$$\mathcal{Z}_{\mathrm{sC}} = \frac{1}{\Phi_{\mathrm{L}}/\mathcal{Z}_{\mathrm{sL}} + (1-\Phi_{\mathrm{L}})/\mathcal{Z}_{\mathrm{sFG}}}\,, \tag{11}$$

where

$$\Phi_{\mathrm{L}} = \frac{W^2}{\pi D^2/4} \tag{12}$$

is the fraction of the inclusion face area relative to the front surface area of the composite sample, see Figure 1 (b). Formula (11) describes in fact the combined surface acoustic impedance of two components, i.e. the air-supported felt matrix and the labyrinthine inclusion arranged (acting) in parallel [21].

4. SOUND ABSORPTION

4.1 Predictions and measurements

This section presents the predictions and measurement results of sound absorption at normal incidence for the acoustic composite studied in this work. The predictions were calculated using the surface acoustic impedances defined in Section 3.4 and the well-known formulae for the reflection and sound absorption coefficients, see e.g. Ref. [1]. The experimental measurements were performed on the composite sample, see Figure 1 (c), using an impedance tube set-up according to ISO standard 10534-2 [22]. The impedance tube has an internal diameter of $D = 63.5\,\mathrm{mm}$, which ensures plane wave propagation within the frequency range of interest up to 3.2 kHz. The transfer function method with two microphones was used to determine the sound absorption coefficient under normal incidence conditions [22].

Figure 4 shows both the experimental and analytical results obtained for the composite sample. A prediction of sound absorption for the labyrinthine material itself is also presented, as well as the absorption curve measured for the homogenous felt panel backed by an air gap.

4.2 Comparison and discussion of the results

The sound absorption curves shown in Figure 4 can be compared, as they all correspond to configurations with the same total thickness of $H = 18\,\mathrm{mm}$.

The black curve with square markers represents the absorption coefficient measured for a reference configuration consisting of a 9 mm polyester felt backed by a 9 mm air gap. As expected, this material exhibits very good absorption capacity in the mid- and high-frequency ranges, but rather poor performance at lower frequencies, although the overall absorption is improved by the air gap. Furthermore, the undesirable effect related to the resonance of the elastic skeleton of the felt is clearly visible around 700 Hz. It locally reduces the already weak low-frequency absorption. Incidentally, such poroelastic behaviour occurs only around this resonant frequency of the skeleton, and the rigid-frame equivalent-fluid model is appropriate and valid for the entire frequency range beyond the elastic-skeleton resonance.

To overcome the limitations of the felt acoustic panel, a labyrinth inclusion was designed using the model described in Section 3 to introduce a subwavelength resonance with a frequency similar to the resonance frequency of the elastic skeleton of the felt. This is evidenced by the corresponding sound absorption calculated for the labyrinthine material, represented with the blue curve with diamond markers in Figure 4. This curve has two absorption peaks and perfect absorption is achieved with the first peak at about 750 Hz.

After embedding the labyrinthine inclusion in the polyester felt to form an acoustic composite panel, significant improvement in sound absorption was achieved in the targeted low frequency range. The predicted and measured acoustic absorption performance of the composite is shown in Figure 4 by two red curves marked with circles. These curves show good agreement with each other, which confirms the validity of the analytical model proposed in Section 3. It is easy to observe that incorporating the labyrinthine inclusion into the polyester felt does not degrade its good mid-to-high-frequency sound absorption. Instead, the combined acoustic absorption performance of a conventional porous matrix and a metamaterial inclusion is achieved.

5. CONCLUSIONS

An acoustic composite panel combining conventional acoustic felt with 3D-printed labyrinthine inclusions was researched and designed to enhance low-frequency sound absorption while retaining the natural ability of the felt to absorb mid- and high-frequency noise.

The impedance-tube measurements performed on a composite sample confirm that tailored labyrinthine inclusions can significantly increase the sound absorption at low frequencies through a quarter-wavelength resonance tuned in design. At the same time, embedding metamaterial inclusions into the felt matrix in the appropriate proportion does not significantly affect the good performance of the matrix material in the mid and high frequency range, offering a lightweight and space-saving solution for broadband sound absorption.

The good agreement of the measurement results with the predictions proved that the applied analytical modelling based on the equivalent fluid approach and the calculation of the surface impedance of the sound-absorbing elements working in parallel are correct and accurate.

Future work will focus on manufacturing larger composite samples and testing them in different configurations and noise conditions, e.g. as liners in a duct or in a diffuse field, to evaluate their performance under real-world conditions.

RAINBOW TRAPPING RESONATOR ARRAY FOR HIGH-LEVEL SOUND ABSORPTION

Adam Cavanagh[1*] **Olga Umnova**[1] **Deepak Akiwate**[1]
[1] University of Salford, Acoustics Research Centre, M5 4WT, Salford, UK

ABSTRACT

This study analyses a proof-of-concept ducted rainbow-trapping resonator array designed for high-level sound absorption. By tuning the dimensions of the array's resonators, it absorbs sound waves over a broad frequency range and with increasing efficiency with incident pressure amplitude. The arrays' acoustic behaviour was modelled numerically, where the greatest attenuation was observed at the highest level considered, 155 dB. The results show the potential applicability of absorber designs that exhibit rainbow-trapping behaviour to high-intensity environments.

Keywords: *high-amplitude sound, acoustic rainbow-trapping, resonator array, sound attenuation, resonator nonlinearity*

1. INTRODUCTION

Sound absorbers based on resonant cavities, i.e. those in perforated liners, can exhibit significant local nonlinear effects at high SPLs, impairing or enhancing absorption properties [1, 2]. The dominating nonlinear effect in resonant absorbers is the increased resistance with incident wave amplitude. A HR side-loaded to a principal waveguide can exhibit increased energy dissipation by converting the incident wave's energy to vortical kinetic energy at the sharp edges of the resonator's neck, i.e., at discontinuities. For instance, this increased dissipation can induce coherent perfect absorption at high SPLs [3]. The perforations in a liner's face sheet exhibit similar effects at high SPL. These effects have been extensively studied (see,e.g. [4, 5], and can significantly alter an absorber's intended performance.

Another approach to increase absorption is absorbers with graded spatial properties, i.e., "rainbow-trapping" structures. These are designed using arrays of critically coupled resonators with frequency-cascaded band gaps to target a broadband frequency range. This way the spatial grading results in a "slow sound" phenomenon where different frequency waves become confined to specific points along the array's length, resulting in highly efficient and even perfect absorption in transmission problems [6]. Moreover, [7] have studied in detail the acoustic properties of an acoustic black hole absorber, providing valuable insights into the effect of geometry on performance and behaviour.

Maintaining efficient broadband absorption at high SPLs remains challenging due to resonators' nonlinear effects at such levels. The works of [6, 7] highlight the effectiveness of spatially graded absorbers for broadband sound absorption, and those of [3–5] offer insights into the theory and design principles of effective high-level absorption. Together, these contributions provide a compelling foundation for designing superior broadband sound absorbers for high-intensity environments.

This work evaluates the sound absorption performance of rainbow-trapping resonator arrays (RTRAs) in linear and nonlinear acoustic regimes. Two designs are considered, the first optimised for maximum linear regime absorption and the second for maximum nonlinear regime absorption. These are respectively denoted RTRA_1 and RTRA_2 hereinafter. Notably that the present configurations and simulations are for the two-dimensional case and serve as a proof of concept for nonlinear-aware optimisation applied to rainbow-trapping absorbers. The geo-

metric configurations and modelling approach, results and discussion, and conclusions and further work are respectively presented in 2, 3, and 4.

2. METHODOLOGY

Both structures comprise an array of $N_1 = 8$ and $N_2 = 5$ differing HRs, respectively, each side-loaded to a principal waveguide of constant height arbitrarily set to 29 mm, see Fig. 1. The RTRAs' lengths and heights are constrained to a maximum length $L_t = 100$ mm and height $H_t = 30$ mm to ensure compactness and applicability to small ducts. Four parameters describe each HR's geometric configuration due to the two-dimensional setup. These parameters are the neck and cavity lengths and widths, respectively denoted $l_n^{[n]}$, $l_c^{[n]}$, $d_n^{[n]}$, and $d_c^{[n]}$ (superscript $[n]$ denotes the n^{th} HR). Each HR is designed such that its resonance frequency f_r is close to the n^{th} value in a set $\mathcal{F}$ of N_n equally spaced frequencies over the range $f_1 = 1$ kHz to $f_N = 2$ kHz. In this way, the resonances overlap to cover a broadband frequency range due to their moderate Q factors.

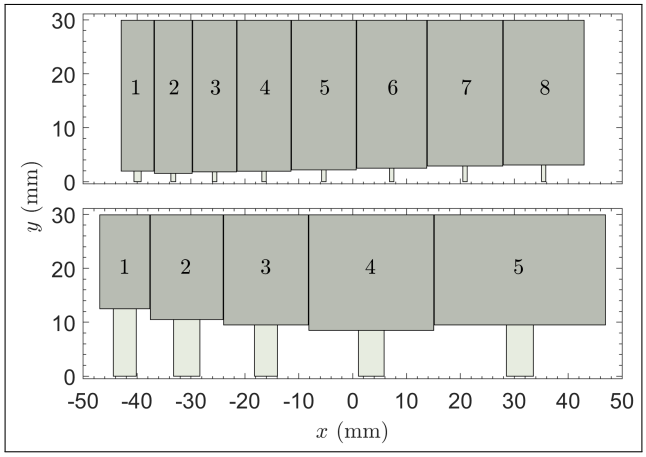

Figure 1. Linear (top) and nonlinear (bottom) optimised RTRA geometric configurations; principal waveguide is not illustrated for clarity, but is placed horizontally at $x = 0$. Geometry is in two-dimensions, meaning the structures extend infinitely into and out of the page.

2.1 Optimisation Scheme

The design process began with the development and numerical validation of an analytical model using the transfer matrix method (TMM) with effective complex and frequency-dependent density and compressibility obtained using the Johnson-Champoux-Allard equivalent fluid model [8, 9]. Then, an optimisation scheme similar to that in [6] was implemented to fine-tune the HRs dimensions. The scheme's genetic algorithm (GA) sought to minimise the cost function,

$$\mathcal{C} = \sum_{f \in \mathcal{F}} |R(f)|^2 + |T(f)|^2 + \varepsilon\,, \tag{1}$$

i.e., to minimise the system's leakage. The quantity ε denotes a conditional penalty applied if the RTRAs' length, L, exceeds L_t ($\varepsilon = |L - L_t|$), $\varepsilon = 0$ otherwise. It controlled $l_n^{[n]}$, $d_n^{[n]}$, and $d_c^{[n]}$ with 0.01 mm minimum step size, the remaining $l_c^{[n]}$ was implicitly defined in the cost function such that $l_c^{[n]} = Ht - l_n^{[n]} - h$, where $h = 0.1$mm is a realistically manufacturable wall thickness value.

2.2 Numerical Model

Nonlinear behaviour was approximated numerically using FEM in COMSOL Multiphysics 6.2™. More precisely, nonlinear effects were accounted for using the interior perforated plate boundary condition (BC) in the Frequency Domain Pressure Acoustics interface. The BC implements the model in [4] for circular micro- and macro-perforations. Although the present configurations are in two dimensions, meaning they have slit-shaped necks, this formulation is considered acceptable under this work's conceptual nature because the underlying theory is general and applies to realistic geometries. Furthermore, the TMM's equivalent fluid model does not account for the distinct flow behaviour in larger holes and hence will not agree with FEM results for the second design, RTRA_2, where the neck widths are not much less than the target wavelength (see Tab. 2). While the RTRA_1 neck widths are significantly smaller, the TMM results were used solely for optimisation and are omitted from this work.

2.3 RTRA_1 – Optimised for Linear Regime

RTRA_1, with $N_1 = 8$ HRs side-loaded to the principal waveguide (see Fig. 1), is optimised for maximum absorption in the linear regime. The resonator geometric parameters were constrained during the optimisation process to

ensure correct cascading of resonance bandgaps. See Tab. 1 for the resulting RTRA_1 resonator dimensions.

Table 1. Geometric parameters for RTRA_1. All dimensions are given in millimetres.

n	$l_n^{[n]}$	$d_n^{[n]}$	$l_c^{[n]}$	$d_c^{[n]}$
1	1.96	1.33	27.94	6.08
2	1.53	0.90	28.37	6.99
3	1.82	0.83	28.08	8.14
4	1.94	0.80	27.96	10.00
5	2.18	0.83	27.72	12.00
6	2.50	0.81	27.40	13.00
7	2.90	0.81	27.00	14.00
8	3.09	0.79	26.81	15.00

2.4 RTRA_2 – Optimised for Nonlinear Regime

RTRA_2 is designed with high SPL absorption in mind. Sound levels inside, e.g. an aeroengine can breach the nonlinear regime during flight conditions ($>$ 150 dB) [10]. Shock waves can form at such levels if the wave can propagate sufficiently far uninterrupted. The distance a shock wave will from its sound source, known as the shock formation distance, is given by [11],

$$\overline{x} = \frac{\rho_0 c_0^3}{\omega \beta p_0'}, \tag{2}$$

where ρ_0, c_0, ω, β, and p_0' denote the density of air in kg/m^3, sound speed in air in m/s, angular frequency in rad/s, coefficient of nonlinearity in air (dimensionless) equally approximately 1.2 , and the incident wave's amplitude in Pa, respectively. Shock formation distance is inversely related to f and p_0', meaning reduction in $\overline{x}$ with increased f or p_0'. The RTRA_2's L should remain minimum one magnitude smaller than $\overline{x}$ to suppress internal shock formation.

The design accounts for nonlinear effects like flow separation and vortex shedding in the necks. These effects are realised as the dependency of the neck's acoustic resistance on incident wave amplitude, increasing the conversion of the incident wave's energy into thermal and vortical kinetic energy. Typical micro-perforation sizes present flow resistivity values that are too high for the effective transfer of wave energy into the resonators due to the non-negligible inertial effects at high SPLs. HR neck widths in RTRA_2 were thus constrained to a minimum size of 4 mm during optimisation. In this way, the GA tuned the resonators close to their respective $f \in \mathcal{F}$ while ensuring sufficiently low flow resistivity. RTRA_2 optimised dimensions are tabulated in Tab. 2.

Table 2. Geometric parameters for RTRA_2. All dimensions are given in millimetres.

4	8.50	4.75	21.40	23.18
5	9.50	5.00	20.40	31.77

3. RESULTS

Both RTRAs' performance is analysed numerically at three increasing excitation levels (80, 130, and 155 dB) to understand linear and nonlinear regime behaviour.

3.1 Linear Regime Performance

Individual resonator α is illustrated in Fig. 2. The f_r cascade is clear for both RTRAs. RTRA_1's resonators (Fig. 2 [a]) exhibit α peaks approximately over the range 750 Hz to 1720 Hz, with a gradual reduction in f from the first to last HR. Although the n^{th} HR's f_r should approximately match the corresponding $f \in \mathcal{F}$, the first four HRs exhibit maxima below 1000 Hz. This discrepancy is not too problematic (see succeeding results) and is likely attributed to the optimisation process, where the GA does not strictly know to tune each HR to each f. Conversely, most of RTRA_2's HRs present α maxima inside the target range $\mathcal{F}$, excluding the final $n = N_2$ HR.

The frequency cascade effect becomes clear when comparing the individual resonator α peaks with the full RTRA α shown in Fig. 3 (a). RTRA_1 exhibits good broadband absorption across most of the target range. The best performance is between approximately 1000–1400 Hz, with consistent $\alpha \approx 0.9$ and minimal R and T. RTRA_2 shows adequate broadband α in the linear regime despite

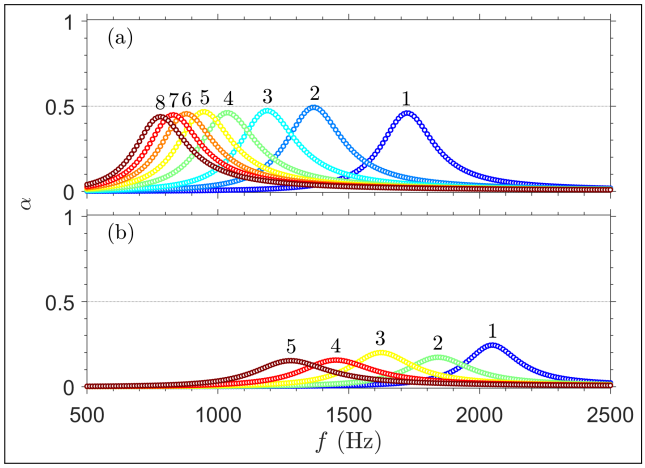

Figure 2. Sound absorption coefficients of each of the $N_1 = 8$ HRs in RTRA$_1$ (a), and for each of the $N_2 = 5$ HRs in RTRA$_2$ (b). The n^{th} HR's absorption curve is indicated by the numbers located at each of the maxima. Dotted horizontal line represents maximum possible α of a single side-loaded HR, i.e., coeherent perfect absorption.

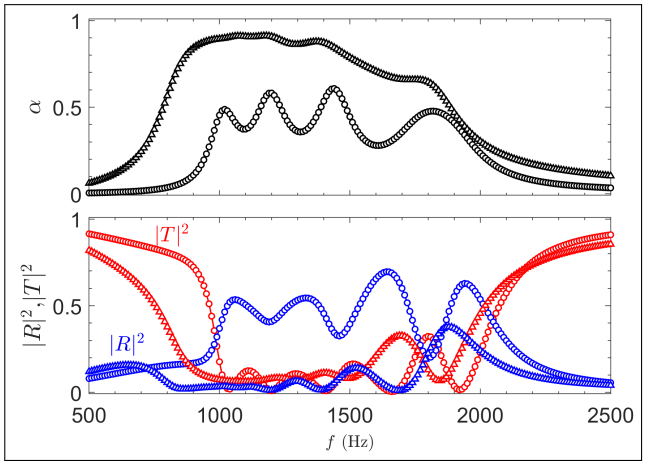

Figure 3. Sound absorption (top), reflection and transmission (bottom) coefficients obtained numerically with FEM model with 80 dB incident SPL. The coefficients for RTRA$_1$ and RTRA$_2$ are indicated by the triangle and circle markers. Red and blue curves represent reflection and transmission coefficients.

the geometric constraints. The four α peaks at approximately 1000, 1200, 1450, and 1820 Hz show the frequency cascade effect clearly, where the n^{th} and $n^{th}+1$ HR resonances accumulate [1], causing maxima between their individual resonances.

3.2 Nonlinear Regime Performance

Nonlinear regime α performance for both RTRAs is presented in Fig. 4. RTRA$_1$ (Fig. 4 [a]) shows a pronounced deterioration from the broadband $\alpha \approx 0.85$ at 80 dB to a broadband $\alpha \approx 0.75$ at 155 dB. This behaviour is mainly due to the neck's small widths, which increases flow resistivity at higher SPLs (i.e., reduced wall admittance in the neck). Notably, the first resonator ($f_r \approx 1720$ Hz) shows an increased α at 130 dB, which then deteriorates at 155 dB. This behaviour can be attributed mostly to the relatively large d_n^1 chosen by the GA, the perforation size is large enough to increase dissipation in the weakly nonlinear regime, but is too small to behave in the same way in the full nonlinear regime.

RTRA$_2$ (Fig. 4 [b]) exhibits significant α growth with incident SPL. The necks' larger widths (see Tab. 2) performed as intended and resulted in their flow resistivities having a weaker amplitude-dependency, resulting in increased dissipation and absorption as expected.

[1] All resonances accumulate in actuality.

4. CONCLUSIONS AND FURTHER WORK

This work investigated the design and optimisation of a conceptual rainbow-trapping resonator array for high-level sound absorption. The arrays' performance were analysed numerically. Results show that, depending on the intended usage, the absorbers are effective broadband sound absorbers in both linear and nonlinear acoustic regimes. The frequency-cascaded resonances of the arrays' resonators cause efficient targetted absorption of differing frequency waves along their lengths.

Further work will focus on realising a rainbow-trapping resonator array for small ducts, including realistic geometry (e.g., axial symmetry), comparisons with TMM results and experimental data.

ABSTRACT

Conventional acoustic black hole (ABH) periodic arrays have been extensively investigated for their effective vibration reduction performance. However, embedded ABHs are not suitable in many problems due to the loss of structural stiffness. That is avoided with additive ABHs, which have also proven to be very valuable in suppressing vibrations. In this paper, we explore their potential for noise reduction. An additive ABH plate is connected to a uniform base plate through the corners, and then coupled to a resonant cavity filled with air. In the first configuration, the base plate is facing the cavity, while in the second one, the ABH plate is oriented towards the cavity. It is shown that, in the first configuration, the vibrations in the base plate are significantly reduced and, consequently, the acoustic energy in the cavity decreases as well. For the second configuration, moreover, the coupling force at the fluid-structure interface diminishes, so that the acoustic energy in the cavity is even lower.

1. INTRODUCTION

Acoustic black holes (ABHs) are very efficient in reducing the vibration and noise from thin-walled structures. However, due to the thickness reduction, the structural stiffness may weaken, limiting its applicability in many situations. Recently, additive ABHs have become a promising method to avoid such limitation. The idea is to treat the ABH components as external vibration absorbers, as done in beams [1–3] and plates [4–6].

However, most existing studies on additive ABHs focus on vibration reduction in structures. In this paper, we explore their potential for suppressing noise within a closed sound cavity, which is interesting for applications such as high-speed trains and airplanes. We consider a periodic ABH plate, with the design proposed in [7], which can be easily connected to the host plate through the corners. When the composite plate is assembled, we can couple it to the resonant cavity. Here, we consider 2 cases: i) the host plate faces the cavity (Config. I) and ii) the ABH plate faces the cavity (Config. II). It will be shown how the acoustic energy in the cavity isreduced when an external force is applied to the plate.

2. MODELING

As shown in Fig. 1a, the composite plate in Fig. 1b is placed on the top surface of a rectangular cavity, with dimensions $L_x \times L_y \times L_x = 0.8 \times 0.6 \times 0.5$ m^3, filled with air with density $\rho_0 = 1.21$ kg/m^3 and sound speed $c_0 = 343$ m/s. The host plate (see Fig. 1b), is made of steel with Young modulus $E_p = 210$ GPa, density

$\rho_p = 7800$ kg/m^3, Poisson ratio $\nu_p = 0.3$, and a thickness of $h_p = 5$ mm. On the other hand, the geometry details of the additive ABH plate are depicted in Figs. 1c and 1d, where the thickness reduces from $h_a = 3$ mm to $h_c = 0.2$ mm following the power laws $h = \frac{h_a - h_c}{r_{abh}^m}|x|^m + h_c$ and $h = \frac{h_a - h_c}{r_{abh}^m}|y|^m + h_c$ in the x and y directions, respectively, where $r_{abh} = 9$ cm, and $m = 2$. The ABH plate is also made of steel. The yellow component in Figs. 1c and 1d is the damping layer, with thickness $h_d = 2$ mm, and half width $r_d = 4.5$ cm. The damping layer has Young modulus $E_d = 5$ GPa, density $\rho_d = 950$ kg/m^3, Poisson ratio $\nu_d = 0.33$, and loss factor $\eta_d = 0.5$.

To characterize the coupled system, we employ the Gaussian expansion method (GEM) [8, 9] to model the host plate, the ABH plate (plus the damping layer) and the resonant cavity, separately. This results in the uncoupled equation of motion,

$$(\boldsymbol{K} - \omega^2 \boldsymbol{M})\boldsymbol{A} = \boldsymbol{0}, \tag{1}$$

where $\boldsymbol{K} = \mathrm{diag}(\boldsymbol{K}_p, \boldsymbol{K}_a, \boldsymbol{K}_c)$ and $\boldsymbol{M} = \mathrm{diag}(\boldsymbol{M}_p, \boldsymbol{M}_a, \boldsymbol{M}_c)$ are respectively the stiffness and mass matrices, and $\boldsymbol{A}$ is the coefficent vector of Gaussian functions.

Next we consider the coupling between substructures, and discretize the constraints for $\boldsymbol{A}$ also with Gaussian functions. Finding the the nullspace basis of the constraint matrix we get $\boldsymbol{A} = \boldsymbol{Z}\boldsymbol{k}$, where $\boldsymbol{Z}$ contains the basis vectors and $\boldsymbol{k}$ is the superposition coefficient vector [10]. Taking this relation back to Eqn. (1) results in the following coupled equation of motion,

$$(\boldsymbol{Z}^\top \boldsymbol{K} \boldsymbol{Z} - \omega^2 \boldsymbol{Z}^\top \boldsymbol{M} \boldsymbol{Z})\boldsymbol{k} = \boldsymbol{0}. \tag{2}$$

To obtain Eqs. Eqn. (1) and Eqn. (1) we have used a displacement formulation to describe all problem unknowns. Details can be found in [9].

3. RESULTS

We apply a unitary force on the plate and compute the total acoustic energy of the cavity, $E_c = \frac{1}{2\rho_0\omega^2}\int \nabla^2 p \mathrm{d}V + \frac{1}{2\rho_0 c_0^2}\int p^2 \mathrm{d}V$, E_c (dB)$= 10\lg(E_c \times 10^{12})$. To better inspect the results, we have converted the spectrum into 1/3 octave bands, see Fig. 2. It can be observed that when the cavity is coupled to the bare plate (i.e., the host plate alone), the cavity energy remains the highest above 150 Hz. When the ABH plate is placed on the top of the host one (Config. I), the sound energy is substantially reduced over the entire frequency range of interest, particularly at high frequencies. The reason for that is that the vibration of the host plate is transferred to the ABH plate where it is efficiently dissipated by the damping layer, resulting in less energy transmitted into the cavity from the

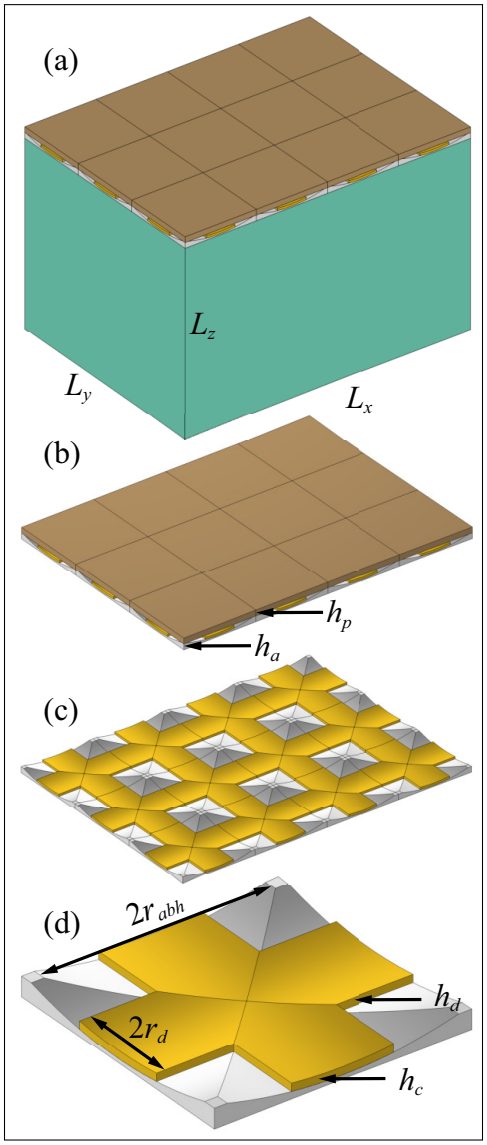

Figure 1. Geometry of the model. (a) The coupled system. (b) The composite plate. (c) The ABH plate with a damping layer (yellow region). (d) A single ABH cell.

host plate. If we change the situation and let the ABH plate face the cavity (Config. II) it is observed that the energy within the cavity is further reduced for $f > 200$ Hz. This is because the radiation efficiency of the ABH plate is lower than that of the uniform plate [11], resulting in a smaller coupling coefficient of the fluid-structure interaction [12]. .

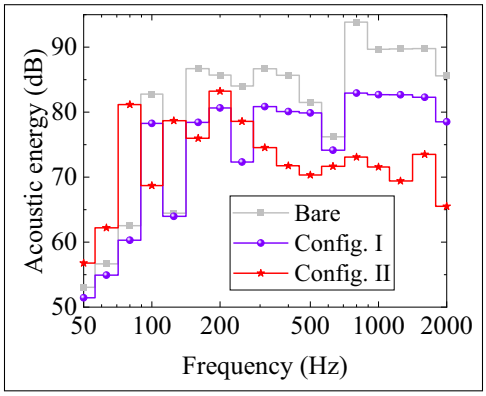

Figure 2. Comparison of the acoustic energy of the cavity of the bare host plate, and the composite plate. Config. I: The host plate is facing the cavity. Config. II: the ABH plate is facing the cavity.

4. CONCLUSIONS

In this paper, we have investigated the potential of additive acoustic black holes (ABHs) to reduce sound energy in resonant cavities. To this end, a semi-analytical model has been developed, incorporating coupling conditions using the nullspace method. Two configurations have been compared. When the uniform host plate faces the cavity, noise is efficiently suppressed due to vibration damping in the ABH plate. Alternatively, when the ABH plate faces the cavity, the sound energy inside the cavity is further reduced because the radiation efficiency decreases, leading to a lower coupling coefficient.

ABSTRACT

Reducing broadband noise in enclosed spaces, such as rooms or the cabins of cars and airplanes, is a challenge for acoustic comfort. In recent years, sonic black holes (SBHs) have been investigated to achieve anechoic terminations in ducts, but their potential for room acoustics remains unexplored. A conventional SBH consists of a wave-guide with concentric inner rings of decreasing radius separated by cavities that are partially filled with absorbing material. This arrangement slows down and traps incident sound waves dissipating their energy, which results in very little reflection beyond the cut-on frequency of the SBH. In this work we study the acoustics of a resonant cavity with an array of SBHs coupled to one of its walls. The patch transfer function (PTF) method is applied to couple the cavity and the set of SBHs. For the former, an analytical modal model is used, while the response of the SBHs is characterized by means of the finite element method (FEM). This substructuring approach provides a low-cost numerical method to investigate how SBH design parameters influence the acoustic response of the cavity.

1. INTRODUCTION

In connection with the need to develop engineering solutions to control vibrations and noise, research in acoustic black holes (ABHs) has been increasing in recent years. In theory, these devices are capable of slowing down impinging elastic waves to a singularity point where the propagation and the reflection become impossible, delivering perfect energy focusing [1]. Two main classes of ABHs are investigated: the vibrational black holes (VBHs), which absorb mechanical vibrations [2, 3], and the sonic black holes (SBHs), that are intended to dissipate sound waves and which were first proposed in [4]. While VBHs consist of thin beams and plates with decreasing thickness profile indentations that can capture and dissipate bending waves, their acoustic counterpart, the SBHs, achieve the black hole effect by means of a waveguide whose inner radius decreases according to a power law profile and whose wall admittance has a specific spatial variation [5]. If a perfectly continuous SBH with a null final radius was possible, perfect absorption could be attained [4, 5].

The most common realization of an SBH is made of a homogeneous wave-guide equipped with various concentric rings of decreasing inner radii that follow the power profile and are separated by cavities. Manufacturing con-

straints such as the end truncation, number and dimensions of rings and cavities and damping mechanisms will limit the performance of the SBH (see e.g., [6–8]). To date, most works have been devoted to better characterize the SBH as a single system by using different numerical approaches [7, 9, 10] and to enhance its performance at low frequencies using microperforated panels for the cavities [11, 12] or periodic SBHs [13, 14]. Efforts have been also made to optimize the SBH design [15, 16] for a better performance, to find alternative approaches based on metafluid analogies [17, 18] and slow-down lattice absorbers [19], or to design SBH inspired mufflers [20].

However, none of the above works have considered coupling a set of SBHs to a cavity, which could be important for many industrial applications. That is the goal of this paper. Given that aiming at a full finite element method (FEM) simulation of the problem would be computationally very costly, it is herein proposed to resort to a substructuring technique. In this context, the so-called patch transfer function (PTF) is used, which has proven to be very effective in characterizing vibroacoustic systems [21–23]. This method offers a viable option to couple linear subsystems through transfer functions evaluated over patch surfaces at a very low computational cost. We will use the PTF to assess the acoustics of a homogeneous cavity when we couple a set of SBHs to it. The cavity and SBHs will be characterized separately and coupled using continuity conditions in the framework of the PTF [21]. The coupled model will be validated against a full FEM simulation of the complete model.

The main technical aspects of the modelling strategy of the proposed approach are presented in Section 2. The validation of the method is provided in Section 3. Conclusions and future research lines are drawn in Section 4.

2. PTF MODELLING PROCEDURE

2.1 PTF approach to describe the coupling between the cavity and the SBHs

As shown in Fig. 1, let us consider a rectangular cavity with dimensions $L_x \times L_y \times L_z$ coupled to N identical SBHs on face $y = 0$. For simplicity, it is assumed that there is no direct interaction between the SBHs. A monopole source is located inside the cavity at point S of coordinates (x_S, y_S, z_S). Our goal is to predict the mean quadratic pressure inside the cavity taking into account the effect of the SBHs. To this end, we use the PTF substructuring approach to partition the problem into two subsystems. The cavity constitutes one single subsystem whereas the N SBHs constitute the other one. There are N coupling surfaces between the cavity and the SBHs which compose the so-called "patches" in the PTF method (see Fig. 2). The following two conditions must be satisfied:

- the patches must be smaller than than half the acoustic wavelength to respect the PTF criterion, i.e., the frequencies of interest must be lower than a critical frequency corresponding to an acoustic wavelength equal to twice the size of the patch;
- the area of the patches must correspond to that of the opening of the SBHs, but their shapes do not need to be the same. For instance, the opening of the SBH may be in the form of a disk while the patch of the cavity in front of it may be square for convenience. It was shown in the past that this approximation is valid if the previous condition is respected.

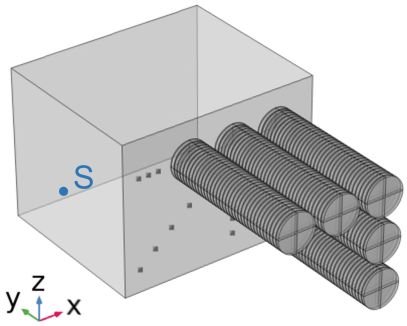

Figure 1. General case of a cavity coupled to N SBHs.

For acoustic domains, the PTFs can be defined as the acoustic impedance of each patch, that is, the ratio between its mean pressure and its mean velocity. The PTFs should be estimated for each subsystem separately (cavity and set of SBHs). For an acoustic subsystem m, the PTF between patches i and j corresponds to a cross-impedance and is defined by,

$$Z_{ij}^m = \frac{\langle p_j^m \rangle}{\langle u_i^m \rangle}, \tag{1}$$

where $\langle p_j^m \rangle$ is the mean pressure on patch j when a mean normal velocity is imposed on patch i and all other patches have zero normal velocity. For the sake of brevity, the

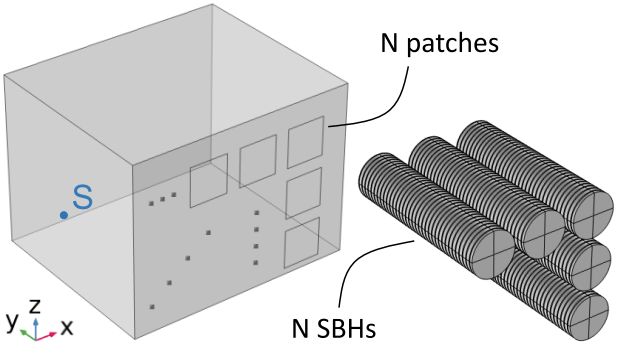

Figure 2. PTF sub-structuring of a cavity coupled to N SBHs.

brackets $\langle \quad \rangle$ will be hereby suppressed, and it is understood that all PTFs are defined from mean values.

Similarly, to account for an arbitrary receiver point R, the patch-to-point impedance is defined as

$$z_{Ri}^{m} = \frac{p\left(R\right)}{u_i^m}, \tag{2}$$

where $p\left(R\right)$ is the pressure at R when a mean normal velocity is imposed on patch i. Finally, the external source (i.e. the monopole at S in our case) is characterized by the patch blocked pressure p_{jS}^{m}, corresponding to the mean pressure on the patch j induced by the source when all other patches are rigid (null normal velocity), i.e.,

$$Z_{jS}^{m} = p_{jS}^{m}. \tag{3}$$

Once all the PTFs of interest for both subsystems have been calculated by any suitable method, we couple them to calculate the total system response by applying continuity conditions on the patches. In the following, we denote by $ss1$ the subsystem 1 (cavity) and by $ss2$ the subsystem 2 (N SBHs). Looking at Fig. 2, it is clear that the mean pressure in each patch will be the same for both the cavity and the SBHs, while the surface normal velocity will have opposite signs when pointing toward the cavity or toward the SBHs. Pressure and velocity continuity at each patch implies,

$$\begin{cases} p_j^{ss1} = p_j^{ss2} & \forall j = 1, ..., N \\ u_j^{ss1} = -u_j^{ss2} & \forall j = 1, ..., N. \end{cases} \tag{4}$$

The superposition principle allows one to compute the pressure at an arbitrary patch j of subsystem 1 as,

$$p_j^{ss1} = p_{jS}^{ss1} + \sum_{i=1}^{N} Z_{ij}^{ss1} u_i^{ss1} \quad \forall j = 1, ..., N, \tag{5}$$

and for subsystem 2 we have,

$$p_j^{ss2} = \sum_{i=1}^{N} Z_{ij}^{ss2} u_i^{ss2} \quad \forall j = 1, ..., N. \tag{6}$$

Applying the continuity condition of Eqn. 4 to Eqns. 5 and 6, we are left with the following matrix system that allows us to compute the coupling velocities in the patches from the impedances of subsystems 1 and 2 and the external pressure,

$$\left[u^{ss2}\right] = \left[Z^{ss1} + Z^{ss2}\right]^{-1} \left[p_S^{ss1}\right]. \tag{7}$$

2.2 Estimation of the PTFs of the cavity using the modal expansion method

The PTF method presents a substructuring strategy that does not depend on how the susbsytem impedances are calculated. Analytical, numerical or experimental approaches, or a mix of them, can be used [21]. In the present study, a modal expansion will be used for the cavity as it is rectangular and homogeneous.

The acoustic pressure inside the cavity admits a standard modal expansion,

$$p\left(x, y, z, \omega\right) = \sum_{q,r,s} \Gamma_{qrs}\left(\omega\right) \phi_{qrs}\left(x, y, z\right), \tag{8}$$

with eigenmodes,

$$\phi_{qrs}\left(x, y, z\right) = \cos\left(\frac{q\pi x}{L_x}\right) \cos\left(\frac{r\pi y}{L_y}\right) \cos\left(\frac{s\pi z}{L_z}\right), \tag{9}$$

and eigenfrequencies,

$$\omega_{qrs} = c_0 \sqrt{\left(\frac{q\pi}{L_x}\right)^2 + \left(\frac{r\pi}{L_y}\right)^2 + \left(\frac{s\pi}{L_z}\right)^2}. \tag{10}$$

The expansion coefficients $\Gamma_{qrs}\left(\omega\right)$ in Eqn. (8) are given by

$$\Gamma_{qrs} = \frac{\mathrm{j}\omega \int_{S_i} \phi_{qrs} dS}{\mu_{qrs}\left(-\omega^2 + \mathrm{j}\omega\eta_c\omega_{qrs} + \omega_{qrs}^2\right)}, \qquad \mu_{qrs} = \frac{L_x L_y L_z}{8\varepsilon_{qrs}\rho_0 c_0^2}. \tag{11}$$

In the above Equations c_0 is the speed of sound, $\mathrm{j} = \sqrt{-1}$, η_c is the modal damping factor and $\varepsilon_{qrs} = \left(\frac{1}{2}\right)^{\Xi}$, being Ξ the number of indices of the mode that equal zero.

From the modal expansion, we can compute the patch-to-patch impedance in Eqn. 1, needed to characterize the cavity (subsystem 1), as in Eqn. 12 below. Modal expressions from Eqns. 2 and 3 can be derived in a similar way,

$$Z_{ij}^{ss1} = -\sum_{q,r,s} \frac{\mathrm{j}\omega \int_{S_i} \phi_{qrs} dS \frac{1}{S_j} \int_{S_j} \phi_{qrs} dS}{\mu_{qrs}\left(-\omega^2 + \mathrm{j}\omega\eta_c\omega_{qrs} + \omega_{qrs}^2\right)}. \quad (12)$$

Note that, to ensure a reliable description of the cavity dynamics and considering that one patch is dedicated to each SBH, the number of vibration modes considered must be such that, for each propagation direction $q \geq N\frac{L_x}{L_x^{SBH}}$ and $r \geq N\frac{L_y}{L_y^{SBH}}$ [21].

2.3 Estimation of the SBH impedance using a FEM model

The SBH has been characterized by means of a FEM model to solve the wave equation using the commercial software COMSOL, see Fig. 3.

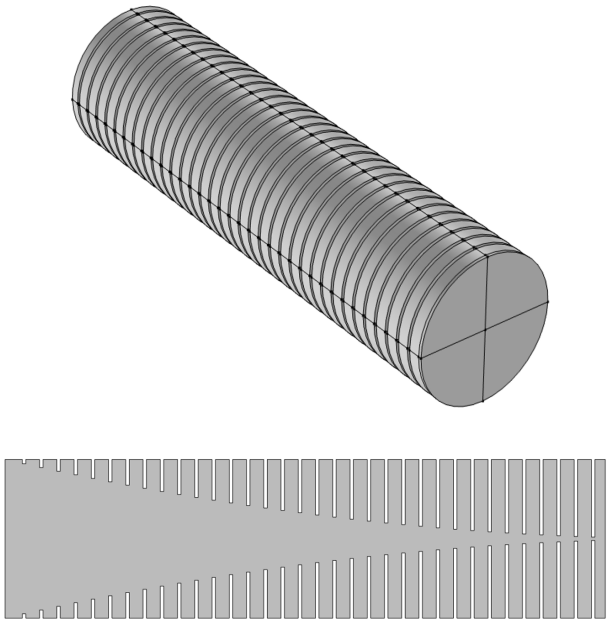

Figure 3. SBH model built in COMSOL: 3D and mid-plane cut view.

Given that we have neglected any interaction between the SBHs the impedance matrix of subsystem 2, Z^{ss2}, is diagonal. Furthermore, all the values on the diagonal will be equal to the impedance of a single SBH, Z_{SBH}, since we have considered all of them to be identical. Z_{SBH} is defined as the mean pressure on the SBH opening surface over the mean normal velocity prescribed at the opening. A unitary harmonic velocity is imposed at the entrance of the SBH FEM model, while the rings and external waveguide that comprises the SBH are considered rigid. By means of a direct FEM computation in the frequency domain, we obtain the pressure in the SBH aperture and get the impedance as,

$$Z_{SBH} = \frac{p_{SBH}}{u_{SBH}}. \quad (13)$$

Since the SBH has a retarding effect on the waves traveling through its interior, causing their effective wavelength λ_{eff} to diminish as the SBH termination is approached, a conservative criterion was established for the maximum mesh element size to be $h_{\max} \leq \lambda_{eff}/12$, where λ_{eff} is the minimum wavelength achieved inside the SBH. The SBH domain was meshed using tetrahedral elements.

2.4 Coupling of the subsystems and computation of the mean quadratic pressure

Having obtained the impedance matrices for subsystems 1 and 2 in the previous sections, we can now compute the mean velocities at the patches from Eqn. 7. Next, it is straightforward to calculate the acoustic pressure at any receiver point inside the cavity, $R \in \Omega_c$, as

$$p(R) = p_S^{ss1}(R) + \sum_{i=1}^{N} z_{Ri}^{ss1} u_i. \quad (14)$$

The mean square sound pressure inside the cavity is finally obtained by averaging over the cavity volume,

$$\langle p^2 \rangle^{ss1} = \frac{1}{\Omega_c} \int_{\Omega_c} p(R)\,\bar{p}(R)\ \mathrm{d}\Omega_c, \quad (15)$$

with $\Omega_c = L_x L_y L_z$ and the overbar denoting the complex conjugate.

3. VALIDATION OF THE PTF STRATEGY AGAINST FEM

To validate the proposed PTF method for the current cavity plus SBH problem, a first case study was conducted.

Fig. 4 shows the tested case. This comprises an air cavity of dimensions $0.24 \times 0.20 \times 0.18$ m^3 and a monopole source located at $(0.034,\ 0.16,\ 0.36)$ m with volume velocity 10^{-6} m^3/s. The air has density $\rho_0 = 1.297$ kg/m^3, sound speed $c_0 = 340$ m/s and damping $\eta_{ss1} = 0.01$. The two SBHs in the model are identical and have a quadratic profile with entrance radius $R_0 = 23$ mm, length $L = 0.175$ m, truncation $l = 1$ mm, 35 rings of thickness $h_r = 1$ mm and minimum radius at truncation $r_l = 0.5$ mm. Viscothermal losses inside the SBHs are accounted for by means of a constant damping factor $\eta_{ss2} = 0.05$. The two SBHs are positioned on the plane xz at coordinates $a = (0.192,\ 0.135)$ m and $b = (0.048,\ 0.045)$ m. The cut-on frequency of a quadratic SBH is given by $f_{\text{cut-on}} = c_0/\pi L \sim 618$ Hz [24] while the cut-off frequency of the duct, beyond which non-planar waves propagate, is extremely high in this case given the small radius of the duct $f = 1.84 c_0/R_0 \sim 27.4 \times 10^3$. Results will be presented for the frequency range between 600 and 2000 Hz.

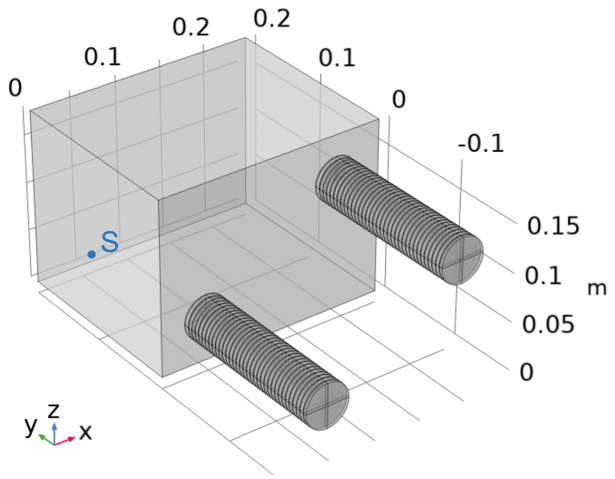

Figure 4. Nominal system to validate the proposed method.

From the SBH impedance obtained in Section 2.3, we can compute the reflection coefficient, R,

$$\mathrm{R} = \frac{Z_{SBH} - Z_0}{Z_{SBH} + Z_0}, \tag{16}$$

where $Z_0 = \rho_0 c_0$ is the characteristic impedance of air. The absorption coefficient, α, is given by,

$$\alpha = 1 - \left|\mathrm{R}^2\right|, \tag{17}$$

and has been represented in Fig. 5. As seen, its values are very close to 1 for the analyzed frequency range.

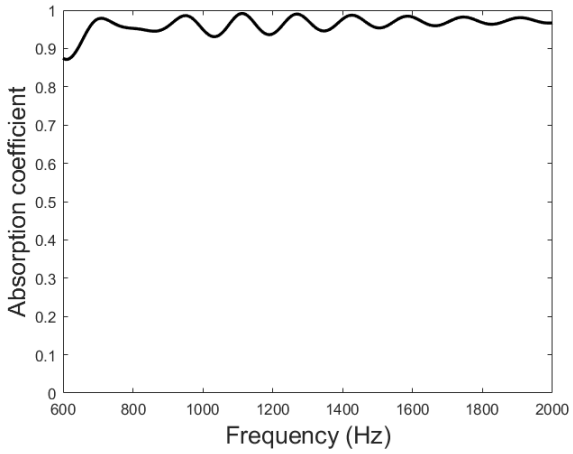

Figure 5. Absorption coefficient of the SBH.

Finally, the complete coupled system (subsystem 1 + subsystem 2) has been modelled using a FEM model and is taken as a reference for comparison with the proposed PTF substructuring methodology. In Fig. 6, we present the mean square sound pressure of the cavity (see Eqn. (15)) without SBHs (black line), with SBHs using the complete FEM model (dashed blue line) and with SBHs using the PTF approach (dashed orange line). The influence of the SBHs on the cavity is very significant for all modes, as it is clearly observed. Surprisingly, for higher frequencies, where the coefficient α remains very high, the influence of the SBHs seems to be less important than at lower frequencies. This is attributed to the fact that the SBHs are located close to the nodal planes of the involved modes.

As for the comparison between the proposed PTF method and the FEM complete model, it is seen that the mean error over the analyzed range is 0.58 dB and that the maximum observed error is $\sim$ 3 dB at 1400 Hz. The FEM model has 345579 elements and took 105 minutes to compute, while the PTF, coded and simulated in Matlab, took only 0.5 seconds.

4. CONCLUSIONS

In this work, a numerical procedure based on patch transfer functions (PTFs) was presented to calculate the response of a closed cavity coupled to sonic black holes (SBHs) when an inner sound source is excited. The cavity

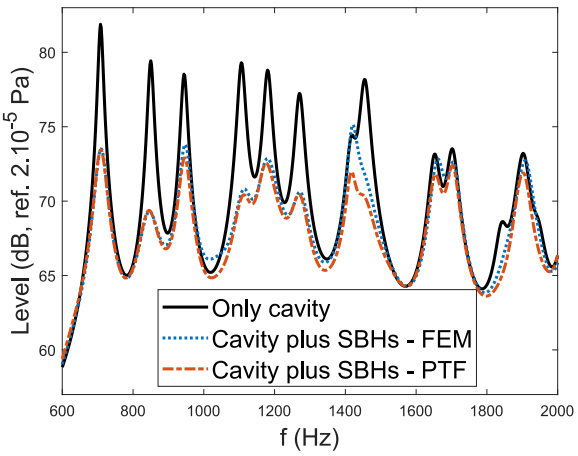

Figure 6. Mean quadratic pressure inside the cavity - Validation.

plus SBHs system was divided into a cavity subdomain and an SBHs subdomain. The former was characterized by means of a modal expansion while a FEM model was used for the SBHs. Also a FEM model of the complete system was built for comparison. The comparison between the latter and the proposed PTF approach shows a very good agreement, and that the PTF requires much less calculation time.

Given the efficiency of the presented approach, in future work it will be easy to test different and optimal distributions of SBHs in cavity walls, as well as to improve their modelling for better characterization. Different types of SBHs, such as those cited in the introduction with, for example, improved behavior at low frequency, could also be easily tested in the proposed framework.

ABSTRACT

This study presents an ultra-thin and ultra-lightweight meta-panel for broadband noise insulation. The meta-panel consists of a multi-scale lattice structure sandwiched between two thin membranes, engineered to induce negative effective material properties for high sound transmission loss (STL) across a wide frequency range. A theoretical model is developed for fast and accurate prediction of the meta-panel's STL by integrating the effective impedances of membranes under elastic boundary restraints and wave propagation through the multi-scale lattice structure. This model facilitates a systematic inverse design process to maximize STL over the 100-1500 Hz range while simultaneously minimizing the meta-panel's thickness and weight. The meta-panel is fabricated via 3D printing, and its insulation performance is experimentally validated through impedance tube tests. Experimental results demonstrate an STL improvement of up to 30 dB compared to a same-weight plate, highlighting the meta-panel's superior weight-to-performance efficiency.

Keywords: *acoustic metamaterial, sound insulation, negative effective material properties, multi-scale lattice structure, meta-panel*

1. INTRODUCTION

The development of ultra-thin and ultra-lightweight soundproofing solutions for low-frequency broadband noise remains a important challenge across a range of industries, including transportation, home appliances, industrial machinery, and architectural structures. Conventional materials such as rubber sheets and gypsum boards are still widely used for noise insulation, but their effectiveness is limited by the mass law [1], which requires increased weight to achieve adequate sound insulation. To address this limitation, this study presents an ultra-thin and ultra-lightweight meta-panel designed to achieve low-frequency broadband noise insulation, by inducing negative effective material properties. The proposed meta-panel incorporates a multi-scale lattice structure sandwiched between two thin membranes, utilizing hierarchical design concepts to enhance broadband sound insulation. A theoretical model is developed to provide fast and accurate predictions of the meta-panel's sound transmission loss (STL), along with a systematic design approach aimed at achieving high STL performance over a broad frequency range of 100–1500 Hz. Finally, the sound insulation performance of the meta-panel is validated through fabrication and experimental testing.

2. THEORY AND EXPERIMENTS

The propagation behavior of sound waves is governed by the acoustic properties of a medium—mass density and bulk modulus. In conventional materials, both of those parameters are inherently positive. However, through the use of acoustic metamaterials, it is possible to engineer either the effective mass density or the effective bulk modulus to take on negative values, enabling significantly

enhanced sound insulation performance compared to traditional acoustic materials [2–5].

When an acoustic metamaterial exhibits a negative effective mass density ($\rho_{eff} < 0$) or a negative effective bulk modulus ($B_{eff} < 0$), the resulting speed of sound c and wavenumber k in the medium are given by:

$$c = \sqrt{\frac{B_{eff}}{\rho_{eff}}}, \quad (1)$$

$$k = \frac{\omega}{c} = \omega\sqrt{\frac{\rho_{eff}}{B_{eff}}}, \quad (2)$$

where the condition is:

$$\frac{\rho_{eff}}{B_{eff}} < 0. \quad (3)$$

Under this condition, the wavenumber k becomes purely imaginary (i.e., $k = i\alpha$ with $\alpha < 0$), leading to an exponential decay of the propagation energy E along the wave path x:

$$E \propto e^{-\alpha x}. \quad (4)$$

This relationship implies that as sound waves propagate through the medium, their energy diminishes exponentially, thereby enabling highly efficient sound insulation using thin and lightweight structures.

Expanding upon the theoretical foundation, this study presents a comprehensive methodology for both predicting and enhancing the sound insulation performance of the proposed meta-panel. To this end, a theoretical model is developed that rapidly and accurately predicts the STL by accounting for the effective acoustic impedance of the membranes and the wave propagation characteristics within the multi-scale lattice channels. Based on this model, a design framework is established to optimize STL performance across a wide frequency range of 100–1500 Hz, all while minimizing structural thickness and overall mass.

Compared to a previous design benchmark [6], the newly optimized meta-panel achieves a 64% reduction in thickness and a 26% decrease in weight. The meta-panel was fabricated via 3D printing, and its acoustic performance was validated experimentally using impedance tube testing. The results revealed that the meta-panel outperformed a reference plate with the same mass by approximately 30 dB in STL. Particularly in the low-frequency range of 100–500 Hz, the panel exhibited high broadband insulation capabilities. Within this range, its performance matched that of a 9 mm thick steel plate, despite weighing only 1/40 as much—demonstrating outstanding insulation performance relative to its weight.

3. CONCLUSION

This study presents an ultra-thin and ultra-lightweight meta-panel designed for broadband sound insulation in the low-frequency regime. The meta-panel features a multi-scale lattice structure sandwiched between two thin membranes, and it is tailored to exhibit negative effective material properties, enabling high STL across a wide frequency range of 100–1500 Hz. A theoretical model was formulated to predict STL, serving as the foundation for a systematic inverse design strategy aimed at maximizing STL while minimizing both thickness and mass. The meta-panel was fabricated using 3D printing techniques, and its sound insulation performance was experimentally evaluated through impedance tube measurements. Experimental results showed an STL improvement of approximately 30 dB compared to a plate of equal weight. These findings confirm that the proposed meta-panel delivers outstanding sound insulation despite its compact and lightweight form factor. Based on its excellent weight-to-performance ratio, the proposed meta-panel offers strong potential as a lightweight soundproofing solution for diverse applications, including electric vehicles, urban air mobility (UAM), drones, consumer electronics, and architectural acoustics.

ABSTRACT

The mitigation of noise propagated along flow path while allowing airflow is crucial in mechanical systems including fluid-guiding structures. While metamaterials are being actively researched to overcome the limitations of conventional materials used for duct noise reduction, most studies have only focused on ducts with uniform cross-sections, limiting their range of application. In this study, we propose a ventilated acoustic metamaterial, called a metaliner, for noise reduction in a duct with non-uniform cross-sectional areas. The design considers the effects of variations in duct cross-sectional areas on noise reduction performance and the influence of locally varying velocity profiles along the direction of flow. In order to achieve this, our impedance model for effective impedance of the metaliner is established to incorporate locally different friction velocities. Using this theoretical model, we design metaliners that achieve high insertion loss and experimentally demonstrate their effectiveness at reducing noise in ducts with non-uniform cross-sections under the presence of flow.

1. INTRODUCTION

Noise mitigation within ducts is crucial in many mechanical systems, including vehicle ventilation systems, building HVAC systems, and power plants. Conventional solutions, such as acoustic louvers [1] and mufflers [2], face limitations due to their bulky structures. Recently, acoustic metamaterials [3-6] have attracted significant attention due to their potential in noise control applications. However, existing studies mainly focused on ducts with constant cross sections, limiting their practical applicability. To address this, we propose an acoustic metaliner, a type of ventilated acoustic metamaterial, specifically designed to achieve high noise attenuation performance in ducts with non-uniform cross sections and validate its performance through experimental investigations.

2. THEORETICAL DEVELOPMENT AND EXPERIMENTAL VALIDATION

2.1 Theoretical development

The acoustic metaliner presented in this study features a thin structure relative to the target acoustic wavelength and is installed underneath the duct wall without obstructing the airflow as shown in Fig. 1. The primary challenge was accommodating the variation of cross-sectional area and associated locally varying flow velocity profiles along the duct length. To this end, a friction velocity-based analytical approach was formulated, enabling precise prediction of the metaliner's effective acoustic impedance under flow conditions in ducts with non-uniform cross-sections.

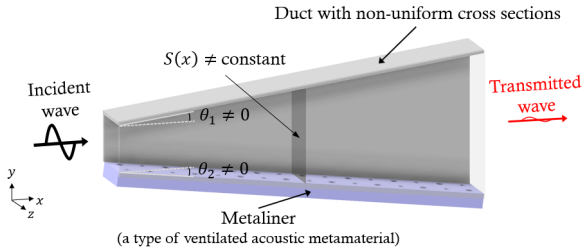

Figure 1. Schematic of an acoustic metaliner and a duct with non-uniform cross sections.

Using the developed impedance model, the metaliner was designed for a target frequency of 900 Hz. The designed metaliner exhibited an insertion loss of 45 dB at the target frequency for an inlet flow velocity (U_0) of 34 m/s, with a length of 408 mm and a thickness of λ/19. This result demonstrates a significant enhancement, exhibiting a 31 dB higher insertion loss compared to the metaliner designed using the methodology proposed in [6], which is suitable for ducts with constant cross sections.

2.2 Experimental validation

An experimental device, the Flow Grazing Incidence Tube (FGIT), was constructed to evaluate the metaliner's noise reduction performance under flow conditions in ducts with non-uniform cross sections. The designed metaliner was fabricated using 3D printing. Experimental measurement result is shown in Fig. 2. The measured insertion loss aligned with theoretical predictions, demonstrating the metaliner's effectiveness in reducing noise in ducts with non-uniform cross sections.

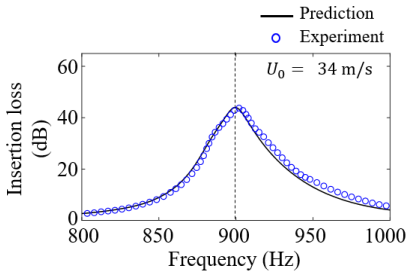

Figure 2. Insertion loss spectrum the designed metaliner. The blue circle indicates the measured results. For comparison, the predicted results are shown as the black solid line.

3. CONCLUSIONS

In summary, we demonstrated that the metaliner effectively reduces noise in ducts with non-uniform cross-sectional areas. To account for the effects of cross section's variation and locally varying flow velocity profiles, a theoretical model for the metaliner's impedance was established in terms of friction velocity. This model was employed to design the metaliner, which was subsequently fabricated using 3D printing. Experimental evaluations validated the impedance model's accuracy and showed the metaliner's effectiveness for noise reduction in ducts characterized by non-uniform cross sections.

DESIGN OF A METAMATERIAL PLATE WITH ACOUSTIC BLACK HOLE ABSORBERS AND ITS APPLICATION TO FLOATING RAFT SYSTEM

Siting Hao[1] **Haiqin Li**[1*] **Qian Ding**[1]
[1] Tianjin Key Laboratory of Nonlinear Dynamics and Control, Department of Mechanics, Tianjin University, China

ABSTRACT

Acoustic metamaterials have demonstrated great application potential in the fields of vibration and noise control. To suppress the broadband and low-frequency vibration in practical engineering, a novel design of the microunit is proposed, which uses a beam-type acoustic black hole (ABH) absorber as the resonator. By the coupling effects of ABH and the local resonance mechanism, a vibration attenuation band with relative bandwidth up to 0.93 can be generated. Furthermore, the microunit is used as the core layer embedded into a honeycomb raft plate, which is applied to the floating raft system. Due to the sandwich design, the stiffness of the novel metamaterial raft is improved. By analyzing the output vibration response of the foundation and the vibration level difference of the whole system, it shows a broadband and better vibration isolation performance, compared with the normal raft. In all, this study may provide a new idea for the design and application of vibration isolation meta-devices.

Keywords: acoustic metamaterial, acoustic black hole, floating raft system, vibration isolation.

1. INTRODUCTION

After the concept of acoustic black hole (ABH) was proposed by Mironov [1], the ABH-based structure has been studied extensively as a passive vibration control method [2]. Recent years, the idea of employing ABH-type structures as dynamic vibration absorbers (DVAs) has been emerged, proposed by Zhou and Cheng [3] first in the form of a unilateral ABH-DVA. Subsequently, various designs such as tree-shaped ABH-DVA [4] and two-dimensional circular ABH-DVA [5] are presented. Utilizing dynamic interaction with the host structure and damping enhancement as a result of ABH-specific energy trapping, resonant peaks can be reduced systematically over a broad frequency range, while the stiffness and strength of the host structure retain intact. Moreover, researchers introduce ABH-DVA into the concept of acoustic metamaterials, and demonstrate burgeoning potential in engineering vibration and noise reduction [6, 7]. For instance, the model and the corresponding calculation method of a host beam with distributed ABH-DVAs are proposed, achieving significant evanescent waves in a very broad frequency range [8, 9]. In research [10], discontinuous broadband vibration attenuation on a meta-beam is realized by using mistuning ABH-DVAs. However, studies for two-dimensional acoustic metamaterials with ABH-DVAs are not enough, and there is also a need for low-frequency vibration suppression.

Floating raft system is a typical vibration isolation technology used in ships and submarines, owing to its ability to inhibit the transmission of vibration generated by multiple equipment to the hull [11]. To further improve the vibration isolation performance of the system, various configurations have been added such as passive or active DVAs [12, 13], quasi-zero-stiffness (QZS) devices [14] and nonlinear energy sink (NES) cells [15]. However, the above studies either need complex structures or neglect the elastic deformation of the raft and foundation in modelling. Thus, some designs based on acoustic metamaterials have been proposed and focus on the substructures themselves in this coupled system. For example, a periodic structure is used to replace the isolators to suppress the disadvantageous effects

[*] ***Corresponding author***: lihaiqin1992@tju.edu.cn
Copyright: *©2025 Siting Hao et al. This is an open-access article distributed under the terms of the Creative Commons Attribution 3.0 Unported License, which permits unrestricted use, distribution, and reproduction in any medium, provided the original author and source are credited.*

of substructure resonances on vibration and noise radiation [16], while this may result in reduced stiffness which affects the practicability. Recent research designs a sandwich-plate-type raft with graded resonators, taking the advantage of light weight, high bending strength and high stiffness of sandwich structures [17]. Nevertheless, too much resonators may also add unnecessary load. Motivated by these studies, this paper aims to propose a light-weight sandwich raft plate to achieve low-frequency and broadband vibration isolation.

The rest of the paper is organized as follows. Section 2 presents the model of the metamaterial design based on ABH-DVA. Section 3 introduces both the numerical and experimental results of the vibration band gap, and the effect of ABH is analyzed. Section 4 illustrates the application of the proposed structure to the design of a sandwich raft, the static stiffness of which and the vibration isolation performance of the entire floating raft system are investigated. Finally, conclusions are drawn in Section 5.

2. MODELLING AND DESIGN

As depicted in Fig. 1, the proposed microunit is comprised of three parts: the inner ABH beam (the side view is shown in Fig. 1(c)), the outer frame, and the connectors in-between them. The whole structure is named as FC-ABH in the followings. The ABH beam is made of TPU (Thermoplastic Polyurethane), with width b (in the x direction) and assumed to undergo bending vibration in the z direction. Its layout in the y-z plane, see in Fig. 1(c), is symmetric about the horizontal line $y = 0$, as well as the mid-surface $z = 0$. As such, the ABH beam contains a plateau region of length $2l_0$ with uniform thickness and two thickness decreasing regions of length l_{ABH}, such that the overall thickness profile $h(y)$, as noted in Fig. 1(c), satisfying Eq. (1), where h_{min} and h_{uni} are respectively half of the thickness of the uniform region and the ABH terminal, and ε is the smooth parameter, defined by Eqn. (2).

$$h(y)=\begin{cases} 2h_{uni} & 0\le|y|\le l_0 \\ 2\left[h_{min}+\varepsilon\left(l_{ABH}+l_0-|y|^2\right)\right] & l_0\le|y|\le l_{ABH}+l_0 \end{cases} \quad (1)$$

$$\varepsilon=\frac{h_{uni}-h_{min}}{l_{ABH}^2} \quad (2)$$

Such an ABH beam is then embedded into a square frame through four identical connectors, each of whom is with thickness δ and with segment lengths l_1 (for segment ①), l_2 (for segment ②), and $(a\text{-}2\Delta a\text{-}b\text{-}2l_1\text{-}2\delta)/2$ (for segment ③). Both the frame and connectors are made of epoxy. All the geometric and material parameters are list in Tab. 1.

Table 1. Structural parameters of FC-ABH. E_1, ρ_1, ν_1, E_2, ρ_2, ν_2 are elastic modulus, density and Poisson's ratio of epoxy and TPU respectively.

Parameters	Value[unit]	Parameters	Value[unit]
a	0.12[m]	h_{min}	0.5[mm]
Δa	0.01[m]	h_{uni}	0.002[m]
l_1	0.018[m]	l_{ABH}	0.042[m]
l_2	0.025[m]	l_0	0.005[m]
δ	0.002[m]	ε	0.85[m^{-1}]
t	0.003[m]	b	0.016[m]
E_1	2.6[GPa]	E_2	61[MPa]
ρ_1	1120[kg/m^3]	ρ_2	1100[kg/m^3]
ν_1	0.41	ν_2	0.47

3. VIBRATION ABSORPTION OF FC-ABH

3.1 Numerical simulation of bandgap

The Floquet-Bloch periodic boundary conditions are applied on the edges of the FC-ABH microunit as in Figs. (3) and (4), where $\boldsymbol{w}$ denotes the out-of-plane displacement vector, $\boldsymbol{k} = (k_x, k_y)$ is the wave vector and $i^2 = -1$[18].

$$\boldsymbol{w}\left(-\frac{a}{2},y\right)=\boldsymbol{w}\left(\frac{a}{2},y\right)e^{ik_x a} \quad (3)$$

$$\boldsymbol{w}\left(x,-\frac{a}{2}\right)=\boldsymbol{w}\left(x,\frac{a}{2}\right)e^{ik_y a} \quad (4)$$

The dispersion curve can be obtained by sweeping $\boldsymbol{k}$ along the boundaries of the irreducible Brillouin zone as shown in Fig. 2(a). The calculation process is carried out using the finite element method (FEM) via COMSOL, and the results are displayed by scatter points in Fig. 2(a). To manifest the dominant of flexural waves in vibration modes, the colors of these points are determined by Eqn. 5, where u and v are in-plane displacements along the x and y axes, and $\iiint$.dV

means that the integration is taken throughout the entire volume of the FC-ABH unit.

$$p = \frac{\iiint w^2 dV}{\iiint \left(u^2 + v^2 + w^2\right) dV} \tag{5}$$

It can be found that there is an omnidirectional bandgap within 61.29-68.78 Hz and several directional bandgaps within 68.78-90.82 Hz, 90.82-104.64 Hz and 119.3-167.12 Hz respectively.

To verify the predicted bandgaps by the dispersion curves, the vibration transmittance of a finite periodic plate consisting of 4 microunits is calculated. The model of the plate is shown in Fig. 2(b), with continuous periodicity boundary conditions applying in the y direction. Two specific points are noted: the bottom point EP denotes an excitation point where a unit harmonic force in the z direction is introduced into, while the top right point RP is the response point. By measuring the dynamic response of the two points, the transmittance is obtained as in Eqn. 6, where A_{out} and A_{in} are the acceleration amplitudes at RP and EP.

$$\text{Transmission} = 20\lg\frac{A_{out}}{A_{in}} \tag{6}$$

As presented in Fig. 2(b), there are three obvious vibration attenuation bands (named as VAB in the followings to distinguish from the bandgap), the frequency ranges of which are in good agreement with those of bandgaps in the dispersion curves. The relative bandwidth Ω of one VAB is defined as in Eqn. 7, where f_{upper} and f_{lower} represent the upper and lower boundary frequencies.

$$\Omega = \frac{2\left(f_{upper} - f_{lower}\right)}{f_{upper} + f_{lower}} \tag{7}$$

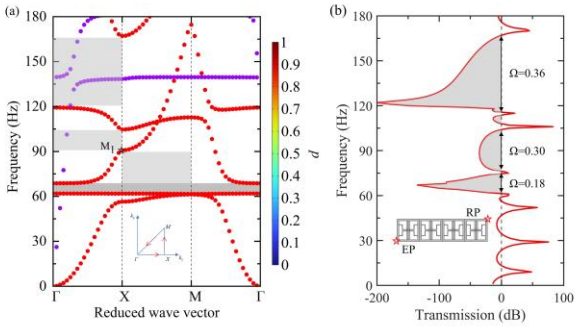

Figure 2. (a) Dispersion curves of the infinite periodic FC-ABH structure. (b) Transmittance of the finite periodic FC-ABH plate. The shaded areas indicate bandgaps or vibration attenuation bands (VABs).

3.2 Experimental validation

A vibration test is conducted to verify the transmittance results of numerical simulation. The 4×1 FC-ABH plate is manufactured by 3D printing, with the ABH portions printed using TPU while the others printed using polylactic acid (PLA). The experiment is carried out at room temperature, and it is noteworthy that the damping characteristics of the two materials are considered here. The material properties of PLA are E_3 = 1.98 GPa, ρ_3 = 1220 kg/m^3 and v_3 = 0.37, and the damping coefficients η of PLA and TPU are set as 0.1 and 0.15 respectively. Boundary conditions and the way of applying excitation are consistent with those set in the numerical simulation mentioned in subsection 3.1. Vibration signals are measured by the laser vibrometer (Ploytec PSV-500-3D).

Fig. 3 shows the experimental results, and the data is filtered using the moving average filter in MATLAB. It can be seen that there is a good agreement compared with the numerical results, especially for the frequency range of the VAB. Within the range of 0-150 Hz, a continuous VAB is generated beyond the third resonant frequency with Ω = 0.93, verifying the effective vibration suppression performance of the finite FC-ABH plate.

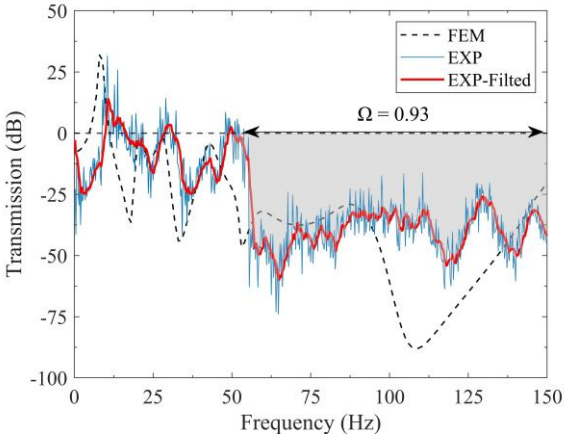

Figure 3. The experimental and simulation results of the transmittance of the finite periodic FC-ABH plate. The shaded area indicates the vibration attenuation band.

3.3 Effects of ABH

Since the bandgaps generated by FC-ABH are beyond the scope of conventional locally resonant bandgaps, one can deduce that the ABH beam acts a special role in the structure. In the view point of vibration absorption, ABH is generally proved to be effective beyond a certain cut-on frequency, which guarantees the tip to reduce the wave speed as well as the reflected energy. To make ABH perform sufficiently, the cut-on frequency is defined as in Eqn. (8) [19].

$$f_\varepsilon = \frac{\varepsilon}{\pi}\sqrt{\frac{3E_2}{4\rho_2}} = 55.17\text{Hz} \tag{8}$$

Therefore, for FC-ABH, ABH keeps absorbing vibration from the beginning of the first omnidirectional bandgap. This explains why the vibration can also be well attenuated at the frequency corresponding to M_1 marked in Fig. 2(a), although it is not within the bandgaps.

To illustrate this advantage more clearly, three frequency points are selected in the three VABs respectively, which are 65 Hz, 90 Hz and 130 Hz, and the displacement fields of the finite periodic plate at these frequencies are shown in Fig. 4. It can be observed that no matter inside or outside bandgaps, the displacement of the ABH portion is prominent, especially concentrated on the microunits near EP, thus reducing vibration at RP.

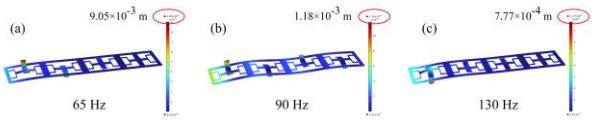

Figure 4. Displacement fields of the finite periodic FC-ABH plate at (a) 65 Hz, (b) 90 Hz and (c) 130 Hz.

4. APPLICATION TO FLOATING RAFT SYSTEM

Since the proposed FC-ABH can achieve broadband vibration suppression, in this section, it is used as the core layer embedded into a honeycomb plate. The periodic sandwich structure is then applied to the floating raft system, which can isolate the vibration transmitted by the machines to the hull effectively, under the premise of ensuring the load-bearing capacity.

4.1 Floating raft system based on FC-ABH

A typical model of the floating raft system is shown in Fig. 5(a), where the proposed FC-ABH is embedded into a conventional honeycomb plate-type raft periodically, forming a novel sandwich raft. The side length of the honeycomb microunit is equal to the lattice constant of the FC-ABH. Considering the practical application of this system, all parts of the raft and the foundation are made of structural steel. Parameters used in the calculation are depicted in Tab. 2.

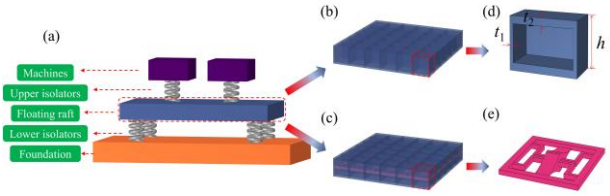

Figure 5. Schematic diagram of floating raft system with (b) honeycomb metamaterial raft and (c) sandwich metamaterial raft based on FC-ABH. (d) Cross-section of the honeycomb microunit. (e) Stereogram of FC-ABH.

Table 2. Structural parameters of the microunit of the raft. E_4, ρ_4, ν_4 are elastic modulus, density and Poisson's ratio of structural steel respectively.

Parameters	Value[unit]	Parameters	Value[unit]
h	0.026[m]	E_4	200[GPa]
t_1	1.05[mm]	ρ_4	7850[kg/m^3]
t_2	0.003[m]	ν_4	0.3

4.2 Load-bearing analysis

In this study, the equivalent elastic modulus of a sample consisting of 2×2 microunits is calculated to predict the mechanical properties of the two types of floating rafts. As we focus on the out-of-plane compression resistance of the proposed model, the elastic modulus E_z along the z direction is investigated as follows. As shown in Fig. 6(a), two rigid plates are connected with the top and bottom surface of the structure to simulate the test in practice. The bottom plate is fixed and a displacement with amplitude U_0 is applied to the top one in the negative direction of z axis. The stress-strain curve is obtained by sweeping U_0 from 0 to 0.3 mm, and the values of the stress and strain at a certain U_0 are derived as Eqns. (9) and (10), where F_r denotes the boundary reactive force at the surface that contact with the top rigid plate, and

∫.dS means that the integration is taken over the entire top surface.

$$\sigma = \frac{\int_S F_r dS}{\left[2(a+2t_1)\right]^2} \tag{9}$$

$$\varepsilon = \frac{U_0}{h} \tag{10}$$

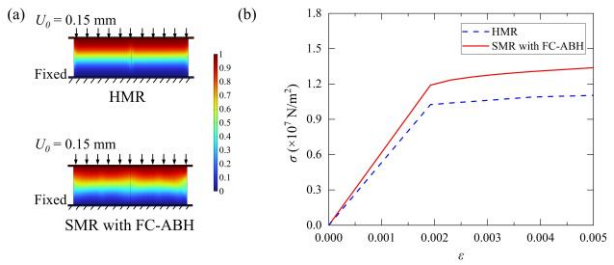

Figure 6. (a) Displacement fields of the sample of the raft in compression simulation when U_0 = 0.15 mm. (b) Stress-strain curves of the sample with and without embedding FC-ABH.

Fig. 6(b) exhibits the simulation results. It can be observed that the linear response for both samples is similar in the initial loading, while the compressive strength of the honeycomb one reaches the peak first, with the appearance of plastic buckling. The yield elastic moduli of the samples with and without FC-ABH calculated by $E_z = \sigma/\varepsilon$ are 5.33 GPa and 6.19 GPa respectively, indicating that the sandwich design improves the static stiffness of the ordinary raft. In addition, by analyzing the displacement fields of the cross-section at the linear segment, it can be observed that the presence of the interlayer changes the distribution of displacement, and partly improves the buckling resistance.

4.3 Vibration isolation of sandwich metamaterial raft

In this subsection, the simulation model of the floating raft system is simplified as shown in Fig. 7(a), where one machine is retained to provide the excitation and the raft is composed of 6×6 sandwich microunits. The side length of the simply-supported foundation is equal to that of the raft, with thickness 0.02 m. Moreover, the upper and lower isolators are substituted by the same 0.1 m×0.1 m×0.027 m rubber pads, with material properties E_5 = 0.02 GPa, ρ_5 = 1300 kg/m^3, ν_5 = 0.47 and η_5 = 0.1. The machine model is set as a rigid domain and a sinusoidal excitation with an amplitude of 20 N is applied to the top of it. To evaluate the vibration isolation performance of the system, the vibration level difference between the machine and the foundation is calculated via Eqn. (11), where A_m and A_f represent the acceleration amplitudes of the corresponding points output-1 and output-2.

$$L_D = 20\lg\frac{A_m}{A_f} \tag{11}$$

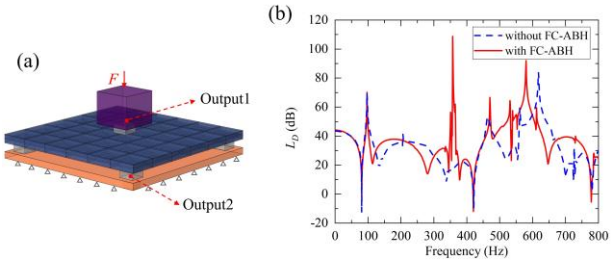

Figure 7. (a) Model of the floating raft system in simulation. (b) Vibration level differences of the floating raft system with honeycomb metamaterial raft and sandwich metamaterial raft based on FC-ABH.

Fig. 7 shows the vibration level difference results, compared with those of the system with honeycomb raft. It can be found that when using the sandwich raft, there is a more significant vibration isolation at 300-400 Hz, which is due to the locally resonant effect. In addition, beyond the locally resonant bandgap, the L_D of the system with the sandwich raft keeps higher than that with an ordinary one, especially at 480-600 Hz, which is because of the ABH absorbers. Due to the limitation of the length of the article, the vibration isolation mechanism of the sandwich raft is not analyzed in detail here. However, to reflect the vibration response of the entire system more comprehensively, the mean quadratic velocity (MQV) of the foundation and the raft surface are calculated, as in Eqn. 12, where ω is the angular frequency and ref = 1×10^{-18} m^2/s^2 [20].

$$\mathrm{MQV} = 10\lg\frac{\omega^2\iint_S w^2 dS}{\left[6(a+2t_1)\right]^2\cdot \mathrm{ref}} \tag{12}$$

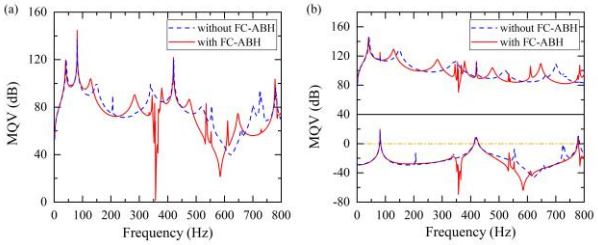

Figure 8. MQV curves of (a) the foundation plate, (b) the raft plate and the difference between them.

As displayed in Fig. 8, the sandwich raft operates at 300-600 Hz, which is consistent with the frequency band that the L_D increases significantly in Fig. 7(b). Furthermore, it can be found that the second peak of the MQV difference disappears in the system with the sandwich raft, presenting broadband vibration isolation performance.

5. CONCLUSION

This paper proposes a novel metamaterial design to achieve broadband and low-frequency vibration suppression, utilizing the coupling effects of local resonance and wave absorption of the acoustic black hole (ABH). The dispersion relation of the infinite periodic structure and the vibration bandgap of the finite periodic plate are calculated, verified by the experimental results. The ABH part acts as a vibration absorber as well as a resonator, allowing vibration to be well attenuated even beyond the bandgap.

After the monomer is analyzed, its application to the floating raft system is studied. The microunit is used as a core layer embedded into a honeycomb plate-type raft periodically. Out-of-plane compression process reveals that the sandwich raft exhibits improved static stiffness, which can meet the requirement of large load-bearing capacity in practical applications. Compared with the conventional floating raft system, the vibration level difference of the one with the proposed sandwich raft is significantly improved in vibration bandgaps, demonstrating low-frequency and broadband vibration isolation performance.

This study offers an effective design with superior static and dynamic properties. The proposed meta-structure may provide a new strategy for ship-vibration technologies.

EFFECTS OF ACOUSTIC BLACK HOLE PILLARS ON THE ACOUSTIC ENERGY OF A WATER-FILLED CAVITY

Junjun Li[1] **Jie Deng**[1,2*] **Oriol Guasch** [1*]

ABSTRACT

Acoustic additive black hole (ABH) pillars are known to significantly reduce vibration energy from a host plate. However, little has been done to investigate their performance when the host plate partially encloses a water-filled resonant cavity, a problem that may be important for marine applications. In this work, the ability of ABH pillars to reduce the acoustic energy of the cavity is investigated and compared to that of standard uniform pillars. The elastoacoustic problem is solved using a displacement formulation and Gaussian basis functions are employed to expand all the unknowns of the problem. Boundary and coupling conditions are imposed using the null space method (NSM). The results show that ABH pillars can substantially reduce the acoustic energy of the cavity, outperforming uniform pillars despite their lower mass.

Keywords: *Acoustic black holes, Vibroacoustics, Heavy fluid, Nullspace method*

1. INTRODUCTION

In recent years, acoustic black hole (ABH) technology has garnered a great deal of attention for its effectiveness in mitigating noise in fluid systems. Bowyer and Krylov [1] pioneered experimental investigations into the acoustic radiation of ABH plates, demonstrating that rectangular plates with tapered indentations can effectively reduce acoustic power radiation. Subsequently, the vibroacoustic behavior of ABH plates coupled to air cavities but their connection to heavy fluids has only started recently. In [2], the fluid-structure interaction of ABHs with heavy fluids was addressed by showing the suppression potential of a composite plate-cavity ABH system under heavy fluid excitation, achieving sound pressure level reductions of 4-9 dB above 300 Hz. More recently, the underwater acoustic radiation characteristics of ABH plates were further examined demonstrating superior underwater sound power suppression between the cut-on and critical frequencies [3,4].

Although embedded ABH configurations are the most common, they compromise the original stiffness of the host plate due to thickness adjustment. To overcome these limitations different types of additive ABHs have been proposed. In [5], a dynamic vibration absorber with ABH features (ABH-RBD) was set on a uniform beam achieving effective vibration suppression without compromising structural integrity. Subsequently, symmetric [6] and eccentric [7] circular ABH dynamic vibration absorbers (2D ABH-DVA) were developed to reduce vibrations in uniform plates. Additional research has been conducted on spiral ABHs [8], curved ABHs [9], and ABH pillars [10] as additive structures.

In this study, we propose to place multiple ABH pillars on a uniform beam coupled to a cavity to reduce noise in a cavity filled with heavy fluid. The equations of motion for the fluid-structure coupling system are established from the displacement formulation in [11], using Gaussian basis functions (GEM expansion method in [12–14]) and the nullspace method (NSM) [15] to impose boundary coupling conditions. Finally, the noise reduction capability of the proposed configuration is computed.

2. THEORETICAL MODEL

2.1 Problem description

As illustrated in Fig. 1, to mitigate the noise inside a water-filled cavity with dimensions $L \times L_c$ (highlighted in the blue region), multiple ABH pillars are uniformly mounted on a uniform beam with thickness h_p. The thickness profile of each ABH pillar follows a power-law distribution given by $h_a(x) = \varepsilon x^m + h_c$, where $\varepsilon = (h_a - h_r)/r_{\text{abh}}^m$. At the ends of the ABHs, some damping layers $r_d \times h_d$ (highlighted in the brown region) have been attached to favor energy dissipation. The geometry and material parameters of the coupled system are detailed in Tab. 1.

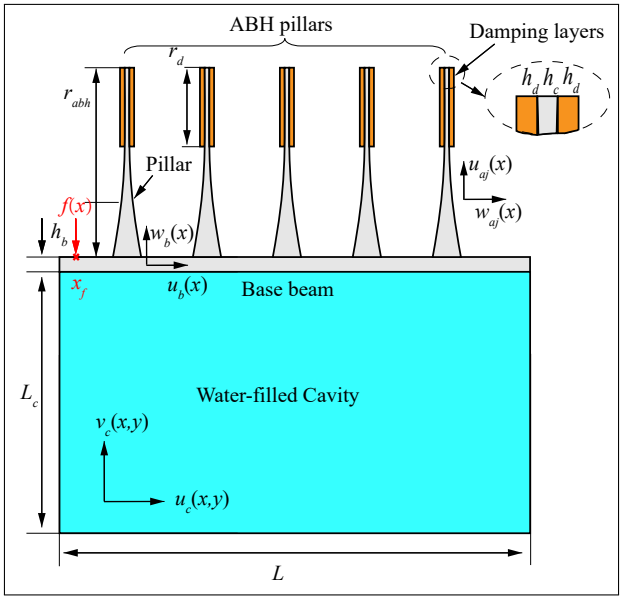

Figure 1. Illustration of the base beam with ABH pillars coupled to a cavity. The blue region indicates the cavity filled with water, while the brown regions represent the damping layers.

2.2 Fluid-Structure Interaction Model

The displacements are represented by variables $u_c(x, y)$, $v_c(x, y)$ for the fluid within the cavity and by $w_b(x, t)$, $u_b(x, t)$ for the uniform beam, respectively. Similarly, the flexural and longitudinal displacements of the ABH pillars can be expressed as $w_{aj}(x, t)$ and $u_{aj}(x, t)$, where $j = 1, 2, \ldots, 5$ denotes the index of the ABH pillars. They are

Table 1. Geometry and material parameters of the coupled system.

Geometry parameters	Material parameters
$L_{cx} = L_b = 0.8\,\text{m}$	$\rho_c = 1000\,\text{kg/m}^3$
$L_{cy} = 0.6\,\text{m}$	$c_c = 1500\,\text{m/s}$
$h_b = h_a = 5\,\text{mm}$	$\eta_c = 0.02$
$m = 2$	$\rho_b = \rho_a = 7800\,\text{kg/m}^3$
$r_{\text{abh}} = 0.4\,\text{m}$	$E_b = E_a = 210\,\text{GPa}$
$\varepsilon = 0.028\,\text{m}^{-1}$	$\eta_b = \eta_a = 0.005$
$h_r = 0.5\,\text{mm}$	$\rho_d = 950\,\text{kg/m}^3$
$r_d = 0.2\,\text{m}$	$E_d = 5\,\text{GPa}$
$h_d = 1\,\text{m}$	$\eta_d = 0.5$

expanded as

$$u_c = \boldsymbol{C}^\top(t)\partial_x\boldsymbol{\varphi}_c(x,y), v_c = \boldsymbol{C}^\top(t)\partial_y\boldsymbol{\varphi}_c(x,y), \quad (1)$$

$$w_b = \boldsymbol{B}_1^\top(t)\boldsymbol{\varphi}_{b1}(x), u_b = \boldsymbol{B}_2^\top(t)\boldsymbol{\varphi}_{b2}(x), \quad (2)$$

$$w_{aj} = \boldsymbol{A}_{j1}^\top(t)\boldsymbol{\varphi}_{aj1}(x), u_{aj} = \boldsymbol{A}_{j2}^\top(t)\boldsymbol{\varphi}_{aj2}(x), \quad (3)$$

where $\boldsymbol{\varphi}_c(x, y) = \boldsymbol{\alpha}(x) \otimes \boldsymbol{\beta}(y)$ are 2D Gaussian functions for the 2D cavity, $\boldsymbol{\varphi}_{b1}(x)$, $\boldsymbol{\varphi}_{b2}(x)$, and $\boldsymbol{\varphi}_{aj1}(x)$, $\boldsymbol{\varphi}_{aj2}(x)$ $(j = 1, 2, \ldots, 5)$ are the 1D Gaussian functions for the base beam and the five ABH pillars, respectively. $\boldsymbol{C}$, $\boldsymbol{B}_1$, $\boldsymbol{B}_2$, $\boldsymbol{A}_{j1}$, and $\boldsymbol{A}_{j2}$ are the coefficient vectors to be determined. The assembled coefficients are defined as $\boldsymbol{q} := [\boldsymbol{C}, \boldsymbol{B}_1, \boldsymbol{B}_2, \boldsymbol{A}_j]$, where $\boldsymbol{A}_j := [\boldsymbol{A}_{j1}, \boldsymbol{A}_{j2}]$.

The Lagrangian of the coupled system is the summation of the Lagrangians of its three components, namely, the cavity, the uniform beam, and the five ABH pillars. This leads to,

$$\mathcal{L} = T_c + T_b + T_a - U_c - U_b - U_a, \quad (4)$$

where T_i and U_i $(i = a, b, c)$ represent the kinetic energy and potential energy of each structure.

By substituting the above expressions into the Euler-Lagrange equations, we can derive the equations of motion,

$$(\boldsymbol{K} - \omega^2\boldsymbol{M})\boldsymbol{Q} = \boldsymbol{0}, \quad (5)$$

where $\boldsymbol{K}$ and $\boldsymbol{M}$ are the stiffness and mass matrices, respectively. However, the above derivation does not explicitly consider the essential boundary conditions of the cavity and the uniform beam, nor the coupling ones at the substructure interfaces. These are accounted for by means of the nullspace method.

The three walls of the cavity are rigid, which implies,

$$u_c(0,y)=0, \quad u_c(L_x,y)=0, \quad v_c(x,0)=0. \tag{6}$$

As for the base beam, it is simply supported on the cavity and coupled with its the upper boundary. The ABH pillars and the uniform beam are coupled at intervals of $d = L_b/6$. These conditions are described by the following equations:

$$w_b(0)=0, \quad w_b(L_x)=0, \tag{7}$$
$$u_b(0)=0, \quad u_b(L_x)=0, \tag{8}$$
$$w_b(x)=v_c(x,L_y), \tag{9}$$
$$w_b(x_j)=u_{aj}(0), \quad u_b(x_j)=w_{aj}(0), \tag{10}$$
$$\partial_x w_b(x_j)=-\partial_x w_{aj}(0), \tag{11}$$

where x_j denotes the connection points of the j-th ABH pillar on the base beam ($j = 1, 2, \ldots, 5$).

Substituting Eqn. (1) to Eqn. (3) into Eqn. (6) to Eqn. (11), we obtain,

$$\boldsymbol{\Xi Q} =: \boldsymbol{\Phi}^\top \boldsymbol{Q} = \boldsymbol{0}, \tag{12}$$

where $\boldsymbol{\Xi}$ is the matrix form of the above constraints.

To avoid numerical instabilities, we square and integrate Eqn. (12) over the interface domain, which yields,

$$\boldsymbol{Q}^\top \left[\int \boldsymbol{\Phi}^\top \boldsymbol{\Phi} \, \mathrm{d}x, \right] \boldsymbol{Q} =: \boldsymbol{Q}^\top \boldsymbol{\Psi} \boldsymbol{Q} \tag{13}$$

where, we have defined matrix $\boldsymbol{\Psi}$ is the constant constraint matrix. Finding a basis for the nullspace $\mathcal{N}(\boldsymbol{\Psi})$, we can express $\boldsymbol{Q}$ as $\boldsymbol{Q} = \boldsymbol{Z}\boldsymbol{k}$, with $\boldsymbol{Z}$ containing the nullspace eigenvectors and $\boldsymbol{k}$ being the coefficient vector. Substituting into the equation of motion, Eq. (5), we arrive at,

$$\left(\overline{\boldsymbol{K}} - \omega^2 \overline{\boldsymbol{M}}\right) \boldsymbol{k} = \boldsymbol{0}, \tag{14}$$

where $\overline{\boldsymbol{K}} = \boldsymbol{Z}^\top \boldsymbol{K} \boldsymbol{Z}$ and $\overline{\boldsymbol{M}} = \boldsymbol{Z}^\top \boldsymbol{M} \boldsymbol{Z}$, represent the coupled stiffness and mass matrices, respectively.

3. NUMERICAL RESULTS

To evaluate the performance of ABH pillars in reducing noise inside the cavity, a unit point force is applied at the left x_f of the uniform beam, see Fig. 1.

In Fig. 2, we first present the mean square velocity (MSV) of the host beam. It is observed that if ABH pillars are attached to it instead of uniform (UNI) pillars, the vibration becomes significantly reduced. On the other hand, Fig. 3 presents the acoustic energy ($E = T_c + U_c$) within the cavity. The results indicate again that ABH pillars are more effective than uniform pillars over almost the entire frequency range.

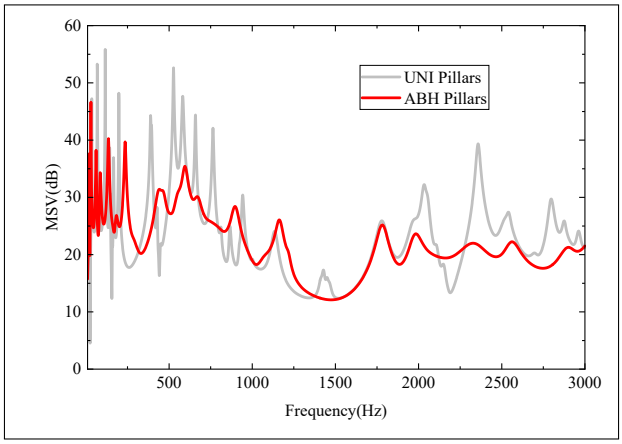

Figure 2. Mean square velocity (MSV) of the host beam.

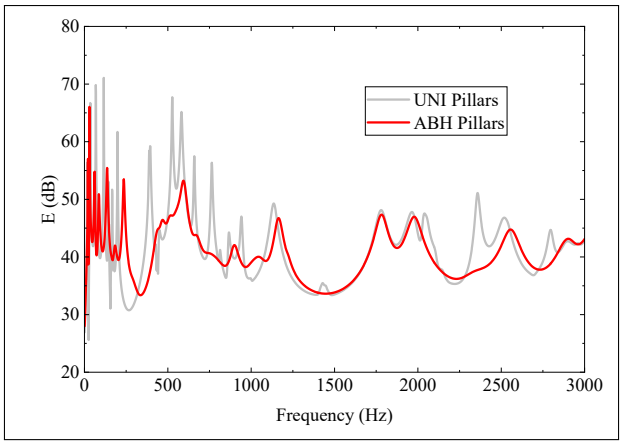

Figure 3. Acoustic energy in the water-filled cavity.

4. CONCLUSION

This paper proposes attaching ABH pillars to host plate to reduce noise transmission inside a heavy-fuid filled cavity. The displacements of the ABH pillars, the base beam, and the fluid have been represented using the Gaussian expansion method (GEM), while the nullspace method (NSM) has been employed to impose the essential boundary and

continuity conditions of the problem. The results indicate that ABH pillars can significantly dampen the vibrations of the uniform beam and reduce the energy transmission to the cavity, thus showing excellent noise reduction capability.

ABSTRACT

Acoustic Black Holes (ABHs) have gained significant attention for their potential in vibration control by effectively trapping flexural waves within structures featuring gradually tapered thickness profiles. In this study, we investigate the wave propagation of bending waves in a honeycomb sandwich panel that integrates ABH effects to attenuate vibrations in a high broadband frequency band and also in a low tunable frequency band. By periodically modulating the thickness of the panel with an ABH-like thickness profile, the design leverages both Bragg band gaps and the ABH effect to enhance wave attenuation. The sandwich configuration offers a high stiffness-to-mass ratio, making it particularly attractive for lightweight structural applications. The band structure is analyzed using a plane wave expansion method based on Kirchhoff's assumptions, and finite element (FE) simulations are conducted to validate the theoretical predictions. The results confirm the existence of tunable low-frequency band gaps controlled by key geometric parameters. This approach provides an effective strategy for designing lightweight, stiff, and highly efficient vibration-damping panels, suitable for advanced engineering applications

1. INTRODUCTION

In recent years, periodic materials and structures have garnered significant attention in physics and engineering due to their unique wave propagation characteristics and their ability to control vibrations [1]. One particularly promising approach is the integration of acoustic black holes (ABHs) into engineered structures. A particularly promising approach involves integrating acoustic black holes (ABHs) into engineered structures. The ABH effect, first introduced by Mironov in 1988 [2] and further developed by Krylov [3], employs a gradual reduction in structural thickness, typically following a power-law decreasing profile, to create a near-zero reflection condition for bending waves. This process results in a progressive reduction in wave velocity and the accumulation of vibrational energy, which, when paired with suitable damping layers, results in effective energy dissipation [4].

Combining ABHs with sandwich panels offers significant advantages in low-frequency vibration suppression. Sandwich structures, widely used in aerospace and automotive industries due to their high stiffness-to-weight ratio and efficient load-bearing capacity, often suffer from poor noise insulation and susceptibility to structural vibrations. To overcome these challenges, periodic thickness modulation has emerged as an effective strategy for enhancing wave attenuation. Recent studies [5] have demon-

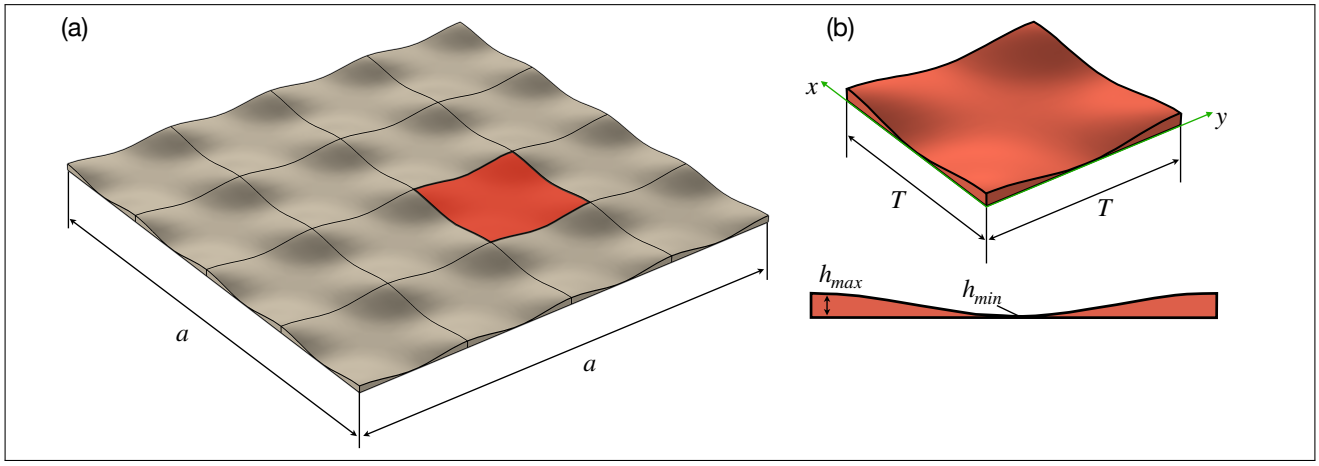

Figure 1. The proposed design of the ABH PC plate: (a) 3D view composed of a 4×4 array of identical rectangular unit cells, and (b) detailed layout of the rectangular unit cell defined in Eqn. (1).

strated that incorporating periodic effects, such as Bragg bandgaps (BGs), into solid panels can substantially reduce vibrations and sound transmission. By integrating ABHs with periodic structures, vibration control can extend beyond the traditional cut-on frequency limitations of ABHs, improving broadband performance. The same undulation periodicity design in plates was explored by G. Trainiti [6], where multiple scattering between the cells of an infinite periodic lattice leads to complete bandgaps. Geometrical undulations have proven to be effective design parameters that can be adjusted to achieve the desired dynamic characteristics.

This study aims to investigate the synergistic effects of ABHs and periodic modulation in sandwich panels for enhanced vibration and noise control. By combining the wave-trapping properties of ABHs with the bandgap effects of periodic structures, we seek to develop a novel approach for lightweight panels with improved acoustic performance. The plate is analyzed based on dispersion relations using the plane wave expansion (PWE) method, alongside the finite element (FE) method, both of which are employed to obtain the band structure. The FE method is also employed to compute the dynamic response of the acoustic black hole phononic crystal plate.

2. DESIGN AND GEOMETRY OF THE MODULATED PANEL

The acoustic black hole phononic crystals (ABH PCs) is shown in Fig.1. The geometry of the panel is characterized by a periodic variation in thickness, h, with a spatial period, T. For simplicity and to ensure an integer number of unit cells in the modulated panel, we consider a rectangular unit cell, as shown in Fig.1b. The curvature undulation is defined as a combination of cosine functions of the spatial coordinates (u, v) for the rectangular unit cell, as follows

$$h(u,v) = \alpha + \beta\Bigg[\cos\left(\frac{2\pi}{T}u\right) + \cos\left(\frac{2\pi}{T}v\right) + \gamma\cos\left(\frac{2\pi}{T}u\right)\cos\left(\frac{2\pi}{T}v\right)\Bigg], \quad (1)$$

where the average thickness of the plate, for the shape parameter $\gamma = -1$, is given by $\alpha = \dfrac{\gamma h_{max} + (\gamma - 2)h_{min}}{2\gamma - 2}$ and the contrast parameter is $\beta = \dfrac{h_{max} - h_{min}}{2\gamma - 2}$, which is defined in terms of the maximum and minimum thickness values. A diverse set of thickness distributions can be achieved by adjusting the shape parameter γ [5].

3. BAND DIAGRAMS AND VIBRATION ANALYSIS

3.1 PWE and FE modeling of a rectangular unit cell

We focus on an inhomogeneous thin plate based on Kirchhoff-Love theory. Using the PWE method, we analyze the band structure of an infinite periodic rectangular unit cell, as shown in Fig.1b. The equation of motion for

the PWE method, described by the flexural displacement $w(\mathbf{r})$, is given as follows:

$$
\begin{aligned}
&-\rho h(\mathbf{r})\omega^2 w(\mathbf{r}) + \Delta(D(\mathbf{r})\Delta w(\mathbf{r})) \\
&\quad = (1-\nu)\Bigg(\frac{\partial^2 D(\mathbf{r})}{\partial y^2}\frac{\partial^2 w(\mathbf{r})}{\partial x^2} - 2\frac{\partial^2 D(\mathbf{r})}{\partial x \partial y}\frac{\partial^2 w(\mathbf{r})}{\partial x \partial y} \\
&\qquad + \frac{\partial^2 D(\mathbf{r})}{\partial x^2}\frac{\partial^2 w(\mathbf{r})}{\partial y^2}\Bigg).
\end{aligned} \tag{2}
$$

where ρ is the mass density, ω is the angular frequency, $D(\mathbf{r}) = \dfrac{Eh(\mathbf{r})^3}{12(1-\nu^2)}$ is the bending stiffness of the plate, $\mathbf{r}$ is the spatial position vector, depending on the coordinates x and y, and ν is Poisson's ratio. Due to the periodicity of the ABH PC, these material parameters can be expanded as a Fourier series [5, 7]. According to Bloch's theorem, the Eqn. (2) can be used to compute the eigenvalue problem of $\omega(\mathbf{k})$, and the energy band structure can be obtained by solving this equation. The wave vector $\mathbf{k} = [k_x, k_y]$ can be taken at the boundary of the irreducible Brillouin zone (IBZ) of a two-dimensional rectangular unit cell. We can calculate energy band properties along the IBZ path ΓXM and obtain the corresponding dispersion curves. The Bloch wave vector $\mathbf{k}$ starts from Γ and moves along the x-direction to X, where $k_x \in (0, \pi/T)$ and $k_y = 0$. Next, the wave vector continues from X to M, where $k_x = \pi/T$ and $k_y \in (0, \pi/T)$. Finally, the wave vector returns to Γ from M, following the path where $k_x = k_y \in (0, \pi/T)$.

Since we are interested in the BGs at low frequencies and assume that the panel does not exhibit shear deformation or core compressibility, the total plate stiffness of the sandwich panel $D(\mathbf{r})$ is considered frequency-independent. The ABH PC is modeled using the following equivalent homogenized material properties: Young's modulus $E = 54 \cdot 10^8$Pa, $\nu = 0.3$, and $\rho = 126$kg/m^3.

The numerical simulations based on the finite element (FE) method are implemented using the commercial software COMSOL solid mechanics package to calculate the band structures. A Floquet periodic boundary condition is applied to both sides of the rectangular unit cell, as derived from the Bloch's theorem. A parametric sweep of the reduced wave vector $\mathbf{k}$ is performed over the first irreducible Brillouin zone. The model materials correspond to the equivalent homogenized material as indicated above, with no damping loss.

The frequency dependence on the wave number is plotted in Fig.2. The geometric parameters of the rectangular unit cell from Fig.1b were chosen as follows: the

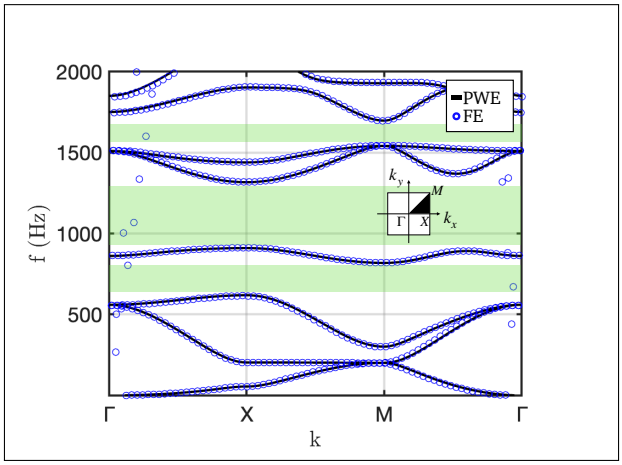

Figure 2. Dispersion curves with green-shaded areas denoting band gap distribution of the rectangular unit cell. The band structure along the IBZ path was computed using FE (blue circles) and PWE (black line) methods.

maximum and minimum thicknesses are $h_{max} = 12$mm and $h_{min} = 0.6$mm, with a length of $T = 200$mm. It is clearly observed that the FE (blue circles) and PWE (black line) results are highly consistent. The green-shaded area in the diagram represents the three generated BGs of the rectangular unit cell, where wave transmission is prohibited. The first band gap opens around 615Hz and continues up to 912Hz. The widest band gap spans the frequency range from 912Hz to 1318Hz. The third band gap appears in the frequency range from 1544Hz to 1696Hz.

3.2 Numerical results for the finite panel with multiple ABHs

We consider an ABH PC plate composed of 4×4 array of identical rectangular unit cells, as shown in Fig.1a, and analyze its response when subjected to an external point force of $F = 1$N. The excitation point is located at the center of the finite structure, and the plate is assumed to be clamped along its edges. The width of the ABH PC plate is $a = 800$mm, with other material and geometric characteristics are taken from the previous section. We focus on the spatial average squared mobility of this plate, defined as $10log_{10}(v/F)$, where v is the velocity.

Fig.3a compares the mobility of the ABH PC plate with a 4×4 array of identical rectangular unit cells (red line), an ABH PC plate with an 8×8 array of identical

unit cells (black line), and the reference plate (blue line), modeled as a uniform plate with a total thickness corresponding to the maximum thickness of the ABH PC plate, $h_{tot} = 12$mm. As shown in Fig.3a, the mobility of the ABH PC plates is significantly reduced, resulting in noticeable vibration attenuation at low frequencies, which is attributed to the formation of BGs.

Additionally, Figs.3b,c,d show the displacement field at 821Hz (green dashed line) for the different panels. These results demonstrate complete vibration isolation in the ABH PC plate, with the wave progressively attenuated as it passes through each unit cell. Furthermore, the mobility decreases substantially as the number of unit cells increases.

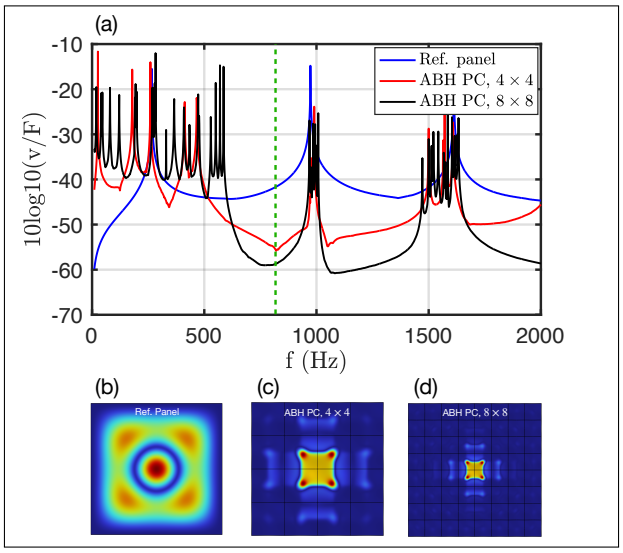

Figure 3. a) The spatial average squared mobility of the ABH PC plate composed of a 4×4 array of identical rectangular unit cells (red line), an 8×8 array of identical unit cells (black line), and the uniform plate (blue line). b,c,d) Corresponding displacement fields at 821Hz (green dashed line).

4. CONCLUSION

This study investigates the synergistic effects of ABHs and periodic modulation in sandwich panels for enhanced vibration and noise control. The band structure analysis using the PWE method and dynamic response evaluated through FE simulations revealed the presence of tunable low-frequency band gaps, which effectively attenuate mechanical waves and significantly reduce vibrational energy. The dynamic response analysis of the ABH PC plate, along with the effect of the number of unit cells, further confirmed a substantial reduction in the spatial average squared mobility compared to the uniform plate, demonstrating the efficiency of the proposed design. This work advances the understanding of acoustic metamaterials and offers a promising approach for developing lightweight materials for noise isolation and vibration suppression in various engineering applications.

ABSTRACT

Acoustic Black Hole (ABH) is a passive vibration control technique that involves introducing a local reduction in the thickness of a panel, combined with a thin viscoelastic coating in the weak area. This approach increases vibration damping with no additional mass, making it particularly attractive for lightweight structures such as honeycomb sandwich panels used in aerospace applications. The vibration field of ABH is mainly controlled by complex localised modes, classified according to their circumferential order. The reflection coefficient of an incident bending wave converging on the ABH, defined for each circumferential order, is analysed in the complex frequency plane. It is shown that each mode corresponds to a pair of poles and zeros symmetrical about the real frequency axis. The viscoelastic ABH coating allows the pairs to rotate about the origin, bringing the zeros closer to the real axis, creating interesting dips in the reflection coefficient as a function of real frequency. A wave-based model is used to identify local modes, study the role of the ABH profile and the effect of the damping layer. The approach provides a list of rules for optimal design of the ABH absorber.

1. INTRODUCTION

Acoustic Black Holes (ABHs) are an effective passive technique for vibration and noise reduction in engineering structures. An ABH consists of a tapered region within a beam or plate that traps and dissipates flexural waves. Introduced by Mironov and Krylov [1, 2], it relies on a power-law thickness profile with a thin viscoelastic layer for enhanced wave absorption. Initial studies on one-dimensional (1D) ABHs analysed wave trapping using geometrical acoustics [3, 4] and impedance models [5], highlighting the role of damping in ABH performance. Later research accounted for evanescent waves and imperfections [6]. More recently, ABHs have been integrated into sandwich structures to improve vibration attenuation despite challenges emerging from frequency-dependent bending stiffness [7–9]. The influence of local modes on ABH performance was first demonstrated in [10]. These modes create local minima in the reflection coefficient, with zeros aligning on the real frequency axis under optimal damping (critical coupling). This study extends the concept to 2D configurations, using a semi-analytical model of a honeycomb sandwich plate with a circular ABH to analyse local modes and reflection coefficients. Inspired by prior wave-based modelling [11, 12], the study compares identical ABHs in sandwich and solid panels to assess modal density effects. The ABH profile is then adjusted to examine effects of positioning of zeros and establish design guidelines for improved ABH performance.

2. EFFECT OF BENDING STIFFNESS FREQUENCY DEPENDANCE ON ABH PERFORMANCE

2.1 Configurations

In order to investigate the effect of the sandwich's bending stiffness decreasing with frequency, an adaptation of the wave based model, described in [9], of an ABH embedded in a infinite panel is used. The local behaviour is studied for two configurations. The first configuration corresponds to a sandwich panel modelled as an uniform Kirchhoff's panel based on Nilsson's sandwich theory [7]. This theory propose modelling of a sandwich structure composed of two identical skin as a uniform material panel with a bending stiffness dependent on frequency. The second configuration, corresponds to the "solid panel", which is identical to the sandwich panel, in geometry and material properties, except for a uniform bending stiffness set to the static bending stiffness of the sandwich panel. The mechanical properties of the skins and the core are given in table 1 with an identical loss factor $\eta = 0.04$. An ABH is embedded in these two configurations. This ABH is composed of 2 main zones, a tapered zone in which the honeycomb core of the sandwich is decreasing with the skins staying of constant thickness and a zone made of a central plateau of a single skin. At the connection of these zones, there is a small region where the two skins connect. The ABH can be characterised with $a = 0.05$m, the radius of the central plateau and $b = 0.15$m the radius of the ABH. A viscoelastic layer is added to the ABH using the RKU model [13]. The ABH placed in the two configurations lead to a bending stiffness profile depending on the radius as demonstrated in Figure1 (a) for the solid panel and in Figure 1(b) for the sandwich panel.

	ρ	ν	E	G
Skin	1541 kg/m^3	0.35	19.3 GPa	7.1 GPa
Core	37 kg/m^3	0.3	55 MPa	21 MPa

Table 1. Mechanical parameters of a honeycomb sandwich panel.

2.2 Reflection coefficient of ABH in sandwich and solid plates

The two configurations previously described are used to investigate the performance and local dynamics of an ABH embedded in an infinite panel composed of either a solid material or a sandwich material modelled with Nilsson theory. In order to do so, the value of the reflection coefficient, R, is evaluated in a complex frequency plane and plotted along the real frequency axis for the circumferential order $n = 0$ (Figure 1(c)). The results show a number of local minima identified by the zeros in the complex frequency plane. It appears that each zero corresponds to a local modes of the ABH. In the sandwich case, an increased number of zeros is observed due to the softening of the structure which increases the modal density of the ABH. When looking at the reflection coefficient value along the real axis, each zero corresponds to a dip, leading to an overall value of $|R|$ being lower in the case of a sandwich panel (for f=1500 Hz, $|R|_{sandwich} = 0.3$ while $|R|_{solid} = 0.5$. An increased number of zeros ,i.e number of local modes, leads to an ABH being more effective. When designing an ABH it is crucial to carefully consider the local dynamics of the scatterer.

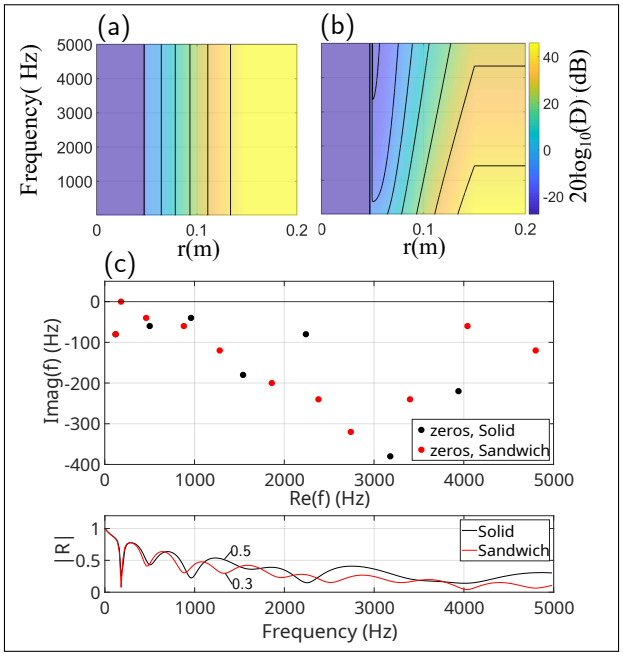

Figure 1. (a) Bending stiffness profile of an ABH placed in a solid panel. (b) Bending stiffness profile of an ABH placed in a sandwich panel panel. (c) Positions of zeros in the complex frequency plane and value of $|R|$ along the real frequency axis for the two configurations at circumferential order $n = 0$.

3. ZERO POSITIONING TO IMPROVE ABH PERFORMANCE

3.1 Selected ABH profiles

As previously shown in section 2, the performance of an ABH is dependent on local modes which create zeros in the reflection coefficient reducing its overall value. The aim of this section is to improve the performance of an ABH by modifying the placement of zeros through geometry variations. Two geometries are compared and correspond to an ABH placed in the same sandwich panel as the previous section with $\eta = 0.01$. In these panels, the two ABH geometries are placed. The first, called 'ABH-1', is identical to the one used in section 2 and its cross-section is shown in Figure 2(a). The second, named 'ABH-2', corresponds to an ABH of radius $b = 0.15$m, with the same power law profile as ABH-1 but with a central plateau twice as large, $a = 0.10$m, its cross section is visible in Figure 2(b).

3.2 ABH performance

These configurations are compared by studying the zeros of the reflection coefficient in the complex plane and the mobility values. The ratio $\chi = im(f)/re(f)$ describes the proximity of the zero to the real axis. The zeros of the reflection coefficient for ABH-1 and ABH-2 are shown in Figure 2(c) for $n = 0$. In this figure, it appears that the zeros of ABH-2 are closer to the real frequency axis ($\chi_{ABH-2} = 2\%$ vs $\chi_{ABH-1} = 10\%$). The proximity of the zeros to the real frequency axis leads to an improvement in the performance of an ABH due to deeper dips in the reflection coefficient value.

To confirm the improved absorption performance of ABH-2, the quadratic mobility averaged over a finite circular sandwich plate is computed using the model presented in [9] and is shown in third-octave band representation in Figure 2(d). In this figure, the mobility of a panel without ABH is compared to the mobility of the panel in the presence of ABH-1 and ABH-2. A mobility reduction of up to 5 dB is observed between the uniform panel and ABH-1, whereas ABH-2 achieves a reduction of up to 8 dB. It appears that the geometry of ABH-2 allows for a greater mobility reduction, particularly between 500 and 2000 Hz. This result correlate with the positions of zeros in the complex frequency plane. These results highlight the importance of the positioning of zeros in the complex plane to enhance the performance of an ABH.

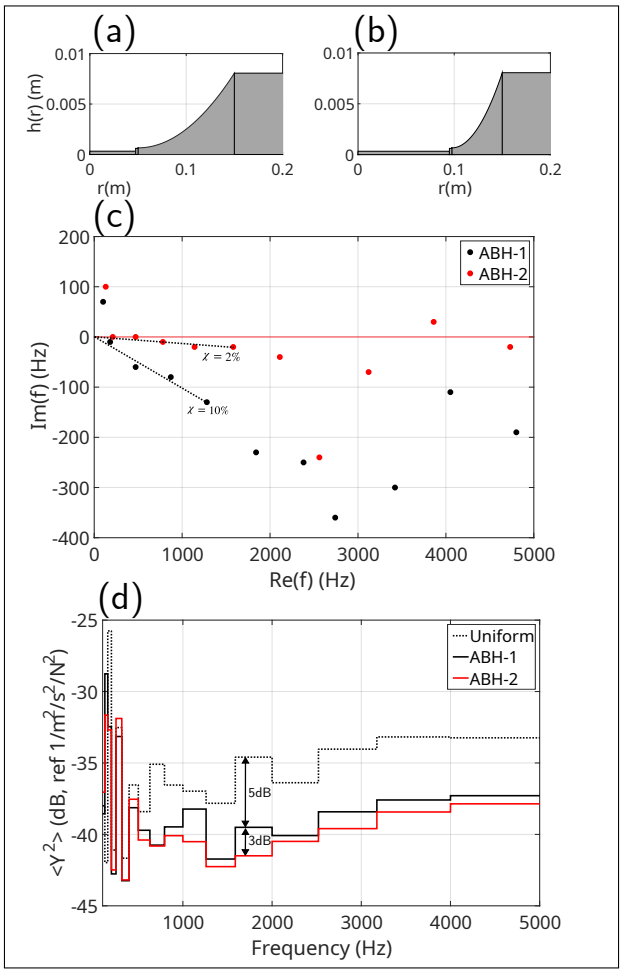

Figure 2. (a) ABH-1 profile with $a = 0.0475$m, $b = 0.05$m and $c = 0.15$m. (b) ABH-2 profile with $a = 0.095$m, $b = 0.0975$m and $c = 0.15$m. (c) Positions of zeros in the complex frequency plane for the two configurations at circumferential order $n = 0$. (d) Spatially averaged quadratic mobility for a plate with no ABH (Uniform), ABH-1 or ABH-2.

4. CONCLUSION

This study investigated the influence of local modes and their positioning in the complex frequency plane on the performance of Acoustic Black Holes (ABHs) embedded in sandwich panels. Using a semi-analytical wave-based model, the analysis demonstrated that an increase in modal density of the scatterer induces an increased number of zeros in the reflection coefficient. This leads, particularly when they are critically coupled, to enhance vibration attenuation. The comparison between ABH-1 and ABH-2 confirmed that a modified geometry can improve the absorption performance by increasing the proximity of the zeros to the real axis. These findings highlight the critical role of local dynamic behaviour in ABH design and provide key guidelines for optimising ABH performance. To create better ABH, careful consideration must be given to the study of local modes and the positioning of zeros, achieved through precise tuning of damping, geometry and materials when possible.

ABSTRACT

The Acoustic Black Hole (ABH) is a passive vibration control technique that enhances damping without increasing structural mass. This effect is achieved by reducing stiffness locally, such as tapering plate thickness following a power-law profile, and adding a viscoelastic coating for increased damping. In lightweight honeycomb sandwich panels, the shear effect significantly influences wave propagation, introducing unique ABH characteristics. This study investigates the behavior of an ABH embedded in a honeycomb sandwich panel (with glass fiber skins and a honeycomb core) in the vicinity of a point excitation force. Using models and experiments, the aim is to evaluate the ABH's ability to absorb vibrations generated by the source. Vibration fields of several samples panels (without ABH, with one and multiple) are measured using a scanning laser vibrometer. The absorption effect (reduction in the average mobility of the panel mobility) is compared with models predictions. Results reveal that the distance between the excitation point and the ABH is critical for good performance. This finding raises the possibility of seeing an ABH not only as a passive vibration absorber but also as a vibrations isolator to decouple the force entry point and the rest of the structure.

1. INTRODUCTION

The Acoustic Black Hole (ABH) is a passive vibration control technique that enhances damping without adding mass. This technique consists of locally reducing the thickness, through a tapered profile, and increasing local loss, with an added viscoelastic layer. Originally proposed by Mironov [1] and Krylov [2], the concept has been extensively studied in uniform panels [3, 4] and more recently in complex structures such as honeycomb sandwich panels [5]. These panels, commonly used in aerospace and automotive applications due to their low weight and relative stiffness, introduce additional challenges due to frequency-dependent bending stiffness induced by shear effects [6, 7].

Experimental studies have demonstrated the effectiveness of ABHs for reducing structural vibrations across various configurations. O'Boy et al. [8] and Georgiev et al. [9] validated the ABH effect through measurements on beams and plates. Recent work [10, 11] extended these findings to composite materials, highlighting the industrial relevance of ABH. In order to further develop the industrial applications of ABH, this study investigates the performance of an ABH embedded in a honeycomb sandwich panel under point excitation. Using experimental measurements and numerical models, the relevance of ABH positioning for performance is studied by comparing configurations with single and multiple ABHs. In highly damped structure, such as honeycomb sandwich panels, the proximity between the vibration source and the ABH is found to be crucial for effective vibration reduction. This finding suggest that ABHs can function not only as vibration absorbers but also as isolators, offering new possibilities for decoupling vibration sources from surround-

ing structures. These insights contribute to the ongoing development of ABH-based solutions for lightweight and high-performance engineering applications.

2. EXPERIMENTAL PROOF OF MOBILITY REDUCTION INDUCED BY ABHS

In order to evaluate the performance of an ABH placed inside a honeycomb sandwich panel, the spatially averaged squared mobility is evaluated outside of the ABH. Such quantity is proportional to the panel's kinematic energy and corresponds to the panel's overall vibratory level. This quantity is experimentally obtained on free boundary panels, using a scanning laser vibrometer (Polytec PSV500 Xtra), an impedance head (PCB 288D01) and an an electrodynamic shaker (Modal Shop 2075E). The excitation is placed close to one corner. A periodic chirp signal is used as excitation. Using this setup, three panel configurations are tested: a uniform reference panel (Figure 1 (a)), a panel with a central circular ABH (Figure 1 (b)), and a panel with four ABHs placed at each corner (Figure 1 (c)). The results of these measurements are shown in (Figure 1 (d)) in one third octave band representation. The single ABH panel shows a reduced mobility of 4dB up to 3500 Hz, demonstrating the effect of the ABH. Above this frequency, the reduction diminishes to less than 1dB . This is due to the highly damped nature of the reference panel. At low frequencies, the displacement field corresponds to a modal field while at higher frequencies, only the propagative field exists in the panel. The propagative field leads to sub-optimal interaction with the ABH leading to a limited mobility reduction effect. To counteract this issue, the ABH is placed closer to the excitation point, aiming to absorb the vibratory energy upon entry and decouple the rest of the panel before it can propagate. Based on this approach, a panel equipped with four ABHs is designed. This configuration offers enhanced low-frequency performance due to the simultaneous operation of all four ABHs, (7dB instead of 4 dB). However, at higher frequencies, 3 out of the 4 ABH are not interacting with the propagative displacement field, rendering them ineffective. This transition phase is observed from 2000 Hz onward leading to an improvement in mobility reduction from 2 dB, for the singular ABH, to 4 dB, for the 4 ABH. The proximity of an ABH to the excitation point ensures sustained efficiency over the entire frequency range for highly damped structures.

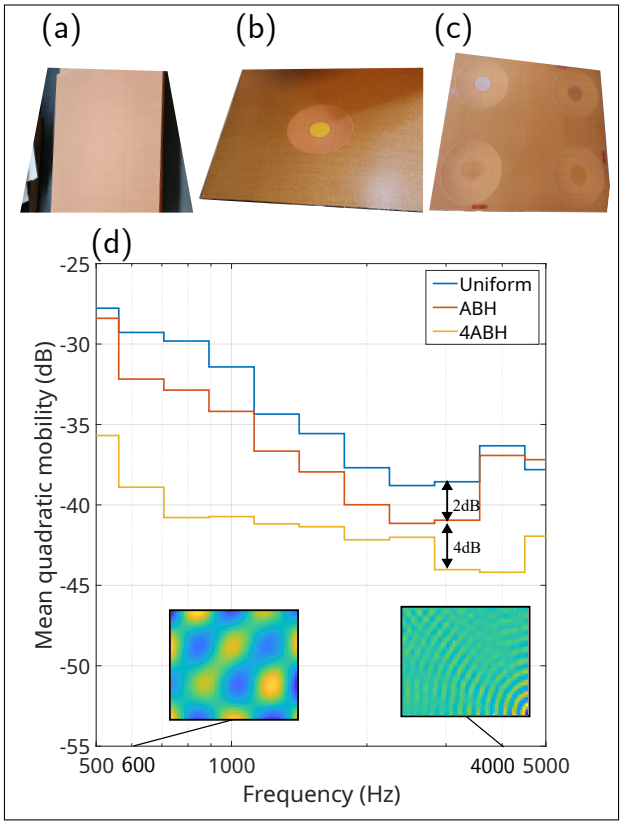

Figure 1. (a) Uniform honeycomb sandwich panel. (b) ABH embedded at the centre of a honeycomb sandwich panel. (c) 4 ABHs embedded at each corner of a honeycomb sandwich panel. (d) Comparison between the spatially averaged quadratic mobility outside of the ABHs for the three panels.

3. NUMERICAL INVESTIGATION OF THE EFFECT OF THE PROXIMITY OF AN ABH TO AN EXCITATION POINT

As stated previously, placing an ABH close to the excitation point of the structure is beneficial to ensure good performance of the device, in both low and high frequency. This is demonstrated by experimental results, under the assumption that ABHs placed too far from the excitation point are not active. In order to verify this assumption, finite element models are created, using the commercial software Comsol Multiphysics, to represent a sandwich panel, based on material properties from [5] with one or multiple ABHs embedded. These models are used to evaluate the spatially averaged quadratic mobility, outside of the ABHs, for different configurations. In total, five panel are tested with the first three being identical to the three experimental configuration (no ABH, centred ABH and 4 ABH) of Figure 1. The last two configurations correspond, respectively, to a single ABH placed next to the excitation point (corner ABH) and 3 ABH placed at the opposite corners of the excitation, (3 ABH) as represented in Figure 2 (a) and (b). The results, shown in one third octave band, are visible in Figure 1 (c). These curves highlight the importance of ABH positioning. The lowest mobility is observed in configurations where an ABH is close to the excitation point (e.g., 4 ABH or Corner ABH), highlighting the importance of proximity. However, the 3 ABH provide similar performance than the centred ABH due to the ABHs being further away from the excitation and them not being active. The models of ABH embedded in sandwich panel are still under development and are not yet giving results that can directly be compared to the experimental results. However, they still demonstrate the importance of ABH proximity and can be used to generate the hypothesis that an ABH can be used not just as a vibration absorber, but also as a vibration isolator, by decoupling an entire structure from a vibration source. This new application of the ABH is especially beneficial in specific scenarios, such as highly damped panels.

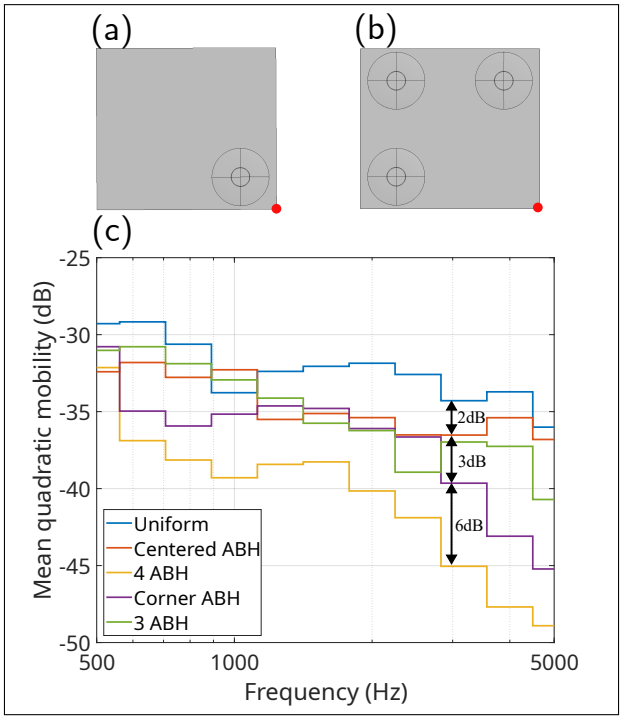

Figure 2. (a) Honeycomb sandwich panel equipped with an ABH placed in the corner next to the excitation. (b) 3 ABHs embedded at the opposites corners of the excitation of a honeycomb sandwich panel. (c) Comparison between the spatially averaged quadratic mobility outside of the ABHs for the five configurations.

4. CONCLUSION

This study explored the performance of an Acoustic Black Hole (ABH) embedded in a highly damped honeycomb sandwich panel using experimental samples and numerical models. The spatially averaged quadratic mobility of a uniform sandwich panel was compared to that of a panel equipped with a centrally located ABH and another with four ABHs positioned at the corners. Results revealed a 4 dB reduction in mobility at low frequencies, with diminished performance at higher frequencies. This decline is attributed to the transition of the displacement field from modal to propagative, which weakens the interaction with the scatterer. The findings highlight the importance of ABH placement, as demonstrated by the four-ABH panel, which achieves improved performance across both low and high frequencies. This insight suggests a novel application of ABHs as vibration isolators, capable of decoupling an entire structure from its excitation source. Ongoing Numerical simulations further confirm that strategic placement of a single ABH can outperform multiple poorly positioned ABHs, reinforcing the potential of this approach for advanced vibration control strategies.

UNCERTAINTIES IN PARAMETER ESTIMATION OF POROUS MEDIA IN TUBE MEASUREMENTS

Ziqi Chen[1*] **Ning Xiang**[1]
[1] Graduate Program in Architectural Acoustics, Rensselaer Polytechnic Institute, United States

ABSTRACT

Characteristic impedance is a critical parameter for porous media. This work discusses the performance of porous materials and how uncertainties in acoustic measurements affect porous material models over an extended frequency range. The three-mic method [Salissou & Panneton, J. Acoust. Soc. Am. 128, pp. 2868–2876 (2010)] is employed to measure the characteristic impedance of porous materials. Impulse responses experimentally measured in an empty impedance tube allow acoustic measurement calibration. Bayesian inference is applied to estimate the parameters in characteristic impedance models associated with the measured impulse response at high frequencies. The uncertainties and inaccuracies in the characteristic impedance of porous materials are analyzed. This paper also addresses challenges for an extended frequency range.

Keywords: *Impedance tube, Characteristic impedance, Bayesian inference*

1. INTRODUCTION

Characteristic impedance is one of the most critical parameters commonly used by the acoustic material community to describe the acoustical performance of porous materials. Multiple models have been established to describe the characteristic impedance, such as the Delany-Bazley-Miki model [1] and the Horoshenkov model [2]. This study combines the three-mic method [3] and cylindrical mode decomposition [4] to measure the characteristic impedance in an extended frequency range, and the measured characteristic impedance is compared to the theoretical values to see the performance of the model.

2. METHODOLOGY

2.1 Measurement

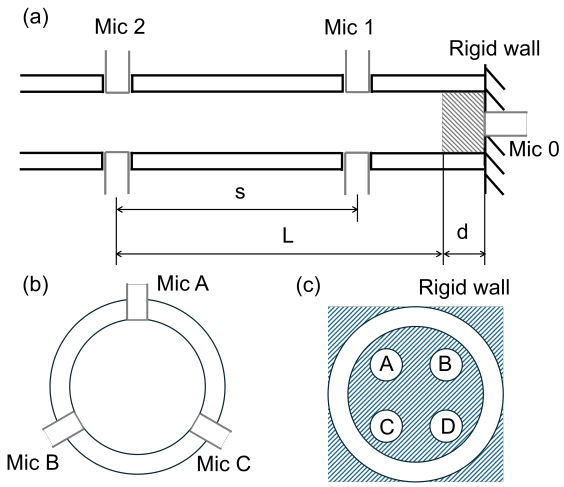

Figure 1. Impedance tube measurement for the characteristic impedance. (a) Arrangement for the measurement. (b) Arrangement of the circumferential position for position 1 and 2. (Arrangement of the Microphone position 0)

Figure 1 shows the impedance tube measurement setup in this work. We measure 3 impulse responses in the same plane for Position 1 and 2 and measure 4 im-

pulse responses at back of the testing material. To extend the frequency range of the impedance tube measurement, we distribute microphone positions evenly along the circumference. The surface reflectance measured is calculated from

$$\underline{R} = \frac{\underline{H}_{12} - \mathrm{e}^{-\underline{\gamma} s}}{\mathrm{e}^{\underline{\gamma} s} - \underline{H}_{12}} \mathrm{e}^{2\underline{\gamma} L}, \tag{1}$$

where γ is the propagation coefficient, s is the separation between position 1 and 2, L is the distance from position 2 to the front surface of the testing materials, and H_{12} is the ratio of the average sound pressures. The transfer function is

$$\underline{H}_{ij} = \frac{\overline{P}_i}{\overline{P}_j} \tag{2}$$

where $\overline{P}$ is defined as the average value of sound pressures measured at different circumferential positions and the same longitudinal position.

$$\overline{P}_i = \frac{1}{N} \sum_{n}^{N} P_{in} \tag{3}$$

(4)

Therefore the wave number and the characteristic impedance of the material is [3]

$$\underline{k} = \frac{1}{d} \cos^{-1} \left(\frac{1 + \underline{R}}{\mathrm{e}^{\underline{\gamma}(L-s)} + \underline{R} \mathrm{e}^{-\underline{\gamma}(L-s)}} H_{10} \right) \tag{5}$$

$$\underline{Z}_D = \mathrm{j} \frac{1 + \underline{R}}{1 - \underline{R}} \tan(\underline{k} d) \tag{6}$$

where d is the thickness of the material.

The cut-off frequency of the extended impedance tube measurement is [4]

$$f_{mn} = \frac{\alpha_{mn} c}{\pi d}, \tag{7}$$

where m is the circumferential modal number of the Bessel function, n is the radial modal number of the Bessel function, α_{mn} is the positive zeros of the Bessel function, c is the sound speed in the tube, and d is the diameter of the tube. With two microphones placed evenly along the circumference, the cutting-off frequency for a tube with a diameter of 1.4 inches (35.6 cm) is 9300 Hz. Note that the valid frequency range for a tube with a diameter of 1.4 inches is only up to 5600 Hz according to ASTM E1050 [5].

2.2 Model

Multiple models have been developed to describe the characteristic impedance of the porous material. In this work, we choose the Miki generalized model for the Bayesian inference to analyze the uncertainties and inaccuracies. According to the Miki generalized model, the characteristic impedance of porous materials can be approximated as a function of frequency and flow resistivity [1]

$$Z_M = \rho_0 c_0 \frac{\sqrt{\alpha_\infty}}{\phi} \left[1 + 0.07 \left(\frac{f}{\sigma_e} \right)^{-0.632} - \mathrm{j}\, 0.107 \left(\frac{f}{\sigma_e} \right)^{-0.632} \right], \tag{8}$$

where ρ_0 is the air density, c_0 is the sound speed in air, α_∞ is the tortuosity, and ϕ is the porosity. the effective flow resistivity σ_e is defined as

$$\sigma_e = \frac{\phi}{\alpha_\infty} \sigma \tag{9}$$

2.3 Bayesian framework

In this work, we estimate critical parameters using Bayesian inference. Bayes' theorem for the estimation is

$$\overbrace{p(\boldsymbol{\theta} | \underline{Z}_\mathrm{D}, \underline{Z}_\mathrm{M}, I)}^{\text{posterior}} = \frac{\overbrace{p(\underline{Z}_\mathrm{D} | \boldsymbol{\theta}, \underline{Z}_\mathrm{M}, I)}^{\text{likelihood}} \times \overbrace{p(\boldsymbol{\theta} | \underline{Z}_\mathrm{M}, I)}^{\text{prior}}}{p(\underline{Z}_\mathrm{D} | \underline{Z}_\mathrm{M}, I)}, \tag{10}$$

where θ collectively represents parameters for characteristic impedance models, and I is the background information, including that '*the prediction model is able to describe the data well*'. The likelihood distribution is assigned to

$$p(\underline{Z}_\mathrm{D} | \boldsymbol{\theta}, \underline{Z}_\mathrm{M}, I) = \frac{\Gamma(K/2)}{2} \left(\pi \sum_{k=1}^{K} \epsilon_k^2 \right)^{-K/2}, \tag{11}$$

where $\Gamma(\dots)$ is the standard Gamma function, and ϵ_k is the residual error. The residual error ϵ_k is defined as,

$$\epsilon_k^2 = \mathrm{Re}(\underline{Z}_\mathrm{D} - \underline{Z}_\mathrm{M})^2 + \mathrm{Im}(\underline{Z}_\mathrm{D} - \underline{Z}_\mathrm{M})^2. \tag{12}$$

3. RESULT

3.1 Air Characteristic Impedance

To eliminate the influence of tube dissipation on the accuracy of measurement [6], we measure the empty tube

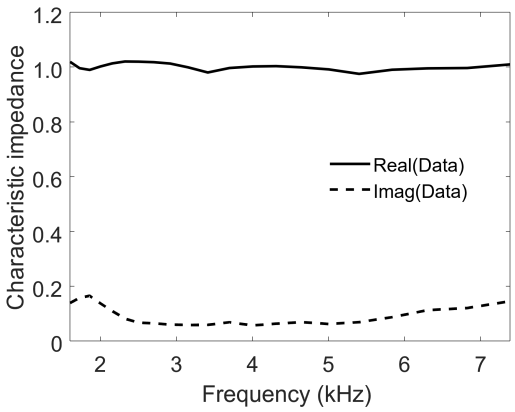

Figure 2. Normalized characteristic impedance of the hypothetical air layer.

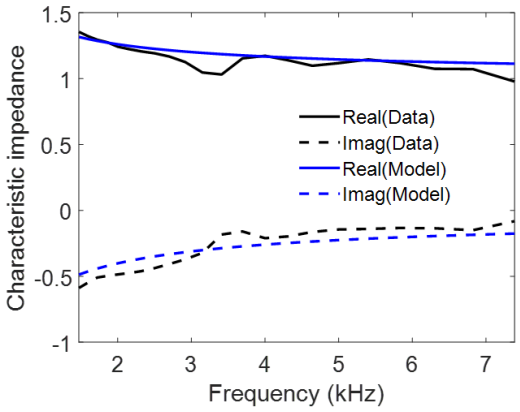

Figure 3. Estimated and measured normalized characteristic impedance.

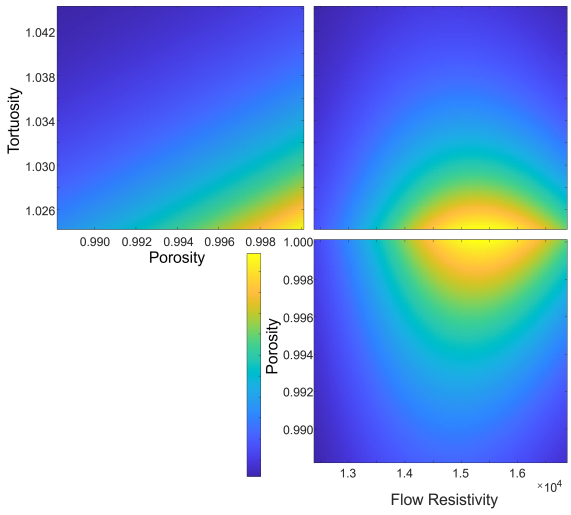

Figure 4. Posterior probability distributions over two-dimensional parameter space for the Miki generalized model.

and assume a hypothetical air layer in front of the rigid termination as the testing material. Figure 2 shows the normalized characteristic impedance of the hypothetical air layer after calibration. Although the calibrated characteristic impedance is not ideal, it is generally equal to the theoretical characteristic impedance of air.

3.2 Porous Material

With the estimated tube dissipation and sound speed after calibration, we are able to estimate the flow resistivity of the porous material. In this work, we used a piece of melamine foam as a test material. Bayesian inference is employed to inversely estimate the critical parameters in the Miki generalized model. Figure 3 demonstrates the estimated characteristic impedance of porous material. The roughness in the measured characteristic impedance may be due to energy leakage on the surface of the rigid termination and the ill-posedness of the testing material [7]. Without microphones evenly distributed along the circumference, the measurement is valid only up to 5600 Hz. Figure 4 shows the posterior probability distributions between parameters.

4. CONCLUSION

In this work, we combine the cylindrical mode decomposition and three-microphone impedance tube measurement to extend the frequency range of characteristic impedance measurements. Bayesian inference is applied to calibrate the impedance tube and estimate the critical parameters in the Miki generalized model based on the measured characteristic impedance. The melamine foam is used to validate the performance of the Miki generalized model at extended frequency.

ABSTRACT

Managing noise and ventilation at the same time is one of the key challenges for acousticians worldwide. This is why, when a new type of solution – e.g. based on acoustic metamaterials – promises to manage both, it is important to have reliable acoustic and pressure measurements. In this study, we review the applicability of ISO 7235 to three different acoustic metamaterials, based on the principle of phase cancellation. We present acoustic measurements in the lab and benchmark them with measurements taken on a building façade, advocating for a potential revision of the standard. We discuss the challenges of measuring total pressure drop and present a dedicated measurement rig. Our work may be useful to any researcher or acoustician considering the placement of metamaterial-based products in their project.

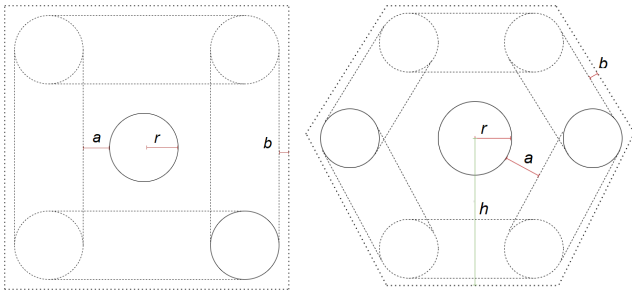
Keywords: *metamaterials, noise, ventilation, measurements.*

1. INTRODUCTION

In a joint paper from 2022, the UK Association of Noise Consultants and the Institute of Acoustics highlighted the challenges of managing simultaneously noise and ventilation in the built environment [1]. This is because traditional solutions rely on absorbing materials, which are bulky and need to be cleaned periodically, or on mass, which opposes the passage of air, by definition. In this context, different research groups worldwide are looking at acoustic metamaterials as the next candidate for the simultaneous management of noise and ventilation.

(a) (b) (c)

Figure 1. The three perforated metamaterials of this study, in order of increasing perforated area (ß).



