmed for one of the monitoring stations, with the following trigger configuration: LAeq (5 min) > 85 dB(A). Thus, if this alarm is triggered during a race, the responsible marshal is notified and, depending on the conditions of the race/event, will act accordingly: for example, by forcing a reduction in speed in the most critical area of the track, through the use of signal flags.

Opening hours

The Estoril Circuit only operates during the day – typically not occupying the full period. In addition and depending on possible noise management needs of private events, schedules may be adjusted for some events (e.g. noisier events).

4.2 Noise management of a large construction project

4.2.1 Background

Construction noise can affect the physical and mental health of construction workers as well as of the people in the surrounding area and has been reported as one of the main reasons for complaints and disputes that cause delays and cost overruns for construction projects. Several studies have been conducted in the subject of construction noise management, and a comprehensive investigation of the current state of the art in this area was presented in the article by Mir et al. [8].

4.2.2 The Ruby line of Porto metro

The Ruby Line (H) of the Porto Metro is a line under construction that will connect Casa da Música, in Porto, to Santo Ovídio, in Vila Nova de Gaia.
Line features

- The new line will add 6.3 kilometers to the Metro do Porto network, with buried sections, on the surface and on viaduct;
- The project is funded by the Recovery and Resilience Plan (RRP);
- The investment is around 379.5 million euros;
- The work involves the construction of tunnels, 8 stations, 5 ventilation and/or emergency wells, a connection branch at both ends of the line (for the injection and removal of vehicles and track to carry out the reversal of vehicles, viaducts, a new bridge over Douro river and reformulation of the urban space (including roads).

Social, economic and environmental impact

- The Ruby Line will bring social, economic and environmental benefits quantified at 1.7 billion euros

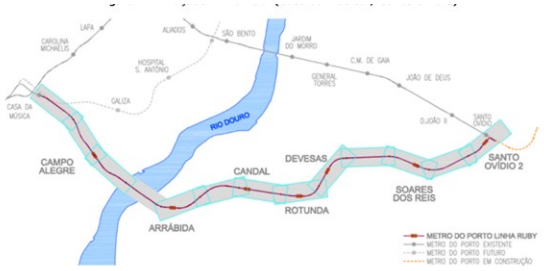

Figure 6. Simplified plan of the Ruby line.

The project was subjected to an Environmental Impact Assessment procedure, which laid out a set of requirements relative to noise and vibration planning and management

during the construction phase. With respect to noise, a management plan was established with the following main steps:

- Identify the sensitive receivers potentially affected and the noise requirements and limits applicable to the project;
- Survey ambient noise levels before construction begins at a number of points nearby the various construction sites involved in the project;
- List all relevant noise sources and noisy activities that will be present on the sites, for each scenario of the construction process, and develop an acoustic model to simulate the various scenarios and the expected noise levels in the nearby sensitive receivers, including residential building façades;
- Propose and implement noise mitigation measures at the source (e.g. less noisy machines, acoustic enclosures), at the propagation path (e.g. noise barriers) or at the receivers (e.g. façade insulation);
- Install continuous noise monitoring stations, at over 20 points and throughout the entire duration of the construction works, connected to a web platform, with capacity of sending automatic exceedance alarms to the various parties involved and information to help identifying the related sources and, also, correlate them to the acoustic model of the site – this enables, works in the first place, to check if the exceedance is related to the construction and, if yes, provide information to quickly take action and correct the exceedance;
- Provide regular noise reports, during the various construction phases and for all construction sites.

4.2.3 Acoustic simulations for various sites and scenarios

For each site, a comprehensive study was carried out before starting the construction works, including a characterization of the construction process, with its successive phases, each involving its specific noise sources, with corresponding sound power levels and working times, and topographic changes (excavations), and, for each phase, simulations were carried out with the acoustic model to check for compliance with noise limits and to test noise abatement measures.

For example, for a typical metro station construction, the following phases were simulated:

- Demolitions, Affected Services and Excavations;
- Excavation of the Tunnel + Coatings
- Internal Structures;
- Urban Insertion and Landscaping

The figures below illustrate the acoustic simulations of two of the construction sites, at a particular phase of the construction process.

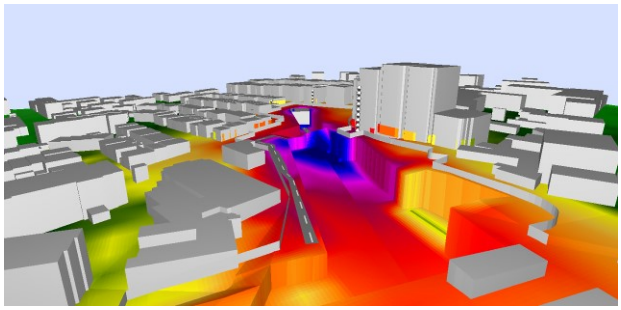

Figure 7. 3D noise map for the Santo Ovidio station.

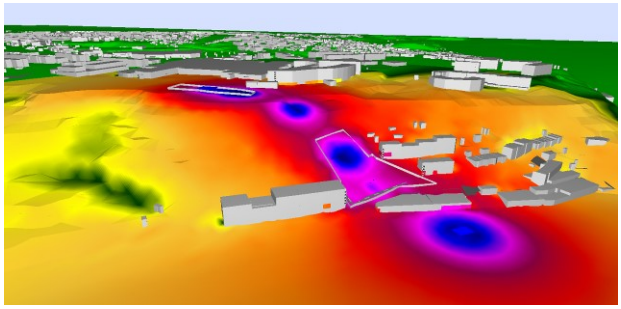

Figure 8. 3D noise map for the south bank side of the bridge over Douro river.

4.2.4 Noise monitoring

At the time of writing this paper, the construction works haver recently started, and the first 3 monitoring stations have just been installed – it is planned that over 20 will need to be working simultaneously, distributed by various sites, as the construction works proceed.

These monitoring stations are being connected to MIRA platform, for automatic reporting and alarm generation. Source detection and correlation with the acoustic simulation models of each site is envisaged and is expected to be tested in the near future.

Next figure shows photos of the noise monitoring stations already installed on site.

Figure 9. Photos of noise monitoring on one of the construction sites.

5. CONCLUSIONS

In this communication, the problem of implementing environmental noise management systems based on permanent monitoring and simulation models was presented, in which it is sought to combine real-time information, from monitoring stations installed next to or within the noisy activity, with an acoustic model that allows predicting sound levels at a distance, typically next to sensitive receptors. The integrated digital platform MIRA, developed by dBwave, which allows the management, communication, registration and analysis of environmental noise monitoring networks, was briefly described and its application was illustrated, together with a simulation model, in the development of an environmental noise management and control system for a racetrack and for a construction site. These were analysed in more or less detail, describing the constituent elements of the system, with emphasis on the monitoring network and the simulation model, as well as describing the procedures for evaluating and controlling the noise generated by the noisy activities. In the case of the circuit, from the experience of 15 months of operation of the system, it can be concluded that it has proved to be very useful, functional and adaptable to different conditions and needs, making it an effective tool in the management and control of circuit noise. In the case of the construction site, although the monitoring part of the project has just started, the almost one year experience with the development and practical application of the simulation models has been proven very useful, helping in the definition and adoption of abatement measures, in the approval and licensing of the construction sites by the authorities and, also, in the acceptance of the unavoidable nuisances by the affected population.

LOW-HEIGHT NOISE BARRIERS FOR RAILWAYS: MEASUREMENT STANDARDIZATION AND METAMATERIALS APPLICATION FOR NOISE REDUCTION

Domenico De Salvio* **Paolo Guidorzi** **Massimo Garai**
Department of Industrial Engineering, University of Bologna, Italy

ABSTRACT

The present work is part of a LIFE project to develop a measurement standard to assess the acoustic performance of low-height noise barriers for railways. Low-height noise barriers (LHNB) present a cost-effective and space-efficient solution to mitigate railway noise, especially in urban and densely populated areas. However, the lack of standardized methods to evaluate their performance challenges their effective implementation. This project addresses these challenges by developing a robust measurement protocol for real-world railway operating conditions. Additionally, the study explores innovative strategies to enhance the absorption performance of these barriers through the integration of metamaterials. Metamaterials, with their ability to achieve tailored acoustic properties, offer promising solutions for maximizing noise attenuation while maintaining compact barrier designs. The research investigates advanced geometrical configurations by combining different resonators to optimize sound absorption across a broad frequency spectrum (100-5000 Hz). Preliminary results indicate significant improvements in noise reduction performance, validating the potential of metamaterial-enhanced barriers. The outcomes of this project will provide critical insights into sustainable noise management for railways, contributing to quieter and more livable urban environments while supporting European Union policy objectives on environmental noise reduction.

Keywords: *noise mitigation, low-height noise barrier, measurements, metamaterials, resonators.*

1. INTRODUCTION

Railway noise pollution is a growing concern, especially in urban areas where proximity to tracks worsens its impact. Sources include rolling noise, aerodynamic noise, and structural vibrations [1]. Long-term exposure is linked to health issues such as sleep disturbances and cardiovascular diseases [2].