Acoustic metamaterials are a special class of materials, whose acoustic properties are determined by their sub-wavelength geometry, more than their chemical properties [2,3]. Supported by the development of advanced manufacturing, broadband acoustic metamaterials are quickly translating from laboratories to applications. One of the key challenges for acoustic metamaterials, however, is measuring their properties, so that their performance can be compared with more traditional solutions. This is because a solution based on metamaterials is often non-uniform and non-homogeneous: two hypotheses that underpin the most common measurement standards in acoustics (e.g. ISO 10534-2:2023, which relies on impedance tubes [5])

Particularly important for ducted silencers and termination units is ISO 7235:2003 [6], which relies on a waveguide to establish flow and allows measurements behind the silencer either in a reverberation room or in a test duct (with anechoic termination) or in "essentially free field" conditions. In this work, we test the validity of this standard to characterize a family of three acoustic metamaterials optimized for transmission loss in the presence of airflow (see Figure 1). We discuss how the challenges of obtaining reliable measurements required dedicated testing rigs – both in acoustic and fluid dynamics – and the need to benchmark potential changes to measurement methods with existing ISO standards.

2. METAMATERIAL DESIGN

The three metamaterials in Figure 1 were fabricated assembling multiple layers. Each layer consists of a 3 mm acrylic sheet, on which unit cells have been excavated in a repetitive pattern (e.g. by laser cutting). Each 2D unit cell is designed to create two paths in the final 3D geometry: a pass-through hole (typically in the center) and a labyrinthine path (typically on the outside). Figure 2 shows the two cases used in this study (a square and a hexagon), both inspired by optical lattices .

(a) (b)

Figure 2. The unit cells at the base of the metamaterials used in this study.

Different values of the perforation rate ß can be obtained by varying the design parameters of these cells: the radius r of the holes, the spacing a between the central hole and the labyrinth, the radius R of the holes in the labyrinth and the spacing $2b$ between one labyrinthine unit cell and next one. For the square cell (Figure 2a), which has one channel in the center and one on the outside of the same radius (i.e. $R = r$) – the perforation rate $ß_{Square}$ is:

$$\beta_S = \frac{\pi}{2} \cdot \frac{1}{\left(3 + \frac{a+b}{r}\right)^2} \leq 17.4\% \qquad (1)$$

The maximum value in equation (1) is $ß_{Square} \sim \pi/18$, which is obtained when a and b are much smaller than r. In this study, we will be using $ß_1 = 2.5\%$ (two 2 mm diameter holes) and $ß_2 = 6.2\%$ (two 4 mm diameter holes).

The hexagonal unit cell (Figure 2b) has two channels on the outside, for a total of three holes. For even comparison with the square cell, in this study we required the holes in the labyrinth to have the same area as the central hole (i.e. $R = 0.71\ r$), so that the perforation rate is:

$$\beta_H = \frac{2\pi r^2}{\frac{1}{2} \cdot \frac{12}{\sqrt{3}} \cdot h^2} = \sqrt{3}\frac{\pi}{3} \frac{1}{\left(1 + \sqrt{2} + \frac{a+b}{r}\right)^2} \leq 31.1\% \qquad (2)$$

where h is the apothem of the external hexagon. In this study, we used $ß_3 = 12.6\%$ for the hexagon shaped plate.

The acoustic insertion-loss of a hole in a perforated plate, at normal incidence, is due to two contributions: one viscous and one inertial [7]. Using the formulae in [7] we calculated that, for 18 mm thick acrylic plates, the acoustic impedance due to the first term dominates for smaller holes (e.g. microperforated panels), while the second wins as the holes become bigger (∅≥2 mm here) or at larger frequencies (Figure 3).

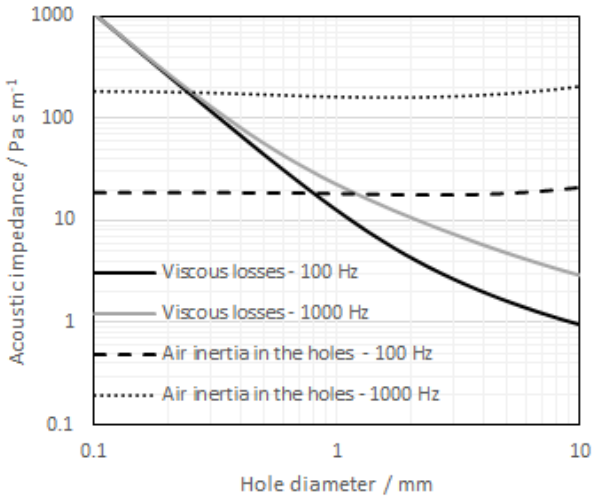

Figure 3. Acoustic impedance for a single hole in an 18 mm thick perforated plate of acrylic as a function of hole diameter and frequency.

(1)

According to Putra and Ismail [7], due to this complex interaction, a perforated plate allows through specific acoustic frequencies with a Lorentzian response, where the center frequency of the Lorentzian (i.e. the frequency with minimal insertion loss) is determined by the size of the holes, by the material of the plate (e.g. density ρ=1180 kg/m^3 and Young modulus E=3 GPa for acrylic) and by the thickness of the plate (t=18 mm for the square plates and t=24 mm for the hexagonal ones). For the 2D unit cells in Figure 2, the length of the (3D) labyrinthine path was designed to cancel the sound that would otherwise go through the central hole (i.e. like a half-wave plate in optics). At first approximation, therefore, the 3D structures originated by the unit cells in Figure 2 combine the broadband insertion loss given by the mass of the layered acrylic plates with the interferometric cancellation between the frequencies going through the two paths [8].

3. ACOUSTIC MEASUREMENTS

In the first instance, the transmission loss of each metamaterial plate was determined starting from the method described in ISO 7235 [6]. A speaker with a metamaterial casing (to remove back-emission – see [9]) was connected to a semi-open cylindrical tube, long enough to provide a planar wavefront for a propagating logarithminc sweep obtained using an arbitrary waveform generator (model RSDG2042X by RS-components) after amplification (model TPA3255 by Fosi audio). Both the speakers used in this part of the study (one for the range 80 Hz – 4000 Hz and one for the range 400Hz – 8000 Hz) had flat frequency response in the range used. ISO 7235 also prescribes to measure the insertion loss using an average over multiple microphone positions. When the measurements are taken in a test duct, the microphones need to be placed along the diagonal of the duct, so that their spacing is at least $\lambda/4$ for each 1/3rd-octave band. In the free-field case, ISO 7235 prescribes microphones to envelope the emission (like in ISO 3746).

In this study, we measured acoustic pressure in essentially free field conditions and calculated the insertion loss as the average over multiple measurements, taken at the exit of the tube with and without the metamaterial plate. The optimal number of microphones and their mutual positions were determined exploiting the traslational symmetry of the metasurface and the guidelines for reducing the number of microphones in acoustic holography (see [10] and references therein). We found that, while three positions were sufficient, they were not supposed to be along a line, so we took a) one measurement along the axis at distance X from the metasurface; b) one measurement off axis, also at a distance X; and c) one measurement off axis, at distance Y from the metasurface. While this method shows some similarities with ISO 7235:2003, a benchmark assessment of the transmission loss was needed.

Figure 3 The metamaterial panel mounted as secondary window by Anderson Acoustics, for the façade measurements.

This was performed by Anderson Acoustics, which used the procedure described in BS EN ISO 16283-3:2016 [11] tipically used for determine the acoustic properties of façade elements. The small square panel ($ß_1$=2.5%) was therefore mounted as secondary window in a standard frame, already containing a PVC window (see Figure 3) A hemi-dodecahedron loudspeaker (Norsonic 250) was used as pink-noise source outside, while a class I, calibrated microphone mounted on a tripod (Norsonic 140) was used to record inside. A potential sound flanking transmission path was identified, via the boiler outlet penetration (see Figure 3), but was neglected due to the mass of the external masonry wall. The window itself was standard thermal double glazing (28 dB Rw+Ctr estimated), with good perimeter seals. The measurement of sound reduction index $D_{ls,2m,nT}$ was performed in two conditions: with the PVC double glazed window open and with the PVC window partially open (i.e. with a 10 cm opening), with and without the metamaterial panel. The results of façade measurements (Figure 4) show a clear effect of the secondary window, whose impact increases with frequency, as expected from a mass-based solution. Once insertion loss was calculated, the results of façade measurements and laboratory tests were found to be similar for $ß_1$=2.5% (Figure 5). The laboratory method was then used for all the other plates (see Table 1).

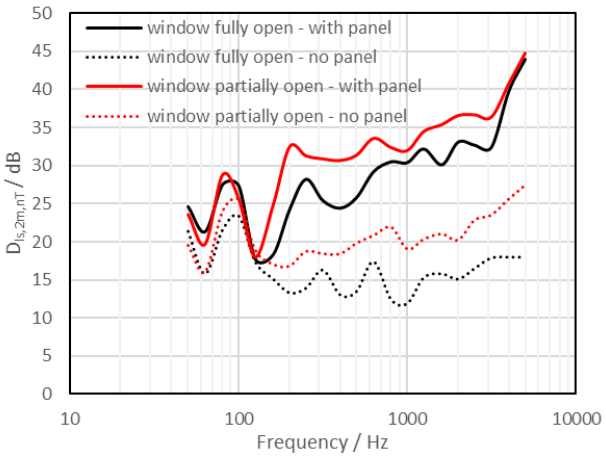

Figure 4 Results of the in-situ acoustic measurements made using the procedure in 16283-3:2016

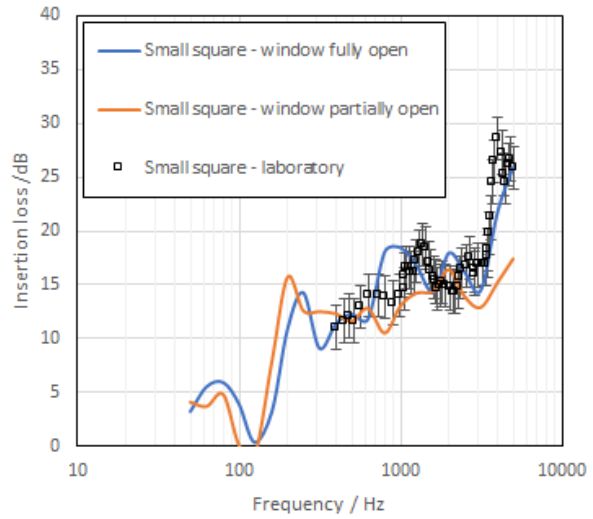

Figure 5 Results of the insertion loss measurements for the metamaterial plate with $ß_1$=2.5%: laboratory tests and façade measurements.

4. PRESSURE DROP MEASUREMENTS

These measurements were conducted using the procedure described in ISO 7235-2: each plate was inserted in the modified square section (hydraulic diameter: D_h = 200 mm) of a suction-type wind tunnel. As shown in Figure 6, each metamaterial plate was secured between two flanges with 12xM8 bolts with a central alignment pin to keep the individual layers in the correct relative orientation. A single-phase axial ventilation fan was positioned downstream of the plate, while upstream the section was extended for 12.2D_h with a square bell mouth to reduce entrance effects. For pressure drop measuring across the plate, two wall mounted pressure tapings were used, whose readings were acquired using an EvoScann P16-D differential pressure scanner. The reference pressure was taken as the ambient atmosphere and measured separately using a precision barometer.

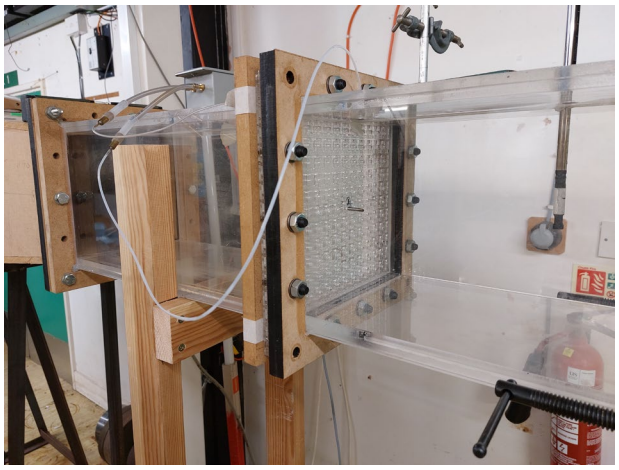

Figure 6 Measurement set-up at Sussex University.

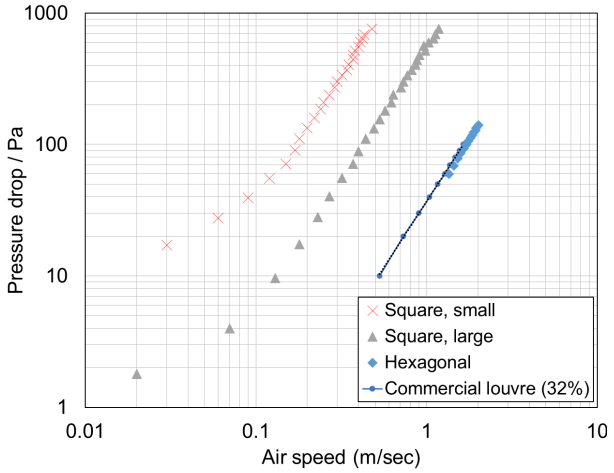

Figure 7 Pressure drop measurements for the three plates in this study and a commercial acoustic louvre.

Volumetric flow rate was measured using a Testo 405i thermal anemometer $10D_h$ from tunnel inlet perpendicular to the flow at the centre over a 30 second average. Given the low flow rate the calculated entrance length to develop a full laminar profile could be up to $1160D_h$ and so a uniform flow in the duct is assumed, and the volumetric flow rate calculated accordingly. Discrete measurement points of pressure drop were obtained by incrementing the fan speed by 100 rpm from 146 (min) to 2800 (max). Figure 7 reports the results of the pressure drop measurements, compared with the pressure drop from the datasheet of a commercial acoustic louvre (model: SlimShield SL-150 by IAC Acoustics, thickness: 150mm thick, weight: 30 kg m^{-2}, effective area: 32%).

5. DISCUSSION

The pressure drop curves in Figure 7 also show the result for a multi-linear fit., with the curve given by the power law:

$$\Delta P = K \cdot v^{\alpha} \tag{3}$$

A multi-linear fit (see Table 1) for velocities above 0.1 m/s gives $\alpha = 2.06 \pm 0.05$, in agreement with Bernoulli's expression which predicts $\alpha=2$ for purely inertial dependence. As shown in Figure 7, the trend deviates from the simple quadratic law for lower velocities, where viscous effects start to dominate, but above 0.1 m/s the constant K corresponds to the total pressure loss coefficient in ISO 7235. The fitting values – $K_1 = 3500 \pm 100$ kg m^{-2} s^{-1} (small squares) $K_2 = 560 \pm 60$ kg m^{-2} s^{-1} (large squares); and $K_3 = 32 \pm 4$ kg m^{-2} s^{-1} (hexagons) – also correspond to the value of the pressure drop at 1 m/s for the three panels. Figure 7 confirms that the pressure drop of the hexagonal panel corresponds to the one of the selected acoustic louvre.

The acoustic measurements show that, in the range 100 – 4000 Hz, the insertion loss of the three panels in Figure 1 follow a similar trend. In Figure 8, we fitted the data with the function [12]:

$$IL = 10 \cdot \log(1 + C \cdot (f - f_0)^{\gamma}) \tag{3}$$

and obtained a similar value for the power law $\gamma = 0.55 \pm 0.5$ where $\gamma = 1$ is expected for a standard mass-based insertion loss. The different values of the constants C (which is related to the surface density of the plate) and f_0 (which is related to the first vibrational thickness mode of each panel) can be found in Table 1.

Table 1. Fitting parameters for the metamaterial panels in Figure 1, as measured in laboratory.

	Small Square	Large square	Hexagon
α	2.02	2.02	2.12
K / kg m^{-2} s^{-1}	3500	560	32
ß / %	2.5	6.2	12.6
γ	0.60	0.50	0.55
C / $Hz^{-\gamma}$	0.38	0.30	0.05
f_0 / Hz	48	78	241
Thickness / mm	18	18	24
Density / kg m^{-2}	16.4	17.6	12.4

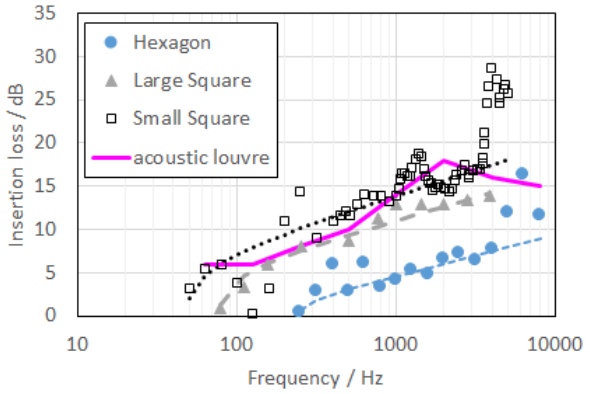

Figure 8 Insertion loss for the panels in Figure 1. The graph also reports the fitting curve from eq. (3) – see Table 1.

According to Figure 8, the acoustic performance of the louvre we selected for comparison falls within the insertion loss of the small square and of the large square. However, 3 dB are lost on average while passing from the Small Square to the large square panel and further 6 dB are lost – on average – while passing from the large square panel to the hexagonal one. This means that, while the hexagonal panel shows the same pressure drop as the selected acoustic louvre, its acoustic attenuation is lower. More work is therefore needed before this type of materials can substitute an acoustic louvre, adding superior acoustic performance to the advantages of less space occupied (24 mm instead of 150 mm) and lower weight (12.4 kg m^{-2} vs 30 kg m^{-2}).

6. CONCLUSIONS

In this work, we characterized three perforated labyrinthine metamaterials using ISO 7235-2. From the fluid dynamic point of view, we highlighted the challenges to run the prescribed measurements and described a dedicated experimental set-up that was built for this purpose at the University of Sussex. From the acoustic point of view, we described the modifications we applied to the standard for having reliable results and the benchmarking procedure followed by Anderson Acoustics using ISO 16283-3.

This study shows how acoustic metamaterials are approaching the performance of traditional solutions, using less space and weight. Like other studies focused on the application of acoustic metamaterials, this work highlighted a design space. Further studies, with more prototypes, will allow us to map the space ($ß$, ΔP, IL) and, consequently, to optimize the design of the panels presented here for specific needs in noise and ventilation management, like silencing heat pumps.

MULTI-DENSITY INVERSION CHARACTERISATION METHOD FOR FIBROUS MATERIAL

Andrea Santoni[1*] **Francesco Pompoli**[1] **Cristina Marescotti**[1]
Patrizio Fausti[1]
[1] Department of Engineering – University of Ferrara, Ferrara, Italy

ABSTRACT

This paper describes a novel inversion methodology for determining the transport parameters of the Johnson-Champoux-Allard (JCA) equivalent fluid model, developed to provide a quick and easy-to-implement characterisation tool. The proposed approach, based on an optimisation algorithm, requires only the experimental evaluation of the normal incidence sound absorption coefficient on fibrous material samples, prepared from loose fibres, at various compression ratios. Unlike existing inversion methods, the proposed approach links the variation of transport parameters to changes in the material's apparent density. The validation presented in the paper considers experimental data measured on two types of fibres: hemp fibres and glass fibres. Validation of the proposed method shows good agreement with well-established techniques and demonstrates its effectiveness across a broad range of fibrous materials.

Keywords: *acoustic optimization, inversion approach, material characterisation, fibrous material, sound absorption*

1. INTRODUCTION

This paper presents a methodological approach for characterising the transport parameters necessary to describe the acoustic behaviour of fibrous materials, using measurements of the normal incidence sound absorption coefficient, in accordance with the transfer function method described in ISO 10534-2. The main objective of this study is to develop a simple and reliable procedure for characterising fibrous materials and optimizing their density. This allows for a significant reduction in the prototyping phases typically required during the design and optimization of sound-absorbing panels. Although several inversion techniques have already been developed for the same purpose, the proposed method is the only one capable of correlating variations in transport parameters with material density. Conventional inversion techniques perform separate minimisations for each material or sample, followed by a possible data interpolation [1]. The developed inversion methodology is based on the semi-phenomenological model of Johnson-Champoux-Allard (JCA) [2, 3], which requires five transport parameters as input data to compute the complex density and the dynamic bulk modulus of an equivalent dissipative fluid: airflow resistivity σ, porosity ϕ, tortuosity α_∞, and the viscous and thermal characteristic lengths Λ and Λ'. This paper presents the main validation results of the proposed methodology by considering two types of fibres: hemp fibres and glass fibres. However, the proposed methodology is also applicable for the characterization of various fibrous materials, including both natural fibres and those traditionally used in acoustic applications, as detailed in reference [4].

2. MATERIALS AND METHODS

The proposed inversion characterization approach requires the experimental measurement of the normal incidence sound absorption coefficient $\alpha_{n,\mathrm{exp}}$, in accordance, for example, with ISO 10534-2, on samples at different compression ratios, which implies different bulk densities of the fibrous material. This methodology is partic-

ularly suitable for investigating loose fibres: the fibres are weighed and placed in the sample holder of an impedance tube, where they can be easily compressed using a movable rigid backing. An acoustically transparent mesh is used to restrain the sample and prevent sliding along the tube, as shown in Figure 1. The sound absorption coefficient $\alpha_{n,\mathrm{exp}}$ is then measured for different combinations of sample thickness h and density ρ of the samples. Increasing the compression ratio of the sample results in an increase in density and a reduction in open-cell porosity ϕ, which can be evaluated knowing the fibre's density ρ_s as:

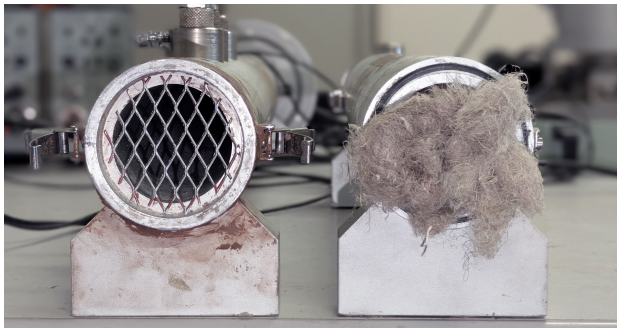

Figure 1. Loose hemp fibres and their installation in the plane wave impedance tube.

$$\phi = 1 - \frac{\rho}{\rho_s} \tag{1}$$

The material's airflow resistivity σ can be approximated as a function of porosity ϕ and the effective radius r_e of an equivalent 2D monodisperse fibrous medium [5]:

$$\sigma = \frac{\eta}{(2r_e)^2} \times \frac{\sqrt{1-(1-\phi)}}{0.21\left(\frac{0.71}{1-\phi} - 3\sqrt{\frac{0.71}{1-\phi}} + 3 - \sqrt{\frac{1-\phi}{0.71}}\right)} \tag{2}$$

The remaining transport parameters used in the JCA model can be expressed analytically as functions of porosity ϕ or the effective radius r_e. The latter is one of the design parameters of the multi-variable function to be optimized. The high-frequency limit of tortuosity α_∞ is computed using Archie's empirical law based on the material's porosity ϕ:

$$\alpha_\infty = \left(\frac{1}{\phi}\right)^{\beta} = \left(\frac{1}{\phi}\right)^{0.9574} \tag{3}$$

While the constant β could be generally treated as an additional design parameter of the multi-variable optimisation, dependent on the microstructural characteristics of the fibrous material, in this case a fixed value $\beta = 0.9574$ was adopted, independent of the fibres' effective radius r_e [5]. The scale-of-pores geometrical quantities representing viscous and thermal characteristic lengths are determined using empirical equations proposed by Pompoli [6]:

$$\Lambda = A_1 r_e (1-\phi)^{-A_2} \tag{4}$$

$$\Lambda' = A_3 r_e (1-\phi)^{-A_4} \tag{5}$$

The unknown coefficients A_i (with $i = 1, 2, 3, 4$) represent, along with the effective radius r_e, the optimisation design variables to be determined through a minimisation algorithm. This algorithm computes the normal incidence sound absorption coefficient using the JCA model $\alpha_{n,\mathrm{JCA}}$, expressing the transport parameters through Eqs. (1) to (5). The optimisation goal is to determine a set of design variables

$$x = \{r_e, A_1, A_2, A_3, A_4\},$$

that minimise an objective function $\mathcal{F}(x)$ defined in terms of the normalized difference between the experimental and JCA-predicted sound absorption coefficients:

$$\mathcal{F}(x) = \sum_{i=1}^{n} \frac{1}{n} \sum_{l=1}^{m} \frac{1}{m} \left|\alpha_{n,\mathrm{exp},i,l} - \alpha_{n,\mathrm{JCA},i,l}\right| \tag{6}$$

The minimisation of $\mathcal{F}(x)$ reduces the discrepancy between the experimental and JCA-predicted normal incidence sound absorption coefficients, summed over all the frequencies m and all the investigated densities n, by adjusting the design variables the transport parameters depend upon. The optimal solution can be computed using different solvers, while specifying search space boundaries, constraints of the optimization problem, and, in some cases, an initial guess for the design variables. The results presented in the following section were obtained using a MATLAB implementation of the proposed approach, employing a nonlinear programming solver. Further details on the implementation and the influence of different solvers are provided in reference [4].

3. EXPERIMENTAL RESULTS

This paragraph presents the main result validating the proposed methodology and assessing its reliability by analysing the accuracy of both the transport parameters obtained from the optimization process and the computed

normal incidence sound absorption coefficient. Two different types of fibres are considered: natural hemp fibres subjected to a carding process (HF_{car}) and traditional glass fibres (GF). The transport parameters obtained through the proposed approach, expressed as functions of material density, are compared with values derived from well-established inversion techniques based on measurements of a single sample [1]. Figure 2 compares the airflow resistivity curve $\sigma_{\text{opt.}}$, obtained using the proposed optimization methodology, with the target values σ_{target}, which are derived from the dynamic density of each sample, experimentally evaluated using the three-microphone transfer matrix method. This comparison follows the relationship proposed by Olny and Panneton [7]. The comparison highlights a good approximation of the target values within the investigated density range. The airflow resistivity curve evaluated for glass fibres (GF, shown on the right-hand side of Figure 2) interpolates the values determined at discrete densities considered in the experimental testing of the samples. For hemp fibres (HF_{car}, on the left-hand side of Figure 2), a slight deviation is observed between the airflow resistivity obtained as a function of density through the optimization algorithm and the discrete values derived from the measured complex density. The optimized airflow resistivity curve slightly overestimates the target values due to the simplifying assumptions in Eq. (2). The assumed condition of a two-dimensional unidirectional fibre orientation, with fibres aligned perpendicularly to the airflow, is generally met by traditional fibrous materials, where fibre dimensions and orientation can be designed, but it does not accurately represent the random distribution of natural fibres. Although tortuosity is not dependent on design variables,

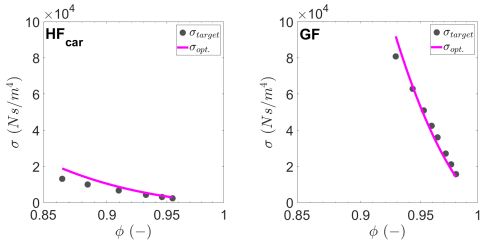

Figure 2. Comparison between the airflow resistivity curve obtained from the proposed method and the values derived from an experimental approach: left hemp fibres (HF_{car}), right glass fibres (GF).

since it is directly defined solely as a function of porosity, which varies with different compression ratios, Figure 3 compares the density-dependent curve $\alpha_{\infty,\text{opt.}}$, used in the adopted model, with the discrete values $\alpha_{\infty,\text{target}}$ obtained from a well-established inverse characterization approach. This comparison aims to demonstrate the reliability of Eq. (3) in estimating tortuosity as a function of porosity. For the HF_{car} material, the optimized tortuosity curve closely approximates the discrete tortuosity values. Although the two trends exhibit a slightly different slope, the values obtained from both approaches remain very close for any given porosity, especially considering the limited variation range of this parameter. For the GF material, the inverted values exhibit significant scatter, making it difficult to identify a clear trend. Nevertheless, the optimized curve remains within the range of scatter across the entire porosity range. Figure 4 presents sim-

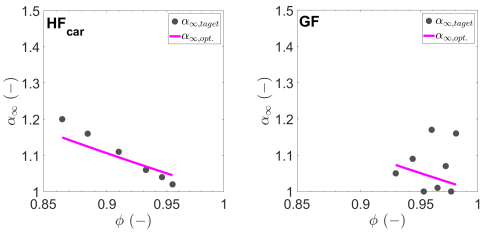

Figure 3. Comparison between the tortuosity curve obtained from the proposed method and the values derived from an experimental approach: left hemp fibres (HF_{car}), right glass fibres (GF).

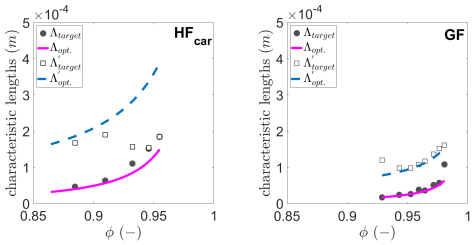

Figure 4. Comparison between the characteristic length curves obtained from the proposed method and the values derived from single inversions: left hemp fibres (HF_{car}), right glass fibres (GF).

ilar comparisons between the optimized $\Lambda_{\text{opt.}}$ and $\Lambda'_{\text{opt.}}$ curves obtained using the proposed methodology and the values of the characteristic lengths Λ_{target} and Λ'_{target} derived from traditional inversion methods. For both HF_{car}

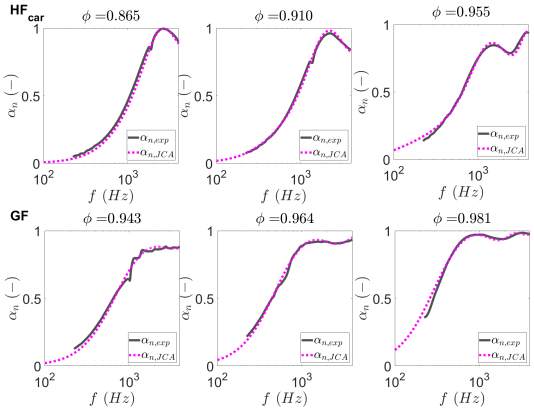

Figure 5. Comparison between the experimental and the JCA-predicted normal incidence sound absorption coefficients: top hemp fibres (HF_{car}), bottom glass fibres (GF).

and GF materials, the method provides results consistent with those obtained through single-sample inversion characterization. In general, with single inversions, the trend of the viscous characteristic length Λ as a function of porosity is more easily identifiable than that of the thermal characteristic length Λ'. Consequently, in the optimized curves, a higher consistency with the target values is observed for the viscous characteristic length Λ. Finally, the accuracy of the method is assessed by comparing the experimental normal incidence sound absorption coefficient with the frequency-dependent curves predicted through the JCA model by using the transport parameters characterized by the proposed methodology. Figure 5 illustrates this comparison for different porosity values, for both hemp and glass fibres. In both cases, the results highlight the high accuracy of the JCA model, confirming the reliability of the transport parameters determined using the proposed method.

4. CONCLUSIONS

This article presented an innovative, fast, and reliable methodology for characterising the macrostructural parameters of fibrous materials, providing a valuable tool for the design and optimisation of sound-absorbing panels while significantly reducing the prototyping phases. The proposed inverse characterization methodology integrates an optimization algorithm with the Johnson-Champoux-Allard (JCA) model and can be easily implemented in any acoustics laboratory, as it requires only the experimental measurement of the normal incidence sound absorption coefficient for samples with different densities. Unlike other inversion methods, the proposed approach allows for the correlation of transport parameter variations with the apparent density of the material. The results presented, referring to two different types of fibres, demonstrate that the methodology provides reliable estimates of the transport parameters essential for the acoustic optimisation of the material. The methodology can be applied to a wide range of fibrous materials used for acoustic applications and is particularly advantageous when working with loose fibres.

MEASUREMENTS AND SIMULATIONS OF A DOUBLE-POROSITY MATERIAL UNDER VARIATION OF PERFORATION PARAMETERS

Manuel Isenegger[1*] **Thomas Graf**[1] **Martin Sonderegger**[2]
Alexandre Bonnard[2] **Silja Fleischli**[2] **Armin Taghipour**[1]

ABSTRACT

Porous materials are used for sound absorption, typically either without perforation or with an additional perforated faceplate for aesthetic, structural, or protective purposes. While the influence of perforated faceplates on sound absorption is well documented, the impact of perforations within the sound absorber itself on its acoustic performance remains insufficiently understood. The present study focuses on this research gap. The material used was made from recycled PET fibers. In a first step, the absorption coefficient of 41 small-scale samples ($20\,\mathrm{cm}$x$20\,\mathrm{cm}$) with varying perforation geometries, sizes, and percentages was measured in an impedance tube. Based on these results, the perforation parameters were selected for a set of larger panels: geometry (circles and triangles), perforation size ($1.13\,\mathrm{cm}^2$-$36.19\,\mathrm{cm}^2$), and perforation percentage (1-32%). The sound absorption coefficient of these panels was measured in a reverberation room. Statistical analysis showed that the absorption coefficient α primarily decreased with increasing perforation percentage. Secondary influences were also observed, such as perforation size. Additional numerical simulations with the boundary element method provided further insight into the acoustic performance of perforated sound-absorbing panels as room dividers. This research provides important insights into the role of double-porosity designs in creating effective acoustic absorber panels.

1. INTRODUCTION

There are several types of acoustic absorption, one important type being porous absorption [1]. This kind of absorber can be made from a plethora of materials with inherently different structural, and acoustic characteristics. Acoustic properties for most porous materials can be partially controlled in manufacturing, in its simplest form by varying the thickness of a panel.

The influence of additional perforations on the acoustic properties have been investigated analytically [2, 3], numerically [4, 5] and empirically [6, 7]. Investigations focused on the material near a rigid backing and in most cases under orthogonal sound incidence. Few publications have empirically analyzed the acoustic properties under diffuse sound incidence, and no publication was found addressing the behavior in the absence of a rigid backing. In addition, no publication investigating the acoustic separation performance of perforated sound absorber panels is known to the authors.

This publication investigates the effects of perforation parameters on acoustic properties of a $24\,\mathrm{mm}$ absorber material, made from polyethylene terephthalate (PET) fibers. A first measurement campaign was conducted in the impedance tube with 41 different sample configurations measured at two different heights. A second measurement campaign was conducted in the reverberation room with 16 different perforation configurations.

Furthermore, numerical analysis using the Boundary Element Method (BEM) compared the acoustic separation capabilities of a perforated and unperforated absorbing and reflective panels in a free-field environment.

2. METHODS

2.1 Material production and perforation

The absorber panel, EchoBoard® 24mm, is made out of 100% PET felt with a percentage of recycled fibers. The fibers are needled into a uniform fleece during production. Subsequent heat and pressure treatment creates a structurally stable sound absorber with a density of $3600\,\mathrm{g/m^2}$. The panels measure $2400\text{x}1800\text{x}24\,\mathrm{mm}^3$ and are available in various colors. They are further processed on a computerized numerical control (CNC) cutting plotter, which offers a wide range of design options with different knives and cutting angles. The perforations are precisely cut using vector data and an oscillating knife. After cutting, the parts are pushed out by hand. The choice of perforation designs is limited by the structural properties of the material and the production technique. Large perforation percentages reduce the structural stability of the panel. Another design limit comes from the CNC blades. The smallest cutting radius is $5\,\mathrm{mm}$ and the distance between individual cuts may not fall below $5\,\mathrm{mm}$.

2.2 Absorption measurements

2.2.1 Impedance tube

Absorption measurements in the impedance tube were conducted at Lucerne University of Applied Sciences and Arts in Horw, based on ISO 10534-2:2023 [8]. The available measurement device allows for a measurement range between $100\,\mathrm{Hz}$ and $3200\,\mathrm{Hz}$. Samples were cut to a size of $201\,\mathrm{mm}$ side length, so they could be mounted flush/snugly to the walls of the impedance tube with minimal compression of the material. The software m|abstube by Müller-BBM Acoustic Solutions GmbH (version 2.75.8515.38409) was used for measurement and evaluation. Temperature, atmospheric pressure and relative humidity were recorded before every measurement session. Only one sample per perforation configuration was measured.

An initial set of 41 perforations with varying perforation parameters (size, percentage, geometry, regularity) was chosen and samples produced (see Fig. 1). The choice of perforations was based on the results of prior research on double-porosity materials. Measurements of the samples were made with $0\,\mathrm{cm}$ and $4\,\mathrm{cm}$ distance to the rigid backing. In total, 84 different configurations were measured in the impedance tube.

Statistical analysis was implemented with the Pearson correlation coefficient (PCC) between numerical independent variables (total perforation area, individual perforation size) and dependent variables (absorption coefficient) per frequency bin. For categorical variables, analysis of covariance (ANCOVA) has been used with the Holm-Bonferroni correction method.

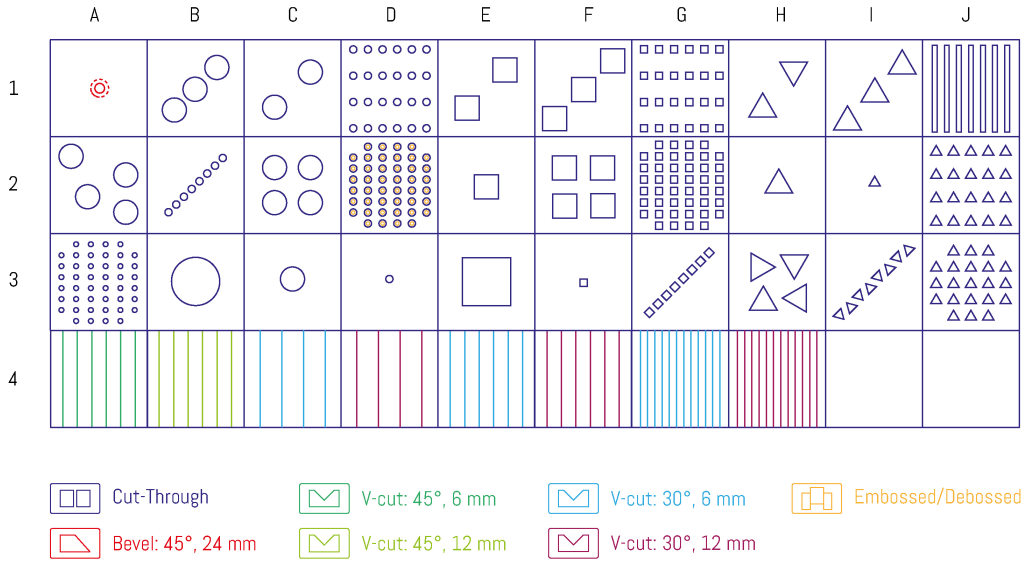

Figure 1: Perforation configurations for impedance tube measurements

2.2.2 *Reverberation room*

Absorption measurements in the reverberation room were conducted at Lucerne University of Applied Sciences and Arts in Horw, based on ISO 354:2003 [9]. The properties of the reverberation room conform to the requirements defined by the standard. The measured absorber panels, in their intended application as room dividers, were considered to be discrete objects, according to section 6.2.2.2 of the mentioned ISO standard. All panels were hung at a single position in the center of the reverberation room. Temperature and relative humidity were measured before both the measurement of the empty room and the measurement of the absorber panels. The interrupted noise method was applied using two loudspeaker positions and ten microphone positions. The software Nor850 measurement system by Norsonic (version 3.2) was used for measurement and evaluation.

The perforation parameters for this second measurement campaign were informed by the results of the impedance tube measurements and adapted dynamically after each measurement iteration. In addition, the availability of three panels resulted in restrictions on the amount and type of consecutive perforations. Ultimately, the three $2400\,\mathrm{mm}$ by $1800\,\mathrm{mm}$ panels were increasingly perforated in 5 consecutive steps before being measured, resulting in 16 configurations (including the unperforated panels). The parameter variation was on perforation geometry (circles, squares, and triangles), perforation size (S = 1.13-36.19 cm^2), and perforation percentage (ϕ_p = 1-32%). The scenarios measured in the reverberation room are visualized in Fig. 2. A description of the relevant perforation parameters can be found in Tab. 1.

For better comparability the sound absorption coefficient has been used, rather than the equivalent sound absorption area, as would be required by ISO 354 for discrete objects.

The following dependent variables have been used for the statistical analysis:

- Absorption coefficient according to ISO 11654 [10]
- Mean value of the (low-frequency) third-octave frequency bands $50-160\,\mathrm{Hz}$
- Mean value of the (mid-frequency) third-octave frequency bands $200-1250\,\mathrm{Hz}$
- Mean value of the (high-frequency) third-octave frequency bands $1600-5000\,\mathrm{Hz}$

2.3 Numerical simulations

The software COMSOL Multiphysics® was used to compute the average sound pressure level (SPL) in a $1\,\mathrm{m}^3$ volume behind $2 \times 2\,\mathrm{m}^2$ panels in free space. The panels were $24\,\mathrm{mm}$ thick and modeled with infinite through-air resistance, enabling the use of surface impedance models. BEM-models were employed in the frequency domain to calculate the sound pressure distribution around the panels for both normal and $45°$ incident plane waves.

Two types of perforated panels were analyzed: one with 400 circular holes, each with a radius of $1.5\,\mathrm{cm}$, and another with 900 circular holes, each with a radius of $1.0\,\mathrm{cm}$. Both panels have the same front surface area of $3.72\,\mathrm{m}^2$ exposed to the incident plane wave in a free field environment. The perforated panels, including the boundary areas of the holes, were assigned an absorption coefficient of $\alpha = 0.8$ or 0.0 (sound-hard) across all frequencies. These two perforated panels were compared to a solid, non-perforated panel, which was also assigned an absorption coefficient of $\alpha = 0.8$ or 0.0.

The absorption coefficient α corresponds to a surface impedance Z for normal incidence, which is determined using the following equation:

$$Z = Z_0 \frac{1+R}{1-R} \tag{1}$$

where $Z_0 = \rho_A \cdot c_A = 413 Pa \frac{s}{m}$ is the characteristic acoustic impedance of air, and $R = \sqrt{1-\alpha}$ is the reflection factor of the panel. The impedance Z serves as the boundary condition in the numerical simulation of plane waves interacting with the panels.

3. RESULTS

3.1 Measurements

3.1.1 Impedance tube

The measurement result of the unperforated panel, as a reference, can be seen in Fig. 3.

The m|abstube software outputs 127 frequency bins from 85 to $3118 Hz$. Measuring 84 configurations, this results in 10'668 data points from the impedance tube measurements. For analysis, the delta between absorption coefficients of the perforated samples and the unperforated sample has been calculated.

Through statistical analysis, different trends could be detected. At $0\,\mathrm{mm}$ distance to the rigid backing, increasing the total perforation area significantly reduced the absorption coefficient across all frequencies. At high frequencies, a larger perforation size led to a significant reduction in absorption, while no such effect was observed below $1800\,\mathrm{Hz}$. The perforation geometry had only a minor impact: although all geometries reduced absorption, the "Circle" shape caused the least reduction and the "V-Cut" the most. The distribution of the perforations showed only weak effects on absorption.

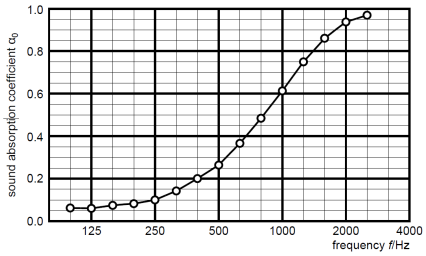

Figure 3: Sound absorption coefficient of the unperforated panel according to ISO 10534-2

At a distance of $40\,\mathrm{mm}$ to the rigid backing, a slight, non-significant increase in absorption was observed around $1\,\mathrm{kHz}$ with increasing total perforation area, while frequencies above and below exhibited a strong and significant reduction. For frequencies above $800\,\mathrm{Hz}$, an increase in perforation size resulted in significant, yet mixed effects depending on the frequency band. Above $170\,\mathrm{Hz}$, the geometry significantly affected absorption: in particular, "V-Cuts" and "Slits" caused the strongest reductions (-0.036 and -0.1, respectively). Once again, the perforation distribution had only weak effects.

3.1.2 Reverberation room

The measurement result of the unperforated panel, as a reference, can be seen in Fig. 4.

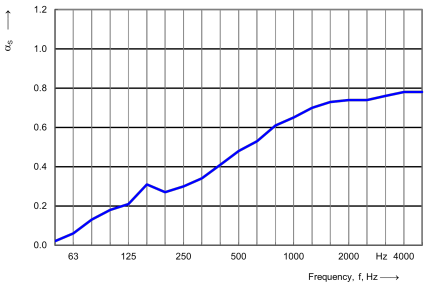

Figure 4: Sound absorption coefficient of the unperforated panel according to ISO 354

With the tested configurations, the primary dependence for all dependent (absorption) variables is the perforation percentage, where higher perforation percentages generally yield lower absorption values for all frequency regions. See Fig. 5 for detailed results.

Furthermore, the absorption dependency on perforation size was evaluated on a subset, including only perforation percentages $4, 16$ and 32% and the $circle$ perforation geometry. See Fig. 6 for detailed results.

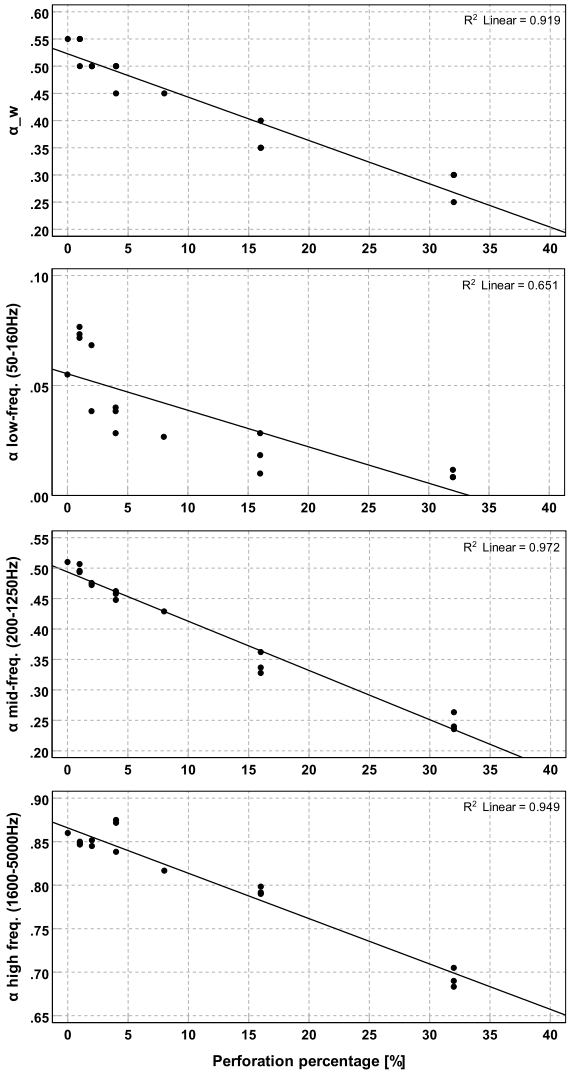

Figure 5: Absorption values plotted against perforation percentage with linear regression and R^2 values

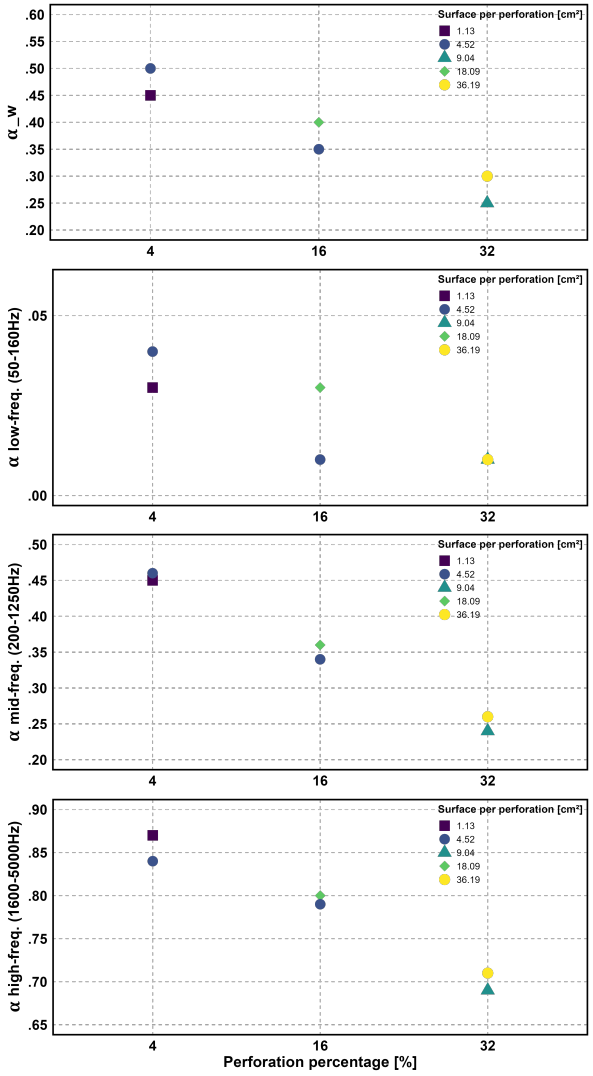

Figure 6: Absorption values plotted against perforation size

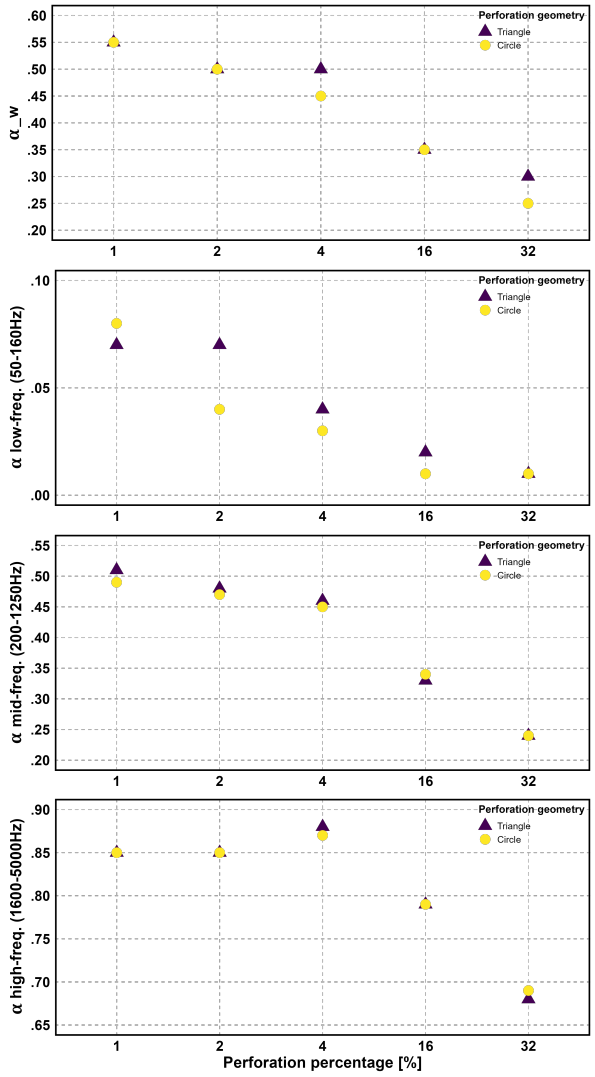

Figure 7: Absorption values plotted against perforation geometry

Finally, the trend influenced by the perforation geometry was analyzed on the subset, including perforation percentages $1, 2, 4, 16$ and 32% and the *circle* and *triangle* geometries. See Fig. 7 for detailed results.

3.2 Numerical simulations

Fig. 8 depicts the SPL at three frequencies in two planes orthogonal to the panel, centered at the panel's midpoints. A plane wave propagates under normal incidence from below. The figure highlights interference patterns resulting

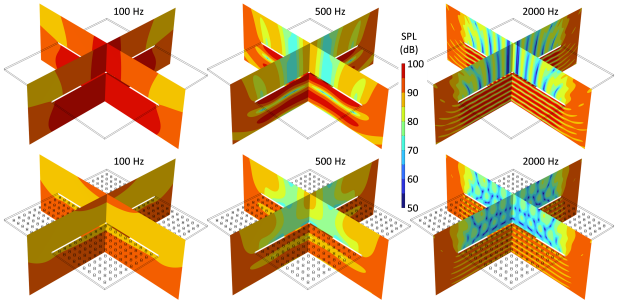

Figure 8: SPL around porous panels (200 x 200 x 2.4 cm^3) under normal incidence of a plane wave (93 dB) from below, at frequencies of 100, 500, and 2000 Hz. Top row: Unperforated panel with an overall absorption coefficient $\alpha = 0.0$. Bottom row: Perforated panel with 400 holes, each with a radius of 1.5 cm, and an overall absorption coefficient $\alpha = 0.8$.

from reflections below and diffraction above the panels. Sound attenuation is observed above both the unperforated, sound-hard panel (top row of Fig. 8) and the perforated panel with 400 holes, which has an absorption coefficient of $\alpha = 0.8$ (bottom row of Fig. 8). The average SPL values for both panels are summarized in Tab. 2. The perforated panel with 900 holes is not included in the table, as its values closely resemble those of the perforated panel with 400 holes.

Table 2: SPL averaged above the panels at three different frequencies. Row 1 and row 4 correspond to the settings of Fig. 8. Row 2 is an unperforated panel with $\alpha = 0.8$. Row 3 is a perforated, sound-hard panel with 400 holes.

SPL, averaged over $1m^3$ volume			
	$100Hz$	$500Hz$	$2000Hz$
unperforated, $\alpha = 0.0$	94.3 dB	80.7 dB	73.2 dB
unperforated, $\alpha = 0.8$	90.8 dB	77.5 dB	69.3 dB
perforated, $\alpha = 0.0$	91.8 dB	82.6 dB	75.9 dB
perforated, $\alpha = 0.8$	90.1 dB	78.5 dB	71.4 dB

At higher frequencies, both the perforated and unperforated panels exhibit greater sound attenuation compared to lower frequencies. This behavior is expected for the un-

perforated panel due to reduced diffraction at higher frequencies; however, it also applies to the perforated panel. Notably, the unperforated, sound-hard panel is less effective as a room divider across all frequency ranges compared to the perforated panel with an assigned absorption coefficient. Furthermore, the difference in sound attenuation between the perforated and unperforated panels, both with assigned absorption coefficients, is minimal. This finding indicates that a perforated, acoustically absorbing panel can serve as an effective alternative to an unperforated absorbing panel as a room divider, particularly when aesthetic design considerations are important.

4. DISCUSSION

The measurements both in the impedance tube and the reverberation room revealed a general dependence of the sound absorption coefficient on the perforation percentage, where the sound absorption decreases with a higher perforation percentage ϕ_p. This result is in accordance with results found in other research, which showed a decrease of absorption in macro-perforated materials with low flow resistivity.

The dependence of the absorption coefficient on perforation size S in the impedance tube is different from the observed dependence in the reverberation room. Especially with large perforations, high frequency sound waves were reflected from the rigid backing in the impedance tube. In the reverberation room, the opposite tendency occurred, where larger perforation sizes (under the same perforation percentage and geometry) showed better absorption. No explanation for this behavior in the diffuse sound field could be found by the authors.

Neither in the impedance tube, nor in the reverberation room, did the sound absorption reveal a strong dependence on perforation geometry.

Numerical simulations show, that for low frequencies (100 Hz) the perforated, sound-absorbing panel has the best sound reduction performance, followed by the unperforated, sound-absorbing panel, the perforated, sound-hard panel and the unperforated, sound-hard panel. For mid (500 Hz) and high (2000 Hz) frequencies, the best sound reduction is achieved by the unperforated, sound-absorbing panel, followed by the perforated, sound-absorbing panel, the unperforated, sound-hard panel and the perforated, sound-hard panel.

Intuitively, these simulation results are rather surprising. One might assume that a perforated panel allows more sound to pass through its openings, making it less effective at blocking sound compared to an unperforated panel, regardless of their sound absorption capabilities. However, the combination of diffracted sounds from the edges and the perforations, which are additionally dampened by the sound absorbing material, result in a lower SPL, compared to a sound-hard, unperforated panel. However, the best overall sound reduction capabilities are achieved by the sound absorbing, unperforated panel.

4.1 Limitations and further research

Measurements of the flow resistivity and further metrics of porous materials (porosity, tortuosity, viscous and thermal characteristic length, etc.) have not been carried out here, but would allow for analytical results to confirm and complement the empirical data and adjust the numerical simulations to the investigated material.

Different sample thicknesses or even different materials would complement the empirical data and allow for a more complete representation of the mechanisms governing the absorption behavior of double-porosity models.

The numerical simulations of double-porosity panels in a free-field environment give a first indication on their possible performance as room dividers. However, BEM-models do not account for sound transmission, which is typically higher for sound-absorbing, porous materials than for sound-hard, non-porous materials. Absorption values found in real materials should be used in further simulations. In addition, room dividers are typically used in rooms with reflective surfaces. Further simulations in typical office environments incorporating sound transmission of the simulated materials would yield a more accurate representation of the sound reduction possibilities of porous materials.

With regards to a demand for flexible room dividers in office environments, more research on the sound absorption behavior of free-standing panels and curtains, in general, and the potential of double-porosity materials, in particular, is needed. Especially, perforations with gradually varying size, as described in [3] and [11], are a promising approach to aesthetically pleasing and highly functional sound absorbers and room dividers.

5. CONCLUSIONS

This study provides valuable insights into the acoustic performance of double-porosity materials, specifically recycled PET fiber absorbers, under varying perforation parameters. Through a combination of impedance tube measurements, reverberation room testing, and numerical sim-

ulations, we observed that increasing the perforation percentage generally led to a reduction in sound absorption. Secondary effects, such as perforation size, also played a minor role in modifying the absorption coefficient.

The results suggest that careful tuning of perforation geometry, size, and percentage can help optimize the trade-off between aesthetic, structural, and acoustic performance in architectural applications.

Future research should explore the transfer of effects, which are well-known in impedance tube measurements, to free-standing configurations.

6. ACKNOWLEDGMENTS

The authors would like to thank the head and staff of the testing laboratory at HSLU for providing access to their measurement infrastructure.

Additional thanks go to Tobias Banz, Mario Rölli, Gregor Heini, Lél Bartha, and Samuel Ulrich for their help in transporting the large panels after each perforation step.

A NOVEL ALGORITHM FOR ESTIMATING BIOT PARAMETERS IN ACOUSTIC SIMULATION OF FIBROUS MATERIALS BASED ON RAW MATERIAL COMPOSITION

ABSTRACT

For an automotive trim supplier, the production of material and component samples for certification and acceptance by vehicle manufacturers is an expensive and time-consuming task. Circumventing the need for these via pure simulation still requires the correct determination of Biot parameters, which can be carried out via batch samples. However, this is a complex task that is sensitive to both the measurement and the condition of the samples. Any discrepancies will propagate through the simulation and will create uncertainties in the results.
This paper describes a novel approach, called *Genetic*, in which the empirical calculation of Biot parameters of fibrous composites is based purely on the blended mixture of fibre types. This technique was the culmination of an extensive measurement and characterisation campaign on a wide selection of fibre types and is part of an ongoing investigation into the use of data science applications to enhance internal methodologies.
The next phase of the project is focused on porous media such as foams.

1. INTRODUCTION

Fibrous materials are increasingly used in automotive NVH (Noise, Vibration, and Harshness) packages due to their effective absorption and insulation properties. Their adoption by OEMs is also driven by sustainability concerns, such as the integration of recycled PET fibers. However, optimizing their acoustic performance requires a precise understanding of their physical properties, commonly referred to as Biot parameters. These parameters are divided into two groups: (i) transport parameters of an equivalent fluid model (e.g., JCA or JCAL), governing viscous and thermal dissipation within porous media, and (ii) solid-phase elastic parameters, which are more relevant for structural interactions but less critical for absorption-related applications [1].
As an automotive NVH trim supplier, it is essential to have access to accurate material properties, not only the Biot parameters but also key acoustic performance metrics such as normal incidence absorption, diffuse field absorption, and transmission loss of flat (planar) samples. These properties are crucial for material selection, simulation and validation. In practice, they are particularly relevant in (i) Request for Quotation (RFQ) phases to ensure compliance with OEM constraints (e.g., thickness, weight); (ii) acoustic simulations, for improved numerical models; and (iii) manufacturing and innovation, guiding material validation and optimization.
Currently, material properties of flat samples are obtained through two primary strategies:

- Material databases: These databases compile data for flat samples of various thicknesses (e.g., 5 to 30 mm), including Biot parameters, normal incidence and diffuse field absorption, as well as transmission loss. However, this approach is

constrained by predefined thicknesses and material types, requiring large-scale material manufacturing and extensive experimental campaigns, making it a less efficient solution.

- Acoustic simulation: Which are based on characterized Biot parameters for a given material composition. While simulations offer a way to estimate material performance, uncertainties may arise due to variations in sample conditions, material characterization methods, and acoustic models. These can be mitigated by validating simulation results against experimental data.

A more elegant approach is to estimate the so called composite "acoustic transport parameters" directly from fundamental raw material characteristics, such as fiber radius (µm) or fineness (dTex, mass in grams per 10 km of fiber), together with composition ratios, thereby enabling a predictive framework that reduces the dependency on costly experimental measurements.

Several methods have been proposed for computing the transport parameters of fibrous media from fiber properties. Publications relating to this computation are listed in the references [2] to [8] but can be categorized into:

- **Empirical regression models** – deriving parameters from experimental datasets (e.g., Biboud et *al.* (2024) on nylon fibers [4].
- **Analytical (or geometrical) models** – developing theoretical formulations based on fiber structures [5]-[6].
- **Hybrid numerical/semi-analytical models** – identifying transport parameters that best fit numerical simulations data [3].
- **Compression-based estimation models** – considering the effect of compression on initial material properties [7].

Pompoli and Bonfiglio [2] adapted existing analytical formulations and validated them through numerical simulations for parallel fiber structures. However, these formulations require the effective radius of the fibrous raw materials, which are typically not provided in manufacturing material data sheets. Santoni et *al.* [8] further utilized these formulations to study recycled fiber mixtures, but they required airflow resistivity and porosity of loose fibers as input parameters to inversely determine the effective radius of each kind of fiber in the composition.

While previous studies primarily focus on validating transport parameter estimations against normal incidence absorption measurements, automotive applications require a broader scope. Diffuse field absorption is an important parameter that must be considered for real-world applications.

In this paper, we propose a novel algorithm, developed through an extensive experimental campaign, to estimate JCA parameters from known manufacturing parameters: fineness in dTex and composition ratios. This algorithm provides reliable input data for simulating impedance tube absorption, diffuse field absorption, and sound transmission loss across a wide range of fibrous material densities and compositions.

Section (2) describes the materials and methods used, including fiber compositions and experimental approaches. Section (3) presents the results, validating the *Genetic* algorithms through various acoustic measurements. Finally, Section (4) concludes the paper, highlighting the practical applications of the proposed methods.

2. MATERIAL AND METHODS

2.1 Fiber Material

A group of fibrous flat samples were studied, each composed from five different mixtures. Each mixture consisted of a fixed number of fiber types with corresponding mass participation ratios. The raw loose fibers were classified as: PET (polyethylene terephthalate), Cotton fibers and PET-CoPET bicomponent fibers, where the core was PET and the surface was CoPET in a 1:1 ratio. The fineness of the input raw materials, expressed in dTex, was also known.

The fiber mixture compositions were selected based on several factors, including acoustic performance, mechanical requirements, processing constraints and cost. The chosen materials spanned a wide range of fiber fineness, with a variation factor of approximately 40 between the finest and coarsest fibers, depending on the mixture.

For each mixture, flat samples were fabricated with varying thicknesses and densities using the Hot Molding Process (HMP). During this process, the CoPET component melts, bonding the remaining fibers. The resulting samples, across all mixtures, have thicknesses ranging from 5 mm to 35 mm, with surface mass varying from approximately 490 to 2700 g/m².

2.2 Method

2.2.1 Experiment approaches

This study aims to define the transport parameters of fibrous materials through experimental data. Various tests were conducted on flat samples, including: (i) identification of transport parameters, (ii) measurement of Normal

Incidence Sound Absorption, (iii) measurement of Diffuse Field Absorption, and (iv) evaluation of Sound Transmission Loss.
From the identified transport parameters, linear or power curve fitting relationships were established. Once the transport parameters were determined, the acoustic performance of the materials were predicted using the "Johnson-Champoux-Allard" (JCA) equivalent fluid model, which requires five key parameters: open porosity ϕ, airflow resistivity σ, tortuosity α_∞ , viscous characteristic length Λ, thermal characteristic length Λ' [1].

2.2.2 Material characterization and acoustic measurements

Diffuse field sound absorption coefficient measurements were conducted on flat samples (1 m × 1.2 m) using a small reverberation room (6.44 m³), known as the Alpha Cabin. Ideally, according to ISO 354 [9], a large reverberation room (>180 m³) and a sample size of 12 m² are required. However, the reduced-size cabin allows for quick measurements with a 1.2 m² sample, which is commonly used in the automotive industry by both suppliers and OEMs.
Transmission Loss measurements were performed using the two-room method, where the flat sample was placed on a 0.9 mm-thick steel plate. Sound intensity and pressure measurements were taken in an anechoic room and a reverberation room, respectively [10].
For each flat sample (1.2 m²), three circular specimens (Ø100 mm) were extracted for airflow resistivity (AFR) measurements [11]. Subsequently, normal incidence sound absorption measurements [12] were carried out using Ø45 mm samples cut from the Ø100 mm specimens, ensuring that measurements were taken from the same locations, see Fig. 1.

Figure 1. Impedance tube samples (Ø45 mm) extracted from AFR samples (Ø100 mm) for different mixtures.

JCA transport parameters were identified for material samples with varying densities and thicknesses but the same raw material composition (i.e., the same mixture). For each given mixture, a minimization-based inversion was performed, simultaneously processing all samples of that mixture to fit the data from AFR and normal incidence sound absorption measurements [13]-[14].

3. RESULTS

3.1 Empirical regression models

Once the JCA parameters were identified for each sample, the datasets were used to develop empirical regression models. For each of the five transport parameters, a unique formulation was derived and validated for all mixtures. These algorithms, referred to as "*Genetic*", enable the calculation of transport parameters for any fibrous material using typical manufacturing inputs, based on linear or power-law relationships: fiber fineness (dT, in dTex), the mixing ratio (ω_i, the weight ratio of each fiber type to the total material weight) and the sample bulk density (ρ). The selection of these input parameters was physically justifiable, as the physical properties of fibrous materials depend on their microstructural characteristics [3]. Specifically, fiber diameters and their distribution can be represented by dT and ω_i, while the bulk density ρ or the open porosity ϕ represents the volume of solid or air within the material.
When the material density increases, the air volume inside decreases, leading to a linear relationship between porosity and density:

$$\phi = 1 - C_1\rho \quad (1)$$

The tortuosity can then be determined using Archie's law:

$$\alpha_\infty = (1/\phi)^\gamma \quad (2)$$

where γ is a constant depending on the material's microstructure [2]. Both constants, C_1 and γ, were determined to fit the identified porosity and tortuosity for the fibrous materials under study.
Previous work [3] has shown that at a fixed density ρ, the airflow resistivity σ is inversely related to fiber diameters. In other words, the thermal permeability k_0, which is linked to the airflow resistivity of porous material via the dynamic viscosity of air η, is inversely related to the total fiber length L_f per cubic meter. This can be formulated using dT,

ω_i and ρ. The thermal permeability can finally be computed as:

$$k_0 = \eta/(f_1 \sum_1^n(\omega_i/dT_i)) \quad (3)$$

where f_1 is a 4th-order polynomial function of density ρ and n is the number of fiber populations in the composition.
Fig. 2 shows a strong correlation between the *Genetic* algorithm (Eqn. 3) and the experimental results for static permeability, which is made non-dimensional using the standard fiber mean diameter d_{ref}.

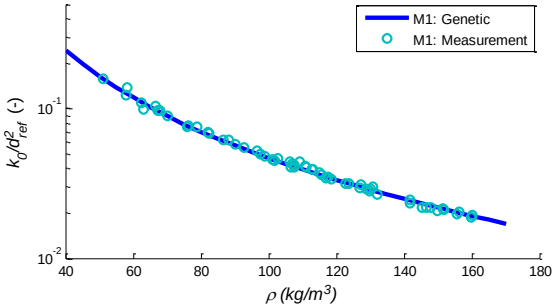

Figure 2. Static Permeability: Correlation between the experimental function (*Genetic* algorithm) and measurements for material mix M1.

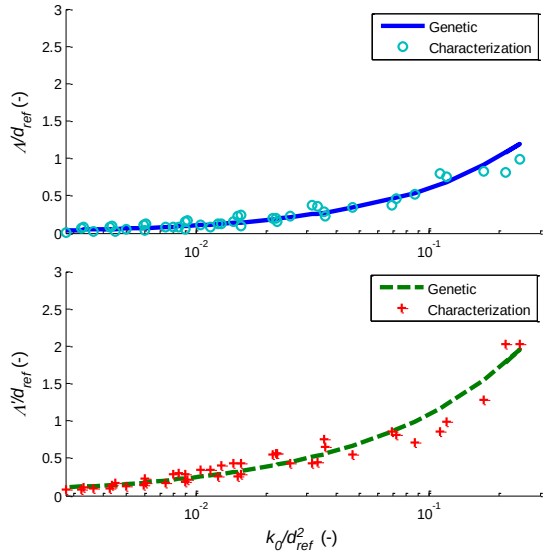

Figure 3. Characteristic Lengths: Correlation between the *Genetic* algorithm and material characterization through global minimization inversion for material mix M1.

As shown in the Eqn. 3, the static permeability k_0 (or airflow resistivity $\sigma = \eta/k_0$), one of the primary factors influencing porous media, contains all the material input parameter information. To put it another way, the two remaining parameters, the characteristic lengths, can be estimated from k_0 using power law functions of the following form:

$$\Lambda = C_2 {k_0}^{C_3}; \qquad \Lambda' = C_4 {k_0}^{C_5} \quad (4)$$

where the coefficients C_i can be easily identified to fit the characterized transport parameters. Using these formulations, good agreement is shown in Fig. 3, with a correlation factor R^2 greater than 0.93 for both characteristic lengths.
For user-friendliness, the *Genetic* functions have been integrated into a transfer matrix simulation tool (internally named PROTEIN), as shown in Fig. 4. Using basic raw material information (e.g., surface mass, thickness, and material composition), the acoustic properties of porous materials can be quickly estimated.

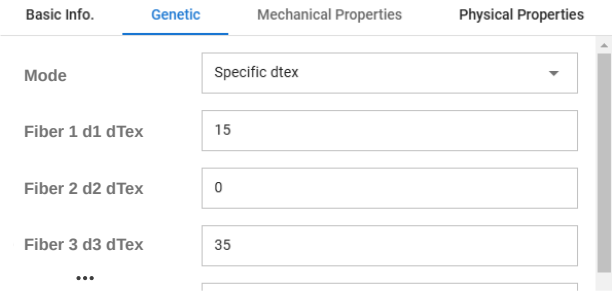

Figure 4. Implementation of a *Genetic* Algorithm model in a Transfer Matrix Simulation (TMM) tool called PROTEIN.

The *Genetic* functions were validated through material performance tests.
Firstly, normal incidence sound absorption, simulated using the Transfer Matrix Method (TMM), showed good correlation with the measurement results, as demonstrated in Fig. 5 for material Mix1. This strong correlation with impedance tube measurements was expected, as such results are commonly used as input for material characterization through inversion approaches. However, this study also presents a strong correlation with diffuse field sound absorption measurements using the Alpha Cabin, as shown in Fig. 6, providing a comprehensive evaluation of absorption performance.

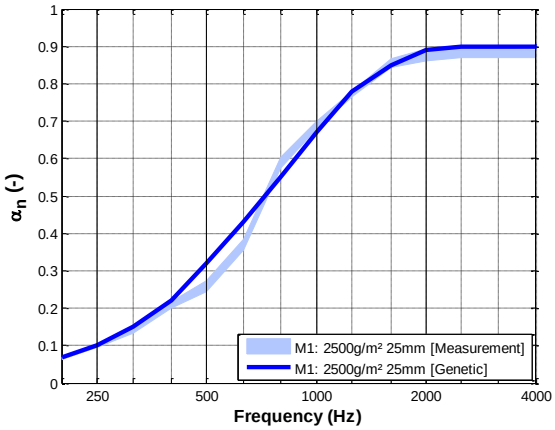

Figure 5. Normal Incidence Sound Absorption: Correlation between the *Genetic* algorithm and impedance tube measurements for material mix M1 at a thickness of 25 mm and density $\rho = 100$ kg/m^3.

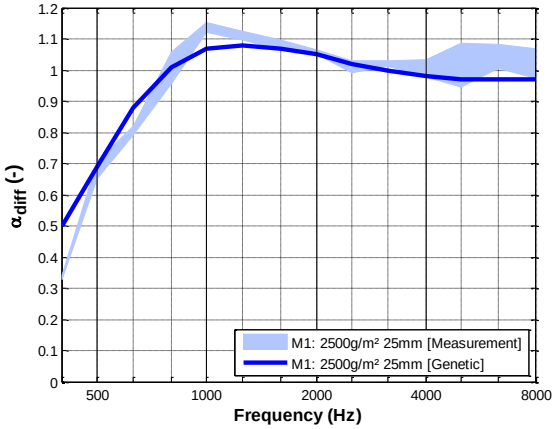

Figure 6. Diffuse Field Sound Absorption: Correlation between the *Genetic* algorithm and Alpha Cabin measurements.

Alpha Cabin measurements are typically problematic for their round robin reliability and the results were not as clear due to the more complex reverberant sound field. However, such a good level of correlation has not previously been reported.

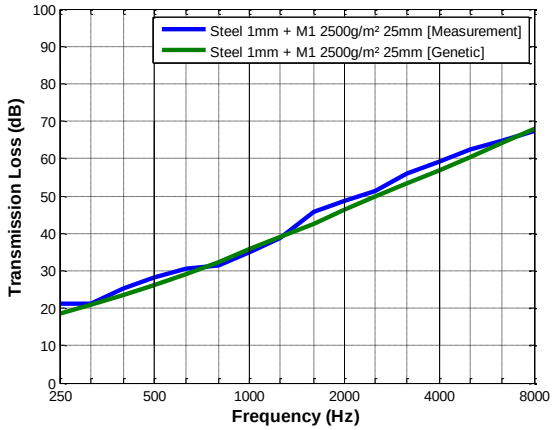

Figure 7. Sound Transmission Loss: Correlation between the *Genetic* algorithm and coupled reverberation/anechoic measurement results.

Additional validation of the *Genetic* algorithms was carried out through Sound Transmission Loss measurements in a simple system where the fibrous flat sample was placed on a steel plate. A good agreement was observed between the simulation and measurement results. Both the acoustic simulations for the Alpha Cabin and Transmission Loss were performed with diffuse field excitation using the Transfer Matrix Method [1].

4. CONCLUSIONS

In this paper, the JCA transport parameters of fibrous materials were computed from raw material information using functions derived from experimental results for various fibrous material compositions and a wide range of bulk densities. These algorithms, referred to as "*Genetic*" were validated, not only through normal incidence sound absorption, but also via diffuse field excitation for both sound absorption and transmission loss. The algorithms were implemented in an internal simulation tool, enabling rapid estimation of acoustic performance based on material typical inputs. This approach has proved useful for several applications, including RFQ responses, manufacturing support and innovation. Future work will involve extending this approach to polyurethane foam materials.

ABSTRACT

This paper introduces a modal decomposition method to retrieve the effective fluid parameters of a sample of anisotropic porous material from multi-modal reflection and transmission coefficients measured in a squared impedance tube. The approach extends on traditional impedance tube methods to include higher-order modes, allowing to characterize the test specimen for plane-wave and multi-modal reflection and transmission coefficients. The proposed formulation uses a modal expansion of the sound pressure and normal particle velocity in the tube, reducing the problem to a system of two differential equations for the components of the pressure and particle velocity projected over the normal modes. The system is solved analytically, which leads to an exact algebraic formulation of the reflection and transmission matrices. An inverse problem is further formulated to infer the bulk modulus and density tensor coefficients of the anisotropic specimen. The method is evaluated numerically on a synthetic anisotropic sample of known porous properties.

1. INTRODUCTION

Acoustic wave propagation and viscothermal dissipation of acoustic energy in porous media can be described macroscopically by an equivalent fluid model, which requires the knowledge of several pore parameters. Although some of the pore parameters can be measured directly, these methods require specialized equipment and are often difficult to perform. In this context, inverse characterization methods that are based on the inversion of the scattering matrix [1] are particularly interesting, as they allow to recover the dynamic density and bulk modulus of the equivalent fluid from simple measurements of the normal incidence reflection and transmission coefficients [2]. If the material is homogeneous and isotropic, these two frequency-dependent fluid parameters are also sufficient to determine the six Johnson-Champoux-Allard-Lafarge (JCAL) parameters [3] that control the dissipation of acoustic energy in the medium.

However, most porous materials are anisotropic and exhibit different properties along orthogonal directions known as the *principal directions*. Specifically, the influence of anisotropy translates into a full symmetric density tensor (in place of a scalar), drastically increasing the number of effective fluid parameters required to describe the medium.

Several studies extended the inversion procedure presented in [2] to characterize anisotropic materials. However, most of these studies are based on simplified assumptions on the nature of anisotropy; e.g., anisotropic materials with principal directions belonging to the layer plane interface [4, 5], or two-dimensional anisotropic materials with principal directions arbitrarily tilted with respect to the reference coordinate system [6–8]. To the authors' knowledge, the only study that characterizes fully anisotropic porous materials in three dimensions (i.e., anisotropic porous materials having principal axes tilted in *a priori* unknown directions) is due to Terroir et al.

[9], who described a general method to recover the effective fluid parameters and the orientation of the material's principal directions from knowledge of the reflection and transmission coefficients at six angles of incidence. Experimental validation was recently achieved by Cavalieri et al. [10], who measured the normal incidence reflection and transmission coefficients of six samples of glass wool cut in six different orientations in an impedance tube.

Following a different approach, the present study exploits the concept of modal decomposition [11–14] to elicit higher order modes in the tube and characterize the test specimen for plane-wave and multimodal reflection and transmission coefficients. Such approach is significant in that it allows to retrieve the effective fluid parameters and the principal directions without changing the orientation of the sample in the tube.

2. THEORY

Consider a layer of homogeneous anisotropic porous material with thickness L, bulk modulus B and density tensor $\boldsymbol{\rho}$ mounted in a rectangular impedance tube with cross section $\mathcal{A} = [0, w_1]\times[0, w_2]$. In the reference coordinate system $(\mathrm{O}, \mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3)$ with position coordinates (x_1, x_2, x_3), its boundaries are defined by the equations $x_3 = 0$ and $x_3 = L$. We further assume that the density tensor $\boldsymbol{\rho}$ is symmetric; that is $\boldsymbol{\rho}^\top = \boldsymbol{\rho}$, where $^\top$ denotes non-conjugate transposition. In particular, the orthonormal coordinate system $(\mathbf{e}_\mathrm{I}, \mathbf{e}_\mathrm{II}, \mathbf{e}_\mathrm{III})$ of the principal directions of the layer can be defined so that the density tensor is diagonal in this system; that is $\boldsymbol{\rho} = \boldsymbol{\rho}^* = \mathbf{diag}(\rho_\mathrm{I}, \rho_\mathrm{II}, \rho_\mathrm{III})$, where ρ_I, ρ_II and ρ_III are the principal densities and the superscript * designates the diagonal tensor. In the reference coordinate system, the density tensor reads $\boldsymbol{\rho} = \mathbf{R}_{rot}\boldsymbol{\rho}^*\mathbf{R}_{rot}^\top$, where $\mathbf{R}_{rot} = \mathbf{R}_3(\theta_\mathrm{III})\mathbf{R}_2(\theta_\mathrm{II})\mathbf{R}_1(\theta_\mathrm{I})$ is the rotation matrix between the two coordinate systems, with $\mathbf{R}_1$, $\mathbf{R}_2$ and $\mathbf{R}_3$ being elementary rotation matrices and θ_I, θ_II and θ_III the roll, pitch, and yaw angles, respectively.

2.1 Formulation

Outside the layer (i.e., for $x_3 < 0$ and $x_3 > L$), the sound pressure and particle velocity fields $(p, \mathbf{v})$ are governed by the equations of mass and momentum conservation:

$$\mathrm{div}(\mathbf{v}) = \frac{\mathrm{i}\omega}{B_0}p, \tag{1a}$$

$$\mathrm{i}\omega\mathbf{v} = \frac{1}{\rho_0}\nabla p, \tag{1b}$$

where B_0 and ρ_0 are the bulk modulus and scalar density of air, respectively, $\omega = 2\pi f$ is the angular frequency and the time dependency $\mathrm{e}^{-\mathrm{i}\omega t}$ is omitted. Similarly, the sound pressure and particle velocity fields in the layer (i.e., for $0 < x_3 < L$) verify

$$\mathrm{div}(\mathbf{v}) = \frac{\mathrm{i}\omega}{B}p, \tag{2a}$$

$$\mathrm{i}\omega\mathbf{v} = \mathbf{h}\nabla p, \tag{2b}$$

where $\mathbf{h}$ is the symmetric inverse density tensor and reads

$$\mathbf{h} = \begin{pmatrix} h_{11} & h_{12} & h_{13} \\ h_{12} & h_{22} & h_{23} \\ h_{13} & h_{23} & h_{33} \end{pmatrix} = \begin{pmatrix} \mathbf{h}_\perp & \mathbf{h}_3 \\ \mathbf{h}_3^\top & h_{33} \end{pmatrix}, \tag{3}$$

where $(h_{11}, h_{12}, h_{13}, h_{22}, h_{23}, h_{33})$ are the individual inverse density tensor components, $\mathbf{h}_\perp$ is a 2×2 matrix, and the subscript $\perp$ designates the transverse components. This tensor is diagonal in the orthonormal coordinate system of the principal directions of the layer.

As the tube is of constant cross-section, the boundary condition at its walls read:

$$\mathbf{n}^\top\mathbf{v} = 0, \tag{4}$$

where $\mathbf{n} = [\mathbf{n}_\perp; 0]$ is the normal vector. The system of differential equations (2a) and (2b) can be rewritten as follows

$$\begin{cases} h_{33}\dfrac{\partial p}{\partial x_3} = -\mathbf{h}_3^\top\nabla_\perp p + \mathrm{i}\omega v_3, \\ \dfrac{\partial(\mathrm{i}\omega v_3)}{\partial x_3} = -\omega^2 B^{-1}p - \mathrm{div}_\perp(\mathbf{h}_\perp\nabla_\perp p + \mathbf{h}_3\dfrac{\partial p}{\partial x_3}), \end{cases} \tag{5}$$

with the boundary condition

$$\mathbf{n}_\perp^\top(\mathbf{h}_\perp\nabla_\perp p + \mathbf{h}_3\frac{\partial p}{\partial x_3}) = 0. \tag{6}$$

Outside the layer, the problem reads

$$\begin{cases} (\Delta + \omega^2\rho_0 B_0^{-1})p = 0 \\ \mathbf{n}_\perp^\top\nabla_\perp p = 0 \end{cases} \tag{7}$$

2.2 Modal decomposition

The pressure p and the axial particle velocity v_3 are now expressed as the superposition of an infinite number of transverse modes $\psi_b(x_1, x_2)$, $b \in \mathbb{N}$:

$$p(x_1, x_2, x_3) = \sum_{b\in\mathbb{N}} \psi_b(x_1, x_2)p_b(x_3), \tag{8a}$$

$$\mathrm{i}\omega v_3(x_1, x_2, x_3) = \sum_{b\in\mathbb{N}} \psi_b(x_1, x_2)U_b(x_3), \tag{8b}$$

where

$$\psi_b(x_1,x_2) = g_m^{(w_1)}(x_1) g_n^{(w_2)}(x_2), \tag{9}$$

with $g_m^{(w)}(x) = \sqrt{\varepsilon_m/w}\cos(m\pi x/w)$, $\varepsilon_0 = 1$ and $\varepsilon_{n>0} = 2$. The modal functions $\psi_b(x_1,x_2)$, $b \in \mathbb{N}$, are the eigenfunctions obeying the transverse eigenproblem $\mathrm{div}_\perp(\nabla_\perp\psi_b) = -\gamma_b^2\psi_b$, with the boundary condition $\mathbf{n}_\perp^\top\nabla_\perp\psi_b = 0$. They form a complete orthonormal basis for the inner product $(f|g) = \int_{\mathcal{A}} \overline{f} g \mathrm{d}S$; i.e., $(\psi_a|\psi_b) = \delta_{ab}$. The modal decompositions in Eqs (8a) and (8b) can also be written as [15]

$$p = \boldsymbol{\psi}^\top \mathbf{p}, \tag{10a}$$

$$\mathrm{i}\omega v_3 = \boldsymbol{\psi}^\top \mathbf{u}, \tag{10b}$$

where $\mathbf{p}$, $\mathbf{u}$ and $\boldsymbol{\psi}$ are column vectors.

Equation (5) is now projected on the orthonormal basis $(\psi_a)_{a\in\mathbb{N}}$

$$\begin{cases} h_{33}p_a' = -\sum_{b\in\mathbb{N}} C_{ab}p_b + U_a, \\ U_a' = -\omega^2 B^{-1} p_a - \sum_{b\in\mathbb{N}} (D_{ab}p_b + \tilde{C}_{ab}p_b'), \end{cases} \tag{11}$$

where $C_{ab} = (\psi_a|\mathbf{h}_3^\top\nabla_\perp\psi_b)$, $\tilde{C}_{ab} = (\nabla_\perp\psi_a|\mathbf{h}_3\psi_b)$ and $D_{ab} = (\nabla_\perp\psi_a|\mathbf{h}_\perp\nabla_\perp\psi_b)$. This yields a system of differential equations in $\mathbf{p}$ and $\mathbf{u}$

$$\begin{pmatrix} h_{33}\mathbb{1} & \mathbb{0} \\ -\tilde{\mathbf{C}} & \mathbb{1} \end{pmatrix} \begin{pmatrix} \mathbf{p}' \\ \mathbf{u}' \end{pmatrix} = \begin{pmatrix} -\mathbf{C} & \mathbb{1} \\ -\omega^2 B^{-1}\mathbb{1} + \mathbf{D} & \mathbb{0} \end{pmatrix} \begin{pmatrix} \mathbf{p} \\ \mathbf{u} \end{pmatrix}, \tag{12}$$

which can be solved using several numerical strategies [14]. Equation (12) can be rewritten as

$$\mathbf{p}'' + \frac{1}{h_{33}}(\mathbf{C} - \tilde{\mathbf{C}})\mathbf{p}' + \left(\frac{\omega^2}{h_{33}B}\mathbb{1} - \frac{1}{h_{33}}\mathbf{D}\right)\mathbf{p} = 0. \tag{13}$$

3. ANALYTICAL SOLUTION

In this study, we consider the particular case in which the principal directions are rotated only around the longitudinal axis $\mathbf{e}_3$ of the tube (i.e., in the transverse plane). In this case, $\mathbf{h}_3 = \mathbf{0}$ so that $\mathbf{C} = \tilde{\mathbf{C}} = \mathbb{0}$ and Eq. (13) reads

$$\mathbf{p}'' = \mathbf{M}\mathbf{p}, \tag{14}$$

where $\mathbf{M} = -h_{33}^{-1}(\omega^2 B^{-1}\mathbb{1} - \mathbf{D})$. The matrix $\mathbf{M}$ is diagonalized according to

$$\mathbf{M} = \mathbf{Q}\boldsymbol{\Gamma}^2\mathbf{Q}^{-1}, \tag{15}$$

where $\boldsymbol{\Gamma}^2$ is the diagonal matrix of eigenvalues and $\mathbf{Q}$ is the associated matrix of eigenvectors. This yields the general solution:

$$\mathbf{p}(x_3) = \mathbf{Q}\mathrm{e}^{\boldsymbol{\Gamma}x_3}\mathbf{Q}^{-1}\mathbf{c}^+ + \mathbf{Q}\mathrm{e}^{\boldsymbol{\Gamma}(L-x_3)}\mathbf{Q}^{-1}\mathbf{c}^-. \tag{16}$$

Let us now consider an incident plane wave propagating towards the layer from the left (i.e., in the region $x_3 < 0$). The multimodal solution to the differential equation (7) reads

$$\mathbf{p}(x_3 < 0) = \mathrm{e}^{\rho_0\mathbf{Y}_c x_3}\mathbf{p}^{(i)} + \mathrm{e}^{-\rho_0\mathbf{Y}_c x_3}\mathbf{p}^{(r)}, \tag{17}$$

where $\mathbf{p}^{(i)}$ is a vector containing the modal components of the incident wave at $x_3 = 0$, $\mathbf{p}^{(r)} = \mathbf{R}\mathbf{p}^{(i)}$ contains the modal components of the reflected wave with $\mathbf{R}$ the reflection matrix, and

$$\mathbf{Y}_{cab} = \frac{\mathrm{i}}{\rho_0}\sqrt{\omega^2\frac{\rho_0}{B_0} - \gamma_a^2}\delta_{ab} \tag{18}$$

is the characteristic admittance of the waveguide. In the region $x_3 > L$, the transmitted sound pressure reads

$$\mathbf{p}(x_3 > L) = \mathrm{e}^{\rho_0\mathbf{Y}_c(x_3-L)}\mathbf{p}^{(t)}, \tag{19}$$

where $\mathbf{p}^{(t)} = \mathbf{T}\mathbf{p}^{(i)}$ contains the modal components of the transmitted wave with $\mathbf{T}$ the transmission matrix.

The scattering matrix can be written as

$$\mathbf{S} = \begin{pmatrix} \mathbf{R} & \mathbf{T}' \\ \mathbf{T} & \mathbf{R}' \end{pmatrix}, \tag{20}$$

where $\mathbf{R}$ and $\mathbf{T}$ are the reflection and transmission matrices for a right-going incident wave (i.e., propagating towards the layer from the left), and $\mathbf{R}'$ and $\mathbf{T}'$ are the reflection and transmission matrices for a left-going incident wave (i.e., propagating towards the layer from the right). Since $\mathbf{h}_3 = \mathbf{0}$, we have $\mathbf{R} = \mathbf{R}'$ and $\mathbf{T} = \mathbf{T}'$. The matrices $\mathbf{R}$ and $\mathbf{T}$ are obtained from the continuity of the pressure and normal component of the particle velocity at $x_3 = 0$ and $x_3 = L$, and read:

$$\begin{cases} \mathbf{R} = (\mathbf{Y}_c + \mathbf{Y}_0)^{-1}(\mathbf{Y}_c - \mathbf{Y}_0), \\ \mathbf{T} = \mathbf{T}_r(\mathbb{1} - \mathbf{H}\mathbf{R}_l\mathbf{H}\mathbf{R}_r)^{-1}\mathbf{H}\mathbf{T}_l, \end{cases} \tag{21}$$

where $\mathbf{Y}_0 = \tilde{\mathbf{Y}}_c(\mathbb{1} - \mathbf{H}\mathbf{R}_r\mathbf{H})(\mathbb{1} + \mathbf{H}\mathbf{R}_r\mathbf{H})^{-1}$ is the admittance matrix at $x_3 = 0$, $\tilde{\mathbf{Y}}_c = h_{33}\mathbf{Q}\boldsymbol{\Gamma}\mathbf{Q}^{-1}$, $\mathbf{H} = \mathbf{Q}\mathrm{e}^{\boldsymbol{\Gamma}L}\mathbf{Q}^{-1}$, $\mathbf{R}_r = \mathbf{R}_l = (\tilde{\mathbf{Y}}_c + \mathbf{Y}_c)^{-1}(\tilde{\mathbf{Y}}_c - \mathbf{Y}_c)$, $\mathbf{T}_r = (\mathbf{Y}_c + \tilde{\mathbf{Y}}_c)2\tilde{\mathbf{Y}}_c$, and $\mathbf{T}_l = (\mathbf{Y}_c + \tilde{\mathbf{Y}}_c)2\mathbf{Y}_c$.

4. NUMERICAL RESULTS

The validity of the method is examined numerically on a synthetic anisotropic sample with known porous properties. Based on the reflection and transmission matrices derived in Sect. 3, the procedure described in [9] and [10] is applied to retrieve the bulk modulus B and the coefficients h_{11}, h_{12}, h_{22} and h_{33} of the inverse density tensor. The results were not available at the time of writing.

5. CONCLUSION

A multimodal method for the characterization of anisotropy in porous media has been formulated. The method is based on the inversion of the scattering matrix to retrieve the effective fluid parameters from multimodal reflection and transmission coefficients measured in an impedance tube.

COMBINING ABSORPTION COEFFICIENT MEASUREMENTS IN REVERBERATION ROOMS WITH DIFFERENT VOLUMES

Heinrich Bietz[1*] **Volker Wittstock**[1]
[1]Physikalisch-Technische Bundesanstalt, Germany

ABSTRACT

One way to reduce the uncertainty of absorption coefficient measurements in reverberation rooms could be the combination of measurement results from rooms with different volumes. To investigate this, a round robin was conducted at PTB using two regular reverberation rooms and five rooms of 50 m³ volume which belong to the building acoustic test stands of PTB. The diffusivity was adjusted following the procedure described in ISO 345. Eight samples were measured in each room employing different staff and equipment, so the results can be regarded as statistically independent. The results show that the "50 m³" rooms deliver reasonable absorption coefficients over a wide frequency range, but in most cases fail at frequencies below 250 Hz. Furthermore, the approach taken to reduce the uncertainty by combining results from two rooms with different volumes provided promising results. One drawback certainly is the small database produced by the round robin; further research is necessary to support the findings presented in this article.

Keywords: *absorption coefficient, reverberation room, room volume, uncertainty, ISO 354.*

1. INTRODUCTION

The measurement of absorption coefficients α_s in reverberation rooms with a volume of at least 150 m³ (200 m³ for newly built rooms) is standardized in ISO 354 [1] at frequencies between 100 Hz and 5 kHz. ISO 12999-2 [2] describes a procedure to assess the uncertainty of these measurements. The uncertainty here is defined as the standard deviation of reproducibility σ_R, which is expressed as a linear relation:

$$\sigma_R = m\alpha_S + n \quad (1)$$

where the slope m and the offset n are frequency dependent constants which had been derived by evaluating a large amount of round robin data from the last decades [3]. The uncertainty can also be expressed as relative uncertainty in decibels, which may be useful for practical applications:

$$u(L_{\alpha s}) = 10\,\mathrm{lg}(1 + \sigma_R/\alpha_s)\ \mathrm{dB} \quad (2)$$

The resulting relative uncertainties are shown in Fig. 1 [4]. They increase at both ends of the frequency range, whereas the influence of the absorption coefficient is much more pronounced at higher frequencies.

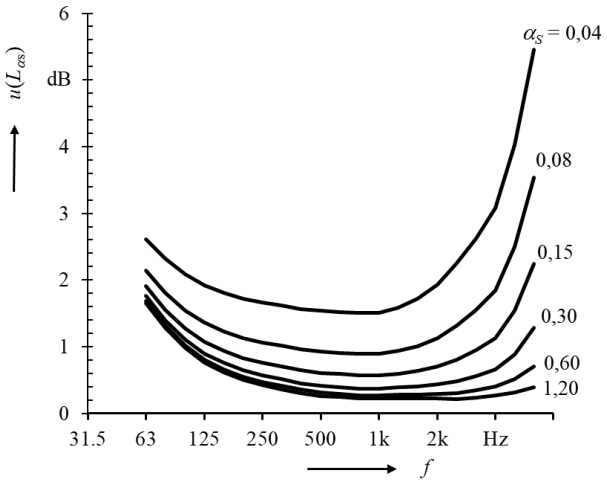

Figure 1. Relative uncertainty of α_s.

For certain applications, e.g. prediction of the speech transmission index (STI), an extension of the frequency range up to 10 kHz is sometimes desirable. As the large uncertainties at high frequencies are commonly attributed to air absorption, one possible way of improvement could be the use of a reverberation room with a smaller volume. If i.e. a room volume of 50 m³ is chosen, this would in theory cause a frequency shift of the figures *m* and *n* from Eqn. (1) and thus also of the relative uncertainty in Fig. 1. For low frequencies, modal density is assumed as the governing factor. We then get

$$\frac{f_2}{f_1} = \frac{\sqrt[3]{V_1}}{\sqrt[3]{V_2}} = 2^{2}/_{3} \text{ when } \frac{V_1}{V_2} = \frac{200}{50} = 2^2, \quad (3)$$

so *m* and *n* would be shifted upwards by two 1/3 octave bands. For high frequencies, air absorption is assumed as the dominant factor influencing the uncertainty. With

$$\frac{4m_1V_1}{\alpha_1 S_1} = \frac{4m_2V_2}{\alpha_2 S_2} \quad (4)$$

where $m_{1/2}$, are the air damping constants in rooms with volumes $V_{1/2}$, $\alpha_{1/2}$ the absorption coefficient of the samples of size $S_{1/2}$ to be measured and the assumption

$$\frac{m_1}{m_2} = \left(\frac{f_1}{f_2}\right)^2, \quad (5)$$

we finally get

$$\frac{f_2}{f_1} = 2^{1}/_{3} \quad (6)$$

under the assumption that the absorption coefficient α to be measured does not change at high frequencies. As a result, the uncertainty at high frequencies would be shifted by one 1/3 octave band to higher frequencies. It must be pointed out that these considerations include numerous simplifications, and the uncertainty is probably influenced by further effects. For the first investigation concerning these aspects, an internal round robin was conducted at PTB.

2. INTERNAL ROUND ROBIN

2.1 Scope

For the round robin, five rooms, all parts of building acoustics test stands, were used. The room volume ranged from 49 m³ to 58 m³. Eight different test samples were examined. In each room, these samples were measured by a different member of the working group staff with mostly different equipment. In addition, one member of the staff measured the samples in all test rooms, and in two reverberation rooms with 204 m³ and 237 m³ volume. For the measurements in the "50 m³" rooms, the area (or number) of the samples was scaled down accordingly, resulting in a sample area of about 4 m².

2.2 Test samples

As the uncertainty is directly dependent on the absorption coefficient, the samples were selected to cover a wide range of absorption coefficients. Tbl. 1 gives an overview of the employed samples. "Poly" refers to absorbers consisting of six rectangular metal frames with a thickness of 100 mm, and filled with a polyester fleece, which has absorbent properties like mineral wool. One side is open, and one side is covered with coated chipboard, which has a thickness of 8 mm for three boxes and 16 mm for the remaining boxes. These boxes were used to create six different absorber setups. For three setups, the boxes were laid out in a 2 x 3 configuration to create an absorber area. For the other three setups, three individual elements, each made of two boxes standing together upright, were realised.

Table 1. Absorbers used in internal round robin

Absorber	Description	Area in m²
WG 35	200 mm mineral wool with wooden frame, like reference absorber suggested by WG 35	4,3
Carpet	Carpeted floor 10 mm thick	3,9
Poly 1	Flat, all open sides upwards	4,3
Poly 2	Flat, 3 open sides and 3 8 mm chipboards upwards	4,3
Poly 3	Flat, all chipboard sides upwards	4,3
Poly 4	Single elements, both outward sides open	4,3
Poly 5	Single elements, 1 outward side open and 1 outward side 8 mm chipboard	4,3
Poly 6	Single elements, both outward sides chipboard	4,3

2.3 Preparation of the test rooms

The test rooms were fitted with diffusers following Annex A of ISO 354. Here, using a broadband absorber, an increasing number of diffusers is employed until a certain saturation of the absorption coefficient is realised. All absorbers that may have been present have been removed beforehand. Polycarbonate sheets with an area of 1,48 m x 0,9 m and 4 mm thickness were used as diffusers. A 100 mm thick, porous absorber with an area of 4,5 m² has been used for the diffusivity test. The rooms were finally fitted with five or 6 absorbers, making up (double-sided) between 15 % and 18 % of the room surface. An example for the qualification test is shown in Fig. 2.

ISO 354 specifies an upper limit for the equivalent absorption area A_1 of the empty room. Fig. 3 shows A_1 for rooms 1-5. The red line is the upper limit as specified by ISO 354 with frequency and magnitude adjusted for 50 m³ room volume. While three rooms stay well under the maximum limit, Room 3 exceeds the limits at some frequencies, and Room 1 is far beyond. Room 1 has some features different from all other rooms: The floor is fitted with a floating screed, the brickwork walls are not painted, and an opening to accommodate windows or glazings is covered with a chipboard laminated with lead. Room 2 and Room 3 are source and receiving room of a building acoustics test stand where a plastered lime brick wall (440 kg m²) was installed in the test opening. It could not be clarified why Room 3 has a significantly higher A_1. It was decided to nevertheless include all 5 rooms in the round robin for the moment to see if the results show noticeable deviations.

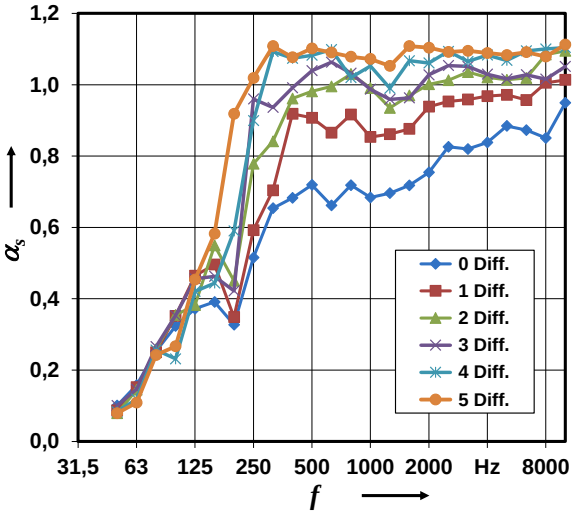

Figure 2. Example of a diffusivity test.

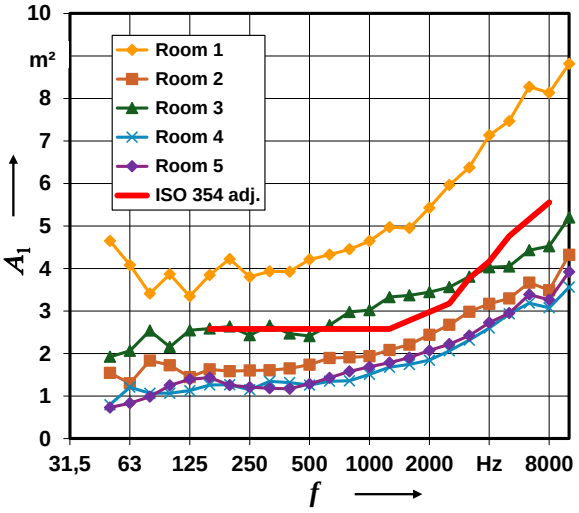

Figure 3. Equivalent absorption areas of empty rooms. ISO 354 specification adjusted for V = 50 m³.

2.4 Measurement results

The participants were requested to observe the specifications of ISO 354 as close as possible. In some cases, compromises were necessary due to the smaller room volume. Fig. 4 – Fig. 7 show some examples of the results.

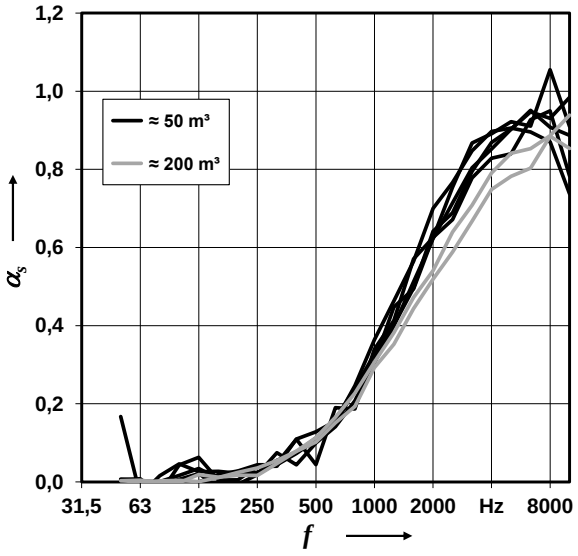

Figure 4. Absorption coefficients of carpet floor sample.

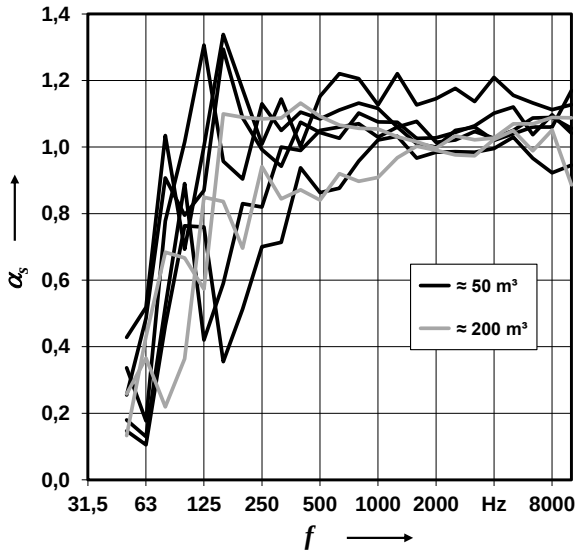

Figure 5. Absorption coefficients of 200 mm mineral wool absorber ("WG 35").

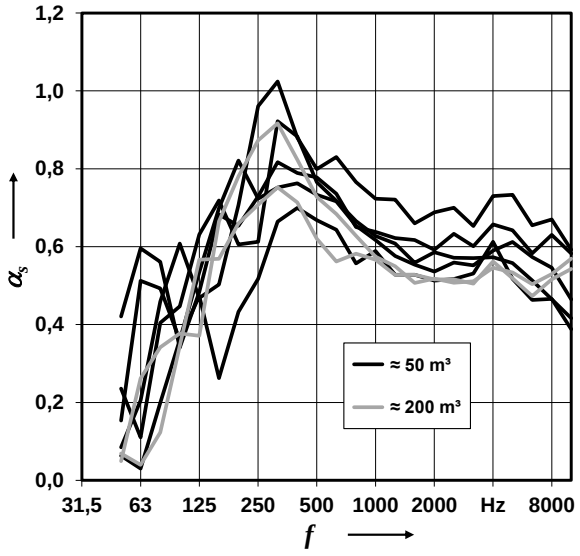

Figure 6. Absorption coefficients of Poly 2 sample.

It turned out that Room 1 delivered outlying results for the setups with individual elements ("Poly 4" – "Poly 6"). It was decided to not include these results for the statistical evaluation of the uncertainty coefficients, but to keep the data of the other absorber setups, because the data base is poor anyway.

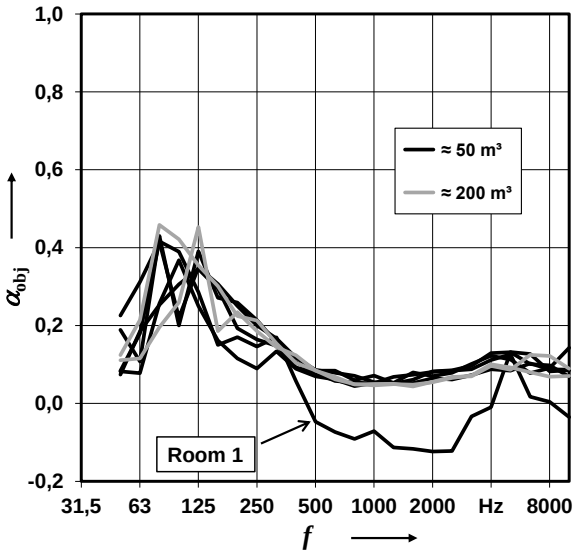

Figure 7. Absorption coefficients of Poly 6 sample.

3. EVALUATION OF RESULTS

3.1 Determination of coefficients *m* and *n*

The determination of the uncertainty coefficients follows the procedure described in [3], although the data base is much smaller. The average values for the individual samples and the respective standard deviations have been calculated and are shown in Fig. 8 and Fig. 9.

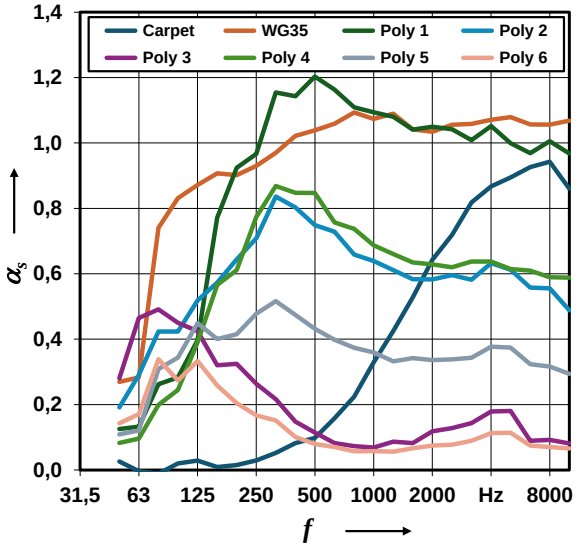

Figure 8. Average Absorption coefficients of individual samples.

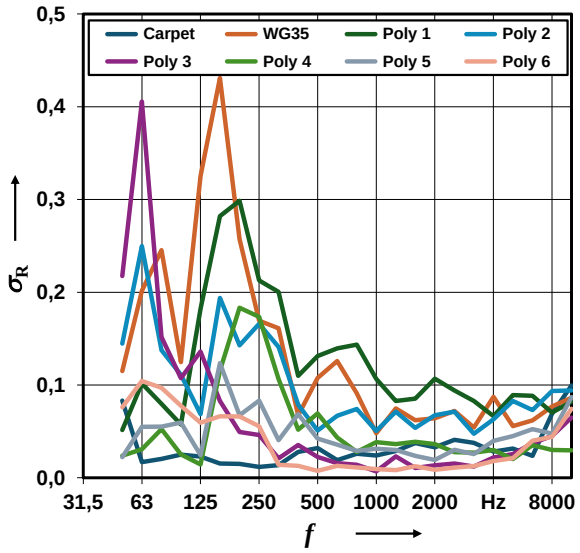

Figure 9. Standard deviation of reproducibility.

With this input data, it is now possible to determine the coefficients *m* and *n* from Eqn. (1) by linear regression. Fig. 10 gives an example for two one-third octave bands. For 125 Hz the correlation is quite low, as was to be expected regarding the small room volume and the low number of input data. For 1 kHz the correlation is much better. Finally, Fig. 11 and Fig. 12 show the coefficients obtained by the round robin data compared with those from [3], both in original form and shifted upwards by two one-third octave bands over the entire frequency range.

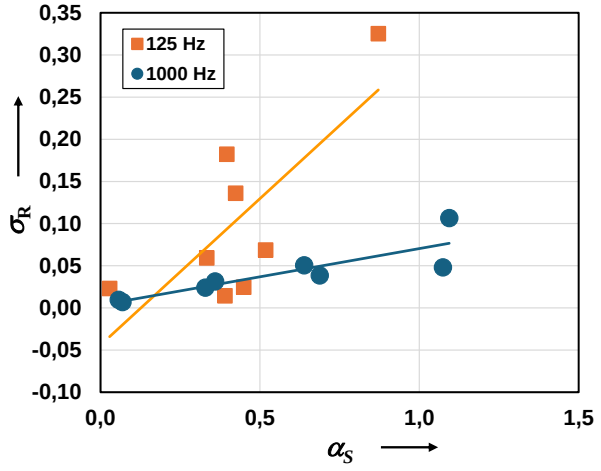

Figure 10. Obtaining *m* and *n* by linear regression.

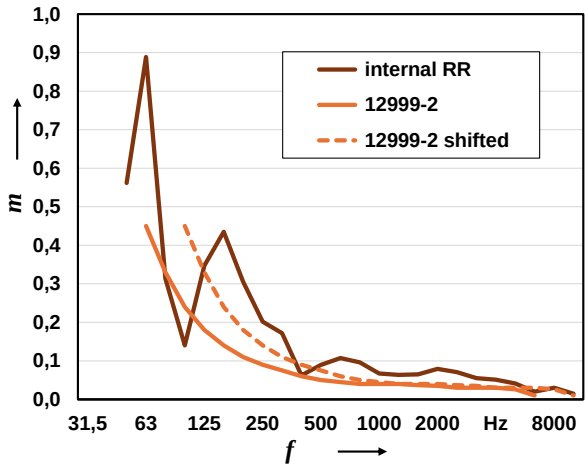

Figure 11. Results for coefficient *m*.

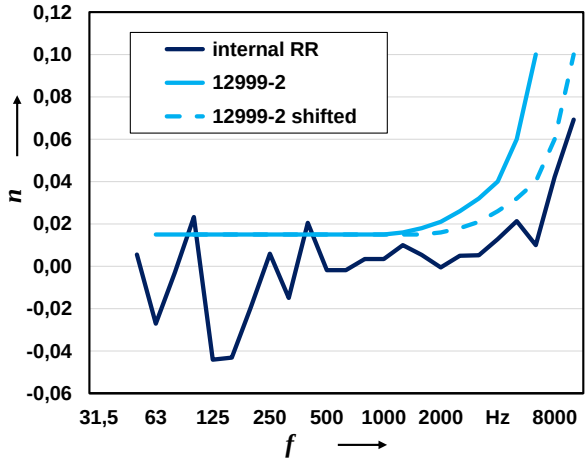

Figure 12. Results for coefficient *n*.

Regarding the low number of measurements considered, it seems to be reasonable to shift the values *m* and *n* from [3] by two one-third octave bands for a room size of 50 m³.

3.2 Combining results from different room volumes.

If the shifted values for *m* and *n* reasonably reflect the uncertainty for 50 m³ rooms, it should be possible to reduce the uncertainty by combining the results from two rooms of different size. In the frequency range where the original uncertainty $\sigma_{R,200}$ and the shifted uncertainty $\sigma_{R,50}$ are overlapping, the combined uncertainty is

$$\sigma_{R,\mathrm{comb}} = \frac{\sqrt{{\sigma_{R,200}}^2 + {\sigma_{R,50}}^2}}{2}. \qquad (7)$$

This would be possible at the one-third octave bands from 100 Hz to 6300 Hz. In the case that both individual uncertainties $\sigma_{R,200}$ and $\sigma_{R,50}$ are equal, $\sigma_{R,\mathrm{comb}}$ will be smaller than $\sigma_{R,200}$ and $\sigma_{R,50}$ by a factor of about 0,71 according to Eqn. (7). Fig. 13 and Fig. 14 illustrate the combination process. Fig. 13 shows the absorption coefficients for the "WG35" sample measured in both a "200 m³" room and a "50 m³" room, and the resulting average. The influence of the edge effect resulting from different sample sizes was not taken into account but should be considered in future research. The resulting uncertainties for the individual measurements and the combined uncertainty are shown in Fig. 14. For the calculation, the coefficients *m* and *n* from ISO 12999-2 were used shifted by two one-third octave bands for the 50 m³ room.

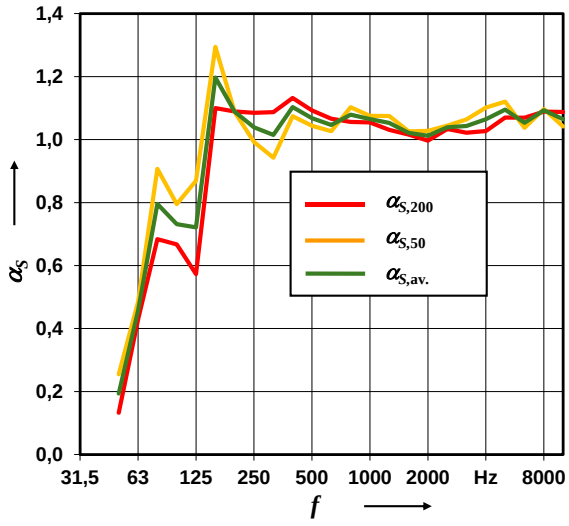

Figure 13: Example for individual and averaged absorption coefficient of "WG35" sample.

This example shows that for most one-third octave bands, the uncertainty of the reverberation room measurement is reduced. To get an idea of how the combination of uncertainties affects the overall uncertainty for all samples and room combinations, a stepwise evaluation procedure has been carried out. In a first step, for each sample the combined uncertainty was calculated for all ten possible combinations of "200 m³" and "50 m³" rooms (eight for the individual objects) using Eqn. (7), displayed in Fig. 15 as grey curves for the "WG35" sample.

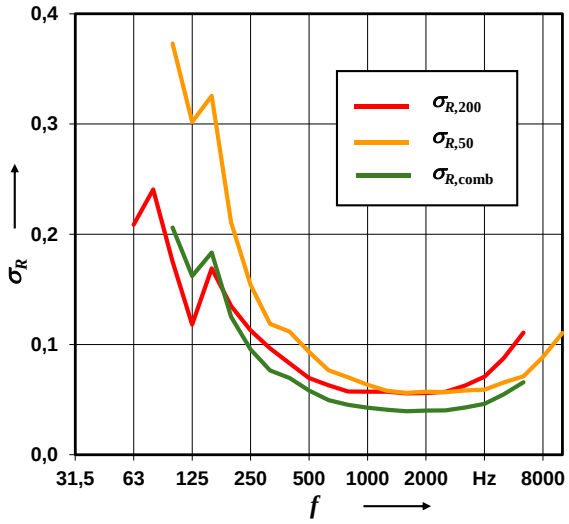

Figure 14: Respective individual and combined uncertainties for the absorption coefficients shown in Fig. 13.

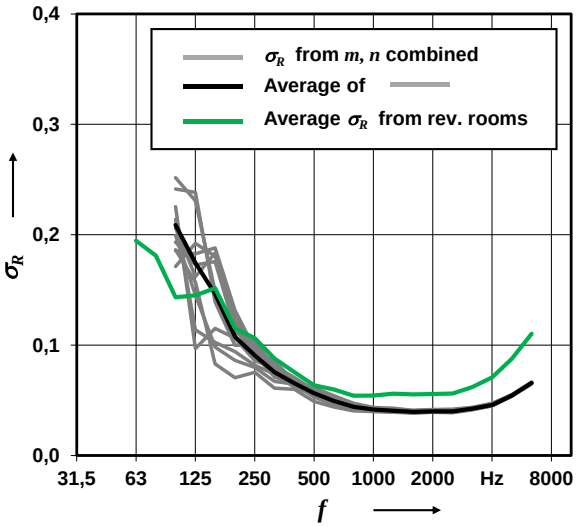

Figure 15: Combined uncertainties for "WG35" sample and average uncertainty of reverberation room measurements.

From these values the root mean square (black curve) was calculated, representing the average uncertainty $\sigma_{R,\mathrm{comb}}$ that can be achieved by combining the different room volumes.

The green curve shows the root mean square of the uncertainties $\sigma_{R,\text{rev rooms}}$ from the two reverberation room measurements which is our best estimate of the uncertainty of a single measurement in a reverberation room.

As a result, the ratio of $\sigma_{R,\text{comb}}$ to $\sigma_{R,\text{rev rooms}}$ expresses the average reduction (if < 1) or increase (if > 1) of the uncertainty that results from the combination of absorption coefficient measurements in two different (nominal 200 m³ and 50 m³) room volumes in relation to a single measurement in a standardized reverberation room. This is displayed in Fig. 16 for all eight samples.

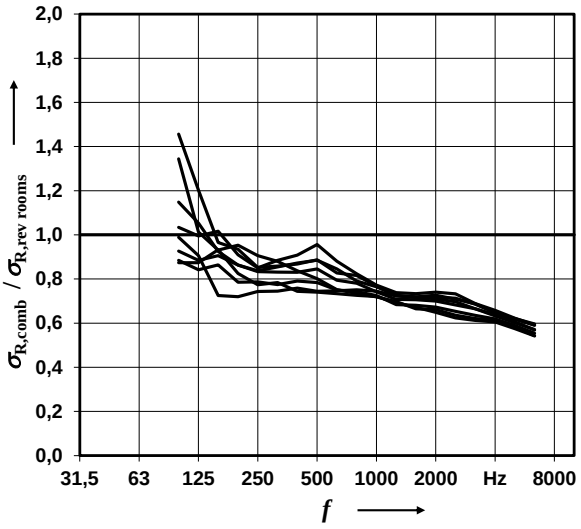

Figure 16: Ratio of $\sigma_{R,\text{comb}}$ to $\sigma_{R,\text{rev rooms}}$ for all samples.

A general reduction of the uncertainty is observed for all samples for all frequencies above 160 Hz. Above 1 kHz the results are quite uniform. A significant reduction of about a factor of 0,6 can be achieved at 6,3 kHz. Above this frequency, the combination is not possible because the coefficients *m* and *n* are not available. It should be mentioned again that of course all these considerations are based on a very small set of data, and further research on the topic is necessary.

4. CONCLUSION

An internal round robin conducted at PTB showed that measurement rooms with a volume in the range of 50 m³ deliver reasonable results for the absorption coefficient α_s, provided that the diffusivity of the rooms is adjusted properly. It was further shown that a combination of the results from the "50 m³" rooms with results from standardized reverberation rooms leads to a reduced uncertainty with respect to a single measurement in a reverberation room, especially at higher frequencies. However, given the very small amount of data this research is based on, further investigations are necessary to verify the presented findings. This also applies to the influence of the edge effect when results from different room sizes are compared.

ANALYSIS OF THE RELATIONSHIP BETWEEN SOUND FIELD ISOTROPY AND ERRORS IN THE RESULTS OF SABINE'S ABSORPTION COEFFICIENT.

Marco Berzborn and Michael Vorländer
Institute for Hearing Technology and Acoustics, RWTH Aachen University, Germany

ABSTRACT

Sabine's absorption coefficient is measured in a reverberation rooms under the assumption of a diffuse sound field. Recently multiple authors presented experimentally approaches using microphone arrays to quantify sound field diffuseness within the context of absorption measurements, indeed highlighting the lack of a diffuse sound field for specific lab environments and frequency bands. This was found to be especially prominent when the absorbing test specimen is mounted in the room.
This work presents a combined factor analysis and linear regression model to investigate the relationship between the results of the aforementioned diffuseness quantification methods and the error in Sabine's absorption coefficient. A numerically predicted finite size absorption coefficient serves as ground truth to calculate the relative error in the absorption coefficient. Finally, the suitability of the model to correct the measurements of Sabine's absorption coefficient is analyzed.

Keywords: reverberation, directional energy decay, microphone array

1. INTRODUCTION

The measurement of Sabine's absorption coefficient according to ISO354:2003 [1] is performed in a reverberation room under the assumption of a diffuse sound field. While the method is widely used since the 1920s, it is well known to suffer from a poor reproducibility between laboratories. This has been shown in several inter-laboratory studies, see for example Refs. [2] and [3]. See Ref. [4] for a overview of the issues associated with the measurement of Sabine's absorption coefficient. Recent studies studies have indeed shown that the sound field in reverberation rooms is indeed not perfectly diffuse, or more precisely not isotropic [5], [6] This was found to be especially prominent when the absorbing specimen is mounted in the room.
To statistically investigate the relationship between the isotropy condition of the sound field in the laboratory and the error in Sabine's absorption coefficient which is calculated as per ISO354:2003 [1] a regression model is developed in this work. The input and output data-sets, as well as the regression model are derived in Section 2. The experimental setup consisting of three different laboratory conditions is described in Section 3. Section 4 and Section 5 present the implementation of the regression model and the results, respectively, followed by a conclusion in Section 6.

2. MODEL

2.1 Target Variables

As target variables for the regression model developed in this section, the relative error in Sabine's absorption coefficients are used. These are computed for the T_{20}, T_{30}, and T_{40} regression intervals

$$\varepsilon_j = \frac{\bar{\alpha}_j - \tilde{\alpha}}{\tilde{\alpha}}, \quad j \in \{20, 30, 40\}, \tag{1}$$

where $\tilde{\alpha}$ is a reference finite-size random-incidence absorption coefficient estimated using a combined finite element and boundary element method simulation similar to Ref. [7]. Material parameters were inferred from

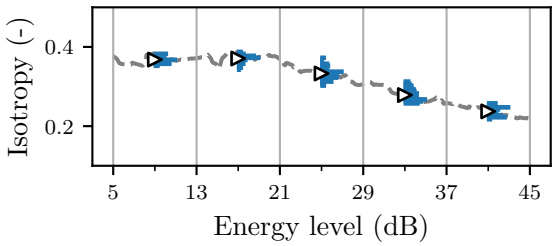

Figure 1: Isotropy evolution (- - -) as function of the decay level as well as the histogram (▬) of the indicated 8 dB intervals and their respective mean (▷).

impedance tube measurements using the method presented in Ref. [8]. Here, the relative error is chosen as it is independent from the absolute magnitude of the absorption coefficient.

2.2 Input Variables

The input data for the model is derived from the temporal evolution of estimators for sound field isotropy and axial symmetry. These estimators are calculated according to Berzborn *et al.* [9]. The isotropy estimator is based on Ref. [5] and the axial symmetry estimator is inspired by the work of Jammalamadaka and Terdik [10]. Both quantifiers are linearly interpolated to a common scale proportional to the decay level of the respective omnidirectional Energy Decay Curve (EDC). This normalization also aligns the evolution of the quantifiers with the reverberation time evaluation ranges. In addition to the estimator magnitude, their rate of change is of interest as well. This information is captured in the first derivative of the quantifiers with respect to the energy level.

The quantifiers are averaged over decay level intervals of 8 dB. The interval is chosen small enough such that the distributions of the data within the interval is uni-modal and is well represented by its mean. In agreement with ISO354:2003 [1], the initial 5 dB of the decay process are excluded from the analysis. The lowest energy level used is -45 dB due to the limited dynamic range of the Directional Energy Decay Curve (DEDC) measurements. An example of the process for the isotropy evolution is given in Fig. 1. Derivatives are typically sufficiently represented by averaging over the entire decay process.

This results in 12 input variables for each frequency band and room configuration. In the following, a matrix $\mathbf{\Gamma} \in \mathbb{R}^{12\times O}$ is constructed by stacking the vectors $\boldsymbol{\gamma}$ for all rooms and frequency bands. To ensure equal weighting of the symmetry quantifiers and their derivatives, the data are normalized to zero mean and unit variance Yong and Pearce [11].

2.3 Factor Analysis Regression

Since the symmetry quantifiers are derived from the same underlying data, they are expected to be correlated. The correlation is expected to be even stronger for cases where consecutive segmentation intervals show similar mean values, as is the case for configurations and frequency bands with uniform damping distribution. In order to identify a set of underlying latent variables and at the same time reduce the dimensionality of the input data vector a factor analysis is performed. The factor analysis is designed to explain the matrix of observations by a linear combination of the latent variables. In matrix notation, the factor analysis model can be written as [11]

$$\mathbf{\Gamma} = \mathbf{\Psi}\mathbf{Z} + \mathbf{N}, \tag{2}$$

where $\mathbf{\Psi} \in \mathbb{R}^{12\times Z}$ is the factor loading matrix, $\mathbf{Z} \in \mathbb{R}^{Z\times O}$ is the matrix of latent variables, and $\mathbf{N} \in \mathbb{R}^{12\times O}$ is an additive residual error matrix. The factor loading matrix is estimated iteratively from the correlation matrix of the input data using orthogonal *quartimax* rotations.

Assuming a linear relationship between the latent variables and the absorption coefficient error, a multiple linear regression model is used, which is expressed as

$$\boldsymbol{\varepsilon} = \boldsymbol{\beta}\hat{\mathbf{Z}} + \mathbf{n}_\varepsilon, \tag{3}$$

where $\boldsymbol{\varepsilon} \in \mathbb{R}^{3\times O}$ is the matrix containing the stacked vectors of absorption coefficient errors calculated for the three reverberation time intervals, $\boldsymbol{\beta} \in \mathbb{R}^{Z}$ is the vector of regression coefficients

$$\boldsymbol{\beta} = [\beta_0, \beta_1, \ldots, \beta_Z]^\mathsf{T}, \tag{4}$$

where β_0 is the intercept and $\mathbf{n}_\varepsilon \in \mathbb{R}^{O}$ represents the additive modeling error. The matrix $\hat{\mathbf{Z}}$ is obtained by adding a column of ones to the matrix of latent variables $\mathbf{Z}$ to account for the intercept term.

2.4 Absorption Coefficient Prediction

Once the factor loading matrix and the regression coefficients are identified, the model can re-arranged to predict a corrected version of Sabine's absorption coefficient based on the symmetry quantifiers. Replacing the reference absorption coefficient $\tilde{\alpha}$ in Eq. (1) with the predicted

absorption coefficient $\hat{\alpha}_j$, the corrected absorption coefficient can be computed as

$$\hat{\alpha}_j = \bar{\alpha}_j(1+\varepsilon_j) \quad j \in \{20, 30, 40\}. \tag{5}$$

Substituting Eq. (3) into Eq. (5) results in

$$\hat{\boldsymbol{\alpha}} = \bar{\boldsymbol{\alpha}} \odot \left(1 + \boldsymbol{\beta}\hat{\mathbf{Z}}\right), \tag{6}$$

where $\hat{\boldsymbol{\alpha}} \in \mathbb{R}^{3\times O}$ and $\bar{\boldsymbol{\alpha}} \in \mathbb{R}^{3\times O}$ are the matrices containing the corrected and measured absorption coefficients, respectively, and $\odot$ denotes the Hadamard product.

3. EXPERIMENTAL SETUP

The spherical and axial symmetry quantifiers were computed from experimental data captured in three different laboratory conditions: A rectangular reverberation room with volume $245\,\mathrm{m}^3$ in a configuration including 22 panel diffusers and a second configuration without any diffuser treatment – referred to as room no. 1 – and a second reverberation room with volume $215\,\mathrm{m}^3$ equipped with a combination of 12 panel and 85 boundary diffusers – referred to as room no. 2. The same glass-wool test specimen with $10.8\,\mathrm{m}^2$ was used in all laboratory conditions.

A Universal Robots UR5 scanning robotic arm was used to sequentially sample a dual-radius spherical microphone array. The sequential microphone array consists of a total of 310 sampling positions including interior points to stabilize the eigenfrequencies of the sphere. Their positions were calculated using the algorithm proposed by Chardon *et al.* [12]. Three different receiver positions were used in room no. 1, while only two receiver positions were used in room no. 2. For each condition, a single source position was used. The procedure to calculate the symmetry quantifiers is outlined in Ref. [9].

The reverberation time used to estimate the respective absorption coefficients was calculated from the omnidirectional EDC at the center position of the microphone array. Instead of using an additional measurement, the omnidirectional EDC was computed as the Schroeder [13] integral of the monopole moment of the omnidirectional response of the microphone array.

Note that while the setup is as similar to the procedure described in ISO354:2003 [1] as possible, it does not fully comply with the standard in the following aspects:

- The number of source and receiver positions per laboratory condition is far lower than the minimum number of 12 required by the standard.
- No frame was used to cover the specimen's sides, which is accounted for in the numerically calculated reference absorption coefficient.

4. MODEL IMPLEMENTATION

The factor analysis and multiple linear regression model were implemented based on the *scikit-learn* library, [14]. In order to later validate the model, a split of the data into a training and test set was performed, where the training set consisted of 75 % of the full dataset. The suitability of the input data for factor analysis was assessed using the Bartlett [15] test of sphericity and the Kaiser-Meyer-Olkin measure of sampling adequacy [11]. The number of latent variables used in the factor analysis was determined using a *scree* plot, and consecutively confirmed using a parallel analysis as suggested by Horn [16]. Estimation of the loading matrix was performed iteratively using the maximum likelihood approach. The linear regression based on the latent variables was performed using a standard least squares approach. A significance test of the regression coefficients was performed using an Analysis of Variances (ANOVA) on the regression models for the three reverberation time intervals. Additional significance tests of the individual regression coefficients were performed using *t*-tests.

5. RESULTS

The results presented in this chapter are based on the symmetry estimator input data derived for the occupied rooms. If not otherwise stated the presented results are based on the training data set.

5.1 Factor Analysis

The factor analysis indicated that the input data can be represented by three latent variables. Most prominently, the first latent variable represents the quantitative value of the isotropy and axial symmetry estimators, with high loadings for all respective intervals. Similarly, the second latent variable primarily represents the rate of change of the symmetry quantifiers. Interestingly, increased loading is also observed for the input variables representing the quantity of both estimators towards the late part of the decay process. This is most likely due to the fact that this part of the decay process shows the largest rate of change in the symmetry quantifiers in the case of non-uniform damping, see for example. Fig. 1. Such cross-loading of

input-variables on multiple latent factors indicates non-ideal separation of the latent variables. Nonetheless, the second latent variable may still be interpreted as the rate of change of the symmetry quantifiers.
In comparison, the third latent variable shows overall lower and slightly inconsistent loadings for all variables, and as a result is not clearly interpretable. As the next section will show, the third latent variable does not contribute significantly to the developed model.

5.2 Multiple Linear Regression

The ANOVA results indicate that the regression model is significant at a level $p < 0.001$ for all reverberation time intervals, with F-statistics of 44.9, 80.7, and 88.4, see Table 1. The individual t-tests of the regression coefficients indicate that all except β_3 are statistically significant with $p < 0.001$. For β_3, that is the third latent variable, the T-statistic is subject to low values while the p-values are between 0.12 and 0.41, indicating that the third latent variable does not significantly contribute to the model. As mentioned before, the third latent variable is consequently excluded from the model for the remaining analysis.

As a goodness of fit measure, the coefficient of determination R^2 was computed. For the training data set the coefficient of determination is found to increase with increasing dynamic range used for calculation of the reverberation time, showing values from 0.75 to 0.86, see Table 1. For the test data the R^2 and mean squared error are found to be slightly lower than for the training data, with R^2 values of 0.68 to 0.80, see Table 1. While the test data shows slightly lower accuracy, the results still indicate sufficient generalization capabilities of the model.

Figure 2 shows the regression lines for the individual latent variables separately, as well as the 95 % confidence interval, and the individually calculated R^2 measure. Each row corresponds to one of the reverberation time intervals. The increase of the reverberation time interval seemingly improves the accuracy of the model. In fact, Fig. 2 reveals that the increase in the goodness of fit is primarily due to the improved goodness of fit for the second latent variable. Interestingly, the R^2 measure obtained for the first latent variable is found to be similar for ε_{20}, ε_{30}, and ε_{40} with values between 0.64 to 0.68, while the R^2 measure for the second latent variable increases from 0.09 to 0.22. This may indicate two things: Firstly, the magnitude of the symmetry estimators is more indicative for the error in the absorption coefficient than their respective rate of change for the given model. Secondly, the rate of change in the symmetry quantifiers reflects the increase in the reverberation time estimation error – and hence increase in the absorption coefficient error – for larger evaluation intervals in the presence of multi-exponential energy decay. Note that the R^2 for the second latent variable is still low for all reverberation time intervals. This is also due to a number of distinct outliers. For the second latent variable outliers for $\Psi_2 > 0$ and $\varepsilon < -0.3$ are observed which result in an increased regression error for all reverberation time intervals, cf. Fig. 2. Similarly, outliers are observed for the first latent variable for $\varepsilon < -0.3$ and $\Psi_1 < 1$, cf. Fig. 2. While the outliers are not clearly interpretable, it is highly likely that they are due to insufficient separation of the input variables, which was already hinted at in the interpretation of the factor analysis.

Table 1: Results of the F-test, as well as the coefficient of determination R^2 for the multiple linear regression model. The F-test statistics are given for the training data only.

			R^2	
	F-statistic	p-value	Training	Test
ε_{20}	44.9	< 0.001	0.75	0.68
ε_{30}	80.7	< 0.001	0.85	0.81
ε_{40}	88.4	< 0.001	0.86	0.80

5.3 Absorption Coefficient Prediction

Figure 3 shows the corrected absorption coefficient (using Eq. (6)) without distinguishing between training and test data, as well as the measured absorption coefficient.Further, Fig. 3 shows the numerically computed finite size absorption coefficient. The depicted data for each frequency band corresponds to the average over three all laboratory rooms and receiver positions. The results indicate that the mean of the corrected absorption coefficient is in good agreement with the reference absorption coefficient for the T_{20}, T_{30}, and T_{40} intervals. Further, the $[2.5\,\%, 97.5\,\%]$ percentiles of the corrected absorption coefficient are smaller compared to the respective percentiles of the measured data. Interestingly, the agreement seems best for the T_{20} interval, and decreases with increasing

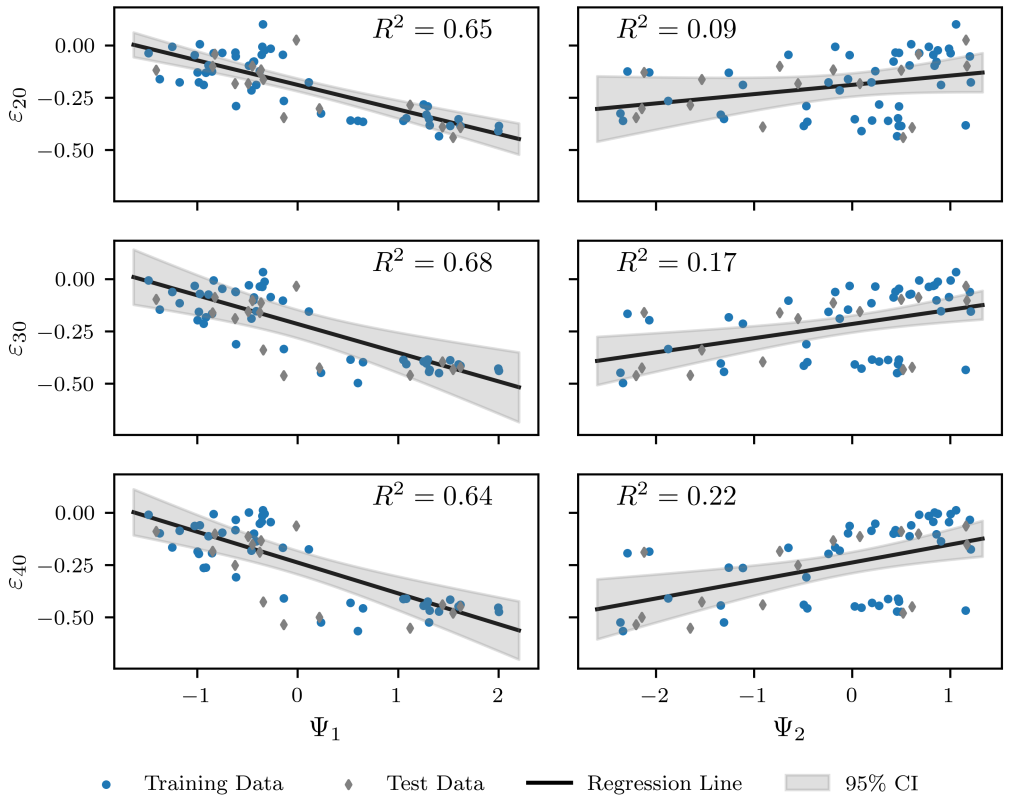

Figure 2: Regression lines for the two predicted relative absorption coefficient error based on the two latent variables. Shaded areas indicate the 95 % confidence interval.

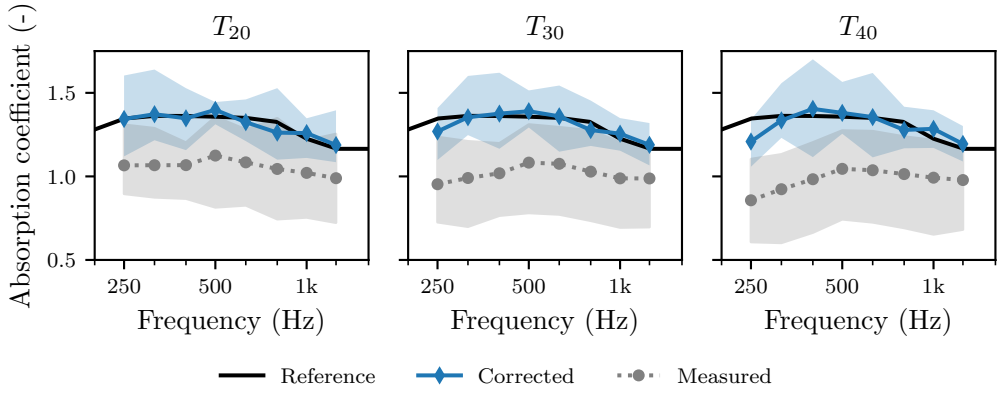

Figure 3: Mean of the corrected and measured absorption coefficient data averaged over all laboratory rooms. Shaded areas indicate the region spanning the 2.5 % and 97.5 % percentiles. The combined test and training data are used. The reference refers to the numerically computed absorption coefficient.

reverberation time evaluation interval which seems counterintuitive as the interval showed the lowest R^2 in the previous section.
An additional room by room analysis revealed that the high variance of the corrected absorption coefficient is primarily influenced by the room configuration without panel diffusers installed for most frequency bands.Similarly, the variance in the measured absorption coefficient is primarily influenced by the room configuration without panel diffusers installed.This observation is in agreement with the results of the previous section, which showed that the outliers in the regression model are primarily associated with the room configuration without panel diffusers installed.

6. CONCLUSION

This paper presented a stochastic model for the analysis between the uniformity of incident energy distributions – i.e. isotropy and axial symmetry – and the error in Sabine's absorption coefficient. The results indicate a statistically significant relationship. While the results of the regression model are promising, the analysis of the relationship between the latent variables and the absorption coefficient error revealed mismatches between the target data and the model. A number of distinct outliers were observed, which are most likely due to insufficient separation of the latent variables in the factor analysis. Future work should involve the development of an improving the identification of the latent variables. Especially a model-based parameterization of the symmetry quantifiers, is expected to improve the performance of the regression model. Nevertheless, initial results indicate that the model can be used to correct Sabine's absorption coefficient if data from multiple laboratory rooms are available to train the model.

ABSTRACT

Reliable descriptions of a room's physical properties are essential for accurately simulating room acoustical fields. An important model input parameter is the impedance of the materials that comprise the boundaries of the room. However, the impedance information of commonly used sound-absorbing materials is generally unavailable. While databases of absorption coefficients are available for commonly used materials, these are of limited use for simulation tools that require impedance (or angle-dependent reflection coefficients) as input data, and it is uncommon to find absorption coefficients below 100 Hz. This study estimates the normal impedance of a sample of sound-absorbing material at frequencies below 100 Hz. An eigenvalue-based impedance estimation method is used to determine a sample's complex-valued, frequency-dependent impedance from measurements in a reverberation chamber. While the results are encouraging, the method is sensitive to model input parameters, and further refinement is required to make the method practical.

Keywords: *Reverberation chamber, Eigenvalue estimation, Impedance estimation.*

1. INTRODUCTION

Understanding the impedance characteristics of surfaces is crucial for accurately modeling room acoustical fields. However, obtaining this information can be challenging, particularly at low frequencies and for complex-valued impedance. Eigenvalue analysis has been suggested in the literature as a solution [1, 2]. This work employs eigenvalue analysis to estimate the normal impedance of an absorbing surface at low frequencies. In this report, the proposed method is used to estimate the normal impedance of the walls of an empty reverberation chamber and the impedance of a material sample placed in the same chamber. The approach is checked by comparing the measured and simulated reverberation times, absorption coefficients, and room transfer functions.

This paper is organized as follows. In Sec. 2, we provide background information by reviewing relevant literature and offer motivation for the work. Section 3 outlines the impedance estimation method. The measurements conducted in the reverberation chamber are described in Sec. 4, and the results of the impedance estimation are presented in Sec. 5. Finally, we discuss the findings of this study in Sec. 6 and conclude the paper in Sec. 7.

2. BACKGROUND

In general, the impedance of an absorbing material is best described by an extended reaction model. However, a local reaction model can be used to approximate the behavior of some commonly used materials. The local reaction model assumes that the surface impedance is independent of the angle of incidence, meaning it only models the impedance at normal incidence, yielding a normal impedance. Descriptions of absorbing materials based on normal impedance can be easily integrated into wave modeling tools. The normal impedance model is also advantageous for certain geometrical modeling tools, such

as the image source method, because it allows practitioners to specify angle-dependent reflection and absorption coefficients (see, e.g., Ref. [3]).

In practice, absorption coefficient tables are often utilized in lieu of normal impedance values, a practice that has several disadvantages. The standard method for quantifying a material's sound-absorbing properties, known as the reverberation chamber method [4], provides absorption coefficients. In theory, these coefficients represent the sound absorption at all angles of incidence, but in practice, only a subset of all possible angles is represented in the data. This limitation leads to measured absorption coefficients that depend on the specific environment in which they were collected. The lack of angle-dependent information and the dependence of the data on the measurement room restrict the usefulness of these absorption coefficients. Therefore, having access to the normal impedances of commonly used materials would be highly beneficial for the room acoustics community.

The impedance tube method [5, 6] yields normal impedances of absorbing materials. The method is limited to small samples, which excludes edge effects and potentially includes unwanted installation effects. Depending on the physical dimensions of the tube being used, there is also a limited range of frequencies for which such a measurement is valid. Measurements at low frequencies typically require tubes of potentially impractical length. Due to these limitations, there are ongoing efforts within the community to develop in-situ impedance measurement methods. These usually depend on multi-microphone measurements and advanced signal processing techniques. The interested reader is directed towards Ref. [7] for a recent review of the work being done in this field. Long wavelengths and modal effects in the rooms under test complicate the in-situ measurement of surface impedance at low frequencies. An interesting approach is to use the room's modes to measure the surface impedance.

Hull and Radcliffe propose an eigenvalue-based impedance method [8]. They successfully demonstrate the method using one-dimensional analytical descriptions of the modes in an impedance tube. Nowakowski *et al.* [9] use the eigenmodes of a two-dimensional problem to estimate surface impedance. Prinn *et al.* [1, 2, 10] present an estimation method based on eigenvalue analysis of impulse responses simulated and measured in rooms containing a test sample. The proposed method is extended here to make the approach more robust and is used to estimate a sample's impedance in a reverberation chamber.

3. ESTIMATION METHOD

The eigenvalue-based estimator has two main steps: first, the reverberation chamber's eigenvalues are computed, and second, the measured eigenvalues are compared to the predicted eigenvalues obtained from a model, and an initial guess of the impedance is refined to obtain an impedance estimate. The following sections will describe these steps. For brevity, derivations are omitted, and the interested reader is directed towards Refs. [1, 2].

3.1 Chamber eigenvalues

The first step is to estimate the empty chamber's eigenvalues. We do this for a set of measured room impulse responses using the matrix pencil method [11], which provides a set of potential eigenvalues. The matrix pencil method can be written as follows: Solve the eigenvalue system

$$\det\left(\boldsymbol{H}_1^{\dagger}\boldsymbol{H}_2 - \gamma\boldsymbol{I}\right) = 0\,, \tag{1}$$

where superscript † indicates the Moore-Penrose pseudoinverse,

$$\boldsymbol{H}_1 = \begin{bmatrix} h_1 & h_2 & \cdots & h_p \\ h_2 & h_3 & & h_{p+1} \\ \vdots & & \ddots & \vdots \\ h_{N-p} & h_{N-p+1} & \cdots & h_{N-1} \end{bmatrix}_{(N-p)\times p}, \tag{2}$$

and

$$\boldsymbol{H}_2 = \begin{bmatrix} h_2 & \cdots & h_p & h_{p+1} \\ h_3 & & h_{p+1} & h_{p+2} \\ \vdots & \ddots & & \vdots \\ h_{N-p+1} & \cdots & h_{N-1} & h_N \end{bmatrix}_{(N-p)\times p}. \tag{3}$$

The entries of Hankel matrices (2) and (3) are samples from a measured impulse response, h_n, with $n = 1, 2, ..., N$, and pencil parameter $p = \text{round}(N/2)$. Solving (1) yields eigenvalues γ_m, which are used to compute the mth resonance frequency

$$f_m = f_\text{s}\arg(\gamma_m)/(2\pi)\,, \tag{4}$$

and the mth damping constant

$$\sigma_m = f_\text{s}\,\log(|\gamma_m|)\,, \tag{5}$$

where f_s is the sampling frequency. The mth measured chamber eigenvalue is then

$$\lambda_m = f_m + \text{i}\sigma_m/(2\pi)\,. \tag{6}$$

The matrix pencil method generates both valid and spurious eigenvalues (see, e.g., Ref. [12]). Given data from multiple measurement positions, the valid eigenvalues tend to form local clusters. From this clustering, the distance of each eigenvalue to its neighbors is calculated, and the eigenvalues with the smallest differences from one another are identified. Thus, in this work, k-means clustering (see, e.g., Friedman *et al.* [13]) is used to identify the valid eigenvalues. This provides us with a set of chamber eigenvalues that contain information on the resistance and reactance, i.e., the complex-valued impedance, of the surfaces in the chamber.

3.2 Impedance estimates

With a set of chamber eigenvalues, a numerical wave model of the chamber is used to find the unknown impedance. The finite element method is chosen to model the chamber since the method robustly models problems with arbitrary geometries. The Helmholtz equation-based eigenvalue problem is written as

$$\left[\boldsymbol{K} + (2\pi\mathrm{i})\frac{\hat{\lambda}}{c}\sum_{j=0}^{J}\hat{\zeta}_j^{-1}\boldsymbol{C}_j + (2\pi\mathrm{i})^2\frac{\hat{\lambda}^2}{c^2}\boldsymbol{M}\right]\boldsymbol{v} = \boldsymbol{0}\,, \quad (7)$$

where matrices $\boldsymbol{K}$, $\boldsymbol{C}$, and $\boldsymbol{M}$, are the usual finite element matrices (see, e.g., Ref. [14]). Here, $\hat{\zeta}_j$ is the impedance of the jth surface of the chamber, $\boldsymbol{v}$ is an eigenvector, and the mth simulated eigenvalue is given by

$$\hat{\lambda}_m = \hat{f}_m + \mathrm{i}\hat{\sigma}_m/(2\pi)\,. \quad (8)$$

For a given eigenvalue, the present method provides one impedance estimate. Therefore, to estimate the impedance of the jth surface for the mth resonance frequency, we assume that, either all impedances of the other surfaces in the chamber are known, or the impedance is spatially uniform ($J = 0$). To obtain an estimate, we refine an initial guess for $\hat{\zeta}_j$. This guess is refined using an optimization algorithm to minimize the differences between the chamber and simulated eigenvalues. Thus, we solve the problem

$$\hat{\zeta}_m = \min_{\hat{\zeta}\in\mathbb{C}}\left[\frac{\|\lambda_m - \hat{\lambda}_m\|_2}{\|\lambda_m\|_2}100\right]\,. \quad (9)$$

The cost function is a relative error. Estimates that fail to reach an upper bound on the error (in this case, 1%) are assumed to be erroneous and are removed from the frequency-dependent estimates set. This is necessary due to the sensitivity of the impedance estimation method.

A significant issue that can arise during optimization is when an eigenvalue is associated with an eigenvector that does not correspond to that eigenvalue. This situation occurs when eigenvalues are closely spaced in the frequency domain. As the impedance is varied, the eigenvalues can exchange their chronological order; for instance, an eigenvalue that was previously higher in frequency than its lower-frequency neighbor can become lower than that same neighbor after a change in impedance.

The consequence is that the impedance estimator may attempt to fit an impedance to the incorrect eigenvalue. To improve the method's robustness, we make use of measurements at multiple positions. We use the magnitude of the normalized transfer functions at the measurement positions to approximate the mth normalized eigenvector. This approach allows us to compare the error of the chosen eigenvector with the errors of its immediate neighbors (in terms of resonance frequency). If an eigenvalue with a lower eigenvector error is identified, it is assumed that the eigenvalues have exchanged their chronological order. The eigenvector with the lowest error is used for the estimation.

This work uses the commercially available finite element tool COMSOL [15] to solve the eigenvalue problem.

4. MEASUREMENT SETUP AND DATA

The reverberation chamber under test is shown in Fig. 1. The chamber is formed by two rooms with non-parallel walls joined by a large open window. The sound field produced by two sound sources is recorded at multiple positions within the room. One sound source is a full-range loudspeaker placed in a corner of the reverberation chamber, while the other is a low-frequency woofer placed in the same position. The measurements are taken in two chamber conditions: the empty chamber and the occupied chamber, in which two copies of a sound-absorbing material sample are placed on the chamber floor. This section outlines the experimental setup and presents the relevant data.

4.1 Empty chamber

The chamber is excited with a swept sine signal. An omnidirectional microphone receives the signal, emitted by either the loudspeaker or the woofer, at 12 evenly spaced receiver positions. These positions are reported in Tab. 1. The received signals are deconvolved to obtain a set of measured impulse responses. The speed of sound is estimated to be 343 m/s, and the medium density is 1.2 kg/m^3.

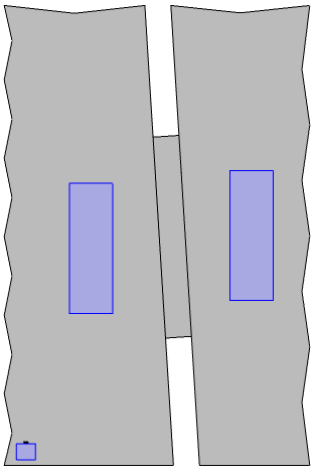

Figure 1: Top view of the reverberation chamber under test. The origin of the coordinate system is the bottom left-hand corner of the chamber. The highlighted rectangle close to the origin is the loudspeaker, facing in the y-dimension, and with the driver's center located at (0.5, 0.5, 0.2) [m]. The highlighted rectangles in the middle of each chamber section are two identical material samples.

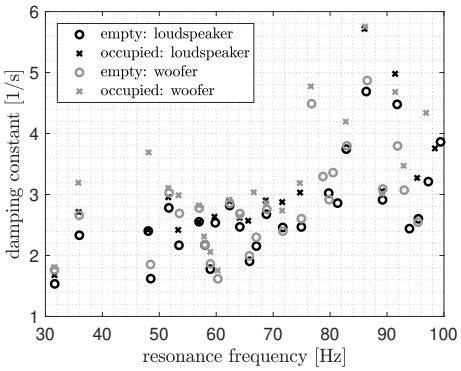

Figure 2: Comparison of empty and occupied chamber eigenvalues, for two sources of sound.

4.2 Chamber with sample

The absorbing material is a polyurethane foam with a porous foam top layer. It is divided into two parts (this is necessary due to the chamber construction; see Fig. 1). The two samples, each with dimensions $1.0 \times 3.0 \times 0.14$ m, are placed on the floor. The measurement procedure described above is repeated for the occupied chamber.

5. RESULTS

First, the unknown impedance of the chamber walls is estimated using the eigenvalues of the empty chamber. This impedance data is then used to estimate the sample's impedance using the eigenvalues of the occupied chamber. The empty and occupied chamber eigenvalues are presented in Fig. 2. Note the increase in damping with the introduction of the sample, and the unexpected damping offset between the sources. This section presents these data and compares the measured and simulated reverberation times, absorption coefficients, and transfer functions.

5.1 Impedance estimates

The estimated impedance of the chamber walls is shown in Fig. 3a for both the loudspeaker and the woofer. Although there are some differences between the two data sets, the general shape of the graphs is consistent. At low frequencies, the resistance of the chamber walls lies in the region between 100 and 250. It is important to note that the lower bound for the resistance optimization is 50, while the upper bound is 250. Thus, for the woofer data, the impedance estimate in the region of 60 Hz might not be correct. For the reactance, the lower and upper bound

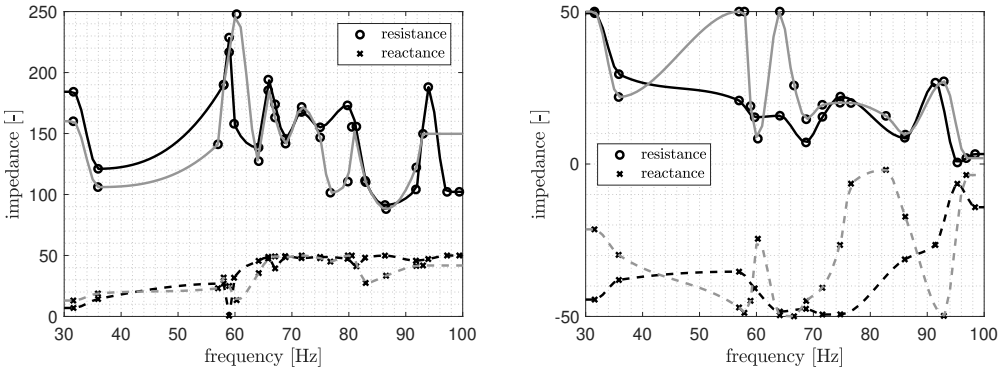

Figure 3: Impedance estimates for the loudspeaker (black lines) and the woofer (gray lines). (a) spatially uniform impedance of all surfaces of the empty chamber. (b) impedance of the material sample.

of the optimization are -50 and 50, respectively. The estimated reactance above approximately 65 Hz is close to the upper bound. It is important to note that this data likely does not represent the actual impedance of the chamber walls, as not all chamber surfaces may exhibit the same impedance (this is a necessary assumption in this work). Instead, this impedance estimate represents the spatially uniform complex-valued impedance.

The estimated impedance of the material sample is presented in Fig. 3b. As expected, the resistance of the sample is lower than that of the chamber walls. Upon comparison of the loudspeaker and woofer data, we see that while the data have similar trends, there are noticeable differences. It is expected that these differences appear due to inaccuracies at the eigenvalue estimation stage.

5.2 Reverberation time estimates

A set of spatially averaged reverberation times can be computed from the measured data. To simulate this quantity, the estimated impedance values are used to describe the boundary conditions of finite element models for both the empty and occupied chambers. A two-microphone method measures the velocity of the loudspeaker and woofer drivers during the measurements. The measured velocity is then post-processed to remove noise and is used to describe the source excitation in the models.

The measured and simulated reverberation times for third-octave bands are compared in Fig. 4. While there is some qualitative agreement between the two, noticeable differences exist. Notice also that the measured reverberation time depends on the source type. Since the same position was used for both sources, it is expected that these differences appear due to the changes in excitation levels as a function of frequency. The exact source of the differences between the measured and simulated data is unknown, but it is expected that improving the estimates of the sample impedance could help reduce them.

5.3 Absorption coefficients

The measured and simulated absorption coefficients are compared in Fig. 5. The measured absorption coefficients for the chamber walls were calculated from the reverberation times obtained in the empty chamber using Sabine's formula. The absorption coefficients for the sample were determined using the reverberation chamber method [4]. The random incidence absorption coefficients (see, e.g., Kuttruff [16]) were derived from the estimated impedances to obtain simulated absorption coefficients. We do not expect the measured and simulated absorption coefficients to be in perfect agreement since the random incidence assumption might not be fulfilled in this reverberation chamber at the low frequencies of interest.

Data for both the loudspeaker and the woofer are included. The results show that the absorption coefficients for the chamber walls are similar, which is reassuring. However, there are noticeable differences between the measured and estimated sample impedances. While improved impedance estimates are expected to yield better agreement for the woofer data, the loudspeaker absorption coefficients at 80 and 100 Hz are concerning.

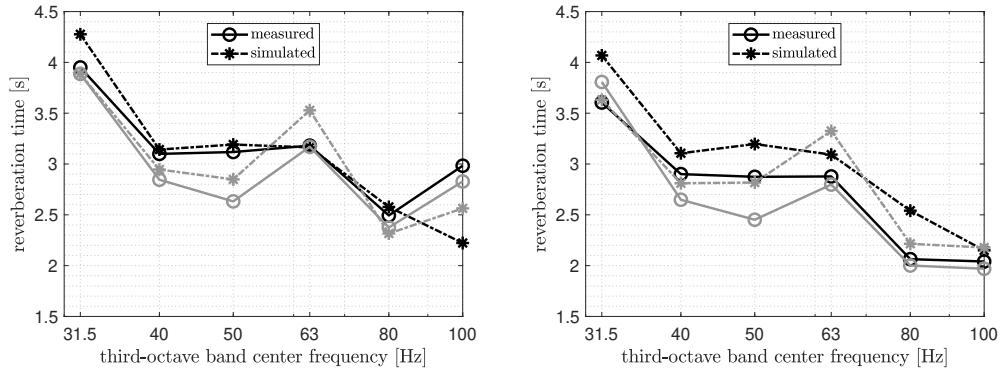

Figure 4: Comparison of measured and simulated spatially averaged reverberation times for the loudspeaker (black lines) and the woofer (gray lines). (a) empty chamber. (b) occupied chamber.

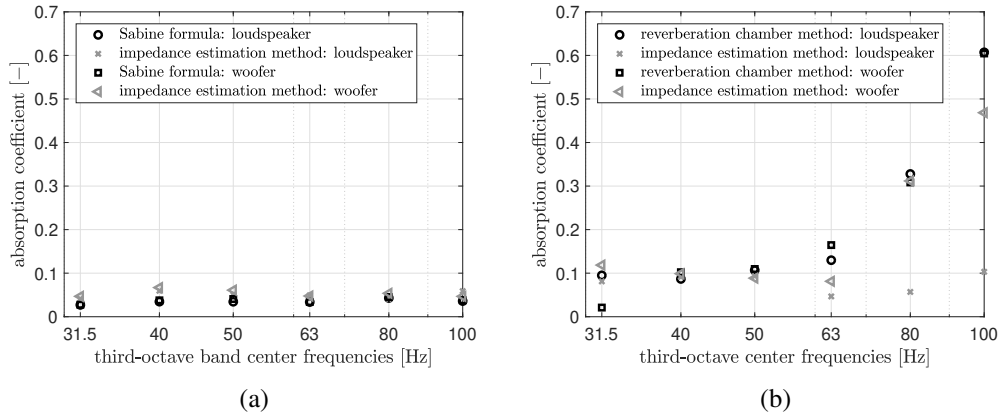

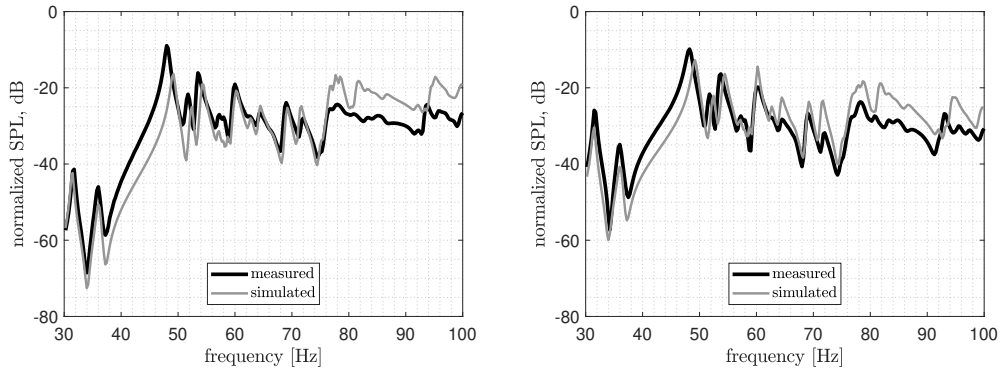

Figure 5: Comparison of the measured and simulated absorption coefficients. (a) chamber walls, (b) material sample.

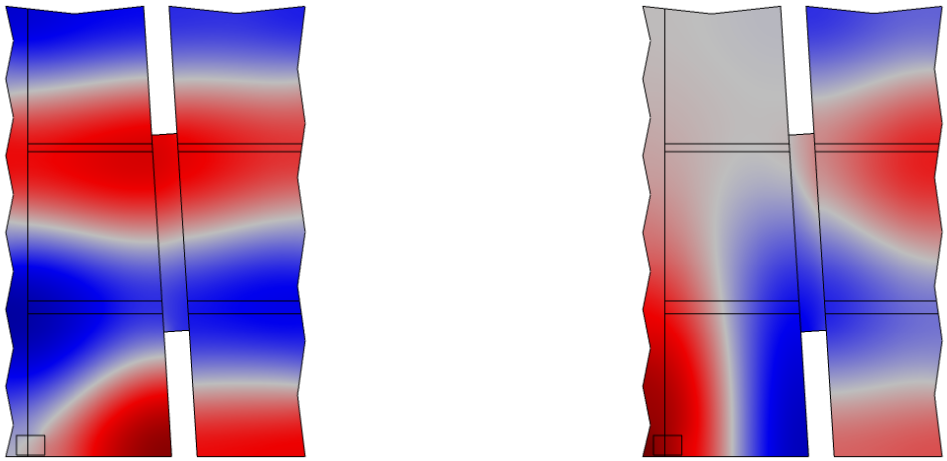
5.4 Transfer functions



The empty chamber's measured and simulated transfer functions are compared in Fig. 6. In general, there is some agreement between the transfer functions; however, noticeable differences appear at certain frequencies. The cause of these discrepancies is not immediately apparent. It is possible that the positioning of the sources, or their acoustic centers, is not identical to those in the simulation.

For instance, at approximately 48 Hz, we observe a significant difference. An eigenvalue analysis of the chamber reveals two eigenvalues in this frequency range, with resonance frequencies around 48 Hz and 49 Hz. For the 48 Hz mode, there is a pressure minimum (a node) at the speaker location, whereas for the 49 Hz mode, there is a pressure maximum (an antinode). (Please refer to Fig. 7 for mode shapes.) One would expect that the 48 Hz mode would not be excited while the 49 Hz mode would be, but in the measured data the opposite seems to be true. Upon examining Fig. 6a and Fig. 6b, it appears that the 48 Hz mode is present in the measured data, while the 49 Hz mode is reflected in the simulations. Clearly, this study could be improved by increasing the precision of both the experimental and simulation setups.

6. DISCUSSION

While the results presented in this paper are promising, the comparisons between the measured and simulated data shown in Figs. 4, 5, and 6 indicate that further work is necessary for this method to be effectively used in impedance measurements. Some of the assumptions made to derive the impedance estimates may need to be modified. For example, we have assumed that the surface impedances of the floor, walls, and ceiling of the reverberation chamber are spatially uniform, which may be an oversight. Efforts should be made to quantify the impedances of all surfaces in the reverberation chamber, possibly including ventilation systems. The differences between the chamber eigenvalues computed for the two different sound sources, shown in Fig. 2, are concerning. In theory, since the chamber eigenvalues are global quantities, these should not depend on the sound source. The observed differences result in similar differences between the impedance estimates, shown in Fig. 3. The cause of the observed differences between the chamber eigenvalues is unknown. A detailed analysis of the measurement setup is needed to refine the input data for the impedance estimation method.

7. CONCLUSION

Measuring the normal impedance of a material sample at low frequencies can be challenging. In this study, we employed an eigenvalue-based method to estimate both the impedance of the walls of an empty reverberation chamber and that of a material sample at frequencies below 100 Hz. The impedance estimation method yielded two different results for two different sound sources, due to unexpected variations in the chamber's eigenvalues. The cause of the discrepancy remains unclear. Therefore, while the method is theoretically sound, it may produce unreliable impedance estimates due to measurement noise and uncertainties in the input parameters for the inverse model.

Future research should aim to minimize the uncertainties associated with this impedance estimation method. For example, more detailed descriptions of the chamber's geometry, the sound source, and the properties of the medium could improve the accuracy of the estimates. Additionally, reevaluating the assumption that a spatially uniform impedance adequately represents the impedance of the chamber walls may also lead to better estimations.

ABSTRACT

ASTM E795-23 specifies a Type J mounting WITHOUT A SURROUND for the measurement of the sound absorption of sound-absorbing units and requires that the measured sound absorption be reported. ISO 354:2003(E) specifies a Type J mounting WITH A SURROUND for the measurement of the sound absorption per unit of rectangular unit sound absorber pads or baffles. ISO 354:2003(E) also says that for a specified array of objects, the result is given as the sound absorption coefficient, and that in the case of a test specimen WITH A SURROUND, it is the area enclosed by the surround that is used. However, ISO 354:2003(E) also allows an array of objects to be measured WITHOUT A SURROUND and requires the sound absorption coefficient to be reported using the area covered by the test specimen. A baffle array could be regarded as being in a Type A mounting without covered edges. ISO 354:2003(E) says that if the edges are not covered, the area of the edges shall be included in calculating the test specimen area. Consultants want sound absorption coefficients so that they can enter in their ray tracing programs. The existence of different ways of measuring and/or reporting sound absorption is unacceptable.

Keywords: *sound absorption coefficients, baffle arrays, reverberation rooms, sound absorption specimen mountings.*

1. INTRODUCTION

There appear to be a number of different ways in the current version of ISO 354:2003(E) [1] that the sound absorption of an array of baffles can be reported. 6.2.2.1 says "Rectangular unit sound absorber pads or baffles shall be installed in a Type J mounting as specified in Annex B." B.7 Type J mounting says "This mounting shall be used for the general specification of the sound absorption per unit of rectangular unit sound absorber pads or baffles." This means that the sound absorption per individual baffle and not the sound absorption coefficient needs to be reported. B.7 Type J mounting allows for the use of two different measurement methods, which are the well approach where “the height of the barrier shall be the same as the height of the baffles or pads”, and the deep well approach where “the barrier shall be 0,8 m higher than the baffles or pads, but the height of the barrier shall not exceed half of the height of the reverberation room”. It also says that “one or two walls of the reverberation room may be used as part of the barrier. This will probably lead to more possible different measurement results.
8.1.4 Calculation of equivalent sound absorption area of discrete absorbers says "For a specified array of objects, the result is given as the sound absorption coefficient." Thus, if the array of baffles is treated as a specified array of objects, the sound absorption coefficient needs to be reported. 3.8 Area of the test specimen NOTE 2 says "In the case of a test specimen surrounded by a structure (type E mounting or

type J mounting), it is the area enclosed by the structure." Thus, the floor area enclosed by the structure is used if an enclosure is used.

Baffle arrays are becoming much more complicated than was envisaged when the type J mounting in ISO 354:2003(E) [1] was written, as is shown in Figure 1 and Figure 2.

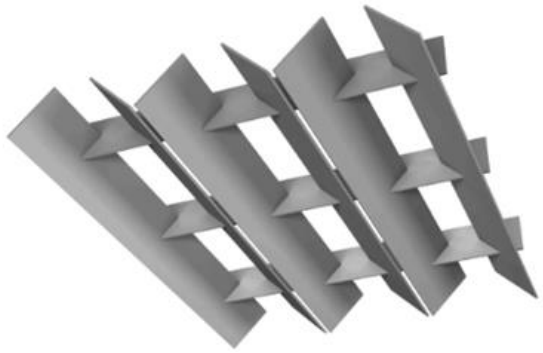

Figure 1. A baffle array with some baffles which are not vertical or horizontal, more than 3 rows of baffles in a measurement size specimen, and baffles running in two perpendicular directions.

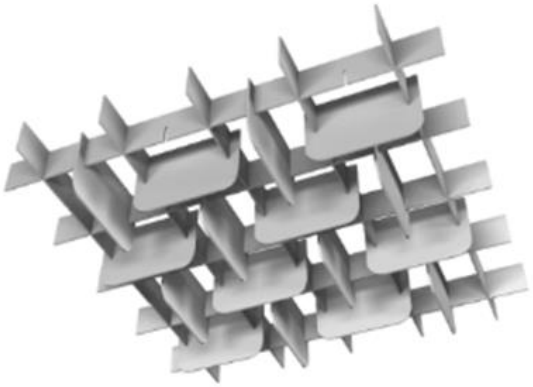

Figure 2. A baffle array with some baffles which are not continuous in their long dimension, more than 3 rows of baffles in a measurement size specimen, and baffles running in two perpendicular directions.

However, because 6.2.2.1 and B.7 Type J mounting only cover rectangular unit sound absorber pads or baffles where "The baffles shall be arranged in two or three parallel rows." most baffle arrays are probably not be covered by the type J mounting because there will usually be more than 2 or 3 parallel rows of baffles, and the baffles may not be rectangular or mounted vertically. In that case the baffle array should probably be tested without an enclosure as a specified array and the sound absorption coefficient should be reported as required by 8.1.4. 8.1.3 says that the area to be used for the calculation of the sound absorption coefficient "is the area, in square metres, covered by the test specimen (see 3.8)." Thus, just the covered floor area is used, and the area of the uncovered sides of the baffle array is not included.

Alternatively, the baffle array could be regarded as being in a Type A mounting without covered edges. B.2 Type A mounting says "If the edges of the test specimen are exposed when the material is normally installed in an actual application, then the edges of the test specimen shall not be sealed or covered during a test. If the edges are not covered, the area of the edges shall be included in calculating the test specimen area." In this case, the areas of sides as well as the area of the top of the cuboid containing the baffle array are used to calculate the sound absorption coefficient.

This possibility in ISO 354:2003(E) [1] to report the sound absorption of a baffle array in many ways is totally unacceptable. Examples of some of the possible different sound absorption coefficients are given later in this paper in Figure 5 and Figure 6 where the sound absorption coefficients differ by up to 0.45.

The Type J Mounting of ASTM E795-23 [2] does not surround the specimens with an enclosing non-absorptive barrier and its Note 13 says “The measured sound absorption is in square metres per unit.” This is because in the absence of an enclosing barrier to define the area, the use of a sound absorption coefficient is completely inappropriate. It is unfortunate that ISO 354:2003(E) [1] used the same Type J mounting name as ASTM E795-23 [2] when specifying a mounting type with a surrounding enclosure when the ASTM E795 Type J mounting is without a surrounding enclosure.

If Sabine’s equation is used, only the sound absorption added to the room by the arrays of baffles is needed. These days, most acoustic consultants use ray tracing programs for which they need the sound absorption coefficient. Also, it is difficult for measurement laboratories to have surrounds with many different lengths, widths and heights to cope with baffle arrays of different lengths, widths and heights. This has led to suppliers of baffle arrays having measurements made without a surround and quoting sound absorption coefficients calculated using only the area of the smallest rectangle covering or enveloping the projection on the nearest room surface of the installed baffle set. The authors of this paper are aware of sound absorption coefficients as high as 1.7 being advertised. This is much greater than the maximum that the edge effect could account for. Because the supplier would not release the

confidential test report, it was impossible to know the area of baffle arrays that had been tested and use that area to back calculate the sound absorption from the advertised sound absorption coefficient to calculate a more realistic sound absorption coefficient. In one case, a supplier advertised practical sound absorption coefficients which were greater than one, in contravention of ISO 11654:1997 [3].

Another complication when considering the best way to report the sound absorption of arrays of baffles, is that they may be installed in different ways. In a meeting room, only one or several baffle arrays may be installed, whereas in a factory or other large space, a large continuous area of baffle arrays may be installed. For a large area installation of baffle arrays, it is more appropriate to measure with a non-sound absorbing surround, because the reflections from the inside surface area of the surround simulate an infinite periodic array in two dimensions of the specimen inside the surround. However, if the installation area is small and the sides of the specimen volume and any airgap are not covered, testing without a non-sound absorbing surround may be more appropriate. If the sound absorption coefficients of the sides and the back side of the specimen volume are very different from the sound absorption coefficient of the front side of the specimen volume, then testing with a non-sound absorbing surround is probably more appropriate.

2. PROPOSED CHANGES TO ISO 354

ISO 354 should state that its primary measurement result is the amount of sound absorption added to the reverberation room by the addition of the specimen minus the sound absorption of any reverberation room surface area that the specimen covers (which is usually considered not to be significantly different from zero). It should require that the sound absorption in square metres be reported for all specimens.

3.8 of ISO 354 which defines the area of the test specimen as the “area of the floor or wall covered by the test specimen” needs to be changed. If a sound absorption coefficient is calculated, ISO 354 should require that any sound which hits the specimen must pass through an imaginary surface whose surface area is the area which is used to calculate the sound absorption coefficient. It should require that, as far as possible, any sound which passes through this imaginary surface hits the specimen, that this imaginary surface, possibly together with part of the room surface and the surface of any surrounding non-absorptive enclosure, encloses a relatively simple volume, and that the area of this imaginary surface is minimized. This enclosing simple volume would normally be expected to be a cuboid or occasionally a cylinder.

If the specimen consists of an array of elements separated by air gaps, the specimen shall consist of the smallest relatively simple volume which enclosures the array of elements. Again, this specimen volume would normally be expected to be a cuboid. This means that the specimen volume will be contained in, and maybe equal to, the enclosing volume used to determine the surface area to be used when calculating the sound absorption coefficient.

If the specimen consists of an array of elements which are placed periodically in a direction with a spacing of d, the specimen volume shall be extended by $d/2$ at each end of the specimen, as shown in Figures B.1 and B.2 of ISO 354:2003(E) [1]. This is because when larger areas of the specimen are installed, the periodic spacing of d would normally be continued in that direction. This extension could apply in two right-angled directions. This would be the case with the Type JV and JH mountings in ASTM E795-23 [2].

For a specimen which has an air gap between it and the room surface from which it is mounted, the enclosing volume will be the extension of the specimen volume to the room surface if the area of the surface of the enclosing volume, excluding the area of the surface of the enclosing volume which is a room surface, is smaller than the surface area of the specimen volume. Otherwise, the enclosing volume will be the specimen volume, and the specimen will be regarded as mounted in free space away from the room surface.

If the specimen volume is a cuboid whose length and width are L and W respectively, the area of the bottom surface of the specimen volume is LW. If the air gap has height H, the area of the skirt around it between the room surface and the specimen volume is $2H(L+W)$. Thus, the enclosing volume is the specimen volume if $H \geq LW/(2(L+W))$. For a specimen volume whose bottom is a square, the enclosing volume is the specimen volume if the height of the air gap is greater than or equal to one quarter of the length of the sides of the square. For a typical ISO 354:2003 specimen size of 3 by 3.6 m, the enclosing volume is the specimen volume if the height of the air gap is greater than or equal to 0.818 m. For a typical ASTM 423-22 [4] specimen size of 2.44 by 2.74 m, the enclosing volume is the specimen volume if the height of the air gap is greater than or equal to 0.645 m.

If a sound absorption coefficient is reported, the area used to calculate the sound absorption coefficient, and the surface used to calculate this area must both be reported.

For type A with a surround, Type B, Type E, Type G with a surround, Type I, and Type J mountings, the above

proposed rules mean that the area used to calculate the sound absorption coefficient is the area of the open top of the non-absorbing surround, as would be expected. For Type A and type G mountings without a surround, the above proposed rules mean that the area of the sides of the specimen volume and if an air gap exists, the area of sides of the air gap, or the area of the bottom of the specimen volume, are also included in the area used to calculate the sound absorption coefficient.

For individual objects which are “arranged randomly, spaced at least 2 m apart” and “mounted at least 1 m from any boundary or room diffusers and at least 1 m from any microphone”, the area of the surface of an enclosing volume should be calculated for each object.

The above proposed rules remove the problematic 8.1.3 which says that the area to be used for the calculation of the sound absorption coefficient "is the area, in square metres, covered by the test specimen (see 3.8)." They also remove the troublesome second sentence of 8.1.4 which says “For a specified array of objects, the result is given as the sound absorption coefficient” because the calculation of a sound absorption coefficient is optional. The proposed rules allow the basic type J mounting to be used for more general items than just two or three rows of rectangular unit sound absorber pads or baffles. In particular, the type J mounting could be used for baffle arrays or theatre seats. The proposed rules also cover functional sound absorbers because they require the sound absorption to always be reported.

In the field, the measured sound absorption coefficient should be applied to the surface calculated using the above proposed rules. This means that the effect of any uncovered sides becomes smaller as the area of the installation increases.

If non-absorbing enclosures are used, it is suggested that the enclosure be allowed to be between 0 and 12.5 mm higher than the object(s) that are being tested for practical reasons. This would enable the stacking of enclosure elements with heights of 12.5, 25, 50, 100, 200, 400 and 800 mm. It is suggested that for each enclosure element height, the enclosure elements consist of two 4.2 m lengths and two 3.6 m lengths so that they can be arranged by adjusting the junction overhangs at all 4 corners to enclose a rectangular area of any size complying with the area and aspect ratio specimen requirements of ISO 354. The areal density of the enclosure should be greater than 5 kg/m^2. The enclosure should not be constructed of gypsum plaster board.

The Type J mounting currently allows one or two of the room walls to be part of the non-absorbing enclosure. It is recommended that this no longer be allowed and that the non-absorbing enclosure be required to be away from all room surfaces except for the room surface that the non-absorbing enclosure is installed on. An exception to this rule would be for full length curtains or drapes and for absorbers that are to be mounted at room edges and corners.

The deep well approach [5] in the Type J mounting is designed to remove the edge effect. However, its use only with the Type J mounting is inconsistent with other mountings. It is recommended that its use be removed from ISO 354.

3. WITH AND WITHOUT AN ENCLOSURE

The sound absorption coefficients of two baffle arrays were measured with (Figure 3) and without (Figure 4) a surrounding enclosure.

Figure 3. The baffle array with 100 mm spacing with a surrounding enclosure.

Both baffle arrays were constructed from the same 12 mm thick polyester material with a density of 192 kg/m^3. The main vertical baffles were 300 mm deep and 3.6 m (2.4 and 1.2 m) long and were held in place by six 80 mm deep and 3 m (1.8 and 1.2 m) cross vertical baffles of the same 12 mm thick material between the floor of the reverberation room and the main baffles. 20 mm deep notches were cut into both types of baffles so that the main baffles and the support baffles could be interlocked together over a depth of 40 mm. This meant that the height of the baffle array was 340 mm.

In the first baffle array the centre planes of the main baffles were 200 mm (200) apart and in the second baffle array the centre planes of the main baffles were 100 mm (100) apart. The support baffle arrays extended half of the main baffle spacing beyond the centre planes of the main baffles at each end of the array. This was done to comply with the

requirement to have half of the main baffle spacing beyond the centre planes of the two outer baffles in the Type J mounting in ISO354:2003(E) [1]. Measurements were made with a 340 mm high non-absorbing surrounding enclosure (Yes) and without this enclosure (No). The enclosure consisted of 32 mm thick 300 mm high medium density fibreboard (MDF) with 1 mm thick 40 mm high steel on top. For the enclosure case, the sound absorption coefficients were calculated using the area of the top surface (Top) of the specimen volume (10.8 m^2). For the no enclosure case, the sound absorption coefficients were calculated using the area of the top surface (Top) of the specimen volume (10.8 m^2) and the area the top and side surfaces (Top+Sides) of the enclosing volume (15.288 m^2).The calculated sound absorption coefficients are shown in Figure 5 and Figure 6.

Figure 4. The baffle array with 100 mm spacing without a surrounding enclosure.

Above 200 Hz, the sound absorption coefficients calculated from the measurements made without a non-absorbing surrounding enclosure using the area of the top and sides of the enclosing volume are closer to those calculated from the measurements made with a non-absorbing surrounding enclosure using the area of the opening at the top of the enclosure, than those made using only the area of the top of the enclosing volume. This is a strong justification for adopting the changes to ISO 354:2003(E) [1] recommended in this paper.

However, there are still differences between sound absorption coefficients calculated with and without a non-absorbing surrounding enclosure. It is suggested that ISO:354 should recommend that sound absorption coefficients should normally be calculated from measurements made with a non-absorbing surrounding enclosure, unless there are very good reasons for measuring without a non-absorbing surrounding enclosure. If sound absorption coefficients are reported, it is further recommended that different names be given to sound absorption coefficients calculated using measurements made with or without a non-absorbing enclosure.

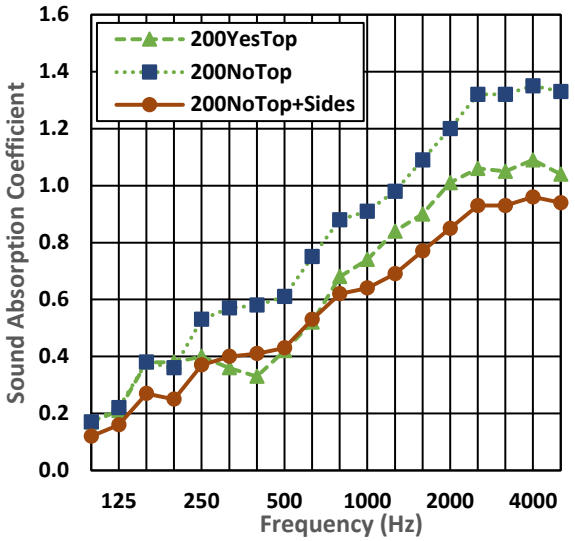

Figure 5. The calculated sound absorption coefficients of the baffle array with 200 mm spacing.

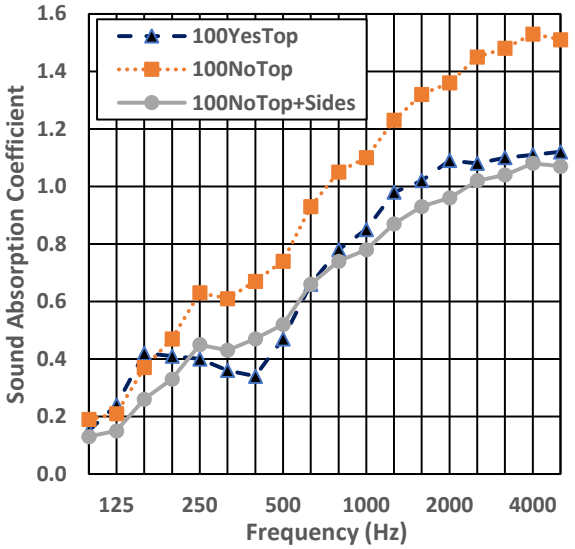

Figure 6. The calculated sound absorption coefficients of the baffle array with 100 mm spacing.

4. CONCLUSION

It is recommended that sound absorption be the fundamental result that is required to be given in ISO 354 reports. If sound absorption coefficients are reported, it is recommended that ISO 354 requires that they be calculated using the rules given in this paper. It is also recommended that different symbols be used for sound absorption coefficients calculated using measurements made with (α_e) or without (α_{ne}) a non-absorbing enclosure and that sound absorption coefficients calculated from measurements made with a non-absorbing enclosure are the preferred ones. These recommendations are made to stop suppliers advertising sound absorption coefficients as high as 1.7.
It is recommended that the room surfaces are not allowed to be part of a non-absorbing enclosure and that, in most circumstances, the only room surface close to a non-absorbing enclosure is the room surface that it is mounted on. It is recommended that the deep well approach be removed from ISO 354 for consistency.

ABSTRACT

A residual neural network is proposed to predict the sound absorption of an infinite rigidly-backed porous material from a classical two-microphone measurement above a finite porous sample. The network is trained using the microphones' transfer functions generated by a boundary element model (BEM), with a Delany-Bazley-Miki material model as a boundary condition. The network is validated numerically with BEM simulations and experimentally using two-microphone measurements of a baffled porous absorber of dimensions 60 cm×60 cm and 30 cm×60 cm, subject to various source locations. The results indicate that the network can significantly enhance the predictive capabilities of the classical two-microphone method. The suggested approach shows potential for accurately estimating the sound absorption coefficient of acoustic materials in realistic operational conditions.

1. INTRODUCTION

The ability to characterize the absorption properties of absorbing materials is essential for a wide range of engineering applications. Standardized methods such as the impedance tube method [1, 2] or the reverberation chamber method [3] are limited to normal and random incidence, respectively. In contrast, angle-dependent absorption data can be obtained with *in situ* and free-field methods [4]. These methods typically rely on measurements of the sound pressure (and/or particle velocity) in the sample's vicinity [5–10] and on an analytical model of the sound field above the sample [4]. Existing models are based on plane-wave [5, 11, 12] or spherical-wave [6, 9, 10] assumptions and generally assume that the sample is infinite in extent. This assumption does not hold in measurements of realistic samples, and edge-diffraction effects result in erroneous absorption properties [13–19].

Several methods for modeling and mitigating edge diffraction effects have been proposed in the literature concerned with characterizing acoustic materials [18, 20–22]. In particular, a number of studies have employed

machine-learning approaches to mitigate the edge effect based on measurements with an array of microphones [23, 24]. Other work utilizes machine learning techniques for efficient work with the impedance tube [25] and physics-informed neural networks [26].

This study introduces a deep-learning-based two-microphone approach to predict the angle-dependent sound absorption coefficient of finite-sized acoustic samples. Such an approach is of interest in that it only requires common instrumentation and a straightforward measurement procedure (the well-established two-microphone method [5]), unlike the more cumbersome approach in [23]. The proposed method uses a 1D residual neural network trained to predict the angle-dependent sound absorption coefficient from transfer function measurements. The network is trained and validated based on BEM-generated data [18, 23]. The validity of the proposed approach is examined numerically and experimentally using fibrous samples of different sizes and orientations. The results are compared with impedance tube measurements and analytical predictions from the two-microphone measurements.

2. METHODOLOGY

2.1 Datasets

2.1.1 Numerical datasets

For training and validation purposes, a numerical dataset is generated with a boundary element method (BEM) [18], following a procedure similar to that of [23]. The two microphones are located at 1 cm and 3 cm above the sample, which is assumed to be flush-mounted on a rigid baffle. The material properties are described based on a Delany-Bazley-Miki model [27]. The remaining BEM parameters span relevant values commonly found in practical scenarios: the sample sizes span from 20×20 cm^2 to 1 m^2, the thicknesses $d \in [5, 200]$ mm, the flow resistivity $\sigma \in [5, 100]$ kNs/m^4, the source distance $\|\mathbf{r}_q\| \in [1.2, 1.8]$ m, the source azimuth $\phi \in [0, 360)$ deg, and the source elevation $\theta \in [0, 80]$ deg. The frequency range is $f \in [100 : 10 : 2000]$ Hz. 50 000 instances were generated and split into $80 : 20$ for training and validation, and an additional 3 000 unique instances (not seen during training) were generated to test the network. More details on sampling these parameters can be found in [28].

2.1.2 Experiental datasets

We also performed eight two-microphone measurements with glass wool samples, model Focus A2 by Saint-Gobain Ecophon, of two sizes (60×60 cm^2 and 30×60 cm^2) to validate the method experimentally for various source distances and incidence angles. The samples were flush-mounted in baffles of medium-density fiberboard (MDF) panels. As in the BEM-generated training set, the microphones (model G.R.A.S. 40 PH) were placed 1 and 3 cm above the sample, and an omnidirectional sound source (model Monacor KU-516) emitted a 10-second-long sine sweep. A Brüel & Kjær Type 2706 amplifier and a National Instruments NI eDAQ-9178 digital acquisition system were used to collect the relevant time signals for postprocessing. The reader is referred to [28] for more details on these experiments.

2.2 Proposed neural network

A 1D residual neural network is designed to take two input features: (i) the complex-valued transfer function between the two microphones, and (ii) the source elevation angle θ, to predict the frequency-dependent sound absorption coefficients. The real and imaginary parts of the transfer function are treated as separate feature channels. At the same time, the elevation angle is skip-connected and concatenated with the latent space resulting from the network's convolutional layers. For precise network design and architecture details, the reader is referred to [28].

The network is trained for 250 epochs, using the mean squared error (MSE) as the loss function. The optimization was performed using an Adam optimizer with mini-batches of 64 samples and a weight decay of 10^{-3} [29]. The learning rate was set to 10^{-3} in the first 10 epochs and reduced exponentially by 0.9 from the 11-th epoch onwards. An early stopping criterion was imposed to prevent overfitting. In general, it is shown in [28] that training converges around 125 epochs.

3. EXPERIMENTAL HIGHLIGHTS

The network predictions were first evaluated using only numerical data, that is, in the same form used for training. As mentioned in section 2.1, 3000 examples unseen by the network during training were used for testing the predictions. With an MSE of $8.42 \cdot 10^{-5}$, the network provides accurate predictions of the sound absorption coefficient in various scenarios.

Figure 1 shows the network's prediction for the two measured glass-wool samples. Figs. 1a and 1d show two example results for normal wave incidence, with the curves "Miki model" viewed as the reference results. The network predictions underestimate the absorption coefficient somewhat, by less than 0.05 for the larger sample (Fig. 1a) and by less than 0.10 for the smaller sample (Fig. 1d).

Physical absorber samples were measured in an impedance tube to offer typical experimental reference results. Results are shown in Figs. 1b and 1e, with predictions based on simulated measurements on a smaller sample, Fig. 1b, and a larger sample, Fig. 1e. Note that somewhat longer source distances were used in Figs. 1b and 1e, compared to Figs. 1a and 1d. Again, the predictions by the network seem to underestimate the absorption coefficient somewhat, but the agreement is very good for the larger sample. It is worth noting that the impedance tube measurement values deviate somewhat above 1.5 kHz and may not be considered as true reference results.

Finally, traditional two-microphone measurement results for a smaller and a larger sample are presented in Figs. 1c and 1f, together with network predictions. Slightly longer source distances were used for this final comparison. For such small samples as were tested here, the finite-size effects are substantial, and it is clear that the network predictions suppress these interference effects completely. For instance, owing to the intrinsic nature of the training of the network, the method inhibits the emergence of negative absorption values.

Finally, the consistency of the network predictions for varying source distances should be emphasized, as only marginal differences within the rows can be observed.

4. CONCLUSION

Based on a deep-learning-based two-microphone approach, we predict the angle-dependent sound absorption coefficient of finite-sized acoustic samples utilizing well-established measurement procedures and a one-dimensional residual neural network. More concretely, appropriate boundary element method simulations, assuming a Delany-Bazley-Miki material model, provide the necessary database for the network training and validation within a frequency range of interest between 100 Hz and 2 kHz. In addition, suitable measurements of fibrous samples of different sizes and orientations provide the transfer functions to validate the methodology. Comparing the results of the analytical model, the impedance tube measurements, and the prediction based on the neural network, one finds a high prediction quality concerning the analytical model and the impedance tube measurements. Furthermore, the neural network predictions toward the traditional two-microphone method are free from the typical edge diffraction effects, providing a suitable strategy for reliable absorption coefficient estimation. The proposed method aims to help engineers in room acoustics and material property identification accurately predict the sound absorption coefficients based on the well-known two-microphone measurement procedure without the common edge-diffraction errors.

[†]A joint institution of the Friedrich-Alexander-Universität Erlangen-Nürnberg (FAU) and Fraunhofer Institute for Integrated Circuits (IIS)

ABSTRACT

The acoustic diffusion equation provides a generalized statistical model of room acoustical fields, allowing for non-uniform distributions of sound energy and spatially varying surface absorption coefficients. Recent studies have shown that the diffusion equation can be used to estimate spatially uniform, frequency-dependent absorption coefficients from in situ measurements. In this work, we extend this approach to handle spatially non-uniform absorption by using the ratio of intensity to energy density. Numerical simulations demonstrate the feasibility of this method when used to estimate frequency-dependent, spatially non-uniform absorption coefficients in a room.

Keywords: *Acoustic diffusion equation, Non-uniform absorption coefficient estimation, Intensity - Energy density ratio, Field index.*

1. INTRODUCTION

Accurate descriptions of sound-absorbing materials are essential for reliable computer simulations of room acoustics [1]. While absorption coefficients can be measured in controlled environments, e.g., reverberation chambers [2], their applicability diminishes once materials are installed in a room. The angle-dependent nature of many sound-absorbing materials means that their absorption coefficients can depend on the room in which they are installed. Consequently, several in-situ measurement methods for measuring absorption coefficients can be found in the literature [3].

The diffusion equation has recently been used for in-situ estimation of spatially uniform, frequency-dependent absorption coefficients in a small room [4]. While the diffusion equation predicts a spatially uniform reverberation time (for an uncoupled room), it also predicts a non-uniform energy flux. The non-uniformity of the energy flux is utilized in this work to estimate spatially non-uniform absorption coefficients in a small room. The proposed inverse method employs eigenvalue analysis of a diffusion equation model of a room to estimate unknown surface absorption coefficients.

This paper is organized as follows: Section 2 provides background information relevant to the work. Section 3 presents the diffusion equation, a numerical implementation, and the post-processed solutions. The method for estimating the absorption coefficient is introduced in Sec. 4, and a simulated room with four different boundary conditions is presented as a test case in Sec. 5. The results of the absorption coefficient estimations are discussed in Sec. 6. Limitations and future studies of the proposed method are discussed in Sec 7, and Sec. 8 outlines the conclusions.

2. LITERATURE REVIEW

The normal incidence impedance of a material sample can be measured using an impedance tube [5], and a random incidence absorption coefficient can be computed from the normal impedance. However, measurements in an impedance tube preclude edge effects and may include unwanted installation effects. Thus, reverberation chambers are often used to measure the random incidence ab-

sorption coefficients of large material samples [2]. Due to room and installation effects, the coefficients measured in a reverberation chamber may not reflect the actual absorption of a material placed in a room. Thus, in-situ methods can provide additional insight into the absorption characteristics of materials.

While many in-situ methods can be found in the literature [3], we limit our scope to those that consider intensity. Tijs and Druyvesteyn [6] propose and validate the use of several spatially distributed intensity measurements to determine the absorption coefficient of a material sample. Kuipers *et al.* [7] numerically verify a plane wave-based intensity method for measuring absorption coefficients of a material sample. Since the intensity over a sample can be non-uniform [8], intensity-based methods often require spatial averaging. Vigran [9] introduces a *field index*, which is the ratio of the intensity to the product of the energy density and the speed of sound. Wijnant *et al.* [10] note that the field index could be used as a measure of sound absorption. A review of the literature suggests that this observation has not been further explored.

Ollendorff [11] proposes a diffusion model of enclosed sound fields, and Picaut *et al.* [12] provide a mathematical derivation of the diffusion equation. Several researchers have developed and evaluated models based on the diffusion equation. For example, Foy *et al.* [13] compare predictions of reverberation time from two diffusion equation models to measured reverberation time data. Billon *et al.* [14] propose a boundary condition for the diffusion equation based on Eyring's absorption coefficient, and Jing and Xiang [15] propose a modified boundary condition for the diffusion equation. Prinn *et al.* [4] use the diffusion equation to estimate spatially uniform absorption coefficients of the surfaces of a measured room.

The diffusion equation allows for the incorporation of random incidence absorption coefficients that can vary spatially. By solving the diffusion equation, we can predict various parameters such as reverberation time, energy density, and intensity. This study utilizes the capability to model spatially non-uniform absorption along with predictions of reverberation time and field index to estimate absorption coefficients across multiple surfaces. The approach is demonstrated using low-frequency finite element simulations.

3. THEORY

In this section, we introduce the diffusion equation, a finite element method implementation, and the processing of the first eigenvalue and eigenvector of the diffusion equation.

3.1 Diffusion equation

Following the derivation by Picaut *et al.* [12], the homogeneous diffusion equation can be written as

$$\frac{\partial w(t,\mathbf{x})}{\partial t} - D\,\nabla^2 w(t,\mathbf{x}) = 0\,, \tag{1}$$

where $w(t,\mathbf{x})$ is the sound energy density, which depends on time t and spatial position $\mathbf{x}$. The diffusion coefficient $D = \bar{l}c/3$ is given in terms of the speed of sound c and mean free path $\bar{l}$. The mean free path is given by $\bar{l} = 4V/S$, where V is the room volume and S is the surface area. [1]

To complete the model, we make use of the sound absorption coefficient boundary condition proposed by Jing and Xiang [15]

$$D\,\frac{\partial w(t,\mathbf{x})}{\partial n} = \frac{-c\,\alpha}{2(2-\alpha)} w(t,\mathbf{x})\,, \tag{2}$$

where $\partial/\partial n$ is the normal derivative, and α is a random incidence absorption coefficient. Note that the absorption coefficient can be spatially dependent, a fact that forms the basis of this work.

Choosing a solution that decays exponentially, we write the sound energy density as [16, Eq. (5.6)]

$$w(t,\mathbf{x}) = \phi(\mathbf{x})\mathrm{e}^{-\lambda t}\,, \tag{3}$$

with amplitude (eigenvector) ϕ and damping constant (eigenvalue) λ.

3.2 Numerical implementation

Equations (2) and (3) are used in combination with the finite element method to reformulate Eq. (1), resulting in the eigenvalue problem

$$\left[D\,\mathbf{K} + \sum_{j=0}^{J} \frac{c\,\alpha_j}{2(2-\alpha_j)}\mathbf{C}_j - \lambda\mathbf{M}\right]\boldsymbol{\phi} = \mathbf{0}\,, \tag{4}$$

where $\mathbf{K}$, $\mathbf{C}$, and $\mathbf{M}$ are stiffness, damping, and mass matrices, respectively, j identifies an absorbing surface, λ is an eigenvalue, and $\boldsymbol{\phi}$ is a discretized eigenvector. The elemental stiffness, damping, and mass matrices are given by

$$\mathbf{K}_e = \int_e \nabla\mathbf{N}^T \cdot \nabla\mathbf{N}\,\mathrm{d}V\,, \tag{5}$$

[1] This mean free path is based on a diffuse field assumption.

$$\mathbf{C}_{e',j} = \int_{e'} \mathbf{N}^T \mathbf{N} \, \mathrm{d}S_j \,, \tag{6}$$

$$\mathbf{M}_e = \frac{1}{c^2} \int_e \mathbf{N}^T \mathbf{N} \, \mathrm{d}V \,, \tag{7}$$

where the subscript e represents an interior element, e' represents a boundary element, S_j is a sound absorbing surface, and $\mathbf{N}$ are interpolating shape functions. The elemental matrices are solved numerically and used to assemble $\mathbf{K}$, $\mathbf{C}$, and $\mathbf{M}$. (For details, see, e.g., Prinn [17]).

3.3 Post-processed quantities

The solution of Eq. (4) provides a set of eigenvalues and eigenvectors. We only concern ourselves with the first (smallest) eigenvalue, λ_0, and the first eigenvector, ϕ_0.

3.3.1 Reverberation time

An estimation of the reverberation time of an uncoupled room can be computed from the eigenvalue as follows:

$$\widehat{T}_{60} = \frac{2\log(1 \times 10^3)}{\lambda_0} \,. \tag{8}$$

3.3.2 Field index

A normalized energy flux, or intensity, can be computed from the eigenvector, as follows

$$\widehat{\mathbf{I}} = -D\nabla \cdot \phi_0(\mathbf{x}) \,. \tag{9}$$

The intensity normal to an absorbing surface is of interest in this work. This is given by

$$\widehat{\mathrm{I}}_n = \widehat{\mathbf{I}} \cdot \mathbf{n} \,, \tag{10}$$

where $\mathbf{n} = (n_x, n_y, n_z)$ is an outwardly pointing unit normal vector. Finally, for the absorption coefficient estimation, the (normalized) intensity to energy density ratio, or field index [9], is defined as

$$\widehat{\mathrm{F}} = \frac{\widehat{\mathrm{I}}_n}{\phi_0 \, c} \,. \tag{11}$$

Note that the field index can be related to the absorption coefficient (as observed in Ref. [10]). This can be shown by replacing the energy density in Eq. (2) with the eigenvector. Thus, for the boundary condition considered,

$$\widehat{\mathrm{F}} \sim \frac{\alpha}{2(2-\alpha)} \,. \tag{12}$$

4. ESTIMATION METHOD

The impedance estimation method consists of two main steps. First, measurements of sound pressure and normal velocity are taken at one or more positions within a room, but close to the surfaces at which we would like to estimate the absorption coefficient. This is because the intensity and energy density normal to the surface are required. The reverberation time, intensity, and energy density at these measured positions are calculated. A field index is then computed from the intensity and energy density.

Second, a diffusion equation model of the room is generated, which incorporates unknown absorption characteristics. For example, if the surfaces of a room have one impedance but an absorbing material with a different impedance is placed on the floor, two frequency-dependent absorption coefficients need to be estimated. An eigenvalue analysis of the diffusion equation model is performed, from which the reverberation time and field index at the measurement positions can be computed. An optimization algorithm is subsequently employed to minimize the differences between the observed and simulated values, allowing for the estimation of the absorption coefficients.

4.1 Reference data

An impulse response measurement is made at each surface of interest. The impulse response's energy decay curve is computed using backward Schroeder integration, and the reverberation time is estimated from a straight-line fit to the energy decay curve between -5 dB and -35 dB.

Using two microphones placed normal to the surface of interest, the normal velocity can be estimated from the conservation of momentum, approximated by a finite difference scheme. The frequency domain pressure, P, and normal velocity, V_n, are computed via Fourier transformation. For a given frequency, ω, the time-averaged active normal intensity is given by

$$\mathrm{I}_n(\omega) = \mathrm{Re}\left(\frac{P(\omega)V_n^*(\omega)}{2}\right) \,, \tag{13}$$

and the normal energy density is given by (see, e.g., [18])

$$\mathrm{E}_n(\omega) = \frac{|P(\omega)|^2}{2\rho c^2} + \frac{\rho |V_n(\omega)|^2}{2} \,. \tag{14}$$

A normal field index can be computed from these two quantities, as follows:

$$\mathrm{F}(\omega) = \frac{\mathrm{I}_n(\omega)}{\mathrm{E}_n(\omega) \, c} \,. \tag{15}$$

4.2 Absorption coefficient estimation

A diffusion equation model of the room under test is generated, and an optimization algorithm is used to refine initial guesses of the unknown absorption coefficients to arrive at final estimates. For the optimization, the reverberation times and field index are compared.

If the absorption coefficient sought is spatially uniform, the field index is not computed. The reason is that the field index will be the same on all surfaces. If two absorption coefficients are needed, an average of the reverberation times measured close to each of the surfaces of interest is compared to the diffusion equation prediction. Noting that the diffusion equation predicts a spatially uniform reverberation time, the averaging can lead to improved estimates. For two unknown impedances, two field indices are measured (one for each surface of interest). The ratio of the field indices is used as a measure of the amount of absorption at each surface. The ratio of field indices for two unknown absorption coefficients is given by

$$\mathrm{G}_{2,1} = \frac{\mathrm{F}_{n,2}}{\mathrm{F}_{n,1}}\,, \tag{16}$$

where the subscripts indicate the first and second surfaces. A similar expression is used for the ratio of the diffusion equation field indices. If three or more surfaces are considered, G will be a vector containing the ratios of the field indices with respect to one of the surfaces. Note that using the field index ratio results in a fully determined optimization problem.

To demonstrate the optimization routine, we consider a problem with three unknown absorption coefficients. An array that contains the reverberation time and two field index ratios is generated. For each frequency, or frequency band, considered, the optimization problem reads

$$\tilde{\boldsymbol{\alpha}}(\omega) = \underset{\hat{\alpha}_1,\hat{\alpha}_2,\hat{\alpha}_3}{\arg\min} \|\mathbf{C}(\omega) - \widehat{\mathbf{C}}(\hat{\alpha}_j(\omega))\|_2^2. \tag{17}$$

where $\mathbf{C} = [T_{60}\ \mathrm{G}_{2,1}\ \mathrm{G}_{3,1}]$ and $\widehat{\mathbf{C}} = [\widehat{T}_{60}\ \widehat{\mathrm{G}}_{2,1}\ \widehat{\mathrm{G}}_{3,1}]$. Using Sabine's formula [19], we obtain an initial estimate of the absorption coefficient from a measurement of the reverberation time, as follows:

$$\hat{\alpha}_j(\omega) = 0.161 \frac{V}{S\,T_{60}(\omega)}\,, \tag{18}$$

where V is the room volume, S is the total surface area, and T_{60} is the measured reverberation for a given frequency band. This value serves as an initial guess for all unknown absorption coefficients. A nonlinear least-squares solver is used to obtain the estimates.

5. SIMULATION TEST CASE

The test data is generated using a finite element model of a reverberant room. Details of the room, the simulation setup, and the post-processing applied to the simulation solutions are presented here.

5.1 Room and parameters

The room is a reverberant space with non-parallel surfaces. It may either be empty or contain a sample of material placed on the floor. A diagram of the room is provided in Fig. 1a, and the coordinates of the corners can be found in Tab. 1.

The air in the room has a speed of sound of 343 m/s, and a density of 1.2 kg/m³. A point source is located at the second corner of the room. Impedance boundary conditions are specified for the room's surfaces and the material sample. Four impedance conditions are considered; these are described below.

5.1.1 Case 0

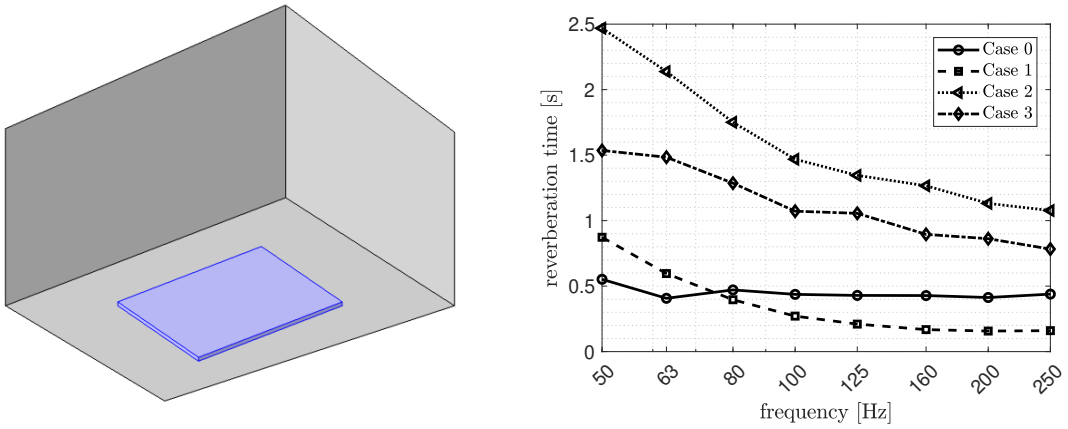
A spatially uniform, frequency-independent, real-valued impedance is considered to demonstrate the inherent error of the diffusion equation-based estimation method. The room is empty, and all surfaces have a normalized impedance of 19.77, which results in a random incidence absorption coefficient of 0.3.

5.1.2 Case 1

In this case, a complex-valued, frequency-dependent impedance is specified on all surfaces of the empty room. The impedance is described using a Delany-Bazley-Miki model [20]. The impedance is given by:

$$\zeta = (R + \mathrm{i}X)\coth\left[(\gamma + \mathrm{i}\beta)l\right] \tag{19}$$

where



$$R = 1 + 0.070\left(\frac{f}{r}\right)^{-0.632}\,,$$

$$X = -0.107\left(\frac{f}{r}\right)^{-0.632}\,,$$

$$\gamma = \frac{2\pi f}{c}\left[0.160\left(\frac{f}{r}\right)^{-0.618}\right]\,,$$

$$\beta = \frac{2\pi f}{c}\left[1 + 0.109\left(\frac{f}{r}\right)^{-0.618}\right]\,,$$

f is frequency, $l = 0.1$ m, and $r = 41 \times 10^3$ rayl/m.

(a) (b)

Figure 1: Test case: (a) reverberant room with non-parallel absorbing walls and a material sample on the floor. (b) average reverberation time as a function of third-octave bands for four different boundary conditions.

Table 1: Coordinates of the corners of the simulated reverberation chamber. The corner at which the sound source is located is shown in bold.

corner	1	**2**	3	4	5	6	7	8
x [m]	0.36	**8**	7.8	0	0.36	8	7.8	0
y [m]	0.57	**0**	6	6	0.57	0	6	6
z [m]	0	**0**	0	0	4.17	4.51	5	4.6

Table 2: Coordinates of sample corners.

corner	1	2	3	4
x [m]	0.50	2.50	2.50	0.50
y [m]	0.50	0.50	2.00	2.00
z [m]	0.10	0.10	0.10	0.10

5.1.3 Case 2

The normalized impedance of the surfaces of the room is 100, which gives a random incidence absorption coefficient of 0.0734. A material sample with a height of 0.1 m is placed on the floor. The coordinates of four corners of the sample are given in Tab. 2. The impedance model described in Eq. (19) is specified on the sample's surface.

5.1.4 Case 3

The impedance of the walls is 100, while the impedance of the ceiling is 19.77. These values yield random incidence absorption coefficients of 0.0734 for the walls and 0.3 for the ceiling. The sample placed on the floor utilizes the Miki impedance model, as introduced in Eq. (19).

5.2 Simulation and post-processing

Finite element method simulations of the reverberation chamber are performed in the frequency domain to incorporate complex-valued, frequency-dependent boundary conditions in the impulse responses. Impulse responses are obtained via inverse Fourier transformation and filtered into third-octave frequency bands using a second-order Butterworth filter. Decay curves are then calculated from these responses using Schroeder integration [21]. The reverberation times, shown in Fig. 1b, are estimated by fitting straight lines to the energy decay curves between -5 dB and -35 dB, adjusting for offset, and determining the time at -60 dB. Field indices are computed from the pressure and normal velocity at the center of each surface of interest.

6. RESULTS

In this section, we compare the specified and estimated absorption coefficients for four test cases. It is important to note that the specified random incidence absorption coefficients are calculated from the specified impedances.

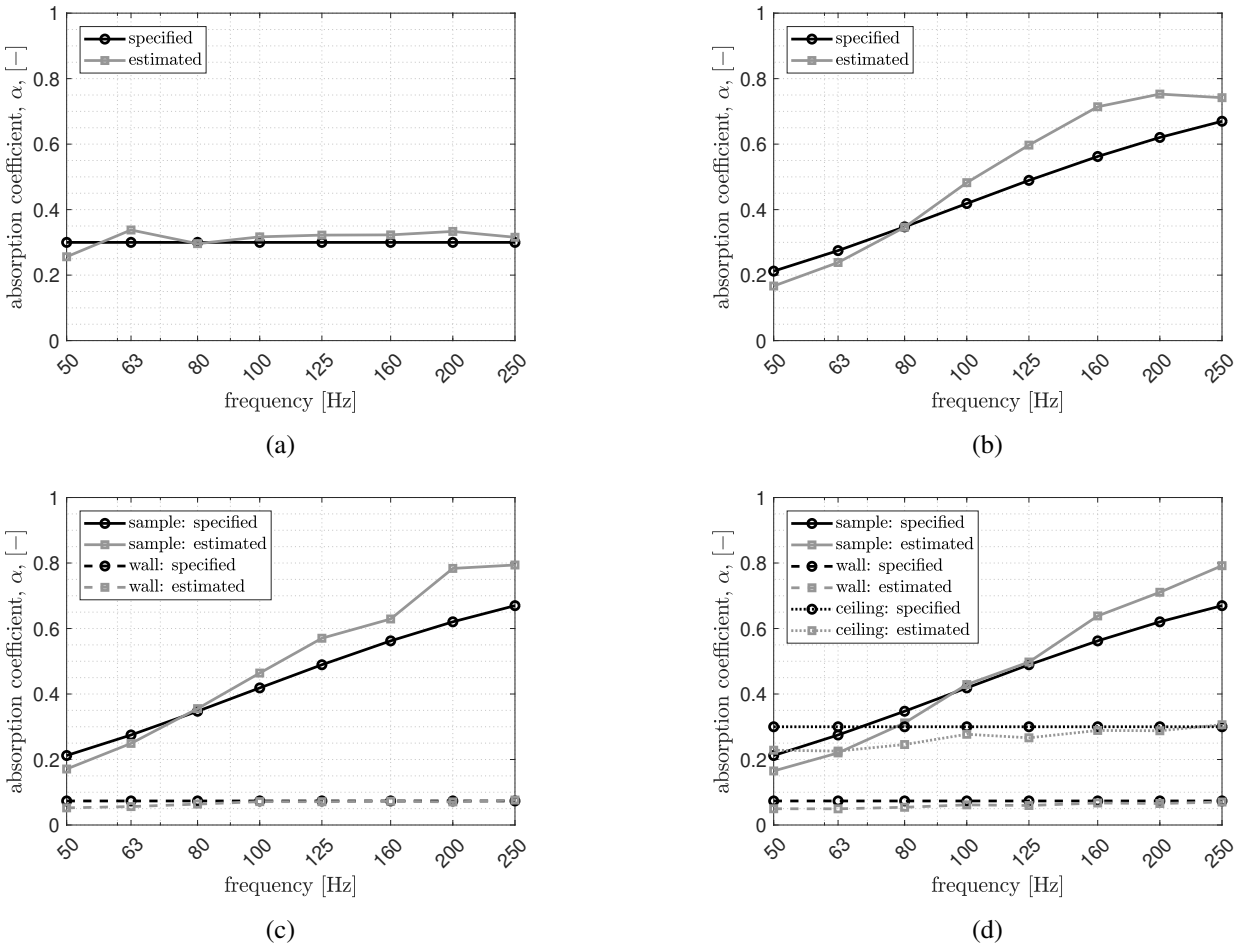


Figure 2: Comparison of specified and estimated absorption coefficients. (a) Case 0 (1 real-valued impedance), (b) Case 1 (1 complex-valued impedance), (c) Case 2 (2 impedances), and (d) Case 3 (3 impedances).

The absorption coefficients for Case 0 are shown in Fig. 2a. A reasonable level of agreement is found. Slight differences are caused by the inability of the diffusion equation to model the spatial non-uniformity of the reverberation time [22] and the assumption of a random incidence absorption coefficient in the diffusion equation, which is an idealization of sound absorption based on a perfectly diffuse field. In Fig. 2b, the spatially uniform absorption coefficients given by the Miki model are compared with the estimated values. The error in this comparison is larger than Case 0. Although the exact cause of this increased error is not fully known, it is believed that the reverberation time and the assumption of random incidence contribute to it. In Case 2, two unknown absorption coefficients are estimated: one for the room's walls and another for the sample itself. As can be seen in Fig. 2c, the absorption coefficient estimation method effectively captures both the frequency trends and the general levels of the unknown coefficients. For Case 3, three unknown absorption coefficients are estimated. This data is compared to the specified absorption coefficients in Fig. 2d. Once again, a reasonable level of agreement is found. We observe that, while there is some qualitative agreement, there are also differences between the specified and estimated absorption coefficients. We expect that these differences will diminish as the frequency increases; however, high-frequency models were not created for this study due to the high computational costs involved.

7. DISCUSSION

The present study has demonstrated that the proposed method can be used to estimate the unknown absorption coefficients of multiple surfaces. In this section, we address limitations and discuss possible future studies.

7.1 Reverberation time

The diffusion equation assumes a nearly diffuse field. Thus, the reverberation time predicted by the diffusion equation in an uncoupled room is spatially uniform. However, the reverberation time in a room tends to be spatially non-uniform. [2] Thus, more accurate measures of the average reverberation time may improve the estimates. While this might be reasonable in a dedicated measurement setting, a high number of measurements might be impractical for some audio applications, e.g., estimating the absorption coefficients of a listening environment using only a few microphones.

7.2 Normal velocity measurement

Accurately measuring the velocity normal to an absorbing surface can be challenging. The spacing of the microphones and their distance from the surface may affect the estimates. Errors in the measured velocity will lead to inaccuracies in the intensity and energy density, which will subsequently impact the estimates of the absorption coefficient.

7.3 Impedance estimation

In-situ absorption coefficients can be useful for certain simulation tools, but wave methods usually require boundary conditions based on impedance or admittance. Additionally, research has shown that using angle-dependent reflection coefficients at room boundaries enhances the accuracy of the image source method, which requires knowledge of the surface impedance. The absorption coefficients estimated in this study can be converted into real-valued impedances using theories like those from Kuttruff [16]. However, these values were calculated during the preparation of this paper but were deemed too inaccurate to be included. While literature exists on estimating complex-valued impedance from absorption coefficients, such as the work by Mondet *et al.* [23], this topic is outside the scope of the current study.

[2] This is well known in the community, evidenced by the need to average multiple reverberation time measurements in the reverberation chamber method [2], and recently demonstrated for low frequencies [22].

7.4 Modal field

This study has considered a range of frequencies that would generally be associated with the modal region of a sound field. While the diffusion equation is frequency-independent, by construction, it does not model modal fields. Some of the observed errors may be related to missing modal effects. While it is expected that the estimation method will perform better at frequencies above the Schroeder frequency, i.e., for frequencies at which the diffuse field assumption becomes reasonable, further testing is required to determine whether or not improved estimates might be found at higher frequencies.

7.5 Further studies

While the proposed method holds potential for real-world applications, several aspects still need to be investigated. These include the effects of the room geometry, source and receiver positions, measurement noise, and the diffusion coefficient, D, on the absorption coefficient estimates. Also, the impact of multiple complex-valued impedance surfaces and the method's performance for a broader range of frequencies should be investigated. Finally, extending the method to wave methods might also be interesting.

8. CONCLUSION

This paper presents an inverse method to estimate spatially non-uniform absorption coefficients in a room. The proposed method is based on the idea that field index ratios can identify areas of varying sound absorption in the room. An eigenvalue analysis of a diffusion equation model of the room is performed, from which the reverberation time and field index ratio(s) at the measurement positions are computed. An optimization algorithm is employed to minimize the differences between the observed and simulated values, allowing for the estimation of the unknown coefficients. The method is demonstrated using low-frequency finite element simulations. This proof-of-concept work has shown that, at least in principle, the diffusion equation can be used to estimate spatially non-uniform, frequency-dependent absorption coefficients. Future work should consider experimental validations of the proposed method.

ABSTRACT

Sound-absorbing materials play a crucial role in various applications, ranging from noise control to architectural acoustics, enabling us to enhance the acoustic environment and improve our quality of life. Cotton wadding samples with four thicknesses and dimensions were investigated in the present paper. They were assembled in panels, including cylindrical (29 mm and100-mm diameter) and square (400*400mm²) samples. A comprehensive investigation into the differences observed when evaluating the acoustic properties of a multi-layered material using two standardized methods was carried out. Through a series of experiments, including impedance tube and in-situ absorption measurements, this study investigates the complexities of accurately estimating sound absorption characteristics in multi-layered materials. The experimental findings highlight the importance of selecting an appropriate evaluation technique for multi-layered materials, particularly in applications where acoustic performance is critical at lower frequencies.

Keywords: *acoustic characterization, sound absorption, in-Situ absorption measurements, Kundt's impedance tube.*

1. INTRODUCTION

Enhancing the sound absorption properties of materials is crucial in acoustical engineering and materials science, contributing to improved quality of life [1]. The growing trends of urbanization and industrial development have made effective noise mitigation strategies essential as the environments where we live, and work become increasingly noisy. Noise pollution is emerging as a significant environmental hazard to public health worldwide. The rising number of cars, trucks, and two-wheelers has significantly contributed to high levels of vehicular noise. Additionally, poor urban planning and limited city space have resulted in constructing homes near railway tracks, airports, industries, and busy traffic routes. This situation presents a serious risk of exposing the general population to noise-induced health hazards [2,3,4]. Noise reduction is a significant concern for both the government and scientists. Measures to reduce noise can be implemented in three ways: addressing the sound source, improving the transmission path, and enhancing the receiver. Passive control methods, such as sound absorption and sound insulation materials that diminish noise propagation, have been widely used and proven effective [5].

A significant issue in acoustic testing is the considerable discrepancies often observed between the results produced by different methodologies [6-8]. These discrepancies can significantly impact accurately characterizing a material's acoustic properties, resulting in challenges when predicting and optimizing its performance in real-world applications.

Over time, various methods have been developed to

measure sound absorption. Conventional techniques for measuring sound absorption include the impedance tube (or Kundt's tube) [9], and the in-situ surface impedance gun [10]. The impedance tube method is widely regarded as one of the most precise and repeatable techniques for measuring the standard incidence absorption coefficient, particularly on small samples. In contrast, the in-situ surface impedance technique has proven highly valuable, offering a complementary approach for characterizing acoustic absorption without requiring specialized testing facilities [11]. This method uses a sound intensity PU probe, providing a strong alternative to traditional microphone-based approaches. Its application across various industries, such as automotive [12], architecture [13], and road construction [14], demonstrates its versatility and effectiveness in assessing sound absorption.

Each of these techniques has specific strengths and weaknesses and combining results from multiple approaches is common. However, even for acoustic engineers, interpreting these results can be challenging, especially when different methods produce conflicting or inconclusive findings [11]. This section will discuss some well-known techniques. It is important to note that a thorough comparison of the two methods using various materials has not yet been conducted.

Studies [15-18] have demonstrated that, in some cases, the results from the in situ measurements can be quite similar to those obtained using Kundt's tube method, provided that the measurement conditions are consistent.

A sensitivity analysis was conducted by Maco et al. [19], on two different materials, rock wool, and melamine foam, with varying densities and sample thicknesses. The goal was to establish a set of guidelines for performing measurements with the in situ (PU probe) technique. The results obtained from both the in-situ impedance method and the impedance tube technique were compared at high frequencies. The findings indicated that the in-situ method (using a PU probe) provided more accurate results than the impedance tube method. A similar study was conducted in [20], which involved a comparative analysis of sound testing methodologies for multi-layered materials. This study revealed a significant discrepancy between the measurements taken with the impedance tube and those obtained from in situ methods, particularly at low frequencies. The alignment between the in-situ results and those from the reverberation chamber challenged prior assumptions, especially regarding the expected similarity between in-situ impedance measurements and those from the impedance tube for porous materials. Overall, the study underscores the importance of selecting appropriate evaluation techniques for multi-layered materials, as conventional methods may not adequately capture their complex acoustic behavior.

In another study by Peter Cats et al. [21], a preliminary comparison was made between PU probe-based in situ absorption methods and Kundt's tube method. It was found that similar results could be obtained for the examined samples using measurements from PU probes under normal incidence excitation as well as from Kundt's tube.

Despite advancements in the field, there is still a significant gap in understanding the most effective methods for evaluating the acoustic properties of complex, multi-layered materials, both porous and non-porous. This gap underscores a broader challenge: the need for a comprehensive approach that not only addresses the limitations of traditional methods, but also incorporates the strengths of newer techniques, such as the PU in-situ absorption method.

This study, a collaboration between Universitat Politècnica de Catalunya and University of Perugia, aims to try to fill this gap by conducting a comparative analysis of Cotton wadding with different layers. The evaluation will be carried out with two different measurement systems: an impedance tube (Kundt's tube, Brüel & Kjær model 4187) and an in-situ impedance measurement system from Microflown technologies. By comparing these methods directly, the research seeks to provide valuable insights into the selection of optimal tools for assessing acoustic properties, of different materials.

1. MATERIAL AND SAMPLES

The material used in this study is cotton wadding, a lightweight, fibrous textile primarily used in quilting and thermal insulation applications. This material consists of 100% cotton fibers, forming a porous and highly compressible structure, which makes it a potential material

for sound absorption applications. To evaluate its acoustic properties, samples were prepared with different layer configurations, ranging from one to eight layers. Each sample was cut into circular specimens with a diameter of 29 mm and 100 mm, following the standard requirements for impedance tube measurements 10534-2 Standard [22]. The thickness of each configuration was carefully measured to assess its impact on sound absorption performance. Figure 1 displays pictures of the measurement with impedance tube.

The characteristics of the different layers of cotton wadding used in the comparison are summarized in Table [1].

Table 1. Description of the samples for acoustic measurement.

Sample	Sample size (mm)	Thickness (mm)	Pictures
1 Layer	300 x 300 mm^2 Φ 29 mm Φ 100 mm	1.5	
2 Layers	300 x 300 mm^2 Φ 29 mm Φ 100 mm	3.0	
4Layers	300 x 300 mm^2 Φ 29 mm Φ 100 mm	6.0	
8 Layers	300 x 300 mm^2 Φ 29 mm Φ 100 mm	12

3. METHODOLOGY

3.1 Sound absorption testing methods

Over the years, several methods have been developed to measure sound absorption, each having its own unique strengths and limitations [23,24]. The results from these different techniques are often assessed from a broader perspective. However, interpreting these findings can be challenging for acoustic engineers, especially when different methods produce conflicting or inconclusive data. This section will provide a brief overview of the testing methods used in this paper.

An experimental investigation was conducted to characterize the sound absorption properties of a multi-layer sample consisting of 1 layer, 2 layers, 4 layers and 8 layers with an airflow resistivity 77600 Pa*s/m2. Different layers of this material were tested with different standardized methods, namely the Impedance Tube method (Brüel & Kjær, model 4206) [22]), as well as the in-situ PU method [11].

3.1.1 Impedance tube

The impedance tube method, commonly referred to as the Kundt tube, is widely used because it requires only small samples. The standard incidence absorption coefficient was measured using a two-microphone impedance tube (Brüel & Kjær, model 4206) and the transfer function method. This involved cylindrical samples with diameters of 29 mm, small tube for high frequencies between 5o Hz and 6400 Hz, and 100 mm, large tube for low frequencies covering a frequency range from 50 to 6400 Hz, in accordance with ISO 10534-2 standard [22].

In this method, the absorbed portion of the acoustic energy from a wave incident on the tested sample is evaluated in relation to the total incident energy; the unabsorbed portion is reflected back toward the source.

Despite its advantages, this method requires careful

sample preparation and manipulation at multiple sample diameters, which may be challenging for certain materials, such as low-density porous materials.

Moreover, differences between the sample and the actual implementation of the material may result in differences in acoustic properties, especially because in the impedance tube the measurements are carried out at normal incidence, whereas in situ the incidence is random end sometimes diffused.

3.1.2 In situ impedance

In this section, the in-situ absorption methods that will be used are briefly introduced. A more detailed description of the methods can be found in [11]. The measurements can be performed in a broad frequency range (typically from 300 Hz up to 10 kHz) on small samples (typically 0.03 m^2 to 0.38 m^2 or larger) while hardly being affected by background noise and reflections [18, 25-29].
The free-field methods originated from a generalization of the Impedance Tube method. Their purpose is to measure the acoustic impedance of ground surfaces by assessing both acoustic pressure and particle velocity above the target material. This approach allows for the capture of the specific impedance near the sample's surface [11,30-32]. Measurements of the sound absorption coefficient were conducted in both laboratory settings and in situ, utilizing an impedance gun provided by Microflown Technologies [11,18,19,33].
The user must specify the measurement range and frequency resolution at which results are displayed (e.g., octave bands, third-octave bands, or narrow frequency bands).

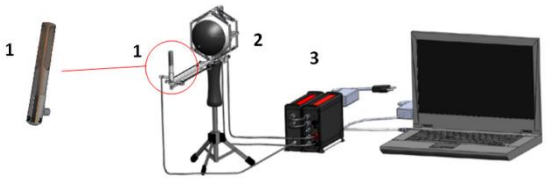

Figure 2. Measurement system assembly provided by Microflown Technologies.

While reflections from surrounding objects can potentially influence results, research has shown that in most relevant environments their impact on test outcomes is minimal, primarily due to the small distances between the sample and the P-U probe. Nevertheless, the impedance gun was calibrated [11] prior to conducting measurements. This calibration process involved pointing the impedance gun towards the best achievable free field conditions, far from any reflective surfaces.

Figure 3. Measurement systems used in the present investigation: in-situ PU method (Left), and impedance tube (right).

4. EXPERIMENTAL INVESTIGATION ON SOUND ABSORPTION

In the in-situ Absorption [19] measurements utilizing the Mirror Source model, each sample approximately is 0.4 m x 0.4 m in size. Measurements were taken by positioning a PU probe about 5mm above the sample's surface, at three arbitrary points (twelve total measurements).

The porosity and airflow resistivity and absorption coefficient of sound-absorb cotton were measured by equipment directly (Figure 4). Airflow resistance is also a powerful tool to characterize sound absorption properties. The airflow resistance has been determined with a Nor1517A airflow resistance measurement system which uses the alternating airflow method described in the standard ISO 9053-2:2020 [34].

Figure 4. Air flow resistance tool.

4.1 Results and discussion

Fiber type, material thickness, density, airflow resistance, and porosity are the key physical parameters influencing the sound absorption characteristics of nonwoven materials [35]. Figure 5 illustrates the specific airflow resistance (Rs) for samples with varying numbers of layers. The airflow resistivity, representing the specific airflow resistance per unit length, has been calculated as the slope of the linear fit, yielding a value of 77,600 Pa·s/m². This result indicates that as the material thickness increases, the resistance to specific airflow rises proportionally.

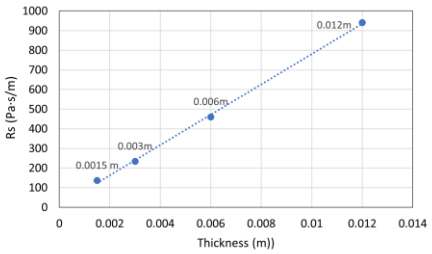

Figure 5. Specific airflow resistance as a function of thickness. The dotted line is a linear fit, the slope of which gives the value of the airflow resistivity of the material.

Sound absorption coefficient trends at normal incidence for the four samples vs. the frequency (range 100 - 6400 Hz), measured using the Impedance Tube and Impedance Gun, are shown in Figures 6 and 7, respectively. The small and a large Brüel & Kjær tube setup were used and later the measurements were combined to obtain sound absorption coefficient in the frequency range 50–6400 Hz.

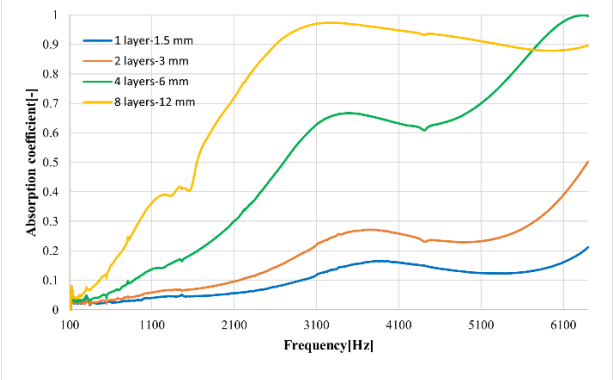

Figure 6. Sound absorption values of cotton wadding vs. frequency with Impedance tube.

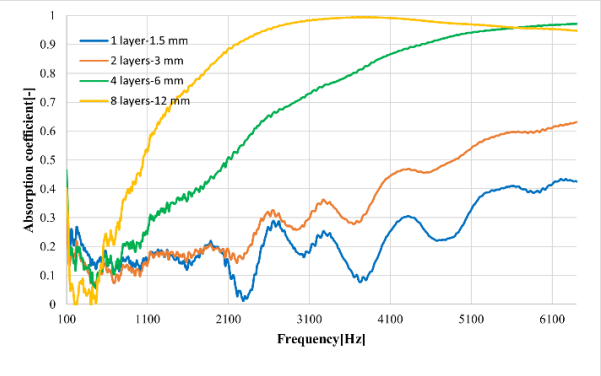

Figure 7. Sound absorption values of cotton wadding vs. frequency with Impedance gun.

Sample	NRC-Impedance Tube	NRC-Impedance Gun
1 layer	0.03	0.16
2 layers	0.05	0.15
4 layers	0.12	0.25
8 layers	0.22	0.37

As observed in Figure 6 and 7, an increase in the number of layers leads to a higher sound absorption coefficient across most frequencies, as expected. Cotton wadding 12 mm-thick (8layers), and 6 mm- thick (4 layers) demonstrate high absorption properties when compared to the 2 layers and 1 layer. This effect becomes more evident at higher frequencies (above 3000 Hz), where the increase in the number of layers leads to a significant improvement in sound absorption. Also, the first peak of the absorption curve increases with thickness, and it is moved to lower frequencies, according to [36], due to the higher tortuosity of the thicker sample. In order to better compare the acoustic behavior of different layers of cotton wadding, the Sound Absorption Average (SAA) index was calculated as the average of the absorption coefficients across the twelve 1/3 octave bands from 200 Hz to 5000 Hz (Table 1 and 2). As the number of layers increases, the sound absorption performance improves significantly both in the measurements carried out with the impedance tube and with the impedance gun. For example, the SAA value rises from 0.06 for a single-layer sample to 0.42 for the eight-layers with impedance tube. Similarly, with the impedance gun, the SAA rises from 0.17 for one layer to 0.49 for eight layers. The Noise Reduction Coefficient NRC (arithmetic average of the absorption coefficient values in the one third octave band at the frequencies of 250, 500, 1000, and 2000 Hz) of samples with impedance Gun is higher than the one of materials with impedance tube. Moreover, NRC increased when thickness increased (see data in Table 3).

5. CONCLUSION

In this research, we studied the sound absorption properties of a commercially available natural fiber material (cotton wadding). We investigated the effect of material thickness and used two different measurement tools to evaluate its acoustic performance. The results demonstrated that both material thickness and airflow resistance significantly affect sound absorption performance.

By utilizing two different tools, the study provided complementary insights, more reliable and accurate findings. It was found that increasing the thickness of the cotton wadding improved sound absorption, while airflow resistance also played a crucial role in optimizing the material's performance. These findings contribute to a better understanding of the key factors influencing sound absorption in cotton-based materials. Additionally, the use of multiple tools allowed for a more thorough analysis, ensuring strong results.

Further research could explore additional variables or alternative different types of materials to improve sound absorption measurements reliability in a variety of applications.

ABSTRACT

The *in situ* characterization of acoustic materials is used to assess material properties of installed devices. The use of sensor arrays guarantees access to spatio-temporal information about the scattered sound field that finite samples or diffusers create in realistic conditions. Such effects can be investigated by formulating suitable inverse problems, which incorporates the complexity of acoustic fields. Since this line of research is in constant evolution, this paper describes the construction of a database of impulse responses obtained with *in situ* measurement techniques and some of the results obtained with different techniques. A 3D scanner is used to move and position the microphone at the coordinates of a pre-established array geometry. The exploited measurement scenarios, the data organization, and post-processing strategies are described. Initial results considering the classical 2-microphone method, plane-wave expansion and the discrete complex image source methods are presented and compared.

Keywords: *in situ measurements, absorption coefficient, dataset, acoustic materials*

1. INTRODUCTION

The acoustic characterization of materials under *in situ* or free-field conditions is valuable for room acoustics and noise-control applications. The work of Brandão [1] extensively reviews such techniques for measurement scenarios with a few sensors. Usually, these methods rely on a mathematical sound field model above the material and assume the sample to be much larger than the wavelength [2]. Additionally, microphone array techniques for absorption measurements have been explored since the early works of Tamura in the 1990s [3, 4], as they provide information about the distribution of pressure and/or particle velocity in space. Recent approaches that seek to evaluate the acoustical absorption coefficient have benefited from the use of microphone arrays in conjunction with inverse problem theories that aim to reconstruct the sound field in the vicinity of the sample under evaluation [5–11].

In order to promote further advancement in this research area, constructing a well-structured experimental dataset is of interest. For instance, some datasets reported in the literature focus on simulations for room acoustics [12], Head-Related Transfer Function simulations [13], and environmental acoustics [14]. This paper outlines the methodology adopted for creating a dataset of *in situ* measurements of acoustical materials.

The experiments described in this study were carried out in a large reverberation chamber using relatively low-cost instrumentation. A time-windowing technique was applied to isolate the direct sound from the reflections caused by the chamber walls. A 3D scanner is employed to move the microphone throughout the spatial coordinates of a pre-defined array, and impulse responses are collected sequentially. A more comprehensive overview of the experimental setup and the routines implemented in the construction of the dataset can be found in Ref. [15]. This study investigates a double planar array topology, as in Ref. [6, 16]. The measured sound pressure serves as

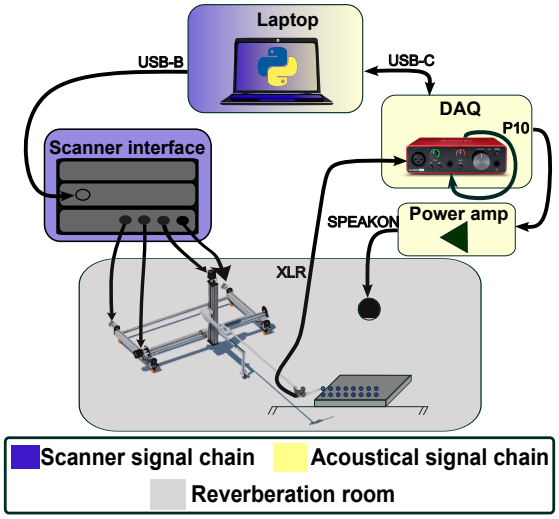
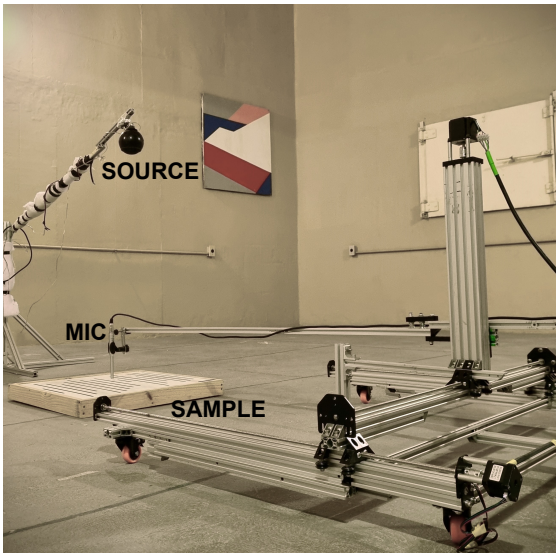
input for two inverse problems: a plane wave expansion (PWE) [9] and a novel approach called the Discrete Complex Image Source Method (DCISM) [11]. The first can be used to study effects like edge diffraction of the sample, and the second is a compact sound field model suitable for short source-receiver distances. The inverse problems results are compared to those obtained with the classical two-microphone technique [17, 18].



This paper is organized as follows: Section 2 outlines the experimental procedures, encompassing the instrumentation built and used, the measured samples evaluated, and the array's geometries. Section 3 presents the mathematical background necessary to understand the inverse problems. Section 4 presents the results and discussions, followed by the conclusions in Sec 5.

2. MATERIALS AND METHODS



The experiments were conducted within a 207 m^3 reverberation chamber at the Acoustic Engineering Laboratory [19] of the Federal University of Santa Maria (UFSM - Brazil). The use of such a room was motivated by its controlled acoustic characteristics and by the fact that the walls can be substantially far from the sample and instrumentation [1]. The samples were positioned directly on the floor and in the center of the room. Figure 1b visually represents the experimental environment. This study presents results for 3 mounting conditions for 48×48 cm polyurethane (PU) foam with 25 mm of thickness. All evaluated scenarios consider the source positioned above the center of the sample at a distance of 1 m (normal incidence).

A 3D scanner, developed by the research team [10] was used to move a transducer through a set of predetermined spatial coordinates $\mathbf{r}_\mathrm{m} = (x, y, z)$. As the scanner operates, it sequentially measures the sound pressure at each coordinate. The scanner system, adapted from 3D printing technology, employs four NEMA stepper motors to move the microphone – two for the x axis (**M1** and **M2**), one for the y axis (**M3**), and another for z axis (**M4**) – providing three degrees of freedom. The scanner's control interface comprises an Arduino that handles the communication between the Python programming and the scanner, along with the drivers that operate the axis motors. A similar measurement system was envisioned and implemented by D'Antonio *et al.* [20]. Figure 1b illustrates the experimental setup mounted within the reverberation chamber, where it is possible to visualize the 3D scanner holding the microphone over the sample positioned directly below the sound source.

[1] Additionally, the laboratory does not have an anechoic room, unfortunately.

(a)

(b)

Figure 1: (a) Signal channeling with the cable connections. (b) Experimental setup within the reverberation chamber.

The acoustic signals reported herein were acquired using a Behringer ECM 8000 measurement microphone connected to a Focusrite Scarlett Solo audio interface

(ASIO driver). Other options were explored in the current dataset but are not reported here for the sake of brevity. The excitation signal consisted of an Exponential Sine Sweep (ESS) ranging from 100 Hz to 20 kHz, radiated from a full-range loudspeaker mounted on a spherical baffle with a diameter of 9 cm. A Brüel & Kjær 2716C power amplifier drives the loudspeaker. Both measurement and post-processing operate using Python, with object-oriented programming. The basic repositories primarily used in the work presented here are available on Github [21, 22]. Furthermore, the open-source library PyTTa Toolbox [23] was used extensively to create the excitation signals, record the responses, and compute the impulse responses. Atmospheric conditions, the name of the material under study, the hardware utilized, the Arduino setup, and the date and time of the measurements are stored as metadata on the measurement object and can be retrieved later.

The array explored in this paper is a double-layered microphone array, which evaluates the pressure above the sample's surface, $z > 0$. Its dimensions are 0.3×0.3 m^2, with 8 microphone positions along the x and y axis, resulting in 64 positions per layer and a total of $\mathcal{M} = 128$ measurement points. The vertical separation between the two layers was set to $\mathrm{z_r} = 0.02$ m, while the distance between the closest layer to the top of the sample was $\mathrm{z_0} = 0.02$ m.

3. THEORY OF INVERSE PROBLEMS

Many inverse problem formulations have been proposed over the years, aiming to reconstruct the sound field above finite or infinite samples. In this study, two approaches are considered: a plane wave expansion (PWE) model formulated as a set of propagating and evanescent plane waves [9] and the discrete complex image source method (DCISM), a novel method recently introduced in the literature by Brandao [11]. This paper briefly describes such methods, and more details can be found in the literature. In both cases, the inverse problem can be formulated as a matrix equation

$$\mathbf{p} = \mathbf{H}\mathbf{x} + \mathbf{n}\,, \tag{1}$$

where $\mathbf{p} \in \mathbb{C}^{\mathcal{M}}$ is the vector of measured sound pressures at $\mathrm{r_m}$, $\mathbf{x} \in \mathbb{C}^{l}$ contains the unknown amplitudes of interest, and $\mathbf{H} \in \mathbb{C}^{\mathcal{M}\mathrm{x}l}$ is the sensing matrix (Kernel), which models the acoustic field according to the method being implemented. Also, $\mathbf{n}$ is representative of noise that contaminates all measurements and model inconsistencies [6,9]. Typically, the dimensions of ℓ and $\mathcal{M}$ differ, and the inverse problem becomes ill-posed, requiring regularization. The main topics regarding the assembly of the sensing matrix for both PWE and DCISM are discussed in Secs. 3.1 and 3.2. Further notes on the reconstruction stage are given in Sec. 3.3.

3.1 Plane wave expansion

The basic formulation presented in this section if based on Refs. [6, 9]. It is assumed that the measured sound pressure can be represented as a superposition of ℓ propagating and evanescent plane waves, separated in an incident and a reflected sound field. Thus, the kernel matrix can be written as $\mathbf{H} = [\mathbf{H}_{\mathrm{inc}}, \mathbf{H}_{\mathrm{ref}}]$. For a given receiver at $\mathbf{r}_\mathrm{m} = (x, y, z)$ and a wave-number $\mathbf{k}_\ell$, the matrix elements are composed of

$$\begin{aligned} \psi_\ell^{\mathrm{inc}}\left(\mathbf{r}_\mathrm{m}\right) &= \mathrm{e}^{-\mathrm{j}\left(k_x x + k_y y + k_z\left(z - z^{+}\right)\right)}, \\ \psi_\ell^{\mathrm{ref}}\left(\mathbf{r}_\mathrm{m}\right) &= \mathrm{e}^{-\mathrm{j}\left(k_x x + k_y y - k_z\left(z - z^{-}\right)\right)}, \end{aligned} \tag{2}$$

with z^+ and z^- related to retracted virtual source planes that help to regularize the problem [6,9].

3.2 Discrete complex image source method

This formulation, proposed in Ref. [11] is based in Ref. [24]. It models the sound field as composed of a monopole (associated with the original source - incident sound field), a component associated with the image source, and a series of monopoles located along a complex line (reflected sound field). The matrix kernel is given by

$$G(\mathbf{r}_\mathrm{i}, \mathbf{r}_\mathrm{m}) = \frac{b}{2} w_\mathrm{i} \frac{\mathrm{e}^{-\mathrm{j}k|\mathbf{r}_\mathrm{i} - \mathbf{r}_\mathrm{m}|}}{|\mathbf{r}_\mathrm{i} - \mathbf{r}_\mathrm{m}|}\,. \tag{3}$$

For the original sound source, $\mathrm{i} = 1$, $\mathbf{r}_1 = (x_\mathrm{s}, y_\mathrm{s}, z_\mathrm{s})$. For the image source, $\mathrm{i} = 2$ and $\mathbf{r}_2 = (x_\mathrm{s}, y_\mathrm{s}, -z_\mathrm{s})$ ($\frac{b}{2} w_\mathrm{i} = 1$ in both cases). For the remaining complex sources $\mathrm{i} = 1, 2, \cdots, N$, $\mathbf{r}_\mathrm{i} = (x_\mathrm{s}, y_\mathrm{s}, -z_\mathrm{s} + \mathrm{j}q_\mathrm{i})$, with w_i and q_i given by the Gauss-Legendre quadrature rule, and b being a suitable truncation value for the integral [11, 24].

3.3 Inverse problem estimation and reconstruction

Given that the Kernel matrix $\mathbf{H}$ in Equation 1 leads to an ill-posed problem, an appropriate regularization technique is required to stabilize the inversion. This issue is addressed through Tikhonov regularization, which is formulated as

$$\tilde{\mathbf{x}} = \underset{\mathbf{x}}{\mathrm{argmin}} \left(\|\mathbf{H}\mathbf{x} - \mathbf{p}\|_2^2 + \lambda \|\mathbf{x}\|_2^2 \right), \tag{4}$$

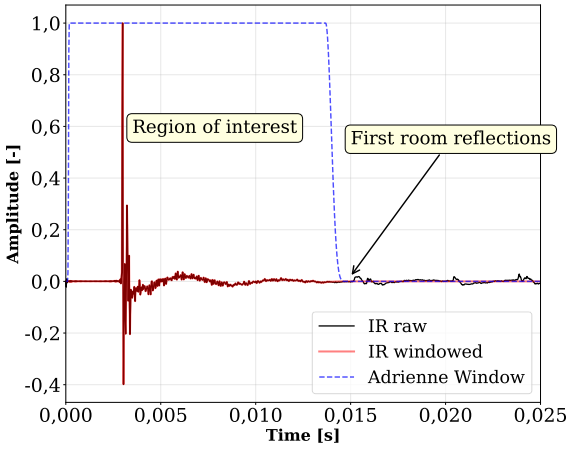
with λ being the regularization parameter selected automatically by generalized cross-validation [25]. After finding $\tilde{\mathbf{x}}$, the sound pressure and the normal component of the particle velocity can be reconstructed over a set of K grid points located at the sample's surface. The reconstructed sound pressure is given by

$$\tilde{\mathbf{p}}_{\mathrm{re}} = \mathbf{H}_{\mathrm{re}}\tilde{\mathbf{x}}\,. \tag{5}$$

with $\tilde{\mathbf{p}}_{\mathrm{re}} \in \mathbb{C}^K$ being the reconstructed sound pressure vector and $\mathbf{H}_{\mathrm{re}} \in \mathbb{C}^{K\times\ell}$ the reconstruction matrix containing the wave functions evaluated at the reconstruction points. The particle velocity vector is retrieved by means of Euler's equation of motion, with $\tilde{\mathbf{u}}_{\mathrm{re}} = \frac{-1}{\mathrm{j}k\rho c}\nabla\mathbf{H}_{\mathrm{re}}\tilde{\mathbf{x}}$. Utilizing the reconstructed sound pressure and the particle velocity, an estimation of the surface impedance can be derived as either a point-wise impedance or the spatial average of a set of grid points used to compute the reconstructed surface impedance, where

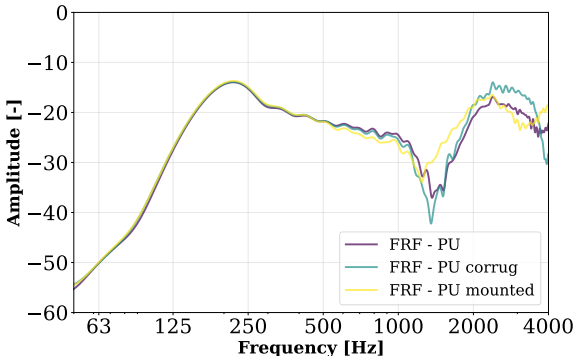
$$\tilde{Z}_s\left(\mathbf{r}_s\right) = -\frac{1}{\rho c}\frac{\tilde{p}\left(\mathbf{r}_s\right)}{\tilde{u}_n\left(\mathbf{r}_s\right)}, \tag{6}$$

where ρ is the air density and c the sound velocity in the air. Subsequently, the sound absorption coefficient is inferred as



$$\alpha = 1 - \left|\frac{\bar{Z}_s\cos(\theta) - 1}{\bar{Z}_s\cos(\theta) + 1}\right|^2. \tag{7}$$

4. RESULTS



This section presents the main results and corresponding discussions from the experimental measurements. The acoustic sound field is analyzed in the wave number domain using the PWE introduced in Sec. 3.1, and the absorption coefficient is reconstructed using both proposed methodologies. For comparison purposes, the absorption coefficient (α) is also estimated using the conventional two-microphone technique [17] for each tested sample.

Three polyurethane (PU) foam configurations are evaluated: (i) a flat rectangular sample (25 mm thick); (ii) a corrugated sample with similar maximum thickness; and (iii) a composite configuration consisting of the corrugated foam mounted on the top of the flat sample.

The initial stage of the post-processing is the analysis of the impulse responses (IRs) and their corresponding frequency response functions (FRFs) to provide an initial assessment of the measurement quality. Figure 2 presents an IR obtained from the measurement of the flat PU foam,

(a)

(b)

Figure 2: (a) Measured impulse response alongside its windowed version and the applied window function. (b) FRF obtained from one measurement of each sample.

showing both the raw and windowed impulse responses, as well as the Adrienne window applied to the signal. The first reflections from the chamber walls reach the transducer at approximately 0,015 s after the direct sound. It is important to note that this time delay can vary depending on the spatial positioning of the microphone within the reverberation chamber.

Furthermore, Figure 2b displays the FRFs (windowed signal) obtained from the first measurement of each sample (near its center). The difference between the samples

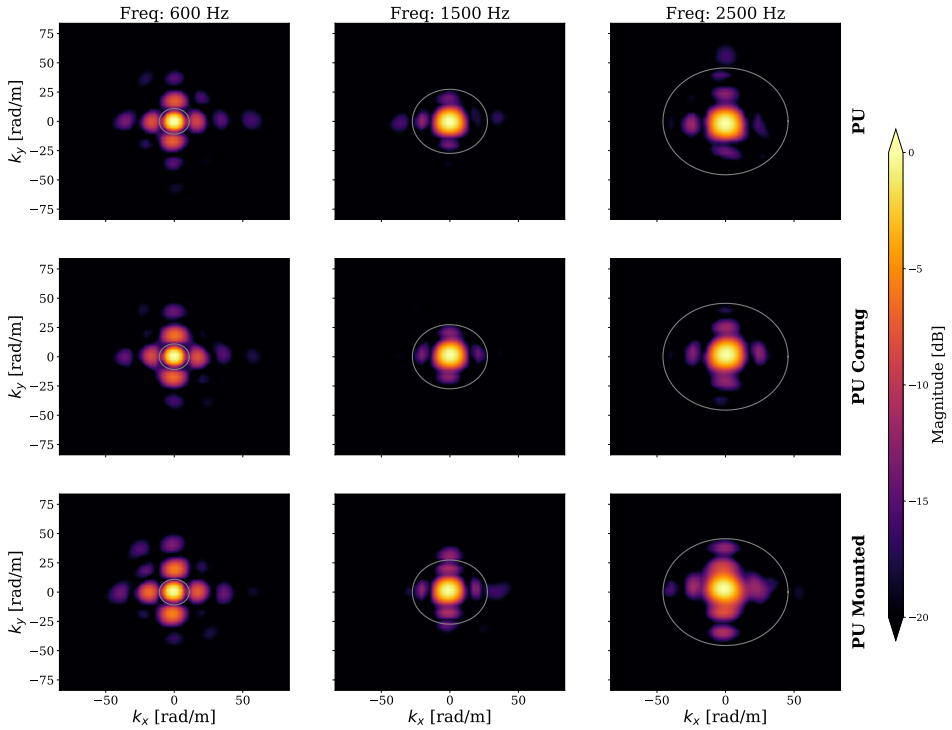


Figure 3: Wave-number spectrum for the PU sample estimated from the microphone array data.

is easier to be observed above 1000 Hz. Note that for the mounted sample, the magnitude of the FRF is significantly different than the others between 1 and 2 kHz.

Figure 3 shows the reflected components of the wave-number spectrum (k-space) at frequencies 500, 1500, and 2500 Hz for the PU flat, corrugated, and the mounted (corrugated + flat) situations. Each subfigure plots the radiation circle as a gray line to distinguish between propagating and evanescent plane waves. The source planes are located 1 cm below the lower layer of the microphone array and at 1 cm above the top layer. That ensures symmetry between the distances from the microphone array to the sample and to the source planes. In Fig. 3, the main lobe at the center of each subplot is associated with plane waves traveling in the direction of specular reflection, while the side lobes are likely due to the finite dimensions of the absorbers [9]. In all cases, at the frequency of 500 Hz, the wave-number spectra are similar and the evanescent components appear more prominent compared to the other spectra. This behavior is attributed to the fact that the wavelength of the incident wave is comparable to the size of the sample, which enhances the diffraction effects. The evanescent components tend to decrease in amplitude with increasing frequency, indicating a greater concentration of propagating waves at higher frequencies. It is interesting to note that the diffraction components for the corrugated samples seem to have slightly larger amplitudes when compared to the flat sample at 1500 and 2500 Hz, which can be attributed to a more irregular reflection pattern caused by the surface irregularities.

The absorption coefficient values for the three mounting configurations are shown in Fig. 4. The solid lines correspond to the results obtained using the DCISM method, while the dashed lines represent the values estimated using the PW approach. Dash-dotted lines are representative of the 2-mics technique. The three inference methods yield similar results across all configurations and mounting conditions. The DCISM and the plane-wave expansion methods show a closer agreement. Notably, the

DCISM tends to underestimate the absorption values below 500 Hz (compared to the plane-wave expansion). This discrepancy can be attributed to the different modeling assumptions. The absorption values for the stand-alone corrugated sample are relatively low because the average material thickness is small. For this reason, the estimates obtained using the two-microphone method show more erratic behavior above 1000 Hz. Note also that the absorption coefficient increases significantly for the mounted condition (corrugated on top of the flat sample). In both corrugated sample cases, it might be challenging to establish a surface to reconstruct the surface impedance on, which may contribute to the discrepancies between the DCISM and the plane-wave expansion models.

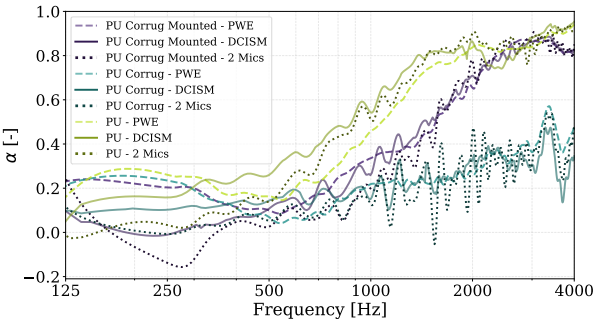

Figure 4: The sound absorption coefficient for 3 mounting conditions of finite PU samples measured with a double planar array.

5. CONCLUSIONS

The proposed experimental setup effectively measured impulse responses near three material configurations. The measurements performed with the double-layered array proved consistent, and the implemented inverse methods yielded satisfactory and insightful results regarding the behavior of the acoustic sound field. Additionally, both the PW method and the DCISM demonstrated consistency in reconstructing the absorption coefficient, with minor discrepancies aligned with predictions found in the literature. The two-microphone technique also proved to be a straightforward and reliable approach for establishing a a metric for comparison. The data presented herein will be included into the *in situ* acoustic database currently under development.

6. ACKNOWLEDGEMENTS

The authors would like to acknowledge the support and infrastructure of the Acoustic Engineering Department (EAC) at the Federal University of Santa Maria (UFSM), which made this work possible. This work is part of a research project into the spatial/temporal characterization of acoustic materials. The authors would like to thank the CNPQ universal project (No. 402633/2021-0) and PIBIC (Institutional Program for Scientific Initiation Scholarships) for their financial support.

ABSTRACT*

The territories characterized by a large woodland area, offer considerable potential for the development of a wood supply chain based on principles of circular economy and sustainability. However, there are limited products and applications of virtuous processes for the valorization of local materials with an optimized acoustic performance. This work focuses on recycled and reused by-products as a secondary raw material for the implementation of acoustic materials for noise barriers applications. Different typologies based on the use of loose wood chips (WCh), stone sawing waste (SS) and their combination in mix designs (WChS), where the WCh has been used as an aggregate, have been investigated. Sound absorption measurements were conducted on cylindrical samples in an impedance tube and on larger samples in a small-scale reverberation room (SSRR). The work analyzed the variability of the sound absorption coefficients in terms of reproducibility due to the loose material selection, mix design casting and testing methods.
Experimental results demonstrated that the variability of the sound absorption of the WCh samples are affected mainly by the measurement method, while the WchS samples are significantly affected by the sample size, the mix design casting conditions, and measurement method.

1. INTRODUCTION

This The development of a wood supply chain based on principles of circular economy and sustainability has gained interest and presents different opportunities [1]. However, there are limited products and applications of virtuous processes for the valorization of local materials with an optimized acoustic performance [2]. For example, Stradzas and Januševičius [3] showed in their review the performance potentials of acoustic barriers made using waste and plant-based materials. Many other applications could be explored through principles of circular economy, clean production and aesthetic integration [4]. The main goal of this research is to transform loose wood chips material obtained from sawmill wood waste into a high-value resource with an acoustic performance in noise barriers. This is further integrated with the use of stone sawing waste. Moreover, the work aims to analyze the variability of the sound absorption coefficients in terms of reproducibility due to the loose material selection, mix design casting and testing methods.
The loose material has been analyzed in a few studies. Lashgari et al. [5] presents a concise review of research on sound absorbers made from natural materials. Furthermore, they present measurements and prediction models for wood chip-based sound absorbers promoting the idea of the creation of sustainable sound-absorbing materials from wood chip wastes. Other studies have focused on specific plant varieties considering also leaves and wood in the mix design [6, 7]. Cottone et al. [4] highlights loose material are

completely recyclable once their service life concludes, unlike other mix designs that present limitations due to the binder characteristics.

Ornamental rock cutting wastes (sawing sludges) have been used in various applications; their function is to act as fine aggregates in conglomerate matrices, reacting by interaction with alkaline solutions [8-10]. However, their use as a binding matrix for wood chips in acoustic panels has been overlooked. The mix design between plant-based materials and stone sawing waste has been considered in [11]. To the author's knowledge, no previous studies have reported the variability of sound absorption due to the loose material selection, mix-design casting and testing methods. This is an important aspect to consider given its impact on the final material performance.

The objective of this work is to provide new perspectives of integration of wood waste material for acoustic applications by promoting the use of natural loose material. To this purpose, for a more sustainable approach, the loose material was used in different typologies based on the use of loose wood chips (WCh), stone sawing waste (SS) and their combination in mix designs (WChS), where the WCh has been used as large aggregate and the sawing stone (reacted with alkaline solutions) as a conglomerate matrix. It analyses the variability of the sound absorption coefficients in terms of reproducibility due to the sample mix design casting conditions, sample size and testing methods. Also, the fabrication place, i.e. laboratory or on-site, was considered as a variable in the analyses.

Table 1. Summary of the samples tested in IT and SSRR and their characteristics.

Sample		Thickness [mm]	Density [kg/m^3]	SSRR	IT
1	WCh	20	-		x (lab)
	WCh	100	-	x (site)	x (lab)
2	SS	60	1392-1415		x (lab)
3	WChS	20	752 -873		x (lab)
	WChS	40	752 -873	x (lab and site)	

2. MATERIALS AND METHODS

The work has been developed in two phases: first, the recycled and reused by-products have been studied in different mix designs and secondly, an acoustic characterization of their performance has been performed on cylindrical samples in an impedance tube and on larger samples in a small-scale reverberation room (SSRR).

The experimental work aims to analyze the variability of the sound absorption coefficient in terms of reproducibility of the samples and testing method given different a) loose material selection, b) mix design, c) sample size, and d) measurement method.

2.1 Materials

Three different typologies (Table 1) based on the use of loose wood chips (WCh), stone sawing waste (SS) and their combination in mix designs (WChS), where the WCh has been used as an aggregate, have been investigated. The wood chips were sorted into randomly mixed mesh sizes ranging from 0.5-25 mm, and it was found that stone sawing waste content of 2.7 times the weight of wood chips was suitable for the WChS samples to show both structural and acoustic performance.

Cylindrical samples with different thickness for measurements in the impedance tube and 50x50 cm sized samples for the small-scale reverberation room (SSRR) measurements were fabricated in the lab conditions and on site (building construction site). Table 1 provides a summary of all variables and characteristics of the samples.

Figure 1. Impedance tube sound absorption measurements: randomly mixed sizes of loose wood chips for samples WCh_20_1-4 and WCh_100_IT.

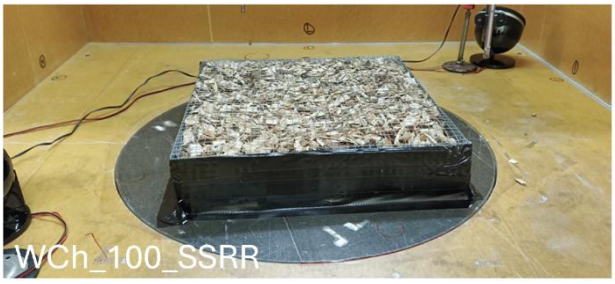

Figure 2. Small-scale reverberation room (SSRR) sound absorption measurements: WCh_100_SSRR.

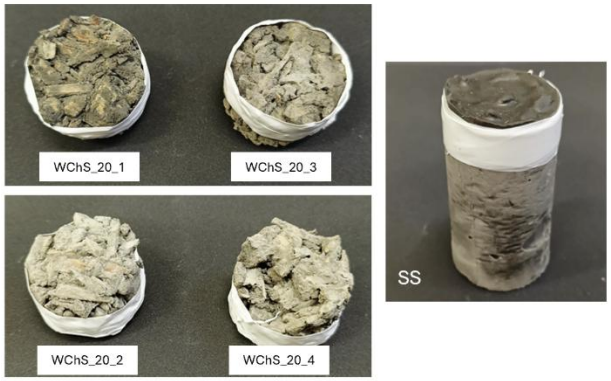

Figure 3. Impedance tube sound absorption measurements: samples WCh_20_ 1-4 and sample SS.

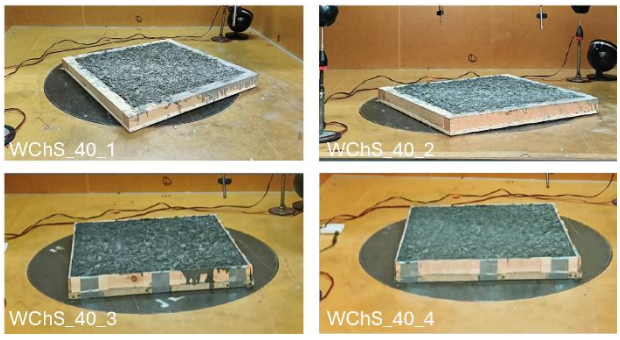

Figure 4. Small-scale reverberation room (SSRR) sound absorption measurements: samples in SSRR WChS_40_ 1-4.

1) Loose wood chips – WCh (Figure 1 and 2):
- 4 samples for impedance tube measurements; thickness 20 mm (WCh_20_1-4);
- 1 sample for impedance tube measurements; thickness 100 mm (WCh_100_IT);
- 1 sample for reverberation chamber measurements; dimensions 50x50 cm; thickness 100 mm (WCh_100_SSRR).

2) Sawing stone SS (Figure 3):
- 1 sample for impedance tube measurements; thickness 60 mm (SS). This sample has been considered as a reflective reference surface for the sawing stone waste material.

3) Mix design wood chips and sawing stone waste casting conditions – WChS (Figure 3 and 4):
- 2 (+2) samples for impedance tube measurements; thickness 20 mm (WChS_20_1-4). These samples were measured on both sides;
- 4 samples for reverberation room measurements; dimensions 50x50 cm; thickness 40 mm (WChS_40_1-4).

2.2 Measurement methods

Two different sound absorption measurements were conducted using cylindrical samples in an impedance tube and on larger samples (50x50 cm) in a small-scale reverberation room (SSRR).

2.2.1 Impedance tube

The acoustic measurements were performed on the three typologies in an ISO 10534-2 impedance tube [12] (two-microphone technique) to assess the normal-incidence sound absorption coefficient. An HW-ACT-TUBE impedance tube at the Applied Acoustics Laboratory (Department of Energy, Politecnico di Torino) was used for these measurements. This device has an internal diameter (ϕ) of 35 mm and is equipped with two ¼'' flush-mounted GRAS 46BD. The method allowed accurate sound pressure amplitude and phase measurements over the whole frequency range of interest, i.e., 100–5000 Hz [13].
The normal-incidence absorption coefficient (α_0) was measured for each composition. Figure 3 shows how the edges of the samples have been adequately sealed with a thin Teflon tape to even out the irregularities generated by the casting technique and to fill the gaps (<1 mm) between the sample and tube [13]. The loose material samples (WCh 20_1-4 and WCh_100_IT have been measured by filling in the tube considering both 20 and 100 mm depth of the rigid backing of the tube piston. The measurements were performed in vertical position for these samples.

2.2.2 Small-Scale Reverberation Room

For the measurement of the sound absorption coefficient in a reverberation room following the procedure of ISO 354:2003 [14] standard, the small-scaled reverberation room (SSRR) of the Department of Energy (DENERG) of Politecnico di Torino has been used. It has been thoroughly described and validated in [15]. The use of the SSRR allows the use of smaller sample sizes than 10-12 m^2 as required in the ISO 354, but maintains the diffuse field conditions of the method. However, this methodology has disadvantages such as the lack of field diffusivity in the mid to low frequencies and diffraction due to the finite size of the experimental samples, which generates so called edge effects. The SSRR measurement methodology specifically consists of an exponential sweep from 100 Hz to 25000 Hz generated through two omnidirectional dodecahedral sound sources. Six microphonic positions for a total of 12 measurements have been performed. To this aim, the measurement chain consists of six 1/400 BSWA Tech MPA451 microphones (BSWA Technology Co., Ltd., Beijing, China) and ICP104; two ITA High-Frequency Dodecahedron Loudspeakers with their specific ITA power amplifiers (ITA-RWTH, Aachen, Germany) and a sound card Roland Octa-Capture UA-1010 (Roland Corporation, Japan). For the measurement of the sound absorption coefficient Matlab software combined with the functions of the ITA-Toolbox (an opensource toolbox from RWTH-Aachen, Germany) [16] was used.
Figure 2 and 4 show the experimental setup and the sample with an area of 0.25 m^2.

3. RESULTS AND DISCUSSION

The sound absorption measurements results have been shown in Figure 5. It presents the variability of the sound absorption coefficient in terms of reproducibility of the samples given different a) loose material selection, b) measurement methods, c) mix design (IT), and d) mix design (SSRR). As shown in Figure 5. a) the SS sample shows a very low sound absorption coefficient similar to very reflective surfaces.

a) Loose material: The comparison of different measurements of four samples of randomly selected loose material shows a good reproducibility of the samples with a variation of the sound absorption of less than 0.2.

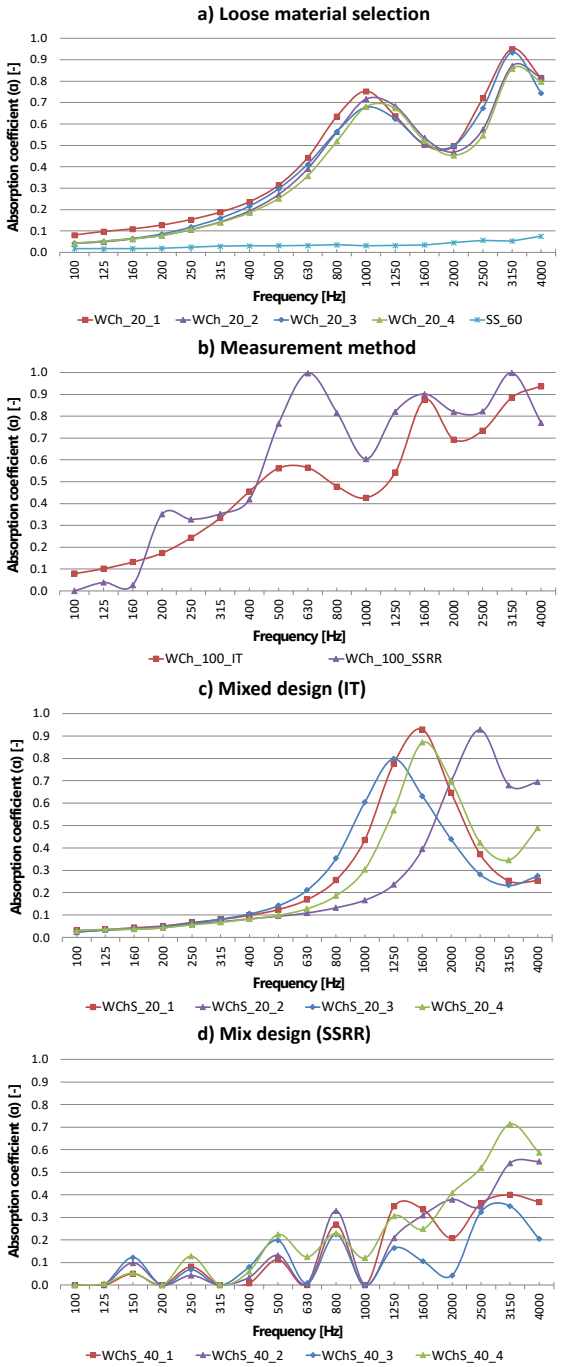

Figure 5. Sound absorption coefficient variation based on a) loose material selection, b) measurement method on loose material, c) mix design for small samples (IT) and d) mix design for larger samples (SSRR).

b) Measurement method: The comparison of the two different measurement methods (IT and SSRR) maintaining the same loose material sample thickness (10 cm) shows a high variability of the sound absorption curves suggesting that there might be significant differences between the distribution of the chips in a larger sample (50x50 cm) that would be complex to select in a representative way with small cylindrical (ϕ=35 mm) samples. The SSRR measurements show a peak at 630 Hz which is higher than the IT sample values of more than 0.4. The correspondence of the peaks with the characteristic geometrical dimensions of the sample patterns has been verified in relation to the thickness of the loose material d=100 mm which corresponds to the quarter-wavelength resonance frequency ($f_0 = c/4d$) of 857 Hz and falls within the 800 Hz third-octave band. This correspondence should be further verified since both curves show a peak at a lower third octave frequency band (630 Hz).

c) Mix design in the impedance tube: The results show significant differences between the two samples WChS_20_1 and _3 (front) presenting different frequency peaks and associated sound absorption at the peak values. Both sides of the same samples show significant differences with the tendency of the inverted samples WChS_20_2 and _4 (back) to shift the peak frequency at higher values. This suggests that the open porosity might be reduced for the back side of the samples which is used to place the samples on the casting plan. This difference was also highlighted in [17].

d) Mix design in the small-scale reverberation room: the curves show a high variability between the four samples, i.e. two fabricated in the lab and two fabricated on site. The variability is higher when comparing the two samples produced in the lab at two different moments. This is more evident at high frequencies above 1000 Hz suggesting that casting conditions may influence in a significant way the acoustic performance. The visual superficial inspection of the samples shows that open porosity could be one of the parameters that may be significantly affected by the casting and curing variables (e.g. operator, weather conditions, sample curing time etc).

4. CONCLUSION

The objective of this work was to provide new perspectives of integration of wood waste material for acoustic applications by promoting the use of natural loose material and stone sawing waste material from local quarries. To this purpose, for a more sustainable approach, the loose material was used in different typologies based on the use of loose wood chips (WCh), stone sawing waste (SS) and their combination in mix designs (WChS), where the WCh has been used as an aggregate. The variability of the sound absorption coefficients in terms of reproducibility due to the sample mix-design, size and testing methods has been presented. Furthermore, the fabrication place that may include the operator, environmental conditions, curing time etc., was considered as a variable in the analysis.

Overall, the work highlighted some of the variables that should be carefully monitored:

- The random selection of the loose material and measurements in the impedance tube samples may not affect or affect to a limited extent the sound absorption in the IT measurements.
- The two different measurement methods (IT and SSRR) showed significant differences suggesting that there might be significant differences between the distribution of the chips in a larger sample compared to smaller samples attempting to be representative of the larger ones.
- The mix-design in the impedance tube measurements showed significant differences in the two front and back oriented samples. This was mainly due to the casting conditions and material deposition on the casting plane.
- The mix-design in the small-scale reverberation room shows a high variability between the four samples, i.e. fabricated in the lab on the building site. In this case the sound absorption is significantly affected by the casting variables (e.g. operator, weather conditions, sample curing time etc.).

Further research could be conducted along this line of research to explore other mix-design and mounting method strategies for the application of sound absorbing porous loose wood chips and stone sawing waste in the frame of the sustainable architectural and urban design strategies. A more systematic study could be developed considering the variables explored in this work in order to build appropriate guidelines that would preserve optimized acoustic performance also in the fabrication/casting and curing phase on site and in lab conditions.

5. ACKNOWLEDGMENTS

The work has been financially supported by the Piedmont Region through the project LA.B. 23-24 – Laboratorio Bosco 2023-2024 (grant nr. 20201396791). The authors would like to thank Segheria Minetti Snc (Crodo, Italy), Pierpaolo Nuzzo, Andrea Bottega, Stefano Di Domenico and Franco Grindatto for their contribution to the sample construction.

SOUND ABSORPTION PREDICTION OF HIGH-DENSITY FOAM-FORMED SOFTWOOD FIBERS

Janis Heldmann[1*] **Jose Cucharero Moya**[2] **Tapio Lokki**[1]

[2] Lumir Oy, Finland

ABSTRACT

Nowadays, porous absorption materials need to be environmentally sustainable. This concerns the sources of raw materials, low energy consumption in the manufacturing process, and options for recycling. Therefore, alternatives for mineral wools are needed and biomaterials offer an attractive solution. Some recently studied sustainable acoustic materials, such as foam-formed wood fibers, can be produced with a negative carbon footprint. However, sound absorption performance must match the less sustainable variants to ensure competitiveness. Therefore, the prediction of sound absorption is important because it supports the optimization of processes and functionality to achieve the best possible solution. In this study, foam-formed wood pulps of increasing density are produced, characterized, and modeled by semi-phenomenological and analytical models. Their density range exceeds an earlier study by choosing a non-ionic surfactant during synthesis and model accuracy across densities is evaluated against experimentally measured sound absorption. The aim is to create foam-formed fibers with maximal density and the possibility to predict sound absorption with accurate models. The results show that the JCAL model performs better than the analytical models, but the less tedious analytical models provide good approximations. The finding contributes to the optimization of foam-formed pulps by choosing feasible models for the aimed density.

1. INTRODUCTION

Density is a crucial factor in producing high performing acoustic absorbers. Increasing the density of a material also increases the low frequency absorption, which is often a key factor for the usability of acoustic absorbers. Usually, higher densities are related to more material per volume and therefore higher costs. However, in the light of biobased-absorbers more raw material used is a desired goal, as it allows to bind more carbon to the absorption material. This increases a negative carbon dioxide footprint, using more base material that is typically from side streams and leftovers from, e.g., the pulp and paper industry. Based on a previous study [1] that explored the prediction of foam formed wood pulp absorption with an analytical model, semi-phenomenological model, and further refined fitting, this study extends the maximum density range from 50 kg/m^3 to 64 kg/m^3. The necessary pore network stability is achieved with a non-ionic surfactant that is added during the material synthesis.

2. MATERIAL AND METHODOLOGY

Sound-absorbing foams were produced using a foam-forming process based on [2]. Pulp, water, and a non-ionic surfactant were mixed under axial agitation (3000 rpm) in a cylindrical vessel. Two pulp consistencies (3.5% and 4.5%) were used to vary foam density. The pulp was pre-soaked for one day, stirred for 10 minutes, then foamed after surfactant addition until the volume doubled.

The foam was poured into a 25 $\times$ 25 $\times$ 25 cm mold with stainless steel nets for drainage and structural support. Samples were dried at 40°C for two days. Denser foams were pre-conditioned at 99% relative humidity and

20°C before compression and final drying. Circular samples (100 mm and 29 mm diameter, 40 mm thick) were cut using a bench drill, and outer layers were trimmed to ensure uniform density. The non-ionic surfactant from the group of ethoxylated alcohol replaced sodium dodecyl sulfate (SDS) from the previous study to improve foam stability and allow higher densities. The density is controlled by air content, stability of the foam and the fibre type and dimensions. The choice of surfactant affects the interaction between bubbles and fibres and therefore the foam stability.

3. MEASUREMENT

The dynamic mass density $\widetilde{\rho}$ and dynamic bulk modulus $\widetilde{K}$ were measured using the three-microphone method in a 100 mm and 29 mm diameter B&K 4206 impedance tube. A broad-spectrum random signal of 50–2000 Hz for 100 mm samples and 50-6400 Hz for 29 mm samples was emitted from a loudspeaker, with the sample placed against a rigid termination. Measurements followed ISO-10534-2 [3], and each sample was tested on both sides to account for potential non-homogeneity. Reported values are averages from the measurements of both sides.

4. CHARACTERIZATION

The characterization of the JCAL parameters was performed with the RokCell software (Matelys, France). It estimates all six JCAL parameters based on measured dynamic mass density $\widetilde{\rho}$ and dynamic bulk modulus $\widetilde{K}$ [4]. The characterization was done for each measurement individually and the final estimated JCAL parameters are averages of parameters obtained from both sides. This is done to compensate for the possible non-homogeneous properties of the samples, even though the top and bottom layers of the materials were cut off.

5. MODELING AND ANALYTICAL FIT

The non-acoustic parameters determined during characterization allow modeling $\widetilde{\rho}$ and $\widetilde{K}$ and therefore the sound absorption coefficient [5]. The analytical model consists of six submodels which predict all JCAL parameters while assuming randomly oriented parallel fibers with a symmetric radius distribution, as described in [6], making it well-suited for naturally formed bio-based materials. The submodels are only based on the effective fiber radius and mass density $\widetilde{\rho}$, calculated from the sample mass and enclosing volume (values in Table 1). The effective fiber radius a = 12.7 μm for softwood pulp was obtained earlier from Kajaani FiberLab measurements on similar foam-formed pulps [7]. Non-acoustic parameters are derived using adapted equations to match the symmetric distribution assumption. Three related analytical models were employed. First, the original model proposed in [6], secondly an adaptation in which the equations for flow resistivity and viscous characteristic length were fitted to the characterized values of flow resistivity and viscous characteristic length of the produced materials. Third, an alternative model was used to fit the flow resistivity and viscous characteristic length to the characterized values. The procedure is equivalent to the preceding study of this work and the detailed equations can be found there [1].

In the original model, airflow resistivity is calculated according to Tamayol et al. [8] using the formula:

$$\sigma = \frac{\eta}{(2a)^2} \frac{\sqrt{1-(1-\phi)}}{c_1 \left(\frac{c_2}{1-\phi} - 3\sqrt{\frac{c_2}{1-\phi}} + 3 - \sqrt{\frac{1-\phi}{c_2}} \right)} \tag{1}$$

where a is the effective fiber radius and η is the viscosity of air. The fitting parameters $c_1 = 0.21$ and $c_2 = 0.71$ are validated for symmetric distributions of parallel fibers. The second model fits the parameters c_1 and c_2 to the characterized values of flow resistivity of the produced materials. The viscous characteristic length is according to the model of Umnova et al. [9]:

$$\Lambda = a \frac{(2-\phi)\phi^{c_3}}{2(1-\phi)} \tag{2}$$

with $c_3 = 2.732$ in the original model. In this study, the second analytical model fits also c_3 to the present set of values. The third model intends to further improve the modelling accuracy of the viscous characteristic length by using

$$\Lambda = b_1 (1-\phi)^{-b_2}, \tag{3}$$

for the viscous characteristic length.

6. RESULTS

Table 1 presents the characterized JCAL parameters in terms of their density and sample diameter. Flow resistivity shows a typical increase with increasing density. The smallest (29 mm) samples were quite tight in the tube and

it is possible that the material was a bit compressed when mounted, resulting in higher air flow resistivity than with 100 mm samples. Tortuosity grows slightly as material is denser but other parameters don't show very clear trends, however, all of them are reasonable.

Figure 1 shows the measured absorption curves across densities of 50-59 kg/m^3 for 100 mm samples and 59-64 kg/m^3 for 29 mm samples. For higher densities, the absorption curves shift towards lower frequencies. There are signs of elastic effects present such that the curves are not totally smooth. Such effects are often present when fitting in the impedance tube is tight. Figure 2 shows the comparison between JCAL, JCA, and the original and fitted analytical models. The original analytical model does not model the absorption precisely as it assumes parallel fibres resulting in lower flow resistivity and higher viscous characteristic length than in the actual randomly oriented fibre network. Fitting flow resistivity and viscous characteristic length of the analytical model improves its accuracy across densities. Unlike the results for lower densities in [1] a second step of fitting flow resistivity does not improve the accuracy further. JCAL and JCA models perform equally precisely. The elastic properties are not included in the model, therefore the curve omits the elastic modulation visible in the measured curve.

7. CONCLUSION

In this paper, the investigation of density dependent absorption and its prediction for foam-foamed fibers was extended towards higher densities by using a non-ionic surfactant instead of previously applied SDS. Sound absorption, dynamic mass density and bulk modulus were measured to characterize the JCAL parameters of the materials. An analytical model based on parallel fibres was adapted in terms of air flow resistivity and viscous characteristic length to improve its accuracy for the investigated randomly orientated fiber network. The JCAL model shows higher precision than the employed analytical models, while the analytical models give good approximations. The differences between measured and predicted sound absorption curves are due to elastic effects that appear by fitting the sample into the impedance tube, and are not included in the JCAL model.

CHARACTERIZATION OF THE SOUND ABSORPTION PROPERTIES OF A FIBROUS BIOMATERIAL: A KEY INPUT FOR ROOM ACOUSTIC SIMULATION SOFTWARE

Joaquin Garcia[1*] **Pablo Alloza**[2] **Edoardo Alessio Piana**[1]
[1] Applied Acoustics Laboratory, University of Brescia, via Branze 38, Brescia, Italy
[2] Track-Noise, Spain

ABSTRACT

In recent years, the search for sustainable materials has gained increasing importance in order to optimize resource use and reduce carbon emissions. In this context, bio-materials have emerged as an alternative due to their low environmental impact. In particular, those with a fibrous morphology, both vegetal or animal based, have proven effectiveness as sound absorbers in room acoustics applications. In this study, the acoustic absorption properties of a type of sheep wool are evaluated. The characterization of the acoustic absorption coefficient under normal incidence was carried out using the two-microphone impedance tube method and compared with the reverberant chamber method. Subsequently, the reverberation time of a selected room was measured before and after the implementation of two walls covered with the chosen material. The impulse response was also recorded using a spherical microphone array, which allowed the visualisation of early reflections applying beamforming algorithms. These measurements were used to validate the simulated impulse response of the room and to determine the most accurate absorption data for the model.

1. INTRODUCTION

The use of sustainable materials has become a significant trend in recent years, towards a strategy of zero-carbon emissions. Building materials typically come from non-renewable and synthetic resources. Porous materials are commonly derived from petrochemical products like polyester or polyurethane, which have a high environmental impact after use. Natural materials have emerged as a viable alternative, utilising renewable resources and generally exhibiting lower levels of environmental impact and embodied energy. Several studies have reported the acoustical properties of oil palm fibres [1], sugarcane bagasse [2], hemp fibres [3] and kenaf fibres [4].

Sheep wool is a natural material that has many advantages compared to others, such us their good thermal insulating performance and low flammability since it is self-extinguishing and does not ignite easily [2]. Furthermore it does not release any toxic particles or gases during combustion and, it is a renewable and recyclable material with a natural decomposition cycle. However, sheep wool is having less demand for applications in the textile industry and nowadays most of the surplus is burned or sent to landfill [5].

The sound absorbing properties of porous materials are normally linked to their porosity and flow resistivity. According to their structure, porous materials can be classified as cellular, fibrous and granular [6]. Fibrous materials are among the most widely used due to their high availability and origins from both animal and vegetable sources. The absorption properties can be measured through various methods. One of them is using an impedance tube. This method requires small samples and relatively inexpensive equipment. However it can only

characterise the absorption at normal incidence and up to the cut-on frequency of the impedance tube, that depends on the tube's diameter [7]. In contrast, the reverberation chamber method (ISO 354) implies the use of 10 m^2 samples, making it less convenient and more expensive. While the absorption coefficient obtained through this method is more representative of the material's behaviour in real world situations — reflecting conditions under a diffuse field — low reproducibility between laboratories can yield varying results [8]. Additionally, the placement of the material within the chamber can influence the measured absorption coefficient [9]. Within this context it can be not clear which values are more accurate to use when feeding computational models for room acoustic simulations in order to have results matching the reality.

In this paper the sound absorption properties of a sheep wool absorber was evaluated and used as an input material for feeding computational models for room acoustics. Furthermore the impulse response of a room was measured and the reverberation time deduced before and after covering the walls with sheep wool panels. Early reflections were observed by using a spherical microphone array and beamforming algorithms. These measurements were used to validate the computational model of the room and investigate which absorption data is more accurate to be used as input material in the model.

2. MATERIALS AND METHODS

The material selected was a sheep wool, wrapped in panels of 6 mm thickness. Three samples of 45 mm diameter were extracted as shown in 1 and their sound absorption properties were measured in an impedance tube. The material was provided by Farrás Home - Spain and in particular this model has also a coating of a series of natural resins that act as a catalytic converter. It absorbs the CO_2 and NOx, contributing to the ecological balance.

Figure 1: Samples of sheep wool.

2.1 Impedance tube measurements

The sound absorption coefficient was measured using a two microphones impedance tube according to the standard ISO 10534 [7]. The system was implemented with a cylindrical tube of 45 mm diameter allowing the characterisation of the sound absorption coefficient up to a cut-off frequency of 3800 Hz. The samples were mounted on a rigid back-end and two 1/4" microphones were spaced 45 mm from each other to measure the pressure field. On the other extreme of the tube a loudspeaker generated a broad band white noise as test signal. The transducers were connected to an OROS Type OR36 analyser, which measures the complex transfer functions between the microphones. The absorption coefficient was calculated given the sample thickness d as:

$$\alpha = 1 - |R|^2 \tag{1}$$

$$R = \frac{Z_s - \rho_0 c}{Z_s + \rho_0 c} \tag{2}$$

$$Z_s = -jZ_c cot(k_c d) \tag{3}$$

Where R is the sound pressure reflection coefficient, Z_s is the surface impedance of the sample, Z_c its characteristic impedance, and ρ_0 and c the density of air and speed of sound.

The results shown in section 3 are the average of three samples. The resulting curves are compared to the results of sound absorption measurements carried out in a reverberant room with the same material.

2.2 Impulse response measurements

The impulse response of a room with a volume of approximately 33 m^3 was measured with a NTi Audio XL2 sound level meter mounting a Type 1 microphone. The impulse was generated wiht a Delta Clapper. The sketch of the room with the measurement positions is presented in Figure 2 and the setup is shown in Figure 3. The reverberation time (RT) was measured in accordance with the guidelines established in ISO 3382-1:2009. According to this standard, the reverberation time T20 and T30 were calculated through the backward Schroeder integration in octave bands from 63 Hz to 8000 Hz. The results obtained from four microphone positions at 1.5 m height were averaged to obtain a representative reverberation time for the room as shown in Figure 2. The same measurement positions and procedures were repeated after applying the

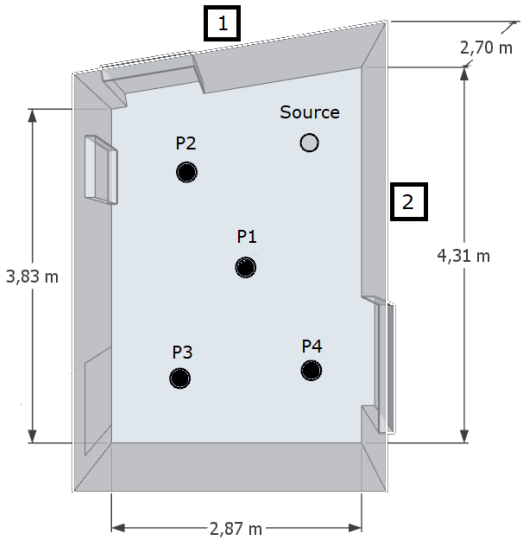

Figure 2: Top view of the room showing the positions of the sound source and microphones. The height is 2.7 m.

Figure 3: Sound level meter placed in the room.

acoustic treatment to the room. In what follows for all the measurements the absorptive material was installed covering walls 1 and 2 indicated in Figure 2.

2.3 Acoustic camera measurements

The measurement campaign was conducted using a Sphere48 AC Pro by gfai tech which is an advanced acoustic camera system designed specifically for 3D localization of sound sources in enclosed spaces. This spherical microphone array is equipped with 48 high-precision microphones arranged to capture sound from all directions, making it particularly suitable for indoor applications such as vehicle interiors, rooms, and architectural spaces. This tool represents a powerful and comprehensive solution for the localisation and visualisation of acoustic reflections in three dimensions. The array was positioned centrally within the room, mounted on a high-stability tripod, ensuring a clear line of sight to all major reflective surfaces (walls, ceiling, floor, furniture) (see Figure 4). The system was connected to a multi-channel data acquisition unit running the gfai tech NoiseImage software suite.

A series of impulsive sound stimuli were generated using a NTi Audio Delta Clapper placed at various locations within the room, mainly corners. Each impulse was recorded by the 48 microphones, capturing both the direct sound and the subsequent early and late reflections. To ensure spatial accuracy, the integrated Intel® RealSense™ depth camera was used to match the array position inside the 3D model captured by a laser-scanner, allowing beamforming results to be mapped directly onto the geometry of the room. The same measurement positions and procedure was repeated after the acoustic treatment.

2.4 Computational simulations

Room acoustics simulations were performed using the software Treble, which is a hybrid room acoustic simulation tool that combines wave-based simulations at low frequencies, to capture the important wave and modal behaviour up to a transition frequency (typically the Schroeder frequency), and geometrical acoustic simulations at high frequencies, to take advantage of the faster calculations. The geometry was first modelled in Sketchup and then imported into the software. The source and microphone positions were introduced according to those shown in Figure 2. After theat the materials and properties of the walls, roof and ceiling were defined according to the Table 1.