Traditional noise barriers are effective but have spatial, financial, and aesthetic drawbacks. Low-height noise barriers (LHNBs) offer a cost-effective alternative for urban settings, though their acoustic performance lacks standardized evaluation methods [3]. Unlike full-height barriers, LHNBs reduce noise differently, focusing on source-level mitigation.

Within a LIFE project, this study aims to develop a standardized measurement protocol for assessing LHNB effectiveness under real-world conditions and integrate metamaterials to enhance noise absorption while maintaining compact designs. Metamaterials, with tailored acoustic properties, optimize sound absorption across 100–5000 Hz [4].

By advancing evaluation methodologies and leveraging innovative materials, this research supports sustainable railway noise management, aiding policymakers and engineers in implementing effective, space-efficient solutions aligned with EU environmental noise directives [5].

2. THE STANDARDIZATION OF THE MEASUREMENT METHOD

Currently, a method for measuring the acoustic performance of low-height noise barriers does not exist. A study is

*Corresponding author: domenico.desalvio2@unibo.it

currently in progress aimed at adapting the European standard EN 1793-6 (also known as "Adrienne") [6], which defines the standard measurement method for measuring sound insulation of highway and railway noise barriers [7], to low-height noise barriers as well.

Figure 1. Insertion Loss: a) measurement of impulse response with the barrier, no obstacles nearby; b) measurement of free-field impulse response; c) setup with reflective surface simulating train body; d) measurement of impulse response with barrier and reflective surface.

The EN 1793-6 standard was conceived for sound insulation measurements on barriers with appropriate dimensions, usually at least 3-4 m high. Two sets of impulse responses are measured using a sound source (positioned on the sound source side at the height of 2 m from the ground and 1 m from the noise barrier) and a 9-microphone grid (positioned on the other side of the barrier at the height of 2 m from the ground and 0.25 m from the noise barrier): one set is measured with the barrier interposed and one in free-field, at the exact relative distances, as described in detail in [6] and [8]. An MLS signal was used to measure impulse response [9]. By selecting data from the two measurement sets and by performing the logarithmic ratio of the transmitted power spectra to the free-field power spectra, the so-called Sound Insulation Index can be obtained averaged over all 9 microphones [6].

This method can be adapted to measure the Insertion Loss of LHNBs. However, as shown in Figure 1, the small size of the barrier and the reduced height on the ground of the microphone and the sound source pose a challenge: the sound reflection on the ground disrupts the measurement. It can be partially reduced using an ultra-directive microphone; however, the low barrier height shortens the data analysis selection window in the time domain and, consequently, a minimum valid frequency analysis of 400 Hz. Figure 1 shows the measurement setup: the microphone and sound source are placed 0.4 m from the noise barrier, both at a height above the ground of 0.21 m. The noise barrier had a height of 0.56 m and a thickness (at the height of the microphone and sound source) of 0.12 m. Figure 1 a) shows the barrier measurement configuration, and Figure 1 b) shows the free-field measurement. Figure 1 c) shows a measurement setup that involves placing the barrier near a highly reflective surface to simulate the train facade, visible in the graphical mock-up in Figure 1 d), in which the sound source is placed in the position corresponding to a train wheel.

3. INTEGRATION OF METAMATERIALS FOR ENHANCED ABSORPTION

As an LHNB is installed close to the track, reducing the rail-wheel noise bouncing between the train body and the noise barrier is essential. Otherwise, it overcomes the LHNB, reducing its efficacy. The proposed metamaterial solution integrates Helmholtz resonators and Fabry-Pérot channels onto the surface of an existing LHNB manufactured by Kraiburg Strail to enhance its absorption performance across a broad frequency spectrum. The design is tailored to achieve an absorption coefficient of at least 0.8 over the 100–5000 Hz range, despite railway noise energy being most concentrated between 500–4000 Hz, as indicated by EN 16272-3-2 [10].

Neck-embedded Helmholtz resonators are incorporated into the barrier surface to address the lower frequency range (100–1700 Hz). These resonators trap and dissipate low-frequency energy by exploiting localized resonance effects [11]. Beyond 1700 Hz, Fabry-Pérot channels enhance absorption at higher frequencies by leveraging quarter-wavelength resonance phenomena [12]. Combining these two metamaterial elements ensures broadband noise attenuation while maintaining a compact barrier profile.

Given the geometrical constraints imposed by the low-height Strail barrier, both perfect and imperfect coupling mechanisms have been exploited to maximize performance. The design carefully balances the interaction between resonators and Fabry-Pérot channels to achieve optimal impedance matching with the incident sound waves, thereby enhancing absorption efficiency across the entire target spectrum. The structural integration of these elements does not compromise the mechanical integrity of the barrier, making it a viable solution for real-world railway applications. The metasurface covering the barrier is subdivided into different bricks, each related to a given frequency range.