The transition frequency was set to 710 Hz and the number of rays for the geometrical solver was set to 20,000, considering up to 5th order reflection. The calcu-

Figure 4: Sphere acoustic camera inside the room.

lations, running on a dedicated server associated with the software, took around 3 minutes per complete simulation.

The measured sound absorption coefficients (both in impedance tube and reverberant chamber) of the sheep wool were entered as input to perform the simulations before after the acoustic treatment. The strategy was to combine the absorption values of the walls with those of the sheep wool, under the hypothesis that the wool panels are thin enough not to introduce significant damping, thus not change the low frequency absorption behaviour of the wall panels. For this purpose, the software allows for the introduction of combined sound absorption coefficients, and it calculates the surface impedance of the component using a fitting algorithm. In Figure 5 an example of the material generation window of the software is shown, where the inserted values (target) and the derived values (results) of sound absorption coefficient can be seen. Internally, during the fitting process, the software estimates the surface impedance, which is necessary to recover the phase information for the modal based solver.

3. RESULTS AND DISCUSSION

3.1 Absorption properties of the samples

The sound absorption coefficient in third-octave bands of the sheep wool is shown in Figure 6. As it can be seen, it has a typical behaviour of a fibrous material with a crescent absorption value towards the high frequency range crossing the 0.3 line at around 3000 Hz. On the same graph it is shown the absorption coefficient of the same material measured previously in reverberant room according to the ISO 354. As expected, the values are higher than the ones measured in impedance tube since in the last one only normal incidence behaviour of the sample is captured, while in the reverberant chamber a diffuse field condition is reached. However, the absorption coefficient in this last case can be overestimated due some drawbacks of the methods such us diffraction effects on the border of the sample. Consequently both curves are fed as input into the computational model and the impact on the reverberation time considering one or the other absorption curve is analysed in Section 3.2.

Table 1: Sound absorption properties of the materials used for the simulation

Frequency (Hz)	10 mm gypsum board + 100 mm mineral wool	Wooden flooring	Brick painted (ceiling)
63	0.39	0.16	0.05
125	0.27	0.15	0.04
250	0.14	0.13	0.04
500	0.08	0.1	0.03
1000	0.05	0.08	0.04
2000	0.05	0.07	0.05
4000	0.07	0.07	0.05
8000	0.07	0.07	0.05

Figure 5: Estimation of the absorption properties of the material after a fitting process inside Treble software.

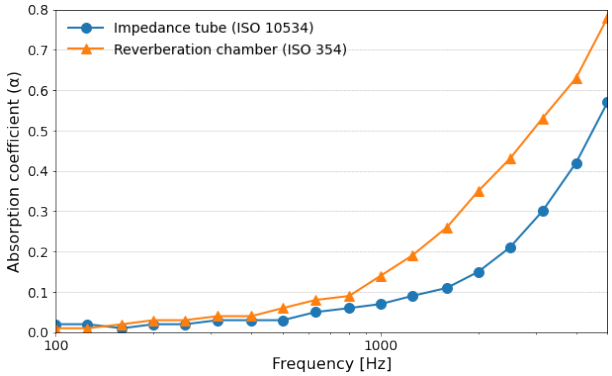

Figure 6: Sound absorption coefficient of the sheep wool measured in impedance tube and reverberant chamber

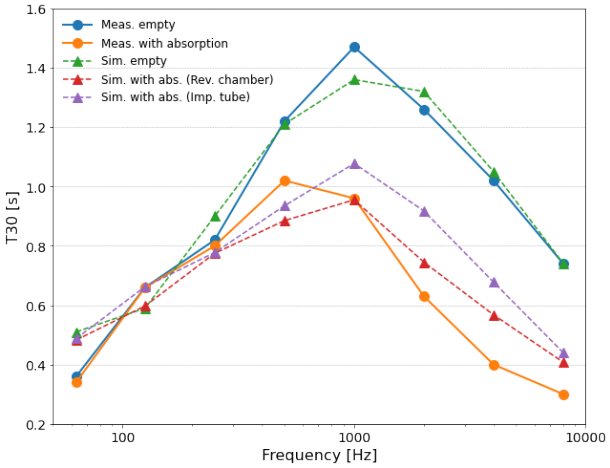

Figure 7: Reverberation time measured and simulated, with and without absorbing material.

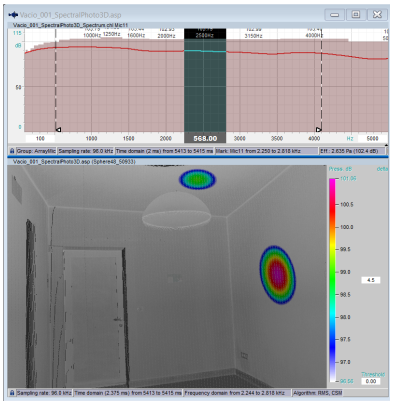
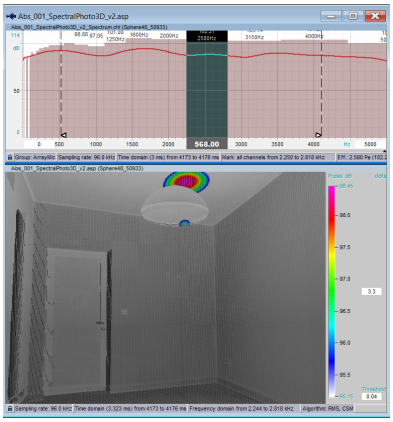


3.2 Impulse response of the room and simulations

The results obtained from the Reverberation Time (RT) measurements, indicate a significant reduction in RT values, particularly from the 500 Hz third-octave band onwards. The overall RT value decreased from 1.35 s to 0.99 s after the installation of the acoustic treatment as it can be seen in the solid line curves in Figure 7. On the same graph the results of the RT from the simulation can be seen. A very good agreement is observed between the measured and the simulated RT of the room without the porous material. When the absorption is applied, the RT curve considering the material measured in reverberation chamber is more close to the measured one than the case considering the absorption values from impedance tube. This might suggest that for non very high absorptive materials the reverberation chamber values potentially can give more accurate results in the model. The mismatch at 63 Hz can be attributed to a fitting difference in the material building module inside the software. For the rest of the frequency the curves follow the same tendency with slight differences.



Additionally, the use of a 3D Acoustic Camera enabled the identification and analysis of early acoustic reflections within the room. This tool was instrumental in comparing the acoustic behaviour of the space before and after installing the absorptive material on two of the walls. The visual data clearly demonstrate the effectiveness of the material in attenuating acoustic reflections at its installed locations. This is particularly evident as shown in Figure 8 in the 2500 Hz third-octave band and with differences of about 5 dB at 1250 Hz and at 800 Hz third-octave bands, where the absorption performance aligns with the material's specified acoustic properties.

4. CONCLUSIONS

In this work a room acoustic study was conducted. First the acoustic absorption properties of a sheep wool material was assessed and used as input data to fed computational simulations. The same material was used to perform an acoustic correction of a room and the reverberation time before and after the acoustic treatment was measured to compare the situations. The acoustic camera was utilised to visualise the first reflections and verify the reduction of level in presence of the sheep wool materials. The room was simulated using a hybrid wave-based and geometrical acoustic software to investigate the response of the room. The model was validated using the experimental measurements. Sound absorption values of the same material measured in impedance tube and reverberation chamber were implemented in the software. It was shown that in the last case the values were closer to the measured ones. Despite normally the reverberation chamber method tends to overestimate the absorption coefficient, this might suggest that potentially for not very highly absorptive materials the most accurate option for use as input data in simulation models is the absorption coefficient measured in reverberant rooms.

ABSTRACT

Raw earth systems are gaining increasing interest in civil engineering due to their low energy and carbon impact, particularly raw earth coatings, which are still underexplored compared to other types of coatings such as those using lime or cement. The objective of this article, which is part of the CarAc'Terre project, is to characterize the behavior of these coatings in terms of acoustic dissipation. The aim is to analyze whether these materials behave in a purely elastic manner or if visco-thermal phenomena need to be taken into account. Experiments have been conducted at material scale on different coatings prepared by masons, with different earths and fiber contents. Acoustical properties were determined with a Kundt Tube in normal incidence and resistivity, porosity, and elasticity of the materials were also measured. These results were then compared with specific models based on theoretical approaches. The analyses revealed that raw earth coatings exhibit complex behaviors that may require consideration of both elastic and visco-thermal dissipation mechanisms. This study contributes to a deeper understanding of the acoustic properties of these materials, opening up new avenues to model the acoustic behavior of a wide variability in earth coating formulation.

1. INTRODUCTION

The building sector is currently facing two major challenges: promoting the well-being of occupants [1] while minimizing the environmental impact of the materials and technical solutions used, which account for 40% of global energy consumption [2]. The use of sustainable materials, such as biosourced or geosourced materials, characterized by high thermal and acoustic performance, is an ideal solution in this context [3–5]. Among these materials, there is growing interest in raw earth systems, particularly hemp-earth concretes commonly referred to as "light earth".

Unlike other traditional hemp concretes, light earth concretes are biosourced granular materials produced by mixing hemp particles with clay. They can be used for construction work using formwork, projection, or block casting techniques, with or without wood. The use of a clay binder offers several advantages, including a carbon footprint around five times lower than that of hemp-lime, as the hardening of clay is reversible, unlike that of lime and cement. The hemp concrete family is valued both for its hygrothermal properties [6–9] and, as porous media, for their acoustic properties, which are crucial for guaranteeing a high level of safety and quality of life for inhabitants [10–13]. These studies have led to a better understanding of acoustic dissipation mechanisms within the material and have tested the applicability of traditional acoustic models such as Biot's poro-elastic approach [14] or the JCAL (Johnson-Champoux-Allard-Lafarge) model [15, 16].

However, analyzing the acoustic properties of light earth is not enough, as this material is rarely used alone at the wall or building scale by craftsmen. Indeed, it is com-

mon practice to add one or more layers of coating, a mixture of binder and additives (fibers, sand, aggregates) that provide better resistance but strongly limit sound absorption [13, 17]. Traditional lime or cement-based coatings are well known but are being questioned for their environmental impact. Raw earth coatings, on the other hand, although less studied, seem promising and are increasingly being considered [13,17–20]. However, there is still a lack of knowledge about the influence of coating formulation, such as its thickness or the nature of the binder employed.

The aim of this article, which is part of the CarAc'Terre project, is to characterize the acoustic behavior of different raw earth coating formulations applied to a layer of light earth, with a view to assessing the influence of formulation and initiating relevant numerical modeling. The aim is to determine whether the coating behaves purely elastically or whether visco-thermal phenomena need to be taken into account. This work is structured in three sections. The first section presents the study materials with the different coating formulations, as well as the experimental procedure for determining their acoustic and mechanical properties. Next, the first experimental results are analyzed, and initial trends are identified. Finally, the measurements are compared with numerical modeling proposals, considering the behavior of the two layers as purely isotropic elastic, as a porous-rigid, or as poro-elastic.

2. MATERIALS AND METHODS

2.1 Materials description

2.1.1 Raw materials

In the case of the light earth (i.e. "l-e"), the hemp particles are processed by the Planète Chanvre association, whose plant is located in Aulnoy (77). The earth used is betonite clay extracted from a single deposit in the commune of Le Buisson de Cadouin (24) and processed in the plant located in the commune of Mazeyrolles (24) by the Lafaure company.

For the coatings, two types of sifted re-employed clay, "Sygogne" and "Paix," were supplied by Totem Terre et Couleur, based in Saint-Gonlay (35). Two varieties of sand were also incorporated: 0/4 sand or 0/2 sand obtained from manual sieving of 0/4 sand using a 2,25 mesh sieve. Finally, four types of biosourced fibers were considered. Short-staple hemp wool was sourced from Agrochanvre (50), flax shiv from the Bosc Nouvel textile flax mill (76), Isocanna-type hemp shiv from Saint-Astier (24), and chopped straw fibers from a farm in Saint-Maden (94).

2.1.2 Samples manufacturing

The samples were made by Arthur Hellouin de Menibus from Matelow (35), a company specializing in light earth construction and training for professionals, Julia Cahour, Morgane Geffroy, Alice Lamy and Andra Varouchas. Moulds with a diameter of $100mm$ and different heights were prepared to form the samples into cylindrical shapes, while leaving a reserve of varying thickness for the coating. A total of 23 coating formulations were applied to the same light earth base. The light earth was applied with low compaction to avoid springback and guarantee a theoretical wet thickness of $30mm$. Four samples per formulation were prepared at the same time with three coatings and one uncoated as shown in Fig. 1.

Figure 1: Formulation example with three coated samples (A, C, D) and one uncoated sample (B).

Each formulation differs in terms of coating thickness, type of sand used, presence or absence of biosourced fibers, type of fibers, and finishes (trowel, sponge) during manufacture. To describe the formulation proposed, the samples are named according to a common nomenclature, $T_F_f_e_X$ or $T_S_f_e_X$, presented in Tab. 1. The dosages were carried out in proportion by volume, and the constituents were weighed each time to find the corresponding mass dosage.

Table 1: Sample nomenclature.

Symbol	Definition		Acronym
T	Type of earth	Earth "la Sygogne"	T1
		Earth "la Paix"	T2
F	Type of fiber	Short-staple hemp wool	L

		Trowelled and sponged surface	TalEp
e	Thickness	$1mm$ thickness	1
		$2mm$ thickness	2
		$3mm$ thickness	3
		$2mm$ thickness	4
		$6mm$ thickness	6
		$10mm$ thickness	10
X	Sample index	N°1	A
		N°2	B
		N°3	C
		N°4	D

It is important to note that during the application of the coating, a certain amount of it penetrated into the microstructure of the light earth. Therefore, for the remainder of this work, it was necessary to estimate the actual thickness of the coating $e_{coating}$, presented in Tab. 2, from the coating density $\rho_{coating}$, the total mass of the sample m_{tot} and the mass of the light earth m_{l-e}. Considering a final coating volume that is always cylindrical, with R being the radius of the cylinder, we deduce $e_{coating}$ with Eqn. (1) below:

$$e_{coating} = \frac{\frac{m_{tot} - m_{l-e}}{\rho_{coating}}}{\pi R^2} \quad (1)$$

According to the results in Tab. 2 and the calculation of the relative deviation Δe between the theoretical and real coating thicknesses, the higher the theoretical coating thickness, the lower the relative deviation. This implies a lesser influence of its penetration into the microstructure of the light earth.

The samples were then stored at room temperature ($15 - 20°C$) and transported to the laboratory where they were weighed, their dimensions recorded, and then dried in an oven for 12 days at $50°C$ with a relative humidity maintained at 20% (Fig. 2a). Once this operation was complete, they were stored for a stabilization phase under the same conditions as in the experimental chamber ($\approx 20°C$, 50% RH) for at least 24 hours before the first tests (Fig. 2b). Once stabilized, the samples were weighed again and their dimensions were recorded to assess the absence of shrinkage after conditioning. The average thickness of the uncoated samples measured at $28,6mm$ with a coefficient of variation of 2% and an average density of $319kg/m^3$ with a coefficient of variation of 3% show that these samples can be considered comparable.

2.2 Experimental methods

2.2.1 *Kundt Tube*

Two main properties characterize the acoustic behavior of our samples at the material scale: insulation, represented by the transmission loss TL (dB), and acoustic correction, characterized by the absorption coefficient α $(-)$. In this work, we consider only the airborne transmission mode, thus not taking into account the so-called solid-borne noise.

The characterization methods used in this work are based on the use of a or Kundt Tube, shown in Fig. 3, at normal incidence. The same device can be used to determine sound absorption, the sound transmission loss, and the intrinsic properties of the material. To obtain the absorption coefficient, the three-position method without a cavity is used, while the transmission loss and intrinsic properties are measured by inducing an 18 mm plenum to free up the rear face of the samples. These two methods are presented in the thesis work of Philippe Glé [13].

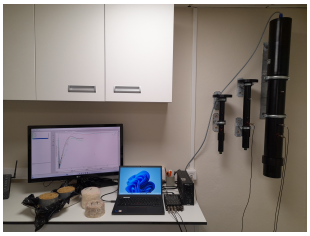

Figure 3: Kundt Tubes of different diameters and measurement acquisition device.

As mentioned in the introduction, taking inspiration from the work of Glé *et al.* [21] we can consider the two layers (light earth and coating) as having purely elastic behavior, with a rigid or poro-elastic skeleton. In the case of a purely elastic material, considered here as isotropic, only the mechanical contributions come into play. They are described by the density ρ, the Young's modulus E, the Poisson's ratio ν and the damping factor η, and can be identified using specific tests. The assumption of a rigid skeleton, considering only the porous phase of the material, is based on acoustic dissipations derived solely from visco-inertial and thermal effects. Advanced acoustic models such as the JCAL model characterize the porous behavior of a material based on six main parameters: porosity ϕ, resistivity σ, tortuosity α_∞, viscous and thermal characteristic lengths Λ and Λ', and static thermal permeability Θ_0. From these parameters, it is possible to derive the sound transmission loss and the sound absorption coefficient. It is generally common to determine the first three parameters (ϕ, σ, and α_∞) directly with experimental devices and to estimate the last three indirectly because they are more difficult to measure. When indirect estimation is also impossible, it is customary to simplify acoustic models, as we shall see in the last section. Finally, poro-elastic behavior combines the three dissipative effects based on the work of Biot [14, 22].

2.2.2 *Porosity*

Porosity ϕ $(\%)$, commonly considered to be open porosity in acoustics, is determined using the air volume comparison method mentioned by Leclaire *et al.* [23], illustrated in Fig. 4a. Conventional porosity measurements are used to characterize the porosity accessible to air. However, in the case of light earth, multi-scale behavior is also based on intra-particle porosity (Olny and Boutin [24]). In this case, an indirect assessment of porosity is required. Porosity can be estimated either from the asymptotic low or high-frequency limits of the dynamic incompressibility modulus, or from the low-frequency limit of the surface impedance. Where this is not possible, porosity can be inverted using a model such as Zwikker-Kosten [25].

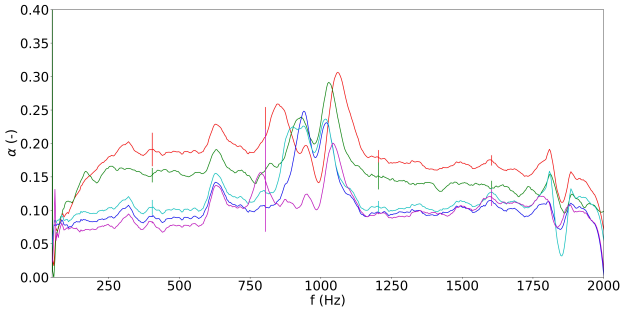
2.2.3 *Resistivity*

The resistivity, denoted σ (Pas/m^2), can be measured directly using a resistivity device (Fig. 4b) as explained in [13]. Resistivity can also be characterized indirectly in a Kundt Tube under the same conditions as absorption and the transmission loss at normal incidence, as described by Jaouen et al. [26]. We refer the reader to Philippe Glé's thesis [13] for more information on direct or indirect estimation methods for other acoustic parameters. In the remainder of this study, we will prioritize data obtained directly, but in cases where it is impossible to obtain such data, we will use indirect estimates.

(a) (b)

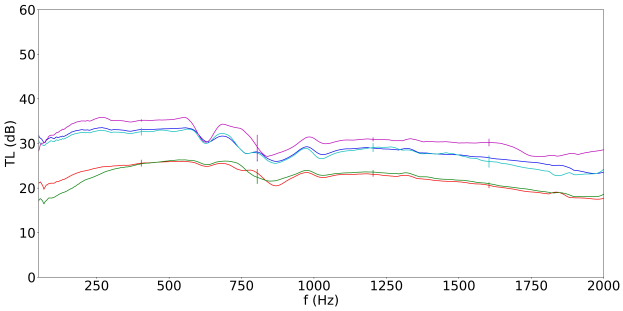
Figure 4: Porosity (a) and resistivity (b) devices.

2.2.4 *Mechanical properties*



The apparent density ρ of a porous material can be measured directly by estimating its mass and volume. This work, presented in Tab. 2, was carried out for coatings by Catherine Guigou Carter and Thibaut Blinet at CSTB, a partner in the project, using bars with dimensions of $284mm \times 24mm \times 24mm$. They also estimated the Young's modulus E and the damping factor η of the coatings, according to the NF EN 14146 standard [27]. The density of the light earth was averaged at Cerema over all 23 uncoated sample measurements. The other parameters are taken from the work of Glé *et al.* [21] or the LOB+HIE project [18], pending future tests at the laboratory's quasistatic mechanical analyzer (QMA).

3. RESULTS



3.1 Experimental results : Influence of thickness

During this test campaign, 23 raw earth coating formulations were tested to observe the influence of the multiple factors mentioned above. In this article, we focus on the influence of coatings thickness with the study on $T1_L$ mixes (n°1 to 5), corresponding to coating thicknesses of 1, 2, 3, 4, and 6 mm. The mean data for the three coated samples, for each thickness, are plotted with their standard deviations as uncertainty bars in Fig. 5a and Fig. 5b.

Fig. 5a shows that the absorption coefficient decreases with increasing thickness. This observation can be explained by the fact that it is easier for the acoustic wave to penetrate the layer of light earth when the thickness of the coating is low. Because of its microstructure, the light earth layer allows more acoustic dissipation within the material, which increases acoustic absorption. However, according to Fig. 5b, and contrary to the absorption coefficient, as the thickness of the coating increases, so does the acoustic insulation of the sample. This finding, shared by [21], suggests that sound attenuation is not solely due to a mechanical contribution but involves other effects, such as viscous and thermal dissipation. Finally, we generally observe a stabilization of performance from a thickness of $4mm$.

(a)

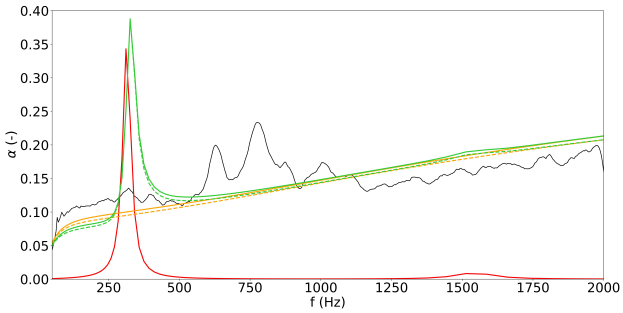
(b)

Figure 5: Evolution of the absorption coefficient $\alpha\ (-)$ (a) and the transmission loss $TL\ (dB)$ (b) as a function of frequency $f\ (Hz)$ for a $T1_L$ sample of coating thickness $1mm$ (—), $2mm$ (—), $3mm$ (—), $4mm$ (—) or $6mm$ (—).

3.2 Numerical modeling

In this final section, we propose to model the acoustic behavior of one material using AlphaCell© software. We have chosen the $T1_L_10_D$ sample, which has the advantage of having a theoretical coating layer $10mm$ thick, meaning its penetration into the layer of light earth is less influential. It is also a formulation for which the porosity and resistivity have been determined directly.

We consider the behavior of the layers to be purely isotropic elastic, porous-rigid, or poro-elastic. As explained above, the mechanical properties of the two layers are derived from experimental measurements or from the literature. The modeling of the porous character of the light earth-layered layer is based on the thesis of [13], who suggests considering hemp concretes with the JCA models coupling those of Johnson et al. [15] and Zwikker-Kosten [25], and globally requiring four param-



eters: porosity ϕ, resistivity σ, tortuosity α_∞, and viscous characteristic length Λ. The resistivity could be determined directly, whereas, due to the double-porosity phenomenon present in the material, the acoustic porosity had to be estimated indirectly, as well as the tortuosity and the viscous characteristic length.

On the other hand, for the porous nature of the coating, two rigid skeleton approaches are considered. Here, we use reduced models for the coating due to the relatively high resistivities of these materials, with other parameters having a more limited impact in this case. The first approach considers the coating with a JCAL model reduced to two parameters following the hypothesis of a perforated material geometry, σ and ϕ, considering the tortuosity equal to 1 and simplifying the relationships of the viscous and thermal characteristic lengths as well as the thermal static permeability. These relationships are shown in Tab. 3, which summarizes the mechanical and acoustic parameters of the two layers modeled, where r_1 is the radius of the pores considered to be cylindrical and μ is the shear viscosity of air, equal to $1,8 \times 10^{-5} Pa.s$. The second approach considers the coating with the Boutin-Geindreau granular model [28], requiring only two parameters, ϕ and r_2, the aggregates radius considered to be spherical, from which all the other acoustic parameters are deduced as described in Tab. 3. Note the closeness of the experimental values to those of [18], whether for light earth with, for example, a density of $295 kg/m^3$ and a porosity rate of 69%, or for earth coating with a density of $1500 kg/m^3$ or a Young's modulus of $2850 MPa$.

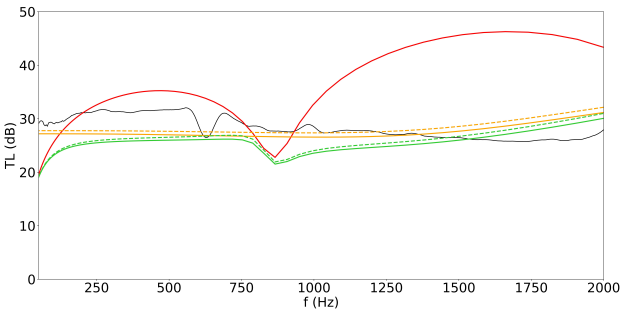


Table 3: Mechanical and acoustic parameters of the modelled layers. Data from [18] and [21] are shown as $^{[a]}$ and $^{[b]}$.

Parameters	Light earth	$T1_L_10_D$ sample	
	JZK Model	JCAL model reduced	Granular model
Thickness (mm)	27,3	12	
$\rho\ (kg/m^3)$	319	1369	
$E\ (MPa)$	$2^{[a]}$	1711	
$\nu\ (-)$	$0,1^{[a]}$	$0,2^{[a][b]}$	
$\eta\ (\%)$	$10^{[b]}$	3	
$\phi\ (\%)$	65	50	
$\sigma\ (Pa.s.m^2)$	1,6E+3	1,5E+6	
$\alpha_\infty\ (-)$	1,6E+3	1,5E+6	
$r_1\ (m)$	×	$r_1 = \sqrt{\frac{8\mu}{\phi\sigma}}$	×
$r_2\ (m)$	×	×	$r_2 = \sqrt{\frac{3\beta^2\mu}{\sigma\left(-1+\frac{2+3\beta^5}{\beta(3+2\beta^5)}\right)}}, \beta = (1-\phi)^{\frac{1}{3}}$
$\Lambda\ (m)$	2,6E-4	r_1	$\frac{4\phi\alpha_\infty}{9(1-\phi)} r_2$
$\Lambda'\ (m)$	×	r_1	$\frac{2\phi}{3(1-\phi)} r_2$
$\Theta_0\ (m^2)$	×	$\frac{\phi r_1^2}{8}$	$\frac{(5-9\beta+5\beta^3-\beta^6) r_2^2}{15(1-\beta^3)\beta^3}$

A total of five models are compared with the experimental absorption coefficient (Fig. 6a) and transmission loss (Fig. 6b).

(a)

(b)

Figure 6: Comparison of the evolution of the absorption coefficient $\alpha\ (-)$ (a) and the transmission loss $TL\ (dB)$ (b) as a function of the frequency $f\ (Hz)$ for the coated sample $T1_L_10_D$ between the experimental measurement (—), simulation of elastic bilayer behaviour (—), simulation of a porous-rigid bilayer behaviour using the reduced JCAL (—) or Boutin-Geindreau (- -) model and simulation of poro-elastic bilayer behaviour using the reduced JCAL (—) or Boutin-Geindreau (- -) model.

Analysis of Fig. 6a reveals that the assumption of purely elastic behavior of the two layers of the sample is insufficient to simulate its absorption behavior. On the other hand, the four other simulations, which take into account the porous character, seem to be closer to the experimental results. This suggests that the measured resistivity of the coating is fairly representative. The two categories of simulations have the advantage of being relatively simple, with few parameters, while providing a fairly relevant

prediction. This is particularly the case with poro-elastic behavior, which reproduces the resonance observed experimentally, although at lower frequencies. This resonance corresponds to that of the light eart layer, which is caused by the compression of its solid phase following acoustic stress. A second simulation later revealed that increasing the Young's modulus to $10MPa$ further improved the position of this resonance frequency. Finally, there was no major difference between the two approaches regarding the pore geometry of the coating.

The overall numerical prediction of the transmission loss by the five approaches is slightly poorer than that of the absorption coefficient, as shown in Fig. 6b. The hypothesis of purely elastic behavior of the sample should once again be ruled out, while the others seem to slightly underestimate the transmission loss at low frequencies and overestimate it at high frequencies. Overall, the simplified poro-elastic approach seems to be the most interesting, as it again reproduces the resonance of the lightened earth while providing a promising prediction regardless of the pore shape hypothesis.

4. CONCLUSION

This work, part of the CarAc'Terre project, focused on characterizing the acoustic behavior of different, as yet little-studied, raw earth coating formulations applied to light earth. We aimed to assess the influence of the formulation and propose an initial numerical modeling campaign for this two-layer material. After presenting the study materials with the different coating formulations, we described the methods for direct or indirect estimation of the acoustic and mechanical parameters required to characterize the acoustic performance of the samples. We then analyzed the initial experimental results, revealing the first trends. Among other things, it appeared that an increase in the thickness of the coating reduced the acoustic absorption of the bilayer, as opposed to the acoustic insulation. Finally, the measurements were compared with a proposal for numerical modeling, considering the behavior of the layers as purely elastic, porous-rigid, or poro-elastic. The poro-elastic approach appeared to be the most relevant, thanks to the simulation of mechanical and visco-thermal dissipation. This study raises a number of prospects for future work like improving the numerical approach by developing more accurate acoustic models or considering the scale of the wall and the entire building, which will be the subject of further studies as part of the project.

5. ACKNOWLEDGEMENTS

We would like to thank Julia Cahour, Morgane Geffroy, Alice Lamy and Andra Varouchas for their contribution to the coating samples. This project was funded by the French government as part of France Relance, now part of France 2030, and operated by ADEME.

ABSTRACT

Micro-perforated panels (MPPs), lightweight structures, are investigated as alternatives to huge or active devices, to attenuate noise induced by external flow into the passenger compartment of automobile or aircraft cabins. Optimal sound absorption performance is achieved by appropriate selection of MPP geometry. The viscous losses through the apertures dissipate the acoustic energy around the Helmholtz resonance and provide high absorption efficiency over a wide bandwidth. Acoustically induced vorticity, due to streaming at the hole inlet/outlet, could also contribute. The experiment quantifies the flow induced by acoustic pressure fluctuations (”streaming”) in the vicinity of the perforations of an MPP placed on a cavity arranged on the wall of a closed tube. Three diameters of perforations ($1mm$, $0.6mm$ and $0.3mm$) are tested. The flow induced by an acoustic plane wave parallel to the surface of the MPP is characterized by TR-PIV (”Time Resolved Particle Image Velocimetry”), a laser optical diagnostics, synchronized with acoustic measurements by microphone. The dynamics of the jets emitted at the holes according to their relative position to the wavelength associated with different identified eigenmodes of the closed tube is highlighted. The objective is to estimate the viscous dissipation associated with these micro-jets and to link it to acoustic absorption.

Keywords: *micro-perforated panel, acoustic absorption, streaming, time resolved PIV.*

1. INTRODUCTION

Under the influence of the development of noise standards, research is being conducted to propose passive and lightweight solutions whose fouling can be resolved in the case of industrial applications such as in the design of aeronautical engine walls and compatible with efforts in the field of sustainable development. Micro-perforated panels consisting simply of holes or based on walls made of metamaterials ([1, 2]) are interesting solutions whose performance must be evaluated. Perforated walls have been particularly studied by Maa [3], for the sizing of holes for optimal efficiency. More recent work by Laurens et al. [4] has proposed an introductory synthesis which describes the three contributions of perforations to the acoustic behavior of a perforated panel. The assumptions made are that the porosity is less than 4% so that the interactions between the holes are neglected, which also amounts to having a large spacing between holes and that the acoustic wavelength is large compared to the characteristic dimensions of the perforations. Among the three physical phenomena mentioned, the first one is a non-viscous effect related to that the flow inside the hole behaves like a small air piston. It induces that, due to inertia effects, one has to consider in the acoustic models a length correction on the depth of the perforations. Then, it is necessary to take into account the viscous effects in the boundary layers which develop on the internal wall of the hole which will participate in the absorption of acoustic energy. Finally, in the presence of high amplitude sound waves striking the opening, a vortex detachment, which converts the acoustic energy

into mechanical energy, then dissipated into heat, can occur.

The present study aims to investigate experimentally the space-time behavior of the flow induced when MPP is subject to such high amplitude sound waves without mean flow. In the experiment, the sound is generated by a plane wave whose wave vector is parallel to the surface of the perforated panel, placed in the bottom of a close tube. Section 2 gives the set-up that allows the measurements of the flow velocity in the vicinity of apertures by high-speed PIV and the acoustic pressure measurements by microphone. Section 3 specifies the acoustic conditions chosen for the study. Results presented in Section 4 highlight and quantify the structure of the flow induced by pressure fluctuations.

2. EXPERIMENTAL SETUP

The MPP (Micro-Perforated Panel) is a perforated metal plate of $D = 100mm$ diameter and $1mm$ thickness. Three types of MPP (Fig. 1) are studied, whose periodic perforation characteristics are summarized in Tab. 1. Each MPP is successively installed above the same cavity located in the center of the floor of the Kundt tube. The diameter of the cavity is $100mm$ and its depth is $30mm$. The Kundt tube (Fig. 2) is a parallelepipedic volume of length $L_x = 1.06m$ and of square cross-section of side $L_x = L_z = 150mm$. Lateral walls are in glass and an optical access is possible on the top wall where the laser sheet is passing.

High-speed PIV (Particle Image Velocimetry) images are acquired and post-processed by a Dantec Dynamics system (RapiDO) that includes one T4040 SpeedSense Phantom high-speed camera ($2560\times1664\,pixels$, 12 bits), and a double pulsed laser. The camera is equipped with a $200mm$ focal lens with a $f\#4$ aperture in order to obtain good resolution on a small field of view in the vicinity of the MPP's surface. The pulsed laser is a Photonics laser (527nm, $2 \times 30mJ$ at a nominal $1kHz$ repetition rate). The DynamicStudio software controls the synchronization of image acquisition. A laser sheet generator constituted of several adapted lenses is installed at the end of the optical arm to illuminate the field of view of interest ($24.3mm \times 15.7mm$). 7000 PIV images are acquired at the frequency $F_s = 6.4kHz$ when the laser is working in a single mode, which means that the delay between two pulses is $1/F_s = 156\mu s$. The volume of the Kundt tube is seeded with olive oil droplets of $2-3\mu m$ diameter injected by a hole located on the upper wall. During seeding, the small hole located in the bottom wall of the cavity is left open so that droplets can flee when also pervading the cavity volume. In order to let the seeding stay in suspension, it is preventively stopped a few minutes before experiments with sound and the small hole located in the bottom wall of the cavity is closed. Thanks to the RapiDO system, the sound pressure inside the Kundt tube is measured synchronously with PIV using a wall microphone GRAS SC40. The microphone is located on the top wall at $\delta X = 55mm$ from the extremity wall. A loudspeaker is mounted on the opposite side.

Table 1. MPP dimensions.

MPP	d (mm)	i (mm)	Porosity
MPP1.0mm	1.12	5.15	2.5%
MPP0.6mm	0.65	4.30	1.4%
MPP0.3mm	0.30	1.87	1.5%

The spatial resolution for PIV is $\delta_x = \delta_y = 154\mu m$. The (O, X, Y, Z) coordinate system is centered on the middle of tube floor where the investigation is focused. The two instantaneous components ($2C$) of velocity (U, V) are measured on the plane ($2D$) $Z = 0$ specified in (Fig. 2) by a green square. Statistics and other post-processing of the 6999 velocity fields and acoustic signals are performed by homemade codes developed in Matlab.

3. CHARACTERIZATION OF THE KUNDT TUBE ENCLOSING THE MPP

3.1 Eigen modes of the Kundt tube

In order to investigate the flow induced by pressure fluctuations through the holes of the MMP, one chooses to generate a pressure field of high SPL (Sound Pressure Level) inside the Kundt tube. For that, the first eigen modes of the Kundt tube volume are first calculated and then checked by acoustic pressure measurement by the microphone for a white noise excitation in the range $200 - 3000Hz$ delivered by the loudspeaker. For this experiment, the microphone signal is acquired with a sample frequency of $25.6kHz$ during $100s$. The experimental frequencies of the modes are obtained by spectral analysis as shown in Fig. 3. The agreement between both series of eigen mode frequencies is quite good (Tab. 2). The retained frequencies for the following

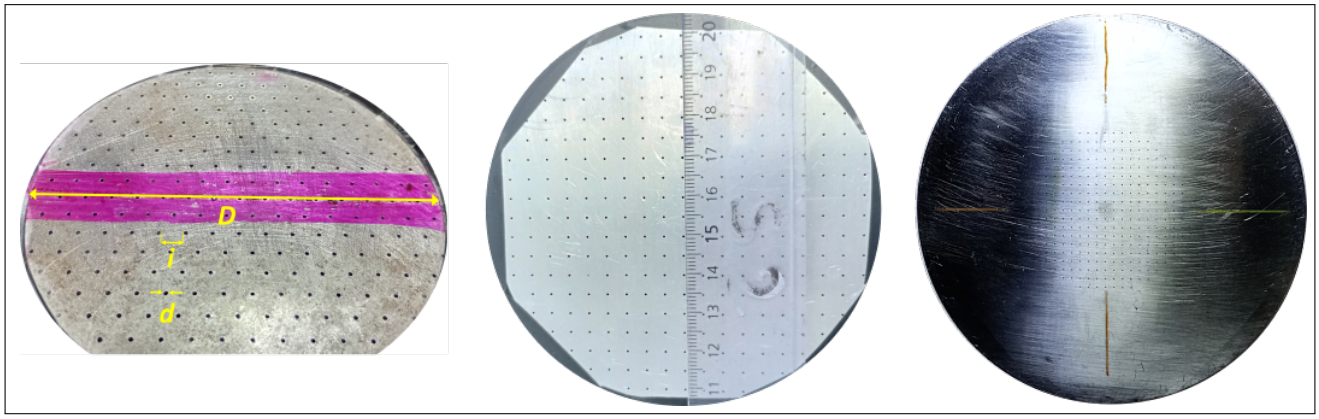

Figure 1. Disks of MPP, from left to right: MPP1.0mm, MPP0.6mm and MPP0.3mm.

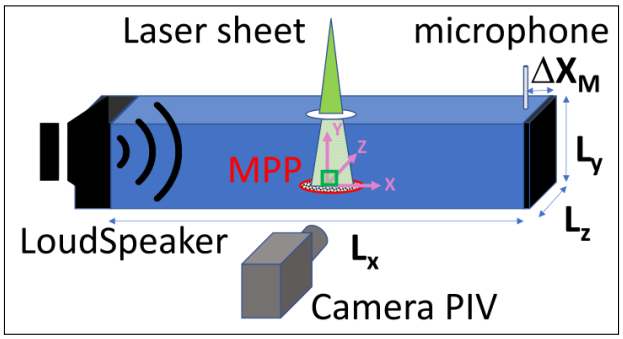

Figure 2. Setup of the high-speed PIV in the near field of MPP mentioned by the centered green square, the scheme is not scaled.

results correspond to the modes $(l, m, n) = (2, 0, 0)$ and $(3, 0, 0)$ along the respective direction (X, Y, Z). The associated frequencies will be named $F_2 = 324Hz$ and $F_3 = 486Hz$ hereafter. In this approach, the eigen modes of the cavity situated under the MPP, which are of higher frequencies, are not considered.

The two selected study frequencies allow to observe the behavior of the flow at the holes depending on whether the acoustic pressure is a node or an antinode. Fig. 4 gives a spatial representation of the amplitude of acoustic pressure in the Kundt tube. The scale of the geometry is respected and the PIV field of view is identified by a green rectangle above the red surface of the MPP centered on $(X = 0mm, Y = 0mm)$. For the long-wavelength $(2, 0, 0)$ and $(3, 0, 0)$ modes considered here, the microphone located at $\Delta X = 55mm$ from the closed end of the Kundt tube measures almost the maximum of the absolute value of the acoustic pressure amplitude.

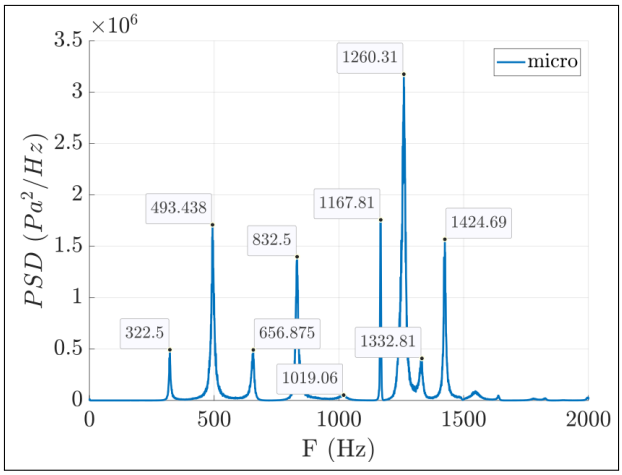

Figure 3. Spectral analysis of acoustic pressure measured by the microphone: experimental characterization of the first eigen modes of the Kundt tube by white noise excitation.

3.2 Measurement of the acoustic velocity by high-speed PIV

The case of the $(3, 0, 0)$ mode is investigated for a smooth wall for which the cavity is covered with a non-perforated

metal plate. This configuration allows us to test whether we can measure the acoustic velocity with the PIV since for $F_3 = 486Hz$, the acoustic pressure is at a node above the MPP, but the amplitude of acoustic velocity is maximum. While measuring a standard deviation of $\sigma_P = 142.7Pa$ by microphone, a standard deviation σ_U of U velocity component, in the direction of plane wave vector generated by the loudspeaker, is measured by PIV. The spatial averaging of σ_U on the vertical direction Y at $X = 0mm$ gives $\sigma_U = 0.332m/s$ quite in a good agreement (4% error) with a theoretical estimation of the acoustic velocity by $\sigma_U = \sigma_P/(\rho c) = 0.347m/s$ with the sound speed $c = 343m/s$ and the air density $\rho = 1.2kg/m^3$. Similar measurements were made for $F_2 = 324Hz$ for which the theoretical acoustic velocity should be zero in the middle of the Kundt tube, one obtained a minimum of $\sigma_U = 0.013m/s$ on all the vertical line $X = -1.4mm$ in the PIV field of view.

Fig. 5 shows how the acoustic pressure signal measured at the Kundt tube end and the velocity components measured at X=0mm are timely synchronised. The signals of P, U and V are non-dimensionalized by their amplitude deduced from their standard deviation σ. All signals are harmonic. The V signal is of weak amplitude ($\sigma_V = 0.004m/s$) and very noisy comparatively to U signal for which $\sigma_U = 0.332m/s$. The phase shift between the velocity and the pressure is $\pi/2$ as it could be predict theoretically for a plane wave. These results indicate that PIV measurements give an applicable estimation of the acoustic velocity with the limitation of drag effects of seeding droplets.

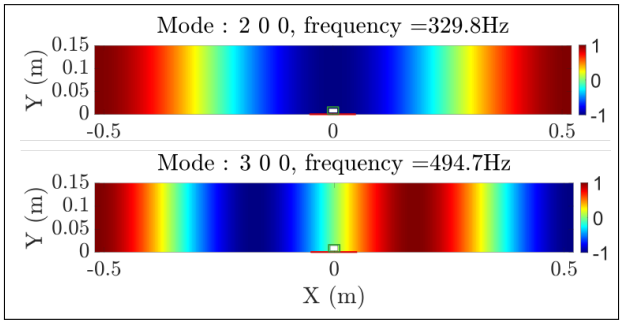

Figure 4. Theoretical acoustic pressure amplitudes for modes (l, m, n) = (2, 0, 0) and (3, 0, 0) of the Kundt tube.

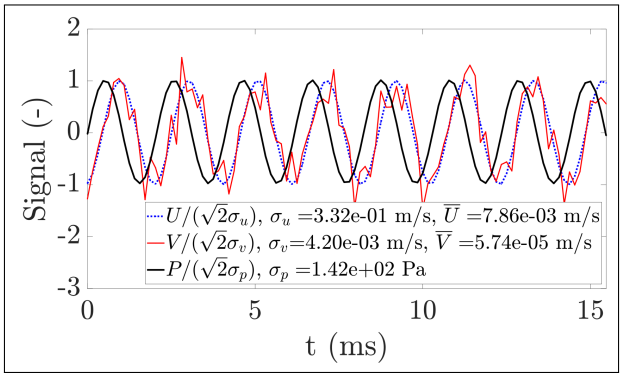

Figure 5. Time series of velocity components (U, V), extracted at position $(X = 0mm, Y = 5mm)$ in the PIV field of view for the smooth wall, and pressure signal measured synchronously by microphone, for $F_3 = 486Hz$ corresponding to a an acoustic pressure node at this place.

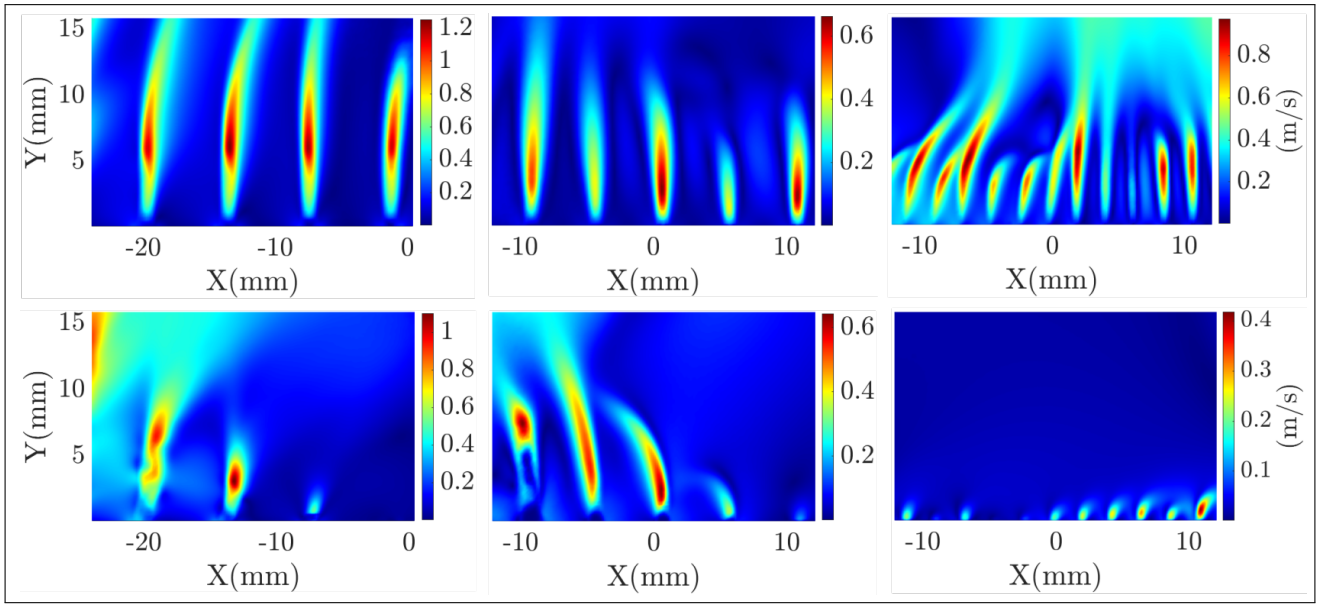

Figure 6. Mean velocity norm $\sqrt{\overline{U}^2 + \overline{V}^2}$ for MMP1.0mm, MPP0.6mm and MPP0.3mm from left to right. Top: for a antinode acoustic pressure (acoustic velocity node) over the MPPs, for $F_2 = 324Hz$. Bottom: for a acoustic pressure node (acoustic velocity antinode) over the MPPs , for $F_3 = 486Hz$.

4. EVIDENCE OF THE STREAMING

The mean velocity norm fields, obtained for all the MPPs, for both excitation frequencies $F_2 = 324Hz$ and $486Hz$, are presented in Fig. 6. The sound pressure levels associated to these PIV experiments are given in (Tab. 3). These results aim to compare the flow behaviour according to the existence of a node or antinode of acoustic pressure above the MPP. The influence of pressure is obvious. For conditions of pressure antinode ($F_2 = 324Hz$), the persistence of an average flow in the form of vertical jets escaping from the holes up to around $Y = 15d$ is an evidence of streaming. Contrariwise, for conditions of pressure antinode ($F_2 = 486Hz$), one observes an extinction of these jets in regions around $X = 0mm$. Remaining average jets have shorter vertical development than for $F_2 = 324Hz$ and seem to be submitted to transverse effects, possibly related to large scale streaming in the Kundt tube. At $F_2 = 324Hz$, the maxima of mean velocity norm occur at $Y/d = 5-6$ for MPP1.0mm and MPP0.6mm and rather at $Y/d = 15$ for MPP0.3mm. In this last case, the jets are not all active and those which have the greater vertical development interact in their far field. The standard deviation of V, not shown here, is maximum , respectively σ_v =0.46, 0.35, 0.49 m/s for the three MPPs, in the jet near field and becomes very weak in the region where the mean velocity norm becomes maximal. Beyond this region, the mean movement becomes predominant relatively to the fluctuating one.

Table 3. Sound Pressure Level (SPL) measured by the microphone with loudspeaker excitation.

SPL for	$F_2 = 324Hz$	$F_4 = 486Hz$
Smooth wall	133.7 dB	137.1 dB
MPP1.0mm	132.1 dB	140.2 dB
MPP0.6mm	129.2 dB	134.6 dB
MPP0.3mm	127.1 dB	133.9 dB

5. DYNAMICS OF THE FLOW

5.1 Spectral analysis

Fig. 7 presents a comparison of the spectral analyses of the acoustic pressure and the V velocity signal extracted

on the axis, in the near field, of one jet for the MPP1.0mm at $F_2 = 324Hz$. For the velocity signal, the excitation frequency and its harmonics are detected. However, the raw instantaneous PIV fields are noisy as shown by an extracted sample of V time series in Fig. 9, so a method is proposed herafter in order to fix the main contributions to the flow dynamics.

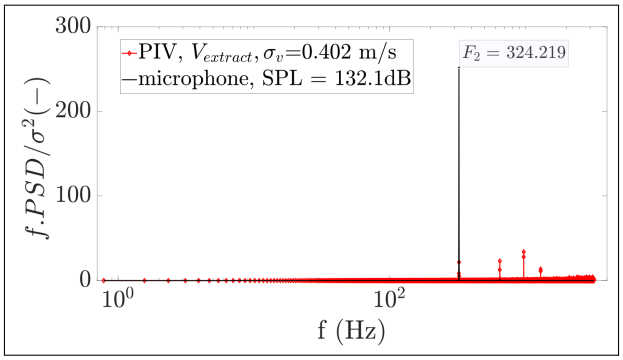

Figure 7. Spectral analysis of the pressure measured by microphone and V velocity components extracted from the PIV field at position $(X = 4.5mm, Y = 5mm)$ corresponding to an axial position on an ejected jet from a hole of MPP1.0mm at $F_2 = 324Hz$.

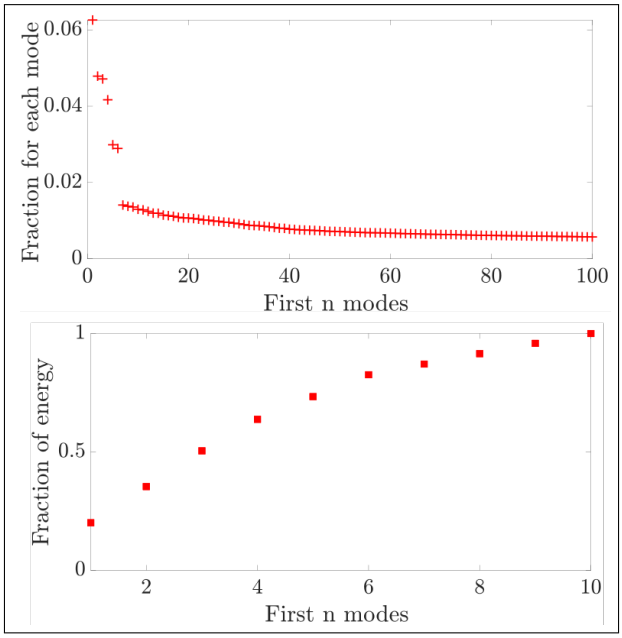

Figure 8. Fraction of energy associated to POD mode decomposition. Top: Ratio of energy for each considered mode to the cumulative energy of the first 100 modes. Bottom : Ratio of the cumulative energy for the n first modes to the cumulative for the first 10 modes.

5.2 POD of the velocity field

In order to highlight the space-time structure of the jets, one proposes to apply POD (Proper Orthogonal Decomposition, [5]) method which interest is to capitalize on the high amount of available fluctuating velocity fields. The principle of this method is to decompose the quantity of interest, here the velocity components, on a basis of eigen modes sorted by their energetic contribution. The decomposition is performed on 2000 uncorrelated snapshots of the two velocity components (U, V), which determines a number of modes equal to the number of realizations.

Fig. 8 illustrates how the energy is distributed according to the considered POD modes. The top figure shows the energetic contribution of each n mode to the cumulative energy of the first 100 modes. The first 6 modes are the main contributors comparatively to the all following ones. The ratio of the cumulative energy for n first modes to the cumulative for the first 10 modes presented in the bottom figure helps to specify that 64% or 83% cumulative energy is obtained by the contributions of the 4 or 6 first POD modes, respectively.

The space-time reconstruction of the instantaneous velocity field with the first 4 POD modes is proposed in Fig. 9 for a chosen jet ejected from one hole of the MPP1.0mm with the $F_2 = 324Hz$ excitation. The six snapshots presented in the top figure from the left to the right are associated to the instants $t_i = t_0, ..., t_5$ marked on the pressure time series plotted in the bottom figure for a duration covering at least one excitation period. According to the spatial representation of the theoretical mode (2,0,0) given in Fig. 4 the amplitude of the acoustic pressure over the MPP is of opposite sign to that can be measured by the microphone at Kundt tube end. So the non-dimensionalized signal of the velocity V extracted at the jet exit is plotted synchronously with the -P signal in order to analyse the flow dynamics in term of pressure fluctuations in the region of the MPP. When the acoustic pressure is negative, at t_1, a hemispherical flow burst is ejected from the hole. This burst continues to rise in the jet column and takes a spherical shape while, between t_2 and t_3,

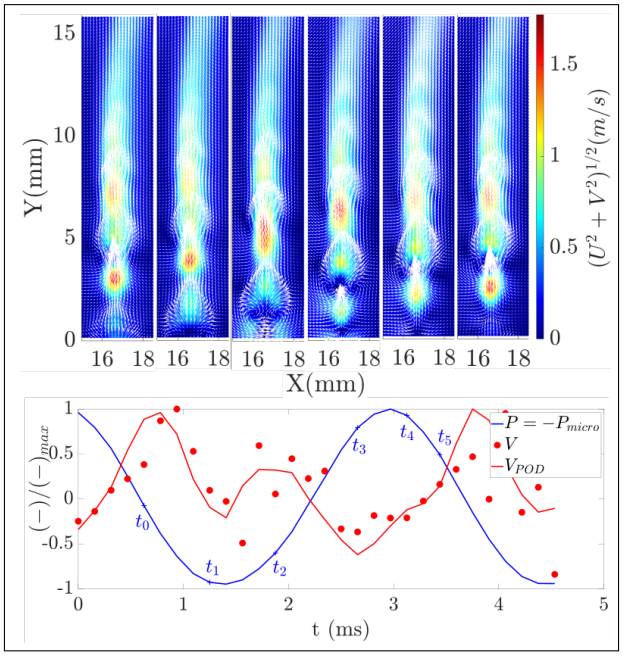

Figure 9. Top: Temporal evolution of the POD [1 2 3 4] velocity field for one jet ejected from a hole of the MPP1.0mm during a period for $F_2 = 324Hz$ excitation (acoustic pressure antinode over the MPP). The colorbar corresponds to the instantaneous velocity norm while the vectors are (U, V). Bottom : Times series of acoustic pressure measured by microphone synchronously with PIV. The vertical velocity component signal (V: raw PIV and V_{POD}: POD reconstruction) is extracted at the center of jet exit cross-section (position : $X = 16.6mm$, $Y = 0.15mm$)

pressure becomes zeros and flow stops moving at the hole exit. When the acoustic pressure is positive, the flow is reverse with negative V velocity in the hole near field and enters the hole as seen in velocity snapshots at t_3 and t_4. This behavior is repetitive over all pressure cycles.

The rotational aspect of the flow in the field of view suggests to calculate the vorticity using the POD reconstructed velocity vectors. Thanks to the high spatial resolution of (U, V) field, the out-plane instantaneous vorticity component:

$$\omega_z(X,Y,t) = \frac{\partial V(X,Y,t)}{\partial x} - \frac{\partial U(X,Y,t)}{\partial y} \qquad (1)$$

can be estimated. This is done with the first 6 POD mode reconstruction of (U, V) for the MPP1.0mm at $F_2 = 324Hz$.
Fig. 10 illustrates a snapshot of the fluctuating vorticity:

$$\omega'_z(X,Y,t) = \omega_z(X,Y,t) - \overline{\omega}_z(X,Y) \qquad (2)$$

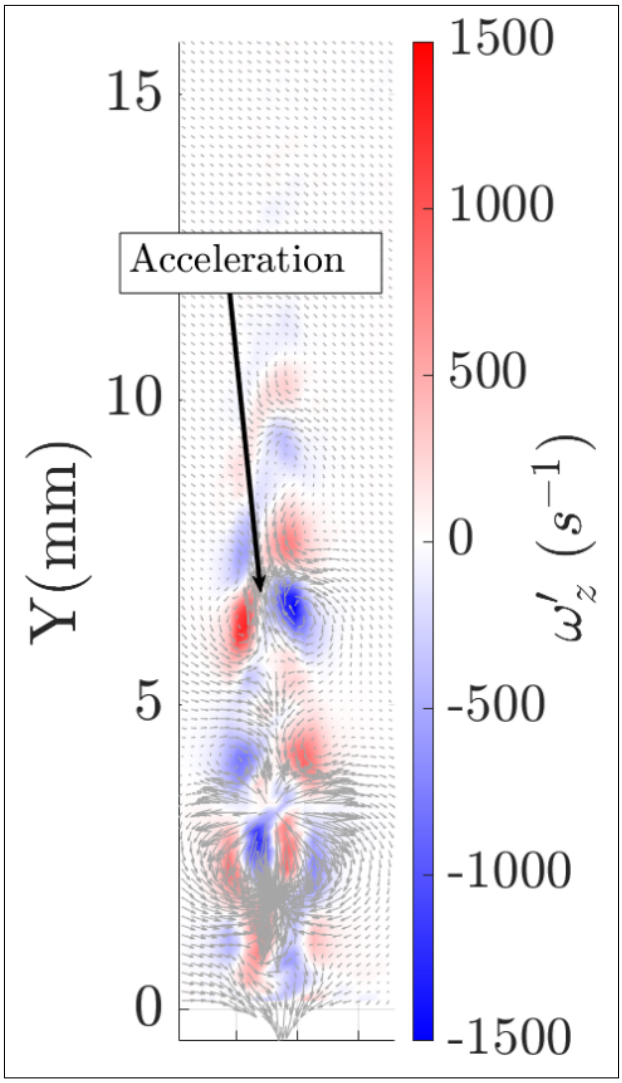

Figure 10. Snapshot of fluctuating vorticity component ω'_z and instantaneous velocity vectors (U,V) calculated from velocity field reconstructed with the six first POD modes for $F_2 = 324Hz$ excitation (acoustic pressure node over the MPP1.0mm).

This representation associated to the plotting of the

synchronous instantaneous velocity vectors underlines the symmetry of the flow on either side of the vertical axis of the jet. The snapshot is chosen for a positive acoustic pressure at the instant t_3 so that the flow entering the hole is clearly observable. Successive counter-rotating vortices are distributed along this symmetry axis. At $Y = 3.5mm$, it is clear that this $2D$ representation gives only a partial view of the $3D$ flow behavior. At $Y = 6mm$, two counter-rotating vortices with the largest magnitude of vorticity detected in the field of view induce an ascending vertical flow acceleration which could be the motor of the jet streaming since the maximum mean velocity is detected in this region as seen for the MPP1.0mm on the top figure of Fig. 6.

6. CONCLUSION AND PERSPECTIVES

The flow induced by high acoustic pressure levels at the apertures of MPP was investigated by measurements of velocity with high-speed PIV associated to synchronous measurements of acoustic pressure by microphone. When the MPP region is submitted to an acoustic pressure antinode, the flow is in the form of pulsated jets which could expand vertically above the aperture up to $Y/d = 15$. Thanks to a POD decomposition of the velocity field, the space-time structure of these jets is quantitatively characterized. The origin of a vertical streaming in the development region of the jet is guessed to be related to the presence of high vorticity counter-rotating vortices located at the end of the region above the apertures where the flow go out or in the perforation. The next step of the study is to quantify the loss of energy induced by this rotational aspect of the flow.

METHOD FOR ASSESSING THE IMPACT OF AGING OF SELECTED BUILDING MATERIALS ON THEIR ACOUSTIC PROPERTIES

Elzbieta Nowicka*
Department of Therma Physics, Acoustics and Environment, Instytut Techniki Budowlanej, Poland

ABSTRACT

The aim of the work is to assess the impact of aging on selected different building materials. Natural climatic exposures of building materials result in the deterioration of their acoustic properties. Laboratory tests performed on small samples, including acoustic tests correlated with climatic exposures in laboratory conditions, will allow for the assessment of the durability of the functional properties of building materials at the stage of introducing the product to the market. Assessment of the durability of acoustic properties of building materials is to consist in changes in acoustic parameters as a result of exposing samples to various weather conditions. This paper presents the results of preliminary tests carried out on small samples in an impedance tube. Based on the tests performed, an analysis of the results will be carried out in terms of the impact of exposure on the acoustic properties of the elements, mainly in terms of parameters specific to road screens..

Keywords: *aging, building materials, sound properties)*

1. INTRODUCTION

The assessment of the durability of the acoustic properties of road noise barriers is one of the elements in evaluating the functional performance of these structures. Currently, there are standards related to such assessment; however, they remain very general and describe the evaluation procedure in an ambiguous manner

Various approaches have been proposed in the existing literature, yet a clearly defined and standardized methodology is still lacking. Each of the considered proposals exhibits both advantages and shortcomings. To date, methods have primarily focused on testing elements already installed and exposed to natural environmental factors [1]. However, such methods are not suitable for application at the stage of product introduction to the market.

Large-scale sample testing has been undertaken, for instance, at the Silesian University of Technology, where the first assessments of the durability of road noise barriers were performed on samples with a surface area of approximately 5 m². This is the only study of this kind currently referenced in the literature [2].

Numerous publications address the ageing of construction materials and their impact on the acoustic properties of building components. Nonetheless, these studies do not concern road noise barriers and do not account for parameters directly related to this product – namely, the DL_R and DL_α indices [3,4].

The innovation of the proposed methodology lies in the use of small samples, approximately 15 cm² in size. This approach enables broader application, particularly under various environmental exposure conditions. Although previous literature indicates certain correlations between the absorption properties of large and small samples, the studies do not specifically address parameters associated with the evaluation of road noise barriers. [5,6]

2. EXPERIMENTAL WORK

The assessment of the durability of the acoustic properties of the barrier is to be based on the change in acoustic parameters resulting from exposing the samples to various atmospheric conditions: alternating UV radiation and rain, UV and condensation-based humidification, elevated temperature, heating–raining cycles and humid atmosphere.

The preliminary research were conducted on the simple samples: mineral wool with cover made of textile.

Based on the conducted tests, the results will be analyzed in terms of the impact of environmental exposure on the

acoustic performance of the elements – see the test cycle on the fig. 1.

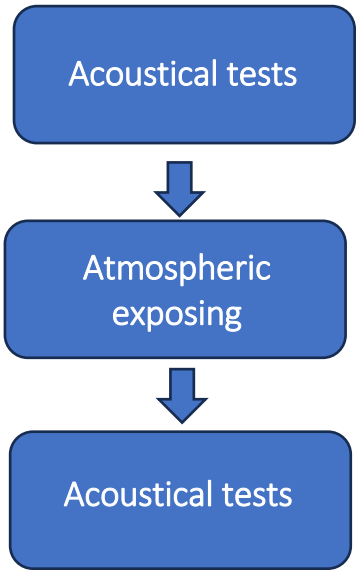

Figure 1. The cycle of test.

Sound absorption tests were carried out in accordance with PN-EN ISO 10534-2 [7], and airborne sound insulation was assessed based on ASTM E1050 [8] and ASTM E2611 [9] standards. Both tests were performed in the impedance tube (see Fig.2).

Figure 2. Impedance tube used for measurement of the acoustical parameters

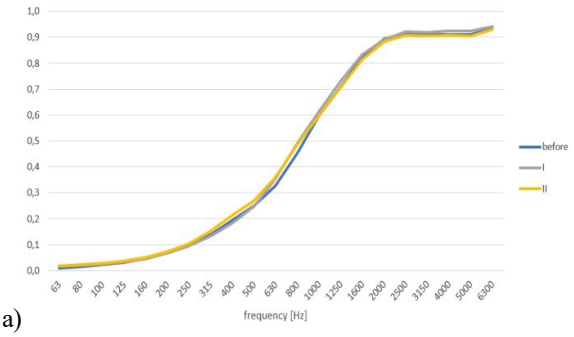

Figure 3. Atmospheric exposing

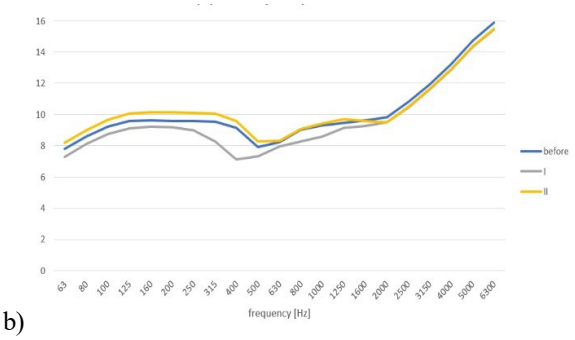

Atmospheric exposing was performed in the following setups:
Setup I – UV + rain: 336 cycles according to EN ISO 4892-3 [10],
Setup II – Temperature and humidity: 1008 hours according to TR024 [11].
Figure 3 presents the samples during atmospheric exposure.

3. RESULTS AND DISCUSSION

Figure 4 presents sound absorption and sound insulation of the samples before and after atmospheric exposing. It is seen, that applied exposing to the mineral wool doesn't change it's acoustical properties.

a)

b)

Figure 4. Sound absorption (a) and sound insulation (b) of samples before and after atmospheric expositions I and II

The results presented above are consistent with the findings reported by Nowoświat et al. [2]. They conducted similar tests on large samples with a surface area of 5 m², which were exposed to heat, cold, and rain. A total of 1000 exposure cycles were performed. Comparable changes in the parameters characterizing road noise barriers were observed — either no change or a decrease of 1 dB. These parameters are presented in Table 1. It means, that the sample size has no influence on this type of researches.

Table 1. Table captions should be placed above the table.

Acoustical parameter	ΔDL_R	ΔDL_α
Setup I	0 dB	0 dB
Setup II	0 dB	0 dB

4. SUMMARY

The method of assessing the impact of aging on selected different building materials and it's acoustical parameters. The preliminary research were conducted on the simple samples: mineral wool with cover made of textile. The applied cycle test included acoustical test of sound absorption and sound insulation with atmospheric exposing. Results confirm previous findings, that there is no influence despite of the sample size.

Future studies will involve samples made from different materials. It is also worth noting the duration of the exposure tests conducted so far, which correspond to approximately five years of natural environmental ageing. The standard requires data after 5, 10, 15, and 20 years of exposure. In the coming years, further research will be undertaken to address these timeframes.

INFLUENCE OF MOISTURE CONTENT ON THE ACOUSTIC PROPERTIES OF TEXTILE MATERIALS

Luisa Euler[1] **Ahmed Mehrem**[1*] **Elena Shabalina**[1]

[1] German Institutes of Textile and Fiber Research Denkendorf, Germany

ABSTRACT

Moisture content in a material affects its ability to dissipate sound energy, particularly at mid to high frequencies. This effect has already been investigated for materials such as soil, perlite, or mineral wool, and trends appear to depend on the material. Therefore, acoustic models might not be accurate for hygroscopic materials in humid environments. Even though some explanations were suggested, underlying mechanisms remain unclear. Hence, in this study, fibrous absorbers (cotton and polyester) were analyzed in terms of their acoustic absorption behavior depending on the moisture content. Experimental methods were employed to measure the sound absorption coefficient with varied moisture contents reaching up to 20 wt-%. The results show an influence of the moisture content on the sound absorption, with an increased absorption coefficient for higher moisture contents. This means that changes in the relative humidity of the surroundings can affect the performance of fibrous sound absorbers. Further, when it comes to acoustic material characterization, conditioning of the test samples might be required to achieve reproducible and comparable results.

Keywords: *Absorption, Textile, Moisture, Humidity*

1. INTRODUCTION

Fibrous materials are effective sound absorbers due to their ability to dissipate acoustic energy within their pore structures. As sustainability is gaining importance, sound absorbers made from recycled and natural fibers are on the rise. However, most natural fibers are hygroscopic, which is why their physical properties are affected by humidity. Researchers have observed a strong correlation between relative humidity (RH) and moisture uptake for natural fibers such as cotton and wool. According to the review by [1], natural fibers exhibit increased swelling and weight gain under high RH conditions. As water molecules fill the voids, the pores are closed, and the airflow resistivity is increased, [2] thus potentially affecting the sound absorption. Here, [3] investigated wool-based materials and reported reduced sound absorption at high frequencies as moisture contents rose. On the other hand, most synthetic textile materials, such as polyester and polypropylene, show different behaviors under humid conditions due to their hydrophobic nature [2]. Therefore, the aim of this study is to determine how changes in moisture content impact the acoustic performance of fibrous sound absorbers, namely cotton and polyester nonwoven.

1.1 Effects of Moisture Content on Acoustic Performance of Materials

The effects of moisture content on the acoustic behavior have already been investigated for materials such as soil, perlite, or mineral wool, and trends appear to depend on the material. For soil, variations in moisture content were shown to affect the material's sound absorption, which can be related to changes in porosity ϕ and airflow resistivity σ. The moisture-dependent parameters are given by [4]:

$$\phi_{\text{wet}} = \phi_0 \cdot (1 - C_m M), \tag{1}$$

$$\sigma_{\text{wet}} = \sigma_0 \cdot (1 + C_r M), \tag{2}$$

where ϕ_0 is the initial porosity, σ_0 is the dry resistivity, C_m describes the moisture-induced porosity factor and C_r describes the moisture-induced air resistivity factor. In Eqs. (1) and (2), some simplifying assumptions were made, such as linear relationships with moisture content and overlooks of material properties, along with a uniform moisture distribution.

1.2 Physical Effects of Moisture on Textile Materials

Many natural but also some synthetic fibers are hygroscopic to some extent, meaning they absorb moisture from air [5]. The amount of absorption depends on the fiber type and the environmental conditions, with natural fibers absorbing up to 30 % of their weight under high RH conditions, while most synthetic fibers usually take up less than 1 % [6–8]. For hygroscopic porous materials, water can be stored in the air voids either as vapor or in liquid form, or it may be bound inside the material itself [5]. Especially the latter can drastically affect fiber properties, including dimensional (mass, swelling), mechanical (tensile strength, extensibility), and electrical (resistance) properties [9]. The first study reporting structural changes in textiles from changes in moisture content can be found in [10]. Here, swelling of cotton fibers was found to affect a material's thickness and porosity [10]. Related to this, [2, 5] investigated the influence of moisture content on the air permeability of hygroscopic textiles and observed drastic changes at high RH caused by swelling, which reduced the free void space.

2. EXPERIMENT

As sound absorption is, among other factors, governed by porosity and airflow resistivity, this gives rise to the assumption that it might as well be affected by the moisture content in the fibrous material. Sustainable sound absorbers are often based on natural fibers (cotton). Cotton is hygroscopic and can bind moisture inside the fiber, whereas, for example, polyester can only store moisture in the voids formed by the fiber assembly. By testing these two types of fibrous absorber materials, namely a recycled cotton nonwoven and a recycled polyester nonwoven as reference material, we evaluate the influence of changes in moisture content on the acoustic properties of sustainable, fibrous sound absorbers.

2.1 Materials and Sample Characterization

The material under investigation is recycled nonwoven cotton, which is referred to as CO20. The material used as reference is a recycled polyester nonwoven (polyethylene terephthalate, PET), which is referred to as PET20. The sample properties are presented in Table 1. We estimated the porosity ϵ_0 of the samples based on the densities of the nonwoven structure ρ_n and the fiber densities ρ_f [11]:

$$\epsilon_0 = (1 - \frac{\rho_n}{\rho_f}) \times 100\ \% \tag{3}$$

The fiber densities from the literature are $\rho_f = 1.51 g/cm^3$ for cotton and $\rho_f = 1.38 g/cm^3$ for PET fibers. The air permeability κ was determined according to DIN EN ISO 9237:1995-12* at 200 Pa.

Name	ρ_n (kg/m³)	ϵ_0 (%)	t (mm)	κ (l/sm²)
CO20	45	97.0	20 ±0.2	538
PET20	40	97.1	20	1422

Table 1. Sample properties: ρ_n = density of structure; ϵ_0 = estimated porosity; t = sample thickness; κ = air permeability at 200 Pa

The recycled cotton samples did not only include loose fibers but also some smaller pieces of shredded fabric from the mechanical recycling process. On the other hand, the recycled polyester samples consisted of distinguishable fibers only. The microscopy and the SEM images of the samples are presented in Table 2.

	CO20	PET20
top view		
SEM images		

Table 2. Microscopy images and SEM images of the samples

2.2 Sample Preparation

To imitate moisture contents in different RH surroundings, prior to measuring the acoustic properties, we steamed the specimens until reaching the desired amount of moisture, determined by the weight change. A moisture content of 0 % is not realistic for application scenarios. Therefore, the baseline for 0 % in this study is regarded as the moisture content in the specimen after being conditioned in a climate of T = 23 °C and RH = 40 % for at least 24 hours. The increase in moisture content M was calculated as a percentage increase in mass relative to the conditioned sample's mass m_{cond} and calculated as:

$$M = \frac{m_{\text{wet}} - m_{\text{cond}}}{m_{\text{cond}}} \times 100\ \%, \tag{4}$$

where m_{wet} is the weight after moisture absorption. We increased the moisture content gradually in increments of 5 % until reaching 20 %, while measuring the acoustic absorption coefficient at each step. We tested three specimens of PET20 and five specimens of CO20 (due to higher expected variations for this material arising from its inhomogeneous structure).

2.3 Measurement of Acoustic Properties

We measured the sound absorption coefficient α over a frequency range of 50 Hz to 1,600 Hz using the two-microphone impedance tube method based on ISO 10534-2 with a tube diameter of 100 mm (impedance tube Brüel & Kjær Type 4206-T). We monitored the climate over the entire testing duration to exclude errors from changing climate conditions. We used linear regression analysis to determine the significance (p-value) of the influence of M on the absorption coefficient α for the different materials.

2.4 Results and Discussion

As shown in Figures 1 and 2, there is an increase in sound absorption coefficient α with higher moisture levels for both materials, particularly at the higher frequencies (M = 15 % not pictured for visibility purposes). Even though the change is small and for cotton the standard deviations are partly overlapping, the regression analysis still found the influence of M to be statistically significant for both materials with p-values of p = 0.001 for cotton and p = 0.000 for the polyester samples. Further, the biggest change in α can be found when going from M = 0 % to M = 5 % for both materials. Hence, small amounts of moisture can already have a noticeable impact on the sound absorption behavior.

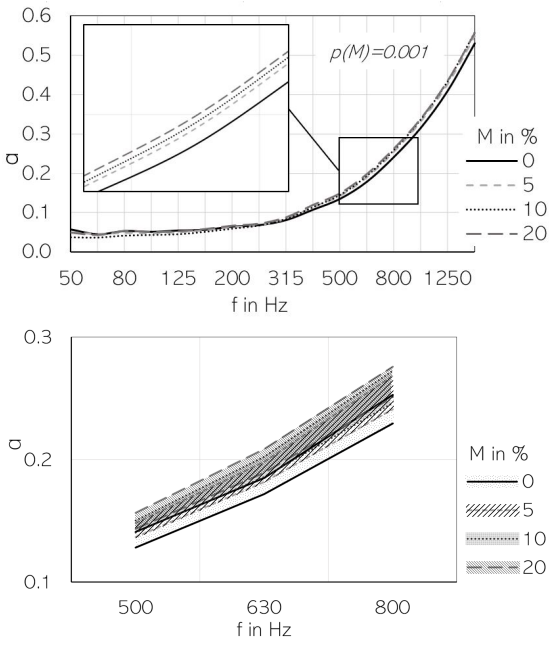

Figure 1. *TOP*: Average absorption coefficient α of CO20 for different moisture contents M; *BOTTOM*: Standard deviations for selected frequencies.

The increase in sound absorption can be attributed to several factors. One of the primary effects of moisture is the increase in airflow resistivity σ. As water fills the pores of the material, it creates additional resistance to airflow, which enhances the viscous damping of sound waves. The higher airflow resistivity in both CO20 and PET20 at elevated moisture levels likely increased sound absorption. Furthermore, thermal conductivity increases with water content, leading to enhanced dissipation of sound energy within the material.

The observed effect was more pronounced for PET than for cotton. This can be attributed to the (presumable) swelling of the cotton fibers in contrast to the PET fibers not swelling. While the water drops start filling the air voids, in the case of cotton, the fiber swelling further closes the pores. Hence, the porosity is reduced to a higher extent, thus counteracting the increase in sound absorption arising from the increase in air flow resistivity. In turn, the change in sound absorption is less dominant for cotton than for PET. Additionally, the inhomogeneous structure of the CO20 increased inter-sample variations, thus potentially overlaying some effects from moisture.

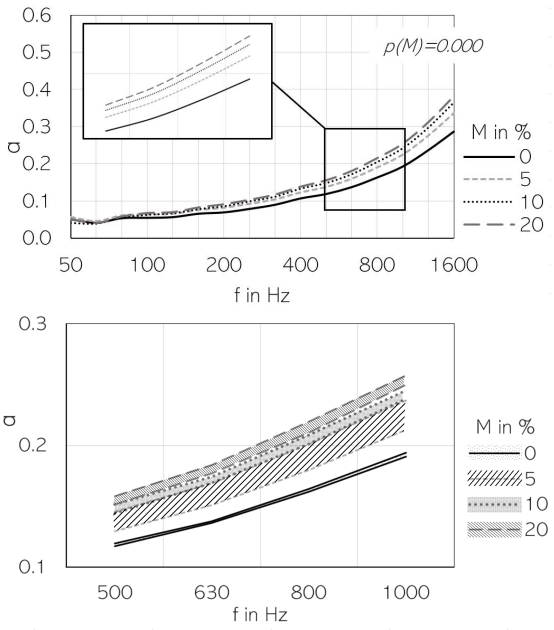

Figure 2. *TOP*: Averaged absorption coefficient α of PET20 for different moisture contents M; *BOTTOM*: Standard deviations for selected frequencies.

Nevertheless, it must be mentioned that the testing procedure not only increased the moisture content in the materials but also involved raised temperatures from the steaming process. Especially for PET this might be relevant as the glass transition temperature is in a similar region. We could not exclude this influence from the experiments, which is why this should be investigated in future work. Further, due to time constraints, we could only test a small number of samples. To increase statistical reliability, more repetitions should be performed.

Concluding we found that changes in the relative humidity of the surroundings can potentially affect the performance of fibrous sound absorbers. Further, when it comes to acoustic material characterization, conditioning of the test samples might be required to achieve reproducible and comparable results.

STUDY OF SOME INFLUENCES ON THE ACOUSTIC BEHAVIOUR OF DISINTEGRATED SAMPLES OF USED CIGARETTES

Celia Moreno González[1*] **Valentín Gómez Escobar**[1] **Guillermo Rey-Gozalo**[1]

[1] Laboratorio de Acústica, Departamento de Física Aplicada & Instituto Universitario de Investigación para el Desarrollo Territorial Sostenible (INTERRA). Universidad de Extremadura. Avda. Universidad, s/n 10003 Cáceres, España.

ABSTRACT

Used cigarette butts are one of the most common types of waste in today's environment. However, there are not many proposals for its recycling, if we take into account the amount of waste generated annually.

Our research group has been working in recent years on the recycling of these wastes to give them an acoustic use. Thus, cigarette butts' samples are prepared by disaggregating the filter of used cigarettes, which, as shown in previous studies, presents promising properties as acoustic absorber. However, due to the heterogeneity of the filters and the disaggregation process, these samples tend to lack consistency and lose their shape when handled. Thus, the use of binders is advised in case of severe disaggregation.

This study examines the use of binders on cigarette butts' prepared samples for acoustic applications. Thus, some natural binders has been applied to enhance the structural strength of the samples and their effect onto the acoustic samples performance is analyzed.

The results indicate that samples treated with low binder concentrations retained their acoustic absorption properties while achieving a stronger and more durable structure.

1. INTRODUCTION

Cigarette butts are among the most prevalent forms of waste worldwide, raising significant environmental concerns due to their composition and the volume generated. It is estimated that approximately 4.55 trillion cigarettes are consumed annually [1], resulting in an equivalent number of discarded filters.

These filters are primarily composed of cellulose acetate, a non-biodegradable bioplastic that can take years to decompose in the environment. Moreover, cigarette butts contain various toxic compounds, including nicotine and heavy metals, which can leach into soil and water systems, contaminating ecosystems [2]. Despite the well-documented environmental impact of cigarette butts, few recycling solutions have been proposed to mitigate this problem [3].

Cellulose acetate, due to its fibrous and porous structure, has shown favorable acoustic properties. Recent studies have characterized and modeled the sound absorption behavior of cellulose acetate fibers from used cigarette filters, suggesting that this material could serve as a viable alternative to conventional acoustic absorbents in building materials [4,5]. This approach not only contributes to reducing the environmental impact of cigarette butt waste but also offers a sustainable solution for the development of construction materials.

The results obtained to date have been promising, indicating that samples fabricated from these residues can achieve sound absorption coefficients comparable to those of commercial products. However, one of the major

challenges identified has been the lack of structural consistency in the samples, which hinders their handling and potential commercialization.

To solve this issue, the use of binders has been proposed to improve structural integrity although their acoustic performance could be compromised [6,7,8]. The use of natural binders shows similar behavior to synthetics, potentially reducing environmental impact, as demonstrated by the study of Mirski et al. [9]

As an initial approach, white glue diluted in water at different concentrations has been used. The aim of this study is to develop a material that not only retains an effective sound absorption capabilities but also meets the mechanical and commercial requirements for real walls.

2. METHODOLOGY

2.1 Equipment used

To determine the absorption coefficient of samples, normal incidence wave measurements were conducted using the transfer function method, as established in ISO 10534-2 [11].

The equipment used for measuring the acoustic properties of the samples includes a Brüel & Kjaer 4206 T impedance tube, a Brüel & Kjaer PULSE multi-analyzer system with four channels (model 3560 C), a Brüel & Kjaer power amplifier (model 2716 C), Brüel & Kjaer ¼-inch microphones (model 4187), and Brüel & Kjaer Material Testing software for PULSE (model 7758).

The impedance tube features two sample holders with diameters of 100 mm and 29 mm, covering frequency ranges of 50–1600 Hz and 500–6400 Hz, respectively. However, for this study, only the 29 mm sample holder was used, limiting the results to the 500–6400 Hz frequency range.

Figure 1 presents a schematic of the experimental setup, while Figure 2 shows a photograph of the impedance tube with the 29 mm sample holder.

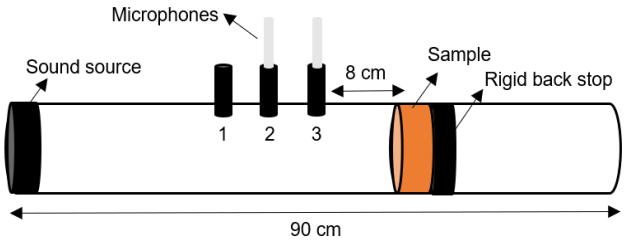

Figure 1. Diagram of sample placement for acoustic absorption measurements.

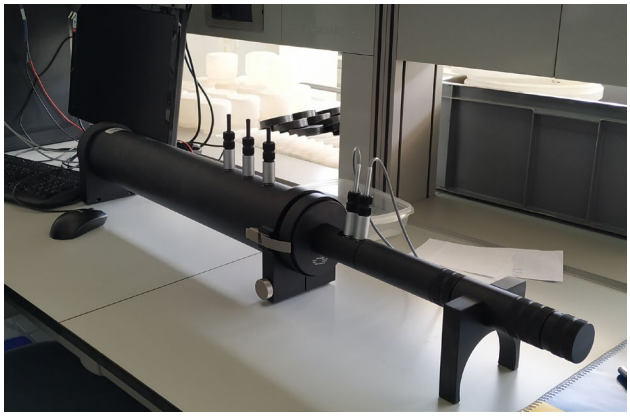

Figure 2. Impedance tube with the 29 mm diameter sample holder.

2.2 Materials

For this study, 30 samples composed of disaggregated cigarette butts were analyzed with the 29 mm diameter holder. Characteristics of the sample set are shown in Table 1.

Table 1. Characteristics of sample set.

Sample number	Thickness	Density
30	21-25 mm	71- 84 kg/m³

The acoustic behavior of the samples has been measured both before and after applying the binder. The binder used has been white glue diluted in water at different ratios (10%, 20%, 40%, 60%, and 80% glue to water ratio). Each combination was applied to six different samples to assess the reproducibility of the results.

Figure 3 shows one of the samples before applying the binder.

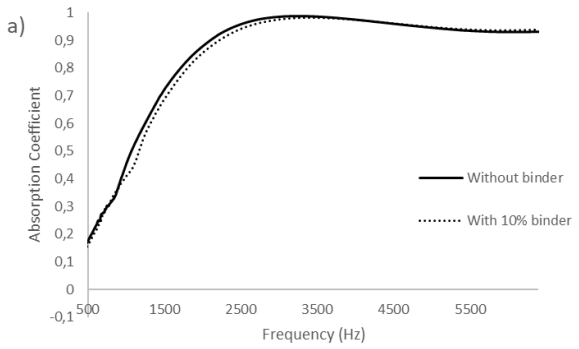

Figure 3. Initial sample before applying the binder.

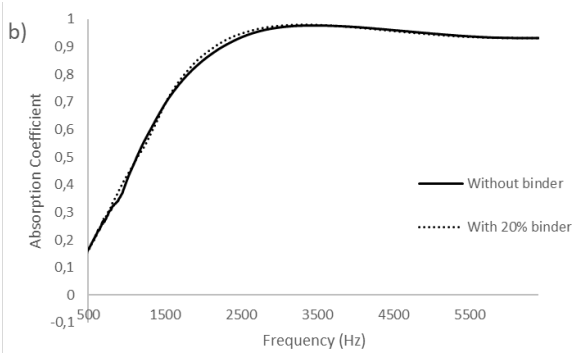
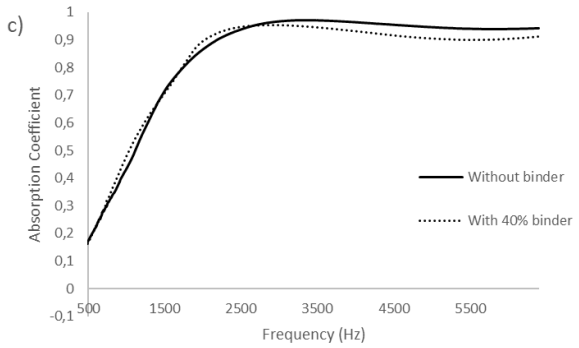


3. RESULTS AND DISCUSSION



As mentioned earlier, 30 different samples were measured, all with similar characteristics. A different proportion of binder was applied to each six samples: 10%, 20%, 40%, 60%, and 80% white glue related to water. This approach allows us to evaluate how the binder application affects each sample (since measurements were taken before and after its application), how the amount of binder influences the acoustic behavior of the material, and whether these results are reproducible.

Figure 4 presents the average absorption coefficient values for sets of samples with the same binder concentration.

Figure 5 compares the behavior of the different sets, the green line represents the average value of all samples measured before the binder was applied, allowing for a comparison of the acoustic absorption before and after binder application.

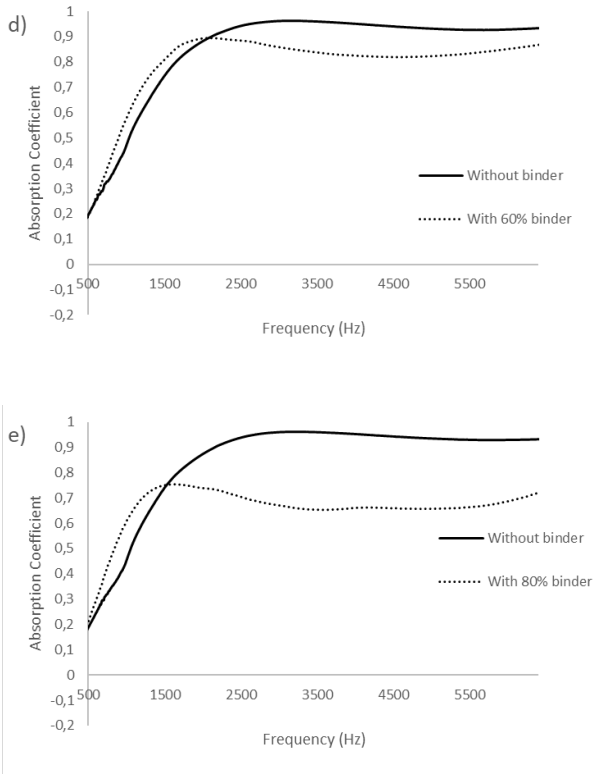


Figure 4. Comparison of samples with a without binder a) 10% b) 20% c) 40% d) 60% e) 80% glue respect water

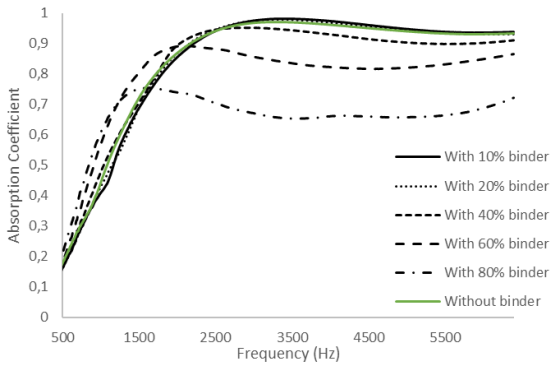

Figure 5. Average sound absorption coefficient before and after binder application

The results show that as the binder concentration in the solution increases, the difference in the measured absorption coefficient becomes more pronounced. Specifically, significantly lower values are observed for samples with solutions containing 60% (Figure 4.d) and 80% (Figure 4.e) of binder. On the contrary, samples treated with solutions with low binder content, such as 10% and 20% (Figure 4.a and Figure 4.b, respectively), show a minimal variation in acoustic behavior, particularly above 3000 Hz, where the difference becomes almost negligible. This decline in acoustic efficiency for high binder ratios can be attributed to a loss of porosity in the samples: the higher the binder content, the more compacted the material becomes, which has a negative impacts on acoustic absorption properties.

These results are corroborated by the data presented in Figure 6, which shows the average differences between each set of samples before and after binder application. It can be observed that, particularly above 3000 Hz, samples with 10% and 20% binder concentration show virtually no differences, while at lower frequencies, the differences remain below 5%. For samples with higher binder concentrations (60% and 80%), the difference increase, reaching a maximum of approximately 12% and 30%, respectively.

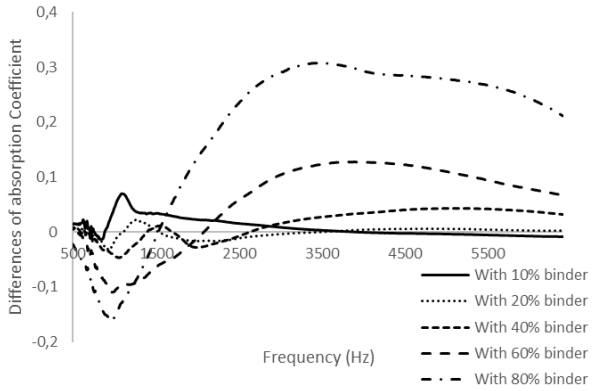

Figure 6. Average differences in sound absorption before and after binder application by concentration

The effect of the binder on the porosity of the samples is shown in Figure 7, which shows two samples: the one on the left was treated with a 10% binder-to-water ratio,

while the one on the right was treated with an 80% solution. At 80% binder concentration, the sample becomes completely rigid, resulting in a significant loss of surface porosity.

Figure 7. Effect of the binder on the samples: 10% concentration on the left, 80% on the right.

4. CONCLUSIONS

The use of white glue as a binder in samples composed of cigarette butts presents a valuable opportunity to enhance the structural integrity of the material, preventing deformation during handling.

When applying a low binder-to-water ratio—between 10% and 20%—the acoustic performance of the samples remains unaffected, with no significant reduction in the absorption coefficient upon the introduction of the binder. However, higher binder concentrations, ranging from 60% to 80%, have a notable impact on acoustic behavior, leading to absorption coefficient values up to 40% lower compared to samples without binder. This decrease is attributed to a loss of porosity in the material.

Therefore, it can be concluded that using low binder concentrations is beneficial, as it results in a more mechanically stable material without compromising its acoustic properties. This behavior will be further validated through an expanded sample set and the evaluation of alternative natural binders in future studies.

A PRACTICAL APPROACH TO THE DETERMINATION OF REPRODUCIBILITY PRECISION (σ_{TARGET}) IN THE FIELD OF SOUND ABSORPTION MEASUREMENTS: EVALUATION OF PROFICIENCY TESTING DATA ACCORDING TO ISO 354:2003

Pedro Rosario[1*], José Luis Martínez[1]
[1] RPS-Qualitas, Madrid, Spain

ABSTRACT

ISO 354:2003 specifies a method of measuring the sound absorption coefficient of acoustical materials used as wall or ceiling treatments. The measured values in one-third octave bands of the sound absorption coefficient are converted to values in the corresponding octaves (practical and weighted sound absorption coefficients - ISO 11654). The adequacy of proficiency tests is guaranteed by means of the assessment of global precision criteria in compliance with the scope stipulated by the normative references in order to determine the reproducibility limits in a regulated measurement method. Unfortunately, the latest revision and endorsement of ISO 354 standard in 2024 does not include any information related precision data. From the experience acquired after seven rounds of the international interlaboratory comparison schemes for sound absorption measurements managed by RPS-Qualitas between 2012 and 2024, according to the methods specified in ISO 354:2003, and in this scenario, a practical approach is proposed to the determination of the reproducibility precision (σ_{target}) in the field of sound absorption measurements by means of the historical records evaluation of the relevant proficiency testing data obtained according to ISO 354:2003

The aim is to provide not only a reliable but also up-to-date criteria for the evaluation of repeatability and reproducibility limits in this field, particularly where there is not at all or very poor normative reference.

1. INTRODUCTION

The standard ISO 354 ‘‘Acoustics. Measurement of sound absorption in a reverberation room’’ [1] specifies a method of measuring the sound absorption coefficient of acoustical materials used as wall or ceiling treatments, or the equivalent sound absorption area of objects, such as furniture, persons or space absorbers, in a reverberation room. The measured values in one-third octave bands of the sound absorption coefficient are converted to values in the corresponding octaves (practical and weighted sound absorption coefficients - ISO 11654) [2].
Since ISO/IEC 17025 [3] requires testing laboratories to put in place external quality control procedures for monitoring the reliability of their measurements, the participation in proficiency testing schemes is the main mechanism for assessing compliance.
In this context, RPS-Qualitas, as an independent consulting and technical advisory company, associated with the Universidad Politécnica de Madrid, has launched since 2012 a project called AQUS, with the aim of providing a

tool for the objective verification of technical competence, through the development of a biannual proficiency testing scheme in the field of acoustic absorption measurements, according to ISO 354 standard, in order to provide participating laboratories with a powerful tool to know the degree of adequacy in the said tests.

2. METHODOLOGY AND LIMITATIONS OF THE STANDARD

2.1 Proficiency test scheme

In order to satisfy this requirement, seven rounds of this proficiency testing scheme for sound absorption measurements have been conducted by RPS-Qualitas between 2012 and 2024, according to the methods specified in ISO 354 at international level. Since it is a proficiency test, the laboratories that were admitted had both a reverberation chamber and an alpha cabin, and the performance of the participating laboratories was also obtained from the results of measurements of the sound absorption coefficient in one-third octave bands. On the other hand, practical sound absorption coefficients were calculated in octaves and single weighted evaluation index was obtained according to the UNE - EN ISO 11654. All participating laboratories are accredited by ISO 17025. On the other hand, we would like to underline that in terms of the design of this proficiency testing programme, both the homogeneity and the stability of the samples have been duly checked throughout the proficiency test. Thus, we have achieved the goal of obtaining globally accurate results of high quality, so the requirements of ISO 17043 [4] have been taken into account from the outset and during the testing and data processing.

2.2 Stability and homogeneity of test item

In the AQUS project, the description of the proficiency testing (PT) scheme is well documented, considering a series of planned stages related to the monitoring, follow-up and control of the measurement items. This monitoring phase was designed to ensure both the stability and the homogeneity of the test item, which was evaluated and monitored by an accredited laboratory as a mandatory rule, allowing to declare that test item condition remain unchanged over time. It is important to mention that in each PT round, either a different type of material or a certain material with a range of thickness values were evaluated, with different absorption characteristics. These aspects are fully evaluated in order to guarantee the adequacy of the interlaboratory comparison through the evaluation of certain global precision guidelines in accordance with the current scope, since there are no regulatory or prescribed values for reproducibility verification in this scope.

2.3 Reproducibility precision

The precision goodness of the PT cannot be estimated via calculation of by the reproducibility of the test (measurement of acoustic absorption in reverberant chamber, according to ISO 354 standard), since there are no published data on this parameter in the corresponding standard. This standard has been recently revised and confirmed as unchanged until 2024. We have only been able to compare with previous data. Once the reproducibility data (SD_R of the revised ISO 354 standard) are available, these values will be selected as the appropriate SD_R value (σ_{target}) of the standardised test method for performance evaluation, adapted to the intended use of the participants.
This is the reason why the main objective of this paper is to propose a practical approach for the determination of the reproducibility precision (σtarget) in the field of sound absorption measurements by means of a proper evaluation of the experimental data obtained in the different proficiency test PT rounds.

3. STATISTICAL DESIGN AND PERFORMANCE EVALUATION

3.1 Statistical procedure

The protocol conducted in these proficiency test schemes outlines a statistical design not only intended for the analysis of the data but also for the evaluation of the proficiency testing results according to the standard ISO 5725-2, that describes the determination of the repeatability and reproducibility in a regulated measurement procedure using classical statistical methods with outlier elimination [5]. As regards the implementation of the PT scheme AQUS, the statistical parameters published for the

magnitudes object of study in the scope of the program are the following:

• assigned value (αs - sound absorption coefficient) in each frequency as consensus value from participants in the frequency range 100 - 5000 Hz

• estimate of the precision of the PT results in terms of repeatability and reproducibility limits

• standardized z-score taken as an assessment of the performance of the participation by each laboratory.

As for the determination of the assigned value, once discarded the outlier results, it is performed in accordance with the established protocol by first calculating the arithmetical average of the four results reported by each laboratory participants, taken as the consensus value for the number of non-excluded participants in each magnitude. This makes it possible to get the most appropriate measure of central tendency based on the distribution of the data of the participants, once verified the normality of them as mandatory previous rule. This condition of statistical normality of the test results allowed us to verify the results obtained with the ISO 13528 standard (robust statistical methods). Interestingly, they were quite similar and consistent in terms of the assigned value and reproducibility of the proficiency test that had been verified since the first round of the AQUS PT programme.Then, in order to define the variability of the proficiency test results, it is first necessary to estimate the values of both the standard deviation under conditions of repeatability (Sr) and the one under conditions of reproducibility (SD_R). These are applied to calculate the related parameters r and R according to ISO 5725-2.

$$r = 2{,}8\, S_r \tag{1}$$

$$R = 2{,}8\, S_R \tag{2}$$

The parameters r and R may be called ‘‘critical differences’’ or ‘‘limits,’’ as they describe the maximum difference of a pair of test results at which these can be considered equivalent at a probability level of 95 %.

3.2 Performance evaluation

The performance of each participant is evaluated by calculating the corresponding z-score, determined in accordance with:

$$z = (x_i - X_{PT})/\sigma_{PT} \tag{3}$$

where x_i is the laboratory result, X_{PT} is the assigned reference value and σ_{PT} is the estimate of the standard deviation of the proficiency test results. In this way, results with a value $|z| \leq 2$ are considered as satisfactory; results with $|z| \geq 3$ are unsatisfactory; results with $2 < |z| < 3$ are considered questionable.

4. PITFALLS TO ESTABLISH PRECISION GUIDELINES

4.1 Scope and purpose

Regarding the evaluation of the precision criteria for the proficiency test according to the recently revised ISO 354 standard, unfortunately there are no regulatory values available that can be used as a prescribed reference, unlike what happens in other standards in the field of acoustics tests. Therefore, it has not been possible to verify whether the reproducibility values obtained during these interlaboratory PT round comparisons following ISO 354 correspond to a normative reference in terms of significant differences.

In addition to the aim of supporting the participants in all proficiency tests conducted, we would like to broaden the understanding of the state-of-the-art regarding the precision of the results obtained with this method. Therefore, once the PT rounds have been completed and with the knowledge acquired during their development, our proposal is to provide some practical data guidance on the precision. Furthemore, these data will be specific for the application of this standard within the considered scope.

A practical approach has been applied to determine the reproducibility precision (σ_{target}) in the field of sound absorption measurements by evaluating historical records of the relevant proficiency test data according to ISO 354, by means of performing some operational steps leading to the prescription/formulation of provisional values of reproducibility precision. A similar approach has been proposed for the assessment of precision criteria in relation to the ISO 140-5 standard in 2015. [7]. The aim is to provide not only a reliable but also up-to-date criteria for the evaluation of repeatability and reproducibility limits in this field, particularly where there is not at all or very poor normative reference.

5. RESULTS AND DISCUSSION

Once the seven rounds have been carried out (see Tab. 1), the assigned values obtained from the consensus of the participants, after rejection of the outliers, are presented for each frequency and each round, together with the corresponding standard deviation of reproducibility (SD_R), which shows a high consistency between the values of the measurable parameter over time. However, it should be noted that the sound absorption coefficient and the reproducibility precision seem to be strongly dependent on the type of material used as the PT test piece.

Therefore, after applying the statistical protocol for the calculation of PT results, the corresponding SD_R values were calculated, taken as an indication of the reliability of the interlaboratory comparison. A comparison of these SD_R values obtained at each measurement frequency for each PT round is presented to facilitate a graphical comparison over time (see Fig.1) with the estimated value of reproducibility precision (σ_{target}). The estimated value of reproducibility precision (σ_{target}) was calculated as a pooled standard deviation (SD_R" pooled") from the individual values of each independent PT round taking into account the number of participants (degrees of freedom) (see Tab.1) [8-9]. In addition, it is interesting to note that the SD_R values in the first (2012) and last (2024) round are more scattered at low and high frequencies compared to the majority of values in the remaining rounds, which are below the estimated target SD_R value (dark blue line). The causes of these higher SD_R values in the first PT Round (AQUS-1_2012) could be due to:

- Damage of PT ítems during transport
- Some participants did not fully comply with the instructions, in particular regarding the mounting of the sample in the reverberation room: the perimeter edge of the sample shall be sealed or covered with a acoustic reflective frame of rigid material according to Annex B point B.2 Type A mounting.

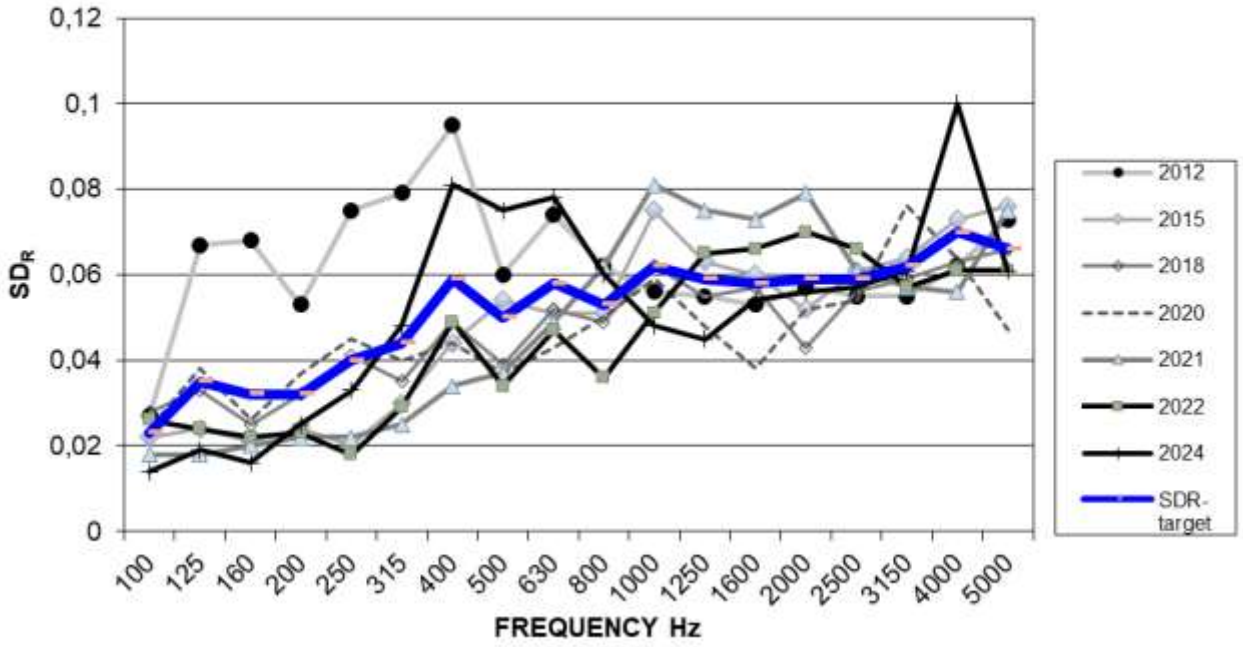

Figure 1. Comparison of standard deviation of reproducibility SD_R obtained in AQUS PT schemes (years 2012–2024) versus SD_R target (dark blue line)

The causes of these higher SD_R values in the last PT Round (AQUS-7_2024) could be due to:

- The material shows maximum absorption between the thirds of 630 and 1000 Hz. These absorption peaks are located differently by different laboratories and consequently there is maximum dispersion in this frequency range.
- Similarly, the material again shows a second absorption maximum around the 4000 Hz third, but not all laboratories clearly define this absorption peak. As a result, the dispersion in this octave third is very high. Some reverberation rooms, even if they meet the requirements of the standard, may lose sensitivity when measuring coefficient at high frequency.
- On the other hand, a slight permanent deformation may occur during transport due to crushing of the PT sample material plates. This crushing slightly alters the structure factor of the material, resulting in a slight change in the frequencies of maximum absorption in the range between 630 and 1000 Hz, and also at 4 kHz. This partly explains the higher dispersion of the SD_R values in the octave thirds shown.

6. CONCLUSIONS, PROPOSAL AND FUTURE OBJECTIVES

The next steps for the completion of the activities related to the present project should focus on developing of a collaborative study to assess the performance of the measurement method. This will allow for the establishment of precision guidelines based on the experience gained from

measurements conducted according to ISO 354. It is expected that the study will enable to assess if the proposed reproducibility values for each frequency (σ_{target}) are suitable in terms of minimum precision level to determine the standard deviation for proficiency assessment.
Furthermore, these prescribed values of precision should be verified regularly, as well as monitoring the practical conditions of application in such a way that the reproducibility values may also be used to verify the proper operation of test procedures of any laboratory involved in this scope of acoustic measurement.
Therefore, in this paper, we propose a practical approach to determine the reproducibility precision (σ_{target}) in the field of sound absorption measurements by evaluating historically relevant proficiency testing data according to ISO 354. Some points of interest that must be foreseen are related to both the applicability and practicability of the method since a collaborative trial requires substantial effort and should only be applied to methods that have received adequate prior testing. These values of the reproducibility precision (σ_{target}) will be used to assess the performance of participants in the next proficiency test AQUS-8 in 2026 for proving the goodness of this proposal.
It is honestly believed that this challenge is quite difficult to achieve, mainly because there are a large number of materials for acoustic testing with quite different characteristics and values of sound absorption coefficient (αs), without being able to make a suitable catalogue of SD_R target for each one. However, to the best of our knowledge, this is the first attempt to determine the reproducibility precision (σ_{target}) using a large experimental weight of data collected over a decade from 2012 to 2024.
The aim is to provide not only a reliable but also up-to-date criteria for the evaluation of repeatability and reproducibility limits in this field, particularly where there is not at all or very poor normative reference. In this way, future participants could have some kind of reference values for the evaluation of precision criteria in this field.

7. ACKNOWLEDGMENTS

We are very grateful to Prof. Juan Sancho of the Universidad Politécnica de Madrid for his technical and excellent support over the last few years, which we have greatly appreciated.

ABSTRACT

Green materials developed in recent decades have found numerous applications. These materials are designed to be recycled after their primary use, reducing waste and environmental impact. Hydroponic systems, widely used for growing plants without direct soil use, often employ alternative sublayers such as expanded clay, glass wool, perlite, paper, hemp and similar materials immersed in water. This study focuses on wheat grains planted on porous sublayers, including hemp, paper, wood chips, triturated sugarcanes from river water, oak leaves, layers of grass. As the wheat plants grew, their roots penetrated these porous materials, forming a single, compact material with a rigid skeleton. In the second stage, the resulting material was dried to thicknesses of 5 and 10 cm and tested using an impedance tube. Acoustic absorption at normal incidence was measured. The results indicate that hydroponic materials have excellent acoustic absorption properties, making them suitable for use in acoustic applications.

1. INTRODUCTION

Hydroponics is a method of growing plants with minimal soil and water. Hydroponic systems enable plants cultivation without direct reliance on soil. This technique uses substrates made from alternative materials, such as expanded clay, rock wool, perlite, paper, hemp, wood chips and natural wool, combined with nutrient solutions or water [1]. Hydroponic cultivation is being studied as an alternative to traditional agricultural production, particularly for growing wheat or other crops while minimizing soil and water usage. One major advantage of hydroponic systems is their ability to produce crops in the absence of soil-borne diseases and pests, thereby reducing the need for chemical pesticides [2]. Additionally, hydroponic systems allow for significantly faster crop production compared to traditional soil-based farming. Today, hydroponic systems are mainly developed to provide animal feed as an alternative to synthetic or chemical processed options. Furthermore, hydroponic farming is being explored as a potential food source for future space missions [3]. In these contexts, plants are grown to provide food for space missions or for potential future colonies on the Moon or Mars. Studying hydroponic systems for human nutrition also offers a solution to challenges related to food production in the context of climate variability, population growth, and freshwater depletion. In the future, hydroponic crops could be used in regions with limited natural resources or extreme weather conditions. Since the Middle Ages, hydroponic cultivation has been a part of Christian Easter traditions. It has historically been used to grow plants for decorating church altars during Easter, as shown in Figure 1. During the Easter period, the faithful would prepare jute sheets on which they sowed wheat, watering them every evening. Within a few weeks, the wheat grew to about 20 cm in height, adorning church altars.

2. MATERIALS AND METHODS

The hydroponic material model was designed to create layers of sound-absorbing materials. In this study, wheat was selected as the primary plant, although other grains such as corn, chickpeas, and beans could also be used. The germinating seed produces a plant above the surface, while the roots penetrate the underlying porous layer, forming a rigid network that compacts the material [4].

The objective of this research is to develop plant-based material layers using hydroponic systems. Layers of varying thicknesses were developed using different porous substrates, which served as growth media for wheat grains [5]. The grains were cultivated at room temperature and watered daily with small amounts of water. The material was housed in food-grade plastic containers and placed in an outdoor environment, where temperatures ranged from about 18°C at night to 35°C during the day.

The porous substrates used include hemp, shredded paper, wood chips, shredded river canes. Wheat grains were germinated on these porous layers, and over a two-week period, the plants grew to a height of 20 cm. During this process, the roots penetrated the porous substrates, forming a compact material with a rigid internal structure. Once dried, the water content was completely removed, yielding a material with promising acoustic properties. Various acoustic tests were performed on the resulting green tiles, which were composed of different porous sublayers [6]. Samples with thicknesses ranging from 5 cm to 10 cm were prepared for testing. The primary aim of this research is to assess the sound absorption coefficient of the tiles at different thicknesses. Measurements were performed using an impedance tube, which determines the sound absorption coefficient at normal incidence over a frequency range of 100 Hz to 2 kHz. The tests were conducted in accordance with the ISO 10534-2 standard [7]. The impedance tube used has the following features: internal diameter of 10 cm (corresponding to an upper frequency limit of 2 kHz), a length of 56 cm, as shown in Figure 2, and two microphones placed 10 cm apart, allowing measurements starting from 100 Hz.

Figure 2. Impedance tube used for measuring the absorption coefficient.

The wheat was sown on a layer of loose granular material. As the roots developed, they formed a rigid skeletal structure, which served as the basis for subsequent sound absorption measurements. Figure 3 shows the grain stalks that grow as the seeds on this material.

Figure 3. Germination of wheat grains.

Figure 4 shows the grain seeds that have grown on the loose granular material to give rise to the grain stalks.

Once the hydroponic material is fully grown, it is dried to create a new type of sound-absorbing material, whose acoustic characteristics are the focus of this study. The resulting material features a rigid skeletal structure formed by the roots, which have penetrated the loose granular substrate during growth. Figure 5 displays the final hydroponic material, showcasing its rigid root-based structure. This drying process results in a completely natural material suitable for acoustic applications.

Figure 4. Grain seeds were grown on the loose granular material, giving rise to grain stalks.

The sound absorption performance of the material varies depending on the type of porous substrate used. The following figures present the absorption coefficients for each material tested:

- Figure 6: absorption coefficient of hemp-based substrate.
- Figure 7: absorption coefficient of wood chips substrate.
- Figure 8: absorption coefficient of triturated paper substrate.
- Figure 9: absorption coefficient of triturated cane substrate.

Figure 5. New hydroponic material with a rigid substrate structure.

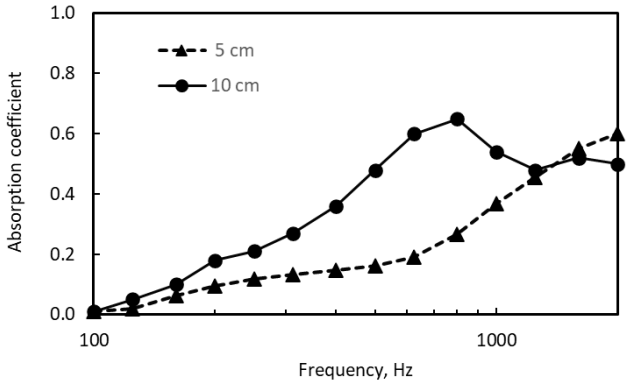

Figure 6. Absorption coefficient of hemp-based substrate.

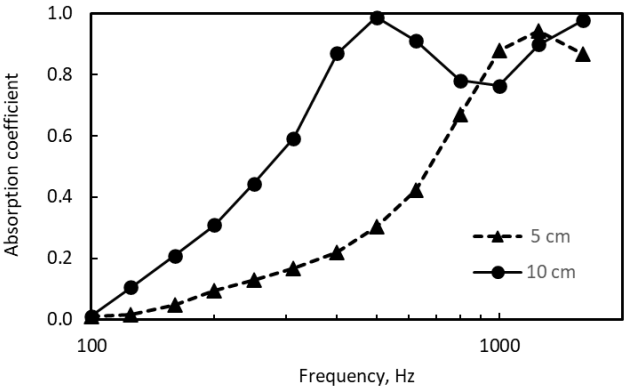

Figure 7. Absorption coefficient of wood chips substrate.

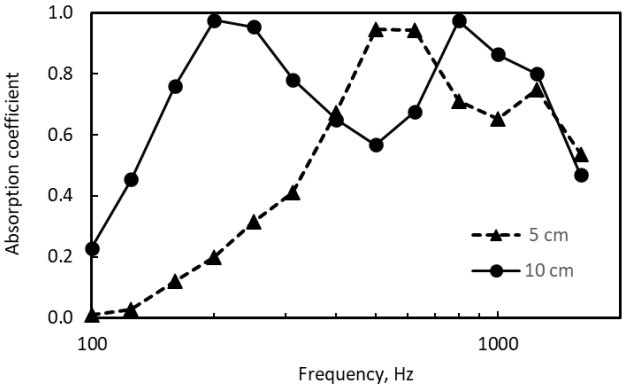

Figure 8. Absorption coefficient of triturated paper substrate.

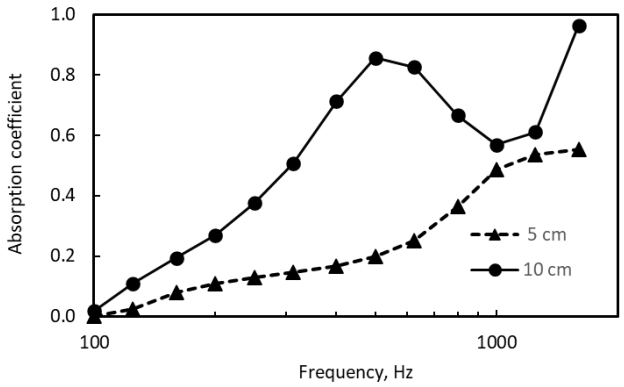

Figure 9. Absorption coefficient of triturated canes substrate.

3. DISCUSSION

For hemp-based substrate samples, when composed of 5 cm thickness, the highest values of absorption around 0.55-0.60 are observed at 2 kHz, while for 10 cm, the highest values are around 800 Hz of the same magnitude. However, the absorption performance at low frequencies remains close to zero [8]. In the case of wood chips, the maximum peak performance is centered on 1600 Hz for a 5 cm thickness and on 630 Hz for a 10 cm thickness. These peak values are around 0.95 and 1.0, which is the best performance. When the substrate consists solely of triturated paper, the absorption coefficients are highly effective, reaching a value of 1.0 at 500 Hz for a 5 cm thickness and at 250 Hz and 800 Hz for a 10 cm thickness. This is significantly remarkable since the absorption at low frequencies is always a challenge for commercial panels, unless their thickness is considerably high. When the substrate consists of triturated canes, the significant absorption is registered with the 10 cm sample, reaching peak values of 0.86 at 625 Hz and 0.96 at 2000 Hz.

4. CONCLUSIONS

The sustainable concept of preserving soil for agriculture can be effectively explored through hydroponic systems. Up to date, hydroponic systems have not been widely used for interior design or architectural finishes. However, this study demonstrates the functionality of green tiles in terms of absorption. A significant change in architectural design is possible by adopting strategies that reduce CO2 emissions and incorporate local, recycled materials aligned with the sustainability principles. Future research studies will focus on applying these green tiles to real case studies by measuring the reverberation before and after installation [9-10].

BOUNDARY ELEMENT METHOD WITH VISCO-THERMAL LOSSES: DEVELOPMENT, IMPROVEMENTS AND APPLICATIONS

Vicente Cutanda Henriquez[1*]

ABSTRACT

Sound waves are affected by viscous and thermal losses, which manifest mainly inside a thin region close to the domain boundaries, the boundary layers [1,2]. Losses at boundaries cannot usually be neglected when modelling small or intricate devices, such as micro-transducers and metamaterials [3]. Over the last years, several numerical methods have been proposed and implemented to include viscothermal losses. Some methods assume restrictive hypotheses, as in the cases of the low reduced frequency (LRF) model by Beltman or the boundary layer impedance (BLI) reported by Berggren [4,5]. A full implementation using the Finite Element Method (FEM) was described by Malinen et al. and later included in commercial FEM software [6]. The Boundary Element Method (BEM) has also been adapted by Cutanda Henríquez and other authors as a full implementation of viscothermal losses, and it is employed as a research tool originally based on the open-source software OpenBEM [7,8,9]. This contribution summarizes the work done on the BEM with losses. Current work on the method will be described.

1. INTRODUCTION

In the past two-three decades, the state of the art regarding the modeling of acoustics with viscous and thermal losses has seen a variety of new approaches, as described in the abstract. Several of these modeling techniques have been implemented in commercial software [10].
However, the user is left with a choice between methods with restrictive hypotheses such as the low reduced frequency model and the boundary layer impedance [4,5], or full methods with the only restrictions of linearity and no flow, existing in FEM and BEM [6,7,8,9]. The latter methods have the drawback of a heavy computational burden which places many relevant simulation problems almost or totally out of reach. Problems involving relatively large setups, high frequencies or intricate geometries with narrow passages cannot be treated with methods with restrictions [11,12].

2. BEM WITH LOSSES: REDUCED METHODS

There has been research in the past few years towards reducing the computational burden of the BEM with visco-thermal losses [13-14]. The BEM has the advantage of being based on a discretization of the domain boundary, not the domain itself as in FEM. This means that the very thin boundary layers do not need to be represented with tiny elements as is the case in the full FEM with losses. However, the BEM presents full, frequency dependent matrices that thwart its initial reduced nature. Ref. [13] presents an improved version of the BEM with losses in [7,9], where the coordinate changes have been simplified and the system of equations reduced to the same size of the lossless BEM. Ref. [14] introduces a Model Order Reduction (MOR) technique to a BEM implementation

with losses, this time based on the more simplified Boundary Layer Impedance.
New research is ongoing with the aim of extending MOR to full BEM with losses, possibly combining it with fast multipole methods.

3. CONCLUSIONS AND FUTURE TRENDS

There is a need for fast, reliable and not restricted modeling techniques that can deal with problems yet unreachable, such as intricate metalmaterials, minute transducers and acoustic devices such as hearing aids. Numerical optimization also needs such fast simulations to run and would open losses-controlled devices to numerical design.
The future probably belongs to a combination of advanced MOR methods and a yet more physics-oriented treatment of losses. Brute-force discretizations such as in the full FEM, or full BEM, with losses are inefficient. The BLI approach makes use of a simplified description of the boundary layers to reduce them to boundary condition. The LRF takes advantage of the behavior of the fluid within certain geometries. In this line, we need methods that cleverly employ the physical behavior of the fluid in an efficient description with less restrictive constraints [10].

LOW-DRAG RAINBOW-TRAPPING FILTERS FOR BROADBAND SOUND DISSIPATION IN A LOW-SPEED DUCTED FLOW

Cedric Maury[1*] **Teresa Bravo**[2] **Fawad Ali**[1]

ABSTRACT

Rainbow-trapping filters (RTFs) have mostly been designed with closed-end terminations to achieve near-unit broadband absorption under acoustic excitation, with applications as shallow wall-treatments in building acoustics or short anechoic terminations. The current study considers opened rib-designed RTFs being traversed by a low-speed grazing flow. The double objective is to design an enhanced silencer able to achieve broadband sound dissipation, e.g. with minute reflection and transmission of the incident wave, while ensuring a low friction factor. A key element is the lining of the interface between the RTF cavity mouths and the flow duct. Micro-perforated panels (MPP) have been chosen that provide holes diameter – holes pitch parameters optimized to determine maximal total dissipation or minimal friction factor. MPPs also contribute to enhance slow sound effects towards lower frequencies than unlined RTFs. Finite Elements (resp. Reynolds Averaged Navier Stokes k-ε) models have been developed to produce acoustic (resp. aerodynamic) design charts with respect to the MPP parameters. A set of MPP parameters has been found that maximizes the aeroacoustic performance of the MPP-RTF silencer. It has been validated against low-speed wind-tunnel experiments that showed an adverse effect of downstream propagation conditions on the wideband dissipative performance of the MPP-RTF.

Keywords: *broadband silencers, micro-perforated panels, aeroacoustic metamaterials, rainbow-trapping filters.*

1. INTRODUCTION

The emergence of acoustic metamaterials has led to the development of sub-wavelength perfect absorbers whose internal geometry can be tailored to achieve the required wideband and/or low-frequency performance [1]. Aeroacoustic, so-called ventilated, metamaterials have been much less studied [2] although their design is highly motivated by the development of soundproof natural ventilation systems or silencers for air-conditioning or automotive exhaust systems.

The current study focuses on the acoustic and aerodynamic properties of axially-graded fully-opened aeroacoustic metamaterials traversed by a low-speed grazing flow. One considers rib-designed rainbow trapping filters with progressive increase of the cavity depths whose mouth is shielded from the flow by (micro-)perforated panels. Insights into the acoustic and drag performance of such silencers under a low-speed flow are provided by analytical and numerical modellings in Sec. 2 and 3, respectively. Experimental verification of these effects are examined in Sec. 4 from low-speed wind-tunnel experiments.

2. AEROACOUSTIC MODELLING

2.1 MPP-shielded rainbow trapping filters

Rainbow trapping filters (RTF) are retarding silencers of rectangular or cylindrical cross-sections, made up of a set of N sidebranch outer cavities of increasing depths $D(x)$ such that

$$D(x)=\frac{H}{2}\left[1-\frac{(-x)^m}{L^m}\right], \qquad (1)$$

with $-L\le x\le 0$, L and H the duct length and height, respectively and $m>0$. One assumes that the RTF silencer is inserted in a duct with a square cross-section duct of height (and width) H. A cross-sectional view of the RTF is sketched in Fig. 1. m is the rate of increase of the cavity depths and is determinant to achieve impedance matching condition over a broad bandwidth at the inlet of the silencer. In the limit of $m\to\infty$, one gets a locally-reacting expansion chamber while $m=0$ corresponds to a rigid rectangular duct without silencer.

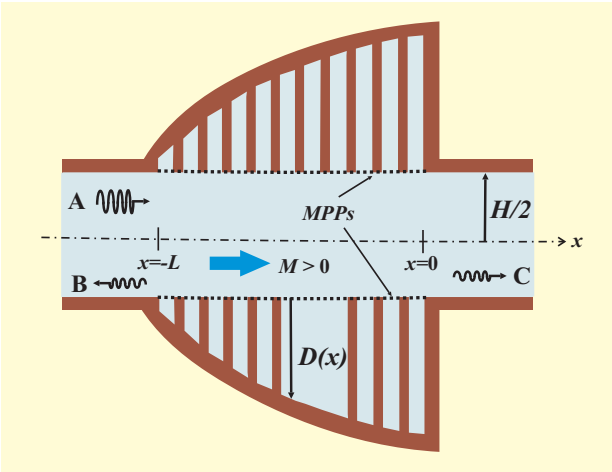

Figure 1. Sketch of a rib-designed rainbow trapping silencer shielded from a low-speed grazing flow of Mach number M (blue arrow) by a micro-perforated panel interface; an incident sound wave propagates along the axial flow.

The power-law increase of the cavity depths when x varies from $-L$ to 0 results in a progressive increase of the wall-admittance monitored by the air cavity stiffness. This produces a slow sound effect [3] with progressive decrease of the acoustic phase speed from c_0 at $x=-L$ down to $c_0/\sqrt{3}$ at $x=0$ where c_0 is the sound speed. The acoustic functionality of a RTF silencer is thus to trap the incident acoustic wave, whose amplitude is denoted A in Fig. 1, and fully dissipate its energy by visco-thermal effects along the inner walls of the cavities. It results in minute reflected and transmitted wave amplitudes, denoted B and C respectively, over the efficiency range of the RTF muffler. If used in transportation sectors, little reflection avoids the occurrence of thermo-acoustic instabilities triggered by acoustic waves back-reflected towards the combustion chamber [4] whereas small transmission contributes to lower noise emissions by thermal engines.

In practice, the entrances of the silencer cavities are shielded from the flow by a perforated or micro-perforated panel (MPP), as sketched in Fig. 1, to prevent clogging by dusts or particle residues, but also to limit the aerodynamic pressure drop when the flow traverses the fully-opened silencer. It will be seen in Sec. 3 that MPPs also have an acoustic functionality, namely to extend the efficiency range of RTF silencers towards the low frequency range.

2.2 Transfer matrix modelling

2.2.1 MPP transfer impedance

The overall transfer impedance, Z_{MPP}, for a MPP with circular holes of diameter d_h and thickness t_h is given by the following expression [5,6] in presence of a low-speed flow with grazing Mach number M

$$\frac{Z_{\text{MPP}}}{\sigma}=\frac{\mathrm{i}\omega\rho_0 t_h}{\sigma}\left[1-\frac{2}{k_h\sqrt{-\mathrm{i}}}\frac{J_1\left(k_h\sqrt{-\mathrm{i}}\right)}{J_0\left(k_h\sqrt{-\mathrm{i}}\right)}\right]^{-1} + \frac{\mathrm{i}\omega\rho_0}{\sigma}\frac{8d_h}{3\pi}F_M + \frac{4}{\sigma}\sqrt{\frac{\eta\rho_0\omega}{2}}+\frac{Z_0}{\sigma}K|M|, \qquad (2)$$

with σ the perforation ratio, η the dynamic viscosity of the air, $k_h=(d_h/2)/r_{\text{visc.}}(\omega)$, the perforate constant, e.g. the ratio of the MPP holes radius to the viscous boundary layer thickness, $r_{\text{visc.}}(\omega)=\sqrt{\eta/\rho_0\omega}$, ρ_0 the air density, ω the angular frequency and $Z_0=\rho_0 c_0$ the air

characteristic impedance. Eq. (2) is valid for linear acoustic regimes and for MPPs with a low perforation ratio, typically lower than 2%, for hole interaction effects to be negligible. Inner viscous dissipation and inertial effects within the MPP holes are accounted for within the first term of Eq. (2) where J_1 and J_0 are Bessel functions of the first kind and orders 1 and 0, respectively. The second term describes the added mass effect at the inlet/outlet of the MPP holes. It is reduced by grazing flow effects, all the more than the flow speed increases, by a correction factor $F_M = \left[1+\left(12.6\,|M|\right)^3\right]^{-1}$. The third term in Eq. (2) accounts for the added resistance at the MPP holes inlet and outlet while the fourth term describes the excess resistance induced at the MPP inlet by the grazing flow. It increases the MPP resistance by $K|M|Z_0/\sigma$, with the value $K=0.15$ educed for $|M|<0.15$ [6].

2.2.2 Transfer matrix model

Assuming plane wave propagation in the duct and in the cavities, an overall transfer matrix can be defined between the inlet ($x=-L$) and outlet ($x=0$) of the MPP-RTF silencer as the following product

$$\mathbf{T}=\prod_{n=1}^{N}\mathbf{T}_n=\begin{bmatrix}T_{11} & T_{12}\\ T_{21} & T_{22}\end{bmatrix}, \tag{3}$$

between the elementary transfer matrices $\mathbf{T}_n$ that relate the acoustic pressure and volume velocity fields [7] across the n$^{\text{th}}$ MPP-cavity-rib units. Each elementary transfer matrix results from the product, $\mathbf{T}_n=\mathbf{T}_d\,\mathbf{T}_t\,\mathbf{T}_{\text{cav},n}$, with $\mathbf{T}_d$ (resp. $\mathbf{T}_t$) the propagating matrices over the cavity width d (resp. the rib thickness t) and $\mathbf{T}_{\text{cav},n.}$ a matrix that describes the wall admittance effect of the n^{th} MPP-cavity. Assuming $\mathrm{e}^{\mathrm{j}\omega t}$ time-dependence, each propagating matrix $\mathbf{T}_w$ reads

$$\mathbf{T}_w=\mathrm{e}^{-\mathrm{j}Mkw}\begin{bmatrix}\cos(kw) & \mathrm{j}y_0^{-1}\sin(kw)\\ \mathrm{j}y_0\sin(kw) & \cos(kw)\end{bmatrix}, \tag{4}$$

with $w=d,t$ the length of each duct unit traversed by a flow with bulk Mach number M, $S=H^2$ the duct cross-sectional area and $y_0=S/Z_0$. The duct wavenumber k in presence of a uniform low-speed flow is given by $k=\left(k_0-\mathrm{j}\mathrm{Fr}M/2H\right)/\left(1-M^2\right)$ in which $k_0=\omega/c_0$. $\mathrm{Fr}=0.0072+0.612\,\mathrm{Re}^{-0.35}$ ($\mathrm{Re}<4.10^5$) is the Froude friction factor that accounts for the dispersion induced by the turbulent flow, and $\mathrm{Re}=MHZ_0/\eta$ is the flow duct Reynolds number.

Coupling between the ducted flow and the nth MPP-cavity is described by the transfer matrix [7]

$$\mathbf{T}_{\text{cav},n}=\frac{1}{1+2MY_{\text{cav},n}y_0}\times\begin{bmatrix}1+MY_{\text{cav},n}y_0 & M^2Y_{\text{cav},n}^2y_0^2\\ Y_{\text{cav},n} & 1+MY_{\text{cav},n}y_0\end{bmatrix}, \tag{5}$$

with $Y_{\text{cav},n}$ the local sidebranch volume admittance of the n^{th} MPP-cavity. It reads $Y_{\text{cav},n}=S_{\text{cav}}\,y(x_n)/Z_0$ with $S_{\text{cav}}=2Hd$ the cavities entrance area and x_n the axial location of the n^{th} sidebranch. The specific admittance is calculated as $y(x_n)=\left[Z_{\text{MPP}}/(Z_0\sigma)-\mathrm{j}\cot(k_0'x_n)\right]^{-1}$ with Z_{MPP}/σ given by Eq. (2) and k_0' a complex frequency-dependent wavenumber that accounts for visco-inertial and thermal effects over each cavity wall following the Johnson-Champoux-Allard-Lafarge model [8].

Assuming that the duct outlet ($x\to+\infty$) is infinite, e.g. there are no back-transmitted wave, as seen in Fig. 1, the following left reflection (resp. left-to-right transmission) coefficients r_{11} (resp. t_{12}) are obtained

$$\begin{cases}r_{11}=\dfrac{(T_{11}+y_0T_{12})-(T_{21}+y_0T_{22})}{(T_{11}+y_0T_{12})+(T_{21}+y_0T_{22})}\\ t_{12}=\dfrac{1+r_{11}}{T_{11}+y_0T_{12}}\end{cases}. \tag{6}$$

On can then deduce the power dissipated by the MPP-RTF silencer, namely $\eta=1-\rho-\tau$ with $\tau=|t_{12}|^2$ the transmission coefficient and $\rho=(1-M)^2|r_{11}|^2/(1+M)^2$ the convected reflection coefficient. The transmission loss (TL) is defined as $\mathrm{TL(dB)}=-10\log_{10}(\tau)$.

3. ACOUSTIC PROPERTIES OF A MPP-RTF

Simulations have been carried out to examine the influence of the MPP holes diameter and flow speed on the

acoustical performance of a MPP-RTF silencer. They have been achieved using the cost-efficient transfer matrix model presented in Sec. 2.2.2. This model has been validated in the no-flow case against finite element visco-thermal acoustic simulations [3], but also against experiments, as shown in Sec. 5.

One considers a MPP-RTF cubic silencer of length $L = 0.15$ m, of square cross-section of height and width $H = W = L$, composed of $N = 15$ cavities of width $d = 7$ mm separated by ribs of thickness $t = 3$ mm. Axial variations of the cavity depths follow Eq. (1). The cavity mouths are covered by a MPP of thickness $t_h = 0.5$ mm, of center-to-center separation $s_h = 5$ mm between the holes whose diameter has been varied to assess its effect on the silencer performance.

3.1 Influence of the MPP holes diameter

Figure 2 shows variations of the fraction of incident power dissipated, reflected and transmitted by MPP-RTF silencers when decreasing the MPP holes diameter from 0.9 mm down to 0.2 mm while keeping a constant holes pitch set to 5 mm. This corresponds to a decrease of the perforation ratio from 2.54% to 0.13%. The performance of the unshielded RTF silencer is also shown. It exhibits a near-unit dissipation plateau, minute reflection and little transmission as from 1 kHz up to the duct cut-on frequency 1140 Hz. Shielding the RTF by a MPP with 0.9 mm holes diameter significantly downshifts the onset of high performance from 1 kHz down to 650 Hz while enlarging by a factor 3.5 the efficiency range of the silencer, that now extends from 650 Hz to 1140 Hz. Over this range, the dissipation exceeds 0.9 and the reflection (resp. transmission) stays below 0.02 (resp. 0.08) respectively. This translates into a TL between 11dB and 18 dB, as shown in Fig. 3. This is due to increased reactance brought by the micro-perforations to the RTF cavity mouths whose resonances are still able to merge due to the added resistance.

Further decreasing the MPP holes diameter increases the extra inertial and resistive effects brought by the MPP holes to the silencer. As observed in Fig. 2, it results in a progressive downshift of the silencer efficiency range towards the low frequency range. It is accompanied by a decrease (resp. increase) of the maximum dissipation (resp. minimum transmission) values, as the holes diameter decreases.

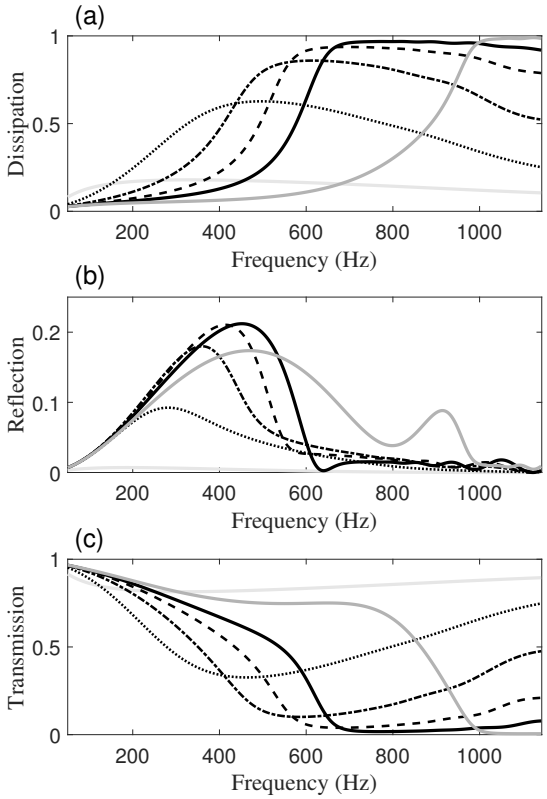

Figure 2. Influence of the MPP holes diameter on the dissipation (a), reflection (b) and transmission (c) coefficients of a MPP-RTF silencer in the no-flow case when decreasing the MPP holes diameter d_h (0.9 mm, plain black; 0.7 mm, dashed black, 0.5 mm, dash-dotted black; 0.4 mm, dotted; 0.2 mm, light grey) and without MPP (plain grey).

Note that variations of the MPP properties hardly influence the minute reflection properties of the MPP-RTF silencer. As for the largest holes diameter, low reflections are due to high dissipation within the cavities. They are due to increased transmission when the holes diameter increases. In the limit of very low perforation ratio (0.13%) with ultra-small holes diameters, almost full transmission is achieved with a TL lower than 1 dB.

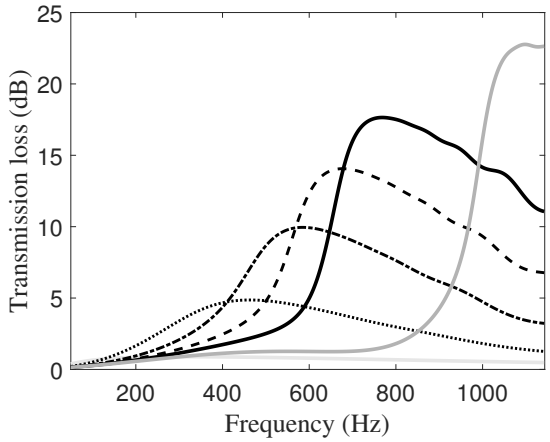

Figure 3. Influence of the MPP holes diameter on the Transmission loss (dB) spectra of a MPP-RTF silencer in the no-flow case when decreasing the MPP holes diameter d_h (0.9 mm, plain black; 0.7 mm, dashed black, 0.5 mm, dash-dotted black; 0.4 mm, dotted; 0.2 mm, light grey) and without MPP (plain grey).

3.2 Low-speed flow effects

In practice, a low-speed flow will travel within the MPP-RTF silencer, as would be the case in a ventilation or an automotive exhaust system. Assuming a discharge flow rate, the sound wave, which propagates from the shallowest to the deepest cavity, will also travel along the flow direction, e.g. under downstream propagation conditions (DPC). The effect of an increasing flow speed on the MPP-RTF acoustical performance has been simulated in Fig. 4. Simulations have been performed on a MPP-RTF silencer assuming a MPP with holes diameter $d_h = 0.9$ mm and holes pitch $s_h = 5$ mm . The main influence is a reduction of the efficiency bandwidth for the dissipation and the transmission loss towards higher frequencies as the flow speed increases. It is accompanied by a decrease of the maximum performance values. The onset of high dissipation values (greater than 0.9) and high TL (greater than 11 dB) is upshifted from 650 Hz (no-flow case) towards 880 Hz (flow at 30 m.s^{-1}). The TL dynamics, 11 dB – 18 dB without flow, reduces to 11 dB – 12 dB with flow at 30 m.s^{-1}. Note that the reflection coefficient is rather unaffected by low-speed flow effects as it stays below 2% over the range of flow speed variations.

Such adverse flow effects are due to an increase of the MPP resistance and a decrease of the MPP reactance, as seen from Eq. (1), when the flow speed or Mach number increases. Such over-resistive and under-reactive conditions could be overcome if integrated in an optimisation process that maximizes the total dissipation of the silencer.

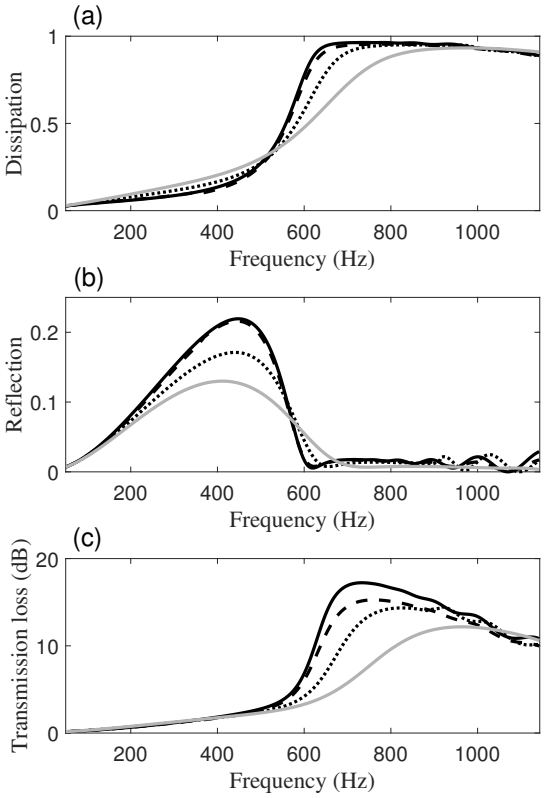

Figure 4. Influence of the flow velocity on the dissipation (a), reflection (b) and transmission loss (c) of a MPP-RTF silencer when traversed by a grazing flow of bulk velocity 10 m.s^{-1} (dashed black), 20 m.s^{-1} (dotted black) and 30 m.s^{-1} (grey); also shown the no-flow case (plain black).

4. AERODYNAMIC PERFORMANCE

Shielding the RTF silencer cavities from a grazing flow by using MPPs not only has an acoustic functionality, as seen in Sec. 3.1, but also limits the pressure drop that would be induced by interaction between the flow and the RTF cavity

mouths through detachment, vortex shedding and re-attachment at the cavity edges. A quantifier of this effect is the friction factor of the cubic MPP-RTF silencer that takes the following form, with $H = L$,

$$\varphi = \frac{H}{L}\frac{\Delta p}{\rho_0 U^2} = \frac{\Delta p}{\rho_0 U^2}, \qquad (7)$$

with Δp the pressure drop across the axial length L of the silencer and U the mean flow speed. These quantities have been calculated from Reynolds Averaged Navier Stokes k-ε model [9] solved by Finite Volume in Ansys Fluent imposing a fully-developed turbulent boundary layer profile at the silencer inlet with outer velocity 30 m.s^{-1} and turbulence rate 2%, typical of low-speed wind-tunnels.

Figure 5 shows a substantial decay of the friction factor when increasing the MPP holes pitch from 0.5 mm to 5 mm. It amounts to 17% for ultra small (0.2 mm) and 14.5% for near-millimetric (0.9 mm) holes diameters. This is associated to a decrease of the perforation ratio from 12.57% to 0.13% in the former case, and from 63.62% to 2.54% in the latter case. Moreover, the friction factor for $d_h = 0.9$ mm stays consistently higher than that for $d_h = 0.2$ mm, by 1 to 4%. As for $d_h = 0.9$ mm, holes pitch values lower than d_h have been excluded.

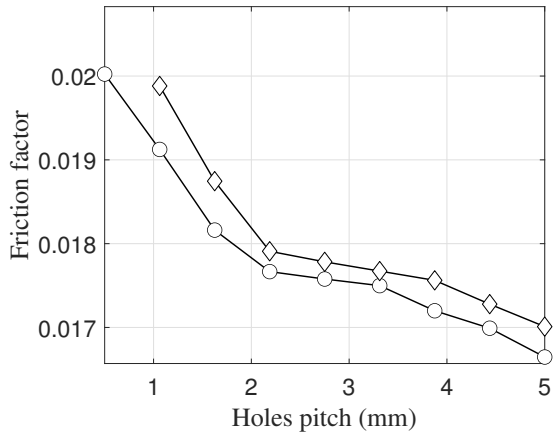

Figure 5. Influence of the MPP holes pitch on the friction factor of a MPP-RTF silencer traversed by a low-speed flow of bulk velocity 30 m.s^{-1} for two MPP holes diameters ($d_h = 0.2$ mm, circles; ($d_h = 0.9$ mm, diamonds).

It appears that the MPP with the lowest friction factor is the one with the smallest holes diameters and the largest holes pitch, e.g. with a very low perforation ratio. Back to Fig. 2 (light grey curves), it is associated to poor dissipation and transmission properties. A compromise thus has to be found to achieve both acceptable acoustical and aerodynamic performance. It can be seen from Fig. 5 that a MPP with holes pitch greater than 2 mm and holes diameter of 0.9 mm (for ease of manufacture) ensures a friction factor below 0.018. Assuming a holes pitch of 5 mm, Fig. 2 shows it provides excellent acoustical performance in the no-flow case, that should however be moderated by the results of Fig. 4 under a low-speed flow at 30 m.s^{-1}.

5. EXPERIMENTAL VERIFICATION

Low-speed wind-tunnel experiments have been performed to verify the simulated acoustical performance of a cubic RTF silencer of length, width and height $L = W = H = 0.15$ m, additively manufactured in ABS material. The silencer is shielded from a low-speed flow (30 m.s^{-1}) by a perforated panel of thickness 1.5 mm, holes diameter 2.6 mm and perforation ratio 2.8%. The RTF is composed of 20 cavities of width 3.5 mm separated by ribs of thickness 4 mm. Figure 6 shows that the silencer is plugged onto a low-speed wind-tunnel duct section. During the measurements, the inlet and outlet of the silencer are prolonged by 1 m length rigid square duct sections to ensure flow channeling. The airflow is generated by a centrifugal fan insulated with mufflers, straightened by honeycomb panels in a settling chamber, then accelerated through a convergent towards the test section. A transitional, almost turbulent, boundary layer has been characterized from hot-wire measurements at the silencer inlet location.

The test section is instrumented in order to measure the scattering matrix of the silencer [10]. Two sources and two pairs of three boundary layer microphones are located respectively in the 1 m duct sections upstream and downstream the silencer. The sources are sequentially driven by white noise to generate two independent states within the duct test section. The associated outgoing and ingoing plane wave amplitudes are deduced from the transfer functions measured between the microphones and the source drive signals after pseudo-inversion of the plane wave propagation matrix that accounts for convective effects and visco-thermal losses in presence of flow up to the duct cut-on frequency 1140 Hz. The scattering matrix

gathers the outgoing and ingoing wave amplitudes for each acoustic state from which the dissipation, reflection and transmission coefficients are readily deduced.

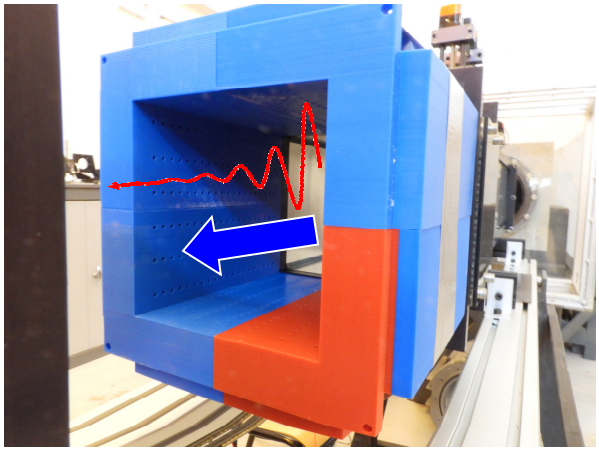

Figure 6. Photography of the outlet of a square RTF silencer mounted on a low-speed wind-tunnel and shielded from the grazing flow by perforated panels; the blue (resp. red) arrows represent the flow (resp. sound wave) travelling through the silencer.

It can be seen from Fig. 7 that the Finite Element simulations and the scattering matrix measurements closely correlate, showing high dissipation values of the perforated-RTF silencer exceeding 0.9 from 650 Hz to 950 Hz in the no-flow case. Over this range, merging occurs between the resonances of the activated perforate-RTF cavities. It is associated to very small values of the reflection coefficient, below 0.02, and a low transmission coefficient that stays below 0.2.

Without perforated coating, it is found from simulations (not shown) that the RTF silencer produces a high dissipation plateau only above 1400 Hz, beyond the plane wave regime that extends up to 1140 Hz. Adding the perforated coating over the RTF cavities thus downshifts by 750 Hz the onset of high acoustical performance. This is due to inertial effects added by the perforates with 2.8% wall porosity. Because of limitations on the minimum holes diameter that can be printed from fused deposition modelling using ABS polymer, such low-perforation ratio was achieved by increasing the perforate holes pitch, 7.5 mm along the streamwise direction and 25 mm along the spanwise direction, as seen from Fig. 6, rather than by decreasing the holes diameter to small sub-millimetric values. Due to the supra-millimetric holes diameters, visco-thermal dissipation occurs essentially within the RTF cavities. It well manages to balance the reflection and transmission leakages around 750 Hz, but slightly over-resistive conditions are observed above 900 Hz. They produce a progressive decrease of the dissipation down to 0.8 as well as an increase of the transmission up to 0.2 when the frequency raises up to 1100 Hz.

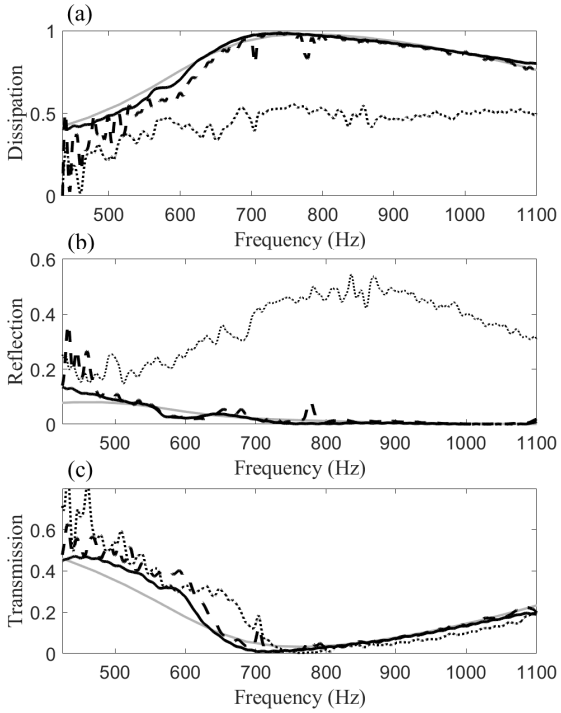

Figure 7. Dissipation (a), reflection (b) and transmission (c) spectra of the perforated RTF silencer simulated by Finite Element method (grey) and measured (black) in the no-flow case and under a low-speed flow at 30 m.s^{-1} assuming upstream (dashed) or downstream (dotted) plane wave excitations.

Under a low-speed flow (30 m.s^{-1}), one observes a slight upshift of the onset of high dissipation and transmission performance, from 650 Hz without flow to 690 Hz with flow, with almost unchanged reflection properties. This trend is in accordance with the low-speed flow effects simulated by the transfer matrix model in Fig. 4. These effects are due to the added resistance and deficit in wall

reactance caused by the flow. However, they appear to be less pronounced with respect to the effect of the same flow speed over a MPP-coated RTF silencer, as seen when comparing Fig. 7 and Fig. 4.

Assuming an incident wave propagating against the flow, e.g. impinging the silencer from the outlet side, Fig. 7 shows that it produces moderate broadband dissipation (that stays around 0.5) due to back reflections (up to 50% of the incident power). This is due to the wall admittance discontinuity encountered by the wave when entering the silencer flow outlet due to the low stiffness of the deepest cavity. This breaks the impedance matching condition that would be satisfied by the wave if it was entering the silencer flow inlet, due to the high stiffness of the shallowest cavity and progressive increase of the wall admittance. One also note from Fig. 7(c) the absence of reciprocity in transmission under grazing flow conditions.

6. CONCLUSIONS

The acoustic and aerodynamic effect of covering the cavities of RTF silencers by MPP or perforated panels has been examined under no-flow and low-speed grazing flow conditions, up to Mach 0.087. Transfer matrix modelling and measurements of the scattering matrix in a low-speed wind tunnel showed robustness of the broadband low-reflection and high dissipation performance to grazing flow effects, albeit over a bandwidth that reduces as the flow speed increases. The transmission loss of the coated RTF silencer is especially sensitive to this adverse flow effect.

A trade-off has to be found on the MPP parameters to ensure both high dissipation performance and low friction factor since either objective requires concurrent parameter sets. Further coupled acoustic and computational fluid dynamic simulations should be performed at the MPP holes local scale to investigate the geometrical parameters favoring visco-thermal dissipation in the acoustic/thermal boundary layers while limiting the occurrence of flow-induced vortex shedding over/within the holes and responsible of the drag. However, the analysis is not straightforward due to the interaction between the near-wall shear layers and the acoustic waves.

TUNABLE MICROPERFORATED PANEL ACOUSTIC ABSORBERS WITH COUPLING EFFECTS UNDER GRAZING FLOW

Ying Li[1] **and Yat Sze Choy**[1*]
[1] Department of Mechanical Engineering, The Hong Kong Polytechnic University, Hong Kong Special Administrative Region, People's Republic of China

ABSTRACT

Design for highly effective acoustic meta-liners with broadband sound attenuation under grazing flow is challenging due to performance degradation with high flow speeds and intricate internal structures involved. In this study, a tunable microperforated panel (MPP) acoustic absorber is proposed that leverages the coupling effects between its sub-components to achieve broadband sound absorption across static and flow conditions. A theoretical framework combining acoustic radiation theory with modal superposition principles is developed to predict the performance of the proposed absorber. The theoretical and numerical analysis clarifies how coupling effects enhance the absorption troughs in the proposed absorber. Finally, a broadband acoustic liner, composed of multiple optimized coupled MPP absorbers is proposed. Experimental investigations validate the sound absorption performance of the proposed acoustic liner under grazing flow, highlighting the potential of our theoretical model and coupled MPP absorbers to advance acoustic meta-liner design.

Keywords: *Flow and acoustic interactions, microperforated panel absorber; two-dimensional theoretical model; broadband sound absorption.*

1. INTRODUCTION

The highly effective broadband absorption of low-frequency sound is a growing and challenging topic for acoustic liners in aero-engines and ventilation ductwork systems [1]. Traditional porous materials and microperforated panels (MPPs) absorbers require sufficient thickness compared with the wavelength to control low-frequency sound, which hinders their wide application in practice. In recent years, acoustic metamaterials (AMMs) [2] that are artificial periodic structures with subwavelength building blocks provide a new idea for the design of low-frequency sound absorbers. A number of functionalities and applications have been proved and achieved based on AMMs. To enhance the sound absorption bandwidth, many metamaterial designs spatially stack resonators with varying cavity depths to connect all resonance frequency peaks. This approach, however, necessitates a surprisingly large number of units to effectively suppress noise. Inadequate numbers of resonant elements lead to unsatisfied absorption in the troughs, thereby limiting the applicability of AMMs in duct systems and room acoustics.

Building on these foundational principles and strategies, current advancements in AMM technology have led to their application in developing effective acoustic liners under flow conditions. However, increasing flow speeds trigger stronger coupling between grazing flows and acoustic waves, resulting in substantial degradation of meta-liner absorption performance [3-5]. To date, few metaliner designs have fully achieved simultaneous broadband noise reduction and stable absorption efficacy across varying flow velocities, representing a critical barrier to practical applications.

In this study, a coupled acoustic absorber (CAA) featuring inserted MPPs and shared cavities is proposed to achieve broadband sound absorption across static and flow conditions. The objectives of this study are as follows: (1) To propose a two-dimensional (2D) model for predicting the acoustic performance of the CAA based on sound radiation theory in a rigid-walled duct. (2) To design a coupled MPP absorbers that achieves broadband noise

reduction while preserving effective broadband sound absorption performance under increasing flow velocities

2. THEORETICAL MODELLING

The proposed CAA comprised inserted MPPs and shared cavities, as shown in Fig. 1. The solid line denotes the rigid wall while the dashed line is the MPP in the TAA. The shaded region denotes the acoustically rigid block. We assumed that a normally incident wave p_{inc} impinged on the surface of the CAA. The acoustic pressure outside of the cavity is $p_a = 2p_{inc} + p_{rad_duct}$, where p_{rad_duct} denotes the pressure radiating from the surface. As shown in Fig. 1, the n-th MPP is located at surface S_{p_n} with a length of L_n. The particle velocity over the MPP surface S_{p_n} is expanded as a series of sine functions as

$$v_{p_n}(x) = \sum_{q=1}^{Q} V_{p_n,q}\phi_{p_n,q}(x), \tag{1}$$

with

$$\phi_{p_n,q}(x) = \sin\left(\frac{q\pi}{L_n}x\right) \tag{2}$$

where $V_{p_n,q}$ and $\varphi_{p_n,q}$ are the q-th modal amplitude and modal shape of the n-th MPP, respectively. q is the modal indices. With the proper truncation of the decomposition series, Eq. (1) can accurately represent the averaged particle velocity fields v_{p_n} except at the boundary edges. Subsequently, the pressure field in the duct above the meta-surface can be formally expressed as a superposition of plane wave modes [6]

$$p_{rad_duct}(x,0) = \rho_0 \sum_{g=0}^{G} \frac{\omega\psi_{d,g}(x)}{W\kappa_{d,g}} \int_{S_{p_1}} \psi_{d,g}(x')v_{p_1}(x')ds' \tag{3}$$

where, $\psi_{d,g}(x)$ is the g-th cross-sectional mode shape function of the duct, $\kappa_{d,g}$ is the propagation constant along the duct given by $-i\sqrt{k_{d,g}^2 - (k - i\alpha_{duct})^2}$, $k_{d,g}$ is the cross-sectional characteristic propagation constant, and k is the propagation constant without absorption. α_{duct} is the absorption coefficient of the duct defined in [7]. $\psi_{d,g}(x) = \sqrt{2-\delta_{0,g}}\cos(g\pi x/W)$ and $k_{d,g}^2 = (g\pi/W)^2$. $\delta_{0,g}$ is the Kronecker delta function, which is equal to zero when $g \neq 0$ and unity when $g = 0$. ρ_0 is the density of air and ω is the radial frequency. g is the modal index.

On the other hand, the acoustic pressure inside n-th channel excited by the velocity distribution on the adjacent r-th MPP ($r = n$ or n+1) can be separated into two parts: the sound radiated from the velocity distribution on the r-th MPP, and the corresponding reflected wave by the boundaries of the channel walls as $p_{MPP_r}^{ch_n} = p_{rad_r}^{ch_n} + p_{ref_r}^{ch_n}$. According to Doak's theory [6], the sound pressure radiated by a sound source distribution in r-th MPP in the n-th channel can be expressed as

$$p_{rad_r}^{ch_n}(x,y) = \rho_0 \sum_{m=0}^{M} \frac{\omega\psi_{n,m}(y)}{2D_n\kappa_{n,m}} \int_{S_{p_r}} \left[H(x-x')e^{-i\kappa_{n,m}(x-x')} + H(x'-x)e^{i\kappa_{n,m}(x-x')}\right]\psi_{n,m}(D_*)v_{p_r}(x')ds', \tag{4}$$

where H denotes the Heaviside function. $\psi_{n,m}(y)$ is the cross-section mode shape functions of the n-th channel, and $\kappa_{n,m}$ is the propagation constant along the n-th channel axis given by $-i\sqrt{k_{n,m}^2 - (k - i\alpha_{n,wall})^2}$, where $k_{n,m}$ is the cross-sectional characteristic propagation constant. $\alpha_{n,wall}$ is the absorption coefficient of the n-th channel, defined in ref [7]. $\psi_{n,m}(y) = \sqrt{2-\delta_{0,m}}\cos(m\pi y/D_n)$ and $k_{n,m}^2 = (m\pi/D_n)^2$. m is the modal index. $D_* = -D_n$ ($n < q$) or 0 ($n = q$).

The reflected wave induced by a sound source distribution in r-th MPP in the n-th channel is calculated in a manner similar to the radiation pressure in Eq. (4), except that the Heaviside functions are replaced by the unknown coefficients $C_{n,m}^+$ and $C_{n,m}^-$ as $C_{n,m}^+ = \frac{e^{ik_{n,m}(2W-2x')}+1}{e^{ik_{n,m}(2W)}-1}$ and $C_{n,m}^- = \frac{e^{ik_{n,m}(2W+2x')}+1}{e^{ik_{n,m}(2W)}-1}$, respectively.

2.1 Pressure gradient at the MPP

The acoustic boundary condition of the MPP mounted on the upper surface S_{p_1} can be described as

$$Z_{MPP_1}v_{p_1}(x,0) = \frac{1}{\rho_0 c_0}\left[p_{MPP_1}^{ch_1}(x,0) + p_{MPP_2}^{ch_1}(x,0) - 2p_{inc} - p_{rad_duct}(x,0)\right] \tag{5}$$

where c_0 is the sound speed of air. Substituting Eqs. (1-4) into Eq. (5), and meanwhile multiplying $\phi_{p_1,q'}(x)$ on both sides to apply the orthogonal property, and integrating over the MPP yields

$$(\boldsymbol{A}^{\mathrm{sur}}+\boldsymbol{A}^{\mathrm{radMPP_1}}+\boldsymbol{A}^{\mathrm{rad_11}}+\boldsymbol{A}^{\mathrm{ref_11}})\boldsymbol{V}_{\mathrm{p_1}} +(\boldsymbol{A}^{\mathrm{rad_12}}+\boldsymbol{A}^{\mathrm{ref_12}})\boldsymbol{V}_{\mathrm{p_2}}=\boldsymbol{A}^{\mathrm{inc}} \quad (6)$$

where $\boldsymbol{A}^{*}$ is the Q × Q matrix, and the $\boldsymbol{V}_{*}$ is the Q × 1 matrix. The acoustic impedance of the *n*-th MPP is determined using the acoustic impedance model (without flow) proposed by Maa [8]:

$$Z_{\mathrm{MPP_n}}=\frac{32\mu t_{\mathrm{MPP_n}}}{\sigma_{\mathrm{MPP_n}}d_{\mathrm{MPP_n}}^{2}}\left[\left(1+\frac{(K_{\mathrm{n}})^{2}}{32}\right)^{\frac{1}{2}}+\frac{\sqrt{2}}{8}K_{\mathrm{n}}\frac{d_{\mathrm{MPP_n}}}{t_{\mathrm{MPP_n}}}\right], +\mathrm{i}\frac{\rho_0\omega t_{\mathrm{MPP_n}}}{\sigma_{\mathrm{MPP_n}}}\left[1+\left(9+\frac{(K_{\mathrm{n}})^{2}}{2}\right)^{-1/2}+0.85\frac{d_{\mathrm{MPP_n}}}{t_{\mathrm{MPP_n}}}\right] \quad (7)$$

where $d_{\mathrm{MPP_n}}$, $t_{\mathrm{MPP_n}}$, and $\sigma_{\mathrm{MPP_n}}$ are the diameter, thickness, and porosity of the *n*-th MPP, respectively. μ are the density and viscosity of air. $K_{\mathrm{n}}=(d_{\mathrm{MPP_n}}/2)\sqrt{\rho_0\omega/\mu}$ is a parameter describing the ratio of the radius to the viscous boundary layer thickness inside the hole.

Analogously, by reorienting the reference axis to the left-hand side of the N-th (last) channel, the acoustic boundary condition on the MPP mounted at the surface $S_{\mathrm{p_n}}$ can be described as

$$Z_{\mathrm{MPP_n}}v_{\mathrm{p_n}}(x,0)=\frac{1}{\rho_0 c_0}\left[p_{\mathrm{MPP_n}}^{\mathrm{ch_n}}(x,0)-p_{\mathrm{MPP_n}}^{\mathrm{ch_n\text{-}1}}(x,0)-p_{\mathrm{MPP_n\text{-}1}}^{\mathrm{ch_n\text{-}1}}(x,0)\right]. \quad (8)$$

Substituting Eqs. (1-4) into Eq. (8), multiplying $\phi_{\mathrm{p_n,q}}(x)$ on both sides and integrating over the MPP yields

$$(\boldsymbol{A}^{\mathrm{rad_(N)(N\text{-}1)}}+\boldsymbol{A}^{\mathrm{ref_(N)(N\text{-}1)}})\boldsymbol{V}_{\mathrm{p_N\text{-}1}}+(\boldsymbol{A}^{\mathrm{radMPP_N}}+\boldsymbol{A}^{\mathrm{rad_NN}} +\boldsymbol{A}^{\mathrm{ref_NN}}+\boldsymbol{A}^{\mathrm{up_rad_NN}}+\boldsymbol{A}^{\mathrm{up_ref_NN}})\boldsymbol{V}_{\mathrm{p_N}}=\boldsymbol{0}, \quad (9)$$

where $\boldsymbol{A}^{*}$ is the Q × Q matrix, and the $\boldsymbol{V}_{*}$ is the Q × 1 matrix.

2.2 System matrix

Based on Eq. (8) and Eq. (9), the first and last row of the systematic matrix equation, considering the coupling of layers in CAA yields

$$\left[\boldsymbol{A}^{\mathrm{sur}}+\boldsymbol{A}^{\mathrm{radMPP_1}}+\boldsymbol{A}^{\mathrm{rad_11}}+\boldsymbol{A}^{\mathrm{ref_11}}\quad \boldsymbol{A}^{\mathrm{rad_12}}+\boldsymbol{A}^{\mathrm{ref_12}}\quad \cdots\quad \boldsymbol{0}\right]\left[\boldsymbol{V}_{\mathrm{p_1}}\right]=\left[\boldsymbol{A}^{\mathrm{inc}}\right], \quad (10)$$

and

$$\left[\boldsymbol{0}\quad \cdots\quad \boldsymbol{A}^{\mathrm{rad_(N)(N\text{-}1)}}+\boldsymbol{A}^{\mathrm{ref_(N)(N\text{-}1)}}\quad \boldsymbol{A}^{\mathrm{radMPP_N}}+\boldsymbol{A}^{\mathrm{rad_NN}}+\boldsymbol{A}^{\mathrm{ref_NN}}+\boldsymbol{A}^{\mathrm{up_rad_NN}}+\boldsymbol{A}^{\mathrm{up_ref_NN}}\right]\left[\boldsymbol{V}_{\mathrm{p_N}}\right]=\left[\boldsymbol{0}\right], \quad (11)$$

respectively.

Under a similar derivation, an equation that describes the *n*-th MPP (n = 2,3···N-1) of the CAA can be expressed as follows

$$(\boldsymbol{A}^{\mathrm{rad_(n)(n\text{-}1)}}+\boldsymbol{A}^{\mathrm{ref_(n)(n\text{-}1)}})\boldsymbol{V}_{\mathrm{p_n\text{-}1}}+(\boldsymbol{A}^{\mathrm{radMPP_n}}+\boldsymbol{A}^{\mathrm{rad_nn}}+\boldsymbol{A}^{\mathrm{ref_nn}} +\boldsymbol{A}^{\mathrm{up_rad_nn}}+\boldsymbol{A}^{\mathrm{up_ref_nn}})\boldsymbol{V}_{\mathrm{p_n}}+(\boldsymbol{A}^{\mathrm{rad_n(n+1)}}+\boldsymbol{A}^{\mathrm{ref_n(n+1)}})\boldsymbol{V}_{\mathrm{p_n+1}}=\boldsymbol{0}. \quad (12)$$

A more generalized systematic matrix for calculating the N-layer CAA is constructed by incorporating Eqs. (10-12). Any remaining entries in this generalized systematic matrix should be filled with zero matrices. For the sake of conciseness, the complete formulation of the generalized systematic matrix for the N-layer CAA is omitted here.

The unknown coefficient $\boldsymbol{V}_{\mathrm{p_n}}$ can be obtained after solving the generalized systematic matrix for the N-layer CAA. Thus, the sound pressures inside the duct and structure can be calculated. After obtaining the sound pressure field, the absorption coefficient of the CAA is calculated as follows [9]:

$$a=\frac{\rho_0 c_0\int_{S_{\mathrm{p_1}}}\mathrm{Re}\left(p_{\mathrm{a}}\cdot v_{\mathrm{p_1}}^{*}\right)ds}{W}, \quad (13)$$

where the asterisk denotes the complex conjugate.

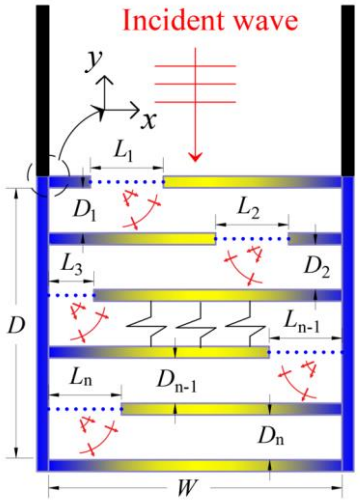

Figure 1. Two-dimensional schematic diagram of the CAA for theoretical modelling.

3. RESULTS AND DISCUSSION

To validate the proposed 2D theoretical model, the commercial software COMSOL Multiphysics and the finite element method (FEM) were used to calculate the absorption coefficients of the CAA. The predicted absorption coefficients for the two-layer coupled CAA are illustrated in. Fig. 2. The following structural parameters of the CAA were used: $W_1 = W_2 = 50$ mm, $D_1 = D_2 = 20$ mm. The diameter, thickness and porosity of the surface MPP are 1 mm, 1 mm, and 0.015. The diameter, thickness and porosity of the interior MPP are 0.15 mm, 1 mm, and

0.0123. As shown in Fig. 2, for the two-layer CAA calculated via the FEM, a near-total absorption peak appears at 600 Hz. The second peak occurs at 980 Hz. The outcome obtained by the proposed 2D model (solid line) is in good agreement with that calculated by the FEM (rhombus) for the two-layer CAA, both in terms of peak frequency and peak value. This demonstrates that the proposed 2D model accurately predicts the acoustic performance of CAA. The first peak is generated by the resonance of the right sub-resonator (star), while the second peak originates from the left sub-resonator (circle). Notably, a pronounced dip occurs at 780 Hz with an absorption value of approximately 0.86. This represents a significant enhancement compared to the case without the interior MPP (square), where the dip value is only 0.48.

To further investigate the enhancement mechanism induced by coupling effects, Fig. 3 presents the sound pressure and velocity distributions within the two-layer CAA at the first peak, dip, and second peak frequencies. As shown by the white arrows, at the dip frequency, a high acoustic velocity passes through the interior MPP, accompanied by high acoustic pressure in both left and right sub-resonators. This suggests that the superior sound absorption performance at the dip frequency arises from the synergistic effects of all MPPs. In contrast, at the peak frequencies, although only one sub-resonator dominates, the partial acoustic velocity through the interior MPP still contributes to a minor enhancement of the peak absorption value.

To further investigate the sound absorption mechanism and the role of the inserted MPPs in the proposed CAA, we conducted a modal analysis. Fig. 4 presents the modal amplitude ($|V_p|$) of particle velocity across each MPP interface in the two-layer CAA, as calculated by our theoretical model, focusing on the first peak (600 Hz), trough (780 Hz), and second peak (980 Hz). At the peak frequencies (Figs. 4a and 4c), while the dominant acoustic velocity occurs at the surface MPP, a non-negligible acoustic flow through the interior MPP is also observed, which can be absorbed by the interior MPP. In contrast, at the dip frequency (Fig. 4b), all MPPs exhibit significant acoustic velocity, further confirming that the enhanced sound absorption at this dip frequency stems from the collective contribution of all MPPs.

4. FLOW EFFECT ON THE CAA

Numerous efforts have been made to establish prediction formulas for the acoustic properties of orifices under various flow conditions. However, they have different assumptions for flow characteristics or do not consider the influence of shallow cavities behind the holes; thus, these formulae may forecast discrepant acoustic properties towards an orifice. To better understand the fluid dynamics when the flow passes over the proposed CAA, the flow patterns of the MPP (d = 1 mm) and four backed cavities with different cavity depths (2 mm and 6 mm) under grazing flow speeds of 34 m/s were investigated using the CFD method. In this study, the Reynolds averaged Navier–Stokes (RANS) simulations were applied to find the statistical average of the turbulent flow, and the shear stress transport (SST) k–ω turbulence model was utilized to account for the effects of turbulence on this averaged flow. The geometry of the computational model is shown in Fig. 5(a). The orifices and accompanying cavity were located on the underside of the duct. The cross-section of the main duct was 24 mm × 24 mm. The length of the upstream duct was set to 1000 mm, to generate a fully developed turbulent boundary layer in front of the orifice. The distance between the tested orifice and outlet (300 mm) was more than 50 times the orifice diameter. This ensured that any vorticity could be dissipated along this distance. The inlet of the duct was set as the mass-flow inlet boundary condition. A pressure-outlet boundary condition was imposed upon the duct outlet at standard atmospheric pressure (1 atm). The non-reflection boundary condition (NRBC) was applied to the inlet and outlet. The remaining walls of the main duct, orifice, and cavities were set as stationary and adiabatic walls, without any slip. Fig. 5(b) illustrates the vorticity distribution across the resonator surface. The consistent vorticity patterns observed at each surface orifice demonstrate that even under moderately high flow speeds (34 m/s), the hole spacing is sufficient to minimize inter-hole coupling effects. Notably, in the shallow-cavity configuration (left resonator), the injected flow through the surface MPP impinges on the second-layer MPP, effectively modulating its acoustic impedance through a mechanism analogous to bias flow. Conversely, in the deep-cavity configuration (right resonator), the injected flow dissipates before reaching the second MPP, thereby eliminating this interference.

Based on these observations for the absence of inter-hole coupling and backing cavity depths exceeding 10 mm, we adopt the flow-dependent MPP impedance model proposed by Li and Choy [10] in Eq. (9) to predict the acoustic liner's acoustic performance under grazing flow (Section 5).

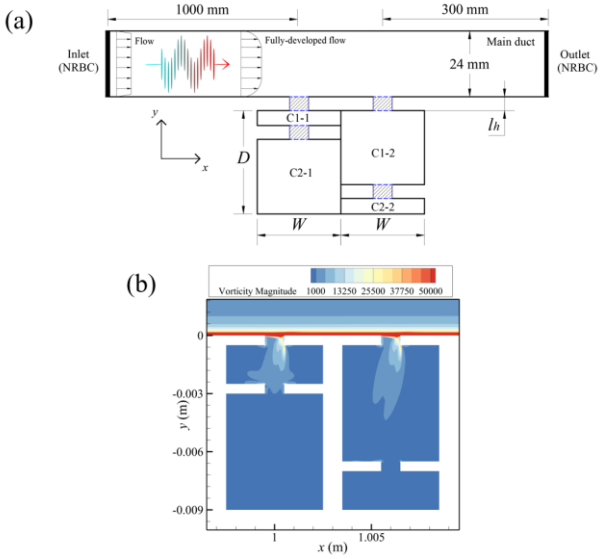

Figure 5. (a) Geometry of the computational model and (b) vorticity distribution.

5. EXPERIMENTAL INVESTIGATION

To test the sound absorption performance of the proposed acoustic liner and validate the proposed theoretical and numerical models under grazing flow, *TL* measurements of the acoustic liner consisting of four CAA were performed. Each CAA contains four layers. The following structural parameters of each CAA were used: $W = 100$ mm, $D_1 = D_2 = D_3 = D_4 = 20$ mm. The diameter, thickness and porosity of the surface MPP are 0.3 mm, 0.5 mm, and 0.022. The diameter, thickness and porosity of the interior MPPs are 0.5 mm, 0.5 mm, and 0.02. A photography of the test rig and tested acoustic liner are shown in Fig. 6(a). The experiment was conducted in a quiet mini-wind tunnel using a working section of dimensions 100 mm × 100 mm (cross-section) and 1.8 m (length). The first cut-on frequency of the duct was 1700 Hz, and the turbulence intensity of the fully developed grazing flow in the upstream sections was below 0.1%. The MPPs of the acoustic liner were fabricated from stainless steel via etching. Other components of the acoustic liner were 3D-printed. Two proposed acoustic liners were mounted on the two sides of the test section of the duct. Two pairs of B&K 1/2 in. condenser microphones (type no. 4187) were installed up- and down-stream of the tested absorber. The installments of four microphones are shown in Fig. 6(a) via the labels M1–4. The travelling wave components in the duct could be resolved by each pair of microphones. Using the approach of two independent sound sources at two positions to simulate physical anechoic termination, the *TL* of the acoustic liner was determined. The measured and predicted TL are present in Fig. 6(b). In general, the experimental results agree well with the predicted TL in terms of the tendency, under different flow speeds. Some discrepancy in peak values between experiments and prediction mainly results from the fabrication error of the 3D-printed model. As demonstrated in Fig. 6(b), the proposed acoustic liner achieves an average transmission loss of 18.92 dB across the 200-1700 Hz frequency range under static conditions (denoted by circles). When the flow speed increases to 25 m/s, the liner maintains an average transmission loss of 17.89 dB over the same bandwidth (square), representing only a 5.7% performance reduction. These experimental findings confirm that by localizing acoustic energy dissipation within embedded MPPs, the CAA significantly suppresses performance degradation caused by grazing-flow-induced aeroacoustic coupling. Our results provide new insights into the design of metamaterials for aero-noise control engineering and may promote the development of meta-liners for airflow applications.

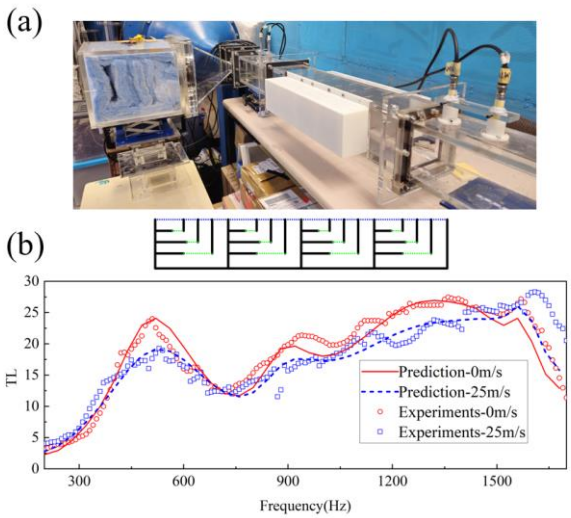

Figure 6. (a) photography of the test rig and tested acoustic liner and (c) TL obtained by prediction and experiments.

6. CONCLUSION

A coupled acoustic absorber (CAA) comprised inserted MPPs and shared cavities was proposed with broadband sound reduction under grazing flow. A two-dimensional model for predicting the acoustic performance of the CAA was proposed based on sound radiation theory in a rigid-walled duct. The sound absorption characteristics of the CAA was investigated via theoretical model and numerical model (finite element method). Consistent predicted results from both models manifested that the 2D theoretical model can accurately predict the acoustic performance of the CAA. In addition, the theoretical and numerical results revealed that the enhancement of the CAA's absorption troughs arises from the synergistic effects of all MPPs. Finally, experimental investigation was conducted and revealed that by localizing acoustic energy dissipation within embedded MPPs, the CAA significantly suppresses performance degradation caused by grazing-flow-induced aeroacoustic coupling. Our results provide new insights into the design of metamaterials for aero-noise control engineering and may promote the development of meta-liners for airflow applications.

ABSTRACT

Vegetal wools are highly porous materials made of vegetal fibres and bicomponent polymer fibres. But despite their high-level multifunctional properties they suffer from poor low-frequency acoustic absorption for thin panels. A solution to this problem can be found in metamaterial methods and in particular double porosity. By using perforated multi-layered hemp wool panels, very good results have been obtained.

This promising use of double porosity has highlighted the necessity to accurately model the acoustic behaviour of vegetal wools in order to optimise their low-frequency sound absorption properties. However, unlike more conventional materials, vegetal wools don't have calibrated fibres, which poses a stalemate this work aims at answering.

Vegetal fibres exhibit high radius polydispersity. Most studies use a mean radius for simulations, and more recent works considered composite methods and used two mean radii (for vegetal and polymeric fibres). This work investigates weighted averaging methods with the aim of improving the estimation of the acoustic absorption for vegetal wools having large radius distribution.

1. INTRODUCTION

From the growth of the plant from which the fibres come to the end of their life cycle, vegetal wools have many virtues that make them a very attractive insulation product for green buildings. These materials store atmospheric CO_2, have a low carbon footprint and reduced environmental impact [1–3]. They are hygroscopic, regulating humidity and temperature, contributing to the interior comfort of living spaces [4, 5], and offer good acoustic absorption thanks to their high porosity. Their main drawback is their low acoustic absorption at lower frequencies. To address this, it is first essential to accurately model their acoustic behaviour. Therefore, micro-macro modelling methods were investigated.

For this article, it seems relevant to use modelling methods to estimate static airflow resistivity (later referred as resistivity) from parameters such as porosity and fibre radii. Based on previous works [6, 7], which led to satisfactory results with monodisperse materials, the chosen formulas come from Tarnow's [8] and Umnova's [9] works.

However, vegetal wools are characterised by a large dimensional variability of their natural fibres [6]. Recent advances in the study of polydispersity in random fibrous materials demonstrated that optimised polydispersity can even lead to improved sound absorption at lower frequencies [10]. With this knowledge, this paper aims at investigating different analytical models for acoustic simulations taking these specificities into account.

To begin with, this paper introduce the materials involved in the study. Different vegetal wools, with different radius probability distributions, were experimented to in-

vestigate radius polydispersity as an optimisation method. To keep on, measurement protocols, methods, and analytical models used for this work are described. Eventually, measurement results on the radius probability distributions of the different wools are displayed. This is followed by analytical experiments to better understand how to implement materials with radius polydispersity in analytical models. As a conclusion, a promising path toward accurate estimation of airflow resistivity for these materials was found.

2. MATERIALS AND METHODS

2.1 Materials

For this work, the materials characterised are three vegetal wools : a wood wool (W), a hemp-flax wool (HF) and a wood-kenaf (WK) wool. The parameters used in the modelling of the resistivity, as well as the indirectly measured resistivity, are listed in Tab. 1.

Table 1: Characteristic parameters of the samples : mass proportion between vegetal and polymeric fibres, thickness (e), apparent density (ρ_a), porosity (ϕ) and resistivity (σ)

Material	W	HF	WK
Veg/pol	88/12	45/45/10	40/40/20
$\boldsymbol{e}$ (mm)	50	90	38
$\boldsymbol{\rho_a}$ $\left(kg \cdot m^{-3}\right)$	60	35	58
$\boldsymbol{\phi}$	0.96	0.98	0.96
$\boldsymbol{\sigma}$ $\left(N \cdot m^{-4} s\right)$	35000	3000	5500

2.2 Methods

2.2.1 *Measuring porosity and resistivity*

Porosity was estimated by weighing the samples and using known mass densities of the fibres. The airflow resistivity is obtained indirectly from measurements of an impedance tube with the 3 microphones methods originally developed by Iwase et al. [11] and adapted by Salissou and Panneton [12]. The cylindrical impedance tube used is the type I Acoustitube from Akustik Forschung, with a diameter of $100mm$. The analysis is done between $100Hz$ and $2000Hz$. Based on the work by Olny and Panneton [13, 14], we were able to indirectly estimate the resistivity with measures made on an impedance tube with the 3 microphones method [11].

2.2.2 *Radius distribution measurement*

To measure the radii of the fibres studied for this work, a Scanning Electronic Microscope (SEM) Hitachi TM3000 was used. Prior to their visualisation, the samples were metallised with a thin gold layer deposited in a plasma.

The images obtained are analysed on the software ImageJ, and after manual treatment the transversal profiles are measured. Vegetal fibres are not perfectly cylindrical, therefore an equivalent diameter is calculated by averaging the longest and shortest Ferret's diameters measurable [15, 16].

2.2.3 *Evaluation of the average radii*

Different ways of calculating an average fibre radius can be found in the literature. For this paper, four of them were selected.

- Piégay et al. [17] used a non weighted arithmetic average (NWA),
- Xue et al. [18] a non weighted quadratic average (NWQ).
- To predict the static viscous permeability of heterogeneous fibrous materials, Peyrega and Jeulin [19] preferred a volume weighted average (VW).
- For characteristic lengths, Tran et al. [10] chose an inverse volume weighted average (IVW).

The equations for these calculations are expressed in Eqn. (1) to (4). It is assumed in these calculations that the fibres all have an equal length L_f and are cylindrical. Therefore the volume and inverse volume weightings are simplified as square radius and square inverse radius weightings ($V_i \propto R_{f,i}^2$).

$$R_{f,NWQ} = \sqrt{\frac{1}{N_f}\sum_j R_{fj}^2} \tag{1}$$

$$R_{f,NWA} = \frac{1}{N_f}\sum_j R_{fj} \tag{2}$$

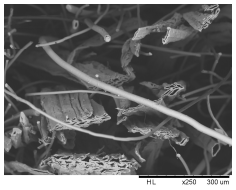
$$R_{f,VW} = \frac{\sum_j V_j R_{fj}}{\sum_j V_j} \approx \frac{\sum_j R_{fj}^3}{\sum_j R_{fj}^2} \tag{3}$$

$$R_{f,IVW} = \frac{\sum_j \frac{1}{V_j} R_{fj}}{\sum_j \frac{1}{V_j}} \approx \frac{\sum_j R_{fj}^{-1}}{\sum_j R_{fj}^{-2}} \tag{4}$$

2.2.4 *Estimation of airflow resistivity*

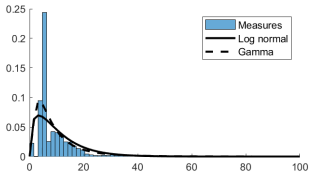
In order to evaluate the relationships presented in Eqn. (1) to (4), it was first decided to use the values obtained to determine the airflow resistivity of the materials, a key parameter in acoustic absorption modelling methods.

Two micro-macro modelling methods, proposing analytical relationships between a fibre radius value and characteristic pore network parameters, were selected for this work. These are the modelling approaches of Tarnow (Eqn. (5) for perpendicular incidence with random fibre arrangement) [8] and Umnova (Eqn. (6) for perpendicular incidence) [9] :



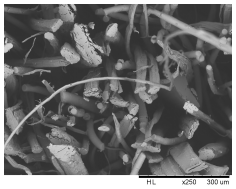
$$\sigma_{\perp} = 4\eta \frac{1-\phi}{R_f^2\left[0.64ln(1/(1-\phi)) - 0.737 + (1-\phi)\right]} \tag{5}$$

$$\sigma_{\perp} = \frac{16\eta}{R_f^2} \frac{(1-\phi)}{-2ln(1-\phi) - 2\phi - \phi^2} \tag{6}$$

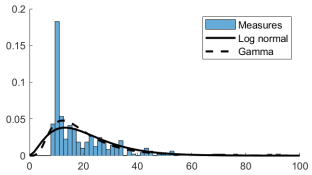


3. RESULTS

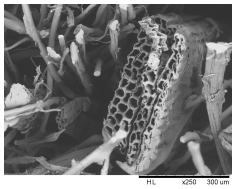
3.1 Measurements of fibre radius distributions



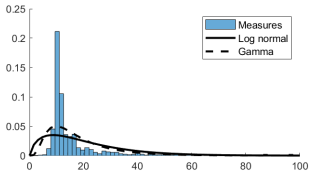
The images obtained with the SEM are displayed in Fig 1(a),(c) and (e). In Fig 1(b),(d) and (f) the resulting radius probability distributions calculated with the software ImageJ are presented.



(a) Wood wool x250



(b) Wood fibres radius distribution



(c) Kenaf wool x250

(d) Hemp-Flax fibres radius distribution

(e) Hemp-Flax wool x250

(f) Wood-Kenaf fibres radius distribution

Figure 1: Photos of wood, wood-kenaf and hemp-flax wools with the SEM, with measured radius probability distributions.

3.2 Average radii

These distributions allowed the calculation of average radii following the methods in Eqn. (1) to (4). They are presented in Tab. 2.

3.3 Using the radii in the calculations

Using the average radii found for the global distribution and this formula, we can compare the predicted resistivity with the values obtained via indirect (Kundt tube) measurements.

The four averaging methods of the global distributions were considered. The results are displayed with the experimental values in Fig 2. To estimate the accuracy of our new analytical results, the ratios for every method was calculated relatively to these characterisation values, as presented in Tab. 3.

4. CONCLUSION AND PERSPECTIVES

All three of the material's radius distributions showcase a peak between $5\mu m$ and $10\mu m$. This is due to the presence of the polymeric fibres. Although they represent a low mass proportion of the fibres used, between 10% and 20%, thanks to their lower mean radius, they can represent between 34% and 77% of the total measured fibres.

When calculating the different average radii, what can be observed is that these calculations show very contrasted results. This is easily explainable due to the quadratic and cubic exponents augmenting the part played by the highest radii in the results. In ascending order, we have radii obtained with Inverse Volume Weight IVW, for which the lowest radii are more impactful, then arithmetic average NWA which is linear, quadratic average NWQ, and volume weight average VW, with quadratic and cubic exponents. The contrast can vary from almost equal for poly-

Table 2: R_f calculated with different averaging methods : Non Weighted Quadratic (NWQ), Non Weighted arithmetic (NWA), Volume Weighted (VW), Inverse Volume Weighted (IVW)

$R_f(\mu m)$		W	HF	WK

	VW	8.6	11.2	26.7
	IVW	5.4	10.1	10.8

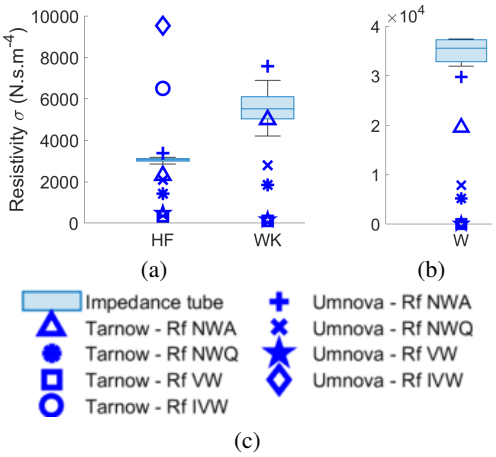

Figure 2: Predicted resistivity versus indirect measurements for the hemp-flax wool (HF), wood-kenaf wool (WK), and wood wool (W)

meric fibres, that have narrow distributions, to thirty-six times between the VW and IVW average radii of the wood wool.

We note that the two averaging methods producing the highest mean radii, NWQ and VW, systematically lead to a underestimation of the resistivity, whereas IVW, which gives the lowest mean radii, always leads to a great overestimation. In our case of our three materials made of mixed vegetal and polymeric fibres, the averaging method giving

Table 3: Resistivity relative error between measures and analytical estimations for the different averaging methods : Non Weighted Arithmetic (NWA), Non Weighted Quadratic (NWQ), Volume Weighted (VW), Inverse Volume Weighted (IVW)

		Resistivity relative error (%)			
		W	HF	WK	Mean
Tarnow	NWA	-44	-23	-9	-25
	NWQ	-85	-52	-66	-68
	VW	-99.9	-89	-98	-95
	IVW	+102	+117	+277	+166
Umnova	NWA	-15	+12	+38	+11
	NWQ	-77	-30	-49	-52
	VW	-99.8	-84	-97	-94
	IVW	+208	+219	+472	+300

the least error for the calculation of resistivity therefore seems to be a non weighted arithmetic average NWA. The mean error also seems to favour Umnova's formula for the calculation of resistivity. Further investigations will be lead in order to verify the current conclusion. Other vegetal wools will be studied to widen the database and have more statistically relevant results. Also, the biggest fibres measured may be wrongfully counted the same way as the others, because of the equal fibre length hypothesis used for this work. The widest fibres are, in fact, usually not as long as the others, and may need to be removed from the calculations. This would lead to a more precise use of the volume weighting in the calculation of resistivity, even though this method is not recommended. Another improvement could be brought with the use of a composite method [6], considering two or three parallel materials made of the types of fibres found in the wools, and in fine combining the results of the calculations.

The next step will then be to replicate this work for the modelling of sound absorption. Eventually, with knowledge on the fibre radius distributions for different vegetal fibres and having suitable analytical modelling methods, it will be possible to optimise the performances of a vegetal wool panel through its fibre radius distribution.

5. FUNDING

This research was funded, in whole or in part, by l'Agence Nationale de la Recherche (ANR), project ANR-23-CE22-0012.

ABSTRACT

Hemp wools are bio-based insulating materials whose applications in green buildings are limited due to their flammable and flame-spreading nature. To overcome this problem while respecting their nature, an environmentally- friendly fire-retardant based on a mix of phosphorus and urea products has been identified. However, experimental characterizations using an impedance tube have shown that this treatment has an impact on the acoustic performance of vegetal wools and therefore on the microstructure of the materials. Until now, this type of impact has not really been studied in the literature. To better understand the effects of fire retardant treatments on the porous and fibrous structure characteristics of hemp wool samples, parameters related to the effects of visco-thermal dissipation such as porosity and airflow resistivity were determined and analyzed. Then, their evolution before and after treatment was evaluated. On the basis of these data, the acoustic absorption of hemp wools could be simulated using equivalent fluid modeling methods (JCAL) and compared with the experimental results for validation. In addition, the variation in fiber radii due to the fire-retardant treatment can be assessed indirectly using micro-macro homogenization methods.

1. INTRODUCTION

On a global scale, according to one of the latest IPCC reports [1], the building field remains one of the main emitters of greenhouse gases (GHG) contributing to climate change. In Europe, with three quarters of the buildings built before 1980, often without thermal regulations [2], this sector has a decisive role to play in achieving European climate objectives. The building sector is also a key element in the fight against noise pollution. According to the EEA [3], in 2019, at least 20% of the European population was exposed to noise levels considered harmful to human health. In this context, acoustic and thermal insulation of both existing and new buildings is therefore a major issue in Europe as on a global scale. In order to respond to these problems, bio-based materials, such as vegetal wools, appear to be the type of insulation that offers the most climate-friendly solution [4, 5]. Indeed, their multifunctional performances, which are directly related to their fibrous and porous microstructure, and their hygroscopic nature contribute greatly to the improvement of acoustic and hygrothermal interior comfort. In addition, they contribute significantly to the storage of atmospheric carbon dioxide [6]. Nevertheless, a number of obstacles still limit their use, such as their flammable and flame-spreading nature [7]. So, to be used in public buildings or as apparent panels such as acoustic baffle or suspended ceiling tile, it is necessary to apply a fireproof treatment. Recent works [8] offer promising ways for

treatment with renewable bio-based compounds which are environmentally friendly and compatible with bio-based materials. However, there are very few studies in the literature concerning the impact of such flame retardants on vegetal wools [9]. As a first step, it would seem appropriate to quantify their impact on the acoustic properties at the wool scale. Then, it is therefore essential to better understand the effect of the selected flame retardant on the microstructure of materials. Indeed, acoustic properties, such as the sound absorption of vegetal wools, are directly related to the diameter of the fibers [10].

2. MATERIALS AND METHODS

2.1 Materials

The materials are hemp wools manufactured using a thermobonding process. A reference wool was manufactured without flame retardant treatment. For the other wools, the hemp fibers were treated before manufacture by a fireproof treatment consisting of a mixture of phytic acid and urea. This treatment is applied by spraying with two different formulations of fireproof treatment concentrations, 3% and 5% . An example of treated and untreated samples is shown in Fig. 1. The characteristics of the treated and untreated samples are referenced in Tab. 1. The samples used have thicknesses (e) and apparent densities (ρ_a) of the same order of magnitude in order to compare the sound absorption properties of the samples.

Figure 1. Reference sample on the left, treated sample on the right

Table 1. Characteristics of treated and untreated samples

Sample	Treatment (%)	e (mm)	ρ_a (kg.m-3)
Ref	-	34	63

T5%	5	35	61

2.2 Methods

2.2.1 Sound absorption

Characterization of sound absorption (α) was carried out using an impedance tube in accordance with standard ISO 10534-2 [11] at normal incidence. The characterization method is based on the use of the 3-microphones method originally developed by Iwase et al. [12] and adapted by Salissou and Panneton [13]. The diameter of the impedance tube (Akustik Forschung - AcoustiTube AFD 1000/1200) used in this work is 100 mm, allowing measurements over a frequency range from 100 to 2000 Hz.

2.2.2 Sound absorption modeling method

The JCAL approach based on the successive works of Johnson [14], Champoux and Allard [15], Lafarge [16] is used to simulate the acoustic performance of the treated and untreated materials. This is a proven semi-phenomenological approach for assessing the effect of the fireproofing treatment on pore geometry. This model is based on the use of 6 input parameters: porosity (ϕ), airflow resistivity (σ), tortuosity (α_∞), viscous characteristic length (Λ), thermal characteristic length (Λ') and static thermal permeability (k_0'). These parameters are characterized by indirect analytical methods presented in Panneton and Olny [17] and Olny and Panneton [18] as a function of the intrinsic parameters, dynamic density and bulk modulus, obtained from impedance tube measurements using the 3-microphone method.

2.2.3 Fiber size modeling method

As well as assessing the impact of fireproofing treatments on the pore network, it would also seem appropriate to evaluate their impact on fiber size. Indeed, the sound absorption properties of vegetal wools are directly related to the size of the fibers [10]. It is therefore possible to use

Tarnow's homogenization method [19], which has already been validated for hemp wools [20]. This method provides analytical relationships between an equivalent fiber radius value (R_f) and acoustic parameters such as porosity (ϕ) and airflow resistivity (σ). The relationship used in this paper, Eqn. (1), corresponds to the configuration of a random fiber distribution and a flow perpendicular to the longitudinal axis of the fibers.

$$R_f = \sqrt{4\mu \frac{(1-\phi)}{\sigma(0.640 \ln(\frac{1}{1-\phi}) - 0.737 + (1-\phi)}} \quad (1)$$

With $\mu = 1.8.10^{-5} Pa.s$ the dynamic viscosity of air.

3. RESULTS AND ANALYSIS

3.1 Sound absorption

As shown in Fig. 2, the experimental results obtained using the impedance tube clearly show a negative impact of fire retardant treatments on the sound absorption coefficient of hemp wool. In addition, there is a correlation between the percentage content of this treatment and the drop in the absorption level and the shift towards higher frequencies.

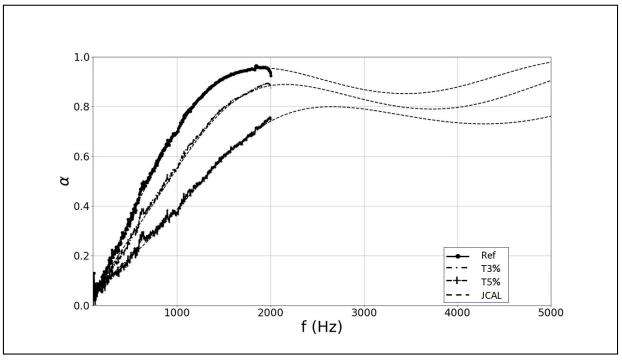

Figure 2. Sound absorption coefficient determined by experimental characterisation and JCAL modelling for reference plant wools, treated at 3% and 5%.

Fig. 2 also illustrates the good correlation between the experimental results and the JCAL modeling. Now, to understand the drop in sound absorption performance, it would seem appropriate to assess the impact of the treatment on the porosity and airflow resistivity of the materials, which are key parameters of the pore network.

3.2 Porosity

There is no significant impact of the fireproof treatment on the porosity of hemp wool. In fact, the porosity of the reference wool was evaluated at 95.8% and at 96.2% for treated wools. This minor difference cannot explain the drop in the sound absorption coefficient observed in Fig. 2. So, it is therefore important to assess the impact of treatment on airflow resistivity.

3.3 Airflow resistivity

The Fig. 3 shows the evolution of airflow resistivity values as a function of treatment concentration. A significant drop can be seen with values of 6257 $Nm^{-4}s$ for the reference hemp wool, 5150 $Nm^{-4}s$ for the wool treated with 3% and 3700 $Nm^{-4}s$ for the wool treated with 5%. Based on this result, we can expect that the fireproof treatment has a coating effect on the fibers, leading to a weakening of the airflow resistivity of the materials.

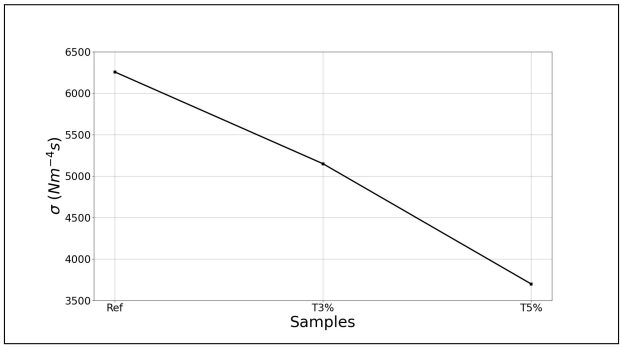

Figure 3. Airflow resistivity for reference hemp wool and treated hemp wools at 3% and 5%.

3.4 Fiber radius

From the above porosity (ϕ) and resistivity (σ) data, it is possible to estimate an effective fiber radius value using Eqn. (1) for each type of treated and untreated hemp wool. The values obtained are indicated in the Tab. 1. The value obtained for untreated hemp wool corresponds to the radius range generally determined from scanning electron microscope image analysis [10]. First of all, we can see higher values for treated wools. This can be explained by a coating effect on the fibers due to the use of the fireproof treatment. In addition, an increase in the value of the effective fiber radii is observed as a function of the concentration of the treatment.

Table 2. Effective fiber radii estimated using the Tarnow modelling method [19]

Sample	$R_f(\mu m)$
Ref	15.5
T3%	16.0
T5%	18.9

4. CONCLUSION

The identification of an effective fireproof treatment that respects the bio-based nature of hemp wool has opened up new prospects for the use of bio-based insulation in green buildings. However, the tests carried out using an impedance tube as part of this work show that the more concentrated the treatment is, the greater the impact both on the level of sound absorption of the wools and on the frequency range, with a shift towards high frequencies. It is shown that the treatment has a minor impact on the porosity of the wools. On the other hand, it has a much more significant effect on airflow resistivity, which helps to explain the impact on acoustic absorption. Tarnow's homogenization method was used to assess the effect of the fireproof treatment on fiber size. A correlation was observed between the concentration of the treatment and the increase in the effective radius of the fibers. This can be explained by a coating effect of the treatment on the fibers. In order to limit these impacts on sound absorption performance, the density of the wools could be considered as a lever for optimization. In addition, it may be appropriate to assess the behavior of materials by applying the treatment by spraying the surface instead of treating all the fibers.

5. FUNDING

This project has received funding from the European Union's Horizon 2020 research and innovation programme under the Marie Slkodowska-Curie COFUND grant agreement No 101034248 and from the French Agence Nationale de la Recherche (ANR) under grant ANR-23- CE22–0012 (Project BIOMETA).

ABSTRACT

Moving towards global zero-emissions in transport and energy supply industries would enable to achieve a quieter, cleaner and healthier urban environment, more resilient to climate-change. The World Health Organisation has classified traffic noise as the second most important cause of ill health in Western Europe, behind only air pollution caused by very fine particulate matter. A leverage effect would be to enhance the agglomeration of the released ultrafine and fine particles into larger particles easily filtered out by classic clean air solutions. However, a major, still unsolved, challenge is to do it without requiring intense sound fields or high-drag flow mixing devices prone to increase flow-particle or particle-particle relative motion. Acoustic rainbow trapping filters (RTFs) have been shown to provide solutions for wideband low-frequency sound dissipation. In this work, we aim at exploiting the effective slow sound – small wavelength properties of acoustic metamaterials traversed by a low-speed flow to provoke mixing and nucleation of the convected ultrafine particles. We will explore conditions on the physical parameters of the RTFs and the seeded particles to produce simultaneous sound dissipation and particle agglomeration. The results open up multi-functional objectives to achieve simultaneous aerosol agglomeration, sound attenuation and low drag performance.

1. INTRODUCTION

Seven million persons in the world are estimated of being killed by air pollution every year [1]. The release of airborne particulate matters (PM) implies a range of adverse health effects. In particular, the growing concentration of fine particles of diameter lower than 2.5 µm per cubic meter in average per year [2] has a significant economic impact on public health system, and additional efforts have to be made to deeper cuts in emission.

Indoor concentration of particles originating inside or outside buildings relies on particle removal by ventilation filtering systems, that depends strongly on the particle sizes. There is a critical gap in the intermediate size range (0.2-1 µm) where classical filters present a pronounced dip for efficiency [3]. Agglomeration can force the smallest particles to aggregate and the filter can then efficiently capture the largest size components. Numerous applications have been tackled using preconditioning of PM agglomeration by generating ultrasonic standing wave fields. They have shown good performance but need very high levels of acoustic intensity to be efficient [4]. Electrostatic particle agglomerators [5] have also shown a great efficiency, but they also require significant electrical energy consumption to be performant.

In this work we propose a new approach based on the properties of acoustic metamaterials. In particular, we will make use of the "slow sound" generation when acoustic waves propagate in a ducted flow surrounded by a

metamuffler [6-9]. If the effective velocity of the incoming sound wave is progressively reduced to zero, sound waves can be eventually trapped in the meta-structure and the particles suspended in the fluid will oscillate and gradually should agglomerate and increase their sizes. The acoustic performance of the metasilencer is presented in Sec. 2, followed by fundamentals of particle agglomeration in Sec. 3. The simulated results will be analysed in Sec. 4 and we will finish with conclusions and some lines for future work in the last section.

2. ACOUSTICAL MODELLING

2.1 Rainbow trapping filters

Rainbow trapping filters (RTF) are composed of a set of outer cavities with increasing depths that are distributed between the inlet at $x=-L$ towards the outlet at $x=0$, as illustrated in Figure 1. One assumes that such acoustic metamufflers are axisymmetric cylindrical of radius R and length L. Progressive increase of the cavity depths ensures impedance matching and low reflection. It also provides axial variation of the wall impedance, resulting in slow sound and trapping of the incident wave.

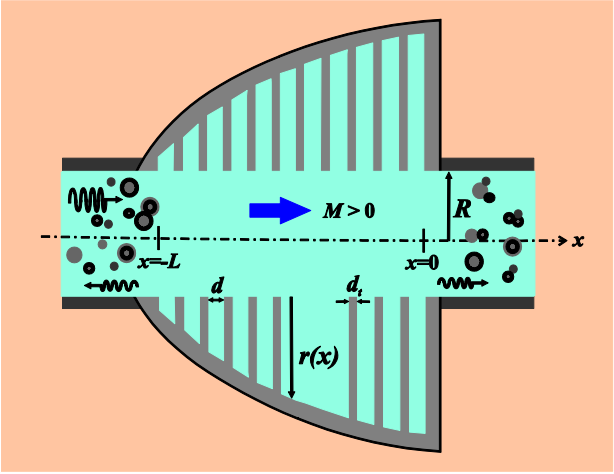

Figure 1. Sketch of a rib-designed rainbow trapping filter traversed by a low-speed flow of grazing Mach number M with an acoustic incident wave travelling along the flow.

A suitable choice of the cavity widths, that can be obtained from optimization of the total dissipation, enables to monitors the amount of visco-thermal losses required to fully dissipate the incident energy trapped within the RTFs.

An RTF with high acoustic performance is characterized by high broadband dissipation, minute reflection and transmission. These properties should be robust when traversed by a low-speed flow. Moreover, the excess friction factor should also be limited, but this aerodynamic constraint will not be considered in the current study. An uncommon design, but with high societal and health impact, is to develop acoustic RTFs that provoke the agglomeration of fine particles into coarser ones that can be readily filtered out by low pressure drop standard filters. The conditions required for these two functionalities will be simulated from transfer matrix modelling for the acoustic part, and from one-dimensional particle transport under drag viscous force for the agglomeration process.

2.2 Transfer matrix modelling

2.2.1 No-flow case

The Transfer Matrix Method (TMM) has been used for the analysis of the widely-opened muffler considering that this device is composed of a set of ring sections separated by air cavities and distributed over an overall length L along the axial dimension. The radii of the air cavities in the fully-opened silencer progressively increase from 0 to R following an expanding power law from the inlet situated at $x=-L$ towards the outlet at $x=0$. Assuming plane wave propagation, the local side-branch volume admittance at $x=x_i$ is given by $Y_{\text{cav},i}=S_{\text{cav}}y(x_i)/Z_0$, with $y(x_i)$ given by Eq. (4) in [6], $S_{\text{cav}}=2\pi Rd$ the cavities entrance area and d their width. Applying continuity of the acoustic pressure and acoustic flow rate across the i^{th} cavity-ring unit leads to the relationship, $[p_i\ u_i]^{\text{T}}=\mathbf{T}_i[p_{i+1}\ u_{i+1}]^{\text{T}}$, between the pressure and volume velocity fields at the input interface $[p_i\ u_i]^{\text{T}}$ and those at the output interface $[p_{i+1}\ u_{i+1}]^{\text{T}}$, with $\mathbf{T}_i$ the associated transfer matrix given by

$$\mathbf{T}_i=\begin{bmatrix}\cos(k_0d) & \mathrm{j}\dfrac{Z_0}{S}\sin(k_0d)\\ \mathrm{j}\dfrac{S}{Z_0}\sin(k_0d) & \cos(k_0d)\end{bmatrix}\times \begin{bmatrix}\cos(k_0d_t) & \mathrm{j}\dfrac{Z_0}{S}\sin(k_0d_t)\\ \mathrm{j}\dfrac{S}{Z_0}\sin(k_0d_t) & \cos(k_0d_t)\end{bmatrix}\times\begin{bmatrix}1 & 0\\ Y_{\text{cav},i} & 1\end{bmatrix} \tag{1}$$

The overall transfer matrix $\mathbf{T}$ between the inlet and the outlet satisfies $[p_1\ u_1]^{\mathrm{T}} = \mathbf{T}[p_{N+1}\ u_{N+1}]^{\mathrm{T}}$ and is expressed as the product of the transfer matrices, $\mathbf{T} = \prod_{i=1}^{N} \mathbf{T}_i = \begin{bmatrix} T_{11} & T_{12} \\ T_{21} & T_{22} \end{bmatrix}$. The expressions for the reflection and transmission coefficients are given by

$$\begin{cases} r = \dfrac{(T_{11} + z_0 T_{12}) - (T_{21} + z_0 T_{22})}{(T_{11} + z_0 T_{12}) + (T_{21} + z_0 T_{22})} \\ t = \dfrac{1 + r}{T_{11} + z_0 T_{12}} \end{cases}. \tag{2}$$

with $z_0 = S/Z_0$ and $S = \pi R^2$. The Johnson-Champoux-Allard-Lafarge model of visco-thermal losses inside the cavities has been used. The power dissipated by the ABH then reads $\eta = 1 - |r|^2 - |t|^2 = \alpha - \tau$ with α the absorption coefficient and τ the transmission coefficient. The transmission loss (TL) is defined as $\mathrm{TL(dB)} = -10\log_{10}(\tau)$.

2.2.2 Low-speed flow effects

The transfer matrix given by Eq. (1) for each cavity cell is extended to account for the convective and dissipative effects of the mean flow on the cell duct sections as well as for the grazing flow effect on the input impedance of the side-branch cavity [10]. It leads to the transfer matrix [11]

$$\widetilde{\mathbf{T}}_L = \mathrm{e}^{-\mathrm{j}M\tilde{k}L} \begin{bmatrix} \cos(\tilde{k}L) & \mathrm{j}\dfrac{Z_0}{S}\sin(\tilde{k}L) \\ \mathrm{j}\dfrac{S}{Z_0}\sin(\tilde{k}L) & \cos(\tilde{k}L) \end{bmatrix}, \tag{3}$$

for a section of length L traversed by a flow at Mach number $M = U/c_0$ with U the mean flow velocity. The duct wavenumber reads $\tilde{k} = (k_0' - \mathrm{j}FM/4R)/(1 - M^2)$ in which k_0' accounts for visco-thermal losses in the duct and $FM/4R$ for the dispersion induced by the turbulent flow, $F = 0.0072 + 0.612\,\mathrm{Re}^{-0.35}$ ($\mathrm{Re} < 4.10^5$) being the Froude's friction factor and $\mathrm{Re} = 2UR\rho_0/\eta$ the ducted flow Reynolds number. Eq. (3) generalizes the two first transfer matrices related in Eq. (1) to sections of length $L = d$ and d_t respectively. Coupling between the ducted flow and the *i*th sidebranch cavity is described by the transfer matrix [11]

$$\widetilde{\mathbf{T}}_{\mathrm{cav},i} = \frac{1}{1 + 2M\widetilde{Y}_{\mathrm{cav},i} z_0^{-1}} \times \begin{bmatrix} 1 + M\widetilde{Y}_{\mathrm{cav},i} z_0^{-1} & M^2 \widetilde{Y}_{\mathrm{cav},i}^2 z_0^{-2} \\ \widetilde{Y}_{\mathrm{cav},i} & 1 + M\widetilde{Y}_{\mathrm{cav},i} z_0^{-1} \end{bmatrix}, \tag{4}$$

so that $\mathbf{T}_i$ in Eq. (1) is replaced by $\widetilde{\mathbf{T}}_i = \widetilde{\mathbf{T}}_d \widetilde{\mathbf{T}}_{d_t} \widetilde{\mathbf{T}}_{\mathrm{cav},i}$. $\widetilde{Y}_{\mathrm{cav},i}$ accounts for the effects of grazing flow on the *i*th cavity input impedance. It can be expressed as [12]

$$\widetilde{Y}_{\mathrm{cav},i} = \frac{1 - M_c H(k_c s)}{Y_{\mathrm{cav},i}^{-1} - 2\dfrac{Z_0}{S_{\mathrm{cav}}} \dfrac{k_0 d}{\pi} \left(1 + \dfrac{\pi d}{4R_i}\right) \dfrac{H(k_c s)}{k_c s}}, \tag{5}$$

in terms of $H(x) = J_0(x)(J_0(x) - \mathrm{j}J_1(x))^{-1}$, $k_c = \omega/U_c$ being the convective wavenumber and $M_c = U_c/c_0$ the convective Mach number with $U_c \approx 0.23\,U$, $R_i = \sqrt{dr(x_i)/\pi}$ and $s = d/2$. The Bessel function terms in H account for the effect of vorticity shed from the cavity upstream edge. Note that Eq. (5) has been derived from linearized perturbation theory [12] assuming a low Mach number flow ($M < 0.3$) and a negligible mean shear across the cavity slit, thereby ruling out any shear layer instability effects.

3. PARTICLE AGGLOMERATION MODELLING

We consider a one-dimensional flow of mean velocity V_a along which propagates an acoustic wave that produces fluid oscillations given by $V_{ac}\sin(k_x x - \omega t)$, so that the total flow velocity reads

$$v_f(x,t) = V_a - V_{ac}\sin(k_x x - \omega t), \tag{6}$$

with $k_x = \omega/c_x$ the acoustic wavenumber and c_x the axial phase speed of the acoustic wave. Assuming that the particle density ρ_p is much greater than the fluid density ρ_0, the effects of inertial and added-mass forces are ignored and only the viscous drag force F_d holds. The equation for particle velocity v_p then reads [13]

$$\frac{dv_p}{dt} = F_d = \frac{1}{St}(v_f - v_p), \tag{7}$$

with $St = \dfrac{\rho_p \omega D_p^2}{18\eta}$ the Stokes number. D_p is the particle diameter. This equation is valid considering a small Stokes number, $St << 1$, meaning that the particles diameter should be small. The condition is achieved for fine ($D_p \leq 2.5\,\mu\text{m}$) and ultrafine ($D_p \leq 0.1\,\mu\text{m}$) particles. It is also required that the particle Reynolds number, $Re_p = \dfrac{2R_p\rho_0|v_f - v_p|}{\eta} \leq 2$. Eq. (7) can then be written in the form $dv_p/dt = (1/t_0)(v_f - v_p)$ with $t_0 = \dfrac{\rho_p D_p^2}{18\eta}$ the particle response time. We can also make the formulation in a moving frame of reference with the phase speed of the acoustic wave c, and in dimensionless form in the position and time by setting $X = kx_p$ and $\tau = \omega t$ [13, 14]. One gets

$$\frac{\mathrm{d}^2X}{\mathrm{d}\tau^2} + \frac{1}{St}\frac{\mathrm{d}X}{\mathrm{d}\tau} + \frac{U_{ac}}{St}\sin(X) = \frac{U_a - 1}{St}, \qquad (8)$$

with $U_a = V_a/c_x$ and $U_{ac} = V_{ac}/c_x$ the dimensionless acoustic and flow velocities. A change of variables can be done such as $\tau' = \tau\sqrt{U_{ac}/St}$, leading to the following equation,

$$\frac{\mathrm{d}^2X}{\mathrm{d}\tau'^2} + \alpha\frac{\mathrm{d}X}{\mathrm{d}\tau'} + \sin(X) = \beta, \qquad (9)$$

with $\alpha = 1/\sqrt{U_{ac}St}$ and $\beta = (U_a - 1)/U_a$. These two parameters control particle agglomeration. The second-order differential equation, Eq. (9), governing the transport of particles under a viscous drag force is solved by a finite-difference Runge-Kutta single-step scheme [15].

4. SIMULATION RESULTS

4.1 Acoustic performance

The acoustical performance of a RTF whose total dissipation has been optimized in plane wave regime [6] are now determined from the transfer matrix formulation presented in Sec. 2.2. It corresponds to a cylindrical rib-designed silencer of radius $R = 0.047\,\text{m}$ and length $L = 0.15\,\text{m}$, comprising a set of $N = 20$ annular cavities of axial width $d = 0.0035\,\text{m}$ separated by ring walls of thickness $d_t = 0.004\,\text{m}$, leading to a wall porosity $\sigma = d/(d + d_t) = 47\,\%$. The optimal rate of increase of the cavity depths is found to be $m = 1.8$. Figure 2 presents the simulated results for the dissipation, reflection and transmission loss power spectra up to the duct cut-on frequency 2142 Hz.

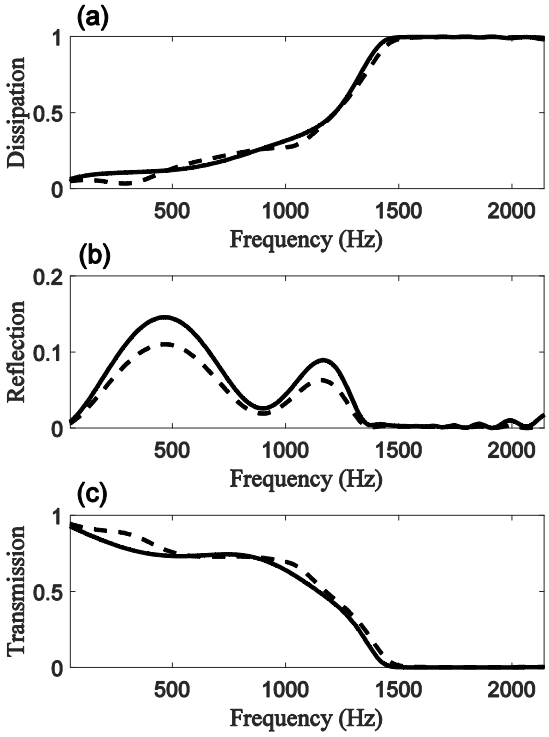

Figure 2. Dissipation (a), reflection (b) and transmission (c) coefficients of a rainbow trapping silencer in the no-flow case (plain) and when traversed by a low-speed grazing flow (dashed) with bulk velocity 20 m.s^{-1}.

Such optimized RTF silencer achieves near-unit dissipation as from 1500 Hz up to the duct cut-on frequency, as seen from Fig. 2(a). The optimization process led to cavity widths with a sufficient amount of visco-thermal losses so that the activated RTF cavity resonances are able to merge and fully dissipate the incident energy over this broad bandwidth. It is accompanied by near-zero reflection that stays below 0.1% over this efficiency range [Fig. 2(b)]. This is caused by the progressive increase of the cavity depths that ensures excellent impedance matching above 1500

Hz. The high dissipative performance result in a minute transmission coefficient above 1500 Hz [Fig. 2(c)]. Figure 3 shows that it translates into high TL values that stays above 27 dB as from 1500 Hz and with a maximum value of 32dB at 1700 Hz. The simulation performance of RTF silencers by the transfer matrix method has been validated against finite element simulations and impedance tube measurements in the no-flow case [6] and against wind-tunnel measurements when traversed by a low-speed flow [10]. The influence of a grazing flow on the acoustical performance of the optimized RTF silencer is also assessed in Figs. 2 and 3 assuming a low-speed bulk velocity of 20 m.s^{-1} (related to a Mach number of 0.06).

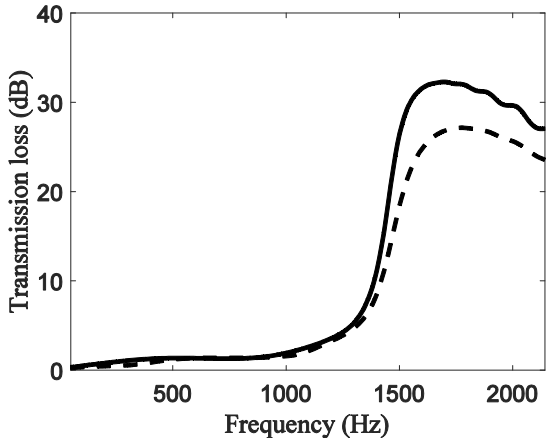

Figure 3. Transmission loss (dB) spectra of a rainbow trapping silencer in the no-flow case (plain) and when traversed by a low-speed grazing flow (dashed) with bulk velocity 20 m.s^{-1}.

As seen in Fig. 1, downstream propagation conditions (DPC) hold in which both the incident wave and the flow travel along the same direction from the inlet to the outlet of the silencer. Such low speed flows produce small effects on the acoustical performance, as seen in Fig. 2. From Fig. 2(a), one observes a moderate upshift (by 40 Hz) of the dissipation spectrum with the near-unit values above 1500 Hz hardly affected by the low-speed flow. The flow influence is mostly noticeable in Fig. 3 with a similar upshift by 40 Hz of the TL bump, but with a decrease by 5 dB of the maximum TL value. This is caused by a decrease of the wall-cavity reactance induced by the flow under DPC as the flow speed increases. A second flow effect is the increase of the wall-cavity resistance under DPC with the flow Mach number. Therefore, the cavity resonances activated over the RTF efficiency bandwidth become slightly over-damped due to the flow effect. This limits the ability of the sound wave to enter the wall cavities and results in a higher transmission and a lower TL. Note that the TL is very sensitive to small amounts of excess damping. Figure 2(b) shows that the impedance matching and reflection properties are weakly modified by the flow.

Of interest is to examine the axial variation of the acoustic velocity within the RTF at different frequencies in plane wave regime: out of the RTF efficiency range (600 Hz), at the onset (1400 Hz) and within (1800 Hz) the RTF high performance bandwidth. The results simulated by the transfer matrix model are illustrated in Fig. 4 with and without flow.

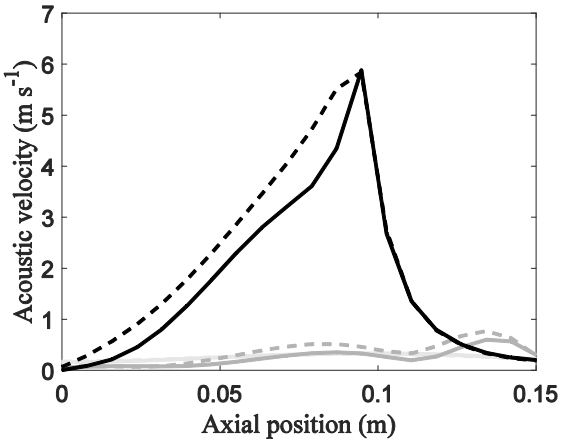

Figure 4. Axial variation of the acoustic velocity within a rainbow trapping filter at 600 Hz (light grey), 1400 Hz (grey) and 1800 Hz (black) in the no-flow case (plain) and when traversed by a low-speed grazing flow (dashed) with bulk velocity 20 m.s^{-1}.

At 600 Hz, the acoustic velocity weakly varies around 0.2 m.s^{-1} (132 dB) along the RTF which is rather inefficient at this frequency. At 1400 Hz, the deepest cavity is about to be activated. Therefore, Fig. 4 shows a slight bump of acoustic velocity around 0.6 m.s^{-1} towards the RTF outlet. At 1800 Hz, the twelfth acoustic cavity (numbered from one to twenty from the inlet to the outlet) is resonant. It results in a significant peak of acoustic velocity at its axial position with a steep (resp. smooth) decay towards the downstream (resp. upstream) cavities. The local rate of increase of the downstream

cavities is smaller than that of the upstream cavities, resulting in a greater density of the downstream resonances (with respect to the upstream resonances). The downstream cavities above order 12 are thus partially activated and also contribute to the dissipation of incident energy. This explains the steep decay of acoustic velocity above these cavities. Converting the acoustic velocity into sound pressure levels (SPLs) requires knowledge of the sound speed which, as seen in Sec. 4.2, varies within the RTF due to slow sound effects. The axial variations of the acoustic velocity in Fig. 4 are not drastically modified by the presence of a low-speed flow. The reactance decrease induced by the flow excites cavities with slightly higher resonance frequencies, e.g. the shallower cavities. This results in higher acoustic velocity for the upstream cavities.

4.2 Slow sound effective properties

Calculations of the axial phase speed $c_x(\omega)$ are achieved from analytical expression of the axial wavenumber $k_x(\omega)$ that appears in the linearized momentum conservation equation [6] that governs the propagation of a plane wave within a RTF with gradual axial variation of the wall impedance along the axial direction. It reads

$$\frac{\mathrm{d}^2 p}{\mathrm{d}x^2} + k_x^2 p = 0\,, \tag{10}$$

with

$$k_x = \frac{\omega}{c_x} = k_0\left[1 - j\frac{y(x)}{k_0 R}\right]^{1/2}, \tag{11}$$

and $y(x)$,defined in Sec. 2.2.1, the specific wall admittance associated to cylindrical cavities of axially increasing depth $r(x) = R\left(1-(-x)^m / L^m\right),\ m>0$.

Axial variations of the phase speed for the sound wave travelling through the RTF is shown in Fig. 5 for various frequencies out, at the onset and within the silencer efficiency range, e.g. at 600 Hz, 1400 Hz and 1800 Hz, respectively. As expected, whatever the frequencies, the axial phase speeds at the inlet of the RTF are equal to the sound speed c_0 of a plane wave travelling in a rigid duct. Within the RTF, the sound wave becomes dispersive and slow sound effects occur. At 600 Hz, $c_x(\omega)$ steadily decays down to 153 m.s^{-1} at the RTF outlet, which is $c_0/2$. At 1400 Hz, the phase speed further decreases and reaches 61 m.s^{-1}, e.g. $c_0/5.6$ at the location of the deepest activated cavity towards the RTF outlet. At 1800 Hz, slow sound effects are even more pronounced with a decay of the phase speed down to 20.5 m.s^{-1}, e.g. $c_0/16.7$, as from 0.09 m, the location of the twelfth activated cavity, until the RTF outlet. A low-speed flow of 20 m.s^{-1} under DPC, simulated by Eq. (5), has a minute effect on the slow sound curves tends to slightly decrease, with only a small uniform decrease of the axial phase speed, whatever the frequency.

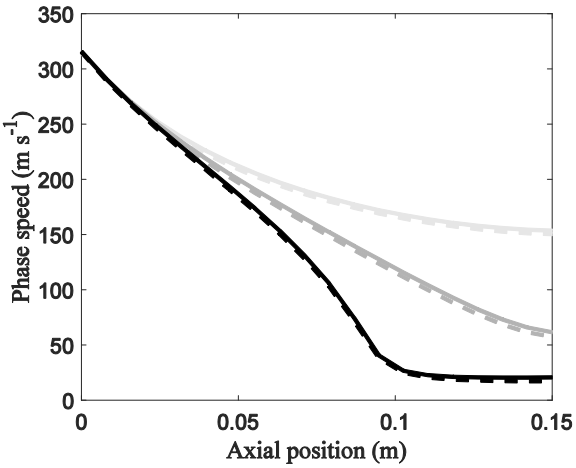

Figure 5. Slow sound effect of an acoustic wave propagating within a rainbow trapping filter at 600 Hz (light grey), 1400 Hz (grey) and 1800 Hz (black) in the no-flow case (plain) and when traversed by a low-speed grazing flow (dashed) with bulk velocity 20 m.s^{-1}.

4.3 Particle axial agglomeration

One considers fine particles of diameter 2µm and density 600 kg.m^{-3}, convected at a mean-flow speed V_a = 20 m.s^{-1} through the acoustically-optimized RTF silencer mounted on a duct. The particles also undergo an oscillatory motion of amplitude V_{ac} and phase speed $c_x(\omega_0)$ due to the slow sound propagation of the acoustic wave at frequency f_0 within the silencer. One assumes monodisperse spherical particles only experiencing viscous drag force induced by the air flow. This is valid for a small Stokes number, defined in Sec. 3, which does not exceed 0.1 at the duct cut-on frequency.

At the initial time, six particles are uniformly distributed over an axial distance of 0.015 m, separated by 3 mm, undergoing the same initial velocity V_a. Eq. (9) is solved using a finite-difference scheme [15]. A condition initially

derived by Sazhin *et al.* [13] for droplet grouping in oscillating flow field, later extended by Zhang *et al.* [14] for acoustic agglomeration in periodic metamaterials, requires that $|\beta| \leq 1$, e.g. $|V_a - c_x| \leq V_{ac}$ for the slow sound to provoke particle agglomeration in an acoustic field with particle velocity V_{ac} convected by mean flow velocity V_a. At 600 Hz, out of the RTF efficiency range, Fig. 6 shows that the trajectories of the particles stay parallel over the length of the silencer, clearly ruling out the occurrence of droplet grouping. Indeed, Fig. 4 showed that V_{ac} stays around 0.2 m.s^{-1} at 600 Hz and Fig. 5 indicates that the smallest phase speed is 153 m.s^{-1} at the RTF outlet. This leads to an agglomeration coefficient β that largely exceeds one, and prevent any grouping of the particles.

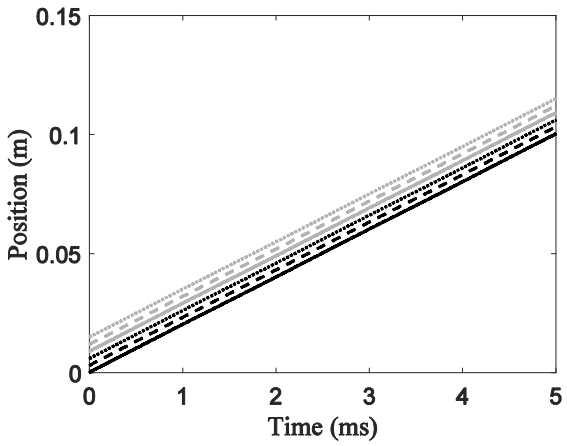

Figure 6. Trajectories of 6 fine particles convected by a low-speed grazing flow with bulk velocity 20 m.s^{-1} within a rainbow trapping filter at 600 Hz, assuming an acoustic phase speed of 153 m.s^{-1} and an acoustic velocity of 0.5 m.s^{-1}.

At 1800 Hz, within the RTF efficiency range, Fig. 7 shows grouping of the six particles into two coarser particles of 6µm diameter, over an axial distance at least 0.09 m apart from the inlet. In this region, at 0.11 m, V_{ac} reaches 2 m.s^{-1} (see Fig. 4) and slow sound effects are prominent with c_x = 20.5 m.s^{-1} (see Fig. 5), resulting in an agglomeration coefficient $\beta = 0.275$ lower than one, that complies with the grouping condition of particles. Figure 8 shows that, if the acoustic velocity is decreased to 0.5 m.s^{-1}, the agglomeration process is still ongoing, but requires a greater duration, and so a longer RTF to ensure slow sound.

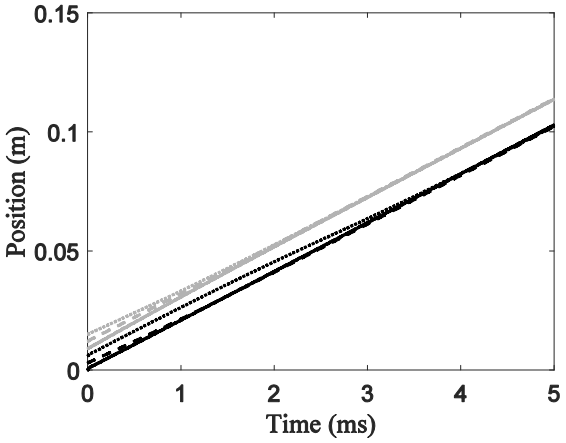

Figure 7. Trajectories of 6 fine particles convected by a low-speed grazing flow with bulk velocity 20 m.s^{-1} within a rainbow trapping filter at 1800 Hz, assuming an acoustic phase speed of 20.5 m.s^{-1} and an acoustic velocity of 2 m.s^{-1}.

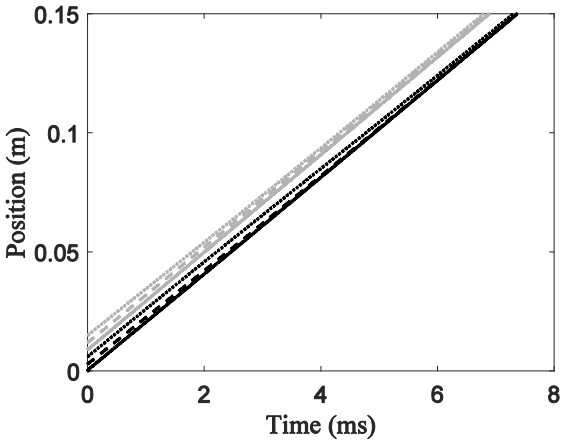

Figure 8. Trajectories of 6 fine particles convected by a low-speed grazing flow with bulk velocity 20 m.s^{-1} within a rainbow trapping filter at 1800 Hz, assuming an acoustic phase speed of 20.5 m.s^{-1} and an acoustic velocity of 0.5 m.s^{-1}.

5. CONCLUSIONS

Conditions under which RTF silencers can achieve multifunctional objectives, namely to fully dissipate the incident sound energy and to agglomerate fine particles into coarser ones, has been discussed in presence of a low-speed flow. Simulations have been carried out based on transfer matrix modelling of the RTF acoustical properties and axial particle transport under viscous drag. It was found that two conditions have to be met to fulfill these objectives. Slow-sound is a pre-requisite to achieve near-unit dissipation over a broad bandwidth, but also for the axial phase speed to get closer from the bulk flow velocity. Moreover, the acoustic velocity within the RTF should be sufficiently high for the agglomeration coefficient to be lower than one and particle grouping to occur at specific axial positions within the RTF. A trade-off should be delineated how to achieve both high attenuation, that creates low acoustic particle velocity, and particle grouping, that requires high particle velocity. This is the object of on-going study as well as the experimental validation of the acoustically-driven particle grouping properties within RTF silencers.

ABSTRACT

The paper presents theoretical and experimental studies on the original multi-resonant sound-absorbing material. A representative geometry of the material contains several channels (disjoint pore networks) of contrasting tortuosity. For the assumed material thickness, one can estimate the quarter-wavelength resonance frequency of each channel based on its tortuosity. The proposed estimate is sufficiently accurate or can be systematically adjusted to eliminate the predictable error. It can therefore be used to design a very effective sound-absorbing layer by tuning the resonance frequencies. This is because the sound absorption peaks for such a layer backed by a rigid wall occur at the resonant frequencies. The tuning is performed by tailoring the shape of the channels to obtain contrasting tortuosities that should distribute their corresponding resonant frequencies over the desired, wide frequency range. In this way, broadband absorption can be achieved. An additional goal of tailoring the channels is to fit them tightly inside the representative space of the material while maintaining their separation. In the proposed material design, all shapes and characteristic sizes are suitable for additive manufacturing, so a sample of the material was 3D printed. It was tested in an impedance tube for sound absorption to validate the theoretical results.

1. INTRODUCTION

Conventional acoustic materials such as open-cell foams, felts, wools and other high-porosity fibrous materials are good sound absorbers, but only in the medium and high frequency range if their thickness is limited to a few centimetres. Broadband sound absorption, including lower frequencies, can be achieved by using very thick layers or almost equally thick multilayer arrangements of such materials [1]. Significant or even perfect sound absorption at individual lower frequencies can be obtained with tuned designs of Helmholtz resonators [2] or micro-perforated plates backed by air cavities with optimised depths [3]. However, these solutions are narrowband and their classical forms are bulky.

Desired sub-wavelength performance, i.e. significant attenuation of low-frequency sound waves by acoustic layers thinner than the wavelength in air, can be achieved using various recently-developed architected acoustic materials and metamaterials [4]. Such acoustic treatments are based on: coiled-up cavities of various geometries [5–8] often covered by micro-perforated plates, labyrinthine channels [9–12], coiled Helmholtz resonators [13], etc. Their performance is typically narrowband. To solve this problem, various multi-resonant solutions enabling broadband absorption of low-frequency sound have been recently proposed and intensively investigated. Representative examples are: parallel assemblies of coiled-up [14,15] or spiral cavities [16], nested networks [17], parallel or nested arrangements of Helmholtz resonators [18, 19].

This work presents a multi-resonant sound-absorbing material based on carefully designed, separated channels. Their shapes are tailored to ensure contrasting tortuosities and fit well into the limited space of the material without overlapping. By increasing (decreasing) the tortuosity, the

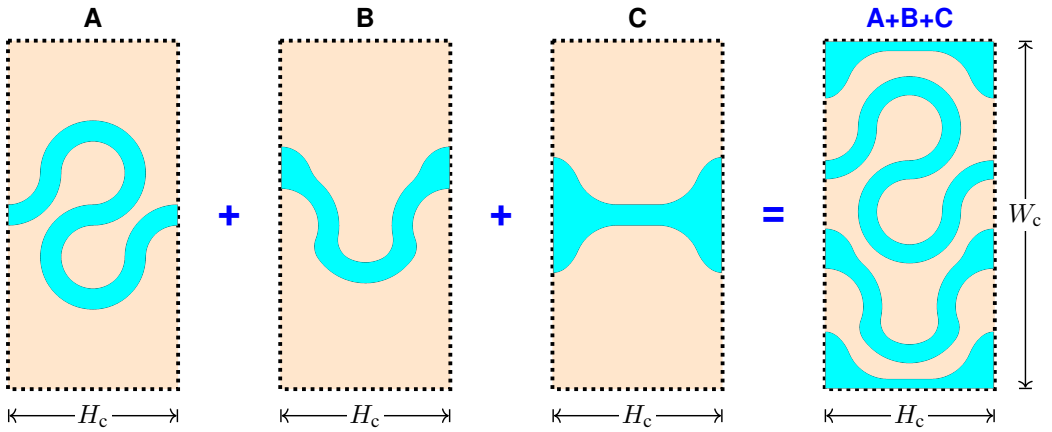

Figure 1. Periodic representative cells for three porous materials, each having a different pore network (A, B, or C), and for a multi-resonant material combining these three networks while keeping them separate.

associated quarter-wavelength resonance can be shifted to the desired lower (higher) frequency [20]. In this way, the resonances are spread over the required frequency range, which ensures broadband operation.

The outline of this paper is as follows. The tortuosity-based design of a multi-resonant material with three separated open-pore networks is discussed in Section 2.1. The main formulas necessary to model sound wave propagation and absorption in such materials are provided in Sections 2.2 and 2.3. Section 3.1 presents a 3D printed sample of the multi-resonant material and its testing configuration. The calculated and measured results of sound absorption by the multi-resonant material are confronted and discussed in Section 3.2. The main findings and conclusions are summarised is Section 4.

2. MATERIAL DESIGN AND MODELLING

2.1 Open-pore networks: designs based on tortuosity

Figure 1 shows four representative cells of periodic porous materials with an essentially two-dimensional structure. All cells are rectangular and have the same dimensions $W_c \times H_c = 16.5\,\text{mm} \times 8\,\text{mm}$. Each of the first three cells contains an open-pore network in the form of a single channel with a carefully designed shape. These networks and consequently the periodic cells and porous materials based on them will be referred to as network, cell or material A, B, and C.

The three networks were designed with the following two objectives in mind:

1. each network should have a designed tortuosity that is significantly different from the tortuosities of other pore networks to ensure different, desired quarter-wavelength resonance frequencies for a material layer of a specified, required thickness;

2. the network shapes should allow for a relatively tight fit within the limited space of a rectangular cell such that all the networks remain separated (i.e. do not overlap and ensure the required wall thickness between them) while providing the highest possible total porosity.

The realisation of the second objective resulted in the construction of the fourth representative cell shown in Figure 1, i.e. the periodic cell with three separated networks A+B+C. The total porosity of this cell (and of a periodic porous material composed of such cells) is the sum of the porosities of the three cells with one network, namely

$$\phi = \phi_A + \phi_B + \phi_C = 42.61\% \,. \tag{1}$$

Here and further in this work, ϕ_N (for N = A, B, and C) denotes the porosity of the periodic cell with a single open-pore network N. The values of these porosities are listed in Table 1.

As part of the design process to achieve the first objective, the Laplace problem for potential, i.e. inviscid flow was solved for each network N = A, B, C, to determine its kinematic tortuosity $\alpha_{\infty N}$ [21, 22]. The calculations were repeated every time the shape of the network was

Table 1. Main design parameters established for the designed networks and periodic representative cells, as well as the estimated and exact values (along with the estimation error) of the quarter-wavelength resonance (QWR) frequencies of the corresponding material layers with thickness $H = 40\,\text{mm}$.

Network N	Porosity ϕ_N [%]	Tortuosity $\alpha_{\infty N}$	QWR frequency* $\widetilde{f}_N$ [Hz]	f_N [Hz]	QWR est. error $\frac{\widetilde{f}_N - f_N}{f_N}$ [%]
A	17.14	9.71	694	645	7.60
B	11.43	3.33	1186	1126	5.33
C	14.04	1.69	1663	1610	3.29

*for $H = 40\,\text{mm}$

modified to tune its resonant behaviour, which was particularly the case for network B. The final tortuosity values are given in Table 1. It should be noted that they are very different from each other and as intended

$$\alpha_{\infty\text{A}} > \alpha_{\infty\text{B}} > \alpha_{\infty\text{C}}\,. \tag{2}$$

One should also notice that $\alpha_{\infty\text{A}}$ is much larger than the tortuosty of any conventional acoustic materials. Moreover, the geometric estimation of this tortuosity is possible and very accurate because network A is a narrow channel with constant width.

The proposed design method based on tortuosity was applied for each of the three networks to tune the respective quarter-wavelength resonance (QWR) frequency f_N of a porous layer with network N and thickness $H = 5H_\text{c} = 40\,\text{mm}$, i.e. containing five periodic cells per layer thickness. This is because, when the network tortuosity $\alpha_{\infty N}$ is known, the QWR frequency can be easily estimated by the upper-limit value $\widetilde{f}_N$, namely

$$f_N < \widetilde{f}_N = \frac{c_0}{4H\sqrt{\alpha_{\infty N}}}. \tag{3}$$

Here, c_0 is the speed of sound in air. The approach was simultaneously applied for all networks $N = \text{A}, \text{B}, \text{and C}$, to distribute the QWR frequencies more or less evenly over the desired frequency range. The upper estimates $\widetilde{f}_N$, listed in Table 1, prove to be very useful for this purpose.

2.2 Equivalent fluid model for sound-absorbing rigid-frame porous materials

The modelling of a multi-resonant acoustic material with multiple separated pore networks is based on the classical model of a porous material with a rigid frame and a single open-pore network. Time-harmonic wave propagation in such materials, with respect to the angular frequency $\omega = 2\pi f$ (f is the ordinary frequency), is determined by solving the Helmholtz equation of linear acoustics. For this purpose, it is first necessary to calculate the effective properties of the porous material modelled as an equivalent fluid, in particular, the effective speed of sound.

Homogenisation by the multi-scale asymptotic method (MAM) [23, 24] results in that the viscous and thermal effects are uncoupled at the micro-scale and the effective properties of a porous material depend on two dynamic permeabilities: one is related to the viscous oscillatory flow through a porous material and the other to the thermal diffusion in the pores. The dynamic viscous permeability $\mathcal{K}_N$ depends, in particular, on the kinematic viscosity ν of the air saturating the pores, while the dynamic thermal permeability Θ_N depends on the the thermal diffusivity of air ν'. Both are complex and frequency dependent functions that can be calculated using the well-known Johnson-Champoux-Allard-Lafarge-Pride (JCALP) model. The JACLP scaling functions depend on macro-parameters related to the structural geometry and static transport properties of the porous material. Therefore, for each porous material N, i.e. each periodic material with an open-pore network $N = \text{A}, \text{B}, \text{or C}$, the dynamic permeabilities are functions of the following parameters

$$\mathcal{K}_N = \mathcal{K}_N(\omega, \nu, \phi_N, \mathcal{K}_{0N}, \Lambda_N, \alpha_{0N}, \alpha_{\infty N}), \tag{4}$$

$$\Theta_N = \Theta_N(\omega, \nu', \phi_N, \Theta_{0N}, \Lambda'_N, \alpha'_{0N}). \tag{5}$$

See Refs. [1, 22] for the actual formulae of the JCALP model. Here, the porosity ϕ_N and the thermal charac-

teristic length Λ'_N are calculated from the geometry of the representative cell with network N, while the viscous characteristic length Λ'_N is determined from the aforementioned Laplace problem that is solved to calculate the kinematic tortuosity $\alpha_{\infty N}$. The static viscous permeability $\mathcal{K}_{0N}$ and the static viscous tortuosity α_{0N} are calculated from the solution of the Stokes flow through the periodic cell with network N, while the static thermal permeability Θ_{0N} and the static thermal tortuosity α'_{0N} are calculated from the solution of the Poisson problem defined on this periodic cell. See Refs. [21, 22, 24] for the details.

The dynamic permeabilities are used to calculate the effective density ϱ_N and the effective compressibility $\mathcal{C}_N$ for each material N, namely

$$\varrho_N = \frac{\nu \varrho_0}{\mathrm{i}\omega \mathcal{K}_N}, \quad \mathcal{C}_N = \frac{\phi_N}{P_0}\left(1 - \frac{\gamma - 1}{\gamma}\frac{\Theta_N}{\phi_N}\frac{\mathrm{i}\omega}{\nu'}\right). \quad (6)$$

where ϱ_0 and γ are the density and adiabatic index of air, respectively, P_0 is the ambient mean pressure, and i is the imaginary unit. Now, the effective speed of sound c_N, the effective wave number k_N, and the effective characteristic impedance Z_N can be calculated as follows

$$c_N = \frac{1}{\sqrt{\varrho_N \mathcal{C}_N}}, \quad k_N = \frac{\omega}{c_N}, \quad Z_N = \varrho_N c_N. \quad (7)$$

Note that not only the wave number but all effective properties are frequency dependent. In particular, $c_N = c_N(f)$ describes the dispersion in a porous material.

The QWR frequency f_N for a porous layer of thickness H can be determined by solving the following nonlinear equation

$$\frac{\mathrm{Re}\, c_N(f_N)}{4 f_N} = H, \quad (8)$$

where the real part of the effective speed of sound defines the acoustic wave velocity in the porous medium. Equation (8) was solved for the three materials N = A, B and C, assuming in each case the same layer thickness $H = 40\,\mathrm{mm}$. The resulting resonance frequencies f_N are compared in Table 1 with their upper-limit estimates $\widetilde{f}_N$, proving that the estimates are quite accurate. The typical expected accuracy is indicated by the relative errors shown in the last column of Table 1.

The surface acoustic impedance is an important acoustic indicator for sound absorbing and isolating materials. For a layer of porous material N and thickness H, it is calculated as

$$\mathcal{Z}_{\mathrm{s}N} = Z_N \coth(\mathrm{i}k_N H)\,. \quad (9)$$

It can be used to calculate other acoustic indicators such as the reflection coefficient $\mathcal{R}_N$ and the sound absorption coefficient $\mathcal{A}_N$, namely

$$\mathcal{R}_N = \frac{\mathcal{Z}_{\mathrm{s}N} - Z_0}{\mathcal{Z}_{\mathrm{s}N} + Z_0}, \quad \mathcal{A}_N = 1 - \left|\mathcal{R}_N\right|^2. \quad (10)$$

Here, $Z_0 = \varrho_0 c_0$ is the characteristic impedance of air.

2.3 Material with multiple, separated pore networks

The material with multiple open-pore networks that are separated from each other can be considered as an assembly of the corresponding single-network materials arranged in parallel, or rather independently occupying the same geometric space. Consequently, in the example investigated in this work, the triple-network periodic material marked as A+B+C (see Figure 1) can be modelled with three effective fluids that are acoustically equivalent to porous materials A, B and C, respectively. These equivalent fluids share the same computational domain, but the wave propagation in each of them is governed by an independent Helmholtz equation. There are therefore three acoustic pressures that are not coupled *within* the computational domain. However, they are coupled – which usually means that they are equalised – on some (or all) of its boundaries, so that wave propagation in the equivalent fluids corresponding to the individual networks is not completely independent. In the case when a layer of the material with multiple, separated networks is backed by a rigid wall, the coupling, i.e. pressure equalisation, occurs only on the front surface of the layer. It is easy to show that the surface acoustic impedance for such a hard-backed layer equals

$$\mathcal{Z}_{\mathrm{s}} = \frac{1}{\sum\limits_{N=\mathrm{A,B,C}} \mathcal{Z}_{\mathrm{s}N}^{-1}} = \frac{1}{1/\mathcal{Z}_{\mathrm{sA}} + 1/\mathcal{Z}_{\mathrm{sB}} + 1/\mathcal{Z}_{\mathrm{sC}}}. \quad (11)$$

This is the classic result for the impedance of a system of components N = A, B, C, set in parallel. It should be noted that the situation becomes much more complicated and dramatically different when the layer is supported by even a very thin air gap and not directly by a rigid wall. This is because in such a case the pressures in all networks also equalise on the back surface of the porous layer. Consequently, determining the surface acoustic impedance requires in this case much more complex calculations [25].

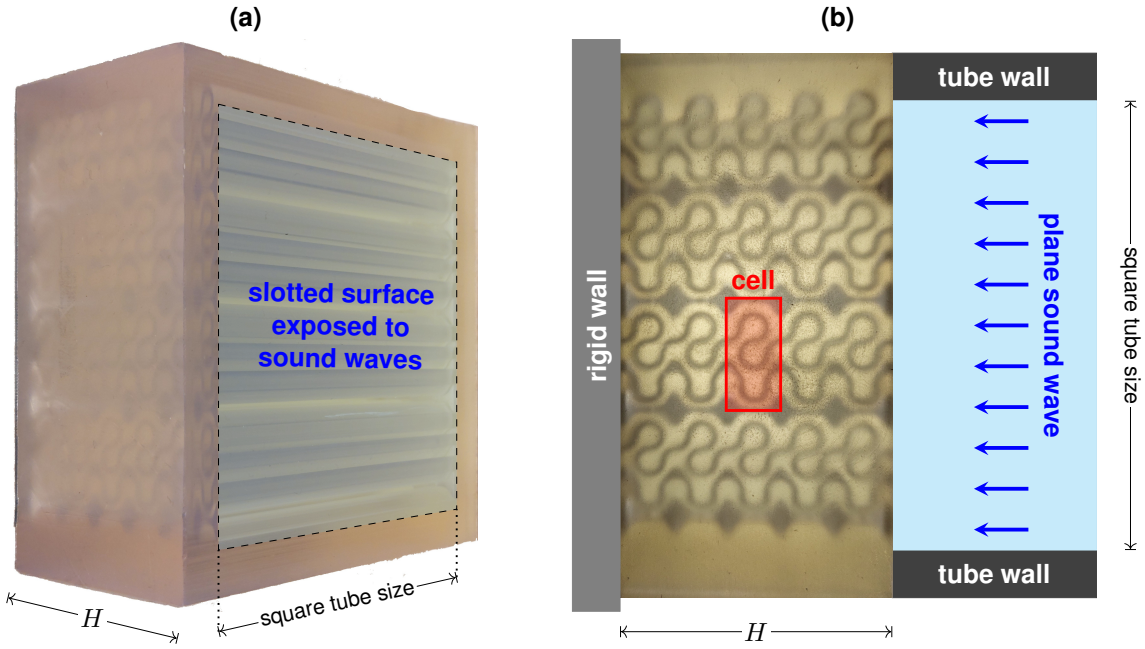

Figure 2. 3D printed sample of the multi-resonant material with three separated pore networks: (a) general view, (b) side view showing all pore networks (due to sample transparency) with one representative cell marked with a red rectangle. In the side view, the sample is placed inside the measurement scheme showing a fragment of a square impedance tube and a plane acoustic wave at normal incidence to the sample surface.

When the surface acoustic impedance $\mathcal{Z}_s$ is determined for the hard-backed multi-resonant material using Equation (11), the corresponding reflection coefficient $\mathcal{R}$ as well as the coefficient of sound absorption $\mathcal{A}$ are calculated using standard formulae, namely

$$\mathcal{R} = \frac{\mathcal{Z}_s - Z_0}{\mathcal{Z}_s + Z_0}, \quad \mathcal{A} = 1 - \left|\mathcal{R}\right|^2. \tag{12}$$

3. PROTOTYPING, TESTING AND VALIDATION OF MULTI-RESONANT MATERIAL

3.1 3D printed sample

Figure 2 (a) shows an additively manufactured sample of the designed multi-resonant material. The sample has a cuboid shape with a square base. Its thickness (height) is $H = 40$ mm. There are twelve slits on the front surface of the sample that lead to (four triplets of) separate networks. The corresponding twelve exit slits on the back side of the sample were sealed with an aluminium tape to prevent sound leakages when the sample was backed by a rigid wall and tested in a 66 mm square impedance tube. The testing configuration is depicted in Figure 2 (b).

The sample was 3D printed in the stereolithography (SLA) technology using a photopolymer resin of low viscosity so that its residues could be removed even from the most tortuous of the network channels. The resin is transparent, so that all the separate networks of the material can be seen in the photograph of one side of the sample shown in Figure 2 (b). The rectangular periodic cell is marked in red in this photograph, mirroring the design labelled as A+B+C in Figure 1. One should notice that there are five such cells per sample thickness. The configuration scheme shown in Figure 2 (b) illustrates how the sample is backed by a rigid wall and impinged at the front by a plane acoustic wave propagating in a square impedance tube.

3.2 Sound absorption: predictions and measurements

The modelling discussed in Section 2 was applied to predict the sound absorption by different material layers in a

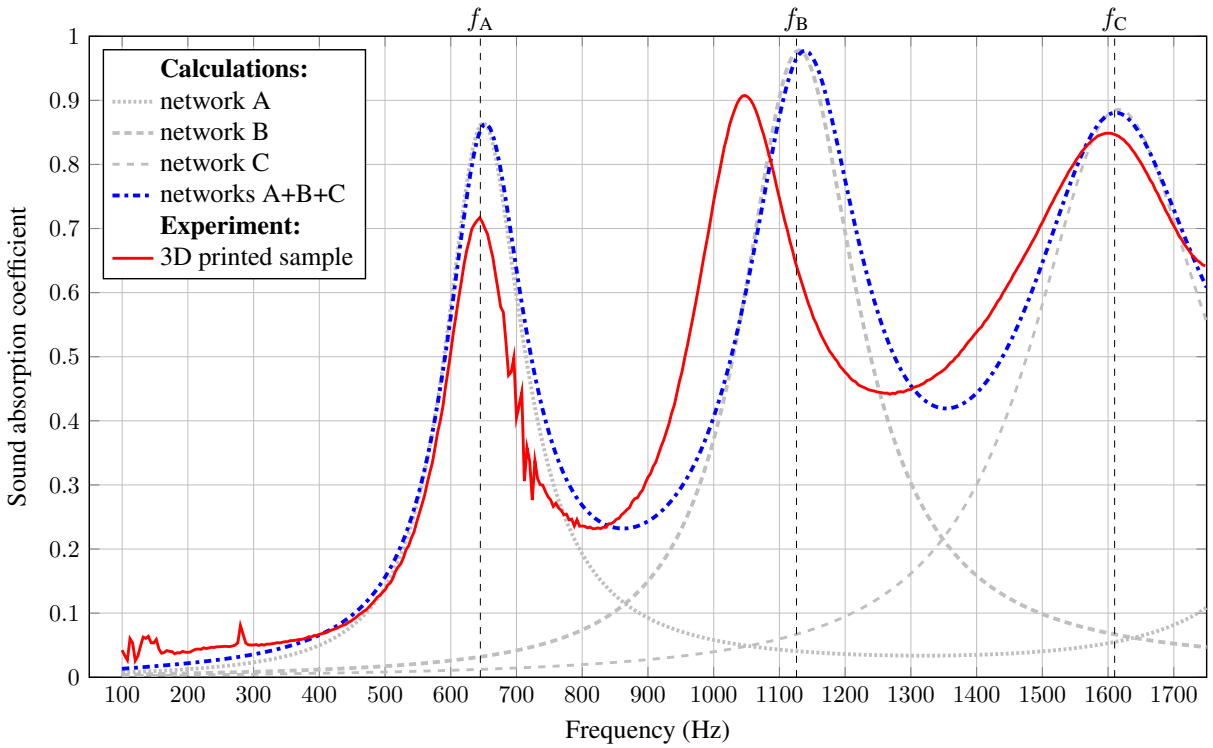

Figure 3. Sound absorption measured for a 3D printed sample of the mutli-resonant material with three pore networks (red curve) compared with the corresponding prediction (blue curve) and with the sound absorption curves calculated for single-network layers (grey curves) of the same thickness.

configuration where the layer under consideration is supported by a rigid wall, as illustrated in Figure 2 (b) for the 3D printed sample. Each material is based on one of the four periodic representative cells shown in Figure 1, which gives the four following cases:

1. a hard-backed porous layer with network A,
2. a hard-backed porous layer with network B,
3. a hard-backed porous layer with network C,
4. a hard-backed porous layer with three separated networks, arranged as in cell A+B+C, see Figure 1.

Each layer has five identical periodic cells along its thickness, which is therefore the same, i.e. $H = 40$ mm, as in the case of the 3D printed sample.

To predict sound absorption by hard-backed layers, the macro-parameters mentioned in Section 2.2 were first calculated for each of the three periodic cells with a single pore network N = A, B, C. In each case, the cell geometry used for calculations was *not exactly* the same as that used to 3D print the sample. However, the necessary geometric modification was minor and generally consisted of reducing the channel width by 0.1 mm to match the actual width of 3D printed channels. Incidentally, the values given in Table 1 were determined for such updated cell geometries. The macro-parameters were used to calculate the effective properties. Then, the sound absorption of each single-network layer was calculated using formulae (9) and (10). Equations (11) and (12) were used to calculate the sound absorption for the layer with three separated networks.

Sound absorption curves determined for the four materials are compared in Figure 3 within the frequency range up to 1.75 kHz. It should be observed that the absorption peak for the hard-backed layer with network A is almost at $f_A = 645$ Hz, which is the QWR frequency predicted for this layer by Equation (8). Similarly, the absorp-

tion peaks for the layer with network B and the layer with network C are close to their respective QWR frequencies. The sound absorption curve marked in blue was calculated for the layer with three separated networks A+B+C. It envelopes the three (grey) curves determined for the single-network layers. This curve envelope closely adheres to the absorption peaks, but not between them, where the sound absorption of the layer with three separate networks is noticeably higher than that of any single-network layer.

The blue sound absorption curve clearly demonstrates the multi-resonant acoustic behaviour of the material with multiple networks. This is confirmed by the experimental results, i.e. the red sound absorption curve in Figure 3, measured in an impedance tube for the 3D printed sample. Discrepancies between calculations and measurements are due to printing imperfections. They should be related to the geometric quality of each 3D printed network. It seems that the shape of the printed network B differs, albeit slightly but significantly, from the shape used to calculate its corresponding macro-parameters. One can expect that the actual tortuosity in this case is slightly larger than the calculated value, because the absorption peak associated with this network occurs at a frequency that is about 80 Hz lower than the predicted value of $f_B = 1126$ Hz.

4. CONCLUSIONS

Broadband low-frequency sound absorption can be achieved by porous materials with separate channels of contrasting tortuosity. Such materials exhibit multi-resonant behaviour and the individual resonant frequencies can be tuned during the design process to the desired values. To ensure overall broadband performance, they should be evenly distributed over the entire frequency range of interest.

In the proposed material design procedure, the main tailoring parameter is the tortuosity of each channel. Knowing this parameter and the material thickness, the quarter-wavelength resonance frequency associated with a given channel can be quickly estimated with acceptable accuracy. In the design process, this resonance can be shifted towards a lower frequency by increasing the tortuosity [20]. Even for a relatively thin material, this can be a very low frequency indeed, provided that the channel tortuosity is sufficiently high.

The design procedure is very efficient, especially for narrow channels of constant width because their tortuosity can be determined analytically with high accuracy based on the channel length [12, 26, 27]. Channel shapes should be designed simultaneously or at least taking into account the already constructed channels. This is because their tortuosities should be significantly different, and moreover, all channels should fit into the material space without overlapping but at the same time allow for the highest possible porosity. Optimised, three-dimensional design of channel shapes should lead to the creation of thin but very efficient and broadband, multi-resonant materials of this type.

ABSTRACT

A numerical approach of multiple scattering based on the resolution of multiple scattering equations for elastic waves inside solid heteregenous media is presented. It is validated by extracting the effective velocity and attenuation of longitudinal and transverse coherent inside a dispersion of spherical scatterers embedded in a duralumin matrix.

Keywords: *multiple scattering, elastic waves, coherent wave, effective parameters, numerical approach.*

1. INTRODUCTION

The propagation of elastic waves in multiply scattering solid media is an old problem that has been less studied than the case of acoustic waves (in fluids) or electromagnetic waves. One of the reasons lies in the existence of conversions between longitudinal and transverse waves at the surface of each scatterer. This work presents a new method for simulating elastic wave propagation in heterogeneous media composed of spherical inclusions embedded in a solid matrix. The MuScat code, initially developed to simulate acoustic wave propagation in heterogeneous fluids [1], is adapted to take into account the vector nature of elastic waves in three dimensions. It is based on the analytical solution of the multiple scattering equations using the spherical harmonic expansion of the incident and scattered fields, which allows to consider very large dispersions of particles. In a first section, we describe this general principle behind the code. In a second section, we show the validation of the numerical approach on dispersions of spherical cavities filled with water embedded in a duralumin solid matrix. Note that a similar study has been performed in two dimensions (cylindrical cavities filled with water) in ref. [2].

2. GENERAL PRINCIPLE OF THE MODELING

The modeling behind the MuScat code for elastic waves will be presented in details in a future work. In the following, we indicate the main principles behind it.

We consider an isotropic and homogeneous viscoelastic medium of Lamé parameters (λ, μ) and density ρ (we denote k_L the longitudinal wavenumber and k_T the transverse one) inside which are embedded N_p spheres of respective radii a_p, Lamé parameters (λ_p, μ_p) and densities ρ_p (fig. 2). There is no limitation on the polydisperisty either in size or elasticity.

We follow the T-matrix approach already used in electromagnetism [3, 4], adding the mode conversations between longitudinal and transverse waves that exist in the elastic case (details about this can be found in ref. [5]). Within this framework, the incident displacement field upon the distribution of scatterers is expanded upon the usual Vector Spherical Wavefunctions (VSWF) $\mathbf{L}_{nm}$, $\mathbf{M}_{nm}$ and $\mathbf{N}_{nm}$, that are solutions of the elastic wave equations in an homogeneous medium (see ref. [6] for their definition and properties), as

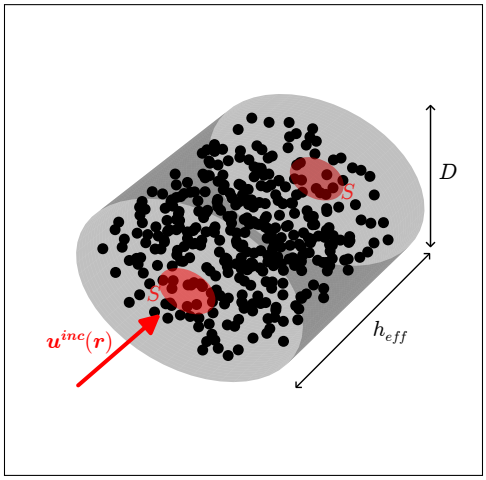

Figure 1. An incident displacement field (plane wave) is sent on a distribution of spherical scatterers placed in a cylindrical slab inside the solid matrix.

$$\mathbf{u}^{inc}(\mathbf{r}_0) = \sum_{n,m}(a_{nm}^{L}\mathbf{L}_{nm}^{(1)}(\mathbf{r}_0) + a_{nm}^{T}\mathbf{N}_{nm}^{(1)}(\mathbf{r}_0) + a_{nm}^{S}\mathbf{M}_{nm}^{(1)}(\mathbf{r}_0)). \quad (1)$$

This field is expressed in an arbitrary coordinates system R_0 ($\mathbf{r}_0$ denotes the position in this system), generally placed at the center of the distribution of scatterers. For convenience we have used the notation $\sum_{n,m} \equiv \sum_{n=0}^{+\infty}\sum_{m=-n}^{+n}$. The superscript (1) denotes the use of the spherical Bessel function of the first kind j_n in the definition of the VSWF. The coefficients a_{nm}^{M} are the amplitudes of the incident field and are known. The L part refers to longitudinal contributions to the displacement field whereas the T and S parts represent the transverse ones. The total field $\mathbf{u}$, which we seek to express, is

$$\mathbf{u} = \mathbf{u}^{inc}(\mathbf{r}_0) + \sum_{p=1}^{N_p}\mathbf{u}_p^{sc}(\mathbf{r}_p), \quad (2)$$

where $\mathbf{u}_p^{sc}(\mathbf{r}_p)$ is the scattered field of the p-th particule expressed in its local coordinates system R_p. Those fields are also expanded on the VSWF and are thus written

$$\mathbf{u}^{sc}(\mathbf{r}_p) = \sum_{n,m}(b_{nm}^{p,L}\mathbf{L}_{nm}^{(3)}(\mathbf{r}_p) + b_{nm}^{p,T}\mathbf{N}_{nm}^{(3)}(\mathbf{r}_p) + b_{nm}^{p,S}\mathbf{M}_{nm}^{(3)}(\mathbf{r}_p)). \quad (3)$$

The superscript (3) indicates here the use of the spherical Hankel function of the first kind $h_n^{(1)}$ in the definition of the VSWF. The coefficients $b_{nm}^{p,M}$ are the amplitudes of the mode $M = L, T, S$ of the scattered field of the p-th particle and are thus the unknowns of the problem. Using the addition theorems for VSWF [4, 7] we can express the excited field on the p-th particle $\mathbf{u}_p^{ex} = \mathbf{u}^{inc} + \sum_{q\neq p}\mathbf{u}_q^{sc}$ in its local coordinates system R_p. Knowing the T-matrix of the particle, we can eventually write a linear system that allows to find the coefficients $b_{nm}^{p,M}$ and then determine the total field. This system is solved numerically by introducing a modal truncature and using iterative methods.

3. EXTRACTION OF EFFECTIVE PARAMETERS OF A MULTIPLE SCATTERING MEDIUM

3.1 The coherent field

The validation of the numerical approach is here realized by comparison with a vector multiple scattering model (denoted as the LCVB model) giving the effective parameters of the coherent longitudinal and transverse waves [5]. Indeed, the displacement field for a realization of the disorder can be written $\mathbf{u} = \langle\mathbf{u}\rangle + \delta\mathbf{u}$, where $\langle\cdot\rangle$ denotes the configurational average. $\langle\mathbf{u}\rangle$ is thus the coherent field. It can be written

$$\langle\mathbf{u}\rangle = u_0 \mathrm{e}^{\mathrm{i}k_{eff}z}\hat{\mathbf{p}}, \quad (4)$$

where $\hat{\mathbf{p}}$ is the polarization of the incident wave and k_M^{eff} is the so-called effective wave number ($M = L$ for a longitudinal wave, $M = T$ for a transverse one). We have $k_M^{eff} = \omega/c_M^{eff} + \mathrm{i}\,\alpha_M^{eff}$, where c_M^{eff} is the effective velocity of the coherent wave and α_M^{eff} its effective attenuation. The propagation of the coherent wave is thus modeled as the propagation of an elastic wave of polarization $\hat{\mathbf{p}}$ inside an effective homogeneous medium. The two parameters c_M^{eff} and α_M^{eff} characterize the multiple scattering medium.

3.2 Results and discussion

We consider the propagation of an elastic wave inside a dispersion of spherical cavities (all with the same radius $a = 250$ µm) filled with water embedded inside a duralumin matrix ($\rho = 2800$ kg/m^3,$\lambda = 57.8$ GPa, $\mu = 28$ GPa). The spheres are put in a virtual volume of transverse diameter D and thickness h_{eff} (see fig. 2) and illu-

minated by a plane wave [1] . We measure the transmissions coefficients for N_{avg} dispersions of spheres. We denote $\mathcal{T}$ the configurationally averaged transmission coefficient [2] . The effective parameters are then extracted from the following expression

$$\mathcal{T} = \frac{e^{ik_{eff}h_{eff}}}{e^{ikh_{eff}}}, \tag{5}$$

with $k = k_L$ (resp. $k = k_T$) if the incident wave is longitudinal (resp. transverse).

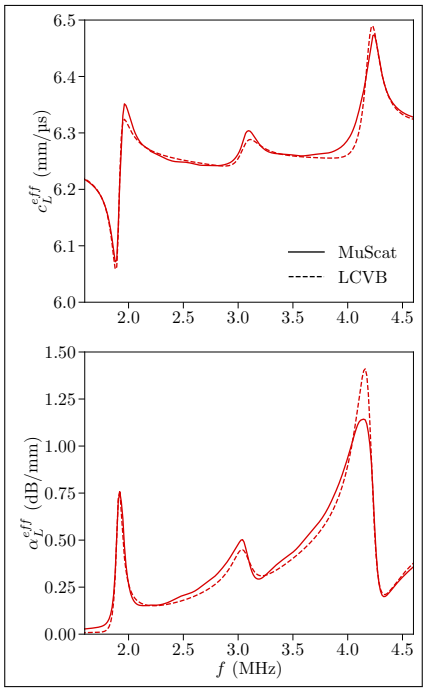

Figure 2. Frequency dependant effective velocity (top) and attenuation (bottom) of coherent longitudinal waves in a dispersion of cavities (filled with water) embedded inside a duralumin matrix ($\phi_v = 2\%$) around several resonances. Comparison between the LCVB model and numerical results obtained with MuScat.

[1] The number of modes to take into account for the truncature is determined from the scattering cross section of the scatterers. For an incident longitudinal (resp. transverse) wave, a maximum of 5 (resp. 6) modes has been taken.

[2] For each configuration of the disorder, we also perform spatial average (over a surface S as seen on fig. 2), as it is often do practically in experiments, to achieve a better averaging process.

Fig. 2 shows the effective velocity and attenuation of the coherent longitudinal wave in the dispersion of spherical cavities for a volume fraction $\phi_v = 2\%$. The spheres are placed inside the heteregenous medium with just a condition of non-overlaping, i.e. the distance between the centers of two scatterers shall be superior to $2a$. The figure shows a good agreement between the LCVB model and the numerical results obtained with MuScat. Several resonances can be observed, they are characterized by a strong dispersion on the effective velocity of the coherent wave and thus also by an effective attenuation peak.

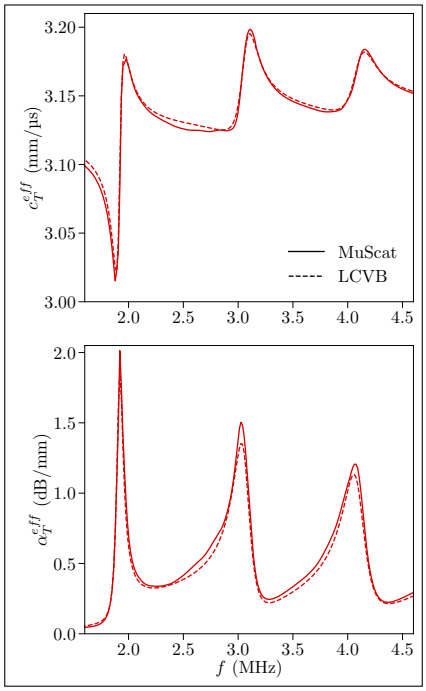

Figure 3. Frequency dependant effective velocity (top) and attenuation (bottom) of coherent shear waves in a dispersion of cavities (filled with water) embedded inside a duralumin matrix ($\phi_v = 2\%$) around several resonances. Comparison between the LCVB model and numerical results obtained with MuScat.

Fig. 3 shows the effective velocity and attenuation for the coherent shear waves in those dispersions. A good agreement can be seen between analytical and numerical results. Several resonances are also observed over the frequency band. In this kind of system, for both longitudinal and transverse waves, those resonances are linked to

the existence of whispering gallery waves and Rayleigh waves modes at the interface of the cavities [2].

4. CONCLUSION

We have presented a numerical approach, MuScat, aiming to study the propagation of elastic waves inside heterogeneous media. It has been validated here by comparison with a vectorial model of elastic wave multiple scattering. This numerical approach opens new perspectives for the study of elastic waves propagation inside dispersions of scatterers both on the coherent part of the field and on its fluctuations. Several types of incident waves can be used (point source, plane wave, Gaussian beam) and the distribution of scatterers can be polydisperse both in size and elasticity.

ABSTRACT

Time-varying systems have emerged as a pivotal approach in wave physics, enabling unprecedented control over wave dynamics through the modulation of spatial and temporal properties. In this work, we analyze wave interactions at spatiotemporal interfaces, exploring the resulting scattering phenomena and their implications for acoustic wave manipulation. Building upon foundational principles, we classify interaction regimes—subsonic, supersonic, and intersonic—through a novel $\alpha - \gamma$ diagram, offering a comprehensive framework for understanding wave-interface dynamics. We extend this analysis to spatiotemporal slabs, which consist of two parallel interfaces moving with the same velocity. These structures combine spatial and temporal modulations, enabling intricate wave behaviors such as asymmetric interference patterns and dynamic frequency shifts. We demonstrate the scattering coefficients and frequency conversion characteristics within these slabs. The results highlight the transformative potential of spatiotemporal slabs for broadband acoustic wave control, paving the way for innovative applications in sound insulation, communications, and wave manipulation technologies.

1. INTRODUCTION

Spatiotemporal modulation of acoustic media has opened new avenues for controlling wave propagation beyond the limitations of stationary systems. By dynamically varying properties such as sound speed or impedance, these systems allow for functionalities including frequency conversion, wave amplification, and nonreciprocal transmission [1–3]. Among the different strategies explored, the use of moving interfaces has proven particularly effective in generating new wave behaviors. When such interfaces propagate through the medium, they induce shifts in frequency and wavelength of the scattered waves, governed by the relative velocities of the interface and the acoustic media [4, 5].

Building upon these ideas, *spatiotemporal slabs*, structures defined by two parallel moving interfaces, represent a more complex configuration capable of producing rich scattering phenomena. Unlike a single interface, slabs introduce internal reflections and interference effects that depend on both the acoustic contrast and the motion of the slab. These configurations enable fine control over transmitted and reflected wave components, with potential applications in advanced sound control and acoustic metamaterials.

In this work, we present a study of wave scattering in spatiotemporal slabs. We peopoaw analytical expressions for the scattering coefficients in the subsonic and supersonic regimes, incorporating internal phase accumulation and frequency shifts due to the motion of the interfaces.

2. THE SPATIOTEMPORAL SLAB

A spatiotemporal slab is a dynamic structure defined by two parallel interfaces moving through an acoustic medium. It introduces a finite thickness region in which the wave speed changes from a background value c_1 to a new value $c_2 = \gamma c_1$, and then returns to c_1 after the slab has passed. Unlike single-interface systems, slabs support multiple internal reflections and wave interactions that significantly affect the overall scattering behavior.

These structures are the dynamic counterpart of classical spatial slabs used in layered media acoustics with additional complexity due to their motion. Conceptually, spatiotemporal slabs also generalize the idea of temporal slabs—media with time-varying properties studied in prior works [6, 7]—by combining both spatial and temporal discontinuities [8].

The interaction between an incident wave and the slab depends on the relative velocity of the interfaces ($v = \alpha c_1$) and the acoustic contrast γ. The first interface generates scattered components whose behavior is governed by the coefficient $\Gamma_f(\gamma, \alpha)$. Once the wave enters the slab, it travels in a medium with speed c_2, and the second interface must be analyzed with transformed parameters $1/\gamma$ and α/γ, effectively reversing the roles of the media.

In the subsonic regime, the slab moves slower than the wave, allowing multiple internal reflections that accumulate over time. In contrast, the supersonic regime occurs when the slab moves faster than the wave, leading to only a few distinct wave components without recursive reflections.

2.1 Subsonic regime

In the subsonic regime ($|\alpha| < \min(1, \gamma)$), the interface moves slower than both media. As shown in Fig. 1, an incident wave hits the first interface, producing a *reflected* wave and a *forward* wave that enters the slab. After traveling a distance L_A, the forward wave reaches the second interface, generating a new forward wave that exits the slab, and a reflected wave that remains within it. This process repeats, forming recursive internal reflections and building up multiple transmitted and reflected components. The final transmitted and reflected waves are superpositions of these components, each phase-shifted and frequency-modulated due to the slab motion.

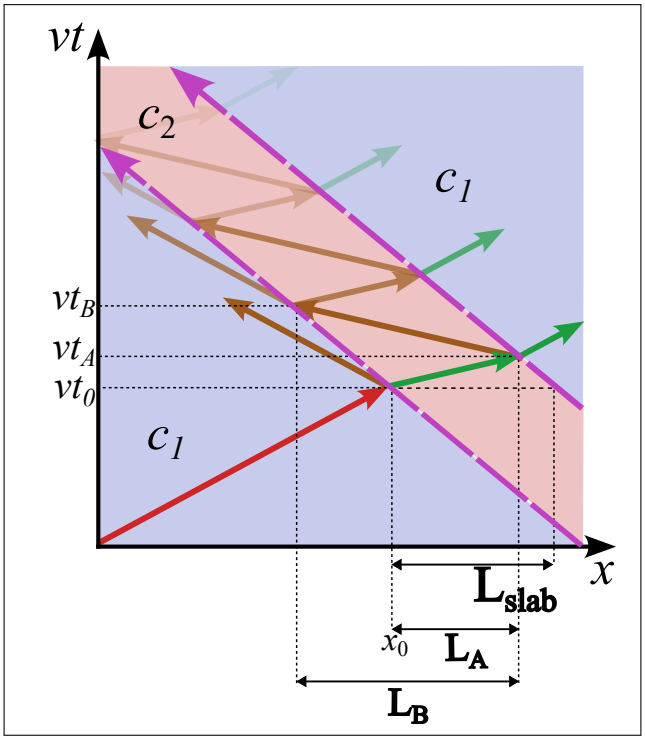

Figure 1. Subsonic slab: multiple internal reflections generate cumulative transmitted and reflected components.

2.2 Supersonic regime

In the supersonic regime ($|\alpha| > \max(1, \gamma)$), the interface moves faster than both media. Upon interaction with the first interface, the incident wave generates a *forward wave* and a *backward wave*, both propagating inside the slab in opposite directions as illustrated in Fig. 2. These components interact with the second interface, producing new forward and backward waves. Unlike in the subsonic case, no recursive reflections are generated.

3. SCATTERING COEFFICIENTS

The scattering response of a spatiotemporal slab is determined by the interference of the wave components that are generated through internal reflections. To compute the global scattering coefficients, three key aspects must be considered:

1. **Acoustic path lengths:** Each wave component travels a different distance inside the slab depend-

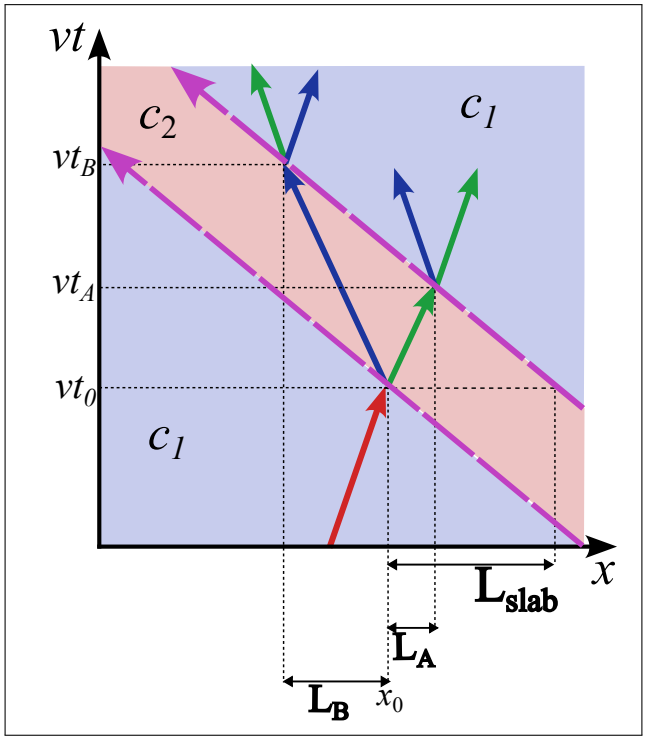

Figure 2. Supersonic slab: wave components interact only once at each interface, producing distinct forward and backward waves.

ing on its propagation direction. These distances are denoted as L_A for waves traveling in the same direction as the moving slab (copropagating), and L_B for waves traveling in the opposite direction (counterpropagating). In the subsonic regime, they are given by:

$$L_A = \frac{\gamma}{\gamma-\alpha}L_{\text{slab}}, \qquad L_B = \frac{\gamma}{\gamma+\alpha}L_{\text{slab}}. \quad (1)$$

2. **Frequency conversion:** Each interaction with a moving interface induces a frequency shift, modifying the phase evolution of the wave inside the slab. These shifts are described by frequency conversion factors.

3. **Interface scattering:** At each interface crossing, the wave amplitude is modified according to a scattering coefficient that depends on the propagation regime.

3.1 Forward Scattering Coefficient

The total forward wave transmitted through the slab is the sum of all forward components. In the subsonic regime, the closed-form expression is:

$$\mathbb{G}_F(\gamma,\alpha,L_{\text{slab}}) = \frac{4\gamma e^{\frac{j\alpha\gamma k_1 L_{\text{slab}} A_{1,F}}{\Phi_F}}}{(\gamma+1)^2 e^{\frac{j\gamma k_1 L_{\text{slab}} A_{2,F}}{\Phi_F}} - (\gamma-1)^2 e^{\frac{j\gamma^2 k_1 L_{\text{slab}} A_{1,F}}{\Phi_F}}}, \quad (2)$$

where:

$$\Phi_F = (\alpha^2-\gamma^2)^2,$$
$$A_{1,F} = \alpha^2+3\alpha\gamma+\alpha-\gamma,$$
$$A_{2,F} = \alpha^2(\gamma+2)-\alpha\gamma(\gamma-1)+\gamma^2.$$

3.2 Reflection Scattering Coefficient

The total reflected wave is composed of the direct reflection at the first interface and all components returning after internal reflections. Its final expression is:

$$\mathbb{G}_R(\gamma,\alpha,L_{\text{slab}}) = \frac{(\gamma^2-1)\left(1-e^{\frac{2jk_1 L_{\text{slab}} A_{1,R}}{\Phi_R}}\right)}{(\gamma+1)^2-(\gamma-1)^2 e^{\frac{2jk_1 L_{\text{slab}} A_{1,R}}{\Phi_R}}}, \quad (3)$$

where:

$$A_{1,R} = \gamma(\alpha-1)(2\alpha^3+\alpha^2+\gamma^2), \quad \Phi_R = (\alpha+1)(\alpha^2-\gamma^2)^2.$$

These analytical expressions capture the essential features of wave propagation through a moving slab, including internal phase accumulation, frequency shift, and multiple reflections.

The analytical results are illustrated in Fig. 3 and 4, which show the forward and reflected (or backward) scattering coefficients for both subsonic and supersonic regimes. The calculations are performed for a slab of thickness $L_{\text{slab}} = 0.1\,\text{m}$ and contrast $\gamma = 2$. The frequency at which the scattering coefficients reach their maxima and minima depends on the slab velocity. The motion of the slab changes the effective thickness that the waves experience as they propagate through it. The relative motion between the slab and the wave causes the wave to travel a longer or shorter distance inside the slab, depending on the direction of propagation. This change in effective thickness modifies the phase accumulation and, consequently, shifts the interference pattern that determines the scattering behavior.

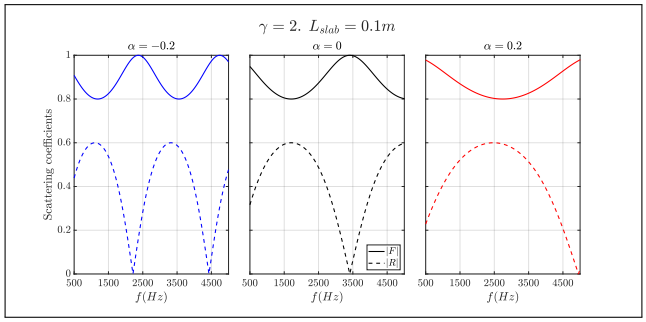

Figure 3. Scattering coefficients in the subsonic regime. Solid and dashed lines correspond to forward and reflected waves. Colors represent counterpropagating (blue), static (black), and copropagating (red) cases.

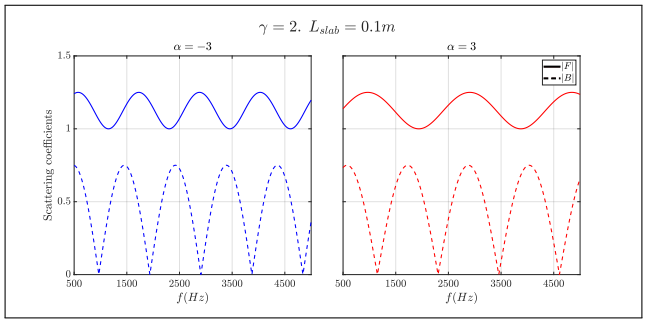

Figure 4. Scattering coefficients in the supersonic regime. Solid and dashed lines correspond to forward and backward waves. Colors represent counterpropagating (blue), static (black), and copropagating (red) cases.

4. CONCLUSIONS

We have presented a study of wave propagation through spatiotemporal acoustic slabs. By considering the combined effects of internal reflections, frequency conversion, and moving interface scattering, we derived closed-form expressions for the global scattering coefficients in subsonic regimes. The results show that slab motion introduces frequency-selective behavior and asymmetric transmission characteristics that are not present in static layered media. These findings provide a useful analytical framework for the design of spatiotemporally modulated acoustic devices for sound control, isolation, and filtering.

ABSTRACT

In this work, we present a bi-directional asymmetric ultrasonic hologram that can simultaneously control both the reflected and transmitted wave-fields. To do that we design a surface made of a discrete spatial distribution of monolithic elements with different properties than the surrounding medium. This allows to compress two identical or different wavefield scattering patterns (for transmission and reflection) into a single monolithic object. We report an ultrasonic hologram based on Quadratic Residue sequences encoded with resonant building blocks behaving as an ideal Lambertian scatterer from both sides, with spatial autocorrelation coefficients of 0.7 each one, therefore diffusing waves in both transmission and reflection.

Keywords: *Acoustic hologram, Acoustic diffusers, Ultrasonic imaging, Acoustic scattering*

Research in ultrasounds covers a broad range of fields as non-destructive testing, underwater acoustics and imaging among others. Recently, there is an increasing interest in biomedical applications, such as non-destructive medical imaging [1, 2] and non-invasive controlled medical therapy [3, 4]. In this work we design of a bi-directional asymmetric ultrasonic hologram that works simultaneously in transmission and reflection. The design framework of such hologram follows a multi-objective optimization procedure which minimizes the difference in reflection and transmission phase values for a given length of polymer material, allowing the creation of a phase-space representing the total phase combinations between the two interfaces, the building blocks of which can be used to replicate any desired reflection and transmission phase profiles. In the work herein, the case of an ideal Lambertian scattering hologram made out of a Quadratic Residue sequence has been demonstrated, where high scattering values with a spatial auto-correlation coefficient around $\delta = 0.7$ have been reported [5].

We consider an ultrasonic hologram composed of a discrete spatial distribution of building blocks made of a monolithic polymer blocks with different height embedded in water. The working frequency is chosen at 1.1 MHz. An example layout can be seen through the artistic impressions in Figs. 1(a,b). We consider first a 1D problem for each constituting building block of the hologram. The building block is made of a monolithic polymer block of length l surrounded by two water blocks of length d_1 and d_2 respectively as shown in Fig. 1(c). The sound pressures, p, and normal particle velocities, v_z, at $z = 0$

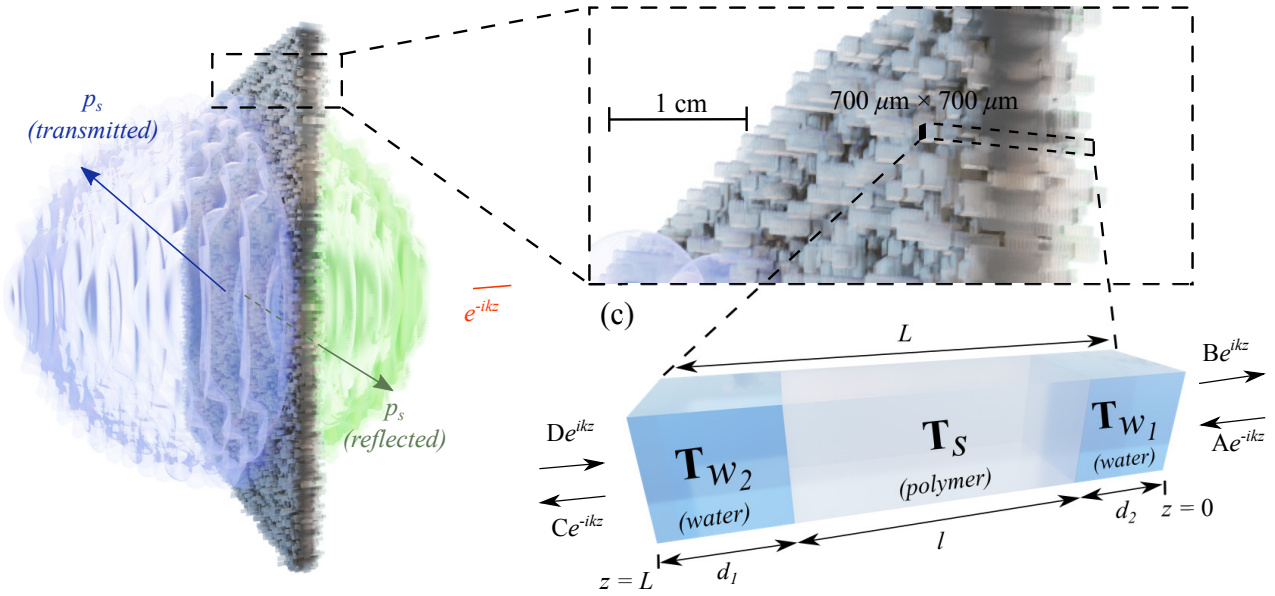

Figure 1. (a) Artistic impression of a 10 × 10 × 1 cm ultrasonic bi-directional hologram diffusing an incident plane wave in a uniform scattering profiles for each direction; reflection in green, transmission in blue. (b) Close-up of the lens; each monolithic block has a lateral size of $\Delta l_x \times \Delta l_y$=700$\mu$m×700$\mu$m. (c) Representative 1D Transfer Matrix diagram of a monolithic block of total length L composed of a solid element (e.g., polymer) and an exterior medium (here, water). The local phase and amplitude of the reflection and transmission coefficients depend on d_1, d_2 and l.

and at $z = L$ can be modelled by means of the Transfer Matrix Method (TMM). Due to the lateral dimensions of the building blocks ($\Delta l_x \times \Delta l_y$=700$\mu$m×700$\mu$m) we can assume plane wave propagation. Therefore, the transfer matrix **T** of the building block can be derived and the reflection, R, and transmission, T, coefficients calculated. This implies that we consider each building block is independent from each other in the structure and considered as an equivalent fluid. Such approximation can be made due to the low difference in impedance between the water and polymer media, with a polymer-to-water impedance ratio $Z_p/Z_w = 1.67$, coupled with the fact that shear waves can also be neglected due to the system being considered under normal incidence.