The acoustic performance of each individual metamaterial brick composing the total barrier surface has been

assessed under normal incidence conditions using an impedance tube [13]. These laboratory tests provide precise absorption coefficient measurements, allowing fine-tuning resonator geometries to optimize real-world performance.

4. RESULTS AND REMARKS

4.1 Measurements of Insertion Loss

The first results from the adaptation of the Adrienne method to LHNBs in the measurement configurations shown in Figure 1, are shown in Figure 2; here, the test barrier is placed away from nearby obstacles (Figure 1 a) and b)) and near a reflective surface, to simulate the reflecting body of the train (Figure 1 c) and d)). The measurements in the two configurations are similar at mid and high frequencies, showing good repeatability of the measurement method, while they differ somewhat at lower frequencies. Studies are underway to reduce soil's effect further and to evaluate the intrinsic effectiveness of the LHNB better.

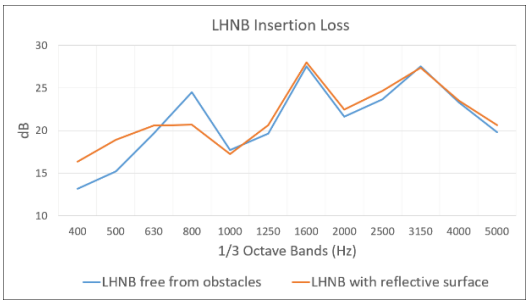

Figure 2. Insertion Loss measurement of the low-height noise barrier shown in Figure 1.

4.2 Metamaterial optimization

This section shows the main results for three "bricks" (sound absorbing units) incorporating imperfect and perfect coupled neck-embedded Helmholtz resonators (NEHR) and a Fabry-Pérot (FP) channel brick. Figure 3 shows the results of brick 1, composed of FP channels. The resonance peaks of the FP channels bricks are designed to keep them away from each other due to the low porosity of the brick (only 6 channels for each brick). The optimal results for FP channels are obtained for high porosity values [14].

Figure 4 shows the results of bricks brick 2, tuned in the 150-220 Hz frequency range and composed by 9 imperfect NEHRs (top), brick 5 tuned in the 550-1050 Hz range and composed by 20 perfect NEHRs (bottom). The imperfect coupling of the NEHRs in brick 2 allows this design to achieve a high absorption performance regardless of the geometrical constraints of the surface.

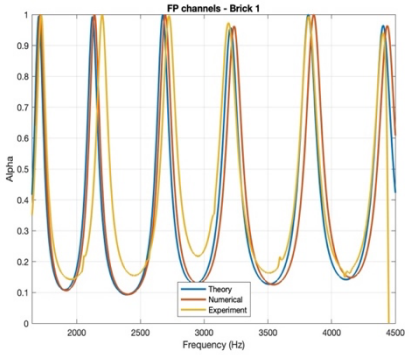

Figure 3. Results for brick 1, including perfect FP channels.

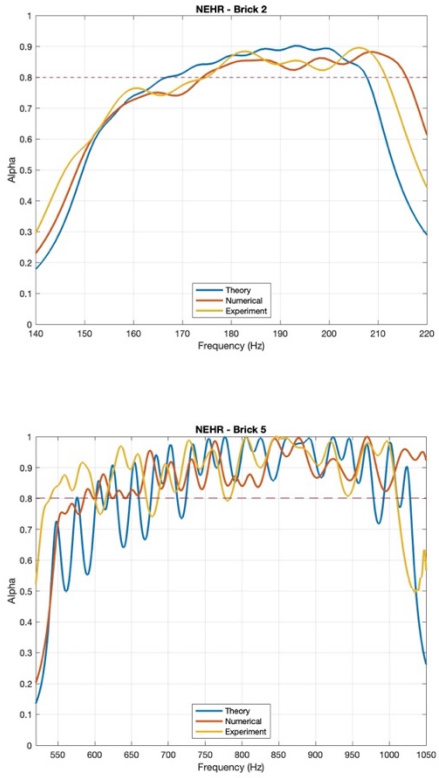

Figure 4. Results for brick 2, including 9 imperfect NEHRs (top) and brick 5, including 20 perfect NEHRs (bottom).

5. CONCLUSIONS

This study highlights the importance of standardizing measurement protocols for low-height railway noise barriers

and explores the potential of metamaterials to enhance their performance. By establishing a reliable assessment framework and leveraging advanced acoustic materials, the project contributes to more effective noise reduction solutions. The integration of metamaterials represents a breakthrough in sustainable urban noise management, supporting European Union initiatives for quieter and more livable urban environments.

FUNDING

The project is co-funded by the European Union under the LIFE 2021-2027 *Environment and Climate Action Program*.