Following Fraunhofer's diffraction theory, the scattered sound pressure distribution over a surface with an anisotropic phase distribution, such as a reflection or transmission coefficient in this case, can usually be resumed as a spatial Fourier transform of the corresponding complex surface coefficient. In this case, the far-field pressure distribution, $p_s(\theta, \phi)$, where θ and ϕ are the azimuthal and elevational angles, respectively, of a radiating rectangular surface with a spatially dependent phase distribution coefficient, $\xi(x, y)$, of size $2a$ and $2b$ in the x and y directions respectively, can be calculated using the Fraunhofer integral [6]

$$p_s(\theta, \phi) = \int_{-a}^{a} \int_{-b}^{b} \xi(x, y) e^{ik(x \sin\phi \sin\theta + y \sin\phi \cos\theta)} \mathrm{d}x\mathrm{d}y. \quad (1)$$

The subindex $s = R, T$ represents the reflection and transmission problem respectively, and $\xi(x, y) = R(x, y)$ ($\xi(x, y) = T(x, y)$) for the reflection (transmission) problem.

In order to design a hologram that can behave as an ideal diffuser in both reflection and transmission sides, we look for a spatial phase distribution for the both the reflection and transmission coefficient such that the spatial Fourier transform of said distribution approximates a flat angular response. There are many number theoretic sequences that can help design such phase distribution, such as the maximum length or quadratic residue sequences [7].

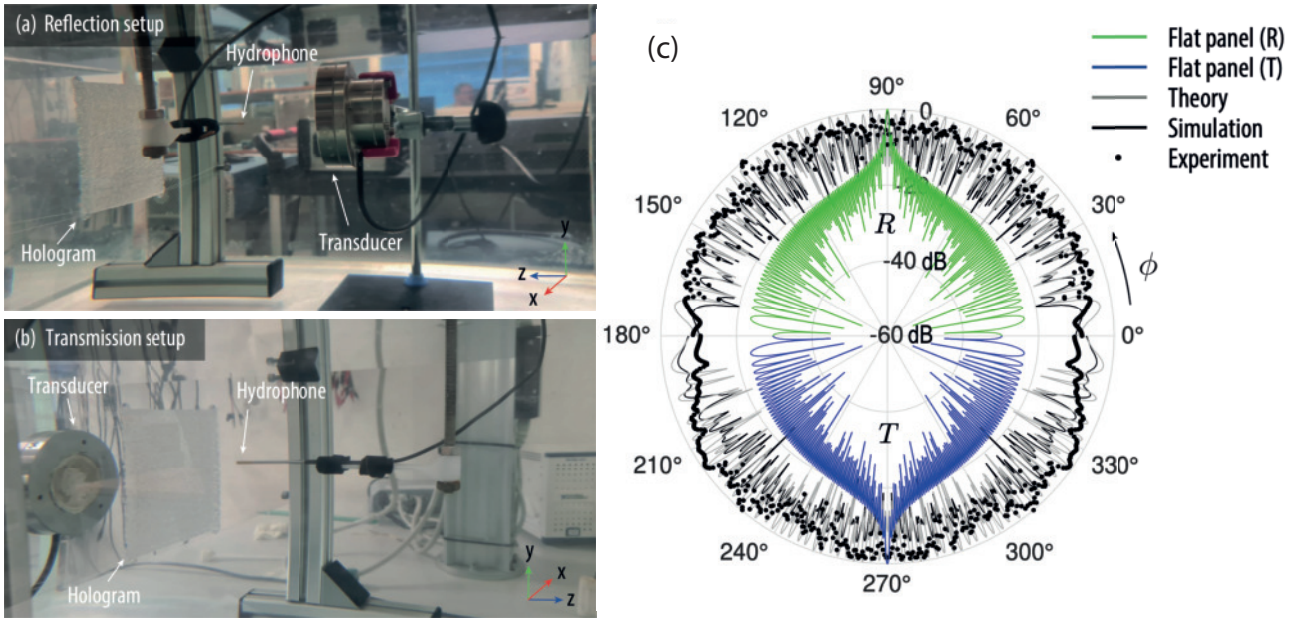

Figure 2. Experimental water tank measurement setup of the 3D-printed diffusing hologram in (a) reflection and (b) transmission situations. (c) Measured (dots) scattered polar pressure distribution in reflection (R) and transmission (T) compared to analytical (black line) values (QR) and the scattered field of a flat vibrating piston (blue and green lines).

Here, the quadratic residue (QR) sequence will be used, which when repeated in space, allows to generate evenly spaced diffraction lobes with even energy.

Experimental measurements of a 3D-printed hologram, with $N = 53$ repeated $M = 3$ times (see Fig. 1(a,b), were made in a water tank for the reflection and transmission configurations. Figures 2(c) show the polar scattered energy distributions measured from both sides of the hologram. It can be observed from Fig. 2(c) that both measured scattering fields are more uniform than the polar response of a planar vibrating piston, which outputs energy narrowly in the normal axis (0°), and are in good agreement with the predicted analytical curve. The Spatial Auto-Correlation Coefficient (SACC) of the polar distributions are $\delta^R = 0.65$ and $\delta^T = 0.71$ for the reflected and transmitted wave fields, respectively. Those can be considered quite high values due to the physical nature of the SACC where $\delta \to 0$ denotes a Dirac-like specular distribution and $\delta = 1$ a fully spherical one. Knowing than a SACC of unity is almost impossible to reach with traditional number theoretic sequences [8], there would be some diminishing returns in successfully increasing the SACC value when aiming closer to unity. A value around 0.7 thus already denotes a strong scattering behaviour, akin to one obtained through a Lambertian distribution.

In this work we have designed a bi-directional asymmetric ultrasonic hologram that can simultaneously control both the reflected and transmitted wave-fields. Depending on the applications, such hologram could be useful in situations where transmitted and reflected wave-fields need to be controlled at the same time, such as a bi-directional diffusing system emitting and receiving equally in and from all directions (equivalent of perfect optical diffusers in optics) or as a bi-directional beam directivity selector. Such hologram could also be used directly in reflection situations for minimizing unwanted specular reflections. This kind of tunable bidirectional hologram could be further optimized to create decollimating/collimating/focusing scattering wave fields for one or both directions, with potential applications ranging from ultrasound-guided medical procedures [9] to compressing sensing [10].

ABSTRACT

We report the necessary conditions for weak scattering of longitudinal and flexural waves in a beam loaded by multiple resonators. The equations of motion of a one-dimensional elastic waveguide with several point resonators are derived by a Green's matrix approach, for any resonator with any number of natural frequencies and morphology modeled by the transfer matrix method. The multiple scattering theory is used to express the response os the system by an infinite series whose convergence is closely linked to the scattering intensity provided by the resonators. The spectral radius of the scattering matrix is used to study of the convergence. Furthermore, we show that the Born approximation is provided by the leading order of the multiple scattering expansion. The work offers approximate expressions for the spectral radius, providing a preliminary step to a clear physical interpretation of weak scattering.

Keywords: *Multiple Scattering, Locally resonant materials, Weak scattering, Born approximation*

Metamaterials are structured composites with engineered wave propagation properties. In elasticity and acoutstics, they offer advanced control over flexural waves, with applications in vibration isolation, energy harvesting, and cloaking [1–5]. The wave response in such systems is influenced by multiple scattering interactions between discrete resonators. When these interactions are weak, simplified models, such as the Born approximation, provide accurate solutions. However, a rigorous criterion for weak scattering in flexural wave systems is necessary.

We consider longitudinal and flexural waves propagating through a straight beam-rod waveguide of infinite length, and also assume that the reference axis x coincides with the centroid of the cross-section, so no coupling between both types of waves occurs if the medium is homogeneous [6]. In this paper, an arrangement of N scatterers with internal resonances distributed along the beam at locations $x_1 < x_2 < \cdots < x_N$, will also be considered. We do not make any restriction except that the motion of both beam and resonators is restricted to the xz–plane. This approximation, known as plane-strain, usually provides good representations of real-life problems.

Assuming time harmonic motion, the state vector can be written as $\mathbf{U}(x,t) = \mathbf{u}(x)\, e^{i\omega t}$ and hence the time dependence is understood and omitted hereafter, with

$$\mathbf{u}(x) = \{u(x),\ w(x),\ \theta(x),\ N(x),\ V(x),\ M(x)\}^T. \tag{1}$$

being $u(x)$ and $w(x)$ the displacements in x and z direction of the reference axis and $\theta(x)$ the cross section rotation; the functions $N_x(x), V_z(x), M_y(x)$ represent the generalized forces associated to the previous kinematics variables, i.e. the normal and shear forces, and bending moment at position x. The system of equations (**??**) is frequency–dependent and can be written in matrix form as

$$\frac{\mathrm{d}\mathbf{u}}{\mathrm{d}x} = \mathbf{A}\,\mathbf{u} + \mathbf{q}(x), \tag{2}$$

where

$$\mathbf{A} = \begin{bmatrix} 0 & 0 & 0 & 1/EA & 0 & 0 \\ 0 & 0 & 1 & 0 & 1/GA_z & 0 \\ 0 & 0 & 0 & 0 & 0 & 1/EI_y \\ -\rho A\omega^2 & 0 & 0 & 0 & 0 & 0 \\ 0 & -\rho A\omega^2 & 0 & 0 & 0 & 0 \\ 0 & 0 & -\rho I_y\omega^2 & 0 & -1 & 0 \end{bmatrix}, \qquad \mathbf{q}(x) = \begin{Bmatrix} 0 \\ 0 \\ 0 \\ -q_x \\ -q_z \\ -m_y \end{Bmatrix},$$

represents the constitutive matrix and the external forces, respectively.

The closed-form expression found for the matrix $\mathbf{K}_\alpha$, representing the response of the α-scatterer and that can be obtained by the Transfer Matrix Method [7], enables us to write Eq. (2) as follows

$$\frac{\mathrm{d}\mathbf{u}}{\mathrm{d}x} = \mathbf{A}\,\mathbf{u} + \sum_{\alpha=1}^{N} \mathbf{K}_\alpha \mathbf{u}(x_\alpha)\,\delta(x - x_\alpha) + \mathbf{q}_e(x)\,. \quad (3)$$

The total solution is written as

$$\mathbf{u}(x) = \boldsymbol{\psi}_0(x) + \mathbf{u}_s(x), \quad (4)$$

where $\boldsymbol{\psi}_0(x)$ denotes the state vector corresponding to the incident wave and is the solution of

$$\frac{\mathrm{d}\boldsymbol{\psi}_0}{\mathrm{d}x} = \mathbf{A}\,\boldsymbol{\psi}_0 + \mathbf{q}_e(x). \quad (5)$$

Moreover, $\mathbf{u}_s(x)$ represents the state vector of the scattered wave, which is solution of

$$\frac{\mathrm{d}\mathbf{u}_s}{\mathrm{d}x} = \mathbf{A}\,\mathbf{u}_s + \sum_{\alpha=1}^{N} \mathbf{K}_\alpha \mathbf{u}(x_\alpha)\,\delta(x - x_\alpha). \quad (6)$$

The solution will be presented in terms of the Green's matrix of the system, $\mathbf{G}(x)$, defined as the solution of

$$\left(\frac{\mathrm{d}}{\mathrm{d}x} - \mathbf{A}\right)\mathbf{G} = \mathbf{I}\,\delta(x). \quad (7)$$

The general solution of Eq. (3) can then be written as

$$\mathbf{u}(x) = \boldsymbol{\psi}_0(x) + \mathbf{u}_s(x) = \boldsymbol{\psi}_0(x) + \sum_{\beta=1}^{N} \mathbf{G}(x - x_\beta)\,\mathbf{K}_\beta\,\mathbf{u}(x_\beta). \quad (8)$$

After evaluating Eq. (8) at $x_1, \ldots, x_N$, the following system of linear equations arises

$$\mathbf{u}(x_\alpha) - \sum_{\beta=1}^{N} \mathbf{G}(x_\alpha - x_\beta)\,\mathbf{K}_\beta\,\mathbf{u}(x_\beta) = \boldsymbol{\psi}_0(x_\alpha) \quad , \quad 1 \le \alpha \le N. \quad (9)$$

Let us now introduce the following auxiliary variables associated with each resonator.

$$\boldsymbol{\phi}(x_\alpha) = \left[\mathbf{I} - \mathbf{G}(0^+)\mathbf{K}_\alpha\right]\,\mathbf{u}(x_\alpha). \quad (10)$$

After some rearrangements, the system of equations (9) is written in terms of the new variables defined above as

$$\begin{bmatrix} \mathbf{I} & -\mathbf{G}(x_1 - x_2)\mathbf{t}_2 & \cdots & -\mathbf{G}(x_1 - x_N)\mathbf{t}_N \\ -\mathbf{G}(x_2 - x_1)\mathbf{t}_1 & \mathbf{I} & \cdots & -\mathbf{G}(x_2 - x_N)\mathbf{t}_N \\ \vdots & \vdots & \ddots & \vdots \\ -\mathbf{G}(x_N - x_1)\mathbf{t}_1 & -\mathbf{G}(x_N - x_2)\mathbf{t}_2 & \cdots & \mathbf{I} \end{bmatrix} \begin{Bmatrix} \boldsymbol{\phi}(x_1) \\ \boldsymbol{\phi}(x_2) \\ \vdots \\ \boldsymbol{\phi}(x_N) \end{Bmatrix} = \begin{Bmatrix} \boldsymbol{\psi}_0(x_1) \\ \boldsymbol{\psi}_0(x_2) \\ \vdots \\ \boldsymbol{\psi}_0(x_N) \end{Bmatrix}, \quad (11)$$

where the new matrices $\mathbf{t}_\alpha$ are defined as

$$\mathbf{t}_\alpha = \mathbf{K}_\alpha\,\left[\mathbf{I} - \mathbf{G}(0^+)\mathbf{K}_\alpha\right]^{-1}. \quad (12)$$

This 6×6 matrix represents the dynamical impedance of each scatterer with respect to homogeneous parameters of the host beam. It contains the mechanical and inertia properties throughout the components of $\mathbf{K}_\alpha$ matrix, so fully described the resonant behavior of the scatterers. Eq. (11)

can be written in compact form as

$$[\mathbf{I} - \mathbf{g}]\ \mathbf{\Phi} = \mathbf{\Psi}_0, \tag{13}$$

where the matrix $\mathbf{g} = \hat{\mathbf{G}}\,\hat{\mathbf{T}}$ and

$$\hat{\mathbf{G}} = \begin{bmatrix} \mathbf{0} & \mathbf{G}(x_1 - x_2) & \cdots & \mathbf{G}(x_1 - x_N) \\ \mathbf{G}(x_2 - x_1) & \mathbf{0} & \cdots & \mathbf{G}(x_2 - x_N) \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{G}(x_N - x_1) & \mathbf{G}(x_N - x_2) & \cdots & \mathbf{0} \end{bmatrix}, \quad \hat{\mathbf{T}} = \begin{bmatrix} \mathbf{t_1} & \cdots & \mathbf{0} \\ \vdots & \ddots & \vdots \\ \mathbf{0} & \cdots & \mathbf{t}_N \end{bmatrix}. \tag{14}$$

The scattering coefficients $\mathbf{\Phi}$ are simply deduced from Eq. (13) as

$$\mathbf{\Phi} = [\mathbf{I} - \mathbf{g}]^{-1}\,\mathbf{\Psi}_0. \tag{15}$$

The state vector is obtained from

$$\mathbf{u}(x) = \boldsymbol{\psi}_0(x) + \sum_{\alpha=1}^{N} \mathbf{G}(x - x_\alpha)\,\mathbf{t}_\alpha\,\boldsymbol{\phi}(x_\alpha). \tag{16}$$

The solution of Eq. (15) and the state vector of Eq. (16) provide the exact approach to the problem for any frequency.

As shown above, the scattering coefficients are found from the solution of Eq. (15). If the elements of the *square* matrix $\mathbf{g}$ are sufficiently small, the inverse is efficiently evaluated by means of the Neumann series expansion, namely

$$[\mathbf{I} - \mathbf{g}]^{-1} = \mathbf{I} + \mathbf{g} + \mathbf{g}^2 + \cdots = \sum_{n=0}^{\infty} \mathbf{g}^n. \tag{17}$$

The necessary and sufficient condition to guarantee that the series converges is that the spectral radius $\rho(\mathbf{g})$, defined as the maximum of the absolute values of the eigenvalues of $\mathbf{g}$, is less than unity. When $\rho(\mathbf{g}) < 1$, the scattering induced by the N resonators can be considered as weak, meaning that a few terms of the series are necessary to accurately reproduce the scattering behavior of the system. In other situations for which $\rho(\mathbf{g}) > 1$ holds, the inverse matrix cannot be approximated by the expansion of Eq. (17).

By employing a Green's matrix approach, this work reports analytical derivations and approximations to effectively model the interaction between waves and resonators en beams [7]. Equations show that weak scattering conditions and the Born approximation depends on the spectral radius is sensitive to both local resonator properties and their spatial configuration, which influence scattering intensity. Future work could explore more complex arrangements and resonator types, potentially extending these findings to applications in structural health monitoring and wave-based material design.

ACOUSTICAL BEHAVIOUR OF VENT HOLES ON BRASSWIND INSTRUMENTS

Marco Aragó Bishop [1*] **Arnold Myers**[2] **Murray Campbell**[1]

ABSTRACT

In most brass instruments, the acoustical resonator forms a cylindrically symmetric tube open at both ends. Sound is produced by the vibrations of the player's lips at the input end and radiates through the bell at the exit. Typically, these are the only two openings in brass instruments. However, in specific categories, such as the trumpets used in many modern performances by period orchestras, additional holes are drilled into the sides of the tube. The player can open or close these holes to improve the instrument's intonation and stability, particularly in baroque performances.

This paper studies the acoustical behaviour of two of the vent holes in a four-hole vented trumpet, for which the most notable behaviour is observed. The input impedance is measured using the BIAS system for all possible venting fingerings. These experimental results are compared with numerical simulations using the Openwind framework, with input data derived from mechanical measurements of the bore profile of the trumpet.

Keywords: *brass instruments, vented trumpet, input impedance, resonances, vent holes.*

1. INTRODUCTION

Brass instruments produce sound by modulating airflow through the player's vibrating lips at the mouthpiece, initiating oscillations in the air column within the instrument. This lip-driven excitation is what acoustically defines the family of brass instruments. Most modern examples, such as the trumpet, trombone, and tuba, are made of metal and incorporate valves or a slide mechanism to vary the effective tube length. By altering the tube's length, the player adjusts the instrument's resonant frequencies to match the lip vibration, allowing different notes to be played.

A notable exception is the natural trumpet, which lacks holes or valves, requiring players to rely solely on their embouchure and breath control to produce a range of pitches. The instrument's geometry is almost cylindrical, with an expanding bell at the end, requiring an appropriate mouthpiece to be played. With this configuration, the instrument can produce a series of pitched sounds close to that of a harmonic series, producing natural notes up to the 16th harmonic and beyond [1].

As with other brass instruments, the frequencies of the resonances of the natural trumpet form an approximately harmonic series. Nonetheless, even if they were perfectly harmonic, those pitches would not necessarily be considered "in tune" since neither the tempered scales nor the specific tuning requirements of a performance situation match a pure harmonic series. Consequently, natural trumpet players must be highly skilled to refine the pitch of the sound emitted by carefully adjusting embouchure, vocal tract, and breathing. Of particular difficulty is the high register, commonly known as the *clarino* register, which includes high-frequency notes that are closely spaced. This register is particularly challenging for players when performed at loud dynamics due to the instrument's resonances strongly dictating the pitches produced, which inherently limits the player's ability to control it with precision.

The vented trumpet was invented in the second half of the twentieth century to facilitate stability and control of intonation in playing. Up to four vent holes were added, connecting the instrument's internal air column to the outside atmosphere, thereby reducing the amplitude of the pressure waves near the holes. This effect is comparable to cutting off the tubing portion below the hole for low frequencies. However, recent research has shown that the acoustical effects caused by opening the smaller vent holes are more subtle and require further analysis [2].

In this paper, the acoustical behaviour of two of the vent holes in an available four-hole vented trumpet crooked in D is presented. The analysis is restricted to the instrument's resonating air column, which is modelled in its linear regime through the input impedance Z_{in}, defined as the frequency-dependent ratio between the acoustic pressure and the volume flow at the instrument's entrance. The input impedance is measured using the BIAS system [3] for all possible venting fingerings. These experimental results are compared with simulations using the Openwind framework [4]. Input data for simulations is provided from mechanical measurements of the bore profile of the vented trumpet.

2. LINEAR ACOUSTICS OF RESONATOR

From a physical point of view, a wind instrument can be characterised by a non-linear excitation source coupled with a passive resonator, which is mainly reduced to its linear response. The latter provides a number of resonances, which interact with the non-linear source to produce the pitch and waveform of the played note [5]. In this study, the analysis is restricted to the linear acoustical response of the instrument.

To describe the system, we make use of the concept of acoustic impedance, which relates the acoustic pressure p to the particle velocity field $\underline{u}$. Since the velocity field is a vectorial quantity, the impedance is, in general, direction-dependent. However, in the case of tubular geometries and under the plane wave approximation, the particle velocity is assumed to be oriented along the longitudinal axis of the tube. As a result, the directional dependence of the impedance can be neglected. This approximation holds when the tube length is significantly larger than its radius, a condition satisfied by the vented trumpet examined.

In particular, the input impedance is of special interest, offering a convenient way to analyse brass instruments, as the magnitude of the input impedance explicitly shows the frequencies and amplitudes of the resonances on which the played notes are based [6]. It is, therefore, used as an invaluable way to characterise the instrument. Furthermore, it is possible to express the input impedance in terms of modal parameters [5],

$$Z_{in}(\omega) = i\omega \sum_m \frac{p_m^2(0)}{\omega_m^2 + i\omega\omega_m/Q_m - \omega^2}, \qquad (1)$$

where each linear term only depends on the angular frequency ω_m, amplitude $p_m^2(0)$ and quality factor Q_m of resonance m. This approach allows for efficient analysis of the resonator and hole effects, as specific resonances can be either boosted or suppressed depending on the playing requirements. In this framework, the behaviour of the vent holes can be analysed through the variation of the modal parameters associated with each resonance, providing a means to characterise their influence on the overall acoustical response.

2.1 Vent Holes

When opening a hole in an axially symmetric tube, the intended musical purpose must be taken into consideration. For vent holes, this corresponds to a strategically placed hole that is not used to define a new fundamental frequency but instead, when opened, helps with intonation correction, response improvement, or sound clarity.

The hole is studied by considering the component as an additional short tube in the instrument's geometry. In energetic terms, when a sinusoid travelling down the pipe encounters a hole, some of the energy is transmitted towards the bell end, some is radiated from the hole, and the remaining energy is reflected to the input. Therefore, the shape of the standing wave formed within the air column changes along the length of the instrument, even if the radius of the tube is constant throughout.

A proper parameter to characterise the energy in the system is the sound power transmission T, defined as the fraction of sound energy which is transmitted past the hole [7],

$$T = \frac{1}{1 + (cb^2/4\pi h_e r^2 f)^2}, \qquad (2)$$

where c is the speed of sound, f is the frequency of the sound wave, b is the hole radius, and h_e is the effective acoustic length of the side branch.

At low frequencies, the power transmission rapidly approaches zero, indicating an effective cutoff of the main

bore's right section. As the frequency increases, the transmission tends toward unity, with most of the sound propagating through the pipe, behaving as a high-pass filter. As a consequence, the effect of the hole on each resonance will vary depending on its frequency relative to this filtering behaviour. A useful parameter to characterise the hole is the cutoff frequency, defined as the frequency at which $T = \frac{1}{2}$. Resonances below the cutoff frequency will be significantly affected by the presence of the hole, while those above it will remain largely unaffected.

3. CALCULATING INPUT IMPEDANCE

The simulations performed on the vented trumpet rely on an accurate description of the instrument's bore profile, as well as ambient conditions matched to those of the experimental measurements. To maximise reproducibility between experiments and simulations, all relevant elements of the instrument were carefully measured. Assuming the main bore of the instrument is an axially symmetric tube, the geometry can be fully characterised by the radius as a function of the axial position. Accordingly, both the length of the pipe and the variation of its radius along the axis were measured mechanically using bore gauges. A three-dimensional reconstruction of the trumpet bore is shown in Fig. 1.

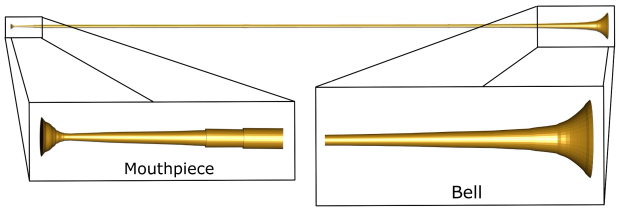

Figure 1. 3D model of vented trumpet geometry used in the Openwind simulation. A zoomed view of the shape of the mouthpiece and bell is shown. The total length of the bore is $L = 2.25\,\mathrm{m}$.

In this setup, following a systematic asymptotic analysis [8], the Webster horn equation, describing wave propagation in pipes of varying cross-sectional area, is reformulated as a pair of Telegrapher equations to model the system while accounting for viscothermal losses [9,10]. A Finite Element Method (FEM) approach, implemented in the Openwind framework, was employed to solve the system numerically. This method allows for the computation of the input impedance, as well as the pressure and volume flow fields along the bore, which were used to analyse the behaviour further.

The scheme enables the definition of the ambient conditions. For consistency with the experimental measurements, the temperature was set to $17\,^{\circ}\mathrm{C}$, and a radiation impedance for an infinitely flanged pipe was imposed as the boundary condition at the pipe end [11].

4. MEASURING INPUT IMPEDANCE

The input impedance was measured using the Brass Instrument Analysis System (BIAS), which offers a fast and accessible method to perform many successive measurements on the impedance of brass instruments [12]. It relies on a capillary-based technique, where two microphones are positioned on either side of a high-impedance capillary, which is then connected to the mouthpiece [3]. The experimental setup of the BIAS head mounted with a vented trumpet is shown in Fig. 2.

Figure 2. Experimental setup of the BIAS head mounted with the vented trumpet in the anechoic chamber.

Impedance data was collected using the Versatile Instrument Analysis System (VIAS) software, which allows for higher energy in the excitation signal and user-selected time and frequency range for each measurement. Measurements were performed using a logarithmic sweep from $20\,\mathrm{Hz}$ to $4\,\mathrm{kHz}$ with a period of $600\,\mathrm{s}$ using a sinusoidal excitation signal, ensuring adequate time for standing wave formation at lower frequencies.

Using this experimental configuration, the input impedance of the vented trumpet was measured systemat-

ically by opening one vent hole at a time. To replicate the opening and closing of holes as a player would with their fingers while ensuring consistency across measurements, all holes were appropriately sealed and maintained airtight closure except for tests when a single hole was opened. To ensure this was the case for all measurements, a reading of the impedance with all holes closed was taken at the beginning and end of the sessions, verifying the stability of the procedure.

5. RESULTS

The positions along the bore and dimensions of two vent holes on the vented trumpet are listed in Tab. 1, referred to as the thumb hole (hole 1) and octave hole (hole 4), with hole 1 having the larger radius. Due to the curved instrument surface, chimney height was defined as the maximum distance from the surface to the top edge of the hole, measured along the local normal and assumed constant across the hole.

Table 1. Position, radius, and chimney length of holes 1 and 4. Errors indicated in parentheses.

Hole	Position [m]	Radius [mm]	Chimney [mm]
Hole 1	1.1920(1)	3.72(5)	0.68(5)
Hole 4	1.0455(1)	1.75(5)	0.63(5)

Thus, opening hole 1 is expected to significantly alter the instrument's resonances. The measured input impedance in this configuration is shown in Fig. 3, where each peak corresponds to a resonance.

The large radius results in minimal energy transmission beyond the hole, leading to a general upward shift in resonance frequencies. In particular, the hole dimensions translate to a cutoff frequency of approximately 1913 Hz, which is well above the intended playing frequencies with the hole open. Consequently, the hole significantly alters the resonance structure in this frequency range. Moreover, Fig. 3 reveals a general trend in the impedance magnitude: odd resonances exhibit increased amplitude due to constructive interference of pressure waves upstream of the hole, whereas even resonances are attenuated as a result of destructive interference, leading to a reduction in the input impedance amplitude. These effects progressively diminish for resonances approaching the cutoff frequency.

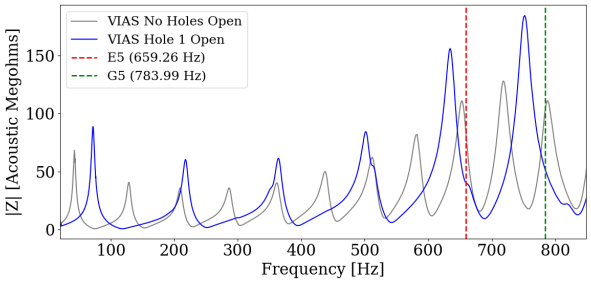

Figure 3. Input impedance magnitude measured for the vented trumpet with hole 1 opened (blue), and all holes closed (grey). The vertical dashed lines indicate the frequencies of the pitches for which the hole is opened, as indicated in the legend.

The intended playing frequencies with the hole open are occasionally E5 and, more importantly, G5, primarily improving playing security and intonation of the notes. However, in both cases, the nearest resonances (nine and eleven) undergo significant frequency shifts, reducing their amplitudes near the playing frequencies. At first glance, considering a simplistic approach in which the pitch is determined mainly by the closest resonance to the playing frequency, this suggests a negative impact on playability. Yet, analysis of the pressure and flow fields for the weak resonance just above G5 reveals a distinct acoustic effect which must be taken into account.

Fig. 4 shows the pressure and volume flow fields comparison between the large resonance with all holes closed at 790.30 Hz and the small resonance with hole 1 opened at 829.19 Hz, those closest to the G5 playing frequency. The apparent small pressure amplitude for the weak resonance with respect to the large resonance at the input is responsible for the small impedance magnitude observed previously.

A closer inspection of the pressure field reveals greater constructive interference occurring between the hole and the instrument's bell rather than between the input and the hole, thus increasing the amplitude of the standing wave pattern downstream of the hole. This suggests that the segment extending from the hole to the bell supports a robust resonance with pressure nodes at both boundaries near the resonance frequency. Consequently, a high flow amplitude is expected at the bell end, consistent with the bottom plot of Fig. 4. The intensified standing wave pattern downstream of the hole corresponds to an

increased energy concentration in that region. Given the relatively high flow amplitude at the bell compared to the overall wave amplitude, significant acoustic energy is radiated efficiently from the bell, facilitating the stable production of the G5 pitch despite the small amplitude of the associated resonance.

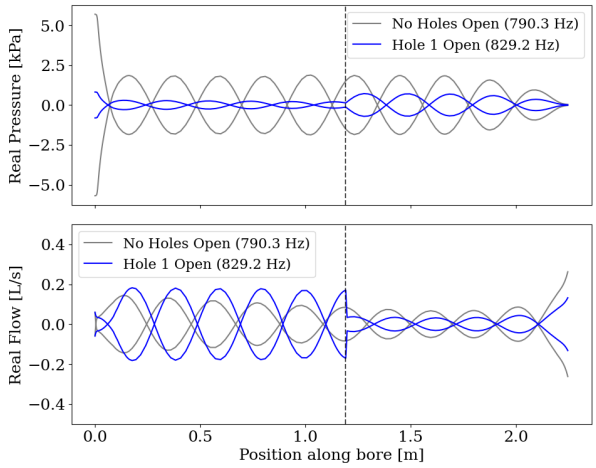

Figure 4. Top: Real part of complex pressure field along the bore for the resonance frequencies closest to G5. Bottom: Real part of the complex volume flow field along the bore is for the resonance frequencies closest to G5. The grey line indicates the closest resonance with all holes closed. The blue line indicates the closest resonance with hole 1 opened. The vertical dashed line indicates the hole position.

A similar behaviour was observed for hole 4. From Tab. 1, hole 4 has the lowest radius, thereby having the smallest cutoff frequency at 817 Hz. The qualitative behaviour of the fourth hole was found to be equivalent for both even and odd resonances. However, due to the small dimensions of the hole, these effects are drastically reduced as the resonances approach the cutoff frequency, giving a significantly different input impedance as compared to hole 1. For instance, the suppression of the even resonances is highly reduced near the cutoff frequency.

Hole 4 comprises the playing of notes corresponding to the even harmonics of D2. Fig. 5 shows three of these notes (D5, F♯5, A5) with their corresponding playing frequency to exemplify the acoustic behaviour of the hole. By opening hole 4, the resonances closest to the even harmonic playing frequencies have been shifted in frequency closer to these, notably improving the intonation of the notes. However, as for the case of hole 1, these resonances are somewhat suppressed by the hole. Therefore, the playability of the notes could be compromised.

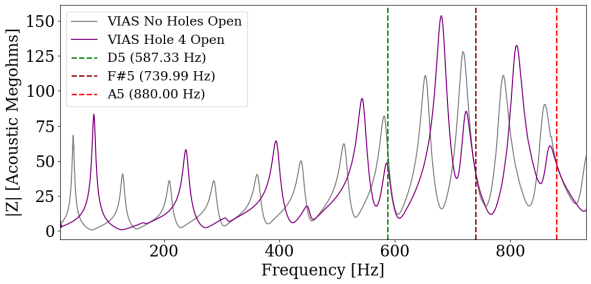

Figure 5. Input impedance magnitude measured for the vented trumpet with hole 4 opened (purple) and all holes closed (grey). The vertical dashed lines indicate the frequencies of the pitches for which the hole is opened, as indicated in the legend.

Nonetheless, the same reasoning applied to hole 1 extends to the acoustic pressure field and volume flow in this case. For the even resonances, a stronger standing wave pattern develops downstream of the hole, increasing flow amplitude at the bell and boosting sound radiation, thereby improving the stability of the even harmonics of D2.

6. CONCLUSION

The acoustical behaviour of the thumb and octave vent holes in an available four-hole vented trumpet has been examined. Under a linear approximation, the input impedance was used to determine the behaviour of the resonances of the system by observing variations in the amplitude, frequency and quality factors of each resonance when a hole was opened along the tube. The input impedance was measured experimentally using the BIAS system, and numerical simulations using the FEM were used to analyse the behaviour of each resonance in greater detail.

The opening of the thumb hole (hole 1) showed the nearest resonances to the intended playing frequencies to undergo a significant frequency shift and an evident reduction in their impedance amplitude, which suggested, at first instance, a negative impact on the playability. However, the acoustic pressure and volume flow fields calcu-

lated from the simulations on the instrument for these resonances showed a constructive interference occurring between the hole and the instrument's bell rather than across the input and the hole, thus increasing the amplitude of the standing wave pattern downstream the hole. The intensified standing wave pattern corresponds to an increased energy concentration in that region, and, as a result, significant energy is radiated efficiently from the bell, facilitating the stable production of the notes for which the closest resonances were observed to reduce their amplitude. A similar behaviour was observed for the octave hole (hole 4).

7. ACKNOWLEDGMENTS

The authors are grateful to Jim Woodhouse for his insightful discussions on modal parameter extraction, which have informed the analysis presented in this work. The authors also wish to thank Sandy McGrattan for sharing his expertise on the practical use of the vented trumpet and for testing the instrument, providing valuable feedback.

EMBOUCHURE PARAMETER VARIATIONS ACROSS BRASS MUSICIANS OF DIFFERENT LEVELS OF PROFICIENCY

Amann Paul[1*] **Chatziioannou Vasileios**[1]
Nicolay Pascal[2] **Willmann Roland**[2]
[1] Institute of Music Acoustics Wiener Klangstil, University of Music and Performing Arts Vienna
[2] Carinthia University of Applied Sciences, Austria

ABSTRACT

Sound production in brass instruments requires complex interactions between embouchure parameters such as blowing pressure, mouthpiece force, etc. This paper presents findings from the use of a custom-developed digital mouthpiece designed to efficiently acquire embouchure data. The digital mouthpiece is able to record the forces of the upper and lower lips separately, as well as air pressure both inside the oral cavity and inside the mouthpiece. Data from 31 trombonists of different levels of progress were recorded, including a wide range from beginners to experts. In this context, the study enhances and expands the existing understanding of forces exerted on the mouthpiece, by considering the forces of the upper and lower lip separately. The collected data demonstrate the widely-discussed pivoting movement during the performance of a brass instrument, and dominant types of playing can be seen with regard to the load conditions of the upper and lower lip.
In addition, data from the 31 participating musicians is shown, demonstrating the relationship between the mouthpiece force applied, the pitch, intensity and air pressure in the mouth under realistic playing conditions.

1. INTRODUCTION

Embouchure parameters, such as mouthpiece force and blowing pressure, are featured in studies across various contexts, contributing to a better understanding of sound production for acousticians, educators, and brass musicians.
For example, the force exerted on the mouthpiece has been used to investigate the acoustical behaviour of brass players' lips with the aid of strain gauges placed between the lip and mouthpiece [1, 2]. The measured phase difference between the acoustic pressure in the lip-driven cylinder and the strain demonstrated the outward and upward striking movements of the lips in relation to the tone height. Other studies investigated the relationship between the mouthpiece force, pitch and sound pressure level, with the result that the force increases with pitch and intensity [3–5]. Besides the perspective of various pedagogical embouchure concepts regarding mouthpiece force [6, 7] and medical studies on the effect of mouthpiece force on tooth position [8], the relationship between the force applied and the level of proficiency was also examined [4, 9]. However, none of the experimental studies have separately examined the force exerted by the mouthpiece on the upper and lower lips. Observations of musicians indicate that a pivoting movement over the tone range is significant for the production of different pitches depending on the musician's embouchure technique [7]. The different angular positions of the mouthpiece of individual musicians and a pivoting movement were also observed in the MRI study on trumpet playing by Schumacher et al. [10]. Depending on the position of the jaw, this pivoting movement results in the mouthpiece being subjected to varying force distributions from the upper and lower lips.
The simultaneous measurement of multiple embouchure

parameters, as demonstrated by Bianco et al. [5], highlights that different combinations of input variables can result in the same output.
This paper gives insight into the data set of 31 trombonists of different levels of proficiency, in which the forces of the upper and lower lip, the oscillating air pressure in the mouthpiece, the air pressure in the oral cavity and the sound were recorded simultaneously. The study was approved by the ethics committee of the University of Music and Performing Arts Vienna.

2. STUDY DESIGN AND DATA AQUISITION

The study was conducted at music schools and music universities and lasted around 30 minutes per participant. After being informed about the study and giving their consent, the musicians had time to familiarise themselves with the measurement set-up. The musicians played a specified sequence of tones in two separate runs, which were recorded for analysis. Subsequently, they completed a detailed questionnaire. A set of sheet music, divided into three levels of difficulty and containing passages from contemporary literature, was developed as the specified sequence of tones. Each participant was required to play all sections corresponding to their level of proficiency.
An enhanced version of the measuring device described by Amann et al. [11, 12] was calibrated and employed for the data acquisition. This mouthpiece, equipped with four load cells and two air pressure sensors, among other components, allows for the recording of mouthpiece parameters without significantly affecting the playing experience. In addition, a clip microphone (Shure BETA98H/C) was attached to the bell to record the audio signal.
The recorded data from the measuring device with a sampling rate of approx. 1750Hz was then preprocessed using Matlab. For detailed analysis and comparability between musicians, it was necessary to assign individual data points to the corresponding notes played. To achieve this, the recorded audio signal was segmented into the individual tones of the .musicxml file of the sheet music using audio score alignment techniques [13]. Subsequent refinement of the segmentation using Sonic Visualiser was necessary. The continuously recorded time stamp from the measuring device with the segmentation enabled the assignment of all data points to their corresponding notes. Each note was labelled with specific attributes, such as articulation, note length, and other relevant characteristics.
For the statistical analysis, features were extracted from the extensive data set using the computing Software R.

3. STUDY RESULTS

A total of 31 individuals participated in the study, out of which 9 identified as female and 22 as male. Regarding age distribution, 20 participants were between 18 and 35 years old, and 11 participants were over 35 years old. To differentiate between various levels of proficiency, a single factor ”P” ranging from 0 to 6 was calculated based on responses from the survey and the musicians' ability to play part 1, parts 1 and 2, or parts 1, 2, and 3 of the music sheets. Although there is no clear distinction between beginners, intermediates, and experts, the differentiation based on the factor was defined as follows: a range of $0 \leq P \leq 2$ for beginners, $2 < P \leq 4.5$ for intermediates, and above 4.5 for experts. Accordingly, 14 beginners, 10 intermediate, and 9 experts participated in the study.

3.1 Upper and Lower Lip Mouthpiece Force

The forces referenced in this paper pertain to the mean force exerted by the upper and lower lips. For better comparability, the initial and final 25% of each note on a time scale were excluded from the calculation as they depend significantly on the articulation, which is not considered in this paper.
Figure 1 presents a box plot illustrating the forces exerted by the upper and lower lips, with each pair of boxes representing one participant. The lighter-coloured box indicates the force exerted by the upper lip, while the darker-coloured box represents the force exerted by the lower lip. In the plot, only those notes that are part of the easy excerpt and thus played by all participants are considered. The musicians are arranged from left to right according to their level of proficiency.
When considering the total mouthpiece force, no statistically significant differences between the applied forces and the level of proficiency can be observed. Although there are tendencies for higher mouthpiece forces and outliers among beginners, there are also musicians within this group who exert very low forces. The observed differences decrease when comparing the mouthpiece force of beginners in the easy excerpt with the mouthpiece force of experts in the hard excerpt.
After the data collection for beginners in music schools, the results were preliminarily discussed with their music teachers. Exceptionally high and very low forces exerted on the mouthpiece were not only revealed by the measurements but were also perceived by the teachers. High force values were commonly associated with the tense appearance of the student, while low force values were linked to

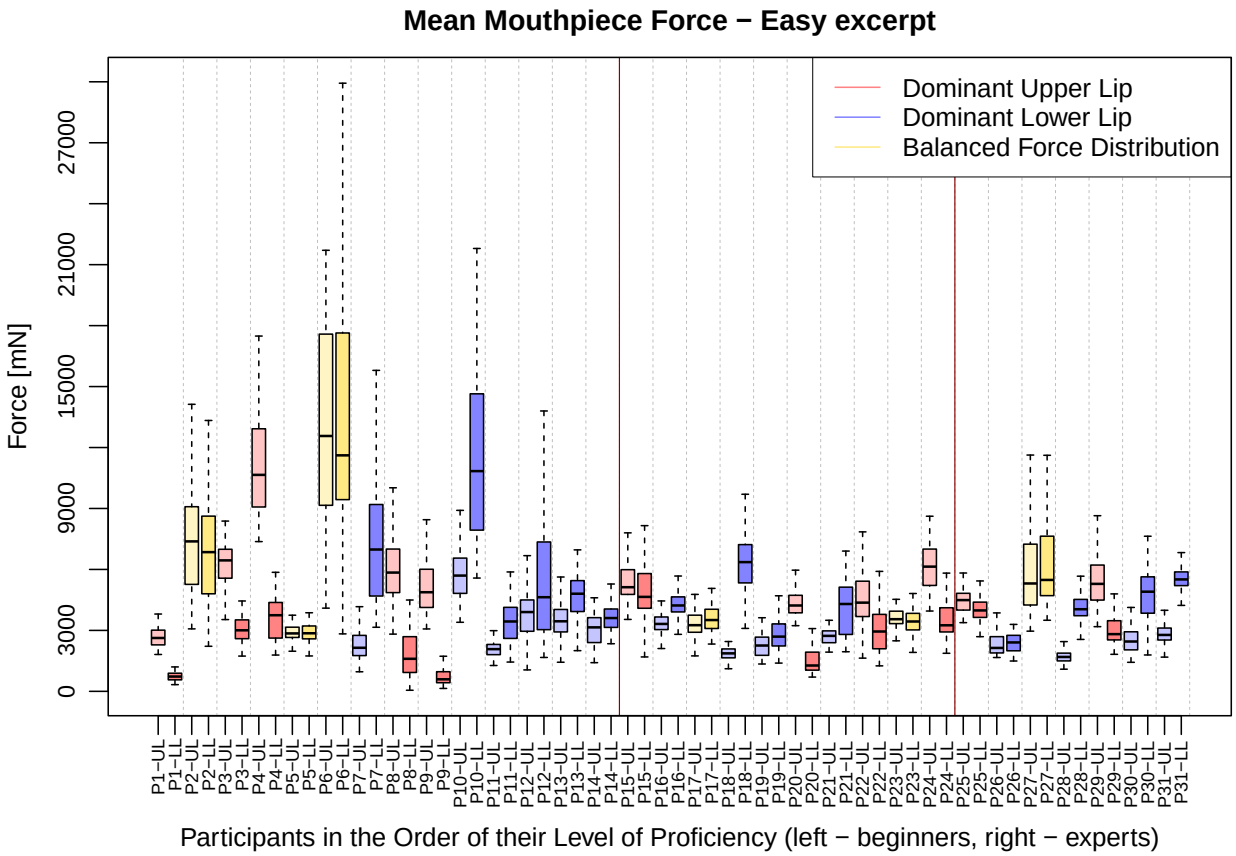

Figure 1. The Mouthpiece force of trombonists at different levels of proficiency is depicted, with UL and LL on the x-axis representing the force exerted by the upper and lower lips, respectively, for each individual. Participants 1 to 14 correspond to the beginner level, participants 15 to 24 correspond to the intermediate level, and participants 25 to 31 correspond to the expert level. The vertical lines separate the bars of the individuals (dashed) and the proficiency groups (red).

a lack of embouchure stability.

Different techniques and force distribution ratios are observed on average when comparing the forces exerted by the upper and lower lips. Musicians can be categorized based on their force distribution: those who apply more force to the upper lip (dominant upper lip, shown in red), those who apply more force to the lower lip (dominant lower lip, shown in blue), and those who maintain a balanced force distribution (shown in yellow). The distribution of forces can be caused both by a pivoting movement of the instrument relative to the head and by a displacement of the jaw. The ratio of the medians of the two forces is used as the threshold value to allow differentiation between the mentioned techniques. If the force exerted on the upper lip is 10% higher than that on the lower lip, the musician is classified as having a dominant upper lip embouchure. Conversely, if the force exerted on the lower lip is 10% higher than that on the upper lip, the musician is classified as having a dominant lower lip embouchure.

When examining the force distribution types in relation to pitch, some musicians exhibit a stable embouchure with minimal changes in force distribution. In contrast, others adjust their force ratios depending on the pitch significantly, resulting in noticeable variations. The change in embouchure when transitioning between different pitches, described by pedagogues as a tilting movement [7], can

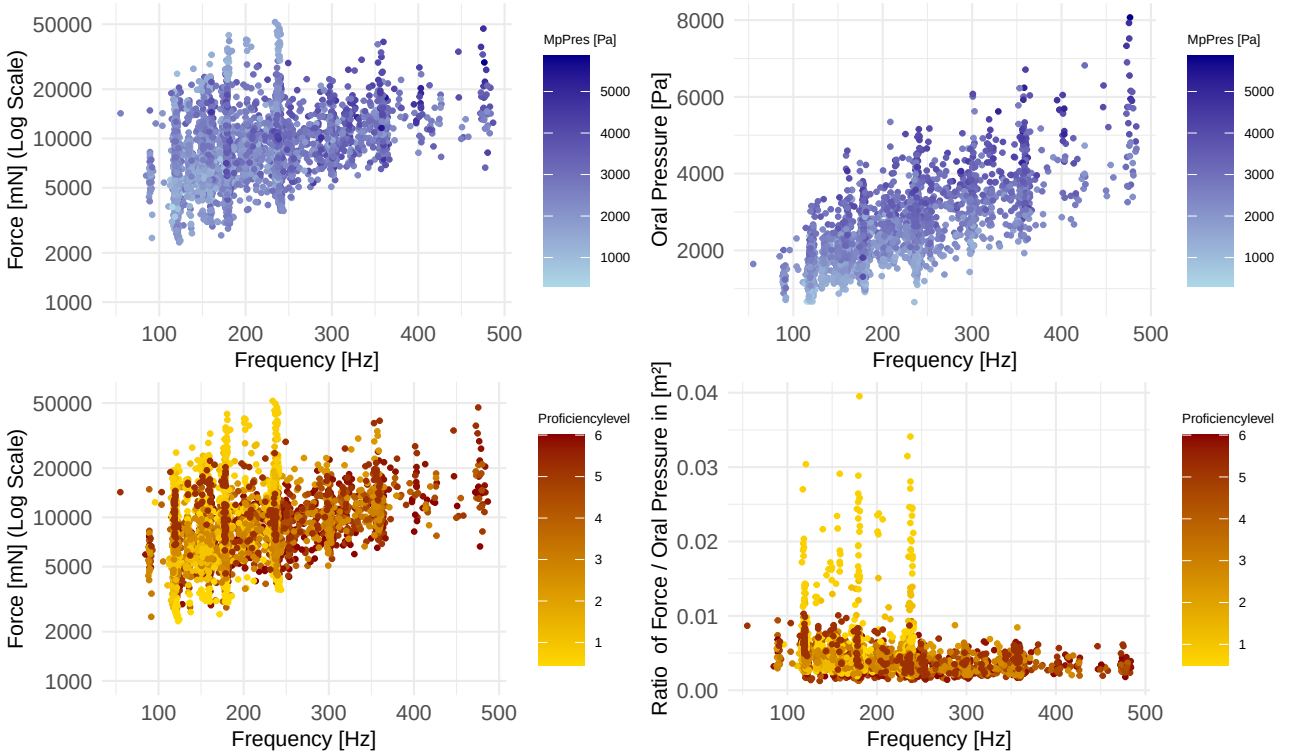

Figure 2. Relationships between force and frequency (top-left and bottom-left side), oral pressure and frequency (top-right side) and the ratio of force and oral pressure in relation to the frequency (bottom-right side) under realistic playing conditions. The colour of the upper plots indicates intensity: light blue for low RMS mouthpiece pressure values and dark blue for high RMS mouthpiece pressure values. The colour of the bottom plots correlates to the proficiency level of the musicians: yellow for beginners and red for experts.

be observed in the variations in the force distribution. The data do not support the popular assumption that certain embouchure techniques lead to increased success. Different force distribution types are observed across all levels of proficiency.

3.2 Interaction between Embouchure Parameters

The following section presents the results of the data analysis concerning the relationships between mouthpiece force, oral pressure, mouthpiece pressure, frequency, and proficiency level. Similar to the calculation of the shown force data, the oral pressure and root mean square (RMS) of the mouthpiece pressure values are derived from the middle 50% of the notes, thereby neglecting the note beginning and note ending.

As shown in Figure 2, the minimum mouthpiece force exerted by musicians to retain a note increases with frequency. When considering the data points of all musicians collectively, no relationship between intensity, represented by RMS mouthpiece pressure, can be discerned. Only by analyzing individual musicians separately does it become evident that, while some musicians maintain a constant force regardless of intensity, others increase their force as intensity rises.

When focusing on oral pressure, a clear positive correlation between frequency and oral pressure can be observed. The data in the lower frequency range align well with the results from brass instrument models regarding the minimum blowing pressure through linear stability analysis [14]. In the higher frequency range, however, the values achieved by musicians are significantly lower than predicted in [14].

The two bottom plots in Figure 2 pertain to the proficiency

level, ranging from 0 to 6, with red indicating high values and thus a high level of proficiency (experts). Since beginners were unable to achieve high notes, low levels of proficiency only extend up to the note Bb3 (approximately 233 Hz). It is notable that very low and very high mouthpiece forces in the lower pitch ranges are primarily utilized by beginners. Additionally, the maximum force values exerted by beginners when playing the note Bb3 are matched by expert musicians when playing Bb4.
In the bottom right plot, the ratio of force to oral pressure is shown as a function of frequency. What immediately stands out is that some beginners exert significantly more force on their lips relative to the corresponding air pressure in the oral cavity. Four individuals with a proficiency level between 0.5 and 1.2 (novice musicians) exceed a ratio of 0.11, while all others remain below this value.

4. CONCLUSIONS

In the paper, we examined the relationship between the embouchure parameters: mouthpiece force of the upper and lower lip, air pressure in the oral cavity, air pressure in the mouthpiece, in relation to pitch and proficiency level based on data from 31 trombonists. The separate examination of the forces of the upper and lower lip is a novelty and allows conclusions to be drawn about different playing techniques, with musicians exhibiting dominant upper lip force, dominant lower lip force, and balanced force distribution, similar to pedagogical methods regarding pivoting movements. A correlation between the dominant force distribution type and the level of proficiency cannot be established. It is also not statistically significant that beginners exert more force while playing than advanced and professional musicians. However, outliers among the beginners can be observed, who exert excessively high forces.
A limitation of this paper is that the force distribution between the upper and lower lip was not presented in relation to pitch and intensity. Musicians who tend to one of the three distribution types may change this distribution depending on the pitch, for example, through tilting. The detailed analysis will be presented in a future paper. Furthermore, the measurement system cannot record the placement of the mouthpiece and its changes during playing, which indirectly affects the force values of the upper and lower lip.
In relation to pitch, the data reveals a minimum necessary force and a minimum oral pressure required to sustain the notes (note initiation and note ending were not considered), which both increase with rising frequency. Additionally, the ratio of force to applied air pressure in the oral cavity is significantly higher for some novice participants. The presented data serve as a preliminary study for a larger study with more participants.

5. ACKNOWLEDGMENTS

We would like to express our sincere gratitude to the Austrian Research Promotion Agency (FFG) for funding the study. We also extend our heartfelt thanks to the musicians of Gustav Mahler Private University and the Carinthian Music Schools for their participation. Additionally, we are grateful to the Austrian mouthpiece manufacturer Breslmair for their crucial support in the development of the measuring device.

ABSTRACT

The modelling approach presented here aims at developing accurate, yet computationally efficient, numerical models of brass instrument resonators including nonlinear propagation, viscothermal losses and 2D radiation effects. Firstly, we propose the use of the Blackstock equation to model the nonlinear acoustic propagation inside the resonator, a more appropriate choice when dealing with nonlinear standing wave patterns, compared to the commonly used Burger's equation. The initial step of the approach consists in obtaining a complex modal basis from a 2D-axisymmetric finite element model of the linearized equations. Here, we include a bounded domain outside the resonator with a nonreflecting boundary condition as well as the effect of viscothermal losses at the interior walls. The nonlinear Blackstock equation is then projected onto the resulting 2D complex modal basis, leading to a compact set of nonlinear ODEs. This leads to exploitable reduced formulations adapted to quick temporal simulations, bifurcation analysis or parametric studies, retaining nevertheless the accuracy of 2D models. The explicit account of the exterior acoustic field also allows for the calculation of radiated sound pressures as well as directivity patterns. Experimental validation and illustrative numerical results are presented for a simplified trumpet geometry in both linear and nonlinear scenarios.

1. INTRODUCTION

The physical modelling of brass wind instruments has received considerable attention in the last few decades [1]. These instruments constitute complex physical systems that, from the point of view of physical modelling, still present many challenging aspects. Here our focus is on the modelling of the instrument itself, i.e. without the influence of the lip vibration and the associated control by the musician.

Widely used and relatively simple models (typically in 1D frameworks) are able to qualitatively reproduce measured behavior. However, simplified models often present inherent limitations that prevent them from capturing the more subtle features of real instruments. For example, 1D models often rely on the assumption of plane wave propagation which, albeit reasonable in the narrower parts of the instrument bore, clearly breaks down at the exit of the instrument. Another important aspect is related to nonlinear acoustic propagation inside the resonator, a particularly relevant feature influencing the timbre of brass instruments [2]. Although some numerical studies have dealt with this topic, they almost exclusively rely on the Burgers equation [3][4]. However, this equation assumes only forward or backward propagating waves and its use in the context of brass instruments is questionable since standing waves are formed inside the instrument.

In commercial contexts, where manufacturers are interested in optimizing/fine-tuning certain aspects of their instruments, the accuracy provided by these simplified models often falls short of the desired goals. The motivation behind this work lies on the need to build a physical model that provides: (1) an accurate description of the pertinent acoustic phenomena, including an appropriate nonlinear acoustic propagation model, viscothermal losses at the walls as well as 2D propagation and radiation effects and

(2) an efficient and exploitable framework (low computational cost) that can be used for quick temporal simulations, parametric studies, optimization, bifurcation analysis, etc. The approach proposed here aims to bridge the accuracy provided by 2D-axisymmetric models and the efficiency of reduced-order modal approaches. The general idea consists in using a 2D finite element (FE) model of the linearized equations to obtain a suitable modal basis that can then be used to project the nonlinear equations, leading to exploitable reduced-order models (composed of a set of nonlinear ODEs). Due to the localized nature of the involved energy dissipation mechanisms (viscothermal and radiation losses), the eigenvalue problem stemming from the linearized 2D FE model leads to a complex modal basis [5]. In this particular context, the full potential of modal decomposition is highlighted. Firstly, the modal basis serves to spatially discretize the problem. Secondly, because modes have characteristic natural frequencies, they also serve to "discretize" the system in the frequency domain, i.e. modes whose natural frequencies fall outside the frequency bands of interest can generally be neglected. Thirdly, modes have characteristic damping ratios which encapsulate, in a simple manner, the often-times intricate dissipation mechanisms. For example, viscothermal losses are notably difficult to model in the time-domain since they give rise to fractional-order derivatives [6]. These can however be easily represented in a modal framework, suited for both frequency and time domain analysis. Finally, modal approaches have also been proven useful to treat nonlinear terms in an efficient manner [7] as well as for mitigating numerical dispersion, a common problem when solving stiff wave equations using finite difference or finite elements methods in the time domain [8].

2. MODEL DESCRIPTION

2.1 Nonlinear acoustics in 3D domains

In most applications, not involving explosions or other supersonic events, nonlinear acoustics are typically modelled through what are called weakly-nonlinear models. Starting from the set of irrotational compressible Euler equations and a state equation for the fluid, a wide variety of models have been proposed over the years, well documented in an historical review by Jordan [9]. Of particular interest to us, are the so-called wave equations, where the acoustic field is represented by a single scalar variable. In this work we propose the use of the Blackstock equation, written here in terms of the velocity potential $\phi(t, \mathbf{x})$

$$\ddot{\phi} - c^2\Delta\phi + 2(\nabla\dot{\phi})(\nabla\phi) + (\gamma-1)\dot{\phi}(\Delta\phi) = 0 \qquad (1)$$

where the over-dot denotes temporal derivatives, ∇ and Δ are the gradient and Laplacian operators, c is the speed of sound in the fluid and γ its adiabatic index. This second-order approximation of the more general Söderholm formulation is bound to be valid for acoustic Mach numbers up to $M < 0.1$. Note that this equation is equivalent to the more commonly used Kuznetsov equation [10].

Assuming the curved bents in typical brass instruments are acoustically negligible, Eq.(1) can be written in axisymmetric cylindrical coordinates (r, z) as

$$\begin{aligned}\ddot{\phi} - c^2\left[\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial\phi}{\partial r}\right) + \frac{\partial^2\phi}{\partial z^2}\right] \cdots \\ +2\left(\frac{\partial\dot{\phi}}{\partial r} + \frac{\partial\dot{\phi}}{\partial z}\right)\left(\frac{\partial\phi}{\partial r} + \frac{\partial\phi}{\partial z}\right) \cdots \\ +(\gamma-1)\dot{\phi}\left[\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial\phi}{\partial r}\right) + \frac{\partial^2\phi}{\partial z^2}\right] = 0\end{aligned} \qquad (2)$$

Additionally, because of the larger cross-section at the exit of the instrument, acoustic levels are relatively weaker. Hence, large amplitude acoustic perturbations and nonlinear propagation are known to occur primarily at the narrower parts of the horn [2], where the plane wave assumption is reasonable. This leads us to the conclusions that, in the context of brass instruments, the nonlinear terms in Eq.(2) involving the radial derivative $\partial\phi/\partial r$ can confidently be neglected, leading to

$$\begin{aligned}\ddot{\phi} - c^2\left[\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial\phi}{\partial r}\right) + \frac{\partial^2\phi}{\partial z^2}\right] \cdots \\ +2\left(\frac{\partial\dot{\phi}}{\partial z}\right)\left(\frac{\partial\phi}{\partial z}\right) + (\gamma-1)\dot{\phi}\left(\frac{\partial^2\phi}{\partial z^2}\right) = 0\end{aligned} \qquad (3)$$

where only two quadratic nonlinear terms subsist.

2.2 Finite element axisymmetric model

As mentioned before, our first aim is to use a finite element discretization of the *linearized* model in order to obtain a suitable modal basis, which will serve as a basis of functions on which to subsequently project the nonlinear Blackstock equation. With regards to the acoustic domain then, we have simply the Helmholtz equation (linear wave equation in frequency domain). But furthermore, we need to consider two important dissipative boundary conditions representing: (1) radiation of energy towards the free-field and (2) the viscothermal losses occurring at the inner walls of the instrument. Concerning the former, we consider an exterior spherical domain whose outer boundary will

contain a nonreflecting condition, aimed at simulating an anechoic environment, as illustrated in Figure 1. For the viscothermal losses we have used the model proposed by Berggren et al. [11], which is based on the fact that, in air, viscothermal acoustic boundary layers (where losses take place) tend to be very small compared to reference dimensions/wavelengths and can hence be accurately approximated via an impedance boundary condition.

The complete linearized axisymmetric problem to be solved can then be written in the frequency domain as

$$\begin{aligned} k^2\phi - c_0^2\left[\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial\phi}{\partial r}\right)+\frac{\partial^2\phi}{\partial z^2}\right] &= 0 \text{ in } \Omega \\ \left(\frac{1}{R}-ik\right)\phi+\frac{\partial\phi}{\partial n} &= 0 \text{ on } \Gamma_r \\ -\delta_v\frac{i-1}{2}\Delta\phi+\delta_t k^2\frac{(i-1)(\gamma-1)}{2}\phi+\frac{\partial\phi}{\partial n} &= 0 \text{ on } \Gamma_{vt} \\ \frac{\partial\phi}{\partial n} &= 0 \text{ on } \Gamma_w \end{aligned} \tag{4}$$

where the acoustic boundary layer lengths are given by

$$\delta_v=\sqrt{\frac{2\nu}{\omega}}\ , \quad \delta_t=\sqrt{\frac{2\kappa}{\omega\rho C_p}} \tag{5}$$

with ρ the fluid static density, ν its kinematic viscosity, κ its thermal conductivity and C_p the coefficient of specific heat at constant pressure.

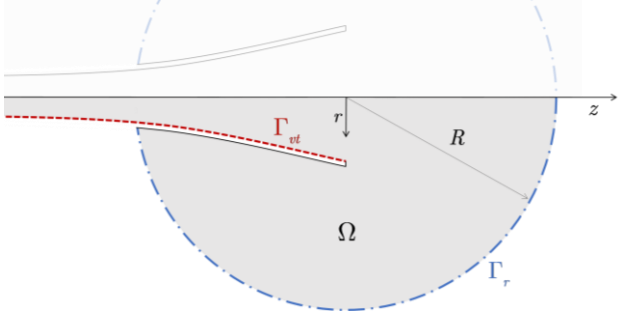

Figure 1. Diagram of the considered axisymmetric model. The dashed and dash-dotted lines correspond to the viscothermal Γ_{vt} and radiative Γ_r boundaries, respectively.

It is worth noting that the problem is here formulated in terms of acoustic velocity potential $\phi(r,z)$, but an equivalent formulation for the acoustic pressure can be obtained by replacing directly $\phi(r,z)$ by $p(r,z)$.

For compactness, we do not derive here the weak formulation or the FE discretization procedures, as these can be found in reference literature [12]. We simply note that second-order (6-node) triangular elements were used and the maximal size of each element $h_{\max}$ was set to at least one-fifth of the smallest considered wavelength.

2.3 Complex modal decomposition

After the FE spatial discretization, we obtain a dynamical system in the following form

$$\mathbf{M}\ddot{\boldsymbol{\phi}}(t)+\mathbf{C}\dot{\boldsymbol{\phi}}(t)+\mathbf{K}\boldsymbol{\phi}(t)=\mathbf{f}(t) \tag{6}$$

where $\boldsymbol{\phi}$ is a column vector of the velocity potential located at nodes of the FE discretized field and $\mathbf{f}(t)$ is a generic force vector that can represent external and/or nonlinear forces. Because of the localized nature of the modeled dissipative phenomena (radiation and viscothermal losses), our system belongs to a class of problems said to have non-classical damping. In practice, this prevents us from using typical modal approaches based on the real-valued modes shapes ($\mathbf{w}$), as these are not able to decouple the damped equations of motion. Here, we need to resort to complex modal analysis which is based around the state-space version of Eq.(6), arrived at by defining $\boldsymbol{\alpha}(t)=\dot{\boldsymbol{\phi}}(t)$, leading to

$$\mathbf{A}\dot{\mathbf{z}}(t)+\mathbf{B}\mathbf{z}(t)=\mathbf{F}(t) \tag{7}$$

with

$$\mathbf{A}=\begin{bmatrix}\mathbf{C} & \mathbf{M}\\ \mathbf{M} & 0\end{bmatrix}\ ;\ \mathbf{B}=\begin{bmatrix}\mathbf{K} & 0\\ 0 & -\mathbf{M}\end{bmatrix}\ ;\ \mathbf{z}(t)=\begin{Bmatrix}\boldsymbol{\phi}(t)\\ \boldsymbol{\alpha}(t)\end{Bmatrix}\ ;\ \mathbf{F}(t)=\begin{Bmatrix}\mathbf{f}(t)\\ 0\end{Bmatrix} \tag{8}$$

Solving the associated eigenvalue problem

$$(\lambda\mathbf{A}+\mathbf{B})\mathbf{u}=\mathbf{0} \tag{9}$$

leads us to the complex eigenvalues $\lambda_n\in\mathbb{C}$ and complex eigenvectors $\mathbf{u}_n\in\mathbb{C}$. Since $\mathbf{A}$ and $\mathbf{B}$ are symmetric, eigensolutions occur in pairs of complex conjugates

$$(\lambda_n,\ \bar{\lambda}_n)\ ;\ (\mathbf{u}_n,\bar{\mathbf{u}}_n)=\begin{Bmatrix}\mathbf{v}_n\\ \lambda_n\mathbf{v}_n\end{Bmatrix},\begin{Bmatrix}\bar{\mathbf{v}}_n\\ \bar{\lambda}_n\bar{\mathbf{v}}_n\end{Bmatrix} \tag{10}$$

where the overbar denotes complex conjugation. The full modal matrix of the first-order system is then

$$\hat{\mathbf{U}}=\begin{bmatrix}\mathbf{V} & \bar{\mathbf{V}}\\ \mathbf{V}\boldsymbol{\Lambda} & \bar{\mathbf{V}}\bar{\boldsymbol{\Lambda}}\end{bmatrix} \text{ with } \begin{cases}\mathbf{V}=\begin{bmatrix}\mathbf{v}_1,\dots\ \mathbf{v}_N\end{bmatrix}\\ \boldsymbol{\Lambda}=\text{diag}\ \lambda_1,\dots\ \lambda_N\end{cases} \tag{11}$$

Then, the complex modal transformation can be written in the following forms, due to its conjugate symmetry

$$\mathbf{z}(t)=\sum_{n=1}^{N}[\mathbf{u}_n q_n(t)+\bar{\mathbf{u}}_n\bar{q}_n(t)]=\mathbf{U}\mathbf{q}(t)+\bar{\mathbf{U}}\bar{\mathbf{q}}(t) \tag{12}$$

where $\mathbf{q}(t)$ are the modal coordinates and $\mathbf{U} = [\mathbf{V}\ \mathbf{V\Lambda}]^T$ is the reduced modal matrix of size $2N \times N$ pertaining to only one side of the conjugate pairs. Finally, replacing Eq.(12) in Eq.(7) and pre-multiplying by $\mathbf{U}^T$ leads to the reduced decoupled system

$$\dot{\mathbf{q}}(t) + \mathbf{\Lambda q}(t) = \mathbf{V}^T\mathbf{f}(t) \tag{13}$$

which is of size N (using only one mode of each conjugate pair), first-order in time and where coefficients and variables are complex-valued.

2.4 Projection of external forces and nonlinear terms

Since we can obtain an (approximate) continuous representation of modes shapes $\mathbf{v}_n$ from the FE model, the same procedure can be performed in a continuous framework where associated integrations (modal projections) can be performed numerically using Gaussian quadrature. With that said, the generic force terms presented in Eq.(13) can also be represented in continuous form

$$\mathbf{v}_n^T\mathbf{f}(t) \quad \Leftrightarrow \quad \int_\Omega f(r,z,t)V_n(r,z)drdz \tag{14}$$

where $f(r,z,t)$ is a generic force term and $V_n(r,z)$ is the continuous version of the n-th complex mode shape. If we now consider an expanded force term composed of a generic external force as well as the nonlinear terms in Eq.(3), expanded in modal coordinates, we obtain

$$\begin{aligned} f(r,z,t) = {} & g_{\text{ext}}(t)S(r,z) \\ & - \sum_{k,m}^{2N} \left[2V_m'V_k' + (\gamma-1)V_mV_k''\right]\dot{q}_m(t)q_k(t) \end{aligned} \tag{15}$$

where, to simplify notation, we use the over-dash represent the partial derivative $\partial\,/\,\partial z$. Note that we considered here an external force with separable spatial and temporal components, i.e. $g_{\text{ext}}(t)S(r,z)$. Finally, replacing the expansion (15) into (13) yields the final set of N nonlinear complex-valued ODEs

$$\dot{q}_n(t) + \lambda_n q_n(t) = g_{\text{ext}}(t)S_n + \sum_{k,m}^{2N} A_{kmn}\dot{q}_m(t)q_k(t) \tag{16}$$

for $n = 1,2...N$, where the constant terms associated with the modal projection are given by

$$A_{kmn} = \int_\Omega \left[2V_m'V_k' + (\gamma-1)V_mV_k''\right]V_n drdz \tag{17}$$

$$S_n = \int_\Omega S(r,z)V_n(r,z)drdz \tag{18}$$

At this point, there are a few important aspects of the derived system (16) that should be underlined. Firstly, the nonlinear tensor A_{kmn} is constant and is calculated "off-line", i.e. prior to any temporal integrations, nonlinear analysis, etc. Secondly, note that even though the original equations have two distinct nonlinear terms, these have the same temporal character. Therefore, when expanded in modal coordinates, they can be combined in a single nonlinear tensor A_{kmn}. On the other hand, because we are using a complex modal basis (as opposed to real modes), nonlinear terms need to be calculated using both modes in each conjugate pair, leading to a complex tensor A_{kmn} of size $2N \times 2N \times N$. Thirdly, by choosing an appropriate truncation N, we can build reduced models that are tailored to specific applications, e.g. large N (say 50-100) for strongly nonlinear scenarios or smaller N (say 10-20) for linear, or weakly-nonlinear ones.

2.5 Illustrative results: complex modes of a trumpet with simplified geometry

Complex mode shapes are awkward to illustrate in a static image. This is because, contrary to the motion of real modes where all points move in unison, complex modes contain phase shifts between different spatial regions. Hence, while real modes represent standing wave patterns, complex modes are a combination of standing and travelling waves. They are generally represented by their real $\text{Re}[V_n(r,z)]$ and imaginary $\text{Im}[V_n(r,z)]$ parts separately. Moreover, complex modes are defined up to a multiplicative complex factor. In this case, it is often useful to "rotate" the complex mode by an angle β (i.e. multiply by $e^{-i\beta}$) such that it maximizes its real part [13]. In this way, we can assess the "degree of complexity" of each mode by examining how large is its imaginary part. Examples of some complex mode shapes of a simplified trumpet model are shown in Figure 2. We note that lower order modes have a nearly null imaginary part, meaning that they represent almost perfect standing waves (i.e. real modes). Higher order modes however have much larger imaginary parts, representing their radiative character. That is, these modes reflect essentially waves travelling out of the horn towards the free-field.

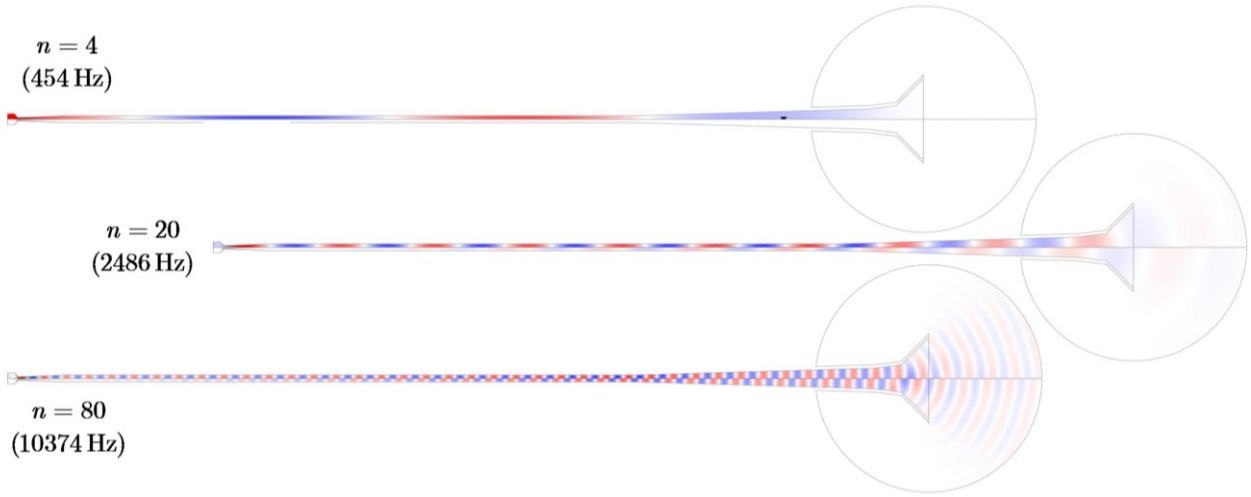

Figure 2. Some illustrative complex mode shapes $V_n(r, z)$ of the simplified trumpet. The real and imaginary parts are represented in the top and bottom of each plot, respectively. Note: modes shapes were rotated such that their real part is maximized (imaginary part minimized).

3. EXPERIMENTAL VALIDATION

To explore the effects of nonlinear propagation, an experimental set-up was prepared to excite the trumpet prototype harmonically. Acoustic excitation was provided by a BMS 4599 compression chamber placed at the entrance of the experimental prototype (without embouchure – i.e. only the cylindrical section plus the flaring horn section). Note however that this sort of set-up will inevitably influence the studied resonator since these drivers have an internal volume that is non-negligible. This volume was taken into account in the model, for validation purposes. However, naturally, the studied system in this case is not the same as that described in the previous section. The modal frequencies of the system were first identified via the exponential sine-sweep method. Subsequently, the system was excited at various modal frequencies at different amplitudes. A pressure sensor (Endevco 8507C-5) was placed iteratively on 40 locations along the resonator's length aimed at giving a spatial illustration of the nonlinear standing wave patterns. A second reference pressure sensor was fixed inside the cavity of the compression chamber to get a phase reference. The spatial distribution of the pressure inside the resonator when excited at the frequency of mode $n = 3$ (503 Hz) at different excitation amplitudes is shown in Figure 4. Analogous results from the model, obtained through temporal integrations using 100 complex modes are shown in Figure 5. Comparison of the experimental and modelled results are very satisfactory, with the model correctly representing the trends of the distorted standing wave patterns observed experimentally. Not only qualitatively, but also quantitatively, as the appearance and "level of distortion" appear to be congruent for the same values of the acoustic pressure. In a future work, different aspects of these results will be analyzed more thoroughly, as there are many more subtle aspects to be discussed.

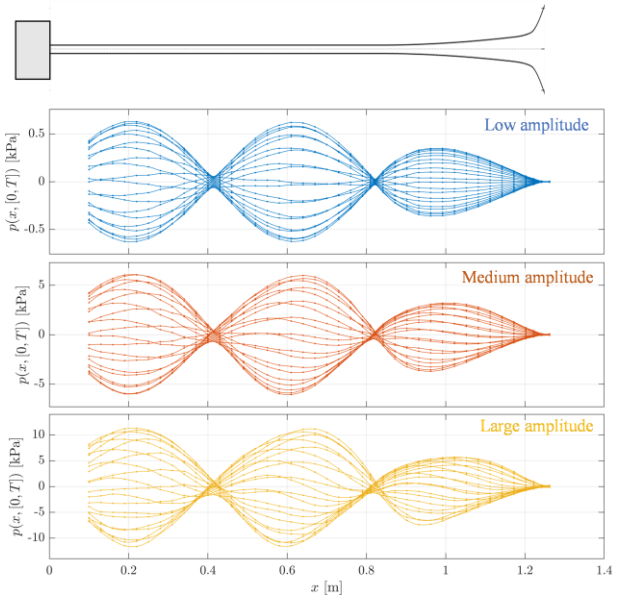

Figure 4. Experimental results: Snapshots of the measured pressure fields inside the trumpet at different amplitudes. Dots denotes the actual measurements while connecting lines were interpolated.

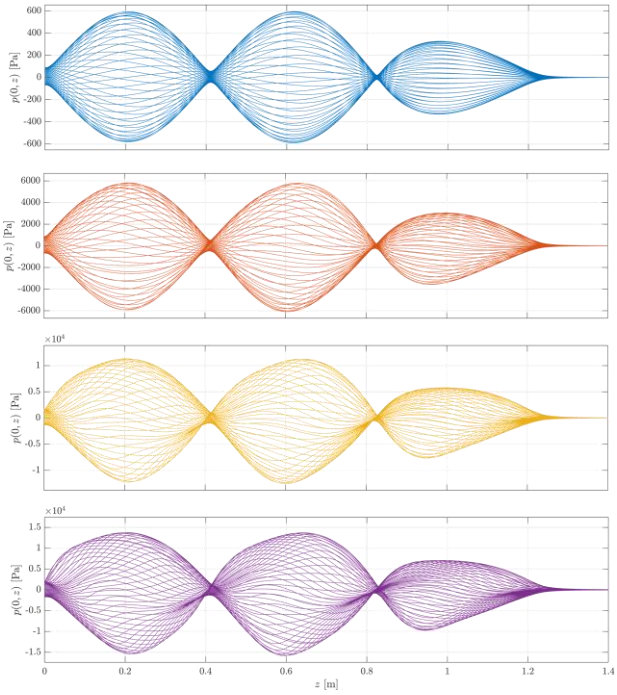

Figure 5. Modelling results: Snapshots of the modelled on-axis (r = 0) pressure fields inside the trumpet, excited harmonically at different amplitudes.

4. CONCLUSIONS

In this work we have shown how refined models of brass instruments, in a 2D axisymmetric framework, can be used to efficiently predict the behavior of real instruments, including a variety of complex physical phenomena like viscothermal losses at the walls, 2D radiation effects as well as nonlinear acoustic propagation. Within a reduced-order modal framework, these refined models convey essentially the same computational costs as the more typical 1D models used widely in the field. Moreover, the use of complex modes enables one to encapsulate intricate dissipative phenomena, like localized radiation or thermoviscous losses, in each modal component. This allows one to easily treat the problem in both the frequency and time domain, be that through temporal integrations, harmonic balance, numerical continuation, etc. The use of the Blackstock nonlinear acoustics equation instead of the more common Burger's equation allows us to calculate nonlinear standing wave patterns that can eventually be used to characterize brass instruments in terms of their capacity to produced "brassy" sounds. It is hoped that the developments shown here can stimulate a transition from descriptive towards predictive models of brass instruments.

ABSTRACT

When calculating the acoustic radiation from vibrating planar structures, engineers are most often obliged to use computationally heavy approaches, like BEM or FEM. These are, however, largely unfit for parametric studies, optimizations, or real-time sound synthesis. The approach proposed here aims to approximate the acoustic fields produced by a vibrating plate via minimal sets of elementary sources. Based around a modal description of the plate vibration, each lobe region in a mode shape is to be represented by an equivalent punctual source. Aside from its evident computationally efficiency, the proposed approach is versatile since baffled and unbaffled cases can be treated using monopole and dipole arrays, respectively, and complex-shaped plates can be dealt with via automatic image segmentation techniques. Additionally, it enables the calculation of both modal radiation curves as well as forced multi-modal scenarios and transient responses. Because it is set in a modal framework, it can easily be combined with typical structural vibration models. The benefits of this reduced multipole approach are demonstrated through a series of illustrative examples, where approximate solutions are compared to reference results from either analytical or large-scale FEM models.

Keywords: *plate radiation, minimal models, equivalent sources, multi-modal radiation, monopoles and dipoles.*

1. INTRODUCTION

Whether driven by the need of understanding or of predicting sound radiation for control requirements, the radiation from plates has long been a topic of considerable relevance in engineering acoustics. The problem consists in predicting the sound field radiated by a planar structure of arbitrary shape, surrounded by a fluid and vibrating with a given surface velocity distribution. To provide useful insights, the analysis commonly proceeds on two approaches, addressing (1) the sound radiation from a specific mode, the so-called modal radiation, and/or (2) the overall radiation caused by unevenly forced excitation (e.g. point excitations), where many modes contribute to the vibrational response, the so-called multi-mode radiation.

Early works were mainly concerned modal radiation from simple analytical configurations and well-known results include asymptotic formulae and closed forms solutions for simply supported rectangular plates [1] [2] [3] [4]. One fact to emphasize is the difficulty of producing predictions for the unbaffled configuration, which considerably complicates the mathematical modelling and might lead to instabilities in the numerical implementations [5] [6]. In general, the radiation from more realistic complex-shaped plates typically requires the use of numerical approaches to solve the integral equations, for which finite element and/or boundary element methods are probably the most use techniques. Although precise solutions can usually be achieved by these techniques it is well known that the computation costs still represent a significant limitation particularly when dealing with optimization problems, parametric studies or real-time sound-synthesis.

Recently, a form of lumped model approach has been presented by Garcia et al. [7] by using combination of circular pistons that replicate modal radiation. In this model,

each lobe of a mode shape is viewed as a baffle piston that radiates the same amount of energy and with characteristics including size, amplitude, phase, and position, determined by the mode shape geometry. This concept, essentially a reduced form of the equivalent source method [8], is surely a powerful one, leading to very low computational cost and easily combined with modal-based structural vibration models. The authors have however dealt only with limited scenarios, namely, modal radiation in baffled configurations. It remains unclear how this could be extended to the unbaffled cases as well as the estimation of radiation patterns from unevenly excited plates (multi-modal).

In generic terms, the present formulation is a variant of the method proposed by Garcia et al. [7] as we use a spatial distribution of punctual sources to represent each lobe of a mode shape function. One major difference resides in considering monopoles and dipoles as the elementary radiators, which presents practical and conceptual advantages to deal with the problem. Monopole and dipole are the simplest acoustic sources and hence, are easy to model. Also, physically, it is well known that at low frequency, radiation from baffled plates can be represented by sets of monopoles and, similarly, unbaffled plates can be represented by sets of dipoles. In practice, the geometry of the mode shape directly determines the number of equivalent sources and the velocity distribution within each modal region defines the source strength and location of the equivalent point-source. Global measures of the pressure far-field, including total power and radiation efficiency, are then estimated using general analytical expressions derived for planar arrays of monopoles or dipoles. It is obvious that our formulation directly produces predictions for modal radiation but one practical advantage of the formalism is to deal easily with the forced multi-modal problem when one adopts a modal description for the plate dynamics. By doing so, the multi-modal problem is a natural extension of the modal case and hence can be addressed using the same expressions. This type of approach is obviously well adapted to programming and offers the possibility of efficient computations through solely one simple generic code for both baffled and unbaffled configurations. Other important feature of our work is the ability to deal with plates of arbitrary shape addressed by optimal and automatic positioning of the point sources achieved through techniques of image segmentation. Finally, note that by deriving the radiation model from the mode shape geometry, our formulation is readily well-suitable for integrating typical structural vibration models and could provide intuitive physical understanding and interpretation of the solutions.

2. MODAL RADIATION DESCRIBED BY A SET OF POINT SOURCES

The case of modal radiation is concerned with the vibration of a flexible plate animated by a simple harmonic motion in one of its natural modes. The velocity distribution of its surface is then written as

$$v(x,y) = v_m \phi_m(x,y) \tag{1}$$

where ϕ_m and v_m are the mode shape and modal velocity of mode m, respectively. The mode shape contains several local maxima/minima and its overall distribution can be then divided into a set of J convex regions containing one single minima or maxima (lobe). As illustrated in Figure 1, within the area of each region S_j, the location of an equivalent point source (x_j, y_j) will be defined by the weighted centroid of the mode shape, given by

$$x_j = \frac{\int_{S_j} x\phi(x,y)dxdy}{\int_{S_j} \phi(x,y)dxdy} \quad ; \quad y_j = \frac{\int_{S_j} y\phi(x,y)dxdy}{\int_{S_j} \phi(x,y)dxdy} \tag{2}$$

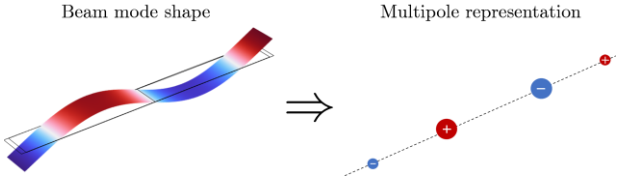

Figure 1. Illustration of the multipole method applied to a free-free beam mode.

2.1 Baffled case and monopoles

Assuming simple harmonic motion with frequency ω, the pressure field from a monopole may be expressed as

$$\hat{p}(r) = i\omega\rho\hat{U}\frac{e^{-ikr}}{4\pi r} = \hat{Q}\frac{e^{-ikr}}{4\pi r} \tag{3}$$

where $k = \omega / c$ is the wavenumber, i is the imaginary unit and quantities with a hat are complex amplitude containing phase information. The source strength $\hat{Q} = i\omega\rho\hat{U}$ represents the injection/suction of fluid into the region (a volume velocity). A generic representation of the source strength for plane radiators with continuous convex velocity distribution $v(x,y,t) = \hat{V}(x,y)e^{i\omega t}$ is given by

$$\hat{Q} = i\omega\rho\int \hat{V}(x,y)dxdy \tag{4}$$

The extension to account for N simple harmonic monopoles of complex source strength $Q_n = i\omega\rho U_n$ results from a direct application of the principle of linear superposition in acoustics. For such arrangement, the complex pressure at point $\mathbf{r}$ in the far-field is given by

$$p(\mathbf{r}) = \sum_{n=1}^{N} Q_n \frac{e^{-ikR_n}}{4\pi r} \tag{5}$$

where $R_n = |\mathbf{r} - \mathbf{r}_n|$ is the distance from the n-th source. Using Eq. (5), it can be shown that the acoustic power radiated by the set of monopoles is given by the sound intensity generated by

$$\Pi = \frac{\rho c k^2}{8\pi}\left(\sum_{n=1}^{N}|U_n|^2 + 2\sum_{n=1}^{N}\sum_{m>n}^{N}|U_n||U_n|\frac{\sin kl_{mn}}{kl_{mn}}\right) \tag{6}$$

where l_{mn} are the distance between source n and m. Eq.(6) states that the total acoustic power is determined by the power radiated by all individual sources when acting in isolation, and their mutual acoustic interaction, which is one of the most important mechanisms governing the effectiveness of sound radiation by vibrating surfaces [9] . It can also be written in the following compact matrix form

$$\Pi = \mathbf{u}^{\mathrm{H}}\mathbf{W}\mathbf{u} \tag{7}$$

where the superscript H is the complex conjugate transpose, $\mathbf{u}$ is the vector of the complex source volume velocities U_n and $\mathbf{W}$ is a matrix whose element (m,n) is

$$W_{mn} = \frac{\rho c k^2}{8\pi}\frac{\sin kl_{mn}}{kl_{mn}} \tag{8}$$

In this equivalent representation of modal radiation, the diagonal terms in $\mathbf{W}$ produce the "self" power radiated by the individual lobes whereas the off-diagonal terms, that clearly are symmetric, are associated to the "mutual" radiated power, i.e. the interference of the sound field radiated by the different lobes.

A useful measure of the effectiveness of sound radiation by vibrating surface, originally defined by Wallace [2], is the radiation efficiency, which is a normalized form of the radiated power. It is defined as

$$\sigma = \frac{\Pi}{\rho c S \langle |v(x,y)| \rangle} \tag{9}$$

where $\langle |v(x,y)| \rangle$ is the spatial and temporal average of the squared velocity distribution, which is defined by

$$\langle |v(x,y)| \rangle = \frac{v_n}{2S}\int_S |\phi(x,y)|^2 \, dxdy \tag{10}$$

Finally, note that all the previous derivations have been presented assuming monopole sources, hence radiating energy in free space. Adaptation to the baffle configuration implies to account for the fluid loading effects on a single side of the plate, so that expressions for the acoustic power must be multiplied by a factor of two.

2.2 Unbaffled case and dipoles

A dipole is typically an oscillating point source that can be conceptually modeled by two close monopoles of identical strength Q but opposite phase, and separated by a distance d . The pressure radiated by a dipole is given by

$$p(r,\theta) = -k^2\rho c\left(1 + \frac{1}{ikr}\right)Ud\left(\frac{e^{-ikr}}{4\pi r}\right)\cos\theta \tag{11}$$

where the dependence on the elevation angle θ evidences the directional character of the pressure field. Similarly with monopole source, a dipole source strength can be defined as

$$F = i\omega\rho Ud \tag{12}$$

where it is important to underline that here the source strength F has the units of a force. Contrary to generating a (unsteady) net volume outflow as in monopoles, a dipole source then exerts a force on the surrounding fluid and this renders their behavior physically and qualitatively different. If the establishment of a low-frequency equivalence between baffled plane radiators and monopoles is relatively straightforward by considering equivalent volume velocities, it becomes difficult to apply an equivalence between unbaffled plane radiators and dipoles. A simple example is that of a piston of area S and arbitrary shape, vibrating harmonically. If the piston is baffled, its volume velocity is independent of the piston shape. However, if the piston is unbaffled, difficulties arise because the same independence on the piston shape does not hold. That is, pistons with the same surface area but different shapes will not radiate the same amount of acoustic power, even at low frequencies. This is a consequence of localized inertial flows along the piston edges, which present large tangential velocities and significantly alter the force applied on the fluid by the vibrating piston. Analytical solutions for the low-frequency radiation of unbaffled circular [4] or elliptical [10] pistons are known, but deriving a generic expression for an arbitrary shaped piston is a more difficult task. However, in a recent work by the authors [11], a relatively generic approximation was proposed based on the piston compactness (ratio of area to perimeter). When looking at Eq.(12), the physical role of the equivalent distance d can be viewed as a correction factor $(d < 1)$ on

the volume velocity U, encapsulating the "edge effects", such that the equivalent force can be written as in (12). In the case of a circular disk for example, the equivalent distance is $d = (8 / 3\pi)a$. From a broad set of numerical results from a finite element model, the authors have proposed the following approximation for the equivalent distance, based on the piston compactness ratio

$$d = 2\left(\frac{8}{3\pi}\right)\frac{S}{P} \approx 1.7\,\frac{S}{P} \tag{13}$$

where P and S are the perimeter and area of the piston respectively. This expression is anchored on the known result for a circular disk, but also provides an excellent approximation for pistons of arbitrary shape. In our representation by means of equivalent modal radiators, Eq.(13) is used to estimate the equivalent dipole source strength F_j for each modal region j, using $d_j = 1.7\ S_j / P_j$ while the local volume velocity U_j is calculated as before (see Eq.(4)). Then, the pressure radiated in the far-field ($(kr \gg 1)$ by a set of N dipoles located arbitrary within a plane surface at position defined by vector $\mathbf{r}_n$ and pointed along the z-axis, is given by

$$p(\mathbf{r}) = -k^2\rho c\sum_{n=1}^{N} F_n\,\frac{e^{-ikR_n}}{4\pi r}\,\frac{\mathbf{r}_n\cdot\mathbf{d}_n}{r} \tag{14}$$

where $\mathbf{d}_n$ is the vector distance between the two dipoles. The total acoustic power radiated by the dipoles array is given by

$$\Pi = \mathbf{f}^{\mathrm{H}}\mathbf{D}\mathbf{f} \tag{15}$$

where $\mathbf{f}$ is a vector containing the dipole source strengths and the elements in the radiation matrix $\mathbf{D}$ are

$$D_{mn} = \frac{\rho c k^4}{8\pi}\left(\frac{\sin kl_{mn}}{(kl_{mn})^3} - \frac{\cos kl_{mn}}{(kl_{mn})^2}\right) \tag{16}$$

ILLUSTRATIVE RESULTS

2.3 Modal radiation of a baffled and unbaffled plate

The surface velocity of a rectangular baffled plate with dimensions L and w, with simply supported boundaries, vibrating at one of its natural modes is given by

$$v(x,y,t) = v_{mn}\phi_{mn}(x,y)e^{i\omega t}$$
$$\text{with}\quad \phi_{mn}(x,y) = \sin\left(\frac{m\pi x}{L}\right)\sin\left(\frac{n\pi y}{w}\right) \tag{17}$$

In this simple case, each mode (m,n) is divided into $J = m\times n$ regions with the same area

$$S_j = \frac{Lw}{mn}\ \forall j \tag{18}$$

The source strength of each equivalent monopole is the same for all sources

$$Q_j = \pm 2ik\rho c\left(\frac{Lw}{mn}\right)\frac{4}{\pi^2}v_{mn}\ \forall j \tag{19}$$

where a factor of two is present to account for the baffle. Note however that the sign of Q_j alternates between adjacent lobes. The weighted centroid of each modal region (monopole location) is located at the center of the lobe, define in a regular grid as

$$\mathbf{x}_j = \frac{L(p-1)}{2m}\ ;\ \mathbf{y}_j = \frac{w(q-1)}{2n}\ \text{for}\ \begin{cases} p = 1,2\ldots m \\ q = 1,2\ldots n \end{cases} \tag{20}$$

from which the inter-monopoles distance matrix l_{mn} can easily be obtained (as in Eq.(6)).

To illustrate the capability of the proposed method, Figure 2 shows the modal radiation efficiency of various modes of a simply supported square baffled plate calculated with the multipole approximation compared to the analytical solutions presented by Wallace [2]. The three plots shown pertain to the different modal families indexed: odd-odd, odd-even and even-even. The radiative behavior of these three modal families is characterized by their low-frequency behavior, which equates to a monopolar, dipolar or quadrupolar radiation efficiency, i.e. with σ_m proportional to $(kL)^2$, $(kL)^4$, $(kL)^6$, respectively. This simple example serves to underline the importance of symmetry in the radiation efficiency of vibrating structures. Here, much of the radiation from lobes of opposite phases, separated by a symmetry line, will cancel each other and severely reduce the amount of radiated power at low-frequencies. We also note, as expected, that the multipole formulation does not provide accurate results at high-frequencies. Since point sources have no characteristic dimension, a finite set of monopoles will not be able to reproduce the radiation of a physical structure when wavelengths λ exceed a critical length λ_c, related to the distance between the point sources (internodal distances).

Similarly, we illustrate the capacity of the dipole approximation considering modal radiation efficiency of a simply supported square unbaffled plate. Here, the dipolar equivalent distance can be easily calculated from Eq.(13)

$$d_j = 1.7\left(\frac{S}{P}\right) = 1.7\,\frac{2Lw}{Ln + wm}\ \forall j \tag{21}$$

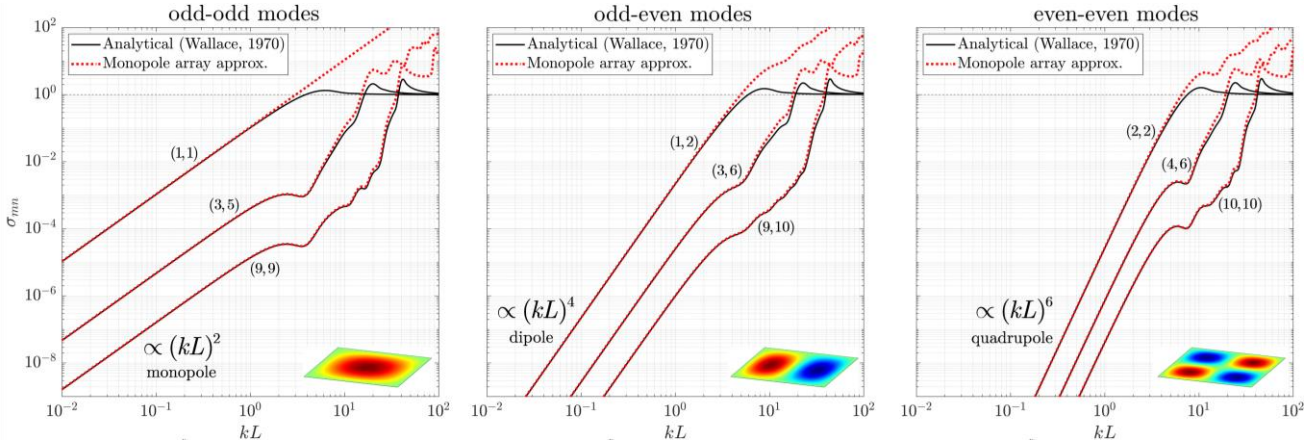

Figure 2. Modal radiation efficiency of square baffled plate with simply supported boundary conditions for odd-odd, odd-even and even-even modes as a function of the dimensionless frequency. The monopole approximations (red dotted lines) are compared to the analytical results (black lines) given by Wallace [2].

In this case, reference results were calculated using the method proposed by Laulagnet [5]. Figure 3 shows the modal radiation efficiency of some modes of an unbaffled plate from the three modal families. It shows that, at least for the case of a simply supported plate, the proposed formulation provides very reasonable approximations, almost as good as for the baffled case. We note however some minor quantitative differences, likely related to the validity of the approximate expression for the equivalent distance.

2.4 Watershed transform and automatic mode shape segmentation

The illustrative results shown in the previous section are simple to obtain since this case is simplified by the fact that all mode shapes have well-defined lobe regions, separated by the nodal lines of the mode shape. Hence, there is no ambiguity on the number and location of point sources to consider. However, this is not the general case and, particularly in complex-shaped plates, mode shapes often contain multiple local minima (representing multiple lobes) whose basins are not separated by nodal lines. Consider for example the well-known Matlab's "peaks" function (Figure 4). We note that this function contains three local minima and three local maxima. Hence, the proposed method would, in principle, require a minimal set of six-point sources to provide an approximation of its modal radiation efficiency. The three local minima (in blue) are indeed contained in regions bounded by nodal lines as opposed to the three local maxima (red/orange), which are in a single

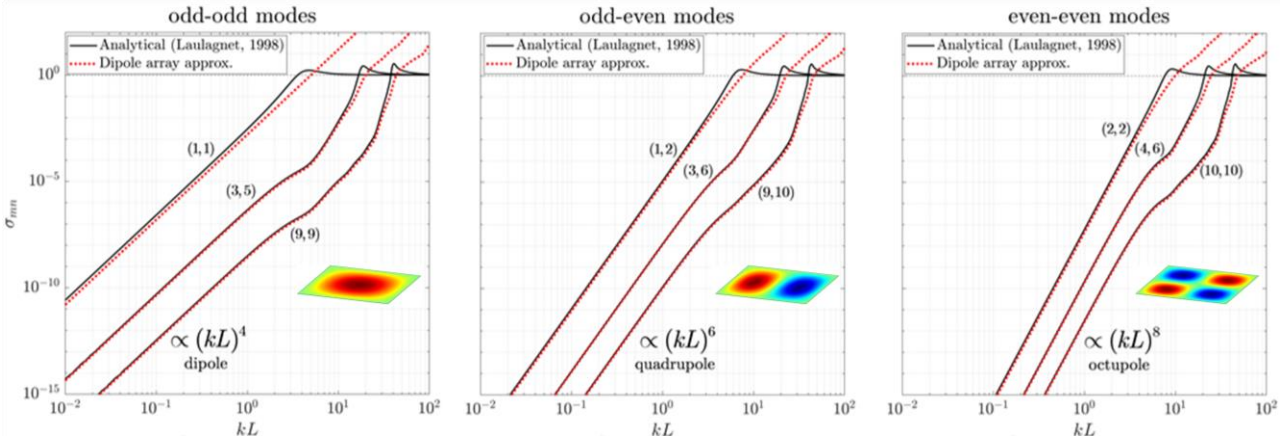

Figure 3. Modal radiation efficiency of square unbaffled plate with simply supported boundary conditions for odd-odd, odd-even and even-even modes as a function of the dimensionless frequency. The dipole approximations (red dotted lines) are compared to the analytical results (black lines) given by Laulagnet [5].

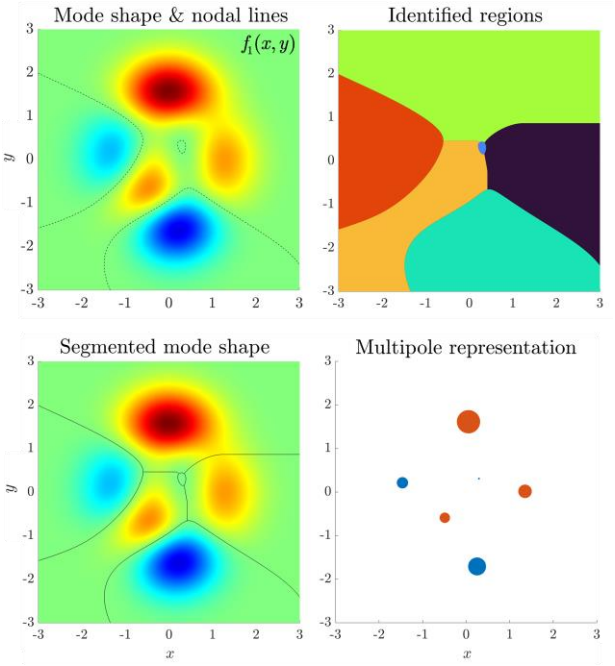

Figure 4. Illustration of the process of mode shape segmentation using the watershed transform on the "peaks" function, as well as the resulting point source representation.

"connected" region. We are then tasked to find lines that enable the segmentation of the three local maxima into different regions. This can be achieved in an automatic fashion using a variety of tailored algorithms. Here we suggest the use of the watershed transform [12] a widely used algorithm for image segmentation, which is simple, computationally efficient and perfectly fits the intended purpose. For brevity, we restrain from showing the details of the procedure here, but it essentially consists in performing the watershed transform on the modulus of the mode shape function $|f_1(x,y)|$. Figure 4 illustrates watershed transform on the peaks function and as well as the resulting multipole representation.

3. RADIATION DUE TO FORCED RESPONSE

3.1 Formulation for multi-modal scenarios

The natural extension of the previous formulation dealing with the sound power radiated by individual modes is to address the acoustic radiation from unevenly excited plates (e.g. from point force excitation), where many modes contribute to the vibratory and radiative responses. The difficulty in the multi-modal case stems from the fact that, although mode shapes are orthogonal from a vibratory point of view, the associated modal radiation fields are not. Hence, the total sound power is not equal to the sum of the sound powers generated by each mode separately but must also include the sound power produced by the radiative interaction between all modes [13]. Following our multipole representation of sound radiation, the total power radiated by a forced plate described by a set of N structural modes can be formulated by considering a large vector $\mathbf{Q}$ built by stacking a set of vectors $\mathbf{q}_n$, containing the source strengths of the point sources associated to each mode. Essentially, we aim to consider the interaction between all point sources in all modal sets. In view of such a structure, the radiation matrix $\mathbf{W}$ for a multimodal baffled plate is now a block matrix, in which the diagonal elements are square submatrices of modal radiation (as in Eq.(8)) and the off-diagonal blocks are submatrices of radiation stemming from inter-modal coupling, thus describing the production of acoustic power due to the interaction between all elementary sources pertaining to the different modes involved in the vibration. Knowing the modal response of the structure in terms of modal velocities u_n, the total acoustic power radiated for multimodal plates can thus be calculated from

$$\Pi = \begin{Bmatrix} q_1^1 \\ \vdots \\ q_1^{M_n} \\ \vdots \\ q_N^1 \\ \vdots \\ q_N^{M_n} \end{Bmatrix}^{\mathrm{H}} \begin{bmatrix} \mathbf{W}_{11} & \cdots & \mathbf{W}_{1N} \\ \vdots & \ddots & \vdots \\ \mathbf{W}_{11} & \cdots & \mathbf{W}_{NN} \end{bmatrix} \begin{Bmatrix} q_1^1 \\ \vdots \\ q_1^{M_n} \\ \vdots \\ q_N^1 \\ \vdots \\ q_N^{M_n} \end{Bmatrix} \quad (22)$$

where $\mathbf{W}_{pq}$ are full matrices whose elements $\mathrm{w}_{pq,rs}$ are given by

$$\mathrm{w}_{pq,rs} = \frac{\rho c k^2}{8\pi} \frac{\sin(kl_{pq,rs})}{kl_{pq,rs}} \quad (23)$$

in which we denote $p,q = 1,2\ldots N$ the modal index and r,s the index of elementary sources in each set, whose upper limit depends on the mode shape. For brevity, we present only the baffled case but the unbaffled case can similarly be formulated using an analogous procedure based on Eqs.(15)-(16) instead.

The local volume velocities q_n^m in Eq.(22) are calculated from the complex modal velocities v_n that can be calculated, when considering a point excitation at $\mathbf{r}_0 = (x_0, y_0)$ as

$$v_n = \frac{i\omega F_0\, \phi_n(\mathbf{r}_0)}{m_n(\omega_n^2 - \omega + 2i\omega\omega_n\zeta_n)} \tag{24}$$

where F_0 is the amplitude of the point force and m_n, ω_n and ζ_n are the modal mass, angular frequency and damping ratio of mode n, respectively.

3.2 Illustrative example on a rectangular plate

For illustrative purposes, we now consider a baffled simply supported rectangular plate with length $L = 0.6\,\mathrm{m}$, width $w = 0.5\,\mathrm{m}$ and thickness $h = 2\,\mathrm{mm}$, centered at $(0,0)$, such that it is defined in $x = [-0.3,\, 0.3]$ and $y = [-0.25,\, 0.25]$. Its natural frequencies and modal masses are given by

$$\omega_{mn} = \pi^2\sqrt{\frac{B}{\rho_s h}}\left[\left(\frac{m}{L}\right)^2 + \left(\frac{n}{w}\right)^2\right];\; m_{mn} = \frac{\rho_s L w h}{4} \tag{25}$$

where B is the bending stiffness and ρ_s is density. Modal damping was fixed uniformly at $\zeta_n = 0.01\ \forall n$.

For simplicity, we consider a unit force amplitude $F_0 = 1$ and two different locations for the excitation: $\mathbf{r}_1 = (0.19,\, 0.11)$ and $\mathbf{r}_2 = (0.24,\, 0)$. Reference results were calculated using an FEM model composed of a plate with prescribed velocity profile, surrounded by a hemisphere with non-reflecting boundaries (PMLs).

Figure 5 shows the vibratory response (collocated mobility), radiated power and radiation efficiency for excitation points $\mathbf{r}_1$, where results from the multipole method were calculated using $N = 100$ modes.

The results in Figures 5 show how the reduced set of point sources is clearly able to reproduce radiative properties of the plate in forced, multi-modal scenarios. At relatively low frequencies $(kL < \pi)$, the estimated radiated power and radiation efficiency are indistinguishable from the reference FEM results. Above $kL < \pi$, we note a drift of the estimated values, with the multipole method slightly overestimating radiated energy. Nevertheless, approximations are still reasonable even at these high frequencies. This is explained by the fact that the frequency limit of each modal approximation is related to the average distance between monopoles in each modal set, as seen in Figures 2 and 3. Hence, this frequency limit increases with

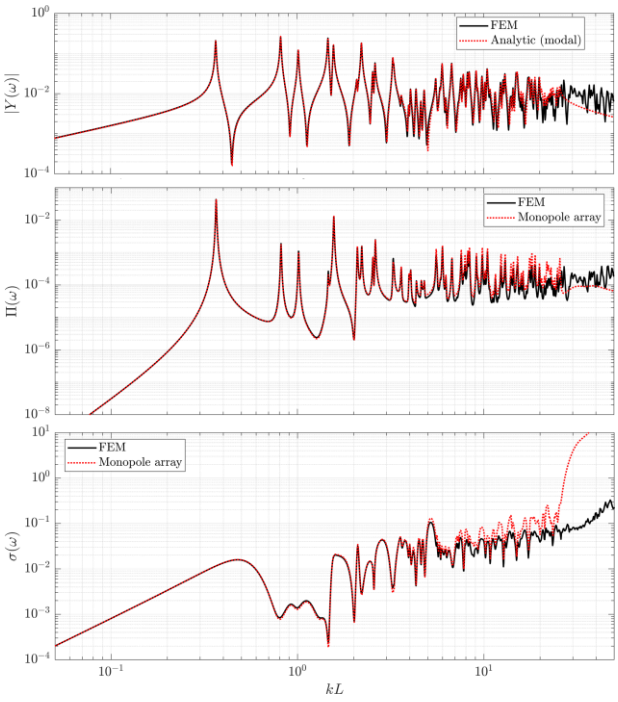

Figure 5. Magnitude of co-located mobility (top), total radiated power (center) and radiation efficiency (bottom) of the baffled rectangular plate excited at $\mathbf{r}_1 = (0.19,\, 0.11)$ as a function of the dimensionless frequency kL. Here, 100 modes were considered.

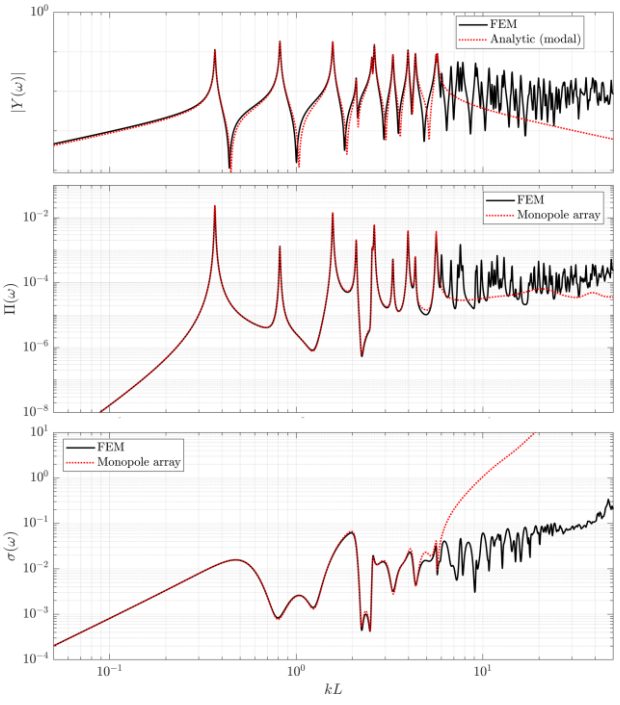

Figure 6. Magnitude of co-located mobility (top), total radiated power (center) and radiation efficiency (bottom) of the baffled rectangular plate excited at $\mathbf{r}_2 = (0.24,\, 0)$ as a function of the dimensionless frequency kL. Here 20 modes were considered.

modal order, as do the natural frequencies of the modes (!).

Figure 6 shows the analogous results for excitation point $\mathbf{r}_2$, and here, only $N = 20$ modes were used for the multipole method estimations. The responses in Figure 6 present less peaks since the excitation point is located on one of the symmetry lines and hence, some modes of the plate are not excited (those of even order in y-direction). Again, we clearly see a good approximation only limited in this case by the number of modes considered.

Finally, and most importantly, is it worth underlining that while the FEM model required approximately 1 to 5 seconds of computation time, per frequency bin, on a desktop computer, the reduced multipole model, with $N = 100$ (i.e. ~2500 sources) took approximately 30-40ms per frequency bin. Furthermore, when $N = 20$ (i.e. ~125 sources) it took about 0.3-0.4ms. Still, this computational time could be further reduced if one considers a threshold on the modal vibratory response. That is, for each frequency bin, considering only a limited set of modes whose vibratory response is dominant.

4. CONCLUSIONS

This paper shows how a method based on the distribution of point sources is able to recreate the radiation properties from vibrating plates, both from single mode excitation as well as multi-modal (unevenly forced) cases. Despite its simplicity, results show a relatively wide range of validity (not necessarily limited to low frequencies). Aside from the commonly treated baffled problem, we demonstrate how this approach can be generalized to unbaffled scenarios by using dipoles instead of monopoles. Also, to deal with complex-shaped plates, we propose an automatic mode-shape segmentation procedure that identifies the spatial distribution of the sources, based on the watershed transform. Illustrative results for the multi-modal case highlight the computational efficiency of the approach reaching acceptable approximations to reference results at computational costs that are several orders of magnitude below the analogous FE model.

An important feature of the formulation is the fact that it is built on a modal description of the plate vibration, which makes it readily integrable in standard structural models. This allows parametric studies and optimization strategies to be carried out for improving sound radiation of structural components, and gives the possibility to simulate very realistic sounds of bars and plates, even in real time.

EFFECTS OF DIFFERENT AUDITORY MONITORING CONDITIONS ON VOCAL INTONATION ACCURACY

Agnieszka Paula Pietrzak[1*]
[1] Institute of Radioelectronics and Multimedia Technology, Warsaw University of Technology, Poland

ABSTRACT

Precise intonation is crucial for ensemble singing performances, particularly when singers record their parts separately under varying monitoring conditions. This study investigated the intonation accuracy of five female choristers from an academic choir under three common feedback setups: speaker, open headphones, and closed headphones. Recordings were made in an anechoic chamber, where participants sang a perfect fifth (while the reference sound was still audible) and a major third (after the reference sound had ended). Intonation accuracy was measured in cents as the difference between the sung pitch and the expected frequency. Results showed that, for the perfect fifth (harmonic interval), using closed headphones resulted in the smallest median error (11 cents), suggesting that greater isolation may enhance pitch focus. However, for the major third (melodic interval), open headphones produced the lowest error (16 cents), indicating that too much isolation can lead to pitch overestimation when reference tones are no longer audible. Across both tasks, speaker monitoring exhibited the highest overall error values. Analysis of variance (ANOVA) confirmed statistically significant differences between these monitoring types. These findings suggest that selecting appropriate auditory feedback in both recording and rehearsal settings can optimize singers' intonation.

1. INTRODUCTION

The quality of ensemble or choir singing depends largely on the precise vocal intonation of its participants. Even small pitch discrepancies, initially below the threshold of casual perception, can accumulate and become audible tuning problem in vocal performances [1, 2].

While such issues can typically be resolved during in-person rehearsals, technological developments have expanded the contexts in which choral or ensemble recordings now take place, including situations where individual singers record their parts separately. From modern "virtual choir" projects to remote recording sessions, singers increasingly rely on various forms of auditory monitoring to maintain pitch accuracy with previously recorded tracks or external reference tones. Considering the advancements in modern recording techniques, understanding how auditory feedback mechanisms can influence pitch accuracy becomes important.

Research on vocal pitch control and intonation has long acknowledged the importance of auditory feedback [3]. Singers rely on both external cues (e.g., accompaniment, other vocal parts, or pre-recorded tracks) and internal cues (e.g., bone conduction, proprioceptive and tactile sensations) to guide their pitch production. When these cues are altered, the singer's ability to accurately judge and produce pitch can worsen [4,5]. Different types of headphones or speaker setups used as auditory monitoring can be a source of this kind of alteration. Previous studies have shown that closed-back headphones, for instance, can help isolate a vocal part and reduce external noise, thereby promoting more focused listening; however, they may also amplify the singer's own internal sounds (e.g., breathing, bone-conducted resonance), potentially leading to overestimation of one's pitch when an external reference is removed [6]. By contrast, open-back headphones allow for a more natural blend of external and internal sound, but they may also introduce ambient noise or bleed, which can

interfere with the clear perception of reference pitches. Speaker monitoring, while common in studio settings, can cause subtle pitch discrepancies depending on room acoustics or speaker placement, and may not offer the same level of isolation as headphones.

To objectively assess the impact of different monitoring methods on intonation, precise measurement metrics are necessary. Pitch accuracy in vocal performance is typically quantified in cents, with one semitone equivalent to 100 cents. Previous studies have shown that well-trained singers generally maintain intonation errors within the range of 10-20 cents [1,3]. In many cases, professional vocalists can achieve even lower error margins, often in the vicinity of 10–15 cents, reflecting their advanced auditory-motor control and extensive training. In contrast, less experienced singers or those operating in less controlled environments may exhibit errors exceeding 30 cents [6].

Based on these observations, this study aims to compare the effects of closed-back headphones, open-back headphones, and speaker monitoring on vocal intonation across both continuous (harmonic) and recalled (melodic) pitch tasks.

2. METHOD

This study investigated the influence of three monitoring conditions: open-back headphones (Beyerdynamic DT 990 Pro), closed-back headphones (Audio-Technica ATH-M50X), and speaker monitoring (JBL 4208), on singers' vocal intonation accuracy. The recordings were conducted with six female volunteers (aged 20–35) who were active members of the Warsaw University of Technology Academic Choir, but not professional vocalists. Of these six participants, one produced only the reference sounds, while the remaining five performed the target singing tasks. The small and homogeneous sample is a limitation of this study, which may restrict the generalizability of the findings, but only female voices were chosen, to limit the number of factors for analysis.

To generate reference material, one chorister recorded designated pitches that were initially presented by pure-tone sinusoids at known frequencies (e.g., 294 Hz, 392 Hz, 440 Hz). From these recordings, samples that demonstrated the most stable pitch and minimal errors were then selected for use as the reference stimuli. This approach was chosen over a fully synthesized tone to better reflect authentic vocal conditions.

All participants stood 15–20 cm from a Neumann U87 microphone, centrally placed in the anechoic chamber. The output level for each monitoring setup (open-back headphones, closed-back headphones, and speaker) was calibrated to 70 dB SPL at the participant's position. While the anechoic chamber was used to ensure experimental control, it may not appropriately represent the typical performance settings encountered in everyday practice.

The experiment comprised two tasks. In the first, singers performed a perfect fifth above a sung reference, thereby creating a harmonic interval. The perfect fifth was chosen for its high degree of consonance and harmonic stability. Three reference frequencies were used for this task (294 Hz, 349 Hz, and 392 Hz) and the singers were asked to sing the perfect fifths in just intonation (3:2 ratio). For each frequency there were five repetitions under each monitoring condition. In the second task, participants heard two sung notes forming a perfect fifth and were asked to sing a major third (5:4 ratio) after the reference tones ended, thus producing the interval melodically and in isolation. In contrast to a perfect fifth, which is a very stable consonant, the major third is generally more sensitive to intonation discrepancies, which could make the second task harder to perform. The reference fifths were sung from 330 Hz, 392 Hz, and 440 Hz and likewise repeated five times for each monitoring condition.

All resulting audio files were tracked in Cakewalk, exported as .wav files, and then analyzed in Python with the Librosa library. Fundamental frequency (F0) was extracted using the probabilistic YIN (pYIN) algorithm [7]. Given the typical pitch variability at note onsets and releases, only the 2-second portion deemed most stable, starting 0.5 seconds after the note attack, was used for subsequent measurements.

Intonation accuracy was assessed by calculating pitch error in cents, as the difference between the singer's average pitch and the expected frequency for the specified interval. Cents were used to compare pitch error at different absolute frequencies. Finally, a one-way analysis of variance (ANOVA) was performed to assess whether the selected monitoring condition exerted a statistically significant effect on intonation accuracy across both the harmonic (perfect fifth) and melodic (major third) intervals.

3. RESULTS

For both considered tasks: singing a perfect fifth while a reference tone was still audible (harmonic interval) and singing a complimentary major third after two reference tones had ceased (melodic interval) – performed analysis revealed statistically significant differences in performance across the three monitoring conditions.

For the harmonic interval of perfect fifth (Fig. 1), results showed the smallest median pitch error for closed

headphones (11 cents). Open-back headphones yielded a slightly higher but still relatively small median pitch error (13 cents), while speaker monitoring produced the largest pitch deviations (18 cents). Additionally, the distribution of individual values was most consistent (i.e., narrowest) under closed headphones, while speaker monitoring had the widest variability among participants.

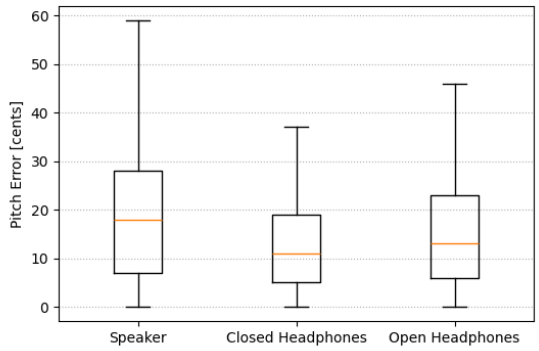

Figure 1. Box plot illustrating the pitch error (in cents) for a harmonic fifth sung under three different monitoring conditions (speaker, closed-back headphones, open-back headphones).

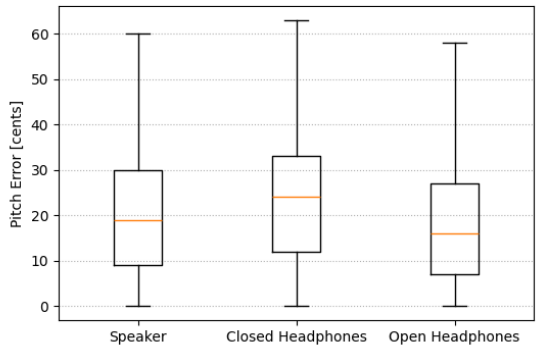

Figure 2. Box plot illustrating the pitch error (in cents) for a melodic third sung under three different monitoring conditions (speaker, closed-back headphones, open-back headphones).

When singing the major third without a continuously sounding reference, the patterns shifted (Fig. 2). Open-back headphones gave the lowest pitch error (16 cents), followed by the speaker setup (19 cents), and then closed headphones (24 cents). In this melodic context, the increased isolation provided by closed headphones appears to have contributed to overestimation of pitch, likely because participants relied primarily on their own vocal feedback once the reference was no longer audible.

A combined analysis of recorded intervals showed that the highest overall median error (19 cents) was observed for the speaker monitoring, followed by closed-back headphones (18 cents) and open-back headphones (16 cents). One-way analyses of variance (ANOVAs) for each interval type (perfect fifth: $F = 1243.4$, $p < 0.05$, major third: $F = 250.0$, $p < 0.05$), as well as for the combined data ($F = 343.4$, $p < 0.05$), confirmed that the differences between monitoring conditions were statistically significant.

Obtained results suggest that while closed-back headphones minimized pitch discrepancies for the harmonic (perfect fifth) interval, open-back headphones were more beneficial when singers had to recall pitch internally for the melodic (major third) task. Speaker monitoring consistently showed higher deviations in pitch accuracy compared to either headphone approach.

In addition to the statistically significant differences observed, the results may indicate, that even though the median differences between conditions are small, ranging from roughly 2 to 7 cents, they can be meaningful in professional contexts. Research indicates that trained musicians and critical listening environments can detect pitch differences as small as 2–5 cents [8]. Therefore, even these modest variations in pitch error may have practical implications for vocal performance quality, particularly in high-fidelity recording and live settings.

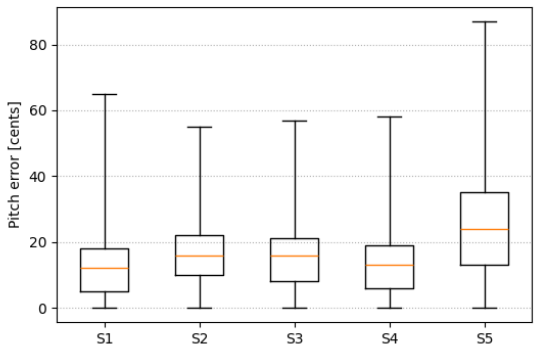

Figure 3. Box plot showing the combined pitch error distributions for singers S1–S5 across both intervals, highlighting individual variations in intonation accuracy.

Some insight can be also obtained by examination of individual singers performance. Figure 3 illustrates the singer-specific aggregated pitch error distributions, combined for both the harmonic (perfect fifth) and melodic (major third) tasks. Overall, S1, S2, S3, and S4 show moderate deviations, typically under 20 cents, indicating stable intonation. S5, however, displays a higher median error (24 cents) with the maximum exceeding 80 cents, suggesting greater difficulty controlling pitch. S5's broader error may suggest a tendency toward larger pitch mismatches, possibly due to individual factors such as technique, reliance on external cues, or comfort with recalling intervals.

4. CONCLUSIONS

This study demonstrates that the choice of monitoring method can affect choristers' ability to achieve precise intonation, especially when considering whether reference pitches are continuously present (harmonic tasks) or must be recalled (melodic tasks). Closed-back headphones produced the lowest intonation errors for a harmonic perfect fifth, suggesting that stronger isolation helps singers maintain focus on a reference pitch. However, for the melodic major third, sung without an ongoing reference, open-back headphones yielded the best results, implying that overly isolated conditions may lead to pitch overestimation once external cues are removed. Speaker monitoring, meanwhile, was associated with generally higher error values, showing its limitations for precise pitch accuracy during individual recordings.

These findings are in line with existing literature, which reports that well-trained singers typically maintain intonation errors in the range of 10–20 cents [1,4], with more experienced vocalists sometimes achieving errors as low as 10–15 cents [5,6]. In contrast, less-experienced singers may exhibit errors exceeding 30 cents. Trained musicians and professionals can detect pitch differences as small as 2–5 cents [8], therefore the pitch error differences observed in our study confirm that monitoring conditions can significantly influence pitch accuracy.

While this study offers some insight to the effects of monitoring conditions on intonation accuracy, it also has some limitations. The small, homogeneous sample, consisting only of non-professional, female choristers, and the controlled environment of an anechoic chamber may restrict the generalizability of these results to more natural performance settings. Moreover, the focus on only two intervals (perfect fifth and major third) simplifies the complex reality of vocal and choral singing. Future research should consider larger, more diverse participant groups and explore a broader range of intervals and musical contexts. Investigating alternative monitoring conditions (such as semi-open headphones or in-ear monitors) and testing in more acoustically realistic environments could give further information on how auditory feedback affects intonation.

ABSOLUTE PITCH AMONG NON-GLOBAL POSSESSORS - TIMBRE AND CATEGORIZATION -

Ébano Resende de Souza[1*]

[1] Acoustics Research Institute, Austrian Academy of Sciences, Austria

ABSTRACT

Perfect or absolute pitch (AP) is typically considered to be an asset for any musician, however it is not well understood and may have some drawbacks. From a case study among students from the Musicology and Analysis Department of the Conservatoire National de Musique et Danse de Paris (CNSMDP), under direction of Dr. Adrien Mamou-Mani (CNSMDP/IRCAM) and Dr. Michèle Castellengo (LAM), we noted important issues raised by the students, in particular the relevance of timbre for AP categorization and identification. Among our findings we can highlight: 1) the strong relationship between AP identification and primary instrument; 2) the importance of the piano (pointed as the easiest timbre for recognition) and the voice (pointed among the hardest timbres for recognition) during AP identification and, 3) the loss of musical pleasure indicated by a considerable number of AP possessors. These highlights call for further research in Psychoacoustics and Cognition fields, including to understand to what extent AP perception can hinder RP perception and therefore the joy of music.

Keywords: *Absolute Pitch, Timbre, Categorization, Music and Cognition.*

1. INTRODUCTION

Built around several preconceived ideas, Absolute Pitch once held a distinguished position among musicians. Perceived as a rare and special phenomenon, it functions in many cases to legitimize a certain superiority in the hearing of its possessors. Currently, we are seeing a shift in this image, with a new understanding of the subject, and the idea of Absolute Pitch is gradually being better constructed. Regardless of this social relationship, the ability to hear specific frequencies remains an interesting tool for musical listening and can represent an important mechanism for learning and performing music. Understanding its role can contribute to a better understanding of musical activity and the relationship between the individual and music.

AP is defined in the literature as the ability to identify the pitch of isolated tones using musical pitch labels or to produce the pitch of any tones designated by note names without comparing to any reference pitch [1-11]. The incidence of AP is estimated to be around 0.1-1% of the population [7,12-14]. Among musicians this number can increase considerably, with estimates varying from between 5 to 50% [15, 16]. There is disagreement in the literature as to how AP is acquired. A more recent and now commonly supported hypothesis falls somewhere between the two previous hypotheses: some individuals have a genetic predisposition that is activated via a critical period during early musical training and it is strongly linked to our pitch categorization process [17-20].

Absolute Pitch remains a rich subject and represents an important part of the study of musicality. The increasing amount of research on this subject, and the exchange between researchers is fundamental in this context. For this research we ware particularly interested in aspects related to

perception and the influence of timbre on pitch perception. Since music is composed mostly of complex sounds, timbre is a key attribute in this perception.

The discussion surrounding the definition of AP makes us reflect on the different aspects of this phenomenon. We can recognize different profiles depending on the type of difficulty encountered by individuals who possess it. We also find that musicians have a certain difficulty self-declaring that they possess this ability, given that, on the one hand, we have a certain lack of understanding of the definition and the different types of AP, and on the other hand, the difficulties encountered by these individuals can lead them to believe that they do not possess it or that they possess a so-called defective ear, given that it does not correspond to the common image of perfect AP. Research such as Bachem (1937) [5], and Takeuchi and Hulse (1993) [4] highlight already the different degrees of listening among those with Absolute Pitch. Differences in pitch perception depending on timbre and register, and difficulties related to singing or the accuracy of this identification lead us to classify them into categories or subgroups that can allow us to better analyze and understand this ability. We believe AP and RP (Relative Pitch) are not on the opposite ends of a continuum. Instead, AP and RP can both be present or absent in an individual.

2. THE CATEGORIZATION

The relationship between the individual and the environment in which they are located is marked by their interaction with objects and other individuals. In our understanding of the world, we need to find mechanisms that allow us to read this world and establish relationships between the different things that form it. We organize it in such a way as to separate and classify things in order to understand it. We classify them into large groups that both give rise to new subgroups and, in turn, form the basis for other subgroups depending on the degree of specialization we have in each concept. In this way, we classify objects, animals, colors, feelings, everything around us. Our perception is entirely based on these groups, which we build since childhood and which develop and subdivide throughout life according to the experiences and specific needs of each individual (in which language plays a fundamental role). In this sense, we can distinguish two types of categorization: prototypical categorization and perceptual categorization. The former refers to the type of categorization we construct based on our reading of the world, while the latter is more closely linked to established systems that individuals must assimilate. In prototypical categorization, two concepts are important: similarity aggregation (operated at the basic level) and pattern (or "typicality") [21].

The basic level encompasses the more general references we build since childhood and allows us, for example, to distinguish between the different objects that make up our environment. Throughout life, we create subcategories, as needed, to specify the differences between objects in the same group. The second type of categorization refers to specific learning, specific to a given culture. It is linked to a theory with fixed boundaries, based on measurements, and has a more scientific perspective, unlike the prototypical categorization, which relates to more variable phenomena and has a more psychological perspective.

3. THE TIMBRE

Among the various aspects of sound, one seems particularly interesting for musical listening and is also important in analyzing aspects of Absolute Pitch. Timbre can be defined as the fingerprint of sound. Each timbre is unique and results from the way the sound is produced. It can vary depending on the musician's playing style, the instrument used (such as a bow or fingers), and also depending on atmospheric conditions such as humidity and temperature, which modify the quality of the resonant materials [22]. We encounter a large number of possessors whose ability to label pitches is directly linked to timbre. The instruments they play have a fundamental role in this process and can even characterize the ability of the AP for a single instrument. This phenomenon is frequently observed in the case of the piano, widely used as a basic instrument in music theory courses [23]. This connection to specific timbre is relatively common and makes us reflect on the relationship between the perception of pitch and timbre. We also question the role of spectra in this context. In this sense, we may ask whether there are instruments that are more difficult to identify, as well as the relationship with their spectra, and also the role of formants and specific harmonics/partials in this process. The temporal envelope, also called ADSR, represents the four temporal stages of the sound: Attack, Decay, Sustain and Release, where the attack is very important for the timbre perception. Human perception does not evolve in a linear, additive relationship. It follows a logarithmic logic. The auditory system also does not behave the same way in different registers. Similarly, parameters such as intensity, duration, and timbre can also influence our perception of other musical elements.

4. CASE STUDY

4.1 Participants and Method

The research was conducted among students in the Department of Musicology and Analysis at the Conservatoire National de Musique et Danse de Paris (CNSMDP) after approval of the department's director, and the support of student representatives. The students enrolled in the department were between 18 and 30 years old and come from a variety of backgrounds and instrumental practices. Most enrolled at the National Conservatory between 2007 and 2014 and were currently pursuing programs such as Musicology, Musical Culture, Analysis, Pedagogy, Composition, Music Writing/Notation, Music History, and Aesthetics.

An electronic survey consisting of 25 questions was proposed to the 80 students of the department between November and December 2014, of whom 39 agreed to participate to this self declared research. Among the 39 participants, 36 were native French speakers, and the 3 foreign students were at an advanced level of language skills. The students began their music studies between the ages of 5 and 14 years old, and most followed the traditional curriculum of French conservatories (fixed do). The participant identification was not mandatory.

The questions we aimed to understand were: 1) the role of timbre in the students pitch identification; 2) aspects related to their auditory perception such as register, identification time, and vocal reproduction of notes; 3) the difficulties related to defining the term Absolute Pitch; and 4) the specificities and characteristics of the group that claims not to be sure if they have AP.

4.2 Results

4.2.1 Timbre

Participants were asked which timbres they found most difficult to identify. Of the twenty-five responses (five of which contained two answers), most (8) indicated the voice. Seven responded with wind instruments, with five specifying: English horn (2), oboe (1), clarinet (1), and brass (1). Lower register instruments were mentioned three times (one of which was the piano) and percussion three times (one of which was bells). The following instruments were mentioned once: piano, guitar, violin, viola, and organ. Two participants reported having no difficulties related to timbre, and one did not specify. Regarding the most easily identifiable timbres, we obtained twenty responses (three of which had two answers each). The highest number of responses was for the piano (6). The oboe and violin were mentioned three times. The harpsichord, voice, strings, and cello appeared once. Strings and woodwinds in general were also mentioned once each. Three participants did not report any particular timbres. We can see the most difficult and easiest timbres for pitch recognition in the Tab. 1.

Table 1. The most difficult and easiest timbres for pitch recognition.

The most difficult timbre		The easiest timbre	
Voice	8	Piano	6
Winds	7	Oboe	3
Percussion	3	Violin	3

Many students prefer the timbre of the instruments they practice when identifying pitches. However, this is not always the case. Other instruments may play an important role, as is the case with two pianists indicating the voice and the violin, or a bassist indicating the voice as the easiest timbre for pitch identification. The piano occupies an important position. Many instrumentalists consider it easier even if they do not practice it. This may be related to its use in theory lessons, leading to greater familiarity with its timbre and, in some cases, the development of what is called "absolute piano"(Instrument-Specific Absolute Pitch [24]). The difficulty in recognizing and notating vocal music with text was also mentioned. The voice occupies an important place among the hardest timbres for recognition, due, probably, to the overlap between AP label and the lyrics of the song during AP identification

We have cases where the instrument being practiced is cited as more difficult to identify than others, such as the case of a violinist who indicates the piano as the easiest and the violin as the most difficult, and that of a clarinetist for whom the piano comes first, unlike the clarinet, which occupies the ninth place, for which pitch identification is the easiest.

4.2.2 Time, Accuracy and Frequency range

Most of the participants (twenty) declared to recognize pitches instantly. Fourteen participants needed between 3

and 5 seconds, and two participants needed between 5 and 10 seconds. One student reported needing more than 10 seconds for recognition, and one reported not being able to do so (See Fig. 1).

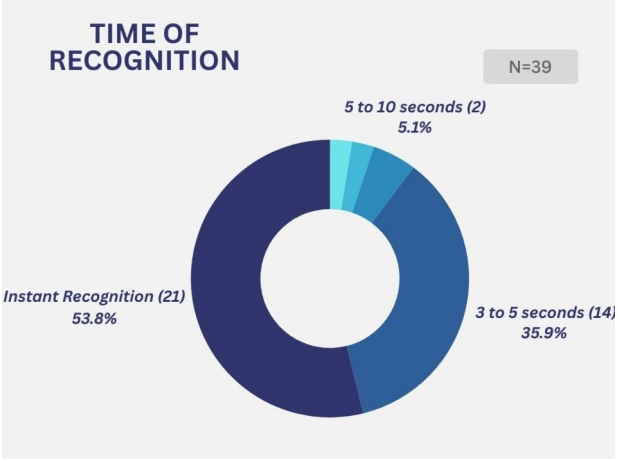

Figure 1. Time of recognition.

Regarding the accuracy of this identification, twelve participants reported always identifying the notes correctly. Twenty-two made errors of a semitone, and three were off by a whole tone or more. A half-tone error was quite common, and difficulties with atonalism and double-sharp or flat keys were also encountered (See Fig. 2).

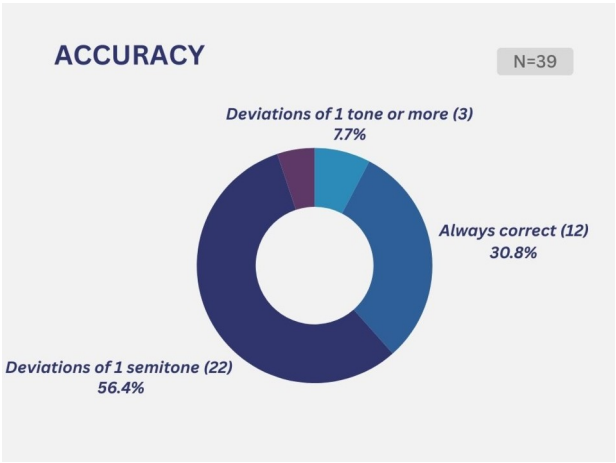

Figure 2. Accuracy of recognition.

Regarding the frequency range, 76.9% of the participants identified the middle register as the easiest register for pitch identification. Six participants (15.4%) identified the high register and two (5.1%) the low register - including one bassoonist (who started at the age of 14 after having previously played violin for six years) who stated he was unsure whether he had the AP, and the other, a pianist since the age of six, who stated he did not have the AP (See Fig. 3).

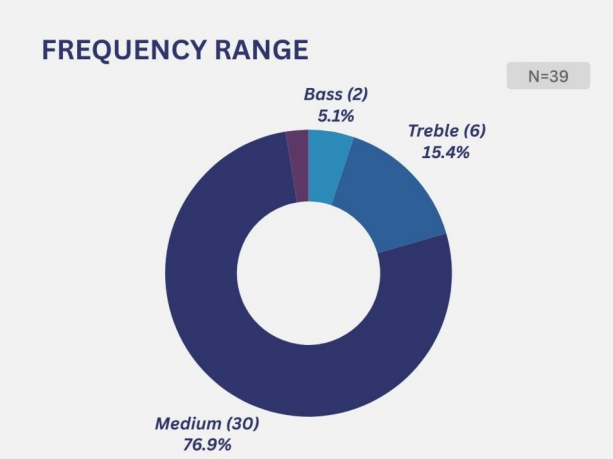

Figure 3. Preferred frequency range

5. DO I KNOW IF WE HAVE AP?

When asked how to recognize pitches, twenty-two participants (56.4%) said they did in the absolute way, compared to seventeen (43.6%) who declared the necessity of a reference note (such as A 440 Hz, for example).

Regarding the question of whether or not a participant has Perfect Pitch, an objective answer suggests some hesitation. Among the thirty-nine responses, eleven participants (28.2%) stated they have Absolute Pitch, seventeen (43.6%) stated they do not, and eleven participants were unsure. This last figure represents 28.2% of the responses and can tell us something about the difficulties in defining oneself as a possessor or not. A certain lack of understanding of the definition and the diversity of problems encountered (related to timbre or to the accuracy, for example) make the self identification as a possessor even more difficult. The preconceived ideas that arise from it, also plays an important role.

Eleven students made up the group who reported being unsure whether they had Absolute Pitch, including four pianists (one of whom is also a guitarist), three violinists,

two oboists, one bassoonist, and one clarinetist. The ages at which they began practicing ranged from 5 to 14 years old. Ten reported identifying pitches without the need for a reference note such as A 440 Hz, and only one relatively. Seven could do so instantly, and four did so after a 3 to 5 seconds of reflection. These ten participants (unsure if they have AP, but stated do not need a reference note for pitch identification) reported experiencing discrepancies of a semitone, while the one who do it relatively report always correct identification. Eight prefer the middle register, two the high register (the oboist—who also reports difficulty with all lower register instruments—and one violinist), and one student the lower register (the bassoonist). Regarding the reproduction of a required note for singing, nine report not needing reference notes (including the one who responded that they identify in relative form), and two report needing them. Three do it instantly, and eight need between 3 and 5 seconds to do it.

AP can appear in many forms. While there are some AP possessors with highly accurate AP across the board, some possessors have more limited AP capabilities. We refer to these groups as "global" and "non-global" AP possessors respectively. Possessors are also able to develop RP at different levels. It is not known how well RP develops among people with AP. As such, AP may actually be detrimental to some critical parts of the musical experience. The lack of understanding the definition and the different types of possessors we may encounter may be the source of this hesitation in declaring oneself a possessor. The group that hesitates to define itself as possessors is probably part of the non-global possessor group. One of the important aspects that differentiates possessors from non-possessors is the natural and intuitive nature of this pitch identification. AP is linked to "pitch memory," a labeling ability, to match a sound to a pre-established word or name. It is not a matter of just trying to identify a note. The sound heard and the associated name of the note (culturally chose) are, for most of these individuals, inseparable.

6. SUMMARY

Possessing AP can be a determining factor in the musical careers of many musicians. AP can be a very effective tool for success in music education in many countries. The importance given to identifying pitches in dictations and music theory lessons creates a favorable environment for those who possess it. In this case, this type of listening will always earn them good grades by giving the sensation of musical evolution. But this situation quickly changes when these musicians are confronted with other practices such as group music without the use of music scores when faced with improvisation within a piece. In some cases, possessors musicians may succeed in their path, but their approach and the relationship they establish with this type of piece are undoubtedly different. In this case, many players will rely on theoretical knowledge, such as tonality, the chords and the scales, rather than on the feeling of improvisation based on sound research. We also encounter cases where the players who hesitate to play in these conditions and remain completely dependent on the scores, and also situations where they change career paths, frustrated by not feeling comfortable playing in groups, either professionally or in informal settings, such as at friends' or family's houses, for example. During the course of this case study, we questioned ourselves a lot about the place of the individual player in the musical world. More than trying to understand how the AP works per se, we are also interested in understanding how these musicians relate to this skill and the relationship they establish with their musical practice.

The way possessors relate to music and code pitch are central to our understanding of music language and have clarified the extent and limits humans approach music, how we categorize acoustic stimuli, how the brain plasticity adapts to different ways of hearing and the impact it has in the music culture and the traditional music education. Some possessors, unlike those without AP, may have the tendency to lose the pleasure derived from music, which, in turn, negatively impacts their musical career. The study of the Non-global possessor subgroups can bring new knowledge to better understanding of AP ability and how humans and, musicians in particular, create different paths according to their abilities and limitations to make music. Despite the increasing number of studies and research about AP, a relatively small number of studies have been dedicated to non-global AP possessors. Studying the differences and the different levels possessors can present, we will be able to have a fine understanding about the categorization process in humans, the strategies non global possessors develop, and the influence of the musical pleasure in this process.

A MEASUREMENT SYSTEM TO CAPTURE THE PLAYER'S CONTROL IN THE NATURAL PLAYING CONDITION OF SINGLE-REED MUSICAL INSTRUMENTS: APPLICATION TO THE PERFORMANCE LOG OF A BEGINNER PLAYER

Tetsuro Shoji[1*] **Yohei Wada**[1] **Yu Takahashi**[1] **Keita Arimoto**[1]
[1] Research & Development Division, Yamaha Corporation, Japan

ABSTRACT

It is well known that the control by players (e.g. embouchure, tonguing, respiration, and so on) gives significant effects on the sound generation of wind instruments. However, it is hard to measure them in actual playing conditions due to the difficulty in putting sensors without disturbing the performance. This paper proposes new devices for measuring the control induced by players of single-reed musical instruments. These devices are capable of acquiring various aspects of the player's control including blowing pressure, biting force, acoustic pressure inside a mouthpiece, abdominal motion, and chest wall motion. The devices are designed to minimize disturbance for players in order to realize measurements in a natural playing condition. A test measurement using the devices was conducted on a person who was completely new to playing the saxophone. The player was asked to engage in daily practice for three months under the supervision of an experienced player, while consistently measuring the control information. The analysis of the performance log reveals clear improvements in certain performance indicators such as loudness, spectral centroid, and respiratory motion.

Keywords: *gesture acquisition, performance log, wind instrument, embouchure, respiration*.

1. INTRODUCTION

There have been several studies on capturing the player's oral control when playing single-reed instruments. One of the pioneer works in this context is the study on the effect of vocal tract resonance by the measurement of the pressure in a player's mouth and the pressure in a mouthpiece [1]. This concept has been further explored in subsequent studies [2-4] and extended to the investigations on the role of player's control during the transient phase of the sound generation [5-6]. A completely different approach involved morphological analysis of vocal tract images obtained through MRI measurements for saxophone players [7].

On the other hand, there have been some studies on the measurement of respiratory motion while playing wind instruments [8-10]. These studies involve time series analysis of videos capturing the motion of optical markers placed on a player's body.

This paper proposes a measurement system to capture both oral control and respiratory motion, simultaneously. The system is expected to be utilized for pedagogical purposes, such as learning how to play musical instruments and understanding the advanced technique by skilled players. To achieve this goal, the measurement system is designed following the concept:

- minimize the disturbance to performance
- easy handling (easy setup, less special equipment)

2. MEASUREMENT SYSTEM

Fig. 1 illustrates a special mouthpiece designed to capture oral control. The mouthpiece is designed to measure similar information as [2][5-6] with introducing the concept of the tunnel employed by [1][3-4]. The tunnel enables a pressure sensor within the mouthpiece to measure the pressure inside

the mouth cavity (Pcav). In addition to Pcav, the mouthpiece is also able to capture reed strain (Sreed) corresponding to the biting force and acoustic pressure inside the mouthpiece (Pmp).
The respiratory motions at abdomen (Abdominal) and chest (Chest) are captured by the belts that wrap around the player's body (Fig. 2). The belts are equipped with CNT sensors to capture the elongation of the belts induced by respiratory motion.

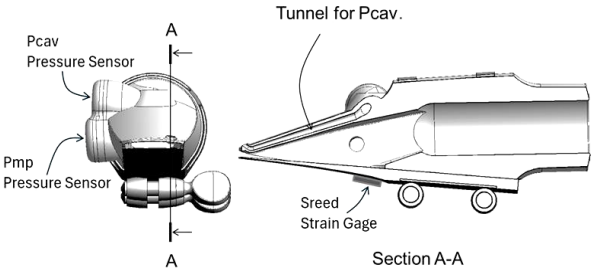

Figure 1. mouthpiece with sensors to capture the oral control.

Figure 2. belts with elongation sensors to measure the abdominal motion and chest motion.

3. EXPERIMENT

A long-term measurement test is conducted on a person who is completely new to playing the saxophone. The player is asked to engage in alto saxophone training under the supervision of an experienced amateur player. The signals from the 5 sensors are recorded throughout the training session, which typically lasts 30-60minnutes. The training is repeated every working day for three months. The player is obliged to play long tone (at Eb3, Eb4, and Eb5) and scale in Eb at least once in a daily training session.

4. RESULT

4.1 Analysis on acoustic pressure at mouthpiece

Fig. 3 and Fig. 4 are the results of the analysis on the Pmp signals (corresponding to acoustic pressure at mouthpiece). A long tone phrase in Eb4 is picked from each daily session and feature extraction is performed for the stable portion of the signal. Fig. 3 shows the median for rms amplitude of the waveform in linear scale. Fig. 4 shows the results on spectral centroid. The Comparison between the beginning (around the left end) and ending (around the right end) indicates that both the amplitude and spectral centroid gets approximately double. The result suggests that the player has improved one's playing skill through the daily training session. Note that there were no long tones in Eb4 observed on 0130 and 0202.

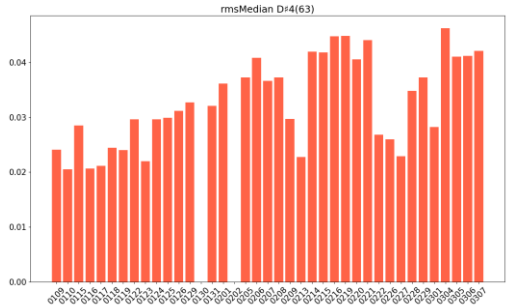

Figure 3. median for rms amplitude (in linear scale) on a Eb4 long tone over daily sessions.

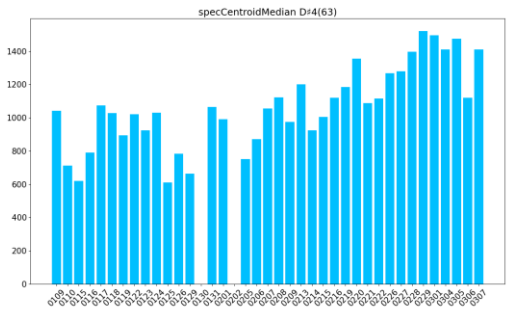

Figure 4. spectral centroid on a Eb4 long tone over daily sessions.

4.2 Analysis on the respiratory motion

From Fig. 5-a to Fig. 5-d show the analyses results of the respiratory sensors attached to the player's chest and abdomen. From the entire training period, data from distinctive four days were picked, and the figures depict the expansion and contraction of the respiratory sensors during the daily sessions. Throughout each daily session, the vertical axis plots the expansion and contraction of the band attached to the chest, and the horizontal axis plots that of the band attached to the abdomen. Comparing the plots, it is noticeable that at the very start of the training, the range of the sensor's expansion and contraction is small (Fig. 5-a). This indicates that breathing is not deep. However, in two weeks, the range of expansion and contraction for the chest sensor becomes larger, suggesting that the player is attempting to breathe more deeply using one's chest (Fig. 5-b). With further repetition of daily training, the range of expansion and contraction for the chest sensor gradually decreases (Fig. 5-c and Fig. 5-d). This suggests that the player has acquired more efficient control through training.

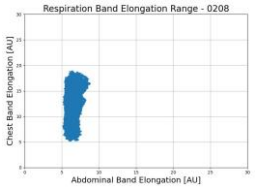

Figure 5-c. 02/08

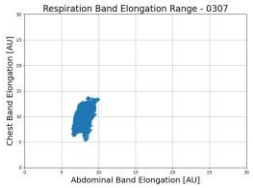

Figure 5-d. 03/07

Figure. 5 respiratory sensor elongations at four different daily sessions. Vertical and horizontal axes correspond to chest and abdomen motions, respectively.

5. FUTURE WORK

The preliminary results indicate that the measurement system has enough potential to assess the player's ability. However, the capability of the measurement system needs to be evaluated through the experiment involving players of different skill levels, from beginners to professionals. Additionally, intensive analysis of sensor signals also needs to be done in order to correlate the player's control and the resulting sound.

A PROCEDURE FOR EVALUATING THE SOFTNESS OF SOUND PLAYED ON THE CLARINETS

Nozomiko Yasui[1*]
[1] National Institute of Technology, Kisarazu College, 2-11-1, Kiyomidaihigashi, Kisarazu City, Chiba, 292-0041, Japan

ABSTRACT

In wind ensembles, aligning not only pitch and timing but also the softness of the sound is said to be essential when multiple performers play the same piece. Particularly in clarinet performance, it is said that without the ability to control the softness, it becomes difficult to adapt to the wind ensemble's repertoire. While many instructional books provide basic exercises for aligning pitch and timing, there are very few that focus on exercises addressing the softness of sound, and there is little research that has investigated procedures for objectively evaluating softness. Therefore, this study proposes a procedure for evaluating the softness of the sound played on the clarinet. Specifically, this study conducted a subjective evaluation experiment by recording clarinet performance sounds and investigating whether listeners could perceive the softness intended by the performer in the same way. The acoustic characteristics of the performance sounds were extracted. The relationship between the characteristics and the softness was analyzed. Based on the results, a procedure for evaluating the softness of clarinet performance sounds was investigated. As a result, it was found that the softness in clarinet performance can be evaluated by three acoustic characteristics: slope of the attack, spectral centroid, and spectral flux.

Keywords: *clarinet, softness, slope of the attack, spectral centroid, spectral flux*

1. INTRODUCTION

In wind ensembles, it is considered important to match not only the pitch and timing, but also the softness of the sound when several musicians perform the same part together. Impressions such as "softness" are, however, difficult to quantify objectively and numerically, as they are subjective and depend on the listener's perception. As a result, there have been very few reports on practice systems designed to unify such sound impressions.

In a previous study [1], the visualization and analysis of reed vibrations in clarinets had been conducted, but the evaluation of softness had not been addressed. In another previous study [2], a prototype of performance support software was developed, which visually displays in real time the relative comparison between the parameters of a target sound and those of a performer's sound using radar charts and other visual tools. A trial evaluation conducted with clarinet players showed that the system was helpful in improving the "beauty" and "softness" of the sound. Specifically, "beauty" was evaluated based on the total power in the frequency spectrum, and "softness" was evaluated based on the slope of the spectral envelope. However, it had not yet been verified whether these parameters could appropriately assess impressions such as "beauty" or "softness."

This study proposes a method for appropriately evaluating softness from acoustic signals.

Based on previous research on the extraction of acoustic characteristics [3-5], three parameters were extracted to investigate the acoustic parameters associated with the perceived softness of sound and their relationship with subjective impressions of softness was analyzed. Based on the findings, a method for evaluating the softness of performance sounds is proposed.

2. SUBJECTIVE EVALUATION EXPERIMENT ON THE SOFTNESS

2.1 Outline of experiment

A subjective evaluation experiment was conducted using recorded clarinet performances to assess the perceived softness of the sounds. The purpose of this experiment was to investigate whether listeners could consistently perceive the softness as intended by the performers. Only the recordings that showed agreement between performer intention and listener perception were selected for further analysis.

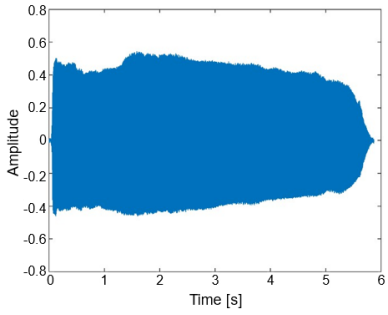
For the recordings, three clarinet players (P_1–P_3) with over 20 years of performance experience each were instructed to play both "hard" and "soft" tones five times each. A total of 30 audio samples were recorded: 15 "hard" tones and 15 "soft" tones. The instruments and components used in the recordings are summarized in Table 1. All samples were standardized to an open G note with a duration of approximately 6 seconds.

The recording setup included a C414 XLS microphone (AKG by HAEMAN) and a DR-680 recorder (TASCAM). Recordings were made in a soundproof room with a sampling rate of 48 kHz and a 16-bit quantization. A waveform example of the recorded performances is shown in Figure 1.

After the recordings, a subjective evaluation experiment was conducted with 20 student members of a wind ensemble. Each participant was randomly presented with the 30 recorded performances and asked to rate the perceived "softness" of each sound on a three-point scale: "soft," "neutral," or "hard."

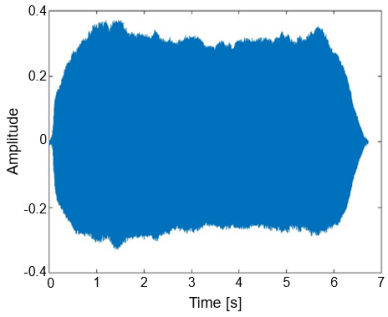
Table 1. Instruments and components used in the recording.

Component	Manufacturer	Model/Specification
B ♭ Clarinet	Buffet Crampon	E13
Mouthpiece	Vandoren	5RV
Ligature	Buffet Crampon	SP
Reed	Vandoren	Traditional



2.2 Experimental results

The accuracy rate was calculated based on the subjects' responses, where the "softness" intended by the performer was considered the correct answer. As a result, 23 of the recorded sounds achieved an accuracy rate of 60% or higher. The accuracy rate for the soft sounds was lower compared to that for the hard sounds.



In this study, the 23 recorded sounds with an accuracy rate of 60% or higher were assumed to be the sounds where the listeners were able to correctly judge the "softness." These sounds were then subjected to further analysis.

3. ANALYSIS OF ACOUSTIC PARAMETERS IN RELATION TO THE SOFTNESS

Based on the results of the experiment described in Section 2, acoustic parameters were extracted from the recorded sounds that were correctly perceived by listeners in accordance with the performers' intended "softness." Among the 23 validated recordings, 12 samples—6 categorized as "hard" and 6 as "soft"—were selected for analysis. A decision boundary was then derived using the Nearest Neighbor (NN) classification method, based on the relationships among the three extracted acoustic parameters. To evaluate the classification performance of this boundary, it was applied to an additional set of 11 previously unused samples (7 hard tone and 4 soft tone) to assess their classification as unknown inputs.

(a) Hard tone

(b) Soft tone

Figure 1. Waveforms of the Recorded Clarinet Sounds.

3.1 Acoustic parameters used in this study

Among acoustic parameters, there are features such as loudness which represents the perceived intensity of a sound, and roughness which describes its perceived roughness. In this study, however, three specific acoustic parameters were extracted and analyzed: the slope of the attack, spectral centroid, and spectral flux.

The slope of the attack was calculated using Equation (1), which represents the gradient between the amplitude values at the onset and end points of the rising segment, as illustrated in Figure 2. Here, min_A and min_T denote the amplitude and time at the onset of the rise, while max_A and max_T represent the amplitude and time at the end of the rise.

The spectral centroid was computed using Equation (2), which defines the center of gravity of the power spectrum. In this equation, h denotes the analysis frame index, N represents the total number of frequency bins within the frame, and $L_h[n]$ refers to the power of the n-th frequency bin in the h-th frame.

The spectral flux was calculated using Equation (3), which expresses the variation in the power spectrum over time.

$$Slope = \frac{max_A - min_A}{max_T - min_T} \tag{1}$$

$$Centroid = \frac{\sum_{n=1}^{N} L_h[n] \times n}{\sum_{n=1}^{N} L_h[n]} \tag{2}$$

$$Flux = \sum_{n=1}^{N} (L_h[n] - L_{h-1}[n])^2 \tag{3}$$

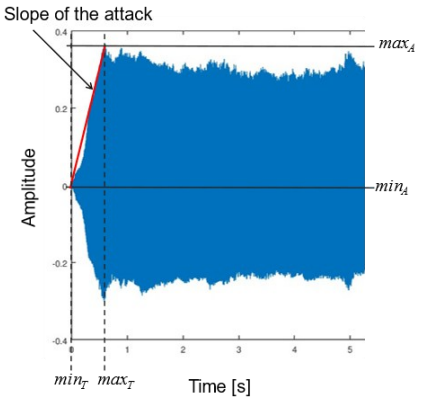


Figure 2. Outline of Slope of the attack.

3.2 Results

The relationships among the three acoustic parameters are illustrated in Fig. 3–5. Figure 3 shows the relationship between the slope of the attack and the spectral centroid. The line in the figure represents the perpendicular bisector connecting the centroids of the "hard" and "soft" tone clusters, which serves as the decision boundary derived using the NN method. This decision boundary is denoted as f_{SC}. Figure 4 shows the relationship between the spectral centroid and the spectral flux, along with the corresponding decision boundary, denoted as f_{CF}. Figure 5 presents the relationship between the spectral flux and the slope of the attack, and the resulting decision boundary is denoted as f_{SF}.

Next, it was examined whether the decision boundaries illustrated in Fig. 3-5 could be used to classify an additional set of 11 previously unused samples (7 hard tone and 4 soft tone). Table 2 shows the classification accuracy of "softness" based on the decision boundaries (f_{SC}, f_{CF}, f_{SF}) when the performer's intended softness is considered the ground truth. From the results in Table 2, f_{CF} and f_{SF} achieved relatively higher classification accuracy.

Table 2. Result of classification accuracy.

Decision boundary	f_{SC}	f_{CF}	f_{SF}
Classification accuracy[%]	73	82	82

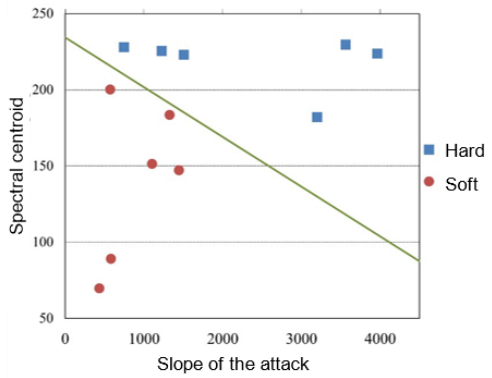

Figure 3. Outline of Slope of the attack.

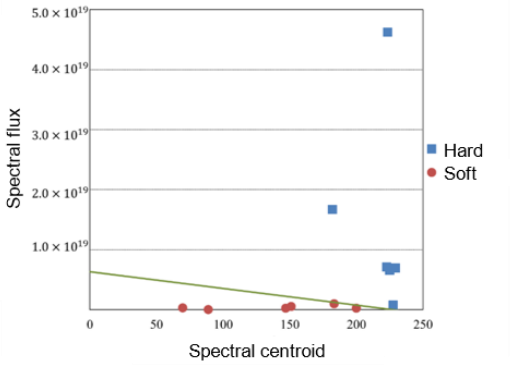

Figure 4. Outline of Slope of the attack.

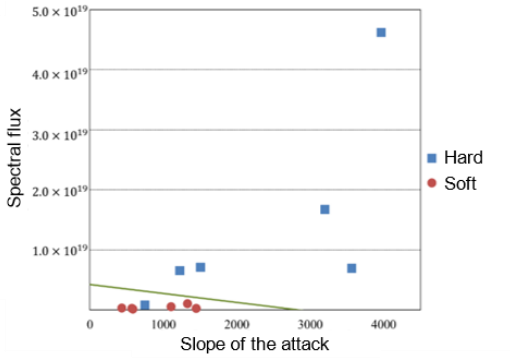

Figure 5. Outline of Slope of the attack.

4. DISCUSSION

From the experimental results shown in Fig. 3–5, it can be observed that data points plotted above the decision boundaries tend to correspond to hard sounds, whereas those below the boundaries are more frequently associated with soft sounds. These findings suggest that the proposed decision boundaries are effective in distinguishing the perceived softness of sound. In particular, the boundaries f_{CF} and f_{SF} appear to enable more accurate classification.

The classification accuracy of the decision boundary f_{SF}, based on the slope of the attack and spectral flux, was relatively low. As shown in Fig. 5, this appears to be due to certain "hard" sounds having spectral flux values similar to those of "soft" sounds, leading to misclassification. While the spectral flux values of "soft" sounds were generally consistent, those of "hard" sounds exhibited considerable variability. Since the value of spectral flux is affected by factors such as data length and frame shift during extraction, further investigation is required to assess the impact of these parameters and to determine whether spectral flux is a reliable feature for evaluating softness.

The findings suggest that clarinet sound "softness" can be evaluated using the slope of the attack, spectral centroid, and spectral flux. However, further validation with more samples and varied pitches is needed to generalize the results.

5. CONCLUSIONS

This study investigated a procedure for evaluating the softness of the sound played on the clarinet. The results showed that the highest classification accuracy was achieved when evaluating "softness" using spectral centroid, slope of the attack, and spectral flux. Therefore, it is suggested that these parameters can be effectively used for accurate evaluation of softness.

For future work, increasing the number of data samples used when constructing these boundaries will be necessary to obtain more accurate decision boundaries. Moreover, it will be important to investigate whether the same acoustic parameters can be used to evaluate "softness" when the pitch of the target sound is varied.

6. ACKNOWLEDGMENTS

The author is deeply grateful to clarinet musicians, Miyu Endo and the musicians from the National Institute of Technology, Matsue College brass band club for their valuable assistance for participating in the experiment.

PSYCHOACOUSTIC ANALYSIS OF VISCOELLASTICALLY DAMPED MEMBRANES USING PHYSICS-INFORMED MACHINE LEARNING

Martínez Orellanos, Cristhiam Fidel[1*] **Bader, Rolf**[1]
[1] Institute for Systematic Musicology, University of Hamburg, Germany
Neue Rabenstr. 13, 20354 Hamburg, Germany

ABSTRACT

The perceived sound of percussion instruments is significantly influenced by Viscoelastic Damping (VD), a mechanism whereby damped energy is temporarily stored and released back into the system, modifying the frequency spectrum. Performers harness this influence by choosing different materials and damping additives to shape the sound of their instruments. However, this process is still not fully understood. To address this, we apply physics-informed machine learning within a psychoacoustically grounded framework to investigate how changes in VD parameters influence the perceived sound of musical membranes. By analyzing a physics-informed dataset, we track spectral centroid differences and spectral flux across time and frequency ranges. Results show that the perceptual influence of VD strongly depends on where along the frequency spectrum the damping occurs, particularly in relation to the fundamental frequency. A temporal drift of the affected spectral region toward lower frequencies was also observed. Self-organizing maps (SOMs), initialized with physically informed features, were used to explore these complex, high-dimensional relationships. This method offers new insights into how specific damping conditions shape perceived sound and provides a foundation for more detailed analyses using alternative time–frequency representations in future research.

1. INTRODUCTION

The sound of musical instruments is highly influenced by the physical properties of the materials with which they are constructed. For percussion instruments, membranes are typically made from materials like leather and polymers. The internal damping of these materials is largely determined by their viscoelastic properties, leading to what is known as Viscoelastic Damping (VD). VD is characterized by the interrelation between stress, strain and time; the present stress is the result of a finite history of previous strains [6]. Given that in viscoelastic materials there is a phase difference between stress and strain, the present stress is damped by the accumulated strain. If by the time the present stress is completely damped there is still energy stored in the history of strains, this energy is released back into the system, starting the cycle again. This is known as the memory effect and leads to a highly nonlinear relation between the parameters of VD and the resulting frequency spectrum [3].

Despite its complex behavior, musicians actively make use of VD either by exploring the diverse sonic possibilities that different materials offer (e.g., when selecting a membrane material), or by intentionally using VD to alter the instrument's original sound [2, 17]. Although this practice is widespread, little is known about how VD influences the perceived characteristics of sound. Specifically, how do modifications in VD parameters lead to particular changes in the perceived sound characteristics.

To investigate the relationship between perception and musical acoustics, different music information retrieval algorithms have been developed to analyze the frequency and temporal characteristics of musical instrument signals during the onset of the sound [4, 15]. Moreover, the development of such features, as well as the advent of data-driven methods have propelled the use of

machine learning and physical modeling in psychoacoustics [5, 14, 16]. Still, many of these approaches primarily target genre or instrument classification and transcription. With regard to damping in drums, an analysis of the influence of drumhead damping patterns in the perception of the sound using convolutional neural networks and physical modeling is presented in [1]. Nonetheless, mapping perceptible changes in the sound of a musical membrane to variations within the VD parameter space remains challenging. This is due to a lack of data reflecting consistent parameter changes in VD, as well as the need for tools capable of navigating a broad parameter space while flexibly and accurately analyzing transient dynamics from a psychoacoustic perspective. To address this, the authors introduced a method in [9], employing physics-informed machine learning to investigate the relationship between systematic variations in VD and the resulting frequency spectra, thereby revealing key characteristics of VD's physical behavior.

Still, a psychoacoustic analysis implies additional challenges. On the one hand, it requires flexible tools for analyzing the transient phase of percussive sounds, which is characterized by its high intricacy [11]—this being the time window during which VD primarily operates, as will be discussed in the next section. On the other hand, it demands a better understanding of which time and frequency features the auditory system extracts and integrates into perceptual categories such as timbre or pitch. Indeed, the fact that VD is embraced by musicians suggests that the auditory system is capable of detecting and extracting patterns from its complex relationships and behaviors. Still, this latter question remains under active investigation. Therefore, the present study is based on an analysis framework developed in previous work [10], which is based on findings from the existing literature related to important temporal cues for the perception of musical sounds—also outlined in the following section. However, a detailed analysis of the auditory cues underlying sound perception, lies beyond the scope of this work.

Accordingly, the aim of this study is twofold: (a) to employ physics-informed machine learning, grounded in a psychoacoustically relevant analysis framework, to identify underlying patterns and relationships between VD and measured features, in order to (b) investigate which changes in the frequency spectrum caused by VD modify the perceived characteristics of the sound—specifically, when, where, and how VD produces these modifications. Correspondingly, this article is structured as follows: Section 2 describes the methods, i.e. the analysis framework, physics-informed dataset data pipeline and experimental design. Sections 3 and 4 present the results and their interpretation, while Section 5 summarizes the conclusions of the study.

2. METHOD

2.1 Physics- and Psychoacoustics-Based Analysis Framework

Despite the highly nonlinear relation between the parametric modifications and the resulting frequency spectra, the musical application of VD points towards the ability of the brain to extract patterns from among these complex physical components. To understand this process, both the physical dynamics of VD and the brain's temporal cues for perceiving musical sounds must be considered. To this end, an analysis framework addressing this has been presented in previous research [10] and is summarized below.

Key physical characteristics of VD in musical membranes, identified in [3, 9], include: (1) the memory effect causes viscoelastically damped frequencies to decay non-exponentially, with a nonlinear amplitude behavior starting around 40-50 ms after an initial constant decrease; (2) modifications to the model parameters lead to nonlinear amplitude fluctuations in neighboring frequencies, with the width of the affected region yet to be determined; (3) VD influences sound most significantly during the first 120 ms, although this temporal interval may vary with frequency; (4) a noticeable increase in spectral fluctuation occurs around 25 ms [10]; (5) the FDTD model requires a minimum number of periods of the damped frequency for the damping to develop completely.

Concerning the perception of musical sounds, previous studies have highlighted relevant integration times for non-percussive and percussive-harmonic sounds [12, 15]. A time window of approximately 10 ms reflects the auditory system's state of inertia, as it requires around 10 ms to establish frequency filter widths on the basilar membrane. Auditory changes occurring above this threshold affect the envelope of the sound, while changes below it influence timbre perception [12]. The interval between 10 ms and 50 ms is closely associated with pitch perception; once the frequency filters are established, their sensitivity plays and important role [12]. For frequencies below 500 Hz, differences as small as 1.8 Hz can be perceived, whereas above this threshold, the detection limit increases with frequency [18]. Changes during this time window also shape timbral characteristics. A broader window of 100–150 ms

represents the upper bound beyond which sensitivity to frequency fluctuations remains relatively constant [12]. If such fluctuations persist up to 250 ms, the pitch percept tends to weaken, and the sound is perceived as more noise-like.

Although the influence of VD unfolds continuously over time, defining specific time points that are both physically and perceptually relevant serves as a starting point for understanding how VD affects the acoustic features upon which the auditory system forms perceived characteristics of a sound. These temporal cues therefore constitute the analytical framework of this study and are summarized in Table 1.

Table 1: Analysis framework.

Time (ms)	Description
10	Filter formation in the basilar membrane. Timbre and envelope perception
25	Increase in spectral flux
50	Non-linearities in amplitude of viscoelastically damped frequencies begin. Pitch and timbre perception. Sensitivity to frequency variations
100	Perception of harmonicity - noisiness
120	Influence of VD decreases

2.2 Physics-Informed Dataset

The behavior of viscoelastic damping can be systematically controlled and modified through four parameters defined in a Finite-Difference Time-Domain (FDTD) model of a viscoelastically damped membrane developed by the second author in [3] (see Table 2). By simulating a circular membrane with a tension of 2284 Pa, a density of 300 kg/m^3, a thickness of 3 mm, a radius of 10 cm, and fixed boundary conditions ($u_{\text{rim}} = 0$), and varying only the parameter space from Table 2, a physics-informed dataset was generated in [9]. For the present study, a subset of 220 time series was extracted from this dataset (see Table 3). Each sample has a duration of 500 ms and a sampling rate of 96 kHz. The selection of viscoelastically damped frequencies—hereafter referred to as VD$_{freq}$—is constrained by the FDTD model, which requires integer multiples of periodicity to maintain numerical stability. Furthermore, when $\Re\{E(s)\} = 0$, no viscoelastic damping is applied; this case is referred to as the *no-damping* condition.

Table 2: Parameters of the FDTD.

Parameter	Description
VD$_{freq}$	Viscoelastically damped frequency
T	Integration time. Length of memory effect
$\Re\{E(s)\}$	Damping coefficient
γ	Rate of decay

Table 3: Parameter space of the dataset.

Parameter	Fixed Value	Min. Value	Max. Value	Increase
VD$_{freq}$ (Hz)	700, 6400			
T (ms)	10			
$\Re\{E(s)\}$		0*	0.003	0.0003
γ		1/100	1/10	1/10

* $\Re\{E(s)\} = 0$ implies no VD (no-damping case).

2.3 Psychoacosutic Features

2.3.1 *Spectral Centroid Differences*

The spectral centroid has been shown to be strongly related to the sensation of brightness in a sound [13]. In accordance with the analysis framework described in Section 2.1, changes in spectral centroid caused by VD at discrete time points are investigated by calculating the difference between the centroid values of a data sample and those of the no-damping case at the same time points. Previous studies have found that the frequency range along which the spectral centroid varies can change considerably across different time points [10]. Therefore, the calculated differences are normalized to facilitate comparison across time. As a result, the centroid differences are calculated as:

$$CD_i(t) = \frac{C_i(t) - C_{\text{ref}}(t)}{CD_{max}(t) - CD_{min}(t)}, \qquad (1)$$

where $C_i(t)$ and $C_{\text{ref}}(t)$ denote the spectral centroids of sample i and the no-damping case, respectively, calculated at the discrete time point t. If $CD_{\text{max}}(t) = CD_{\text{min}}(t)$, then $CD_i(t) = 0$. The results are visualized as a heat map following the approach proposed in [10], with damping coefficients along the x-axis, decay rates along the y-axis, and centroid values mapped to color. This visualization enables a comprehensive overview of how changes in the parameter space of VD affect the spectral centroid at discrete time points.

2.3.2 *Spectral Flux per Mel Band*

Building on the approaches proposed in [11] and [4] to evaluate spectral dissimilarities in a logarithmically filtered Mel spectrogram between discrete time frames t and $t - \mu$, a measure of spectral dissimilarity based on the decibel scale and preserves values per Mel band was introduced in [10] and is calculated as:

$$SF(t, m) = X_{\text{dB,filt}}(t, m) - X_{\text{dB,filt}}(t - \mu, m), \quad (2)$$

where $X_{\text{dB,filt}}$ denotes the decibel-filtered Mel spectrogram, t the discrete time point, m the Mel band index, and $\mu = 1$. Quarter-tone Mel bands were employed in the present study. The objective of this approach is to investigate how and where VD affects the frequency spectrum, enabling the localization of spectral regions where VD-induced changes occur. This, in turn, provides insight into how the spectral centroid is affected and which frequency ranges are most impacted by the energy introduced through the memory effect.

2.4 Self-Organizing Maps (SOM)

Self-Organizing Maps (SOM) transform non-linear statistical relationships in high-dimensional data into geometric relations on a 2D $n \times n$ grid [8]. The dimensionality of each neuron in the SOM matches that of the feature vectors extracted from the dataset. Both neurons and data samples are normalized before training. During training, the Euclidean distance between each sample and neuron is computed to determine the Best Matching Unit (BMU). The BMU's weights and those of its neighboring neurons are updated iteratively using a Gaussian neighborhood function. This process continues for P iterations, refining the SOM structure. Cluster assessment is performed using a U-Matrix, with values ranging from 0 (complete similarity) to 1 (max. distance).

2.5 Data Pipeline and Experiments

Figure 1 depicts the data pipeline of the proposed method. For the frequency-domain transformation, a Short-Time Fourier Transform (STFT) was applied using a Bartlett window with a window size of 85.3 ms and a hop length of 1 ms. Since the highest simulated frequencies in the FDTD model reach approximately 15 kHz, only frequency bins up to this value were considered for the calculation of psychoacoustic features under each VD_{freq} condition.

At this stage, the pipeline branches into two processes. On one hand, the spectral centroid is calculated from the magnitude coefficients of the STFT frequency bins. Centroid differences at the discrete time points defined in the analysis framework are then computed and analyzed with respect to changes in the VD parameter space (Experiment 1). On the other hand, a decibel-scaled Mel spectrogram with quarter-tone Mel bands is computed, and spectral flux per Mel band is calculated, also at the time points t defined in the analysis framework.

Subsequently, the dissimilarity coefficients obtained from the spectral flux are segmented into three frequency ranges: (1) one octave below, (2) one octave around, and (3) one octave above VD_{freq}. For each range, a peak-picking algorithm is applied using minimum width and distance constraints to retain relevant information. The spectral dissimilarities corresponding to the extracted peaks are then isolated, normalized, and incorporated into the feature vector. Principal Component Analysis (PCA) is used to initialize the SOM's weights, and one SOM is trained per frequency range at each time point. Note that each SOM involves three stages of dimensionality reduction: frequency range selection, peak-picking, and PCA for initialization. The results are then analyzed with respect to both the VD parameters and the centroid differences (Experiment 2).

Each SOM is configured with $n = 20$ neurons, a Gaussian neighborhood radius $o = 1.5$, an initial learning rate $\eta(\ell) = 0.5$, and $P = 1000$ iterations. For visualization, the centroid difference coefficients and the parameter-space annotations of the FDTD dataset are used as metadata: the inner color of each data point represents the damping coefficient $\Re\{E(s)\}$ (darker = stronger damping), the outer color indicates the centroid difference (darker = higher difference), and the shape size encodes the rate of decay γ (larger = slower decay). The U-Matrix employs a black-to-white scale, where black denotes complete similarity and white indicates maximum dissimilarity. In this context, the term *physics-informed* refers to the principle of observational bias in physics-informed learning, where observational data inherently reflect the physical laws governing the system and thus serve to embed these laws into the machine learning model [7].

Both the analysis of centroid differences and the segmentation of the frequency spectrum into distinct ranges are key steps in the proposed method (see Fig. 1, rounded purple rectangles), as they directly address the central research question posed in the introduction—namely, where, when, and how VD influences the perceived char-

acteristics of a sound. Results are presented in the following section.

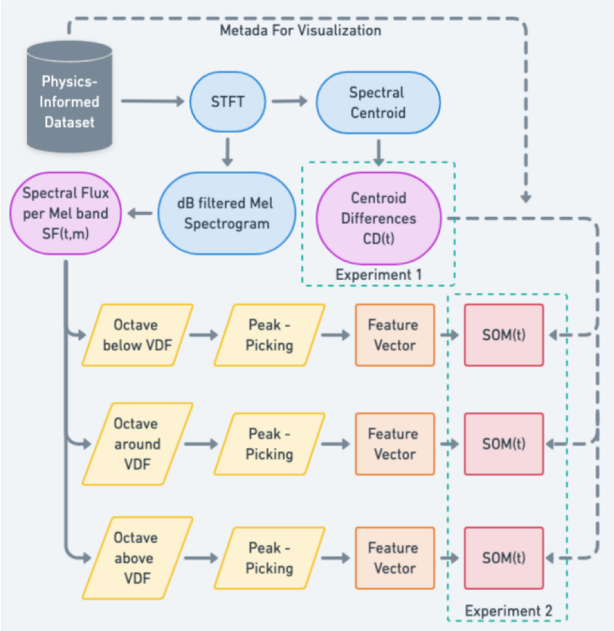

Figure 1: Overview of the data pipeline. An STFT with a Bartlett window (85.3 ms size, 1 ms hop) is applied. The pipeline branches into two processes: (1) spectral centroid, leading to centroid difference analysis (Experiment 1) and (2) computation of spectral flux per quarter-tone Mel band. Flux dissimilarities are segmented into frequency ranges relative to VD_{freq}, followed by peak picking, normalization, PCA initialization, and SOM training. Analysis is conducted in relation to VD parameters and spectral centroid differences (Experiment 2)

3. RESULTS

3.1 Experiment 1 - Centroid Differences

Figure 2 shows the analyses for the centroid differences for each VD_{freq} across the four time points defined in the analysis framework. For the 700 Hz case, at t =10 and 25 ms the centroid difference increases linearly with higher damping and slower decay, while at t = 50 and 100 ms the difference continues to grow with increasing damping but focuses towards $1/20 < \gamma < 1/70$. Moreover, at t = 50 ms some configurations of the parameter space of VD lead to a lower spectral centroid than that of the no-damping case (see Fig. 2 top row third column left to right, three first columns within the heat map).

In the 6400 Hz case, results show that at t = 10 and 25 ms the stronger the damping and the faster the decay the lower the spectral centroid. This trend persists at t = 50 ms, but the decrease is no longer linear throughout——for instance, the centroid decreases less at medium damping ($0.09 < \Re\{E(s)\} < 0.18$) than at higher damping values (≥ 0.21). At t = 100 ms, changes in the centroid become highly nonlinear; while medium damping values produce the greatest differences, this index varies with almost every decay rate. Since in both damped frequencies the 10 ms and 25 ms cases behave similarly, the 10 ms time point is discarded for the SOM analysis presented below.

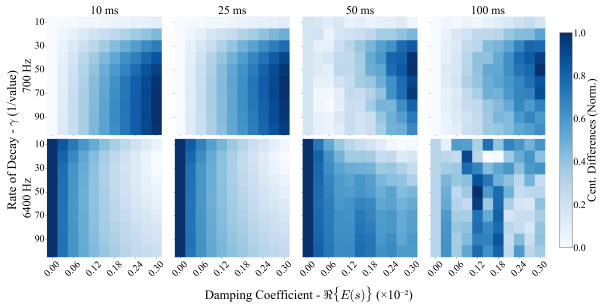

Figure 2: Centroid difference analysis for VD_{freq} = 700 and 6400 Hz. Each column, from left to right, represents one of the four time points defined in the analysis framework, increasing sequentially. Within each heat map, the damping coefficient increases left to right and the rate of decay decreases top to bottom. The darker the color, the higher the centroid difference. For the 700 Hz case, at t = 10 and 25 ms, centroid differences increase with higher damping and slower decay. At t = 50 and 100 ms, differences continue to rise but focus on damping values between $1/20 < \gamma < 1/70$. Notably, some configurations at t = 50 ms result in a lower spectral centroid than the no-damping case. For the 6400 Hz case, at t = 10 and 25 ms, stronger damping and faster decay lead to lower spectral centroids. This trend becomes nonlinear at t = 50 ms. At t = 100 ms, centroid changes become highly nonlinear. Based on these observations, the 10 ms time point is excluded from the SOM analysis.

3.2 Experiment 2 - Physics-Informed Self-Organizing Maps

Figure 3 shows the results for VD_{freq} = 700 Hz. In the octave below the VD_{freq} (first row top to bottom), at t = 25 ms data is distributed in three different regions following an increase in the damping coefficient. This distribution shows that an increase in both the damping coefficient and, in a lesser degree, the rate of decay lead to a higher centroid difference. At t = 50 ms, centroid values for low damping coefficients ($\Re\{E(s)\} < 0.12$) fall below those of the no-damping case represented by a lighter outer color, with the degree of reduction varying based on the decay rate. Furthermore, the gradual transition between clusters based on damping coefficients becomes

more diffuse, particularly separating data with a fast rate of decay. At t = 100 ms the gradual transition becomes even more fuzzy, still, centroid difference increases with increasing damping coefficient. In all three time points the clustering patterns of the SOM strongly match the centroid difference patterns found in Experiment 1 (see Fig. 2 top row). In the octave around the VD$_{freq}$ (Fig. 3 second row), at t = 25 ms the linear relation between the damping coefficients and the centroid differences remains. Moreover, the regions created by the U-Matrix group data according to their centroid difference values, although this distribution breaks the gradual transition found in the octave below the VD$_{freq}$. Small clusters based on damping coefficient are visible, but not clearly formed. At t = 50 ms, the overall data distribution aligns with the corresponding centroid differences heat map (see Fig. 2 center map). The U-Matrix groups data according to similar centroid difference values, clearly separating the two data samples with the highest difference. At t = 100 ms no pattern is found. In the octave above VD$_{freq}$, the previously observed clustering pattern related to the damping coefficient does not emerge at any of the three time points. However, small regions associated with centroid difference values are formed by the U-Matrix, particularly at t = 50 ms, where areas corresponding to low centroid differences (top left) and high centroid differences (top right) become noticeable. No distinct pattern is observed at t = 100 ms.

For the VD$_{freq}$ = 6400 Hz results are shown in Figure 4. At t = 25 ms, a gradual transition from low to high damping coefficients is displayed by the clustering pattern across all frequency ranges, which matches the trends found in Experiment 1 (see Fig. 2 bottom row). However, the octave above the damped frequency displays a clustering pattern that spans across both principal components of the SOM extensively, while the clustering from the octave below focuses only on one part of the map (bottom right), suggesting that its variance is mostly explained by only one of the principal components. Concerning the octave around the damped frequency, although it also coincides with the heat map, the SOM allocates some data points outside the overall pattern (see Fig. 4, second row, first column, top right), resulting in a decrease in how accurately the SOM matches the heat map. At t = 50 ms the octave below shows a general cluster distribution that matches the changes in centroid seen on the heat maps, while the octaves around and above cluster data mostly based on the damping coefficients with no pattern regarding the centroid, although the intra-cluster distance increases with lower rate of decay. This fuzzy clustering is also observed at t = 100 ms in the octave below the damped frequency.

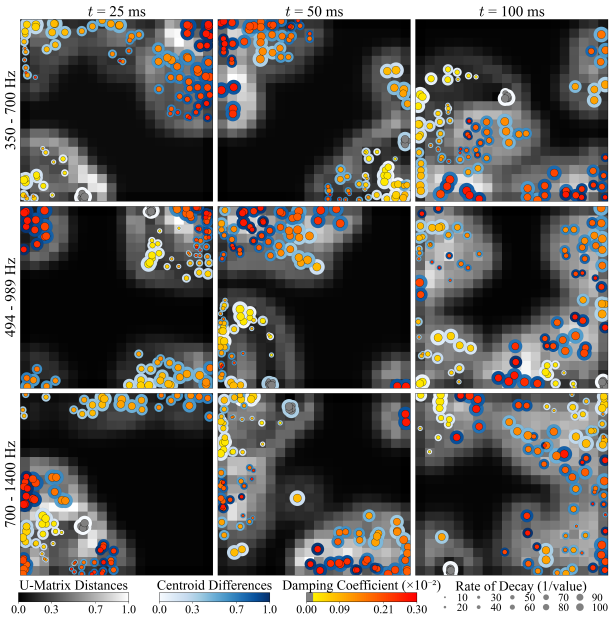

Figure 3: Physics-Informed SOM for VD$_{freq}$ = 700 Hz. Each row corresponds to a frequency range—one octave below (top), around (middle), and above (bottom) VD$_{freq}$—and each column to a time point (t = 25, 50, 100 ms). The U-Matrix displays local dissimilarities between neurons (lighter = more dissimilar). Outer color indicates spectral centroid difference (darker = higher difference), using the same color scale as in Fig. 2. Inner color shows the damping coefficient $\Re\{E(s)\}$ (redder = higher; gray = no damping). Point size reflects decay rate γ (larger = slower decay). In the octave below, a clear relationship emerges between damping coefficient, decay rate, and centroid difference—most evident at t = 25 and 50 ms—mirroring the patterns in Fig. 2. At t = 100 ms, patterns become more diffuse but the trend persists. In the octave around, data is grouped according to centroid differences, especially at t = 50 ms, though clustering is less consistent than in the lower octave. At t = 100 ms, no clear pattern emerges. In the octave above, no clustering by damping coefficient is observed, though at t = 50 ms, regions of low and high centroid difference are weakly distinguished.

4. DISCUSSION

Results suggest that how VD influences sound perception largely depends on the proximity of the viscoelastically damped frequency to the fundamental frequency. This proximity has consequences in the frequency domain that translate to the time domain and ultimately to the perception of the sound. In the frequency domain, when the damped frequency is close to the fundamental——as in the 700 Hz case—the influenced frequency region includes

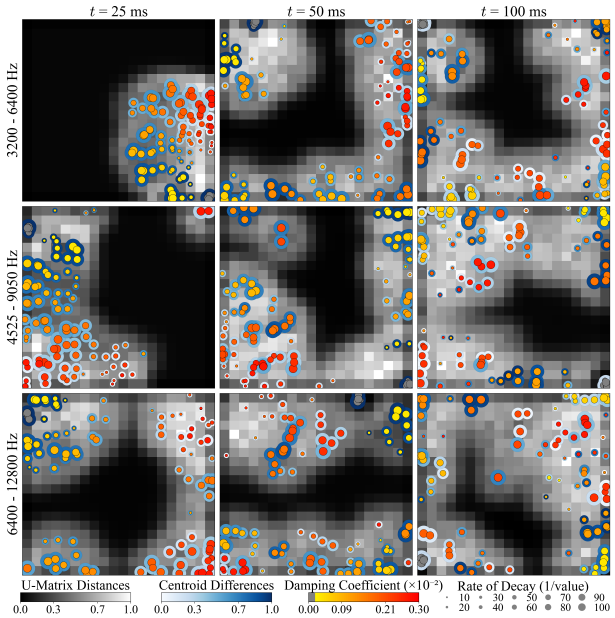

Figure 4: Physics-Informed SOM for VD$_{freq}$ = 6400 Hz. Visualization parameters (color and size coding) are consistent with those used in Fig. 3 for comparability. At t = 25 ms, clustering reflects a gradual increase in damping coefficient across all frequency ranges, aligning with centroid difference heat maps (Fig. 2). The lower octave shows compact clustering driven by the second principal component, while the upper octave spans both components. In the middle octave, some outliers reduce alignment with the heat map. At t = 50 ms, clustering in the lower octave matches trends observed in centroid differences, whereas middle and upper octaves group mainly by damping coefficient, with fuzzier patterns and greater intra-cluster distance for lower decay rates. At t = 100 ms, only the lower octave shows weak clustering; patterns in the higher ranges become increasingly ambiguous.

eigenmodes close to the fundamental frequency. Now, since lower eigenmodes carry more energy than higher ones, the memory effect stores and injects more energy in this frequency region than in a higher one. However, this is not a linear process due to the way the damping coefficient, which acts as both energy supplier and damper, and the rate of decay, which administrates the speed with which the stored energy is inserted back into the system, work together, specially when both have a middle to high value: the higher the damping coefficient, the more energy is available, but also the stronger this new injected energy is damped, on the other hand, if the stored energy decays slowly during the integration time of the memory effect, energy decays nonlinearly in the long run. According to the analysis framework, how long this decay lasts decides wether its the timbre, the pitch or the harmonicity/roughness of the sound what is influenced by the VD. In the 700 Hz case, results show that the spectral dissimilarities caused by VD may persist for 100 ms or more, affecting both the perception of pitch and the sensation of harmonicity. This phenomenon is observed in musical instruments such as the pat wain, where VD enhances pitch perception by influencing the lower modes [2]. Conversely, when the damped frequency is farther from the fundamental, as in the 6400 Hz case, the effect remains perceivable until approximately 50 ms, as shown by the clustering patterns found until this time point, sufficient to influence the timbre but unlikely to impact pitch perception or harmonicity.

Results also suggest that the size of the frequency region influenced by VD decreases over time, gradually shifting towards the region below the damped frequency. Although this size is still frequency dependent because of the different energy levels present in different parts of the spectrum as discussed above, this hypothesis is based on the absence of overall clustering patterns found in higher frequency ranges at longer time points as well as on the continuous decrease in spectral centroid found in the centroid analysis of 6400 Hz case. With regard to the clustering patterns, the clustering of data based on the damping coefficient aligns with the fact that, despite the nonlinear behavior, the damping coefficient is the driving parameter of VD [9].

In relation to the method, the proposed features (centroid differences and spectral flux per Mel band) offer a flexible tool for transient analysis in percussion instrumens. Together, they provide a framework for examining the impact of VD on perceived sound characteristics using psychoacoustically relevant metrics. Specifically, decibels measure the loudness of dissimilarities, determining whether they should be perceptible; quarter-tone Mel bands capture frequency changes that remain perceptible depending on the frequency range; and the spectral centroid serves as a well-established psychoacoustic metric for comparison. Furthermore, focusing on time intervals that are relevant to both the perception of musical instrument sounds and the physical evolution of VD provides insight into the research questions posed in the introduction—namely, how VD influences the perception of sounds produced by musical membranes, how the frequency spectrum evolves over time, and the psychoacoustic implications of the observed patterns. Additionally, each preprocessing step contributes to reduce the dimensionality of the feature vector based on psychoacoustics characteristics of the data, yielding clear results while preserving essential information.

5. CONCLUSSION

A method for analyzing the influence of viscoelastic damping on the perceived sound of musical membranes has been presented. This approach is grounded in the physical characteristics of viscoelastic damping and as well as in temporal cues relevant in the perception of musical sounds. The influence of viscoelastic damping was found to depend largely on the location along the frequency spectrum where damping occurs, specifically in relation to the distance from the fundamental frequency. A decrease in the size of the frequency region affected by viscoelastic damping was also found, with the region gradually shifting towards frequencies below the initially damped area over time. Further studies are needed to investigate additional parts of the spectrum beyond those addressed in the present work, as well as to examine scenarios involving simultaneous damping across multiple frequency regions. Also, future work should incorporate alternative time–frequency representations with higher frequency resolution—such as wavelet transforms—allowing for a more detailed analysis of both the extent and development of the affected regions. Finally, the results demonstrate that physics-informed self-organizing maps offer a powerful tool for analyzing viscoelastic damping given the complexity and high dimensionality of its parameter space.

ABSTRACT

Deep Audio Processing (DAP) introduces a novel approach to personalized audio optimization, bridging established techniques such as time stretching, remixing, and audio channel separation with a groundbreaking dual-mode application for offline and real-time scenarios. While traditional audio processing methods excel in specific domains, their adaptation to dynamic real-time environments or offline pre-processing with synchronization constraints has been limited. DAP addresses this gap by integrating adaptive latency management and user-specific audio adjustments to deliver an enhanced listening experience tailored to diverse hearing capabilities and preferences. Key innovations in DAP include latency reduction techniques leveraging silent or non-speech segments and extended temporal flexibility for optimizing speech rates, singer-to-instrument ratios, and dynamic loudness ranges. Additionally, machine learning–driven auditory scene classification dynamically adjusts acoustic weights and parameters, optimizing intelligibility and comfort. This unified framework supports applications ranging from live-streaming accessibility enhancements to personalized audio delivery in cinema, teleconferencing, and music playback.

Keywords: *deep audio processing, source separation, time scale modification, real-time processing, accessibility*

1. INTRODUCTION

Audio experiences are central to communication, entertainment, and education. Yet common consumer systems lack flexible, adaptive approaches to personalize audio for listeners with diverse hearing capabilities-particularly those requiring specialized real-time adjustments. Traditional settings such as "Movie Mode" or "Rock Mode" provide fixed equalization filters without dynamically adapting to listener needs or acoustic conditions.

Recent progress in deep learning has enhanced the ability to analyze and manipulate complex audio signals, particularly through advanced source separation [1,2] and non-uniform time scale modification [3]. However, fully deploying these technologies in everyday consumer applications remains challenging, as two main issues persist:

1. **User-specific personalization:** Beyond simple equalization, listeners may require adjustments of signal-to-noise ratio (SNR) and speech tempo that reflect their hearing needs or preferences.
2. **Synchronization constraints:** Maintaining accurate sync across events is essential in real-time or time-sensitive contexts (e.g., live streams or cinematic audio). Excessive time-stretching can introduce objectionable delays and user disapproval.

Deep Audio Processing (DAP) addresses these limitations by integrating classical audio methods (channel separation, time stretching, remixing) with modern machine learning algorithms for source separation and content recognition. A central contribution is DAP's non-uniform time scale modification (NU-TSM) procedure, which balances

the user's desired speech rate with the need to remain within allowable latency limits. The main contributions of this paper are:

1. **Personalized Deep Audio Processing System:** We propose an assistive architecture that seamlessly unifies audio source separation, content classification, and user-driven mixing/time-stretch control.
2. **Time-Scale Modification Under Latency Constraints:** We formulate a synchronization problem that constrains how speech segments can be stretched without violating lip-sync or real-time requirements.
3. **Speech Rate Preference Experiment:** We present an empirical user study measuring preferred speech rates in noisy backgrounds for listeners with varying degrees of hearing loss, informing the default target speech rates presets for our DAP system.

2. METHODS

2.1 System Architecture

Figure 1 provides a high-level depiction of the DAP system. The system operates in two layers:

- **Processing Pane (Upper):** Source separation, mixing, and time-scaling.
- **Analysis & Control Pane (Lower):** Content classification, user preference retrieval, and adaptive logic for mixing and stretching.

The input is an original audio signal plus user-specific settings (e.g., target SNR and preferred speech rate). The output is a newly reconstructed signal, where speech intelligibility or vocals are enhanced according to personalized criteria.

Next, we briefly describe the basic building blocks of the DAP system.

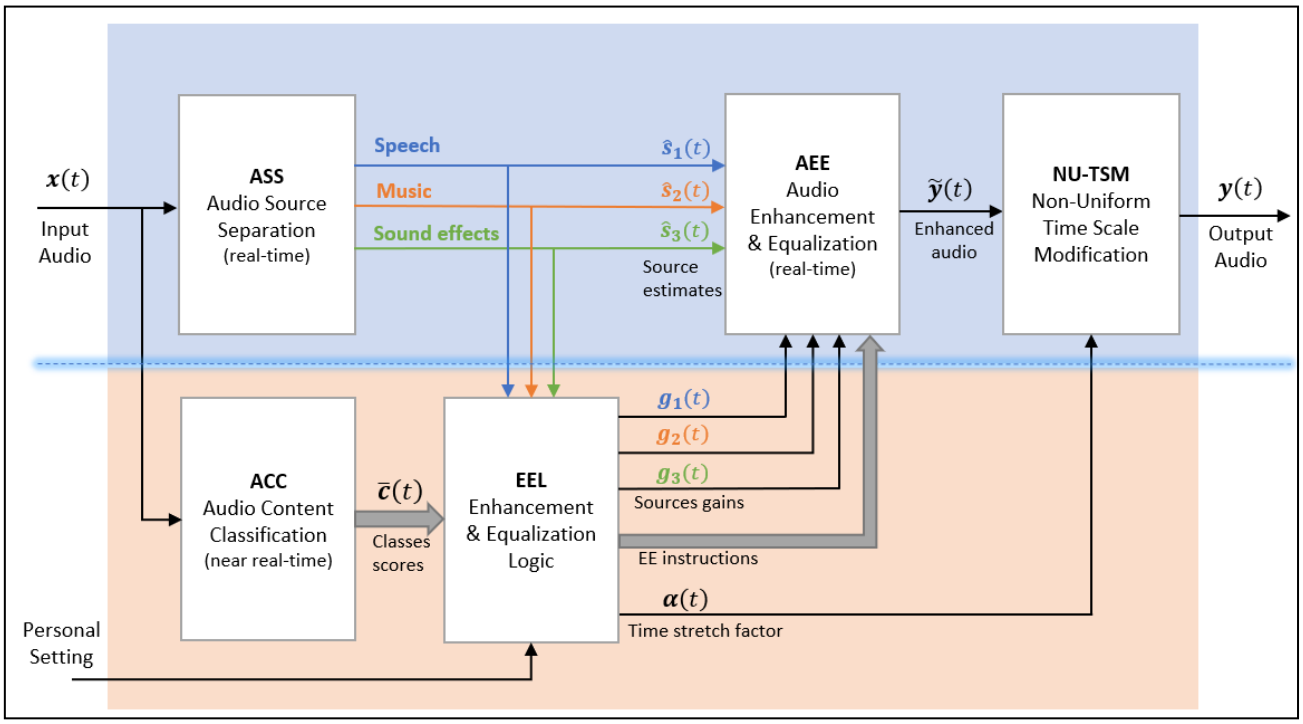

Figure 1. High level architecture of the Deep Audio Processing (DAP) system for assistive audio applications, illustrating the integration of audio capturing, source separation, content classification, enhancement logic, and audio enhancement modules. The upper pane is the "processing pane" and the lower is the "analysis & control pane".

2.1.1 Audio Source Separation (ASS)

The ASS module splits incoming audio into constituent sources such as speech/vocals, music, and sound effects. It uses a deep neural network architecture inspired by the MRX model [1]. Separated sources are crucial for fine-grained manipulation - particularly for adjusting gain or stretching specific elements (e.g., speech) without affecting background signals. Given an input signal $\boldsymbol{x}(t)$, the goal is to decompose it into constituent sources. This step is critical for enabling individualized control over each source's gain and temporal characteristics. Our current implementation follows the "cocktail-fork" concept [1], that separates the audio into three sources, speech, music, and sound effects (sfx). In the more general case, the output of the ASS module is a set of N source estimates,

$$\{\hat{\boldsymbol{s}}_1(t), \hat{\boldsymbol{s}}_2(t), \dots, \hat{\boldsymbol{s}}_N(t)\} \tag{1}$$

fed into subsequent processing blocks for enhancement and personalization.

2.1.2 Audio Content Classification (ACC)

In parallel, a convolutional neural network (CNN) classifies audio content into categories (inspired by [4]) (e.g., conversation, music, ambient noise). This "pseudo" real-time classification produces a time-varying score vector indicating the probability of each category.

$$\bar{\boldsymbol{c}}(t) = [\, c_1(t), \dots, c_K(t) \,]^T \tag{2}$$

where each component $c_k(t)$ reflects the likelihood of a specific content category k, and K is the total number of contents categories. These scores guide the system's adaptive mixing and time-scaling decisions. The index t refers to the corresponding audio frame starting time[1].

2.1.3 Personalized Targets

User preferences for (i) speech/vocal SNR relative to accompaniment and (ii) speech rate in various noise conditions is stored in an external module. These preferences can be specified manually (e.g., through an interface) or derived from user data. The system references these targets to dynamically apply mixing gains and stretching factors. These targets guide the subsequent processing steps within the EEL module.

[1] For simplicity we use the same notation for time indexing, while in all analysis modules and in most processing modules it applies to the index of the audio frame

2.1.4 Enhancement & Equalization Logic (EEL)

The EEL module interprets classification scores and user targets to generate control logic signals to subsequent processing blocks. It carries out:

2.1.4.1 Mixing Logic for SNR Target

In this module gains are computed for each source to match the desired speech-over-background ratio. The time-varying gain parameters are denoted as

$$\{\boldsymbol{g}_1(t), \boldsymbol{g}_2(t), \dots, \boldsymbol{g}_N(t)\}\,. \tag{3}$$

Practically, the SNR calculation is performed frame-by-frame. The calculated gain parameters are then passed to the mixer, which applies the adjustments to ensure that the desired SNR is maintained throughout the audio signal.

2.1.4.2 Speech Rate Estimation and Time Scale Logic

The time scale logic module focuses on the dynamic aspects of speech. It first estimates the local speech rate from the separated speech signal $\hat{\boldsymbol{s}}_1(t)$, to quantify the speech tempo in terms of phonemes-per-second (PPS). There are various approaches for approximating the PPS. The simple ones may consider spectral transition differences between time frames, while the more complicated may use a phonetic recognizer or speech recognition (more applicable to offline mode). This measurement is critical for determining how to adjust the audio timescale. Based on this estimation and the user's preferred speech rate, the module computes an adaptive time-scale factor $\boldsymbol{\alpha}(t)$ to achieve the desired speech rate,

$$\boldsymbol{\alpha}(t) = \boldsymbol{\alpha}\big(\bar{\boldsymbol{c}}(t), \mathrm{PPS}(t)\big)\,, \tag{4}$$

where $\bar{\boldsymbol{c}}(t)$ represents the classification scores from the ACC block, and $\mathrm{PPS}(t)$ represent the estimated momentary speech rate at time t. Eqn. 4, emphasizes that the scale factor is not only adjusted according to the momentary PPS, but is also oriented to the auditory scene, whether it contains merely speech (and may need to be stretched) or if it contains a sound effect (for instance the sound of a gunshot) that needs to maintain the same ratio (factor of 1 indicating no need for stretching), or whether it is a non-speech or a pause section that may be shortened.

The $\boldsymbol{\alpha}(t)$ factor guides the NU-TSM process, allowing for localized adjustments that slow down or speed up audio

segments while preserving the natural timing of non-speech elements.
Together, these two components enable the EEL module to output two sets of control signals: the gain parameters for achieving the desired SNR and the adaptive time-scale factor for targeted speech rate modification. This logic-based stage lays the groundwork for the subsequent re-mixing and time-stretching that occur in the Audio Enhancement & Equalization and NU-TSM modules respectively, ensuring that personalized audio processing meets user preferences.

2.1.5 Audio Enhancement & Equalization (AEE)

The AEE module rebuilds the final audio from the separated sources using the gains calculated by the EEL. Additional filters or effects may also be applied to each separated source as desired. The remixing is performed by:

$$\tilde{\boldsymbol{y}}(t) = \sum_{i=1}^{N} \boldsymbol{g}_i(t)\hat{\boldsymbol{s}}_i(t). \quad (5)$$

2.1.6 Non-Uniform Time Scale Modification (NU-TSM)

The final component, NU-TSM, applies the adaptive stretch factor to slow down high-rate speech segments and optionally compress silence or non-speech segments. A key challenge here is ensuring overall synchronization. Excessive stretching can cause noticeable latency or lip-sync mismatches, so the NU-TSM module operates within strict deviation bounds.

2.1.6.1 NU-TSM in Sync – Problem Derivation

Time scale modification in sync poses additional limitations on latency or on "run ahead" in offline scenarios. Typically, TSM algorithms relate to two parameters – the analysis frame step (which is a constant) and the synthesis frame step which is set according to the required stretch factor $\boldsymbol{\alpha}(t)$. when adding sync constraints, we wish to force the synthesis frames to be located inside a certain shift from the original location of the corresponding analysis frame, and this poses a new optimization problem, which is derived next. In the following derivation we use a discrete notation for the stretch factor $\alpha_t \equiv \boldsymbol{\alpha}(t)$, suggesting that t is a running frame index.

Problem derivation:
- Assume a given audio signal has T analysis steps, and a series of stretch factors (per frame) is given by $\{\alpha_0, \alpha_1, \dots, \alpha_t, \dots, \alpha_T\}$ where $\alpha_0 = 0$.
- Let $\boldsymbol{a}$ be the constant analysis step (samples or time units).
- Hence, a requested synthesis step at time t would be $\boldsymbol{a}\alpha_t$.
- The analysis frame position at time t is defined by:

$$x_t = x_0 + \boldsymbol{a}t \quad (6)$$

where x_0 is the initial position of the analysis.
- The "requested" synthesis position at time t follows the recursion

$$z_{t+1} = z_t + \boldsymbol{a}\,\alpha_{t+1} \quad , \quad (7)$$

where z_0 is the initial position of the synthesis (typically $x_0 = z_0$), and the momentary stretch time between two consecutive frames is defined by

$$z_{t+1} - z_t = \boldsymbol{a}\,\alpha_{t+1} \quad . \quad (8)$$

- The terms z_t are the requested synthesis positions without sync limitations. We seek a new set of synthesis positions, $\{y_0, \dots, y_t, \dots, y_T\}$ that aim to maintain the momentary stretch time of all steps, $z_{t+1} - z_t$, while satisfying strict sync conditions to the original analysis positions, defining L to be the allowed time deviation from the original position, the optimization problem is formulated as follows:

$$\begin{cases} \text{minimize} & \sum_{t=0}^{T-1} |(y_{t+1} - y_t) - (z_{t+1} - z_t)| \\ s.t. & |y_t - x_t| \le L \quad \forall \quad t \in \{0, \dots, T\} \\ & y_{t+1} - y_t \ge 0 \quad \forall \quad t \in \{0, \dots, T\} \end{cases} \quad (9)$$

Simplifying by replacing variables produces the following optimization problem,

$$\begin{cases} \text{minimize} & \sum_{t=0}^{T-1} |y_{t+1} - y_t - \boldsymbol{a}\alpha_{t+1}| \\ s.t. & |y_t - x_0 - \boldsymbol{a}t| \le L \quad \forall\ t \in \{0, \dots, T\} \\ & y_{t+1} - y_t \ge 0 \quad \forall\ t \in \{0, \dots, T\} \end{cases} \quad (10)$$

This formulation guarantees that the solution's time sync will not deviate from the preset boundaries however, the requested target scale is not guaranteed, it only tries to optimize it to the best effort.
Various real-time or offline approximation methods can solve this optimization efficiently. One approximation uses a greedy regressive procedure that may fit real-time scenarios due to its simplicity. In some conditions, the solution may be further simplified. For example, when assuming $\alpha_t \ge 1$ for all $t = 1, \dots, T$; the problem reduces to a convex problem with an analytical solution. In an offline scenario over an audio part of original length T_s where the requested total length is calculated by $z_T = \boldsymbol{a}\sum_{n=1}^{T} \alpha_n$ (following Eqn. (7)),

and the total margin is L before and after the speech part; setting $z_0 = x_0$, leads to a simple solution,

$$y_t = \begin{cases} z_t & \text{, if } z_T \le T_s + L \\ -L + z_t\left(\frac{T_s+2L}{z_T}\right) & \text{, if } z_T \ge T_s + 2L \\ -\left(\frac{z_T}{T_s} - 1\right) + z_t\left(\frac{T_s+L}{z_T}\right) & \text{else} \end{cases} \quad (11)$$

This offline solution obtains a "run ahead" time on y_0 (having a non-speech margin before the referenced part), allowing to compensate for the latency accumulated in the stretched part. This simplified result (Eqn. (11)) provides satisfactory outcomes in many situations.

2.2 User Experiment: Speech Rate Preferences Noise

2.2.1 Participants

A total of 44 participants with bilateral hearing impairment took part in the study. Participants were categorized by the severity of their hearing loss (HL) [5]; mild HL (n = 23), moderate HL (n = 8), severe HL (n = 6), and profound HL (n = 7). All provided informed consent and completed an online auditory profile questionnaire prior to testing, including hearing loss characteristics, onset, stability, and type of hearing impairment. The experiments were conducted remotely, with participants using their own listening devices in a quiet home environment. Stimuli and Equipment

2.2.2 Stimuli and Equipment

Speech stimuli consisted of recordings of a professional female narrator in a studio environment. The narrator read aloud multiple pages from a novel, ensuring natural prosody and articulation. The speech stimuli were presented simultaneously with a separately recorded police siren. The speech and siren were mixed to create a controlled background noise condition, ensuring consistency across all participants. All audio files were presented in MP3 format (44,100 Hz, 32-bit sampling rate). Participants were instructed to use headphones or their regular hearing aids/cochlear implants (if applicable) and to avoid adjusting device settings during the experiment. For further information, see [5].

2.2.3 Procedure

The experiment consisted of two phases. In the preliminary task, each participant determined their most comfortable level (MCL) for listening to speech in the presence of background noise. This was done using two pre-prepared audio files: one containing the narrated recordings and the other containing a constant-level police siren noise. The noise was played at a fixed intensity, while participants used a slider to adjust the intensity of the narrator's voice until they reached the minimal SNR that allowed for comfortable speech understanding.
Once the participant's individual SNR was determined, they proceeded to the main task, where they adjusted the speech rate of the narrator while listening under the same background noise conditions and using the SNR established in the preliminary phase. Participants used a sliding control to modify the recorded speech rate to the maximum speed at which they could still comprehend the story content.

2.2.4 Data Collection and Analysis

Data collection was conducted remotely via an online interface as described in [5]. Only participants who fully completed the experimental tasks were included in the analysis. An SPSS software was used for statistical analysis. Preferred speech rates (mean ± standard deviation) were calculated for each participant and group. A one-way analysis of variance (ANOVA) was conducted to assess whether speech rate preferences differed significantly between groups. Post hoc tests (Tukey's HSD) were performed to evaluate pairwise differences. Effect sizes (η^2) were calculated to quantify the magnitude of observed differences.

3. RESULTS

3.1 DAP System Outcomes

Figures 2 and 3 illustrate qualitative examples of how DAP adjusts SNR and speech tempo over time. Figure 2 presents a snapshot of the DAP system in the time domain, over a short audio example. It shows the speech SNR adjustment obtained through the mixing gains, the speech rate measurement and the time-scale modification in term of accumulated latency. It is observed that the NU-TSM algorithm stretches the speech section (during the first second of the audio), followed by shortening the non-speech segment of the audio.
Figure 3 presents an example of an audio recording containing a heated debate between two people. One can observe the time-scaling applied non-uniformly, where the pre-treated higher speech rates receive a larger stretch factor, while the pauses in the speech sections are shortened to compensate for the latency caused by the stretching process.

Thus, the maximum latency does not exceed a predefined limit of $L = 240$ msec. This parameter can be adjusted according to user needs or even according to the audio content classification.

Clearly, the effectiveness of NU-TSM is highly influenced by the allowable sync deviation and the structure of the speech segments. When a conversation or cinematic audio track includes sufficient pauses, users can experience improved intelligibility without perceiving noticeable synchronization issues.

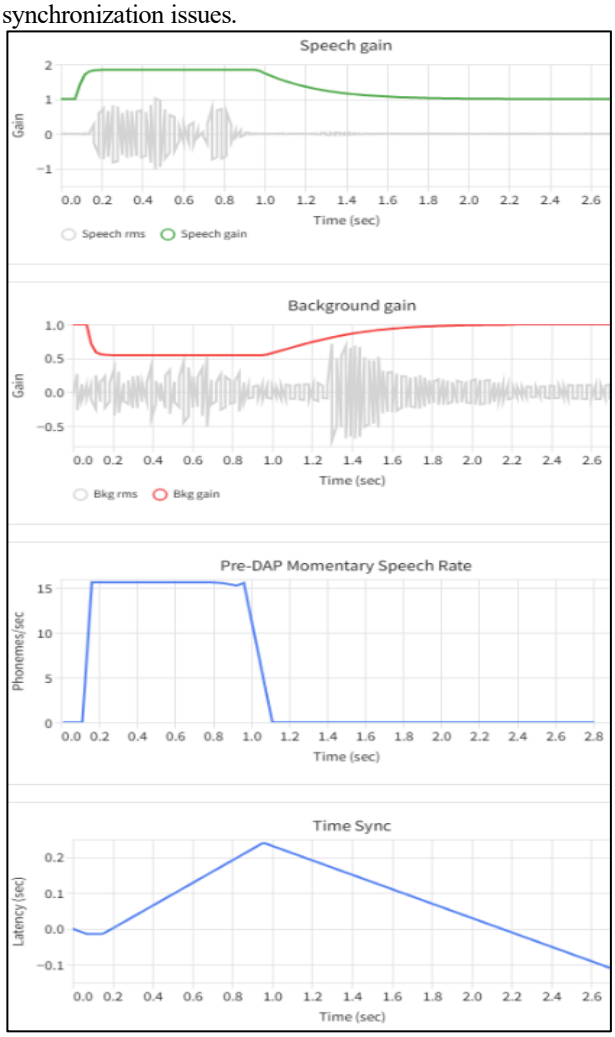

Figure 2. A snapshot of a processed audio example from the DAP system. The two upper plots describe the separated sources of 'speech' and 'background' (music and sound effects combined) with the gain factor (green and red gain curves) applied to emphasize speech. The third plot describes the approximated original speech rate, which is over 15 PPS, and the bottom plot describes the time scale modification in terms of latency. The speech part is stretched by almost 20%, allowing a latency of 240 msec, while the non-speech part is shortened to reduce the time latency. Notice that the line slope presents an effective scale factor.

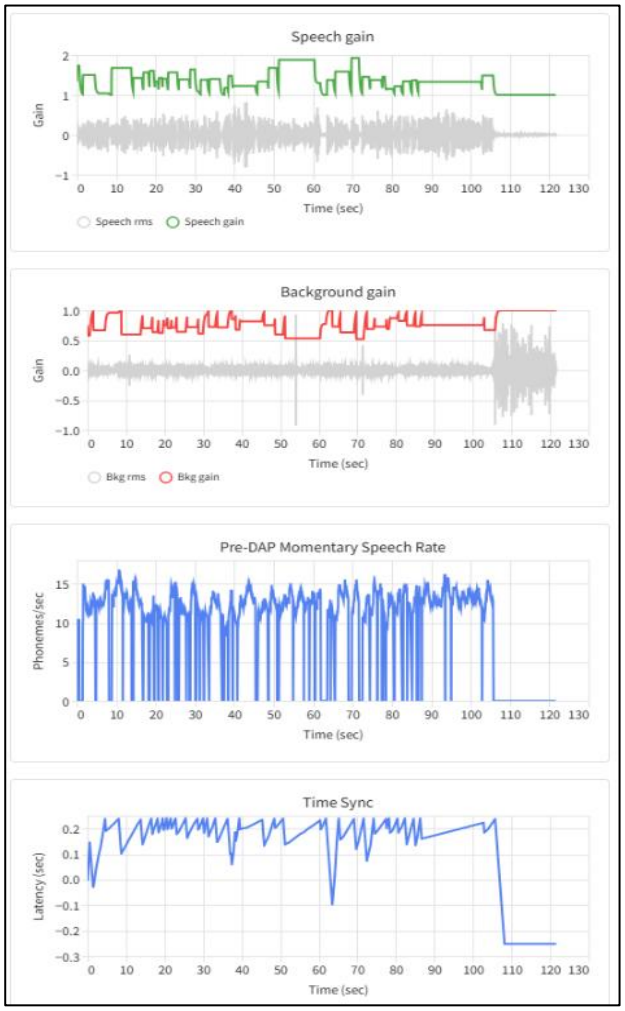

Figure 3. A snapshot of an audio recording of a heated debate. The target SNR is applied to most of the frames. Bursts of high speech rates exceed 15 PPS, and the time-scaling is applied non-uniformly. The maximum time deviation is 240 msec - as predefined in the system setting.

3.2 User Experiment Speech Rate Preference in Background Noise

Descriptive statistics for speech rate preferences in the presence of a background police siren are provided in Figure 4. Results show a general trend of decreasing preferred PPS with increasing hearing loss severity. Participants with mild HL preferred a mean PPS of 10.94, moderate HL preferred 10.42, severe HL preferred 9.30, whereas those with profound HL preferred a significantly slower rate of 8.51. On average, the preferred speech rate in background noise was 10.24 PPS.

A one-way ANOVA revealed a statistically significant effect of hearing loss severity on preferred PPS [$F(3,40) = 3.084$, $p = .038$, η^2=0.188]. Post hoc tests showed that the maximal preferred PPS for the perception of a female narrator speaking in background noise decreased significantly from mild to profound HL (-2.43 PPS, $p = 0.039$). No other significant group differences were observed.

These results suggest that individuals with greater hearing impairment prefer slower speech rates when background noise is present. Future studies should explore additional auditory factors influencing speech rate preference, such as spectral balance and dynamic range compression.

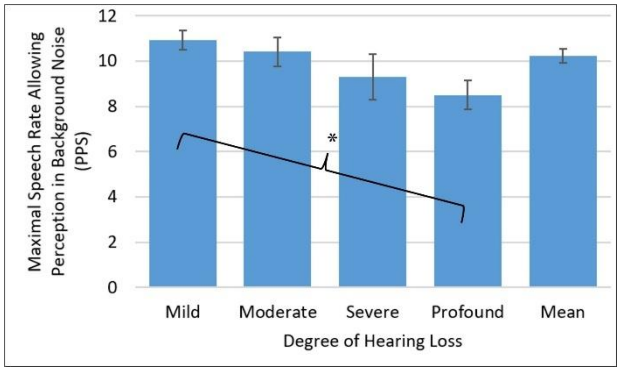

Figure 4. Maximal Speech Rate Allowing Perception (in PPS) of a female narrator in background noise across different hearing loss groups (Mild, Moderate, Severe, Profound and Mean). Error bars represent the standard error of the mean. ⋆ Indicates a statistically significant difference between the marked groups ($p < 0.05$).

4. DISCUSSION

This paper suggests a basic and general description for an assistive audio processing system. The practical system is more complicated and is not detailed here. Since the final output of the system depends on a series of different modules, source separator, content classification, auditory-scene oriented logic of time-scale modification, and time-constrained stretching algorithm, many independent variables may affect it. Because of this complexity, it is difficult to quantitatively validate the most influencing factors as they are entangled together. Future user experiments should address this issue. It also seems that to examine the quality of different algorithms, further comparative experiments should be conducted to provide empirical quantitative analysis.

While our study provides valuable primary insights about speech rate preferences in the presence of background noise, some limitations should be noted. First, hearing loss severity was self-reported rather than audiometrically verified, which may introduce variability in group classification. Future studies should incorporate objective hearing assessments to strengthen classification accuracy. Second, the experiment was limited to a single type of noise which in future experiments would be expanded to variable types of noise. The present study primarily examined speech intelligibility improvements. Additional research is needed to assess how DAP's strategies affect non-speech content such as music or sound effects, especially in scenarios where the artistic intent or emotional impact of the audio track must be preserved.

5. CONCLUSION

This paper has introduced a personalized DAP framework that combines advanced source separation, content-aware mixing, and NU-TSM to enhance audio in both offline and real-time contexts. By leveraging machine learning for audio content classification, DAP enables targeted improvements in speech intelligibility, adaptable speech-rate manipulation, and precise synchronization with visual media or other concurrent events. While the primary focus is on speech intelligibility, the underlying system can be adapted to enrich various user experiences - for example, by emphasizing a specific instrument or sound source.

Crucially, our NU-TSM approach shows how intelligibility can be improved without exceeding predefined latency constraints. We also introduced a user study on speech-rate preferences in noisy environments, establishing baseline presets that reflect listeners' auditory needs across different degrees of hearing loss. Although our findings suggest that DAP meets many user preferences, practical challenges persist - especially

regarding real-time processing demands and stringent latency requirements.
Moreover, fully understanding users' preferences and requirements necessitates subjective hearing experiments, due to the wide range of factors that shape listening experiences - hearing profiles, attention deficits, age, and content variability (e.g., music genres, cinematic audio, special effects). These complexities underscore the individualized nature of audio preferences and highlight the importance of extensive user-centric testing to capture diverse needs accurately.
Future research will address these constraints and further refine personalized audio processing by exploring more robust adaptation strategies, investigating broader content types, and incorporating formal audiometric evaluations. Ultimately, this work lays the groundwork for a versatile DAP system capable of serving a wide audience with varied listening preferences and challenges.

6. ACKNOWLEDGMENTS

The authors would like to express their gratitude to the participants who took part in this study and provided valuable insights and to Shaked Bigi for her assistance. This research was supported by a grant from The Israel Innovation Authority (Grant #83364) as part of the research and development project titled: "Development of Technology for the Accessibility of Auditory Content for Populations with Hearing Difficulties or Attention Deficit Disorders."

INDIVIDUAL VIOLIN SOUND IDENTIFICATION USING AUDIO FEATURES AND MACHINE LEARNING

Hugo Pauget Ballesteros[1*] **Philippe Lalitte**[2] **Claudia Fritz**[1]

[1] Institut d'Alembert, Sorbonne Université, France
[2] IReMus, Sorbonne Université, France

ABSTRACT

Identifying individual instruments of the same type from their recordings is a rarely addressed challenge. This paper explores violin sound identification using two datasets of recordings, featuring multiple violinists playing multiple violins. Several long-term audio features were compared, and their performance in violin classification was evaluated using classical machine learning algorithms. Among these features, long-term MFCCs demonstrated the ability to distinguish individual violins while taking into account player-induced variability, enabling reliable violin recognition. Additionally, the influence of key parameters – such as the number of violinists and choice of musical excerpts – on classification performance was analyzed. These findings offer guidelines for optimizing future data collection aimed at capturing a violin's unique sound signature.

Keywords: *violin identification, classification, features*

1. INTRODUCTION

Musical instrument classification is a key task in Musical Information Retrieval (MIR), aiming to identify the instruments present in a recording. This topic has been extensively studied in the literature, and for monophonic recordings (containing only one instrument), state-of-the-art models commonly reach accuracies of almost 100%. However, few articles have addressed the issue of identifying individual instruments of the same type, and even less so when focusing specifically on instruments from the violin family. Only a handful of studies ([1–3]) have tackled this challenge. These studies suggest that cepstral coefficients offer enough discriminative information about individual violin timbre for effective classification. Nevertheless, these studies relied on limited datasets, where not all violins were played by multiple violinists. This raises an important question: do these algorithms recognize the instruments themselves, or simply the unique playing styles of the performers?

This paper aims to address this challenge by reviewing and comparing various approaches to identify individual violins, from data collection to processing. It provides guidelines for recording sessions and introduces a long-term adaptation of MFCCs. The paper is organized as follows: section 2 describes the methodology, including data collection, feature extraction, data exploration, and classification using machine learning. The experimental results are presented and analyzed in section 3. Finally, section 4 provides concluding remarks and outlines potential directions for future work.

2. MATERIALS AND METHODS

2.1 Datasets

Two datasets were collected for this study, each consisting of recordings where a group of violinists played a set of violins. The violins and violinists sets were different in those two experiments. The first dataset includes a larger number of violins and violinists, while the second dataset comprises more recording time.

2.1.1 Bilbao Dataset

During the Bilbao Project, thirteen violins were built to relate their material and geometrical characteristics with their tonal quality [4]. These violins were played in 2019 by twenty-three professional violinists, each of them having recorded a 3-octave G chromatic scale on each violin and a short musical excerpt on a violin of their choice. The resulting dataset comprises 13×23 recordings of scales and 23 recordings of musical excerpts (one excerpt per violinist). The recordings were made under the same conditions in a large rehearsal room at the Bilbao conservatory, keeping a constant distance between the player and the microphone (Zoom H4n Pro) and using a sample rate of 48kHz.

2.1.2 CNSM Dataset

Another dataset was created at the Paris Conservatoire (CNSMDP), involving thirteen violinists and three violins. Participants were given time to familiarize themselves with each instrument before recording a chromatic scale and selected excerpts from the classical violin repertoire. These excerpts were taken from pieces by Bach, Mozart, Tchaikovsky, Sibelius, and Glazunov. The recordings were made under the same conditions in a large recording studio at the CNSM, keeping a constant distance between the player and the microphone (DPA 4006) and using a sample rate of 48kHz.

2.2 Features

2.2.1 Long-Term Average Spectra (LTAS)

The Long-Term Average Spectra (LTAS) of a recording is obtained by dividing the input signal into overlapping segments, then calculating the windowed DFT of each segment and finally averaging the power of those DFTs.
LTAS has been used in [5] to compare the tonal quality of violins. More specifically, the author compared the sound of old Italian violins (Stradivari/Guarneri) and modern violins. He concluded that differences between these two groups could be demonstrated using LTAS

2.2.2 Long-Term Cepstral Coefficients (LTCC)

LTCC were introduced in [1] for individual instrument identification. Their calculation is similar to that of MFCCs (see next section) except that a mel-filterbank is not applied and that the final step is given by an Inverse Discrete Fourier Transform.

2.2.3 Mel-Frequency Cepstral Coefficients (MFCC)

MFCCs are obtained by mapping the frequencies of a spectrum onto a nonlinear mel-scale (a perceptual scale of pitches judged by listeners to be equal in distance from one another), taking the logarithm, and then computing the Discrete Cosine Transform (DCT) of the result. Here, instead of calculating the MFCCs on overlapping segments, we use an LTAS as input spectrum as we want features with a long-term meaning.
MFCCs are a set of features that has been extensively used for Automatic Speaker Recognition and for Instrument Classification (e.g. [6, 7]).

2.3 Classifiers

We compare the results of three popular classification algorithms : K-Nearest Neighbours, Support Vector Machines and MultiLayer Perceptron. These three classifiers use different learning strategies and thus will give different results on our data.

3. RESULTS AND DISCUSSIONS

This section analyses classifier performance for violin identification. First, we provide an overview of the performance achieved by different features and classifiers, followed by the introduction of a fine-tuned baseline model. Subsequently, the influence of key hyperparameters on the performance of this baseline model is systematically examined. The results highlight the impact of dataset subsets and hyperparameter configurations on model effectiveness, offering insights into optimal settings for violin identification tasks.

3.1 Model performance

We first compare the performance of various features and classifiers. For each combination, we systematically tuned hyperparameters to determine optimal configurations. As our datasets are small, we use a repeated random subsampling cross-validation to compute the accuracy of each model. The best performing model is then selected as our baseline. The results of this comparative analysis are summarized in figure 1 for the Bilbao dataset and in figure 2 for the CNSM dataset. Note that the accuracies obtained for the two datatasets can not be compared as the number of violins involved is not the same.
On the CNSM dataset, all combinations of classifiers and features achieve comparable accuracy. In contrast, with the Bilbao dataset, which is both smaller and involves

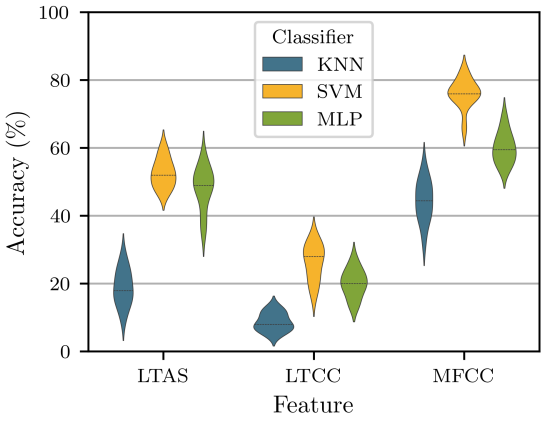

Figure 1. Cross-validation accuracy, Bilbao dataset.

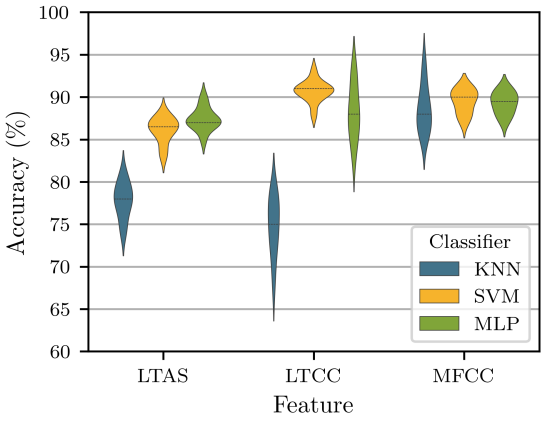

Figure 2. Cross-validation accuracy, CNSM dataset.

a larger number of classes, the selection of appropriate features and classifiers significantly impacts performance. We observe that MFCCs consistently deliver the best results, regardless of the classifier used. This suggests that MFCCs are the most effective features for distinguishing between violins, while taking into account variations in the playing styles of individual violinists. Optimal performance was observed when using MFCCs with an SVM classifier. This model utilized audio recordings downsampled to a 10kHz sampling rate, retained 60 MFCC coefficients, and employed a linear kernel in the SVM algorithm. In the rest of this paper, this model is referred to as "SVM-MFCC".

3.2 Influence of the training data

In this section, we use the fine-tuned SVM-MFCC model to assess the influence of training data on classification results. We focus solely on the CNSM dataset, better suited for this specific investigation due to the longer recording durations and the diversity of musical excerpts.

3.2.1 Influence of the number of players and excerpts per player

To understand the impact of both the number of violinists and the number of excerpts per violinist in the training data, we designed an experiment varying both parameters. First, 20% of the data was held out for testing. Next, for systematically varied numbers of violinists (n) and excerpts per violinist (m), we trained our SVM-MFCC model using randomly selected subsets. The performance of the model was then measured on the fixed test set. The resulting accuracy values, for different (n, m) pairs, are presented as a matrix in Figure 3.

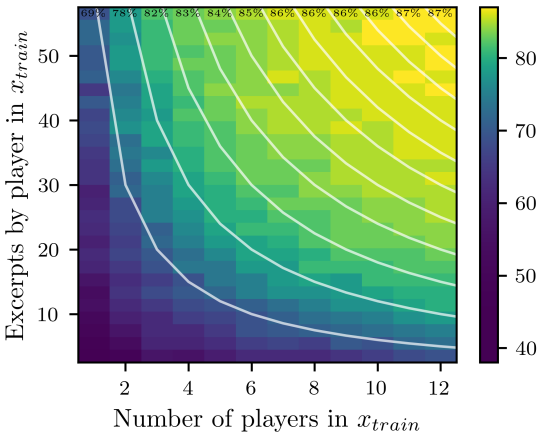

Figure 3. Test accuracy (%) of our baseline model for random training data subsets of n violinists and m excerpts per violinist. The white isolines represent fixed training-set sizes.

We observe that generally, accuracy increases with both the number of players and the number of excerpts per player. While optimal performance (87% accuracy) was achieved when both the number of players and the number of excerpts per player were high (more than 10 players, 50 excerpts per player), moderate performance (70% accuracy) could be reached with different trade-offs, such

as using data from many players with fewer excerpts each, or fewer players with many excerpts each (as shown by the accuracy along the white lines). If achieving moderate performance is sufficient, the specific balance between the number of players and excerpts per player can be chosen based on practical constraints.

3.2.2 Influence of the musical excerpt type

To assess the impact of different excerpts on the accuracy, we trained our SVM-MFCC model using only recordings of the same type for training, while keeping 20% of the data for testing. Figure 4 compares accuracy in two scenarios: (1) "same as training", where the model was tested only on data from the training set that corresponded to the same excerpt on which our model was trained, and (2) "different", where it was tested on all other excerpts.

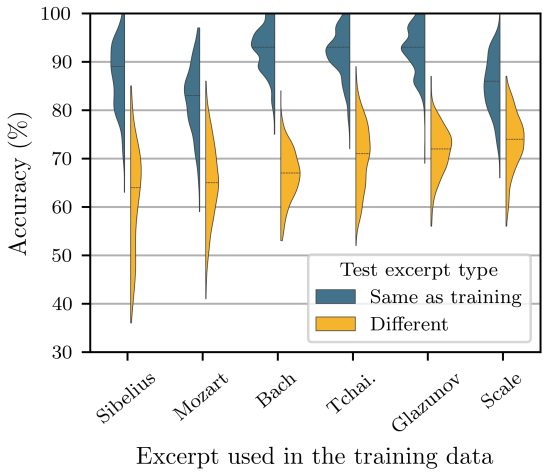

Figure 4. Violin plots of the test accuracy obtained with a SVM-MFCC model using different excerpts as training data. CNSM dataset.

Figure 4 shows that, unsurprisingly, the case "same" leads to better accuracy than the case "different". Moreover, while the accuracy is little influenced by the type of excerpt in average in both cases, the standard deviation is larger for Sibelius and Mozart, in particular for "different". This can be explained by the fact that these excerpts cover – mostly for Mozart and entirely for Sibelius – the upper-end of the register. It thus appears that using Scales, Glazunov, and Tchaikovsky recordings are better candidates for such classification task.

4. CONCLUSIONS

Few studies have addressed the problem of identifying individual violins based on their sound. Furthermore, the limited existing research often relies on datasets where not all violins are played by all musicians involved in the study. Utilizing two purpose-built datasets to address this limitation, and through comparison of various features and machine learning algorithms, this study confirms the feasibility of individual violin identification. Additionally, it provides practical guidelines for selecting the number of violinists and the types of excerpts to record. Future work will focus on exploring how MFCCs can explain perceptual evaluations of violin timbre by listeners.

ABSTRACT

This study presents a data-driven methodology to estimate transfer matrices modeling saxophone mouthpieces based on their geometric parameters. A novel parametric model was developed to generate more than 1000 unique mouthpiece geometries. Key geometric features, such as chamber and throat cross-sections, shape radii, and baffle inclination angle, were varied to create the dataset. The training data are generated through Finite Element Method (FEM) simulations, from which transfer matrices were extracted and approximated using Chebyshev polynomials. Polynomial coefficients were then modeled using fully connected neural networks to enable efficient prediction. The results demonstrate the system's ability to accurately predict transfer matrix coefficients, highlighting the potential of computational methods to enhance the customization and design of specific elements of musical instruments, such as mouthpieces.

1. INTRODUCTION

The saxophone mouthpiece plays a crucial role in defining the tonal characteristics and playability of the instrument [1–3]. The design of a mouthpiece involves balancing complex geometric parameters that influence airflow dynamics and, consequently, sound production [4,5]. This study focuses on the internal geometry of the mouthpiece, particularly the throat, chamber, and baffle, which significantly affect its acoustic properties [6].

Traditional evaluation methods for mouthpiece designs often rely on physical prototypes and subjective auditory assessments. These approaches are inherently time-consuming and limited in their ability to explore large design spaces [7, 8]. Recent advances in computational modeling and data-driven techniques in musical acoustics [9, 10] present new opportunities to study and optimize mouthpiece designs systematically.

In this work, we propose a parametric modeling framework for saxophone mouthpieces, enabling the automated generation of a large dataset of internal cavity geometries. Finite Element Method (FEM) simulations are employed to compute the corresponding acoustic transfer matrices (TM) for each design [**?**, 11]. Subsequently, neural networks are trained to capture the complex relationships between geometric features and the resulting acoustic responses encoded in the transfer matrices.

Furthermore, the mouthpiece models are integrated with a simplified saxophone body representation to investigate the effects of estimation errors in the transfer matrices on the overall acoustic output. This analysis provides insights into the sensitivity of the saxophone acoustics to

the geometry of the mouthpiece and the accuracy of predictive models.

The insights gained from this study provide a foundation for the design of mouthpieces customized to specific acoustic preferences, paving the way for innovations in saxophone performance and personalization [12].

2. GEOMETRIC MOUTHPIECE PARAMETERS

To establish the geometric framework for the saxophone mouthpiece, we conducted a detailed analysis of a wide range of commercially available models. Drawing on the studies of [13] and [12, 14], we identified key geometric parameters that capture the essential variations among different mouthpiece designs. The primary objective was to define a minimal yet versatile set of parameters capable of approximating a broad spectrum of mouthpiece geometries, ensuring adaptability across various styles and manufacturers.

Although this study focuses specifically on the alto saxophone mouthpiece as a representative case, the proposed methodology is generalizable and can be extended to other saxophone families, including soprano, tenor, and baritone models.

Given the large number of variables that influence mouthpiece performance, our design strategy prioritizes parameters that directly affect internal airflow and acoustic response. Based on the acoustic modeling framework presented in [15], we intentionally excluded variables associated with the reed tip interface from the parametric space. Instead, the reed channel is simplified and approximated as a rectangular window to reduce complexity and computational cost.

A geometric schematic of the internal cavity of the mouthpiece model is shown in Fig. 1. To characterize the chamber and throat, we define parameters that describe their cross-sectional dimensions and shapes. Specifically:

- the heights of the cross-sections are denoted as s_c (chamber) and s_t (throat);
- the shape radii are denoted as r_c (chamber) and r_t(throat), which determine the curvature of the cross-sections by adjusting the fillets.

For the baffle, the parameter α is introduced to represent the angle of its inclination. A lower value of α corresponds to a narrower mouthpiece, and a larger baffle is typically associated with a brighter and more focused sound. In contrast, a larger α results in a wider mouthpiece and a lower baffle, often producing a darker and warmer tone.

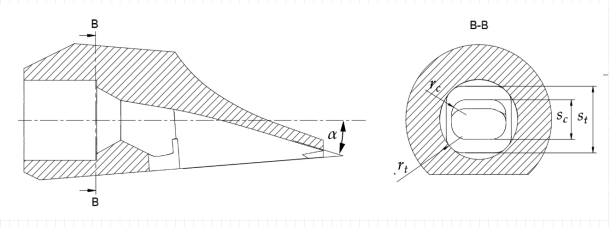

Figure 1: Scheme of the saxophone mouthpiece geometry. The left diagram shows a longitudinal cross-section highlighting the baffle angle α and internal cavity design, while the right diagram depicts the transverse cross-section (B-B plane) illustrating the chamber and throat dimensions s_c, s_t and their respective shape radii r_c, r_t.

It is important to recognize that the geometric parameters are constrained by the physical interfaces with other saxophone components, particularly the neck and the reed. Features such as the table, lay, tip opening, tip rail, and side rails must remain fixed to ensure compatibility with the wide variety of commercially available reeds. These constraints were explicitly integrated into the model to ensure that all generated geometries remain practical and compatible with standard saxophone configurations, preserving usability across a wide range of instruments and performance setups.

3. TRANSFER MATRIX METHOD

To describe the acoustic characteristics of the mouthpiece model, we employ the Transfer Matrix Method (TMM) introduced in [15]. The TMM is widely used in the study of wind instrument resonators (e.g., [11, 16, 17]), and is based on two-port acoustic theory. This theory models the reference acoustic system as a linear network with interconnected two-port elements, following the framework outlined in [15].

Specifically, a region between two ports is treated as a "black box" characterized by a 2×2 transfer matrix $\mathbf{T}(\omega)$, expressed as

$$\mathbf{T}(\omega) = \begin{bmatrix} T_{11}(\omega) & T_{12}(\omega) \\ T_{21}(\omega) & T_{22}(\omega) \end{bmatrix}, \tag{1}$$

such that the relationship between the input and output

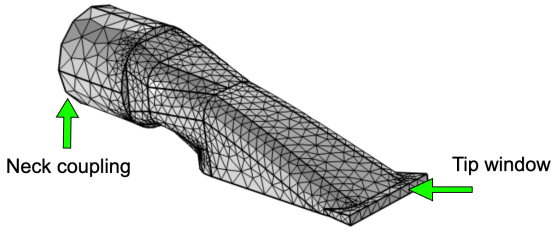

Figure 2: Finite element (FE) mesh of the saxophone mouthpiece used for acoustic analysis. The green arrows indicate the positions of the input and output ports, where acoustic pressure and volume velocity (P_i, U_i, P_o, U_o) are measured for transfer matrix derivation.

acoustic variables is given by:

$$\begin{bmatrix} P_o(\omega) \\ U_o(\omega) \end{bmatrix} = \mathbf{T}(\omega) \begin{bmatrix} P_i(\omega) \\ U_i(\omega) \end{bmatrix}. \tag{2}$$

Here, $\omega = 2\pi f$ is the angular frequency (in rad/s), while $P_i(\omega)$, $U_i(\omega)$ and $P_o(\omega)$, $U_o(\omega)$ represent the input and output acoustic pressure (in Pa) and volume velocity (in m³/s), respectively.

The transfer matrix of the mouthpiece is derived under the assumptions of linearity and passivity, which are valid when the sound source is decoupled from the mouthpiece. The reed's vibration is excluded, allowing the excitation and the nonlinearity to be modeled independently. Only propagating modes are considered, with a plane wave at the input and negligible output discontinuities. In addition, internal discontinuities are assumed to be far enough from the output plane to avoid interference. In Fig. 2 the positions of the input and output ports are shown in an example model. To derive $\mathbf{T}$, the two-load method proposed in [15] is employed. Then the following matrix equation can be solved to obtain the four terms of the TM

$$\begin{bmatrix} P_o^1 & Z_o^c U_0^1 & 0 & 0 \\ 0 & 0 & P_0^1 & Z_o^c U_o^1 \\ P_o^2 & Z_o^c U_o^2 & 0 & 0 \\ 0 & 0 & P_o^2 & Z_o^c U_o^2 \end{bmatrix} \begin{bmatrix} T_{11} \\ T_{12} \\ T_{21} \\ T_{22} \end{bmatrix} = \begin{bmatrix} P_i^1 \\ Z_i^c U_i^1 \\ P_i^2 \\ Z_i^c U_i^2 \end{bmatrix}, \tag{3}$$

where we dropped the argument ω for readability, and the superscripts 1 and 2 represent two different boundary conditions, with the loads set as a theoretical unflanged radiation impedance and the characteristic impedance, respectively.

4. DATASET CREATION

To generate a comprehensive dataset of mouthpiece parameters, we design the parametric model of the air cavity using COMSOL Multiphysics.

For our dataset, we generated five uniformly distributed values for each of s_c, s_t, and α within the predefined ranges shown in Table 1. To represent various cross-sectional shapes of the chamber, we computed three values for r_c and r_t relative to s_c and s_t using scaling factors that correspond to square, medium-smooth, and circular shapes. These parameter ranges and values, derived from [14], were informed by an analysis of the geometric characteristics of widely used commercial mouthpieces.

By combining these parameters, we obtained a dataset consisting of 1125 unique mouthpiece models. Each combination represents a plausible design variation in terms of throat and chamber shapes, as well as baffle inclinations. As an example, Fig. 3 illustrates four different mouthpiece models generated using this approach. These models demonstrate the impact of parameter variations on the throat and chamber cross-sections and the angle of the baffle.

Parameters	***Ranges Values***
s_c	[6.0 : 8.5] [mm]
s_t	[6.0 : 8.0] [mm]
α	[-5 : 25] [deg]
r_c	[0.05, 0.5, 1] $\times$ s_c
r_t	[0.05, 0.24, 0.49] $\times$ s_t

Table 1: The ranges or values of the selected geometric parameters. Five values in the ranges show in the table are randomly generated for s_c, s_t and α. Three different values with respect to each related cross section radii are generated for r_c and r_t.

4.1 Geometry Refinement

When musicians play the saxophone, it is common practice to adjust the depth of insertion of the mouthpiece into the neck to fine-tune the pitch. This mechanical coupling is critical for achieving proper intonation. To replicate this tuning behavior in our simulations, we adjust the length of

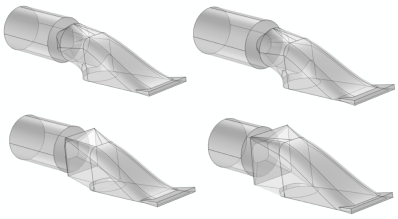

Figure 3: Four different parametric mouthpiece models obtained by different combinations of values of the selected parameters.

the coupling tube using a lumped acoustic model, ensuring that the system accurately reflects the tuning conditions.

The input impedance of the cylindrical equivalent of the mouthpiece is defined as $Z(\omega) = \frac{1}{\iota\omega\frac{\rho c^2}{V_m}}$ [15], where ι is the imaginary unit and V_m is the total volume. This relationship shows that maintaining a consistent volume of the mouthpiece in different models helps to preserve a similar resonance frequency. To match the neck diameter of the saxophone (1.7[cm] as measured on a Selmer Series III), the radius of the neck coupling's cross-section is fixed. Thus, to maintain the same volume of the mouthpiece, we adjust the length of the coupling tube accordingly.

4.2 FEM Simulation

Simulations are performed using COMSOL Multiphysics® software, employing the Pressure Acoustics, Frequency Domain finite element method (FEM) [18] to model the acoustic behavior of the air column within the saxophone mouthpiece. The accuracy and computational efficiency of this approach for wind instrument modeling have already been validated in previous studies [15].

As detailed in Section 3, two simulation scenarios are performed by applying distinct boundary conditions at the output: one with unflanged radiation impedance and the other with characteristic impedance. This setup enables the extraction of the elements of the transfer matrix necessary for subsequent acoustic analysis. A 1kPa pressure source is applied at the input tip window of the mouthpiece, depicted in Figure 2. The studied frequency range is [10,8000] Hz with a step of 50 Hz. The maximum mesh element size is $c/f_{max}/5$, with f_{max} the highest frequency.

We then extracted the TMs from the FEM simulations by solving (3), resulting in $\bar{\mathbf{T}} = [T_{ij}^{(\ell)}(\omega)] \in \mathcal{C}^{159\times1125\times4}$, where 159 is the number of sampled frequencies ω, 1125 is the number of geometry models ℓ, and we stacked them in 4 elements ij of TM $\mathbf{T}$ in (1). The obtained dataset is available at `https://kaggle.com/datasets/6c7d1b3c947d395b6d7954f9a628294e262baff0a7bee454bb119e8545ce9476`.

5. DATA-DRIVEN RECONSTRUCTION

5.1 Feedforward Neural Networks

We employed four Feedforward Neural Networks (FNN) to model the relationships between the geometric parameters and the four corresponding TM terms. The input consists of $\mathbf{x} = [s_c, s_t, \alpha, \frac{r_c}{s_c}, \frac{r_t}{s_t}]^\top \in \mathbb{R}^5$. To reduce the dimensionality of the neural network output, inspired by the approach discussed in [15], we used 10th-order Chebyshev polynomial coefficients for $\mathbf{T}$, resulting in 11 complex parameters arranged in a vector $\mathbf{p}_{ij}^{(\ell)}$. An example comparing $\mathbf{T}$ with its reconstruction from the polynomial approximation is presented in Fig. 4, demonstrating a good alignment and providing confidence in the accuracy of the polynomial fitting. For each neural network ij, the output is designed as $\mathbf{y}_{ij} = [\Re(\mathbf{p})^\top, \Im(\mathbf{p})^\top]^\top \in \mathcal{R}^{22}$, obtained by first converting $\mathbf{P}$ into a real-valued representation. The resulting vector is then normalized using the mean value across various mouthpiece models in the training dataset. Thus, given a set of geometric measurements $\mathbf{x}$, the ijth FNN must output a corresponding set of staked Chebyshev polynomial coefficients $\mathbf{y}_{ij}$ to define the ijth entry function of TM $\mathbf{T}(\omega)$.

Indeed, the dataset is divided into training, validation, and test sets with proportions of 70%, 15%, and 15%, respectively. This ensures that the model is not only trained effectively, but also evaluated for generalization on unseen data. The employed FNN architecture is shown in Fig. 5, featuring a single hidden layer with 10 neurons. The $\tanh$ activation function is used in the hidden layer to introduce nonlinearity, while no activation function is applied to the output layer. The loss function is defined as the mean squared error (MSE) between the neural network output and the exact target values $\mathbf{Y}$. The Levenberg-Marquardt backpropagation algorithm was utilized for optimization. The *MATLAB Deep Learning Toolbox* is used for the implementation.

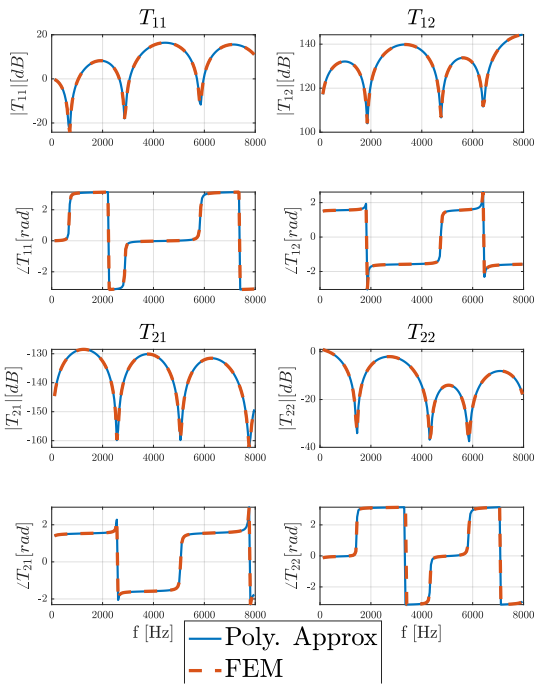

Figure 4: An example of magnitude and phase of TMs $\mathbf{T}$, comparing FEM and polynomial approximation results.

5.2 Linear Regression

As a comparison with the proposed data-driven method, we use a linear regressor. The linear regression assumes that the relationship between the dependent variable $\mathbf{Y}$ and the independent variable $\mathbf{X} = [\mathbf{x}]_\ell \; \forall \ell \in$ Training set (described in 5.1) can be expressed as

$$\mathbf{Y} = \mathbf{X}\beta + \varepsilon, \tag{4}$$

where β is the vector of regression coefficients; $\varepsilon \in \mathbb{R}^{n\times 1}$ is the vector of random errors, assumed to follow a normal distribution with zero mean and constant variance.

The vector of coefficients β can be estimated as

$$\hat{\beta} = (\mathbf{X}^T\boldsymbol{X})^{-1}\mathbf{X}^T\mathbf{Y}. \tag{5}$$

6. RESULTS

6.1 Closed Mouthpiece and Coupled System

The input impedance of the mouthpiece with a closed termination can be determined by setting the end impedance to infinity and evaluating it using the mouthpiece TM. Furthermore, to assess the influence of the mouthpiece on the saxophone body, we model the main bore of the saxophone as a truncated cone and couple it with the mouthpiece. The truncated conical resonator has an input radius of $8.05\,\mathrm{mm}$, which is equal to the radius of the mouthpiece neck coupling. The apex angle is $0.035\,\mathrm{rad}$, and the truncated cone length is $0.72\,\mathrm{m}$, which is aligned with the study in [19]. The input impedance is then derived accordingly with the unflanged radiation condition at the output. The elements of the transfer matrix for the truncated conical duct, $\mathbf{T}^{cone}$, are determined by Equation (5) in [20].

6.2 Metrics

To evaluate the performance of the proposed method, we employ three different metrics that are typically used in the literature [15]: the Normalized Mean Square Error (NMSE), the Frequency Shift (FS), and the coefficient of determination R^2.

Given a generic impedance Z_A and a ground truth impedance (i.e. Z_{FEM}) the NMSE of Z_A is defined as

$$\mathrm{NMSE}(Z_A) = ||Z_A - Z_{\mathrm{FEM}}||^2/||Z_{\mathrm{FEM}}||^2, \tag{6}$$

such that the discrepancy between estimated and reference impedance is quantified. FS expresses the deviation between the peak frequencies of two different functions and is defined as

$$\mathrm{FS}_k(Z_A) = |f_k(Z_A) - f_k(Z_{\mathrm{FEM}})|/f_k(Z_{\mathrm{FEM}}), \tag{7}$$

where k denotes the peak index and $f_k(\cdot)$ represents the resonance frequency of the magnitude peak of the given argument.

The coefficient of determination R^2 is used to evaluate the prediction accuracy. It is defined as

$$R^2 = 1 - \frac{\mathrm{SS}_{\mathrm{res}}}{\mathrm{SS}_{\mathrm{tot}}}, \tag{8}$$

where $SS_{\mathrm{res}} = \sum_{n=1}^{N}(y_n - \hat{y}_n)^2$, y_n is the value of the dependent variable for observation n, $\hat{y}_n$ is the predicted value from the model for observation n, $SS_{\mathrm{tot}} = \sum_{n=1}^{N}(y_n - \bar{y})^2$, and $\bar{y}$ is the mean of the observed values of y. R^2 values range from 0 to 1, with values closer to 1 indicating a better fit of the model to the data.

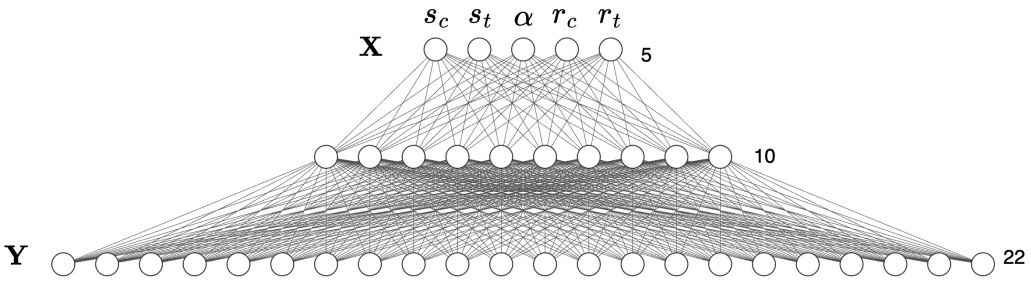

Figure 5: FNN architecture designed for modeling a single TM term.

6.3 Discussion

Performance metrics for input impedance predictions using both the FNN and linear regression models are summarized in Table 2. In all cases, the FNN consistently outperforms linear regression. Furthermore, Fig. 7 presents the coefficient of determination (R^2) for the input impedance of the coupled system, confirming the superior predictive accuracy of the FNN model.

An example of the input impedance comparison is shown in Fig. 6, where the FNN predictions closely match the FEM results, while linear regression exhibits notable deviations. These results reveal the presence of a nonlinear relationship between the mouthpiece geometric parameters and the corresponding TM elements. This underscores the importance of employing nonlinear models to adequately capture the relations between the geometric model parameters and the acoustic response.

	FNN	Linear
NMSE($\lvert Z_{in,\text{coupled}}\rvert$) [dB]	**-55.6**	-39.9
NMSE($\lvert Z_{in}\rvert$) [dB]	**-81.1**	-57.1
$\text{FS}_1(Z_{in})$ %	**0.36**	4.10
$\text{FS}_2(Z_{in})$ %	**0.24**	0.42
$\text{FS}_3(Z_{in})$ %	**0.36**	2.07
$\sum_{k=1}^{3} \text{FS}(Z_{in})/3$ %	**0.32**	2.19

Table 2: Comparison of performance metrics for FNN and Linear models, including NMSE and FS averaged for all the test dataset results.

7. CONCLUSION

In this study, we construct a synthetic dataset using a parametric model of saxophone mouthpieces that results in 1125 different designs. We consider the parameters related to the internal airflow cavity: the cross-section heights and radii of chamber and throat, and the angle of baffle inclination. The TMs of these models are then retrieved using the Finite Element Method (FEM). Additionally, a truncated cone is coupled with the parametric mouthpieces to serve as a simplified representation of the main bore of the saxophone. The acoustical influence of the mouthpiece is investigated on the basis of the input impedance spectra, which highlights the mouthpiece emphasis or modulation effect. Moreover, comparative analyses of the input impedance spectra reveal potential underlying relationships between the mouthpiece parameterization and the characteristics of the instrument. The presented dataset has significant potential for further research on the acoustic behavior of saxophone mouthpieces and sound generation. These studies can contribute to advances in the design of saxophone mouthpieces.

ABSTRACT

Input impedance is a physical quantity that allows the objective characterization of wind instruments. It is now a common measurement in research labs and wind instrument factories. To be relevant, these measurements must achieve a precision higher than what a musician can detect. Although the sensitivity of musicians to slight impedance variations is not known, it is important to have an idea of the precision of impedance measurements in realistic situations. In order to evaluate the accuracy and different type of variability (e.g.: intra- and inter-operator) of impedance measurements and to identify key sources of error in the process, a collaborative study has been conducted involving multiple operators using the experimental setups developed by the CTTM. Measurements were performed on simple pipe geometries, including cylindrical, with a focus on boundary conditions, material properties, and calibration procedures. Variability in experimental results is linked to the calibration steps, the pipes manipulation, and challenges with wall surfaces, particularly in wooden pipes. The study also revealed significant inter-operator variability and emphasizes the importance of rigorous calibration procedures and standardized measurement practices. These findings provide actionable insights for enhancing the reliability of experimental methods and support further research into more complex and realistic geometries.

1. INTRODUCTION

Input impedance measurements of wind instruments are now commonly used tools in research laboratories and wind instrument manufacturing companies [1-3]. This tool can be used both during the prototyping phase of an instrument and for manufacturing control. However, the question of the accuracy that can be expected from such tools has rarely been asked. The objective of this work is therefore to provide quantitative elements on this accuracy and compare it with the accuracy that can be achieved in machining. This work focuses on the sensor developed jointly by LAUM and CTTM (now Almacoustic) [4].

To assess measurement uncertainty, standards are required. These standards are cylindrical tubes for which the errors related to the theoretical model are significantly lower than the uncertainties expected with the measurement. A number of tubes were manufactured in different materials and in multiple copies. Different operators with different sensors measured the different tubes several times, which allowed the repeatability uncertainty of each operator to be assessed,

as well as the uncertainties related to the operators. Sample variability could also be assessed and compared with the measurement uncertainties.

2. THE SAMPLE PANEL

Tubes in different materials have been fabricated with a target length of 180mm and a target inner diameter of 14mm. Each sample consists of five specimens, so that measurements can be compared with simulations, taking into account manufacturing uncertainties. The three materials chosen for the cylinders are brass, boxwood, and Acrylonitrile Butadiene Styrene (ABS), a common polymer used in 3D printing.

After manufacturing, the actual geometrical parameters are measured with a ruler for the length and a telescopic gauge and caliper for the internal diameter (the wall thickness being deduced from internal and external diameters). The mean μ and standard deviation σ_{tot} of each dimension is given for each type of sample in Table 1. The standard deviations are estimated from the measurement tools resolutions (0.5 mm for the ruler and 0.1 mm for the caliper) and the measured variability. The same pipes are used for the open (O) and closed (C) conditions, using 3D-printed caps for the closed conditions and grease for the airtightness.

Table 1 Samples dimensions

Material	**Length** (mm)	**Diameter** (mm)
Brass	180.0 ± 0.3	13.92 ± 0.03
Wood	179.9 ± 0.65	13.97 ± 0.07
ABS	179.85 ± 0.3	14.03 ± 0.09

From Table 1, it appears that the brass tube sample is the most uniform. The boxwood sample, made by hand, has the largest length deviation, and the 3D printed samples have the largest wall thickness variation. The temperature (°C) and relative humidity (%) have been also measured to apply corrections on the speed of sound in the post processing step. The scientific sensors have generally a great precision (0.1°C and 1%), however due to possible air heterogeneity between the measured point and the air inside the tube the uncertainty on the speed of sound may remain large and might lead to rather large deviation between experiments made in different conditions.

3. MEASUREMENTS

The Measurements have been performed with impedance sensors produced by the CTTM [4]. This device necessitates one calibration step (measurement of a cap with an "infinite" impedance) and has a 16 mm output diameter. Logarithmic sine sweep which frequency range was 100-4000 Hz. Most of operators (2 to 4) attached the tubes to the impedance head with a connector printed in flexible material (thermoplastic polyurethane, TPU) to facilitate their alignment and to deal with small external diameter variations between specimens. Operator 5 preferred to place the tube by hand. The quality of the impedance measurement strongly depending on the air tightness at the contact between the impedance head and the sample, cork grease (for Wind instruments) has been used at this junction (or clay for O5). For a batch of five tubes, the measurements have been repeated five times for a given tube, the first one, to estimate the intra specimen variability for a given tube. Then, the four remaining tubes have been measured to estimate the inter specimen variability. Each batch has been measured this way for closed-closed and closed-opened boundary conditions. The complete protocol being time consuming, some experimenters have focused on some configurations (at least closed cylinders), but by measuring all the requested repetitions (intra + inter = 9). It is specified that operator 4 didn't measure the tube in the open configuration. Each operator was free to redo some measurements using his/her own criteria.

4. RESULTS

In this section, the reference values used to display the observables are taken from the calculation of the analytical solution for the closed cylinder [5-6]. All these simulations have been calculated for the average geometry of each sample (Table 1).

Both sound velocity and air density depend on air temperature T and relative humidity RH. This dependence affects the magnitude of the impedance and shifts the frequency axis. The calibration steps naturally scale the obtained data by the lossless characteristic impedance Z_c, removing the main magnitude dependence. However, in order to compare the data, it is necessary to correct the effect on the frequency axis, by applying to frequency a correction factor $c_{25}/c_{T,RH}$ where c_{25} is the speed of sound in dry air at 25°C and $c_{T,RH}$ is the speed of sound during the measurement taking into account temperature value and relative humidity.

Frequency and amplitude deviations from theory of first four maxima and minima of the input impedance are

analyzed. The deviations are expressed in cents for the frequencies, that is $1200\log_2(f_{meas}/f_{theo})$, and in dB for the amplitude, that is $20\log_{10}(Z_{meas}/Z_{theo})$.

4.1 Measurements of a single brass tube

In this section the modal characteristics of a single closed brass tube are analysed. Results are shown in Figure 1. For each operator and each configuration, the standard deviation of each observable is computed along the five measurements on the same specimen. These deviations do not seem to be related to the absolute frequency of the peak. For most operators, the deviations are even similar for all "resonances" (max amplitude) and for all "anti-resonances" (min amplitude). This suggest that deviation are related to small temperature or geometrical variations.

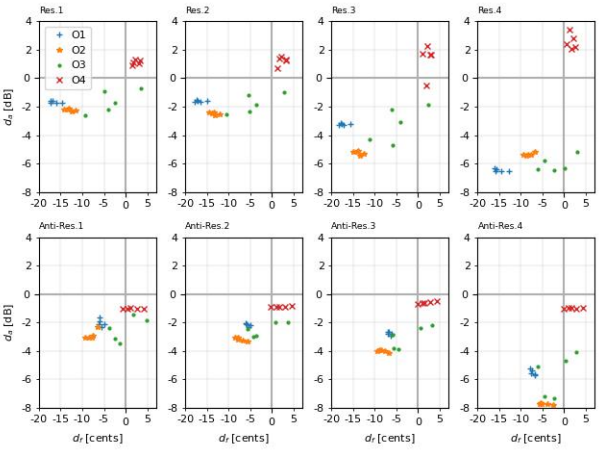

Figure 1. Deviation to the reference values of the frequency (d_f in cents) and magnitude (d_a in dB) of the 4 resonances and 4 anti-resonances, for the 5 repeated measurement of a given closed Brass cylinders. Each operator is associated to a marker shape and a color.

A result is that intra operator (same operator) deviations are much lower than inter operator deviations. Indeed, the standard deviation for all peaks and dips is less than 2 cents for operators 1, 2 and 4 and less than 4 cents for operator 3 for frequency and for amplitude it is 0.3 dB pour operator 1 et 2, 1 dB pour operator 4 et 1.5dB pour op. 3. This corresponds to the value obtained in previous studies [1-3]. The deviations between operators are much larger since it is around 10 cents in frequency and 2 dB in amplitude. The large difference for the amplitude is probably due to the difficulty to ensure a perfect closure of the tube since it is observed that the deviations are lower when the tube is open (1dB).

The origin of the inter-operator deviations is difficult to pinpoint. It can be due to a biased estimation of the temperature in the tube, a different placement of the sample on the sensor or differences between sensors. In practice to explain a 10 cents deviation a 3°C error on the temperature or a 1mm error on the tube length are needed. This deviation could also come from a deviation between sensors. To test this hypothesis, an operator measured the same pipe with five different sensors. This experiment being carried out a posteriori, a different tube has been used (about 1 m long and a 20 mm inner diameter). The obtained standard deviation between the sensors is about 3 cents and 0.5 dB. This is similar to the intra-specimen variability which suggests that the difference between the sensors cannot alone explain the inter-operator variability. The inter-operator variability is certainly due to the conjunction of multiples factors.

4.2 Measurements of various tubes

In order to compare the variability linked to manufacturing processes and the uncertainties of impedance measurement various tube have machined and their impedance measured (see table 1). It appears that the inter-specimen deviations are in the range or larger than the intra-operator variability. For 3D printed and brass tubes deviations in frequency cannot be assessed while for wooden tube significant deviation can be detected. Also, significant amplitude deviations can be detected for the wooden and 3D printed tubes. This validates the fact that the impedance measurement is capable of detecting small machining variations. However, this is only possible if measurements are performed by the same operator in the same experimental conditions.

Table 2 Median value over all operators of the inter-specimen standard deviation (open tubes)

Standard deviation	Brass	3D	Wood
Frequency (cents)	3	4	8
Amplitude (dB)	0.2	0.5	1.3

5. CONCLUSION

It appears that input impedance measurements – at least with the sensor we used - allow the determination of eigenfrequencies with a relative accuracy of about 3 cents

on frequency and 0.5 dB on amplitude. This means that it is possible to detect differences between two instruments as small as this provided that both instruments are measured under the same conditions. Measurements with different sensors and different operators suggest that below 10 cents and 1 dB it would be doubtful to conclude that the deviations betray a significant difference between the measured instruments. It can be estimated that the absolute accuracy of the measurements is of this same order of magnitude as long as the measured impedances are adapted to the sensor used. Here, the sensor has an input diameter of 16 mm and the measured tubes have a diameter of 14 mm. In the case of significantly narrower or wider tubes, the absolute errors will a priori be larger.

In another work, the sensor will be used to evaluate the accuracy obtained on the input impedance calculated from numerical models. It should be possible to assess if models can reach an accuracy of less than 5 cents on eigenfrequencies.

A question remains open: to what extent is a musician able to detect a difference between two similar instruments? This question has been little explored [2, 3] and the answer to this question will obviously depend on the instrument considered. We find an example in reference [2]: on saxophone necks, measurements were able to unambiguously highlight differences of the order of 8 cents on the first eigenfrequency. For his part, the musician tester was able to distinguish without difficulty the necks which had the lowest frequencies. Are musicians able to be more accurate than impedance measurements? The question remains open.

ABSTRACT

Numerical simulation of the input impedance of wind instruments is the basis of much work in music acoustics. However, the accuracy and reproducibility of such simulations across different contributors remain little documented. This study aims to benchmark the reliability of numerical simulations for pipe impedance, focusing on simple geometries such as cylindrical and conical pipes, and to identify key factors influencing simulation variability. A collaborative approach was adopted, involving multiple contributors employing various numerical models, including TMM, FEM (1D or 3D), etc., and eventually different physical models for the propagation, the boundary conditions, and the thermo-viscous effects. Significant variability in simulation results was observed due to differences in implementation, numerical precision, and boundary condition modelling. Incomplete convergence in some methods also contributed to discrepancies. Despite these challenges, the collaborative work and exchanges reduced variability and improved consistency across contributors. The study highlights the importance of such benchmark and the interest to adopt good practices including verification of the numerical tools through comparative analysis and identification of convergence criteria. This work provides a framework for improving the reproducibility an accuracy of numerical simulations in musical acoustics context.

1. INTRODUCTION

The input impedance of wind instruments is a fundamental quantity in musical acoustics. It serves as a basis for most physical modeling approaches, including sound synthesis, time-domain simulations, automatic design, etc. In practice, researchers often implement their own numerical models to compute this quantity, adapting them to the specific constraints of the studied objects or their research objectives.

However, the development of a new numerical model can introduce several sources of inaccuracy: the omission of physical phenomena that may significantly affect results (e.g. humidity rate), implementation errors, numerical approximations (e.g. rounding), and eventually artifacts due to spatial discretization. To address such issues, the scientific computing community has established the Verification and Validation (V&V) framework, particularly in fields such as Computational Fluid Dynamics (CFD) and Mechanical Engineering [1, 2].

Verification aims to ensure that the model accurately solves the underlying mathematical equations. This step typically involves comparisons with analytical solutions when available, or with results from independent numerical models in configurations where both are expected to be valid. Validation, on the other hand, focuses on assessing how well the model reproduces experimental data, accounting for uncertainties due to variability in geometry, material properties, boundary conditions, and measurement procedures.

In musical acoustics it is common to compare simulations and experiments (e.g. [3, 4]). However, the verification step is less systematically applied. Often, studies focus on validating new developments in configurations where existing models fail (e.g. [5]), without first verifying consistency between models on simpler, well-understood test cases.

This study specifically addresses the *verification* step, by comparing impedance results computed by different researchers using independent implementations. The focus is on simple geometries—closed or open cylindrical and conical tubes—for which reference or analytical solutions exist and for which numerical models are expected to agree. By identifying and resolving discrepancies in this controlled context, we aim to assess the robustness of current modeling practices and contribute to improving the reliability and reproducibility of impedance computations in musical acoustics.

2. CONSTRUCTION OF THE DATA SET

2.1 Configurations

The cases studied are 180 mm long pipes. This relatively short length gives the possibility to use heavy simulation methods (e.g. 3D-FEM) with a relatively low computation cost even at "high" frequency (5 kHz). A cylindrical pipe with a 14 mm internal diameter has been simulated with three radiation conditions: closed, open with infinitly thin wall (unflanged) and open with 7 mm wide wall (circular flanged). A closed conical pipe with an internal diameter from 10 mm to 22.6 mm (half angle: 2°) have been also simulated. For the latter, contributors assumed either plane or spherical wavefronts, which can be seen as different shapes of boundary conditions (plate or spherical caps). The wall material is assumed perfectly smooth, rigid, non-porous and a perfect conductor of heat.

The values of the physical quantities (speed of sound, air density, etc) are imposed. They are calculated, from [6, Chap.5.5.2], for a temperature of 25°C. For the lightest calculation methods, the recommended frequency axis for simulation is set to [0.2 Hz, 20 kHz] with a 0.2 Hz step. However, for methods necessitating high computation cost, a multiple of the frequency step could be used. Only 5 arbitrary frequencies was imposed for comparison ($f_{obs} \in [20, 100, 500, 1000, 5000]$ Hz) (see Sec.2.3).

2.2 Numerical methods

The input impedances of this set of configuration have been simulated by seven contributors, named A to F, using their own software or implementation of the models. For each simulation, the resulting impedance $\tilde{Z}$ is shared.

To simulate the wave propagation, contributors A to D use the one-dimensional (1D) telegrapher's equations including the visco-thermal losses with the Zwikker and Kosten expression (see e.g. [6, Chap.5]) or approximation proposed by Keefe [7]. The closed condition is modelled by an infinite impedance. For the open conditions, a radiation impedance computed with the expressions proposed by Silva [8] and Dalmont [9] are used. Contributors A, B and D used their own implementations of the Transfer Matrix Method (TMM). This technique combines solutions of the telegrapher's equation for cylinders (exact solution) or cones (approximation). For cone it is possible to refine the solution, by subdividing the geometry in small cones. Contributor C uses the software Openwind [10] given the possibility to solve the equations with TMM or 1D-finite elements method (1D-FEM) [11], which converges to the

exact solution if the mesh is refined enough.

Contributor E used its own implementation of the multi-modal (MM) approach [12]. The thermo-viscous effects are taken into account as a modification of each mode shapes through the expressions proposed by [13]. For open pipes, the radiation domain is modeled using a wider pipe surrounding the actual pipe studied [14].

Contributor F used the software Montjoie [15] to solve 3D (or 2D axi-symmetric when it is possible) acoustic propagation with FEM. The thermo-viscous effects are taken into account using a two steps simulation (sequential linearized Navier-Stokes model or SLNS) [16], or effective boundary conditions based on Cremer approach [17]. More detailed are given in [18]. For open pipes, a radiation domain bounded by perfectly-matched-layers condition (PML) is added.

In order to study the practical use of simulation, each contributor was responsible for choosing the spatial discretisation, making his/her own compromise between accuracy and computation time. This choice is strongly influenced by the scientific culture of the contributor (numerician, experimentalist, etc.) or by the intended application (model comparison, manufacturing application, etc.).

2.3 Distance quantification

In numerical studies, it is common to use the L2-norm to quantify the distance between two simulations. However, the presence of peaks in the impedance curve can lead to large deviations from small variations (e.g., a slight shift in a resonance peak). To mitigate this, the reflection function is used:

$$\mathcal{R} = \frac{Z-1}{Z+1}. \tag{1}$$

where $Z = \tilde{Z}S/(\rho c)$ is the input impedance scaled by the lossless characteristic impedance. The distance between two simulations (p, q) is then computed as the L2-norm at the five arbitrary imposed frequencies $f_{obs}^{(i)}$:

$$d_R^{(p,q)} = \frac{\sum_i^N |\mathcal{R}_p(f_{obs}^{(i)}) - \mathcal{R}_q(f_{obs}^{(i)})|^2}{\sum_i^N |\mathcal{R}_p(f_{obs}^{(i)})|^2}. \tag{2}$$

For two equivalent models, this distance should reach machine precision (here, 10^{-6}).

From a musical perspective, the "modal characteristics" are also analyzed for simulations with sufficiently fine frequency resolution. Both resonances and anti-resonances are characterized by their frequency and magnitude. For the i-th (anti-)resonance peak, the frequency $f^{(i)}$ is defined as the point where the impedance phase crosses zero, and the magnitude $a^{(i)}$ as the modulus of the impedance (or admittance) at that frequency. Simulations are compared through their deviation from a reference value, expressed in cents for frequencies:

$$d_f^{(i,p)} = 1200 \log_2 \left(\frac{f_p^{(i)}}{f_{ref}^{(i)}} \right) \tag{3}$$

and in decibels for amplitudes:

$$d_a^{(i,p)} = 20 \log_{10} \left(\frac{a_p^{(i)}}{a_{ref}^{(i)}} \right). \tag{4}$$

The reference values are taken from the analytical solution when available, or otherwise from the average across all simulations.

3. ANALYSIS

3.1 Closed cylinder

The first test case is a closed cylindrical tube. The "closed" condition is numerically defined by enforcing zero normal velocity at the cap wall, corresponding to zero flow in 1D, or equivalently, infinite acoustic impedance. This assumption neglects the thermo-viscous effects at the cap wall.

For this geometry, the telegrapher's equation admits an analytical solution including thermo-viscous losses. With the above boundary condition, the input impedance reads:

$$Z_{\text{closed cyl}} = Z_{cc} \coth(\Gamma L) \tag{5}$$

where L is the cylinder length, $Z_{cc} = \sqrt{Z_v/Y_t}$ is the complex characteristic impedance, and $\Gamma = \sqrt{Z_v Y_t}$ the complex wave number. This configuration is well suited for validation, as all TMM implementations should yield identical results, apart from the specific thermo-viscous formulations, since this method is formally similar to the analytical solution Eq. (5) in this configuration.

Contributors A, B, and C used the ZK formulation. C also tested the first- and second-order Keefe approximations (Keefe 1 and 2); D used Keefe 2. Contributor E implemented the multimodal (MM) model, and F used 3D FEM with 2D-axisymmetric SLNS resolution.

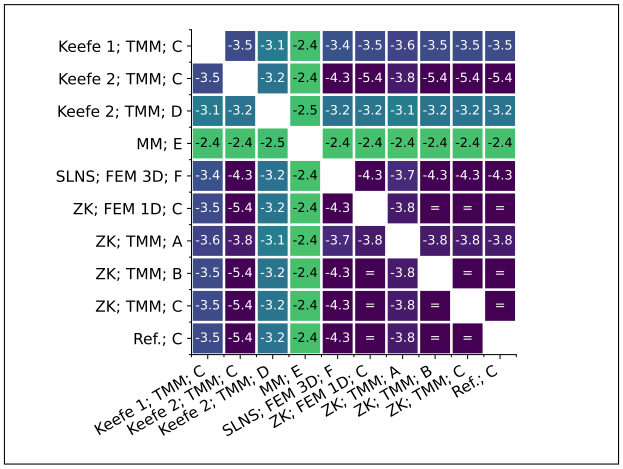

Figure 1. Closed cylinder. Relative distance matrix of the reflection function at reference frequencies ($f \in [20, 100, 500, 1000, 5000]$ Hz) in log scale ($\log_{10}(d_{\mathcal{R}})$). The symbol "=" denotes distances below machine precision (10^{-6}).

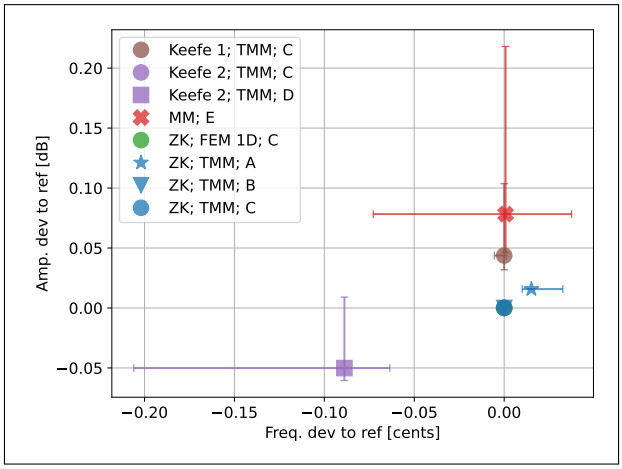

Figure 2. Closed cylinder. Deviation from the analytical modal characteristics (Eqs. 4, 3). Markers indicate median values; error bars denote the full range. Marker shapes identify contributors; colors indicate models and numerical methods.

Figure 1 presents the distance matrix for the reflection function (Eq. 2), and Figure 2 shows deviations in modal characteristics over 10 peaks (5 resonances, 5 anti-resonances). In this second Figure, the 3D FEM results are omitted due to insufficient frequency resolution for modal fitting.

From a musical point of view, all simulations exhibit good overall agreement, with frequency deviations remaining within ± 0.2 cents and amplitude deviations within ± 0.2 dB. The results provided by contributors B and C (ZK-TMM, 1D FEM and analytical solutions) are consistent to within machine precision across all metrics. Similarly, the 3D FEM results from contributor F and the second-order Keefe approximation from contributor C are nearly indistinguishable, with reflection distances below $10^{-4}\%$, frequency deviations below 10^{-3} cents and amplitude below 10^{-3} dB. Contributor A shows slightly larger but still minor discrepancies, attributed to a numerical issue in the implementation of physical quantities, after the sharing of the data.

The impact of thermo-viscous modeling choices is clearly visible. The multimodal (MM) model introduces more noticeable deviations, in reflection distance ($d_{\mathcal{R}} \approx 4 \cdot 10^{-3}$), in frequency ($d_f \approx 0.08$ cents) and amplitude ($d_a \approx 0.2$ dB). The first-order Keefe approximation also leads to moderate differences. By contrast, contributor D, who used the second-order Keefe approximation, exhibits unexpected deviations (-0.05 dB, -0.1 cents, $d_{\mathcal{R}} \approx 7 \cdot 10^{-4}$) not observed in C's results with the same model, suggesting a probable but yet-unidentified implementation issue.

3.2 Other geometries

Similar figures and analyses can be produced for other test cases. However, for clarity, the agreement between simulations is here assessed through statistical indicators.

Table 1. Mean and maximal values of the logarithm of the distance $d_{\mathcal{R}}$ between simulations for each configuration.

Case	Mean $\log_{10}(d_{\mathcal{R}})$	Max $\log_{10}(d_{\mathcal{R}})$
Cyl. C.	-4.0	-2.4
Cyl. Unfl.	-3.0	-2.4
Cyl. Wall	-2.7	-2.2
Cone Pl.	-2.1	-1.7
Cone Sph.	-3.3	-3.0

Table 1 shows the mean and maximal values of

Table 2. Root mean square (RMS) and maximal values of the deviations d_f (in cents) and d_a (in dB) between simulations for each configuration.

Case	RMS d_f	Max d_f	RMS d_a	Max d_a
Cyl. C.	0.05	0.24	0.05	0.22
Cyl. Unfl.	0.07	0.62	0.05	0.18
Cyl. Wall	0.20	0.60	0.11	0.32
Cone Pl.	0.8	5.7	0.4	2.2
Cone Sph.	0.04	0.17	0.04	0.07

$\log_{10}(d_{\mathcal{R}})$ for each configuration. Table 2 provides the root mean square (RMS) and maximal deviations of the modal characteristics between simulations.

Agreement between results decreases as the simulated configuration becomes more complex. The best match is observed for the closed cylinder (Cyl. C.), followed by the unflanged open cylinder (Cyl. Unfl.) and the open cylinder with finite wall width (Cyl. Wall). The largest deviations occur for the closed cone with plane wavefronts (Cone Pl.), with errors reaching a few cents, a few dB, and around 1% for $\mathcal{R}$. Conversely, the closed cone simulated with spherical wavefronts (Cone Sph.) shows excellent agreement, comparable to the closed cylinder. This may be due to the fact that this case was only simulated by contributors using software that had already been verified.

4. CONCLUSIONS

Even though simulations are generally consistent from a musical perspective ($d_f < 1$ cent, $d_a < 1$ dB), this study shows that achieving strict numerical consistency remains challenging. Variations arise when different researchers use distinct physical models and implementations, even for simple cases.

The presented values already reflect extensive discussions, data comparisons, and issue resolution. For instance, deviations for the conical pipe reached 20 cents in the initial dataset. Despite these efforts, increasing model complexity leads to growing discrepancies, highlighting the sensitivity to boundary conditions and the importance of careful numerical implementation. The most consistent results were observed for simple cases and by contributors with strong numerical skills.

Beyond the analyses of the presented implementations, this study emphasizes the importance of verification when developing new models or tools. This includes comparing results with existing tools on simple cases for which both are valid, identifying sources of discrepancies (e.g., convergence, simplifications), and quantifying deviations. In simulations requiring discretization (e.g. sliced conical pipes in TMM), the convergence behavior should be systematically evaluated and reported.

Promoting such practices is key to improving reproducibility and accuracy in simulations. A practical solution for sharing the numerical results of this study is under consideration, which should allow anyone to *verify* their tools by comparing them with this dataset and then to carry out validation with experiments.

ABSTRACT

This paper deals with the experimental characterization of single cane reeds. According to some authors, the reed stiffness symmetry of the unmounted reed may explain it's perceived quality. Other studies show that the nonlinear stiffness of a reed mounted on a mouthpiece partially explains it's behavior in playing situations. According to these results, the aim of this work is to study the link between measurements performed on unmounted and mounted reeds.

We adapted two experimental test rigs to characterize 90 reeds with 3 different strengths. The first is dedicated to unmounted reeds. It enables to measure the local stiffness at a known distance from the reed tip by imposing a displacement and measuring the force. The second test rig focuses on the reed mouthpiece interaction. Using a force sensor and a camera, it enables to estimate the nonlinear characteristics between lip force and reed channel area.

Using these numerous measurements, we investigate the relation between the indicators by the use of statistical analysis and machine learning techniques. These methods enable to show several correlations between parameters obtained from unmounted and mounted reed measurements.

1. INTRODUCTION

Woodwinds instruments use a small piece of cane or synthetic material to produce a sound. According to musicians, this piece is very important for the control and the quality of sound and this was already said by Frederic Berr in 1836 [1] "Une bonne anche est un point capital pour l'exécutant, puisque la qualité du son dépend de sa confection et du choix du roseau ; aussi a-t-on dit qu'une bonne anche faisait la moitié du talent de l'exécutant" (A good reed is essential for the performer, since the quality of the sound depends on the way it is made and the choice of reed; it has been said that a good reed is half the talent of the performer.)

Today single reeds are made in an industrial manner so that the reed can be described by three parameters, its brand, its cut and its strength. However, even if the manufacturing process is very accurate, different reeds sold as identical (same brand, cut, strength) can be perceived as extremely different by musicians. This is even the case when the reed is chosen to be adapted to the mouthpiece tip opening [2]. Indeed the mouthpiece plays an important role in the ease of playing (linked to the oscillation threshold) and in the external sound pressure level and in the pitch variation [3].

According to previous results [4], the strength of the reed (obtained thanks to a measurement of the reed stiffness at a certain distance from the reed tip) is correlated with the subjective descriptor "ease of playing" but the strength does not enable to predict all musicians sensa-

tions. This explains the variability of musicians perception when they play identical reeds. The variability in the perception may be due to the reed symmetry [5,6] or to the interaction between the reed and the mouthpiece [7, 8].

For this reason, the work proposed in this paper aims at characterizing the reed thanks to two different experimental methods. First, measurements of the reed alone are conducted. They enable to estimate two different reed compliances (local and transfer compliance). Second, the interaction between the reed and the mouthpiece is analyzed by estimating the reed channel surface —the front surface between the mouthpiece tip and the reed— as a function of the force applied on the reed as described by Gaillard et al. [8]. Finally, relations between the two data sets are searched in order to investigate to what extend measurement on the reed alone can give information the reed-mouthpiece interaction.

The second half of this study covers measurement methods. Data analysis methodologies are discussed in Section 3, while Section 4 presents results obtained with 89 reeds before concluding and providing work perspectives.

2. MEASUREMENT TECHNIQUES

Two experimental set-ups were used. The first test rig uses a rod to apply a force on a clamped reed. It measures the local stiffness at various reed points and the deflection of the reed tip (figure 1). The second device (figure 6) consists of a mouthpiece, an artificial lip, and a reed. It allows to measure the nonlinear relationship between the opening of the reed channel and the force applied by the lip on the reed.

2.1 Measurements of the reed alone

The experimental set-up used to characterize the reed alone is described in figure 1. The thick part of the reed is clamped and its free length is set at ℓ = 2.7 cm. This length is controlled using a removable stop giving good repeatability during measurements. A camera (Imagine Source DMK 37BUX252) takes pictures of the reed tip, in order to capture the deflection $z_t(y_t)$ along y axis (tip displacement). A pointed rod that can move in the three directions in space imposes a known displacement z_p at the coordinates (x_p, y_p). The position of the rod in the reference frame linked to the reed is controlled in the y direction using a calibration procedure to compensate for any defects in the positioning of the reed on the bench. A sensor (Omega LCM703-5) measures the force F_p applied by the pointed rod to the reed for different positions along the z axis.

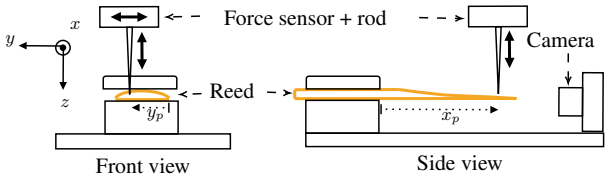

Figure 1. Schematic diagram of the bench used to measure the local stiffness and the tip deflection of a single reed.

Thanks to this test rig, two types of reed measurements are performed simultaneously : reed local stiffness (the compliance inverse) and reed tip deflection. The measurement procedure involves positioning the rod tip over the reed and then displacing it according to z. The force is recorded and a picture of reed tip is captured (as presented in figure 2.a). This automatic procedure is repeated for 4 positions along z and 9 points along y centered on the middle of the reed. This choice results from a compromise between the accuracy and the duration of the measurement. Indeed, as a large amount of reeds will be measured, the maximum measurement time for one reed is set to 10 minutes.

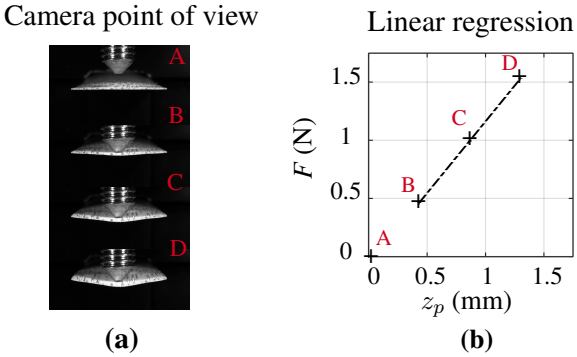

Figure 2. (a) Four rod positions and resulting in reed deflection (b) Estimation of local stiffness by linear regression between force and displacement imposed by the rod.

2.1.1 *Measurement of local stiffness*

For this measurement, a linear regression estimates the local stiffness K at coordinates (x_p, y_p) using the rod im-

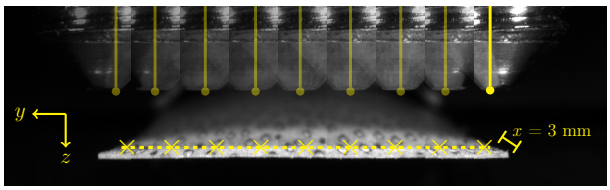

Figure 3. Nine points (yellow crosses) along the reed width y from y_0 (left) to y_8 (right) at $x = \ell - x_p = 3$ mm from the reed tip.

posed displacement and the measured force.

The local stiffness is measured for the nine y_p leading to the estimation of reed stiffness profile. The stiffness is modeled by a parabola described in a previous article [9] with three coefficients K_0, K_1 and y_0 leading to the theoretical stiffness $\hat{K} = K_0 + K_1(y_p - y_0)^2$. We also include $\Delta K = K(y_8) - K(y_0)$ to capture the symmetry of the reed.

2.1.2 Measurement of transfer compliance

In this measurement, only the force applied by the rod and the reed tip deflection are used as shown in figure 4. The reed tip deflection $z_t(y_t)$ is obtained with an image processing. For each z_p, the image is converted in black and white using a threshold value according to Almeida [10]. The contour between the white (reed) and dark zones (air) is obtained by thresholding the gradient of each y slice between the left and right side of the reed.

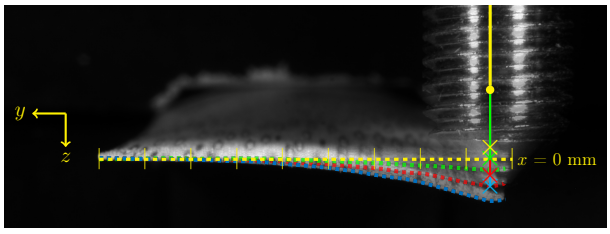

Figure 4. Four reed tip deflections (colored dotted lines) caused by four vertical displacements of the rod. The reed is at rest for the first displacement as in Figure 3, in yellow in both figures.

The full contour is interpolated to extract the reed tip deflection $z_t(y_t)$ at the nine segments between the small yellow vertical bars in Figure 4. Finally, these measurements result in a bunch of 4 z_p (rod displacements) $\times$ 9 y_p (rod positions) $\times$ 9 y_t (reed tip average deflection) $= 324$ deflection values for a reed. This enables to get first the reed tip profile at rest $z_r(y_t)$ (no force). Second it leads to the transfer compliance $c_{tp} = \frac{z_t}{F_p}$ at different rod positions y_p and tip positions y_t using a least mean square regression for 3 rod positions z_p. An example of such a transfer compliance matrix $\boldsymbol{C_{tp}}$ is given in figure 5.

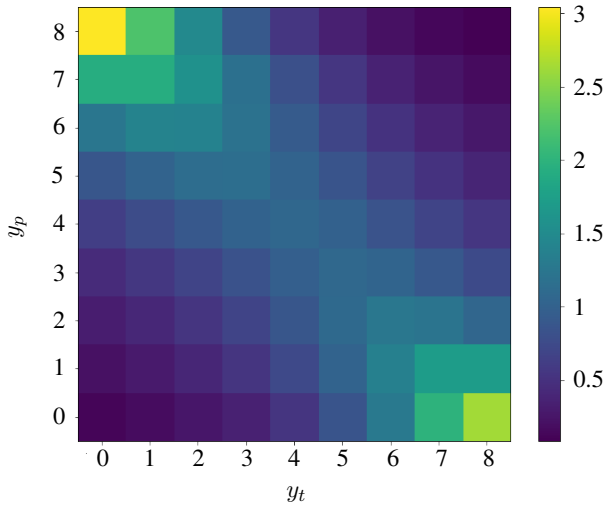

Figure 5. Example of compliance matrix $\boldsymbol{C_{tp}}$ (mm.N^{-1}) for reed 1.

2.2 Characterization of reed mouthpiece interaction

The second test rig (figure 6) is used to characterize the interaction between the mouthpiece and the reed. A mouthpiece (Vandoren BD4 - tip opening = 115.5 1/100 mm), on which a reed is held by a ligature (Vandoren Optimum), is fixed to the test rig. An artificial rectangular silicone lip (30 mm $\times$10 mm $\times$7 mm) moves along the x-axis (parallel to the height of the reed). In this case, the force F_L applied by the artificial lip is measured with a force sensor (Omega LCM703-5). A camera takes pictures of the reed channel for every lip force. This method of measurement is very similar to the one proposed by Taillard [7] but enables to measure the lip force (instead of lip position) automatically on a large number of reeds. It is the same as described in [8].

The lip is moved in steps of 0.2 mm along the z axis thanks to a manual micrometric screw leading to 31 force values. When the lip is in its first position, it does not touch the reed and the channel is fully opened. For each position of the lip until the channel is completely closed,

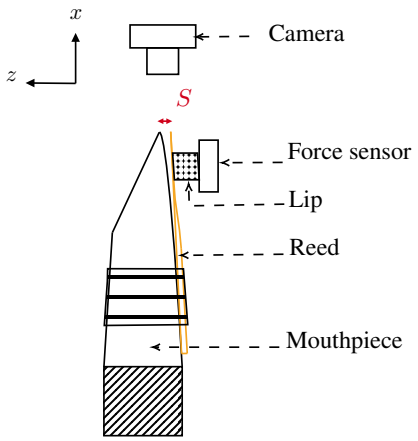

Figure 6. Test rig used to characterize the reed-mouthpiece interaction.

the force signal is recorded and a photo of the channel is taken. In this experiment, the presence of the artificial lip can create light reflections that make the processing more tricky than for the previous experiment. First, the image with the reed at rest is analyzed. The grayscale image is converted into a binary image choosing a threshold value which enables to get a reed contour having a width similar to the mouthpiece contour width, the contours being detected using the function *bwboundaries* of Octave software [11]. Then, for each force, each image is cropped such that the lip and the sides of the reed are not seen. Each image is converted into a binary image choosing a threshold value which enables to get a reed perimeter similar to the perimeter of the reed at rest. The contours of the mouthpiece and reed are detected and the height of the reed channel is estimated along the reed width. An example of a measurement obtained with this system is shown in Figure 7 (crosses). In addition to the total channel surface, the surface is also estimated for 9 different parts centered on y_t, distributed in a similar way to the reed alone.

As the lip positions are imposed, the lip forces are all distinct from all reeds, so it is not practical to study the raw data collected by image processing. Then, for every reed, the 10 (9 segments and total) surface area are modeled as proposed by Gazengel et al. [12]. Using this model, each characteristic is divided into three parts as shown in figure 7 (blue curve). For low lip forces, the linear part of the curve can be approximated by a straight line (in red in figure 7). Its y-intercept indicates the opening surface at rest S_{00} (without lip force). The x-intercept indicates the maximum closing force F_M. At intermediate forces, the reed bends on the curved rails of the mouthpiece. This part can be approximated by a parabola with length E (elbow). Finally, for high forces, the entire reed is in contact with the mouthpiece, leading to complete closure of the channel or to a residual leakage S_{inf}. If there is not any leakage, the measured area should be zero but because of lightning, sometimes the image processing can lead to a residual leakage which is not physical. This piece-wise function is defined by the 4 coefficients S_{00}, F_M, E and S_{inf}. It is of class C^1, and its derivative is continuous.

An example showing the 9 opening sections as a function of F_L is given in figure 8.

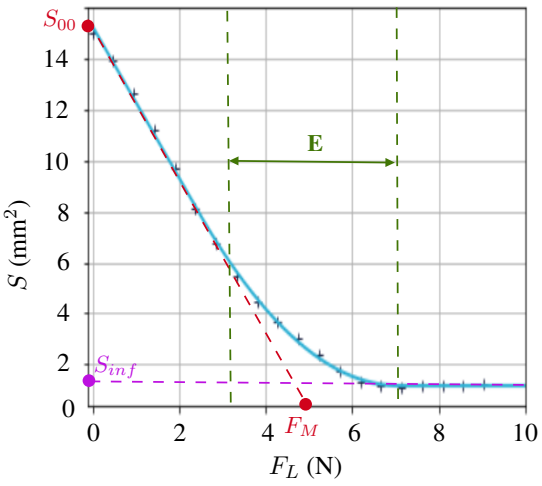

Figure 7. Total opening section of the channel with measurements (crosses), model (blue curve) and associated parameters.

3. DATA ANALYSIS

Eighty-nine reeds were randomly selected among commercial reeds. They are all of the same cut *V12* from the same manufacturer *Vandoren* but of three different strengths: 2 1/2 (29 reeds), 3 (30 reeds) and 3 1/2 (30 reeds). All the reeds were measured with the two test-rigs presented above.

The following data analysis has been realized to confirm and explore the relation between measurements on the reed alone and in interaction with the mouthpiece. All the code used to compute the different parameters and to

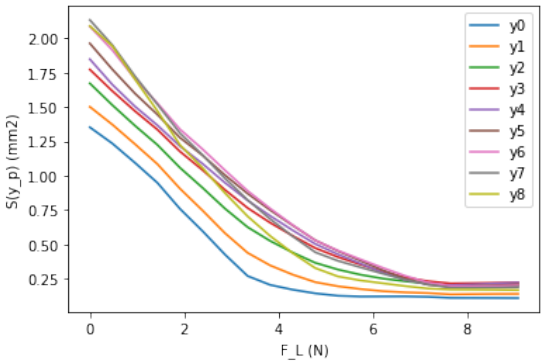

Figure 8. Example of nonlinear characteristics obtained by analyzing 9 opening sections $S(y_p)$ as a function of the lip force for reed 1.

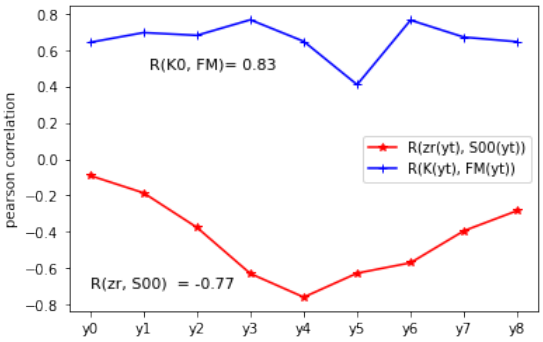

Figure 9. Red curve : $\rho(z_t(y_t), S_{00}(y_t))$ for the reed deflection at rest. Blue curve: Pearson correlation $\rho(K(y_t), F_m(y_t))$ between the reed local stiffness $K(y_t)$ and maximum force $F_M(y_t)$.

analyze the code is made available [1] . In this exploratory work, we mainly used correlations, however, more advanced techniques using mutual information or PCA are currently under investigation.

3.1 Reed tip position at rest

The reed tip position at rest is not supposed to vary according with the test rigs. Therefore we expect a high correlation between the reed tip deflection $z_r(y_t)$ of the reed alone, and the S_{00} parameter obtained in interaction with mouthpiece (segmented and total). We observe that the correlation between the mean rest deflection $\bar{z}_r$ of the reed and the S_{00} of the total opening section is high ($R = -0.77$). However, when comes to the local correlation, the highest correlations are found for the middle of the reed ($t = 4,\ y_t = 0$) which might due to the shape of the mouthpiece (red curve, figure 9).

3.2 Local stiffness

We first investigate how the reed stiffness parameters are correlated. We confirm that the correlation between stiffness K_0 and K_1 is high (0.953), and also the correlation between symmetry parameters y_0 and ΔK (0.867). However all other correlations are rather low (< 0.09). We also explore the relations between the local stiffness $K(y_t)$ (reed alone) and the maximum force $F_M(y_t)$ (reed is in contact with the mouthpiece). First, the Pearson correlation between K_0 and F_M associated to the total area is high (0.83). Then, the Pearson correlation for each position y_t is given by the blue curve in figure 9. We observe that the local stiffness $K(y_t)$ is strongly correlated with the force $F_M(y_t)$, thus confirming the consistency of the measures between the two rigs. Unfortunately, the correlation between y_0 or ΔK and E parameter are too low (< 0.17) to conclude to a relation between asymmetry of the reed alone and the bending of the reed on the mouthpiece.

3.3 Transfer compliance

Finally we analyze, the correlations between each of the 81 compliances c_{tp} (for a position of the rod y_p and a position of the reed tip y_t) and the equivalent parameters $S_{00},\ F_M,\ E,\ S_{inf}$ describing the total opening section between the reed and mouthpiece. Figure 10 shows the results.

We observe that S_{00} and S_{inf} are not correlated to the compliance at any position on the y axis. On the contrary, F_M and E are highly correlated with the 81 transfer compliance. Moreover, the correlation coefficient between F_M and E being 0.54, it suggests that the bending of the reed on the mouthpiece depends on the maximum force F_M. More precisely, the highest correlations between F_M and c_{tp} can be found when the rod is in the middle of the reed, for any position in the reed ($p = 3 \ldots 6,\ \forall t$). When the rod is applied at the edge of the reed ($p = 1, 2, 8, 9$), the correlation reaches its maximum value close to the rod position (2 to 3 segments around the rod position).

[1] https://git-lium.univ-lemans.fr/tahon/reedsml.git

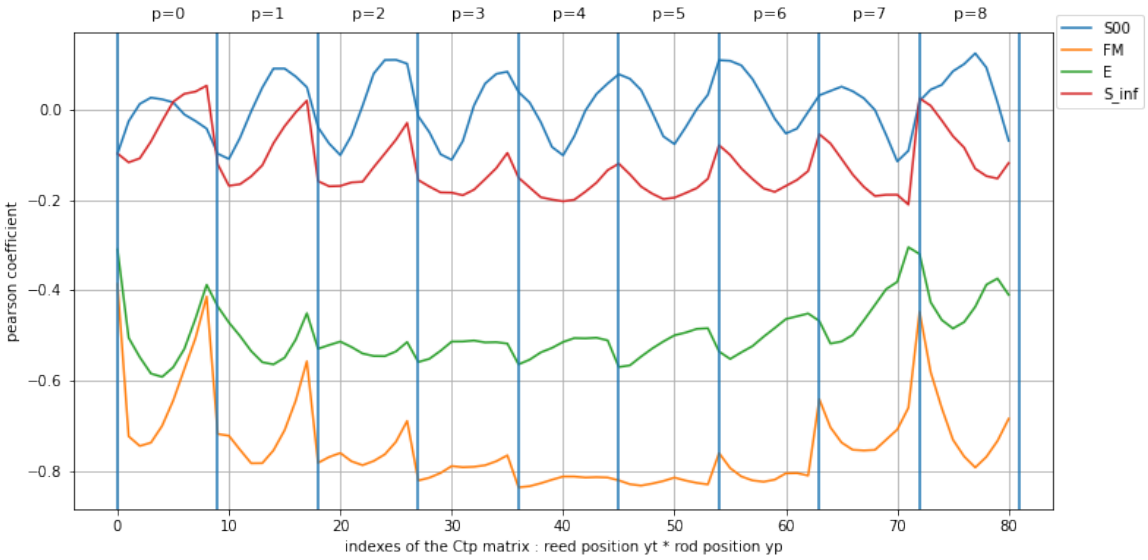

Figure 10. Pearson coefficient between the transfer compliance c_{tp} and the four mouthpiece-reed interaction parameters. The abscissa corresponds to the flatten matrix coordinates : $9 \times p + t$. For instance, if the rod position is at $p = 2$ and the observation of the reed deflection is at $t = 1$, the abscissa will be $2 \times 9 + 1$. Blue vertical lines indicates a change of position of the rod y_p.

4. CONCLUSION

This study used two different test rigs to experimentally characterize 89 clarinet reeds.

The first employs a clamped reed with a pointed tip that exerts force at a predetermined distance from the reed tip. First, it enables the measurement of local stiffness. Second, an image processing measures the reed tip displacement. This enables to get the reed tip position at rest and the transfer compliance matrix (ratio between the tip displacement and force at different coordinates). The local stiffness can be described by a parabola (3 parameters).

The second test rig employs a reed mounted on a clarinet mouthpiece, with an artificial lip exerting a force on the reed. It uses image processing to measure the height of the reed channel. This leads to the nonlinear characteristics (force-section) that are modeled using 4 parameters.

The analysis of the relation between the 2 data sets shows that the reed tip position at rest is consistent for both test rigs. The maximum local stiffness K_0 is strongly correlated to the maximum force F_M derived from the total opening section measured on the mouthpiece. At this stage, the asymmetry measured on the reed alone does not correlate with any parameter obtained with the reed + mouthpiece system. The transfer compliance is highly correlated with the maximum force F_M of the total opening section when the point force is applied in the middle of the reed, indicating that the force applied on the sides have a small effect on F_M. Finally, the correlation coefficient between F_M and the elbow E suggests that the bending of the reed on the mouthpiece depends on the maximum force F_M.

Deeper investigations will be conducted with more advanced data analysis such as Principal Components Analysis and entropy based approaches. Future work will use these two test rigs in parallel to perceptive tests in order to try to determine a link between physical parameters and subjective descriptors.

ABSTRACT

This study aims to quantify the reproducibility of 3D-printed soundboards for string musical instruments by comparing the frequency responses of ukulele tops made of three materials: Engelmann spruce (traditional tonewood), Chilean laurel (local tonewood), and PLA+ (3D printing material). Traditional Latin American luthiers fabricated the soundboards and the PLA+ plates were produced using FDM printing.

The frequency response of free soundboards and admittance measurements coupling the plates to printed bodies were performed. Pearson correlation coefficients assessed the similarity between free plates' responses within each material. As expected, the results show notable variability in the wooden plates: correlations between laurel plates range from 0.19 to 0.50, and between spruce plates, from 0.36 to 0.65. In contrast, the PLA-printed plates show high consistency, with correlations close to 0.94. Similar trends were obtained comparing admittance measurements in plates coupled to printed soundboxes, although the correlation values decrease significantly when compared to those of the free plates. These findings suggest that 3D printing offers promising consistency for the construction of reproducible musical instruments, which may benefit not only the commercial manufacturing of instruments but also research based on them.

Keywords: *3D-printing, 3D-printed guitar, guitar making consistency*

1. INTRODUCTION

One of the major challenges in the construction of string instruments is reproducibility. Even when working with wood from the same trees, using identical techniques and following parallel processes to ensure identical environmental conditions, the resulting instruments will still differ. This is due to the intrinsic variability of wood [1]. This difficulty in achieving consistent construction, combined with the rapid evolution of digital design and manufacturing techniques, has led to the proposal of 3D printing as an alternative to traditional fabrication methods [2-4]. This raises the question: how reproducible are instruments made using these techniques, and how does this reproducibility compare to traditional materials? To address this question, a vibroacoustic study of ukulele soundboards was conducted. The study involved comparing the frequency response of three sets of soundboards made from different tonewoods and 3D printing material. The response was measured under free boundary conditions and when coupled to 3D-printed resonance boxes, and the comparison was done using the Pearson correlation coefficient.

2. METHODS

This study selected three materials to fabricate ukulele soundboards: Chilean laurel (*Laurelia sempervirens*), Engelmann spruce (*Picea engelmannii*), and PLA+. The three materials' density (ρ) and elastic constants (E_L and E_R) were measured. For the wooden samples, the elastic constants were obtained applying Caldersmith's equations [5], following the method proposed in [6]. For PLA+, tensile tests were conducted on specimens with the same orthotropic geometry as applied in the soundboard printing. The tensile tests followed the ASTM D638 standard, using a Type IV specimen. The equipment used was an Instron testing machine, and the tests were conducted at a speed of 50 mm/s. All tests were repeated on three different samples of each material.

The soundboards were fabricated once the materials were characterized, including the internal bracing structure. Fig. 1 shows (a) a printed soundboard, (b) a template for constructing the wooden soundboards and (c) a 3D-printed resonance box. The wooden soundboards were crafted by local luthiers. Unlike traditional construction, the ukulele soundboards were made from a single piece, rather than by joining two identical halves. The bracings were made using Spanish Cedar (*Cedrela odorata*). (see Fig. 2). The plates were printed with orthotropic geometries, with the direction of greatest stiffness aligned parallel to the string direction.

The frequency response of the soundboards was analyzed under free boundary conditions supported by elastic bands. A Stanford SR780 spectrum analyzer generated a swept sine from 20 Hz to 1 kHz. The signal was amplified using a Gemini XGA2000 amplifier and fed into a loudspeaker, which excited the plates. The response was recorded using a PCB 356A14 micro accelerometer connected to a PCB 408E09 signal conditioner. The signal was then returned to the spectrum analyzer, obtaining the frequency response spectrum for each plate. To quantify the degree of similarity, Pearson's correlation coefficient (r) was used [7]:

$$r = \frac{\Sigma(X_i-\bar{X})\Sigma(Y_i-\bar{Y})}{[\Sigma(X_i-\bar{X})^2\Sigma(Y_i-\bar{Y})^2]^{1/2}}, \quad (1)$$

Figure 1. (a) Printed soundboard, (b) Template for constructing the wooden soundboards and (c) 3D-printed resonance box.

Figure 2. Wooden soundboards.

where X and Y are the two datasets being compared, and $\overline{X}$ and $\overline{Y}$ are their respective means. This coefficient is a statistical measure that quantifies the linear relationship between two variables. It ranges from -1 to 1, where: (a) r = 1 means a perfect positive correlation (both variables increase together, (b) r = -1 means a perfect negative correlation (one variable increases while the other decreases), (c) r = 0 means no correlation (the variables are independent). The usefulness of this coefficient has been demonstrated in various studies where it was necessary to compare spectra obtained through different techniques as Raman Spectroscopy, Infrared Spectrometry, among others [8-10].

After characterizing the soundboards, they were glued to 3D-printed ukulele bodies. The assembled bodies were again supported on elastic bands, and their admittance was measured at the bridge position. This was done using a PCB 086C03 impact hammer and a PCB 356A14 micro accelerometer. The measurements were performed using the ObieApp software (see Fig. 4). The resulting spectra were again compared using Pearson's correlation coefficient.

3. RESULTS, ANALYSIS AND DISCUSSIONS

Table 1 presents the results of the measured properties for the different materials. Additionally, it indicates from which specific plates each soundboard plate was extracted.

Fig. 3 shows the spectra obtained for the printed plates, while Fig. 4 presents the spectra associated with the wooden plates. In each case, a zoomed-in view is included to observe the low-frequency behavior. It is possible to observe significant differences in the spectra of the wooden plates (Fig. 3a,b), while more similar behaviors are observed in the printed plates (Fig. 3c). The quantification of these similarities is shown in Fig. 4.

Table 1. Properties of the applied materials

Material	E_L (GPa)	E_R (GPa)	ρ (kg/m³)	Soundboard
Engelmann Spruce A	7.96 ± 0.66	0.70 ± 0.06	317 ± 11	1 - 2
Engelmann Spruce B	8.40 ± 0.47	0.59 ± 0.04	331 ± 8	3
Chilean Laurel A	16.23 ± 1.73	0.83 ± 0.09	505 ± 24	1 - 2
Chilean Laurel B	10.98 ± 1.17	0.77 ± 0.08	513 ± 24	3
PLA+	2.05 ± 0.03	1.83 ± 0.04	1039 ± 214	1 - 2 - 3

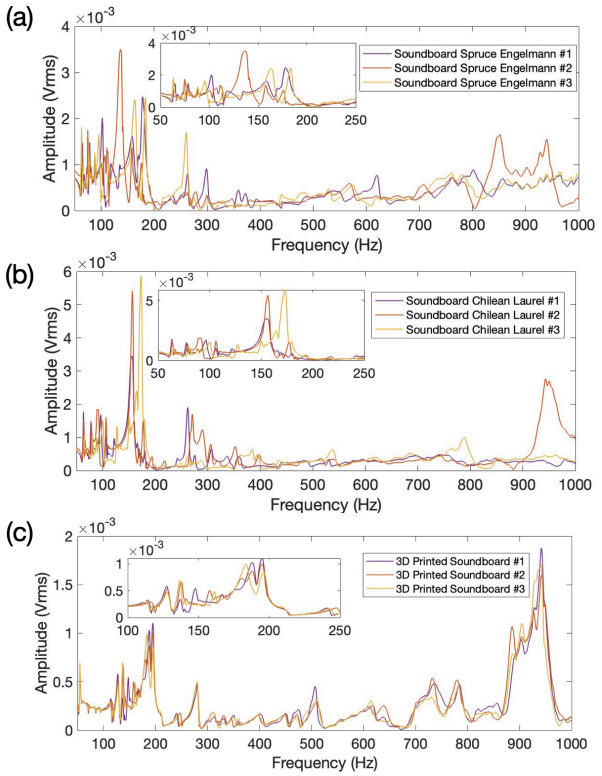

Figure 3. Measured spectra for (a) Spruce Engelmann soundboards, (b) Chilean Laurel soundboards, and (c) 3D-Printed soundboards.

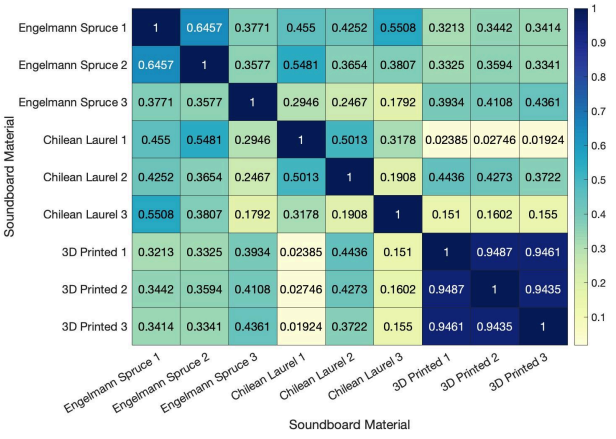

Figure 4. Pearson correlation coefficient obtained for each pair of plates.

Correlations between laurel plates range from 0.19 to 0.50, and between spruce plates, from 0.36 to 0.65. In contrast, the 3D-Printed plates show high consistency, with correlations close to 0.94. Similar trends were obtained comparing admittance measurements in plates coupled to printed soundboxes, although the correlation values decrease significantly when compared to those of the free plates (see Fig.5). In the case of the wooden soundboards, it can be observed that those made from the same plate have a higher correlation coefficient when compared to each other.

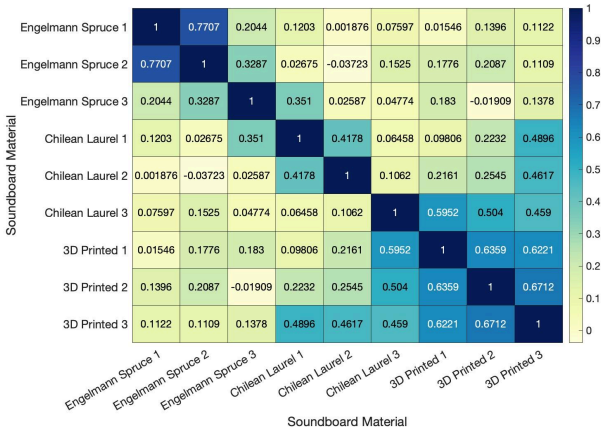

Figure 5. Pearson correlation coefficient obtained for each pair of plates coupled to 3D-Printed soundboxes.

4. CONCLUSIONS

Resonance plates for ukuleles have been made from different materials, including a traditionally used wood, a local wood, and PLA+ (a 3D printing material). The reproducibility of their vibratory behavior was assessed through acoustic response and admittance tests on both free plates and plates coupled to 3D-printed resonance boxes. The similarity between resonance spectra was measured using the Pearson Correlation Coefficient, showing that 3D-printed plates generally exhibit better reproducibility in their responses compared to wooden plates.

The fact that the Pearson Correlation Coefficient decreased with the coupled bodies (despite these being 3D printed and therefore expected to have the same level of reproducibility as the soundboards) highlights the relevance of the vibratory behavior of elements that are often overlooked, difficult to control, measure, and even model numerically, such as adhesives and joints between parts.

In any case, the consistency observed in the behavior of the printed parts could be useful for exploring other factors, such as how geometry affects the acoustic behavior of individual components from traditional instruments, while eliminating variability due to material differences.

These results highlight the potential of 3D printing as a manufacturing method that offers greater consistency in vibratory behavior, which could be advantageous for instrument design and production.

ABSTRACT

Crafting a guitar demands expertise and skill from the artisan in selecting the appropriate tonewood and working with it. Despite these efforts, the outcome remains highly unpredictable. The above is due to inherent variability in material properties and manufacturing procedures. In contrast, 3D printing, coupled with parametric modeling, enables precise control over structural characteristics, replicability, and quick prototyping. Furthermore, the printing process offers potential benefits, including reduced waste generation and the use of bio-based materials.

In this work, an interdisciplinary team of luthiers, designers, and scientists designed, constructed, and characterized a scaled-down, fully functional guitar with a modular design, enabling its fabrication in desktop 3D printers. Acoustic measurements were conducted compared to a mass-produced guitar, highlighting the need to improve certain key aspects of the printed one, such as sustain and low-frequency response. Despite that, the results pave the way for future studies to optimize materials and techniques to enhance the acoustic quality of 3D-printed instruments.

1. INTRODUCTION

The variability of wood's mechanical properties has been a significant challenge in consistently building musical instruments such as the guitar [1]. Considering this, additive digital manufacturing techniques emerge as an alternative to traditional instrument-making, allowing not only the replication of conventional models but also the development of new design alternatives that would be impossible to achieve with subtractive or manual techniques [2]. Regarding string instruments, preliminary studies have explored the FDM printing of functional violins and ukuleles [3-5].

This work presents a functional 3D-printed guitar model, designed as an assemblable modular structure and manufacturable using desktop 3D printers. The model has undergone acoustic studies to compare specific timbral properties with those of a low-cost, mass-produced wooden guitar. The sound production when playing open strings has been analyzed, and the instruments' frequency content and time response have been compared.

2. GUITAR DESIGN

At the beginning of the research, specific fundamental characteristics were established for the 3D-printed guitar model:

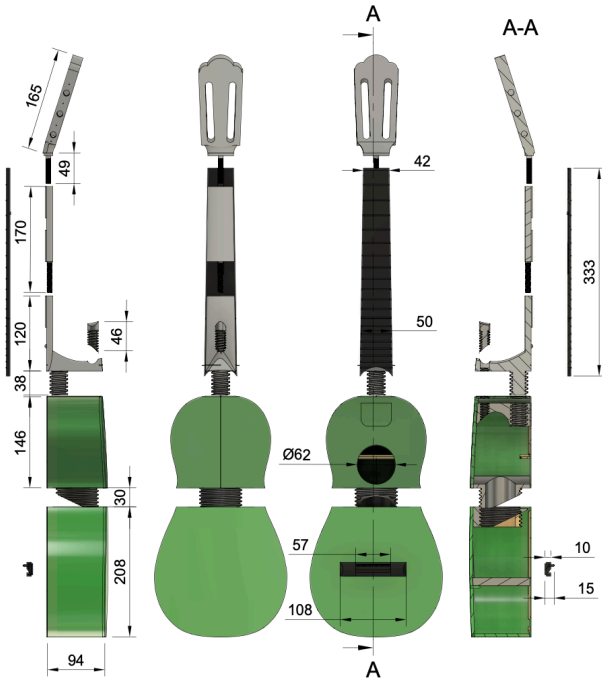
1. It had to be manufactured using desktop 3D printers with an approximate build volume of 220 mm × 220 mm × 220 mm. This decision aims to facilitate the instrument's fabrication in different work environments.

2. IIt needed to be easily assembled, minimizing the use of adhesives.

3. It had to be functional and capable of standard tuning, like a traditional acoustic guitar.

All these characteristics align to create a replicable model in manufacturing and assembly, making it accessible to audiences interested in instrument fabrication. Based on these requirements, a modular, thread-assembled design was proposed, inspired by an 1886 Torres model [6] and Latin American instruments with a *golpeador*. In these traditional chordophones, the section of the soundboard that covers the upper bout is overlaid with a rigid and dense wood.

Given the limited printing dimensions, the proposed design corresponded to a 1/4-scale guitar with a vibrating string length of 480 mm (see Fig. 1).



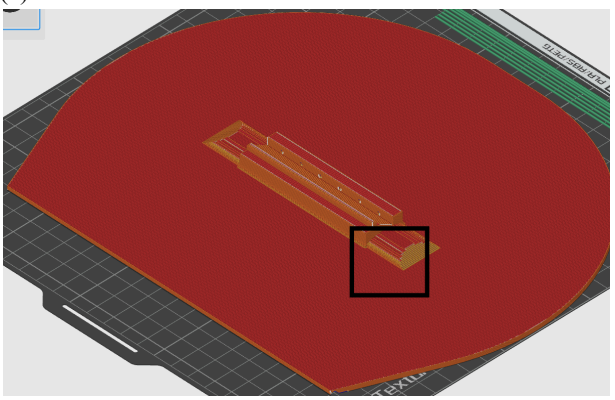


Figure 1. Main Dimensions of the Proposed 1/4 Guitar Model. The vibrating length is 480 mm.

3. MODEL SLICING

The slicing process was carried out using the open-source software Orca Slicer. The aim was to impart orthotropic properties to the printed components through specific printing parameters. To achieve these properties, printing directions were assigned following the grain orientation of the wood traditionally used in guitar making. For example, in the soundboard case, printing patterns were designed to align the primary strength direction to the strings, following the fiber orientation found in traditional soundboard construction. Fig. 2 shows details of the printing directions in the soundboard and bridge.

(a)

(b)

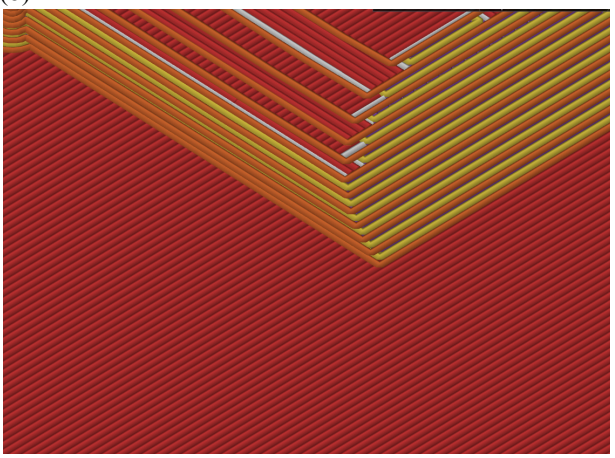

Figure 2. Printing orientation of the soundboard and bridge (a) View of the soundboard with the bridge attached. (b) Close-up showing details of the preferred orientations.

4. INSTRUMENT MANUFACTURING

PLA+ was used for manufacturing. Preliminary material characterizations were performed and elastic modulus measurements were conducted using tensile tests. The printing patterns corresponded to 100% infill of (a) longitudinal fibers "L" (aligned with the tensile direction) and (b) transverse fibers "T" (perpendicular to the tensile direction). Using a Type IV specimen, the tensile tests followed the ASTM D638 standard. The equipment used was an Instron testing machine, and the tests were conducted at a speed of 50 mm/s. The measured density was $\boldsymbol{\rho}$ = (1039 ± 214) kg/m³, with elastic moduli of $\mathbf{E_L}$ = (2.05 ± 0.03) GPa and $\mathbf{E_T}$ = (1.83 ± 0.04) GPa.

The printing time with a Bambu Lab X1 Carbon Combo printer was approximately 50 hours, while the assembly time was around 5 hours. The assembly process required post-processing of components, including support removal, thread cleaning, and minor adjustments.

Figure 3. 3D-Printed parts of guitars.

Finally, approximately 1 kg of filament was used. Fig. 3 shows various printed components. The tuning pegs and strings used are traditional. The guitar was strung with high-tension strings. Finally, Fig. 4 shows a fully assembled guitar.

Figure 4. Fully assembled printed guitar.

5. ACOUSTIC CHARACTERIZATION

For the acoustic characterization of the 3D-printed guitar, certain timbral attributes were compared with those of a reference guitar. The study involved recording the sound produced (a) when plucking each string individually in open position and (b) when strumming all strings open simultaneously.

The reference instrument was a 3/4 guitar (540 mm vibrating length), made of wood, mass-produced, and low-cost. This instrument was chosen for being the closest in price and size to the 3D-printed guitar.

The recordings were conducted in a semi-reverberant room, with the strings manually excited at L ~ (vibrating length)/3. A Dayton EMM-6 microphone was positioned 10 cm from the soundhole of each guitar, and a Focusrite Clarett interface was used for signal acquisition. The sound produced by each guitar was analyzed in both the time domain and the frequency domain.

In the time domain, the decay time was studied following the approach used in [7]. The RMS envelopes were obtained, and in the decay region, a function of the form $A_0e^{-t/\tau}$ was fitted. In this function, τ is the exponential time constant and corresponds to the time at which the signal amplitude has decayed to 36.8% of its maximum value. The results are shown in Fig. 5. It can be observed that while the decay constants for the strings tuned to E4 (~330 Hz) and D3 (~147 Hz) are practically the same, the strings tuned to A2 (~110 Hz) and E2 (~82 Hz) exhibit significantly longer decay times in the reference guitar. Despite the previous results, when evaluating the decay of the instruments when strummed with open strings, the decay times were practically identical.

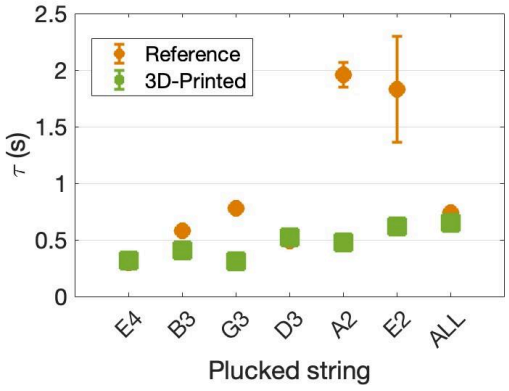

Figure 5. Time decay constant for open strings

In the frequency domain, the Power Spectral Density (PSD) was analyzed for each case. In general, the most significant differences appear in the low and mid-frequency ranges. In the low frequencies, the reference guitar exhibits a stronger response between 100 Hz and 200 Hz, whereas the 3D-printed guitar shows areas of greater response in the mid-frequency range. Figs. 6–8 show examples of the PSD obtained for the E2, E4, and all open strings cases.

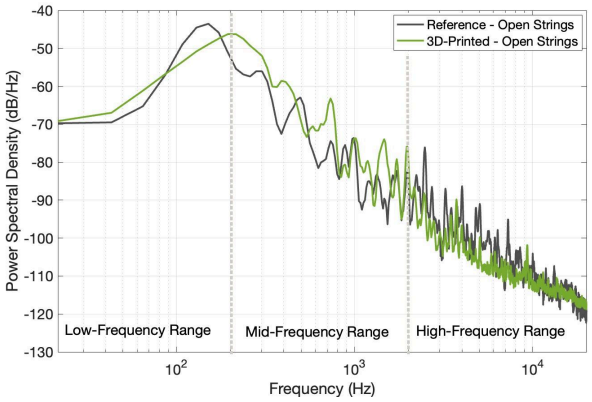

Figure 6. PSD for all open strings strummed.

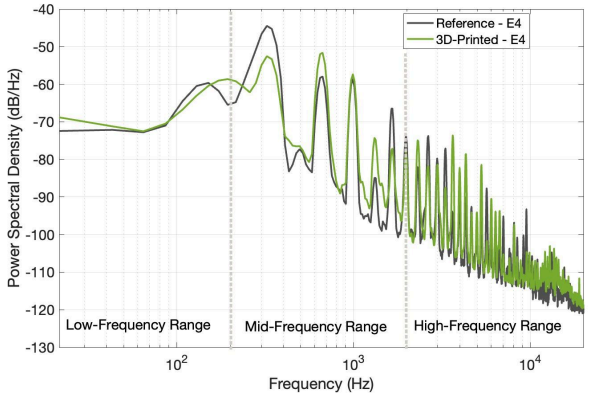

Figure 7. PSD for plucked E4 string.

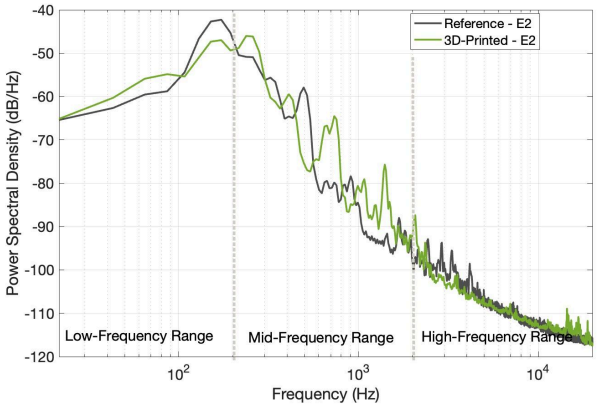

Figure 8. PSD for plucked E2 string.

6. CONCLUSIONS

Details on the design, slicing, and fabrication of a fully functional 3D-printed modular guitar were presented. The manufacturing time for the model is approximately 55 hours in a desktop machine, requiring around 1 kg of PLA+ filament.

The results demonstrate the feasibility of producing functional, low-cost instruments with rapid prototyping capabilities. This opens possibilities for both the construction of study guitars made from alternative, low-cost materials aimed at beginners and the development of scientific research using instruments built in a more controlled way compared to traditional wooden guitars.

Acoustic analyses generally show shorter decay times than those observed in wooden guitars, highlighting an area for improvement in future versions of the instrument. Additionally, a weaker low-frequency response is observed when compared to the reference instrument, which should also be addressed in the next stages of research.

ABSTRACT

This study evaluates perceptual and acoustic differences in timbral characteristics between two guitars: (1) a wooden, mass-produced, low-cost guitar designed for beginners and (2) a 3D-printed guitar. Blind listening tests were conducted with seven students specializing in musical performance, composition, and music theory. An experienced performer played identical musical pieces on both instruments—strumming, arpeggios, open strings, and harmonics—under controlled recording conditions. Participants rated the perceived timbral characteristics in low, mid, and high-frequency ranges and sustain for each recording using a five-point Likert scale.

Results showed considerable variability in participant responses, suggesting that the timbral differences between instruments were not easily distinguishable. The most significant difference was observed in the sustain rating, which was generally lower for the printed instrument. A preliminary acoustic analysis was conducted using the same evaluated recordings, and the results aligned with the perceptual findings. These results highlight the timbral characteristics of the 3D-printed guitar that require further development and demonstrate the potential of 3D printing in musical instrument manufacturing.

1. INTRODUCTION

The application of digital fabrication techniques, including 3D printing, has expanded into musical instrument manufacturing [1-3]. Given the increasing interest in 3D-printed instruments, it is important to assess how their timbral characteristics compare to those of traditional materials instruments. An example is presented in [4], where the sound quality of a 3D-printed ukulele and a wooden one is compared.

This work presents the results of perceptual evaluation and acoustic characterization of the timbre in two guitars: a mass-produced, low-cost acoustic guitar and a 3D-printed guitar made of PLA+. The evaluation was conducted through an acousmatic listening test, where participants evaluated pre-recorded performances of identical musical excerpts played on both instruments.

2. METHODS

The instrument under evaluation was a 1/4-scale 3D-printed guitar made of PLA+ with a vibrating string length of 480 mm. This instrument was designed to be a functional, low-cost alternative that could be produced quickly. The printing process required 50 hours using a Bambu Lab X1 Carbon Combo 3D printer, followed by approximately 5 hours of manual assembly. The total material consumption was 1 kg of PLA+ filament, with an estimated cost of 35 USD (see Fig. 1).

As a reference, we selected a 3/4-scale, mass-produced acoustic guitar designed for beginners, with a vibrating string length of 540 mm. This model was the smallest commercially available, and it had a price comparable to the manufacturing cost of the printed guitar (approximately 50 USD).

An acousmatic blind listening test was conducted with seven advanced music students to evaluate the sound of the printed guitar. A professional guitarist performed the same musical excerpts on both instruments, including strumming, arpeggios, open strings, and harmonics, which were referred to as 'categories' of playing. The recordings were made on the same day and location, using Dayton Audio EMM-6 microphones placed 50 cm from the instruments' soundholes. For each recording, participants used a five-point Likert scale to rate four perceived timbral characteristics: the frequency content in the low, mid, and high ranges, as well as sustain.

Each pair of recordings was presented twice consecutively for each category while maintaining the same order (e.g., for strumming, first the reference guitar, then the 3D-printed guitar). Across categories, the order was alternated randomly to reduce bias (e.g., a participant might hear the 3D-printed guitar first in the strumming category but the reference guitar first in the arpeggio category). The listening tests took place in a semi-reverberant room, where each participant was positioned approximately one meter in front of a pair of studio monitors. Example recordings of both guitars being strummed can be accessed at the following link.

Figure 1. Professional guitarist recording the 3D-Printed Guitar, Prof. Héctor Sepúlveda.

In order to compare the perceptual evaluations, acoustic analyses were conducted on the recorded audio samples. The spectral magnitude was obtained using the open software Audacity using a Hamming window of size 4096. The analysis was done for the complete audio recordings to provide a general assessment of their frequency content.

3. RESULTS, ANALYSIS, AND DISCUSSION

Tables I–IV show the means and standard deviations σ of the participants' evaluations. In the Strumming category (Table I), the most significant difference was observed in the sustain evaluation, where the 3D-printed guitar scored 3.0 ± 0.0, while the reference guitar scored 3.7 ± 0.5. These results suggest a clear perception of longer sustain in the reference guitar. The treble, midrange, and bass ratings were relatively close, with only minor differences.

For the Arpeggio category (Table II), the sustain rating again showed the most significant difference, with a mean of 2.4 for the 3D-printed guitar compared to 2.9 for the reference guitar. Although this suggests a perceptible difference, the higher standard deviation (0.9) for the reference guitar reduces the statistical significance of this result. Interestingly, although the difference is small, the bass frequencies were rated slightly higher for the 3D-printed guitar (3.1) than for the reference guitar (2.9).

In the Open Strings category (Table III), the most pronounced difference was observed in the sustain rating, with the reference guitar scoring 4.1 ± 0.9, compared to 3.1 ± 1.2 for the 3D-printed guitar. Additionally, the treble rating was noticeably lower for the 3D-printed guitar (2.7 ± 1.0) than for the reference guitar (3.3 ± 0.8), indicating that the printed instrument may have a perceived loss of brightness in open strings.

Finally, in the Harmonics category (Table IV), the most significant difference again appeared in the sustain rating, where the reference guitar scored 4.1 ± 0.7, while the 3D-printed guitar scored 3.4 ± 1.0. The ratings for treble, midrange, and bass, with minor variations, remained pretty close.

Overall, the results indicate a consistent trend of lower sustain ratings for the 3D-printed guitar across all categories. Additionally, the printed instrument's treble

ratings tend to be slightly lower, particularly in open strings. However, midrange and bass frequencies showed comparable ratings; in some cases, the 3D-printed guitar matched or slightly outperformed the reference instrument. Despite these tendencies, the large standard deviations in several evaluations suggest that individual perceptions varied significantly, making it difficult to establish definitive conclusions.

Table 1. Results for the Strumming category

Category: Strumming				
Frequency Range	3D-Printed guitar		Reference guitar	
	Mean	σ	Mean	σ
High	3,0	0,8	3,1	0,7
Mid	3,9	0,7	3,7	1,1
Low	3,4	0,8	3,4	0,5
Sustain	3,0	0,0	3,7	0,5

Table 2. Results for the Arpeggio category

Category: Arpeggio				
Frequency Range	3D-Printed guitar		Reference guitar	
	Mean	σ	Mean	σ
High	2,9	0,7	3,0	0,6
Mid	3,4	0,5	3,6	0,8
Low	3,1	0,7	2,9	0,9
Sustain	2,4	0,5	2,9	0,9

Table 3. Results for the Open Strings category

Category: Open Strings				
Frequency Range	3D-Printed guitar		Reference guitar	
	Mean	σ	Mean	σ
High	2,7	1,0	3,3	0,8
Mid	3,4	1,1	3,6	0,8
Low	3,3	0,8	3,7	0,5
Sustain	3,1	1,2	4,1	0,9

Table 4. Results for the Harmonics category

Category: Harmonics				
Frequency Range	3D-Printed guitar		Reference guitar	
	Mean	σ	Mean	σ
High	3,1	0,4	3,4	1,1
Mid	3,7	0,8	3,7	0,5
Low	3,0	0,8	3,0	0,8
Sustain	3,4	1,0	4,1	0,7

Regarding the acoustic analyses, Figs. 2-5 presents the results for the four categories. The graphs have been divided into three bands: the low range (20 Hz to 200 Hz), the mid-range (200 Hz to 2 kHz), and the high range (2 kHz to 20 kHz). In all categories, the overall response in the low range is similar, except around 100 Hz and 200 Hz, where the response of the reference guitar is greater. In the mid ranges, certain areas stand out for the 3D-printed guitar, particularly between 180 Hz and 1.2 kHz. In the high-frequency range, the response remains similar up to 4 kHz, after which the response of the 3D-printed guitar becomes more prominent.

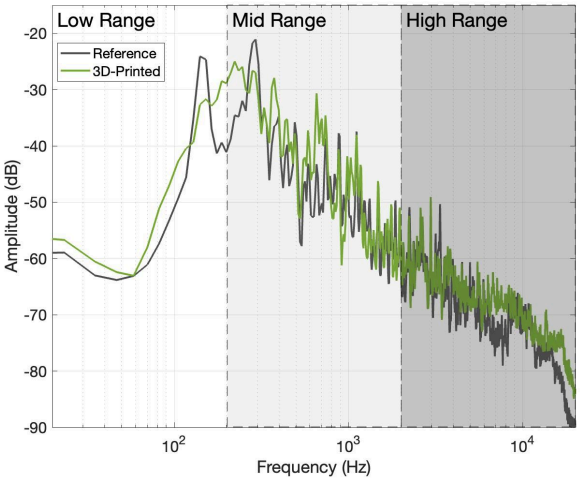

Figure 2. Spectral Magnitude for the Strumming category.

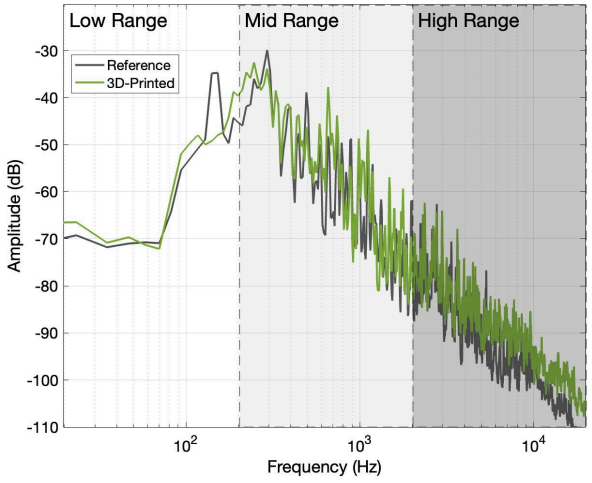

Figure 3. Spectral magnitude for the Arpeggio category.

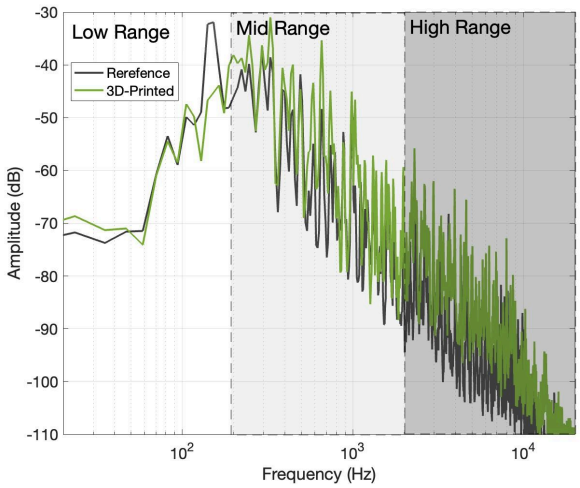

Figure 4. Spectral magnitude for the Open String category.

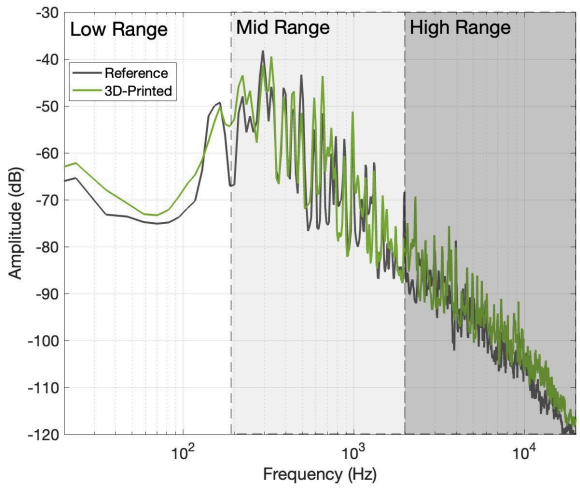

Figure 5. Spectral magnitude for the Harmonics category.

Certain correspondences can be observed between the perceptual and acoustic results. For instance, the spectral analysis showed that both guitars have similar low and middle-frequency responses, with localized differences (a greater response of the reference guitar between 100 Hz and 200 Hz and specific emphasized frequencies in the printed guitar). These results align with the perceptual results, where the ratings associated with bass and mid frequencies were similar across all categories.

The most significant difference is found in the treble response. Acoustic analyses showed that the printed guitar exhibits a more prominent response above 4 kHz. However, the printed guitar received lower treble ratings in the open strings category in the perceptual evaluation. This discrepancy, along with the perception of larger sustain in that category, could be because the perception of treble depends not only on spectral energy in the high-frequency range but also on other factors, such as the distribution of energy over time.

Regarding sustain, due to the characteristics of the playing style, it was impossible to study the strumming, arpeggio, and harmonics categories. However, frequency analysis was conducted for the open strings category. Fig. 6 shows spectrograms for both guitars. Both cases were plotted with the same time scale to facilitate the comparison. It can be observed that the reference guitar sounds for a longer time than the 3D-printed guitar. Although these results agree with the perceptual evaluation and serve for preliminary comparisons, it is necessary to conduct more measurements, focusing on the instrument's timbral properties.

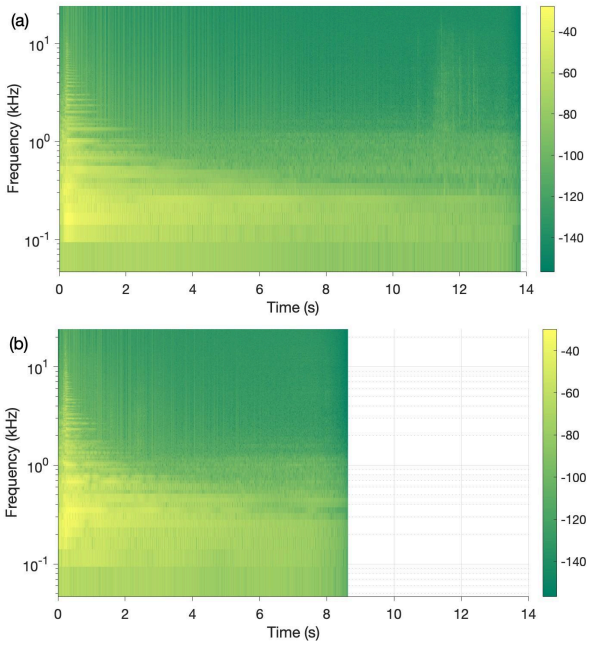

Figure 6. Spectrogram for the Open String category. (a) Reference guitar. (b) 3D-Printed guitar.

4. CONCLUSIONS

The results exhibited substantial variation in participant responses, indicating that the instrument's timbral differences were not easily perceived. Regarding the frequency content, no relevant perceptual differences were evaluated in the midrange and bass frequencies, while the high-frequency content was rated lower for the 3D-printed guitar. On the other hand, acoustic analyses showed differences only in specific frequencies in the low and mid ranges (which aligns with the perceptual evaluation). At the same time, the printed guitar displayed higher content in frequencies above 4 kHz (which differs from the general evaluation). This difference may be due to factors such as the listening conditions. For example, poor performance of the monitors above 4 kHz or background noise.

The most significant difference in the rating of the printed guitar compared to the reference instrument was observed in the sustain criterion, where the PLA+ instrument was evaluated lower in general. This could be solved by using materials with higher density or elastic moduli and optimizing the structural design, particularly of the soundboard and bridge. Although preliminary acoustic results were obtained that align with the perceptual results regarding the sustain, they should be repeated in future stages of the research.

For the perceptual study, several points for improvement were observed. In the future, the number of participants will be increased to improve the statistics. On the other hand, in addition to the evaluations conducted, discrimination tests will be added to assess the randomness of participants' responses. It has also been decided to improve the listening conditions for participants by replacing the studio monitors with hi-fi flat-response headphones so that the listening experience is not affected by the evaluator's position or background noise. Additionally, open-ended questions will be added to assess qualitative responses regarding the sound of each instrument.

Finally, more acoustic analyses remain pending to allow for a deeper study of the acoustic properties of the 3D-printed guitar, which, together with perceptual evaluations, will guide future versions of the instrument.

NUMERICAL DESIGN OF A TRUMPET LEADPIPE: FROM THE NUMERICAL MODEL TO THE EVALUATION OF THE HARDWARE PROTOTYPE

Jean-François Petiot[1*] **Vincent Freour**[2,3] **Keita Arimoto**[3]

ABSTRACT

In a previous work, a machine learning model was trained using numerical simulations in order to predict intonation and playability descriptors of trumpets from the bore geometry [1]. Using this technology, a numerical design procedure was conducted where a new leadpipe geometry was proposed using a bi-objective optimization on the Equivalent Fundamental Pitch (*EFP*) and minimum blowing pressure (*Pth*), computed over five regimes. This recommendation led to a leadpipe numerical prototype that was manufactured by *Yamaha Corporation*, Japan. In this paper, we present recent investigations conducted on this hardware leadpipe prototype in order to compare the performances of the real instrument with the numerical expectations in the design phase. At first, impedance measurements of the prototype were performed, and sound simulations were computed from these measurements to assess the *EFP* and *Pth* descriptors. They were compared to the results of the numerical prototype. In a second step, playing tests with musicians were conducted in order to assess perceived differences between the original and prototyped leadpipe. These results are discussed in light of the potential sources of uncertainties through the whole procedure, from the model to the perception.

1. INTRODUCTION

An interesting mean to study the objective quality of musical instruments is to carry out sound simulations by physical modelling [1]. They constitute a very interesting approach because they allow, by working on a virtual prototype, the exploration of the design space, by the creation of a large number of virtual instruments. The main interest of these simulations is that the sound result is driven by the causes that create the sound, as for a real instrument: if the physical model used is accurate enough to generate simulations in agreement with the real behavior (such as it is perceived by the musician), then the simulations can constitute a predictive tool for the development of the instrument (virtual acoustics) [2].
In recent years, machine learning (ML) has become an essential approach for the modeling of systems. Using this technique, we have developed in previous works [1,4] a procedure for optimizing the leadpipe of a trumpet. Two criteria were considered for the optimization: the Equivalent Fundamental Pitch (*EFP*), which may represent the global intonation of the instrument, and the minimum blowing pressure (*Pth*), which may represent the ease of emission of the note. The procedure led to the definition of an "optimized leadpipe", that was manufactured by *Yamaha Corporation of Japan*.
The objective of this paper is to give the first results about this new leadpipe, mainly by comparing the performances of the real prototype to the theoretical expectations in the design phases, and to compare it to the standard leadpipe.

Section 2 presents the background on the project, mainly the procedure defined to lead to the "optimal" leadpipe. A reminder of the physical model and the bore reconstruction process is proposed. In section 3, the first results are presented. They concern the simulation of instruments from measured or calculated impedances, and the analysis of differences between instruments when played by musicians.

2. BACKGROUND: OPTMIZATION OF THE TRUMPET LEADPIPE

2.1 Sound simulations

In this study, we use a classical elementary model of a brass instrument under playing conditions, described in [2]. The vibrating lips are modeled as a one-degree-of-freedom (1-DOF) outward-striking valve, non-linearly coupled to the air column of the brass instrument. From the input impedance *Ze* of the instrument (calculated or measured), different regimes of the trumpet can be simulated using different virtual musicians. The parameters used for the simulations are described in [1, 4]. Five regimes of the instrument were considered (regime 2 to 6), corresponding to the notes Bb3, F4, Bb4, D5 and F5 (concert-pitch) (Fig. 1).

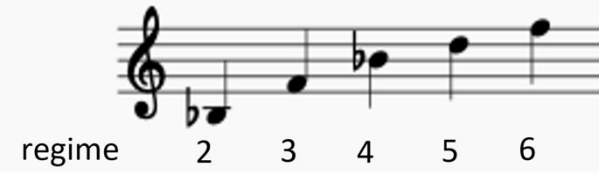

Figure 1. Notes corresponding to the five different regimes simulated on a Bb trumpet (concert pitch)

To characterize the intonation of each regime of a virtual instrument, the Equivalent Fundamental Pitch (*EFP* – Eqn. 1), that represents the deviation in cent of the average playing frequency f_n from a reference frequency f_R, according to natural intervals, was calculated. The reference frequency was chosen arbitrarily according to the common tuning note of the instrument (the regime 4, Bb4) (with $f_R = f_4 /4$, the *EFP* of the regime 4 is then necessarily equal to "0").

$$\overline{EFP_n} = 1200.log_2(\frac{\overline{f_n}}{n.\overline{f_R}}) \quad (1)$$

To characterize the global intonation of each virtual instrument, the global average *EFP* was computed. It corresponds simply to the average value of the absolute values of the *EFP* of all the regimes (2 to 6) (Eqn. 2).

$$\overline{EFP} = \frac{1}{5}.\sum_{k=2}^{6}|\overline{EFP_k}| \quad (2)$$

To characterize the global ease of playing of the instrument, the threshold pressure $P_{th,k}$ of each regime k was obtained by Linear Stability Analysis (LSA) [5]. The sum of the threshold pressure P_{th} for all the regimes was calculated (Eqn. 3).

$$\overline{P_{th}} = \sum_{k=2}^{6}\overline{P_{th,k}} \quad (3)$$

2.2 Optimization of the impedance

The general approach for the optimization of the impedance of a trumpet based on simulations and ML models consists of the following three stages:

Stage 1: Generation of sounds (section 2.1). Sound simulations by physical model are used to create a database of sounds (1000 trumpet samples), with the input impedance of the instrument as an input (modal parameters), and the sound signal as an output. Two descriptors are considered to characterize a virtual instrument: the global average *EFP* (Eqn. 2) and the threshold pressure P_{th} (Eqn. 3),

Stage 2: Supervised learning. ML models are fitted to the database, with the characterization of the impedance Z as an input (modal parameters) and the 9 different features as outputs (EFP_n (n =2, 3, 5, 6) and $P_{th,n}$ (n=2, 3, 4, 5, 6)),

Stage 3: Optimization. Using the previous ML models, the input impedance is optimized by a minimization of two descriptors: global average *EFP* and the threshold pressure P_{th}. A bi-objective optimization is considered, leading to a Pareto front, using a gradient-free method (Genetic Algorithms). An optimal target Z_{opt} was selected.

In addition to these stages, 2 more steps are necessary to obtain a real optimized instrument:

Stage 4: Bore reconstruction (section 2.3). The objective of this stage is to obtain the geometry of the bore that corresponds to the optimal impedance Z_{opt} identified in stage 3 (optimization),

Stage 5: Manufacture of the optimal instrument (section 2.4). Given the geometry of the bore (stage 4), a real instrument can be manufactured and tested with musicians, to assess the efficiency of the approach. Before manufacturing, a smoothing of the initial profile of the leadpipe was applied, to obtain a class C^1 profile (manufacturing of the trumpet leadpipe with a mandrel) Details of stages 1 to 4 are available in [1, 4].

2.3 Bore reconstruction

Instead of optimizing the whole bore of the trumpet (difficult to manufacture), it has been decided to focus only on an important part of the bore: the leadpipe. The leadpipe of a trumpet, located after the mouthpiece and before the tuning slide, plays an important role in the intonation. Its shape is evolutive, generally divergent. At the end of the process, only the leadpipe will need to be manufactured, resulting in a cost-effective and faster solution. The rest of the instrument corresponds to a Yamaha trumpet model for which accurate impedance measurements are available, and called in the next the "S" trumpet.

Six optimization variables were defined in the leadpipe, 5 diameters and one length (Fig. 2). The leadpipe is considered as a juxtaposition of truncated cones. The design variables are defined by vector X=(d_1, d_2, d_3, d_4, d_5, L).

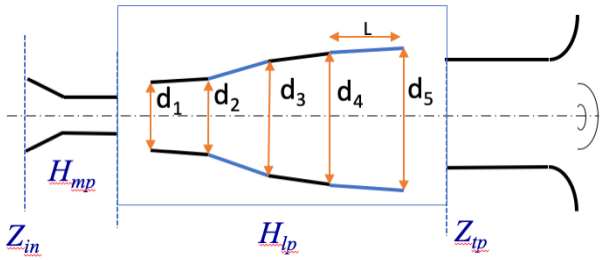

Figure 2. Overview of the bore of the trumpet (from the mouthpiece to the bell), with the definition of the design variables. The optimized part corresponds to the leadpipe, with the diameters d_1 to d_5 and the length L

To obtain the current input impedance of the trumpet, a transmission line model of the impedance has been used [6]. The input impedance of the instrument is a result of a calculation that involves three terms:

- The transfer matrix of the mouthpiece (Yamaha model), denoted as H_{mp}
- The transfer matrix of the four sections of the leadpipe, denoted as H_{lp}
- The input impedance Z_{tp} of the rest of the trumpet (a Yamaha model, S), measured with the CTTM impedance sensor at the entrance of the tuning slide.

Finally, the overall input impedance Z of the whole instrument is calculated as follows (Eq. 4):

$$\begin{aligned} H &= H_{mp}.H_{lp} \\ [P_{in}\ U_{in}] &= H.[Z_{tp}\ 1] \\ Z &= \frac{P_{in}}{U_{in}} \end{aligned} \tag{4}$$

The bore optimization problem of an instrument can be formulated as the search for the optimal geometry X* whose impedance Z fits as best as possible the target impedance Z_{opt}. A Genetic algorithm, NSGAII [7], with 300 individuals per generation, and a budget of 500 generations was used to solve this problem. From the Pareto front obtained at **stage 3**, which provides a range of optimal impedances that promote either a significantly lower *EFP* or a lower P_{th} than the training set and than the commercial trumpets, different target candidates were considered.

Nevertheless, one difficulty we have to face is to find, through bore reconstruction, leadpipe geometries that precisely produce the impedances of the Pareto front (or at least one impedance selected). Indeed, there is no guarantee that a solution to this inverse problem exists or can be easily reached, given the chosen design variables X=(d_1, d_2, d_3, d_4, d_5, L).

In this context, we could only obtain satisfactory bore reconstruction results by selecting a Z_{opt} with a lower *EFP* and P_{th} than commercial trumpets (namely the S trumpet), but located within the training set.

Different target instruments were considered for bore reconstruction. The optimal instrument $Z_{opt\text{-}rec}$ considered for the continuation of the study is presented in Fig. 3. Compared to instrument S, it presents a slight improvement of *EFP* and a decrease of P_{th} of around 70 Pa.

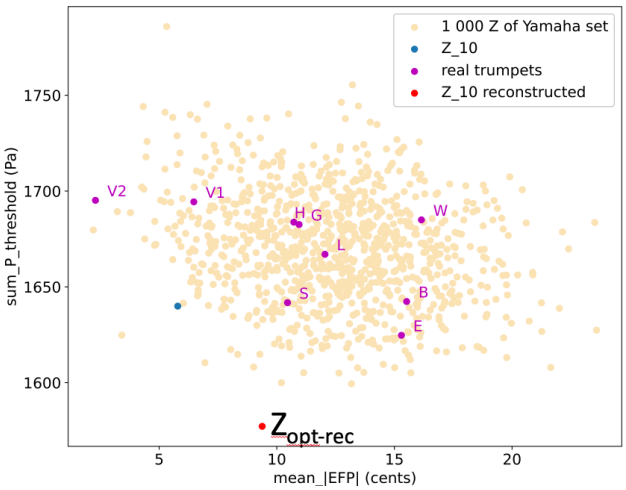

Figure 3. Position of different instruments in the plane of the two descriptors *EFP* and P_{th}: in particular, the Yamaha S trumpet, the reconstructed instrument $Z_{opt\text{-}rec}$ after re-simulation from the input impedance parameters. The training set counts 1000 instruments, corresponding to the beige colored points. The magenta points correspond to measured commercial instruments.

In perspective, one way to overcome this issue of "bore reconstruction" would be to compute a ML model of the descriptors directly from the design data (geometry of the leadpipe), and not from the modal parameters. We actually followed that strategy in another study not reported here, and that we conducted after this first phase of the project [9].

2.4 Manufacturing of the new leadpipe NL

The optimal leadpipe X* =(d_1, d_2, d_3, d_4, d_5, L)*, called NL, was communicated to *Yamaha Corporation* for the manufacturing (after a smoothing of the shape with a degree 4 polynom to have a class C^1 profile). A picture of the NL leadpipe is presented in Fig. 4, together with the current S leadpipe.

Figure 4. Picture of the NL new leadpipe and the S leadpipe

3. RESULTS: COMPARISON OF THE INSTRUMENTS

3.1 Simulations of S and NL

Impedance measurements of the NL prototype were performed, and sound simulations were computed from these measurements to assess the *EFP* and *Pth* descriptors.
Fig. 5 presents the results of the simulations for different versions of the instruments:

- S_{meas} corresponds to the S instrument, from the impedance measured on the real instrument,
- NL_{meas} corresponds to the NL instrument, from the impedance measured on the prototype,
- NL_{th} corresponds to the NL instrument, from the impedance calculated ($Z_{opt\text{-}rec}$) after bore reconstruction,
- $NL_{th\text{-}ycj}$ corresponds to the NL instrument, from the impedance calculated after a degree 4 smoothing of the optimal bore X* =(d_1, d_2, d_3, d_4, d_5, L)*.

Except for regime 6 (note F4), there is a remarkable degree of agreement between the position of the NL instruments resulting from impedance calculations and impedance measurements. This observation gives a good level of confidence in the quality of the Z models and the quality of the leadpipe manufacturing. The only difference is for regime 6, for which the P_{th} of the measured instrument NL_{meas} is slightly larger (+20Pa) than that of the theoretical instruments.
The agreement between the theoretical leadpipe NL_{th} and its version with a degree 4 smoothing $NL_{th\text{-}ycj}$ is excellent, indicating that this regularization has no

visible effect (in fact, it only changes the geometry of the leadpipe by a few hundredths of a millimeter).
The comparison between the S and the NL leadpipes leads to the following comments:

- The pitch of the Bb3 note is slightly higher for the S leadpipe (+30 cents), so the octave Bb3-Bb4 is closer to a theoretical octave (Ratio 2) for the NL instrument than for S. For the other notes, the EFP are very similar for the 2 leadpipes,
- For the note D5, the threshold pressure is higher for the S instrument than for the NL (+ 50Pa). For the other notes, pressures are comparable (lower than 30 Pa).

These results provide indications on the nature of the differences between the S and NL instruments, which must be confirmed by tests in playing conditions.

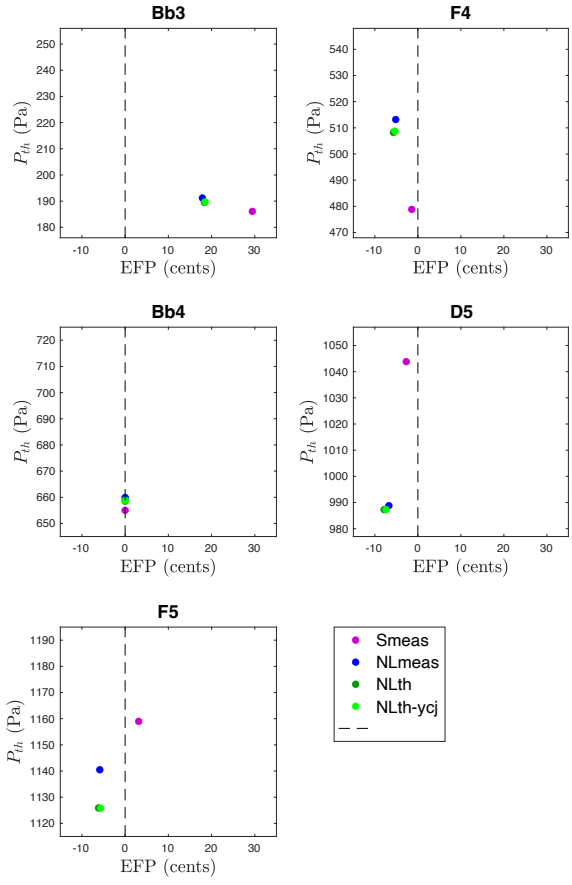

Figure 5. comparisons of the NL and S instruments for the different regimes. Different versions of the NL instruments are considered to estimate the deviation between theoretical and real instruments.

Fig. 6 presents a comparison of the input impedance of instrument NL, measured (NL_{meas}) or calculated ($NL_{th\text{-}ycj}$).

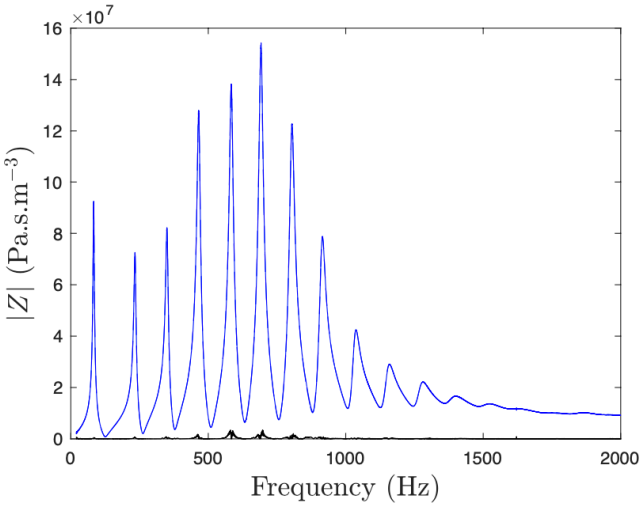

Figure 6. comparisons of the magnitude of the impedance of instrument NL, either measured or calculated. The difference between the 2 curves is presented in black lines.

Results show that the two impedance are very close and that the model agreement between the calculation and the measurements is large.

3.2 Recordings of the instruments and first analysis

The two instruments S and NL were played and recorded by 5 musicians. A series of five notes was recorded, in an ascending then descending arpeggio (Fig 7).

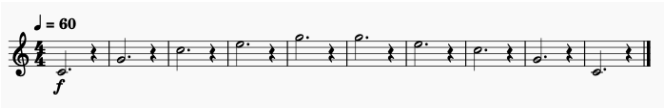

Figure 7. Sequence of notes played be the musicians (Bb writing)

Players were instructed to play as naturally as possible (without pitch corrections). The sounds were recorded with a Zoom H4 recorder (48kHz, 24 bits). Three repetitions of each sequence were performed, for each instrument S and NL.
From the audio recordings, the playing frequency of each note was estimated with the YIN algorithm [7], and similarly to the *EFP*, the deviation (in cent) from natural intervals was computed.

The intonation diagrams of the different notes are presented in Fig. 8, with the error bars corresponding to the 95% confidence interval calculated on the sample size of 3*2*5 = 30 observations.

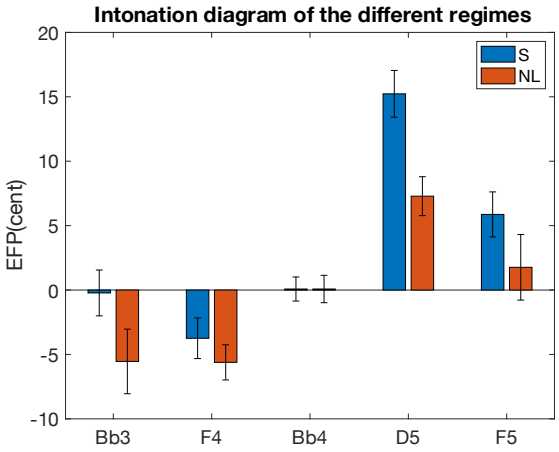

Figure 8. Intonation diagram for the different notes of the trumpet (in cent), with the 95% confidence intervals – Bb4 is the reference note (tuning note).

There are slight differences in intonation between the two instruments:

- Octave Bb3-Bb4 is larger with NL than with S
- Notes D4 and F4 are slightly higher with S than with NL

It is interesting to mention that this relative position of the played notes is in agreement with the relative positioning of the simulated sounds (Fig. 5): simulations can make interesting predictions of the pitch, at least from a relative point of view.

To characterize the spectrum of each instrument, the spectral centroid Sc_n of each regime n was considered, calculated as the power-weighted average spectral frequency (Eqn. 5).

$$\overline{Sc_n} = \frac{\int_0^\infty f.\left|\overline{S(F)_n}\right|^2 df}{\int_0^\infty \left|\overline{S(F)_n}\right|^2 df} \qquad (5)$$

The diagrams of the spectral centroid for the different notes are presented in Fig. 9, with the error bars.

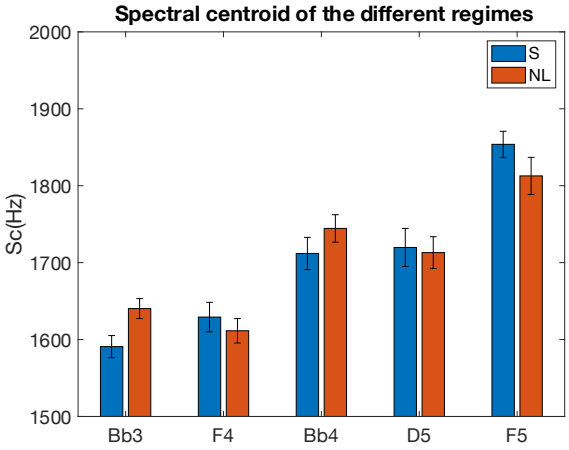

Figure 9. Spectral centroid of the different notes of the trumpet (in Hz), with the 95% confidence intervals.

Concerning the spectral centroid, instruments S and NL are extremely similar and no clear difference can be highlighted. Further investigations are needed to determine whether timbre differences are significant.

4. CONCLUSIONS

The work carried out in this article allows us to study to what extent theoretical differences, observed on a prototype of a virtual instrument, remain valid when the instrument is actually built. A trumpet leadpipe, developed and optimized using physical model simulations, was produced and mounted on an instrument. It should be noted that it is extremely rare in musical acoustics to be able to compare performances on virtual instruments to performances on a real instrument, as instrument manufacturing requires extensive resources and advanced know-how. This work constitutes a pioneering contribution. The first results show that the performances between virtual instruments and real instruments are rather in agreement, in particular with regard to playing frequencies. The continuation of this work will consist of determining whether the differences between the initial instrument and its optimized version are actually noticeable in playing conditions.

5. ACKNOWLEDGMENTS

We thank Yamaha trumpet designers for the manufacturing of the leadpipe prototype, and the

students of the specialization “Science et Musique” at Ecole Centrale de Nantes for their participation in the project.

REAL-TIME BOWING PARAMETER SENSING METHODS FOR ARTICULATED BOW-STRING PHYSICAL MODELLING

Eoghan Ó Néill* **Maarten van Walstijn** **Miguel Ortiz**
SARC: Centre for Interdisciplinary Research in Music and Sound
Queens University Belfast

ABSTRACT

This paper presents bowing parameter estimation techniques developed specifically for real-time control of bowed-string physical models. By placing the sensors on the resonator instead of on the bow, the ability to seamlessly employ traditional bowing techniques is preserved. The sensing methods presented here are part of a larger project that aims to design and develop stage-ready virtual-acoustic bowed-string instruments.

The proposed approach utilizes load cells mounted beneath the string supports to sense bowing force and position in real time. An automatic offset adjustment algorithm is implemented to counter sensor drift, which enhances accuracy and long-term reliability. A Kalman-like feedback loop that implements level-dependent adaption of the bowing position was designed to avoid noisy estimates at small bowing forces. Experimental validation shows that this approach provides robust, usable estimates of bowing force and position with minimal calibration.

Bow velocity is inferred from string velocity data captured by an electromagnetic pickup system, utilising an approximation of the short-time probability density function. Preliminary bow velocity estimation results were obtained with an offline algorithm, showing promising capability for real-time application.

1. INTRODUCTION

Among sound synthesis methodologies, physical modelling stands out for its distinctive advantage: its control parameters bear a direct physical correspondence to those of the acoustic instrument being simulated [1]. Recent advances in bow-string interaction modelling have yielded significant progress, including improved alignment with measurements [2, 3], guaranteed passivity [4, 5], and enhanced computational efficiency [6]. Although the accurate modelling of frictional dynamics at the bow-string interface remains an open challenge (see, e.g., [7]), these ongoing developments are steadily advancing toward real-time implementations that faithfully reproduce the salient acoustic characteristics of bowed-string interaction. Realising the full potential of such models, however, also requires the development of robust, real-time estimation techniques for bowing control parameters.

The excitation of a bowed-string physical model requires the specification of several key control parameters. This study concentrates on three primary bowing parameters: bowing force, bowing position, and bow velocity. Bowing force denotes the normal force applied by the bow at the point of contact with the string; bowing position specifies the location along the string where this contact occurs; and bow velocity corresponds to the relative tangential speed of the bow perpendicular to the string. Together, these parameters capture the dynamics at the bow-string interface, where frictional interaction gives rise to sound production. Although secondary factors such as bow tilt and inclination angle can influence the character of the interaction, the aforementioned primary parameters are generally sufficient to drive physically based bowed-string models with high fidelity [8].

Bowing parameter estimation has been the subject of

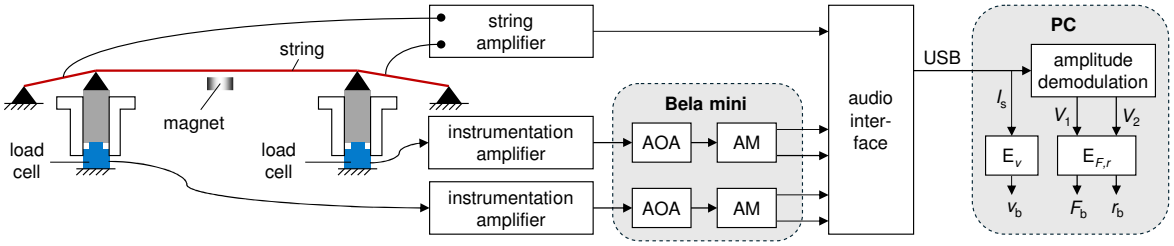

Figure 1: Bowing parameter estimation apparatus - system schematic.

extensive research for the past 40 years, driven by different motivations across disciplines. Researchers studying musical acoustics and gesture analysis aim to understand and quantify the mechanics of bowing, often prioritizing accuracy to capture the nuances of the bow-string interaction [3, 9–11]. In these areas of study, bowing parameter estimation is usually performed offline to achieve greater accuracy [3, 10, 11]. In the realm of pedagogy, bowing parameter estimation is pursued to enhance learning and teaching methods for string players. By analysing bowing techniques in real-time, educators and students can receive immediate feedback, fostering more effective practice and skill development [12–14]. Accuracy remains important in this context, but the primary concern is ensuring that the system is relatively non-intrusive and that the instrument retains familiarity with the traditional acoustic instrument being learned. The same holds for studies focused on instrument innovation, with additional emphasis on developing systems that are robust and capable of functioning in diverse performance environments. While precision is important, these systems do not require the same level of accuracy as those used in musical acoustics or gestural studies. They must be designed to accommodate different playing styles and instrument variations without requiring extensive calibration or modifications to the bow, allowing musicians to leverage their existing bowing techniques seamlessly [15, 16]. This paper is concerned with the latter research area, and as such, the methodology presented here reflects the priorities of developing a stage-ready bowed-string physical model interface.

2. METHODOLOGY

2.1 Selected Sensing Systems

Figure 1 provides an overview of the sensing system for bowing parameter estimation presented in this paper, illustrating the bowed-string interface and how the sensors are arranged, as well as the signal processing and routing.

In prior work, Lampis et al. [11] employed two load cells positioned beneath one of the string boundaries to estimate both the normal and transverse components of bowing force in controlled musical acoustics experiments. Building on this approach, we introduce a modified configuration in which a single load cell is placed beneath each of the string's boundaries (Figure 1). This arrangement enables simultaneous estimation of the normal bowing force and inference of the bowing position. Each load cell is mechanically coupled to its respective string boundary via a cylindrical shaft guided by a linear ball bushing, which constrains motion to a single plane – parallel to the shaft and perpendicular to the string. This mechanical design ensures accurate transmission of the normal component of bowing force while maintaining consistent coupling between the string and the sensing elements. The full assembly is mounted onto a 20×20, 55 cm-long aluminium profile using custom-designed, 3D-printed fixtures (Figure 6). While the current setup does not capture the transverse component of the bowing force – potentially leading to a slight underestimation when the bow is applied at an angle – this trade-off enhances structural rigidity and ensures robust sensor-string coupling, with the introduced difference being minor enough for musicians to adapt to comfortably. Each load cell operates on the Wheatstone bridge principle, producing millivolt-range output signals proportional to the applied force, which are subsequently amplified using AD620 instrumentation amplifiers.

In contrast to many existing methods for bowing parameter estimation, our approach eliminates the need for sensors to be mounted directly on the bow, thereby preserving the natural feel and freedom of motion familiar to string players. This design choice ensures that performance remains as unencumbered and authentic as possible. Although alternative bridge-force sensors – such as

piezoelectric discs – have been employed in prior studies, their AC-coupled nature renders them ineffective for capturing low-frequency or quasi-static variations in bowing force. Load cells, by contrast, provide DC-coupled measurements, enabling the accurate detection of both rapid transients and slow, gradual changes in applied force [11].

For bow velocity estimation, we propose a sensing methodology inspired by the work of Pardue et al. [16], which employs an electromagnetic pickup system to measure string velocity. This method again offers a non-intrusive means of acquiring bowing data without requiring direct modification of the bow. A neodymium magnet is positioned beneath the string at a fixed location, with one end of the string connected to the analogue input of a low-noise string amplifier, and the other end of the string connected to ground. In accordance with Lorentz force principles, the induced current in the string is directly proportional to its velocity at the location of the magnet. This string velocity information can then be used to infer the bow velocity at the point on the string directly above the magnet (see Section 2.5).

Alternatives to the above sensing techniques include the indirect estimation of parameters from AC-coupled sensor signals, which for example has been successfully applied to the estimation of plucking position in plucked-string instruments [17–21] and to tracking bowing parameters [15, 16]. However, all these methods share the disadvantage of relying on a particular structure in the waveform or spectrum, which may not be generally present under playing conditions. For estimating bowing parameters, machine learning techniques have been applied successfully for a specific set of notes [22], but with no follow-ups demonstrating more general estimation robustness covering a wide range of oscillation regimes.

Also worth noting here is that fully external sensing solutions such as camera-based motion tracking systems [8] offer high-resolution data in controlled laboratory settings, but their reliance on line-of-sight, controlled lighting, and computational overhead make them less suitable for real-time applications and live performance contexts – the target scenarios for our system.

Despite the advantages offered by the chosen sensing methodologies, several challenges must be addressed to ensure reliable and accurate parameter estimation. Although load cells are capable of capturing both rapid transients and slow variations in force, they are susceptible to signal drift over time, potentially compromising long-term measurement stability. Moreover, fluctuations in string tension and shifts in the string's equilibrium position introduce variability into the measured force signals, thereby affecting the accuracy of both bowing force and position estimations. Potential non-linearities in the load cell response further complicate matters and necessitate rigorous calibration procedures to ensure measurement fidelity.

The signal quality is also constrained by the limitations of the amplification stage. The employed load cell amplifiers exhibit a relatively poor signal-to-noise ratio, particularly at small force levels, where reliable data acquisition becomes more difficult. Electromagnetic pickups are particularly vulnerable to noise and interference from external electromagnetic sources. Mitigation strategies – such as the low-noise string amplifier developed by Pardue et al. [12] – have proven effective in reducing such interference, and as such has been implemented in the system presented here.

A further challenge arises due to the semi-chaotic nature of bowed-string interaction – particularly under expressive or unsteady bowing – which complicates the use of typical indirect sensing methods. This unpredictability demands a system that is robust across a wide range of performance conditions.

To address these challenges, a series of compensatory strategies have been implemented, detailed in the following sections.

2.2 Automatic Offset Adjustment

The load cell output, $V(n)$, represents the instantaneous voltage reading at time $t = n\Delta_t$, reflecting the combined effect of all forces acting on the system, including string tension and any external load. During startup, a calibration period occurs in which no external forces are applied, and the offset voltage $V_0(n)$ is calculated as an average over $M = 4410$ samples. This value serves as the baseline for adjusting the estimated applied force by subtracting $V_0(n)$ from $V(n)$. Ideally, $V_0(n)$ would remain constant; however, in practice, $V(n)$ does not always return to the same value upon bow release due to sensor drift, changes in string tension, and changes to the string's equilibrium state.

To counteract this artifact, an Automatic Offset Adjustment (AOA) algorithm is implemented. This Kalman-filter-like algorithm, illustrated in Figure 2, employs a feedback loop to update the offset voltage during periods of inactivity. Inactivity is defined as periods where the variance of both load cells falls below a threshold – set at 5% above a calibration-period variance reading taken

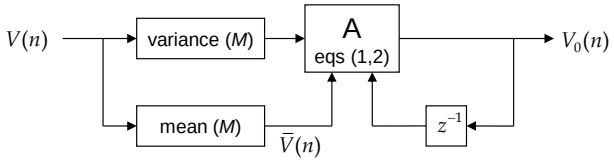

Figure 2: Schematic diagram of the automatic offset adjustment (AOA) algorithm. The variance and mean are calculated over M samples.

when the system is left undisturbed.

During these periods of inactivity, the following adaptation calculation is performed:

$$V_0(n) = V_0(n-1) + \Delta_V(n) \underbrace{g\,\Delta_t\,W(\Delta_V(n))}_{\gamma(n)}, \quad (1)$$

where:

$$\Delta_V(n) = \bar{V}(n) - V_0(n-1) \quad (2)$$

The term $\gamma(n)$ represents the effective adaptation rate at each step, and is composed of the scaling factor g – which statically determines the overall responsiveness of the adaptation, the time step Δ_t – ensuring proper temporal scaling, and the weight function $W(\Delta_V(n))$ – which dynamically modulates the adaptation rate based on the magnitude of $\Delta_V(n)$. This weight function is defined as:

$$W(\Delta_V(n)) = e^{-\psi\,|\Delta_V(n)|}, \quad (3)$$

where ψ is a tunable weight control factor. This formulation ensures that adaptation occurs more quickly for small deviations and more gradually for large deviations, preventing instability while still allowing for long-term drift correction.

2.3 Signal Routing

As illustrated in Figure 1, a Bela Mini is used to sample the amplified load cell signals at audio rate, maintaining high temporal resolution. To preserve this fidelity, the signals are transmitted at audio rate to a laptop via the Bela mini's audio outputs. This method leverages the Bela mini's low-latency audio path rather than relying on USB communication. Since many standard audio interfaces AC-couple their inputs – effectively filtering out DC components – an amplitude modulation (AM) scheme is used to encode the signals within the audio band. To mitigate phase misalignment issues that can arise between modulation and demodulation stages, each load cell signal modulates two carrier signals in quadrature. This approach enables robust demodulation in Max/MSP, ensuring accurate signal reconstruction for real-time bowing parameter estimation.

2.4 Bowing Force and Bowing Position Estimation

Equations for bowing force and bow position estimation are derived from heavily simplified acoustics of the string- assuming constant string tension, small string vibration, ideal string behaviour, and simplified boundary conditions. Under these assumptions, the force exerted on the string by the bow at the point of contact, $\tilde{F}_\mathrm{b}(n)$, is equal to the sum of the forces exerted by the string on the string's fixed boundaries, $\tilde{F}_1(n)$ and $\tilde{F}_2(n)$:

$$\tilde{F}_\mathrm{b}(n) = \tilde{F}_1(n) + \tilde{F}_2(n), \quad (4)$$

and these forces are distributed in such a way that:

$$\hat{r}_\mathrm{b}(n) = \frac{x_\mathrm{b}(n)}{L} = \frac{\tilde{F}_2(n)}{\tilde{F}_\mathrm{b}(n)}, \quad (5)$$

where $r_\mathrm{b}(n)$ is the relative bowing position, $x_\mathrm{b}(n)$ is the distance from the left string boundary to the bowing position, and L is the distance from one string boundary to the other-the effective length of the string.

Simulations were used to verify that these equations remain valid in the presence of stiffness and with different boundary conditions. However, it is less straightforward to predict whether they remain accurate under larger bowing forces, which induce large string deflections and significant increases in tension. In such cases, the resulting string slopes at the supports mean that the applied force is no longer purely parallel to the shafts, and thus is not fully captured by the load cells.

More importantly, the reliability of the estimates resulting from applying equation (5) deteriorates for small bowing forces, in which case the sensitivity to noise becomes extremely high, leading to large estimation errors. In practice, this can result in significant drift from the true position, occasionally producing values outside the expected range. To address these challenges, a feedback loop-similar in structure to the AOA algorithm is introduced. This adaptive mechanism improves stability when bowing forces are small and ensures that, in the absence of force input, the system retains the last reliable position estimate.

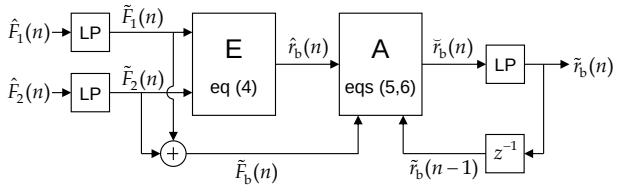

Figure 3: Bowing force and position estimation block diagram.

The following adaptation calculation is performed within the adaptation block A shown in Figure 3:

$$\breve{r}_b(n) = \tilde{r}_b(n-1) + \Delta_r(n) \underbrace{g\,\Delta_t\,W(\tilde{F}_b(n))}_{\gamma(n)}, \quad (6)$$

where,

$$\Delta_r(n) = \hat{r}_b(n) - \tilde{r}_b(n-1). \quad (7)$$

Here the term $\gamma(n)$ once again represents the effective adaptation rate at each step, only in this case the weight function $W(\tilde{F}_b(n))$ dynamically modulates the adaptation rate based on the magnitude of $\tilde{F}_b(n)$. The weight function is defined as:

$$W(\tilde{F}_b(n)) = 1 - e^{-\psi\,\tilde{F}_b(n)^2}, \quad (8)$$

where ψ is again a tunable weight control factor. This formulation ensures that adaptation occurs more quickly for large bowing forces and more gradually for small bowing forces, preventing wild fluctuation at small bowing forces where the noise can begin to affect the accuracy of the bowing position estimation.

2.5 Bow Velocity Estimation

The characteristic sound of a bowed string arises from a periodic cycle of 'sticking' and 'slipping.' The bow hairs grip the string momentarily, pulling it in one direction until friction is overcome, causing the string to slip back – only to stick again. This repeating motion, known as the Helmholtz motion, produces the characteristic sound of a bowed string [23]. Even when a periodic Helmholtz motion is not established, the bowed string's sound still results from instances of sticking and slipping. Our envisaged bow velocity estimation methodology relies upon the fact that the string velocity and the bow velocity are equal to each other during periods in which the bow hairs stick to the string. By measuring the string velocity, the bow velocity can be extrapolated by way of a probability density function – under the assumption that the sticking velocity is the dominant velocity in the signal, while slipping plays out over a more distributed range of velocities.

3. EXPERIMENTAL PROCEDURES AND RESULTS

A series of experiments were conducted to evaluate the efficacy of the proposed bowing parameter estimation methods.

3.1 Calibration and Validation with Static Forces

A bench experiment was devised to record load cell signals for various forces and positions along a 20cm string. A series of weights were suspended from the string using a 3D printed cradle to apply known static forces. The cradle was suspended in 5 known locations along the length of the string, limited to the middle 40% of the string due to the physical dimensions of the cradle and the strings supports.

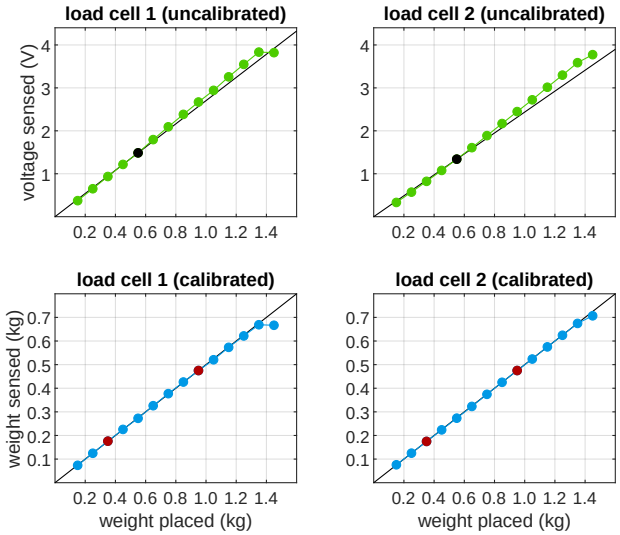

Figure 4: Load cell signals before and after logarithmic scaling calibration procedure. Black dots represent an arbitrary reference reading through which the linear black line is drawn. Red dots represent the calibration reference weights.

The load cell signals were recorded post-demodulation in Max/MSP. They were then rescaled to match the voltage read by the Bela mini, and a calibration scheme was devised to estimate the applied weight, as illustrated in Figure 4.

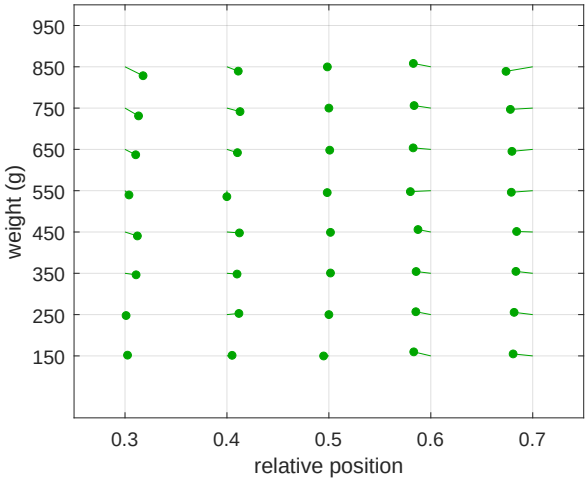

Figure 5: Estimation results for a known set of static weights and positions. Green dots show how estimation compares to nominal values at the grid line intersections.

Two reference weights are selected at the midpoint of the string, plotted as red points, upon which to scale the data logarithmically to correct for the slight nonlinearity observed in the uncalibrated data. In accordance with the project's overall goal of musical instrument implementation, the calibration procedure is intended to be practical and time efficient, so using as few calibration weights as possible is preferred. In this particular arrangement, we observe the beginning of saturation occurring in the upper region of the plot around 650g for load cell 1, or roughly 6.5N. As these plots represent the readings at the midpoint of the string, we can expect to measure a maximum of 6.5N at all points along the string, while larger forces can be measured the closer one bows to the centre of the string, up to 13N at the centre – double the maximum bowing forces measurable at the ends of the string.

The position estimation data is then calculated using equation (5) with the calibrated force data. Figure 5 illustrates the general accuracy of the bowing force and position estimation across a range of the string. As observed in Figure 5, the estimation errors can be largely described by an inward trend indicating lower accuracy for positions nearer the string ends. This can be attributed to the simplifications underlying equations (4) and (5), as discussed in section 2.4. While our calibration process ensures precise results at the center of the string, part of the total force remains unaccounted for when weights are hung away from the center, as variations in slope angles affect the proportion of the total force captured by the load cell. Consequently, the position estimation is less accurate when applying a load nearer to the string ends.

Figure 6: Monochord in cello orientation.

3.2 Bowing Experiment

In order to observe how the proposed estimation methods perform in the context of bowing practices, the third author, who is a cellist, bowed the experimental rig in an upright angled cello orientation using an *NS Design* electric cello stand, as shown in Figure 6.

Four short passages were recorded, where the cellist used four different cello bow strokes. As illustrated in Figure 7, the signal from a contact microphone placed on the monochord (green), bowing force estimation (blue), and bowing position estimation (red) were recorded in real-time. In these examples, the bowing force peaks at around 4N during *martelé* playing, well away from our saturation range of 6.5N, indicating that this will be enough headroom to capture most typical bowing techniques. We can also observe the slight inertia in bowing position estimation – for example, at around 7.5 seconds – when force is applied to the string and the bowing position estimation takes a few milliseconds to reach the new bowing position.

3.3 Preliminary Bow Velocity Sensing Results

In order to observe and validate the dominance of the sticking velocity in the string velocity signal, string velocity measurements were taken at a fixed position along the string using the apparatus detailed in Section 2.1 and illustrated in Figure 1. These measurements, as shown in Figure 8, illustrate that even when bowing away from the location of the magnet, the sticking velocity – and therefore the bowing velocity – can be estimated by finding the

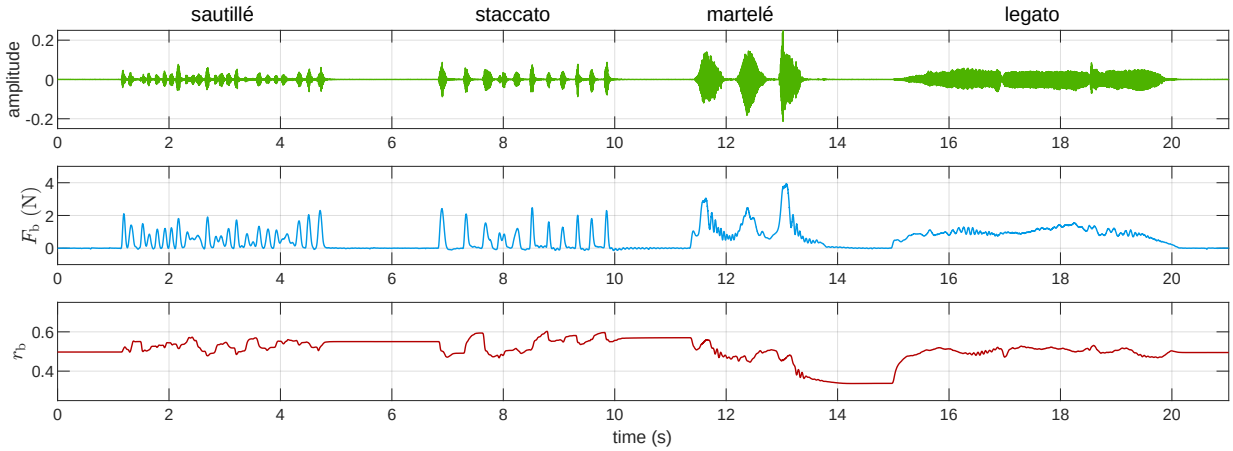

Figure 7: Real-time bowing force and bow-bridge distance estimation for four short cello bowing techniques performed on experimental rig.

peak of a probability density function. These preliminary results were calculated offline.

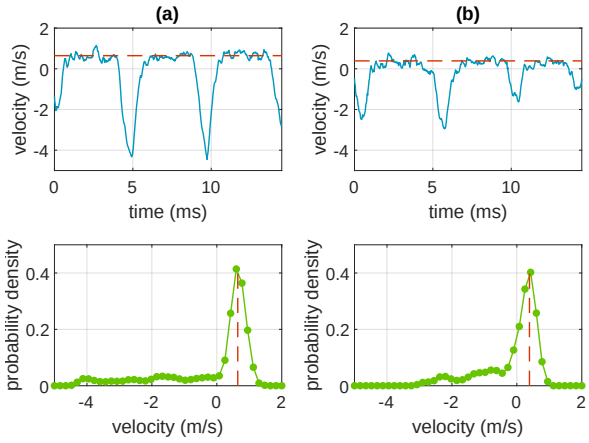

Figure 8: Bow velocity estimation - preliminary offline results. (a) - bowing above the magnet. (b) - bowing 2cm away from the magnet. Dashed red lines represent the estimated bow velocity.

4. CONCLUSION

This study contributes to the ongoing development of a sensing methodology for bowed-string instruments that avoids the limitations of on-bow sensing by positioning all sensors at the string interface. By eliminating the need for sensors on the bow itself, this approach preserves natural bowing technique and ergonomics – key considerations for integration into robust, stage-ready digital musical instruments with minimal calibration overhead. Our results demonstrate that load cells, when appropriately configured, can reliably estimate bowing force and position in real time within a compact, instrument-compatible design.

Experimental results indicate that accurate bowing force estimation can be achieved using only two calibration weights, offering a practical and time-efficient setup. Bowing position can be accurately tracked in the region around the string midpoint, with small errors arising for bowing nearer to the string ends. Preliminary investigations into bow velocity estimation via the string's sticking velocity – extracted using a probability density function – show promising potential.

Future work will focus on improving the calibration procedure to enhance relative bowing position estimation while preserving short setup times. Robust real-time estimation of the bow velocity for a wide range of bow-string interaction regimes remains an open challenge. Success in these areas would enable full real-time control of bowed-string physical models, unlocking new possibilities for expressive digital instrument design and performance-oriented applications in computer music.

A TWO-REGISTER HAPTIC INTERFACE FOR ARTICULATED CONTROL OF HARPSICHORD PHYSICAL MODELS

Matthew Hamilton* **Riccardo Russo** **Craig J. Webb**
Michele Ducceschi
NEMUS Lab, Dept. of Industrial Engineering, University of Bologna

ABSTRACT

A two-register haptic interface is presented for the articulated control of physically modelled harpsichord sounds. While physical modelling synthesis affords realism and nuance, standard MIDI-based controllers lack the resolution to capture the fine temporal detail required for historically informed keyboard performance. A custom three-key harpsichord mechanism was commissioned from an expert builder, and augmented with optical and force-sensitive sensors to track independent jack displacements per register. These data inform a real-time nonlinear string synthesis engine, enabling control over subtle inter-register plucking delays characteristic of historical instruments. The interface supports velocity-sensitive articulation across registers and integrates with a real-time software model employing modal energy-preserving techniques. The system reintroduces key expressive features absent from sample-based approaches, offering a viable solution for high-fidelity digital reconstruction of early keyboard gestures.

Keywords: *physical modelling, harpsichord, musical interface, MIDI controller, Virtual Studio Technology*

1. INTRODUCTION

The evolution of digital sound synthesis has transformed the relationship between human gesture, performance, and sound production. Early digital instruments offered sonic flexibility but introduced a degree of abstraction, primarily due to reliance on indirect parameter manipulation rather than direct physical interaction [1, 2]. With advances in computational power, real-time processing and expressive controllers have reintroduced immediacy to digital performance, allowing musicians to interact with sound more intuitively [3–5]. Nevertheless, the fundamental challenge of expressive control remains central across domains such as live electronic music and interactive performance systems, where continued exploration has led to the creation of complex multimodal interfaces [6].

The challenge of control remains open and becomes relevant when applied to historical musical instruments, where physical fragility often precludes direct interaction [7–9]. Physical modelling synthesis presents a promising solution by enabling real-time simulation of an instrument's behaviour [10, 11]. However, digital reconstructions often struggle to capture the fine-grained control and responsiveness required for historically informed performance practices.

The harpsichord exemplifies this difficulty. Characterised by its distinctive articulation and multiple registers, it requires nuanced control to produce its characteristic sound [12]. In traditional harpsichords, jack staggering creates intentional time offsets between multiple plucks triggered by the same key [13]. This prevents the player from engaging multiple strings with excessive force simultaneously. Yet, such subtle timing is often overlooked in sample-based libraries, where a single MIDI note triggers all registers simultaneously. Standard MIDI keyboards compound the issue, lacking the tactile feedback and mechanical complexity necessary to replicate historical instruments' expressive intricacies—especially the delayed plucks across registers. Previous work has

enhanced a museum-based keyboard replica with a sensor system [14] to control a commercial sample library, but sample-based implementations remain fundamentally limited. The core issue lies in their one-to-one mapping of MIDI events to sound triggers.

This paper introduces a novel control interface designed to overcome these constraints. By incorporating a custom sensing system that independently tracks the movement of each register, the proposed design enables precise articulation and timing control. This restores essential performance characteristics of historical harpsichords and strengthens the link between digital synthesis and authentic historical expression. A public repository containing supplementary material is available [1]. In particular, videos demonstrating the pluck detection mechanism are relevant for supporting the results discussed in the following section.

2. DETECTION MECHANISM AND INTERFACE PROTOTYPING

Rather than relying on commercial weighted-key MIDI controllers—which fail to replicate the mechanical resistance profile of a harpsichord [7]—a physical prototype of the harpsichord mechanism was commissioned from a professional instrument maker. The prototype includes three keys, each coupled to two jacks tuned in unison (Figure 1). While scaled down and unpitched, the string selection and mechanical dimensions were informed by a luthier to approximate the C2–D2 register with comparable tension and gauge. Each key acts as a class-1 lever, lifting jacks from different points along its length. This staggered design results in varying jack velocities, influencing the timing of plucks. Two complementary sensor types, QRE1113 reflective optical sensors and Interlink Electronics FSR 400 force-sensitive resistors (FRS), were employed to track gestures. The optical sensors—selected for their precision in short-range applications and prior success in musical interfaces—were directed at greyscale gradient tags attached to the sides of each jack. This setup largely draws from the original design by McPherson [15]. Mounted on custom PCBs (one per register), the sensors output voltage (`V_OUT`) in proportion to reflected infrared light, feeding analogue data into the microcontroller's ADC inputs (Figure 2(a)). Signal integrity was improved by shielding the open prototype construction against ambient light and power line interference through

both physical means (3D-printed cover plates) and software calibration (4-point moving average).

In a previous project involving the augmentation of a full-scale keyboard for the San Colombano Museum exhibition [14], a single-threshold detection system was implemented using only optical sensors. Although functional, it was prone to both false positives and missed events due to sensor noise, as occasional spikes led to unreliable threshold crossings during expressive play. Furthermore, artificially dragging the string with the plectrum, without producing an actual pluck, resulted in a series of false positives, as the detection system was unable to distinguish true plucks using simple thresholding alone.

A two-register pluck mechanism is reliable only if such false detections can be removed altogether. To

```
if(value > pluck_threshold AND state != PLUCKED)
   send_note_on(channel, note_number, velocity);
   state = PLUCKED;
else if(value < release_threshold AND state == PLUCKED)
   send_note_off(channel, note_number, velocity);
   state = PRESSED;
else if(value < rest_threshold)
   state = RELEASED;
```

Figure 3: Diagram of optical sensor signal transitioning through each state, and corresponding pseudocode.

achieve this, the current system uses a two-threshold hysteresis mechanism implemented as a finite state machine with three states: `RELEASED`, `PLUCKED`, and `PRESSED`. A MIDI `Note_ON` is triggered only when the sensor reading exceeds the `pluck_threshold` and the system is in the `RELEASED` state. Conversely, a `Note_OFF` is issued when the value falls below a lower `release_threshold`, and the system is in the `PLUCKED` state. This avoids instability from minor fluctuations near a single threshold and prevents rapid state toggling. Figure 3 presents a diagram of the hysteresis setup, and the corresponding pseudocode is given. Figure 4 presents snapshots of the plectrum-string interaction during a pluck, and the reflective sticker used by the optical sensing mechanism.

In the current design, FSR signals complement optical data by indicating actual force application. FSRs were installed beneath each jack to detect actual string excitation. Connected in a voltage divider circuit (Figure 2b), the output voltage reads:

$$V_{OUT} = \frac{R_0}{R_0 + R_{FSR}} V_{CC}, \tag{1}$$

from which the varying sensor's resistance R_{FSR} can be estimated. Such varying resistance can ultimately be converted to a force signal measured in Newton's via a conversion table from the supplier.

In addition to measuring force magnitudes, the FSR signal functions as a validation layer. When the optical

Figure 4: (Top): Snapshots of the plectrum-string interaction during a pluck. Note how the plectrum initially pushes the string but is eventually pushed back by the string before release. (Bottom): side view of a jack showcasing the colour gradient in the reflecting sticker used by the optical sensing mechanism.

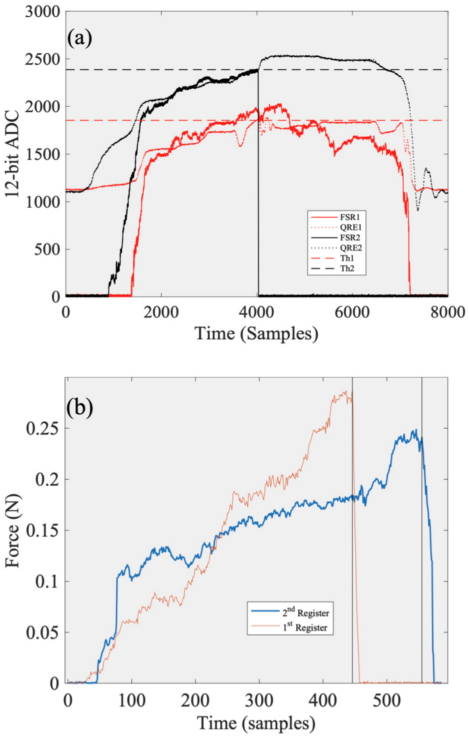

Figure 5: (a) FSR and optical sensor data for both registers of a key, as recorded by the ADC. **Th1** and **Th2** lines are the thresholds for the first and second set of optical sensors. (b) FSR data at 8 kHz sample rate. Black lines show the pluck point for each register. Time difference between plucks: 14 ms (110 samples).

sensor reading exceeds the pluck threshold, the system verifies whether a corresponding rate of change is present in the FSR signal. If no such drop is detected—indicating an absence of string contact—the event is disregarded. As a result, only deliberate plucking gestures lead to sound output, while unintended movements are effectively disregarded. Figure 5(a) displays the four signals captured from a single key gesture—two per register, representing the optical and force-sensitive sensors. It can be observed that one string is correctly identified as plucked, evidenced by a sharp drop in the force signal (black solid curve), while the second string (red curves), despite the optical threshold being crossed, is not plucked.

Figure 5(b) shows a time series from both sensors on a single key, sampled at 8 kHz and converted to Newtons. The onset of key motion is marked by displacement without resistance, followed by a sharp drop in the FSR signal that corresponds to the pluck. Together, the optical and force signals show strong temporal alignment across gestures. Based on recordings and sensor data, the delay between register plucks during normal performance ranged from 12ms to 30ms.

The current configuration supports per-register velocity assignment at note onset, with `Note_ON` velocities derived from the peak force measured by the FSR prior to its decay. Since FSRs are insensitive to key release, `Note_OFF` velocity is instead estimated from the rate of downward motion, as captured by the optical sensor when crossing the release threshold.

3. PHYSICAL MODELS AND IMPLEMENTATION

The control interface drives a nonlinear, two-register string model emulating the physical response of early Italian harpsichords. These instruments typically employed yellow brass strings, which, being relatively soft and unable to withstand high tension, contributed—together with the flexible soundboard and thin case sides—to a characteristically bright and sustained tone. For a digital reconstruction to sound convincing, it must account for behaviours like pitch glides, modal coupling, and amplitude modulation. Such features lie beyond the reach of linear string models and require the inclusion of geometric nonlinearities. Consider the following nonlinear model:

$$\rho A \partial_t^2 u(x,t) = \mathcal{L}u(x,t) + \partial_x \phi'_{nl}(\partial_x u) + \delta^{(x_f)} f(t), \quad (2)$$

where $u(x,t)$ denotes the transverse displacement; ρ is the material density; $A = \pi r^2$ is the cross-sectional area of a circular string; $\delta^{(x_f)} = \delta(x - x_f)$ is a Dirac delta representing the point of external excitation. The notation ∂_z^n denotes the n^{th} partial derivative along z, and primes ($'$) denote total differentiation. The operator $\mathcal{L}$ models linear dynamics:

$$\mathcal{L} := T_0 \partial_x^2 - EI \partial_x^4, \quad (3)$$

with T_0 the string tension, E Young's modulus, and $I = \pi r^4/4$ the area moment of inertia. The nonlinear potential function ϕ_{nl} governs the geometric nonlinearity:

$$\phi_{nl}(\partial_x u) := \frac{EA - T_0}{8} (\partial_x u)^4. \quad (4)$$

This expression approximates a low-order expansion of the geometrically exact string model (for the full model and a discretisation employing finite elements, see [16]), sufficient to produce perceptually relevant nonlinear effects such as pitch glides and modal coupling [17]. Note that the interactions with the soundboard and the radiation into the surrounding medium, whilst important for sound synthesis, are neglected at this stage, as they do not influence the structure of the control data stream of this proof-of-concept.

Boundary conditions are taken as simply supported: $u = \partial_x^2 u = 0$ at $x = \{0, L\}$. Applying modal decomposition:

$$u(x,t) := \sum_{m=1}^{M} X_m(x) q_m(t) = \mathbf{X}^\intercal(x)\, \mathbf{q}(t), \quad (5)$$

with $X_m := \sqrt{2/L} \sin\left(\frac{m\pi x}{L}\right)$ and $\mathbf{q}(t)$ the vector of modal coordinates, results in the following projected system:

$$\ddot{\mathbf{q}} = -\boldsymbol{\Omega}^2 \mathbf{q} - \mathbf{C}\dot{\mathbf{q}} - \int_{\mathcal{I}} \mathbf{X}' \phi'_{nl}\, dx + \boldsymbol{\eta} f(t), \quad (6)$$

where $\boldsymbol{\Omega} := \text{diag}[\Omega_1, ..., \Omega_M]$ is a diagonal matrix of eigenfrequencies defined as:

$$\Omega_m = \sqrt{\frac{T_0}{\rho A}\left(\frac{m\pi}{L}\right)^2 + \frac{EI}{\rho A}\left(\frac{m\pi}{L}\right)^4}. \quad (7)$$

The diagonal damping matrix $\mathbf{C} := \text{diag}[2\sigma_1, ..., 2\sigma_M]$ was arbitrarily added after modal projection, and it approximates the light, uncoupled modal losses. The damping coefficients σ_m can be estimated experimentally or be derived from a model such as Cuesta and Vallette's [18].

3.1 Energy quadratisation and time stepping scheme

The modal system is passive and satisfies the energy balance:

$$\frac{\mathrm{d}H}{\mathrm{d}t} = -\dot{\mathbf{q}}^\intercal \mathbf{C}\dot{\mathbf{q}} + \dot{\mathbf{q}}^\intercal \boldsymbol{\eta} f(t), \tag{8}$$

with total energy:

$$H = \frac{1}{2}\dot{\mathbf{q}}^\intercal\dot{\mathbf{q}} + \frac{1}{2}\mathbf{q}^\intercal\boldsymbol{\Omega}^2\mathbf{q} + \int_{\mathcal{I}} \phi_{nl}\,\mathrm{d}x, \tag{9}$$

and note that the energy is strictly decreasing when the source is inactive ($f(t) = 0$). To ensure numerical stability in the presence of nonlinear terms, the system is reformulated using the Scalar Auxiliary Variable (SAV) method [19, 20]:

$$\psi := \sqrt{2\int_{\mathcal{I}} \phi_{nl}\,\mathrm{d}x}, \tag{10}$$

yielding:

$$\ddot{\mathbf{q}} = -\boldsymbol{\Omega}^2\mathbf{q} - \mathbf{C}\dot{\mathbf{q}} - \psi\nabla_{\mathbf{q}}\psi + \boldsymbol{\eta} f(t), \tag{11a}$$

$$\dot{\psi} = (\nabla_{\mathbf{q}}\psi)^\intercal\dot{\mathbf{q}}. \tag{11b}$$

System (11) is discretised using staggered time series for $\mathbf{q}$ and ψ. Let $\mathbf{q}^n \approx \mathbf{q}(Tn)$ and $\psi^{n-\frac{1}{2}} \approx \psi(T(n-\frac{1}{2}))$ at time step n and with sampling period T. Discrete-time operators are defined as:

$$\delta_2\mathbf{q}^n := \frac{\mathbf{q}^{n+1} - 2\mathbf{q}^n + \mathbf{q}^{n-1}}{T^2}, \tag{12a}$$

$$\mu_2\mathbf{q}^n := \frac{\mathbf{q}^{n+1} + 2\mathbf{q}^n + \mathbf{q}^{n-1}}{4}, \tag{12b}$$

$$\delta_\cdot\mathbf{q}^n := \frac{\mathbf{q}^{n+1} - \mathbf{q}^{n-1}}{2T}, \tag{12c}$$

$$\delta_+\psi^{n-\frac{1}{2}} := \frac{\psi^{n+\frac{1}{2}} - \psi^{n-\frac{1}{2}}}{T}, \tag{12d}$$

$$\mu_+\psi^{n-\frac{1}{2}} := \frac{\psi^{n+\frac{1}{2}} + \psi^{n-\frac{1}{2}}}{2}. \tag{12e}$$

Using these, the time-stepping scheme employed here is:

$$\delta_2\mathbf{q}^n = -\tilde{\boldsymbol{\Omega}}^2\mu_2\mathbf{q}^n - \tilde{\mathbf{C}}\delta_\cdot\mathbf{q}^n - \mu_+\psi^{n-\frac{1}{2}}\mathbf{g}^n + \boldsymbol{\eta} f^n,$$

$$\delta_+\psi^{n-\frac{1}{2}} = (\mathbf{g}^n)^\intercal\delta_\cdot\mathbf{q}^n,$$

$$\mathbf{g}^n := (\nabla_{\mathbf{q}}\psi)\big|_{t=Tn},$$

where:

$$\tilde{\Omega}_m^2 := \frac{4}{T^2}\frac{1 - 2e^{-\sigma_m T}\cos(T\sqrt{\Omega_m^2 - \sigma_m^2}) + 2e^{-2\sigma_m T}}{1 + 2e^{-\sigma_m T}\cos(T\sqrt{\Omega_m^2 - \sigma_m^2}) + 2e^{-2\sigma_m T}},$$

$$\tilde{\sigma}_m := \frac{2}{T}\frac{1 - e^{-\sigma_m T}}{1 + 2e^{-\sigma_m T}\cos(T\sqrt{\Omega_m^2 - \sigma_m^2}) + 2e^{-2\sigma_m T}}.$$

This discretisation has several desirable properties. First, it ensures that the linear part is discretised exactly [21], as it appears in previous works employing modal synthesis [20, 22]. Second, it is unconditionally stable. Finally, the system's update -not shown here for brevity- is performed explicitly via the Sherman-Morrison formula [17, 19, 23], avoiding nonlinear root finding algorithms -often requiring several iterations per time step- or large matrix inversions.

To manage computational complexity further, full nonlinearity is applied only to modes below 3 kHz; higher modes are treated linearly. This hybrid approach preserves perceptual features while reducing floating-point cost. Additionally, a constrained version of the SAV method, adapted from [20], is employed to enforce the non-negativity of $\mu_+\psi^{n-\frac{1}{2}}$, preventing spurious numerical artefacts from appearing in the solution and allowing the auxiliary variable to decay toward zero. A detailed description can be found in [24, 25].

4. REAL-TIME SOFTWARE IMPLEMENTATION

The software component of the prototype system consists of a real-time instrument plug-in (VST3/Audio Unit), designed for integration with standard Digital Audio Workstations (DAWs). The selected DAW must support the transmission of MIDI channel information to the active track, enabling multi-channel polyphonic expression (MPE)-style communication.

4.1 System Overview

The software simulates a pair of nonlinear strings, forming a single voice whose pitch is determined by the mechanically actuated key. For the purposes of computational benchmarking, low-pitched notes were selected: specifically, C2 (65 Hz), along with the adjacent C#2 and D2. Each string is modelled with a length of 2 m and a radius of 0.3 mm, employing appropriate material parameters for brass.

The system processes `Note_ON` and `Note_OFF` events received over two independent MIDI channels, supporting individual excitation and damping of each

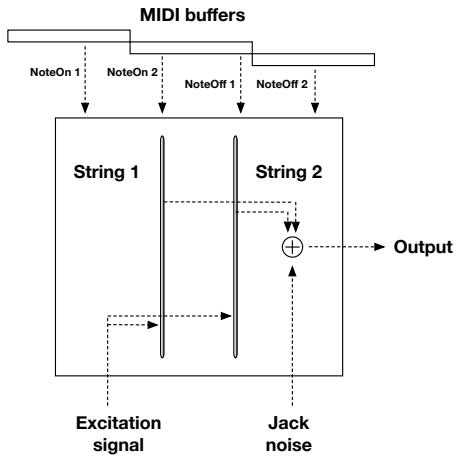

Figure 6: Real-time system implementation comprising a pair of nonlinear strings triggered by MIDI signals distributed across multiple buffers.

string and preserving temporal offsets between the associated jacks. These MIDI events may span multiple processing buffers; therefore, each is timestamped and rendered within the correct frame. Additional components include an excitation signal and jack noise, as illustrated in Figure 6.

Excitation is applied as a time-limited forcing term at a designated point along each string, informed by the pressure sensor beneath the mechanical key. The excitation signal, approximately 50 ms in duration, is selected via linear interpolation between two stored waveforms, based on the MIDI `Note_ON` velocity. Additionally, the sound of the jack returning to its rest position is incorporated via a pre-recorded noise sample. The `Note_OFF` velocity is used to modulate the amplitude of this signal prior to mixing with the output audio.

4.2 Computational Challenges

The use of nonlinear modal string synthesis in a real-time audio environment is computationally demanding, both at the model initialisation phase (`Note_ON`) and during continuous audio rendering at each time step. In contrast to a linear string model—which requires a single vector update and dot product per time step—the nonlinear system entails substantially more operations. For instance, the C2 note requires a modal resolution of 150 modes. Each time step involves two matrix-vector multiplications, seven vector updates, and six dot products. When matrices are square, multiplication accounts for over 80% of the total computational load.

To attain viable single-core CPU performance, both algorithmic and low-level code optimisations were implemented. As mentioned previously, one effective strategy involved partitioning the modal range into two segments: a low-to-mid frequency band up to approximately 3 kHz, and a higher frequency band extending to the upper modal limit. The lower segment (approximately 50 modes for C2) is computed using the full nonlinear model, whereas the higher modes are updated using a simplified linear routine. This segmentation reduces matrix dimensionality and lowers the cost of associated vector operations. With this approach, CPU usage per string was reduced to approximately 10%. Further optimisation is anticipated through under-sampling of the nonlinear modal segment.

Beyond real-time rendering, the initialisation of each string model introduces additional processing overhead. Specifically, the computation of modal shapes—involving thousands of trigonometric evaluations at each `Note_ON` event—can lead to transient CPU load spikes, potentially causing buffer under-runs. To mitigate this, a caching system for precomputed modal matrices is recommended for scalable polyphonic implementation.

5. DISCUSSION AND CONCLUSION

The system presented in this paper builds upon previous work on sensor-augmented harpsichord interfaces—most notably the San Colombano project [14]—by introducing substantial refinements in both gesture detection and synthesis integration. While earlier designs relied solely on optical displacement tracking, the present system introduces a dual-sensor architecture, combining reflective optical sensors with force-sensitive resistors (FSRs). This hybrid approach enables robust pluck detection through velocity-sensitive hysteresis and force validation, reducing false positives, particularly during complex or expressive gestural input. These developments address known shortcomings of threshold-based detection and allow for a more reliable mapping between mechanical gestures and sonic outcomes. The current prototype setup is visible in Figure 7.

Conventional digital control of plucked keyboard instruments suffers from several shortcomings, namely: the lack of control resolution in standard MIDI devices, the inability to articulate register-specific timing offsets, and the absence of mechanical feedback needed for histori-

Figure 7: The prototype setup, showing the three-key harpsichord model connected to a 2023 MacBook Pro. The prototype VST is visible, along with a list of triggered MIDI messages.

cally informed performance. The proposed system addresses these challenges through a custom-built harpsichord mechanism with staggered dual-register jacks, paired with real-time gesture tracking and nonlinear physical modelling. The resulting interface supports temporally resolved articulation across registers, required for expressive control.

From the perspective of sound synthesis, the system incorporates a physically realistic, nonlinear string model that supports two independently plucked registers per key. By constraining nonlinear computations to low-order modes (below 3 kHz), and employing a modal energy quadratisation scheme with a constrained Scalar Auxiliary Variable (SAV), the model achieves a balance between physical fidelity and computational tractability. As a result, real-time synthesis is attained on consumer-grade hardware with a CPU footprint of approximately 10% per voice on the most computationally demanding strings in the bass register, while preserving key nonlinear characteristics such as pitch glides and modal coupling.

The prototype shows that a high level of expressivity can be achieved through targeted hardware augmentation and physics-informed synthesis. It reaffirms the value of context-specific interfaces when coupled with physically grounded models, particularly in the domain of historically informed digital instrument design. Future work will extend the current architecture to a full keyboard, explore enhanced mapping strategies for velocity and dynamics, and incorporate more detailed models of soundboard interaction and acoustic radiation.

REAL-TIME DEMONSTRATORS TO EXHIBIT, INVESTIGATE AND TEACH TRANSIENT BEHAVIORS IN NONLINEAR DYNAMICS, FOCUSED ON MUSICAL INSTRUMENTS

Tom Colinot[1,2*]
[1] Buffet Crampon, Mantes-la-Ville, France
[2] Aix Marseille Univ, CNRS, Centrale Marseille, LMA, Marseille, France

ABSTRACT

Nonlinear dynamical systems exhibit various transient behaviors, whose understanding is required to fully apprehend how the system responds to sollicitations. This work focuses on multistable systems, where several stable solutions coexist for a given value of the system's parameters. In these settings, transients condition which solution actually appears during time integration. Then, a comprehensive description of the system's behavior entails mapping out the infinite possibilities of variations of the system's parameters with respect to time. This is impractical for models whose phase space is of high dimension, or in limited timescales such as practical activities for students. This work proposes real-time demonstrators of dynamical systems as a way to still investigate these phenomena. The construction of such demonstrators is detailed, including a display outlining the zones of stability of the solutions, and control inputs mimicking a musical instrument (such as a MIDI controller). We show how these elements coupled with audio and visual feedback enables users to quickly gauge a large variety of transient behaviors, for academic proofs of concept or pedagogical activities. A demonstrator for a Van der Pol toy model and one for a woodwind model used for a lab in a master's degree are used as examples.

1 INTRODUCTION

It is very rarely possible to exhaustively predict the behavior of a nonlinear dynamical systems. Therefore, a lot of work in the dynamical systems community is descriptive: one observes, documents and explains the various behaviors that the system displays in its different configurations [1]. This leads to graphical representations such as bifurcation diagrams that represent behavior as a function of one parameter, or cartographies when two or three parameters are taken into account. This work presents two real-time construction of bifurcation diagrams. In a pedagogical context, the real-time audio and graphical representation tool allows impactful and flexible demonstrations, in which the students and the professor can decide to investigate a specific point and do so immediately. The audio feedback is especially interesting for music-related curriculums, where students want to interpreted dynamical system behaviors in terms relevant to music as often as possible.

2 A TOY OSCILLATOR ILLUSTRATES DIRECT, INVERSE AND DYNAMICAL HOPF BIFURCATIONS

A fifth order Van der Pol model [2], close to the normal form of a Bautin bifurcation [3], displays a Hopf bifurcation [4] that can be either direct or inverse. Its toy model nature makes it easy to write with a single equation

$$\ddot{x} + (\mu + \sigma(\dot{x}^2 + x^2) + \nu(\dot{x}^2 + x^2)^2)\dot{x} + x = 0 \quad (1)$$

Its solutions as well as the locus of its bifurcations are both completely described analytically. This good *a priori* knowledge of the system's steady states means the demonstration can focus on transient aspects such as hysteresis

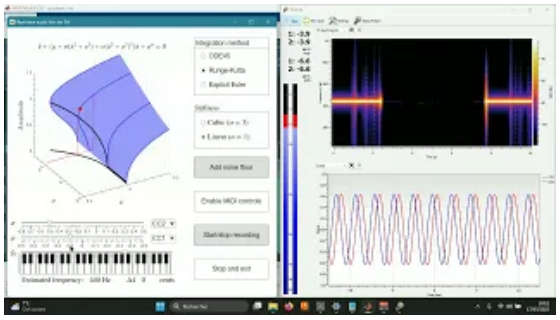

Figure 1. Snapshot from the demonstration video linked at https://youtu.be/a0S7l7Hjl1s.

and dynamical bifurcations. Figure 1 links to a video capture of such a demonstration. The full demonstrator is available online [5].

Negative values of σ lead to an inverse Hopf bifurcation at $\mu = 0$, which is followed by a saddle-node bifurcation [6]. In the region between these two bifurcations, the system is multistable. Therefore, the system displays a hysteresis cycle (0:00 timestamp) wherein the existing stable solution (constant or periodic) is maintained until the parameter leave the multistability region. When demonstrating this phenomenon, another feature is immediately apparent : the oscillations start and stop brutally. For music-oriented students, this observation is very interesting as it means that self-oscillating instruments that have an inverse Hopf bifurcation will likely be difficult to play at a *pianissimo* nuance. To the contrary, the Hopf bifurcation is direct for positive σ values. The user can experience that a fine adjustment of parameter μ enables arbitrarily low amplitude oscillations (0:23 timestamp).

Dynamical bifurcations are a phenomenon whereby the system's parameter cross a bifurcation point, but the effect of that bifurcation is only felt some time after the crossing [7]. For a Hopf bifurcation, this can mean that the oscillations only appear after a certain delay after μ crosses 0. This delay can be rather long, especially when the system is allowed to converge very close to the equilibrium. When the system is near the equilibrium and it becomes unstable, the distance between it and the position of the system is amplified exponentially. If this distance is very small, the time needed for it to become big enough for oscillations to be heard can be long. In the case of our real-time Van der Pol oscillator, 0:52 timestamp showcases a long bifurcation delay (of about 1 s). In a musical context, this duration is not negligible at all

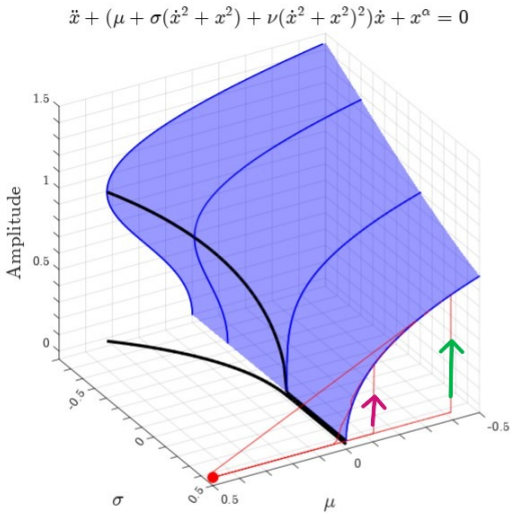

Figure 2. Bifurcation diagram: theoretical static solution amplitudes in blue, and time-integration trajectories in red for two increases in parameter μ from -0.5 to 0.4: first without added noise (green arrow) and then with added white noise (pink arrow).

(half a bar at 120 bpm). Then, a small white noise of standard deviation 10^{-5} is added to the variables of the system at the 1:04 timestamp. By preventing the system to approach the equilibrium too much, this modification greatly shortens the bifurcation delay. Figure 2 compares the two trajectories : compared to a short bifurcation delay, the long bifurcation delay also entails that oscillations appear when μ is larger and thus with a greater amplitude – which translates to a more sudden attack.

This demonstration shows the importance of the nature of the bifurcation in a musical context, as well as the more subtle phenomenon that is bifurcation delay.

3 A CLARINET MODEL SHOWS SIMPLE AND COMPLEX MULTISTABLE BEHAVIOR, AS WELL AS CHAOTIC REGIMES

A more applicative example, used in a lab for a master's degree, puts the student with a real-time integration of a woodwind model, whose modal parameters can be fixed by the user. The two variable control parameters are the

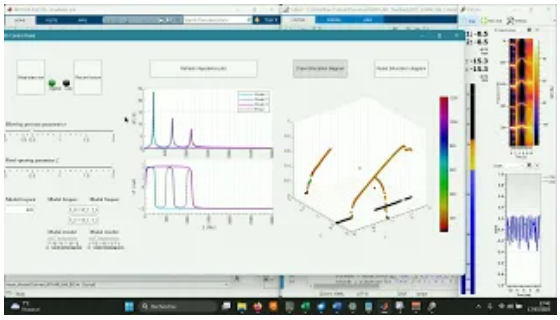

Figure 3. Snapshot from the demonstration video linked at https://youtu.be/D8AUCYr-XXg.

pressure in the mouth and the opening of the reed at rest. Although it is more involved than the previous toy model, this woodwind model writes rather simply as

$$\begin{cases} \dot{p_1} &= s_1 p_1 + C_1 u \\ \dot{p_2} &= s_2 p_2 + C_2 u \\ \dot{p_3} &= s_3 p_3 + C_3 u \\ p &= 2\Re(p_1 + p_2 + p_3) \\ u &= \zeta \max(p - \gamma + 1, 0)\text{sign}(\gamma - p)\sqrt{|\gamma - p|} \end{cases} . \tag{2}$$

where p_1, p_2 and p_3 are complex modal pressures associated with the three modes whose complex residues and poles are C_i and s_i, and ζ and γ are reed opening and blowing pressure dimensionless parameters [8].

Figure 3 shows the time integration results for this model, when the user manipulates sliders to control the parameters of the system.

The video first showcases the apparition of oscillations through direct Hopf bifurcations when increasing the blowing pressure γ (0:00 timestamp). This is explained as the system only producing sound if the musician blows into it sufficiently hard. Another Hopf bifurcation with respect to the reed opening parameter ζ (1:25 timestamp) is interpreted as the clarinet only producing sound if the reed is open enough at rest. A large multistability zone is explored through a hysteresis cycle at timestamp 0:35 timestamp. Then, the system's ability to produce chaos for a large reed opening is showcased though intermittent regimes (1:55 and 2:35 timestamps). A real-time sound synthesis model enables direct comments of the produced sounds. This parameter region also displays subharmonic regimes (2:21 timestamp). This subharmonic regime produces a note that is unexpected when looking at the resonances of the instrument, as it is lower than the lowest resonance frequency. Then (3:20 timestamp), it is shown that through chaos the system can transition from the first register (regime associated with the first resonance) to the second register (regime associated with the second resonance). These two registers are actually multistable for a large portion of the parameter space : when the second register is obtained it can then be easily maintained.

INFLUENCE OF THE BASINS OF ATTRACTION IN THE REGISTER JUMPS OF THE CLARINET

Nathan Szwarcberg[1,2*] **Tom Colinot**[1] **Christophe Vergez**[2]

ABSTRACT

When playing the clarinet, opening the register hole allows for a transition from the first to the second register, producing a twelfth interval. On an artificial mouth, the blowing pressure range where the second register remains stable can be determined by gradually varying the blowing pressure while keeping the register hole open. However, when the register hole is opened while the instrument is already producing the first register, the range of blowing pressures that lead to a stable second register is narrower than the full stability zone of the second register.

This phenomenon is investigated numerically by performing multiple hole openings at different times for each blowing pressure value. The evolution of the probability of reaching the second register is computed, and its relationship with the structure of the basin of attraction of the second register is analyzed.

Keywords: *clarinet, multistability, basins of attraction, nonlinear losses, phase tipping*

1. INTRODUCTION

When characterizing a clarinet fingering, one of the first steps consists in measuring the minimum and maximum blowing pressure that play a note, for a fixed embouchure. The artificial mouth [1–4] is commonly used to determine these limits, known as the oscillation and extinction thresholds [5–7], by gradually increasing the blowing pressure. Above the extinction threshold, the reed is pressed against the mouthpiece and stops vibrating. When the pressure is then reduced, the reed starts oscillating again at a lower pressure, sometimes called the "inverse threshold" [6]. This difference between the extinction and inverse thresholds creates a hysteresis cycle, where the equilibrium (no sound) and the oscillating regime are multistable [8, 9].

The basin of attraction of a regime defines the set of initial conditions that lead to it. In a multistable system, knowing these basins helps predict which regime a musician is most likely to play [10]. However, calculating the full basin of attraction is highly time-consuming due to the high dimension of the phase space. Additionally, it is unclear whether a chosen initial condition accurately represents a musician's playing.

This study addresses these challenges by focusing on transitions between two notes. In this case, all initial conditions lie on the limit cycle of the regime of the first note.

A well-known transition on the clarinet happens when pressing the register key, which shifts from the first register to the second by an ascending interval of a twelfth. For beginner clarinetists, practicing this transition is important to avoid unintended notes when opening the hole.

This paper investigates a physical model of a cylindrical clarinet with a register hole. To allow the model to reproduce the register transition, nonlinear losses in the register hole are included [11, 12]. The model is introduced in Section 2. Time-domain simulations, similar to artificial mouth experiments, are then conducted. First, blowing pressure ramps are tested with the register hole both closed and open (Section 3.1) to identify stable and multistable regions. Next, for blowing pressure values in the multistability range between the second register and

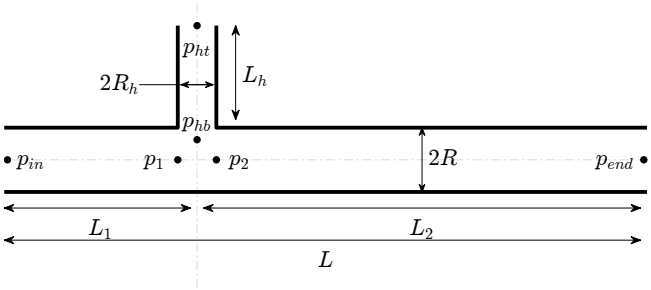

Figure 1. Definition of the digital resonators studied.

the equilibrium, several hole openings are performed to observe how the first register's limit cycle interacts with the attraction basins of the two competing regimes (Section 3.2). Finally, basin stability is investigated by introducing random perturbations when opening the register hole [13].

2. NUMERICAL MODEL

2.1 Digital resonators

The digital resonator is presented on Figure 1. It is composed of a first tube of length $L_1 = 132$ mm, radius $R = 7.5$ mm and cross-section $S = \pi R^2$. The characteristic impedance of plane waves propagating through the tube is $Z_c = \rho_0 c_0 / S$ where $\rho_0 = 1.23\ \mathrm{kg \cdot m^{-3}}$ and $c_0 = 343\ \mathrm{m \cdot s^{-1}}$. The acoustic field in the first tube is described by the pressure at the left extremity p_{in}, and at the right extremity p_1.

The tube is branched to a side hole of length $L_h = 12.7$ mm, radius $R_h = 1.5$ mm, cross-section $S_h = \pi R_h^2$, and characteristic impedance $Z_{ch} = \rho_0 c_0 / S_h$. The acoustic field in the side hole is described by the pressure at the bottom of the hole p_{hb} and at the top of the hole p_{ht}.

A second tube of length $L_2 = 166$ mm and cross-section S is branched downstream from the side hole. The acoustic field in this tube is described by the pressure at the left extremity p_2 and by the pressure at the right extremity p_{end}.

2.2 Viscothermal losses

Viscothermal losses are introduced through the complex wavenumber $\Gamma_i(s)$, where s is the Laplace variable and $i = \{1, 2, h\}$ refers to the index of the tube considered.

The function $G_i(s)$ is defined, such that

$$G_i(s) = e^{-\Gamma_i(s) L_i} = \lambda_i e^{-\epsilon_i \sqrt{s}} e^{-\tau_i s},$$

with

$$\lambda_i = e^{-(\alpha_2 \ell_v L_i)/R_i^2}, \quad \epsilon_i = \frac{\alpha_1 L_i}{R_i} \sqrt{\frac{2\ell_v}{c_0}}, \quad \tau_i = \frac{L_i}{c_0},$$

where $\alpha_1 = 1.044$, $\alpha_2 = 1.080$, and $\ell_v = 4 \cdot 10^{-8}$ m (Chap. 5.5 of [14]).

In practice, $G_i(s)$ are approximated by a first-order low-pass filter and a delay $\tilde{G}_i(s)$, following the work from [15]. Fractional delays are also accounted for through the order 1 filters proposed by [16].

2.3 Forward and backward-propagating pressure waves

In the following, time-domain variables are written in small letters (e.g. $p_2^+(t)$), and frequency-domain variables are written in capital letters (e.g. $P_2^+(s)$).

The propagation of the acoustic waves in the resonator is described through the forward and backward-propagating acoustic pressures p^+ and p^-. They are related to the acoustic pressure and flow (p, u) through the relationships:

$$p = p^+ + p^-, \qquad u = \frac{p^+ - p^-}{Z},$$

where $Z = Z_c$ in the main tube of cross-section S, and $Z = Z_{ch}$ in the side hole.

Since the tubes L_1, L_2 and L_h are all cylindrical, the acoustic field can be described as transmission lines equations in the frequency domain. For the tube of length L_1:

$$P_1^+ = G_1 P_{in}^+, \qquad P_{in}^- = G_1 P_1^-. \tag{1}$$

For the tube of length L_2:

$$P_{end}^+ = G_2 P_2^+, \qquad P_2^- = G_2 P_{end}^-. \tag{2}$$

For the tube of length L_h:

$$P_{ht}^+ = G_h P_{hb}^+, \qquad P_{hb}^- = G_h P_{ht}^-. \tag{3}$$

2.4 Boundary conditions

The boundary conditions in the tube are described hereafter.

2.4.1 Radiation

First, radiation from the open end is neglected: the pressure p_{end} is written consequently as

$$p_{end} = 0. \tag{4}$$

2.4.2 Hole junction

Secondly, since the register hole has a small diameter and a long chimney length, the series impedances of the hole can be neglected (section 3.3.2.2 of [17]). The boundary conditions at the bottom of the hole are therefore given by:

$$p_1 = p_2, \tag{5}$$
$$p_2 = p_{hb}, \tag{6}$$
$$u_1 = u_2 + u_{hb}. \tag{7}$$

2.4.3 Flow crossing the reed channel

The next boundary condition involves p_{in} and comes from the nonlinear characteristics of the flow entering the resonator. In this relationship, the acoustic flow u_{in} depends on the difference between the blowing pressure of the musician p_m and the pressure at the input of the instrument p_{in}. By assuming that the jet experiences total turbulent dissipation [18] and modeling the reed as a massless, undamped spring [19], the nonlinear characteristics is defined as [20]:

$$\hat{u}_{in} = \zeta[\hat{p}_{in} - \gamma + 1]^{+}\mathrm{sgn}(\gamma - \hat{p}_{in})\sqrt{|\gamma - \hat{p}_{in}|}, \tag{8}$$

where the function $[x]^+$ returns the positive-part of x, i.e. $[x]^+ = (x + |x|)/2$. The dimensionless blowing pressure is given by $\gamma = p_m/P_M$, where P_M is the minimum pressure needed to close the reed channel in a quasi-static regime. Typical values of P_M are in the range $P_M \in [4, 8]$ kPa, according to [6, 7]. The parameter ζ represents the embouchure, with common values for the clarinet between 0.05 and 0.4 [6]. The dimensionless quantities are defined as

$$\hat{p}_{in} = p_{in}/P_M, \qquad \hat{u}_{in} = u_{in}Z_c/P_M.$$

In Eq. (8), the dynamics of the reed are neglected to obtain a direct relationship between p_{in}^+ and p_{in}^-. This relationship is given in [21] and is detailed in the Appendix of [22]. It is expressed as:

$$\hat{p}_{in}^+ = f_{\gamma\zeta}(\hat{p}_{in}^-) = \gamma - X[\gamma - 2\hat{p}_{in}^-] - \hat{p}_{in}^-, \tag{9}$$

where the function X is defined in Appendix A of [21].

2.4.4 Localized nonlinear losses in the register hole

Localized nonlinear losses in the register hole are modeled using the following boundary condition for p_{ht}:

$$p_{ht}(t) = \rho_0 C_{\mathrm{nl}} v_{ht}(t)|v_{ht}(t)|, \tag{10}$$

where $C_{\mathrm{nl}} > 0$ is the nonlinear losses coefficient, which depends on the roundness of the edges of the hole [7], and v_{ht} is the acoustic speed at the top of the side hole. An explicit relationship between p_{ht}^+ and p_{ht}^- is given in [12]:

$$p_{ht}^-(t) = r_{\mathrm{nl}}\left[p_{ht}^+(t)\right], \tag{11}$$

where

$$r_{\mathrm{nl}}(x) = x\left(1 - \frac{4}{1 + \sqrt{1 + K_{\mathrm{nl}}|x|}}\right), \tag{12}$$

with $K_{\mathrm{nl}} = 8C_{\mathrm{nl}}/(\rho_0 c_0^2)$. For $K_{\mathrm{nl}} = 0$, we get $r_{\mathrm{nl}}(x) = -x$, which corresponds to an open hole boundary condition. As $K_{\mathrm{nl}} \to \infty$, $r_{\mathrm{nl}}(x) = x$, meaning the hole is closed.

In a dimensionless form, r_{nl} is rewritten as $\hat{p}_{ht}^- = \hat{r}_{\mathrm{nl}}\left[\hat{p}_{ht}^+\right]$, where

$$\hat{r}_{\mathrm{nl}}(x) = x\left(1 - \frac{4}{1 + \sqrt{1 + \hat{K}_{\mathrm{nl}}|x|}}\right), \tag{13}$$

with $\hat{K}_{\mathrm{nl}} = P_M K_{\mathrm{nl}} = 0.2$, assuming a moderate P_M and a hole with sharp edges.

2.5 Extraction of the modal acoustic pressure

Modal acoustic pressures are useful to visualize the limit cycles of the different oscillating regimes. However, they are not directly accessible through waveguide modeling. Filtering is applied *a posteriori*, using the modal decomposition of the input impedance $Z_{in} = P_{in}/U_{in}$:

$$Z_{in} = Z_c \sum_n \frac{C_n}{s - s_n} + \frac{\mathrm{conj}(C_n)}{s - \mathrm{conj}(s_n)}, \tag{14}$$

where C_n and s_n are the complex residues and poles, computed through the residues theorem from the analytic definition of the input impedance. In particular, the modal frequencies are given by $f_n = \Im(s_n)/(2\pi)$. The n-th modal acoustic pressure at the input p_n is defined through the following ODE:

$$\dot{p}_n(t) = Z_c C_n u_{in}(t) + s_n p_n(t), \tag{15}$$

where $\dot{p}_n = \partial_t p_n$ and $u_{in} = (p_{in}^+ - p_{in}^-)/Z_c$. Modal acoustic pressures can then be computed by filtering u_{in} with an IIR filter.

3. SIMULATIONS

Blowing pressure ramps are first carried out to find the ranges for which the first register is stable when the hole is closed, as well as the range for which the second register is stable when the hole is open.

Multiple hole openings are then performed for constant control parameters to assess the playability of the register jumps.

3.1 Blowing pressure ramps

The embouchure parameter is fixed at $\zeta = 0.3$ (average value for clarinet playing [6]) throughout the simulations. First, two blowing pressure ramps (*crescendi*) are performed: one for the hole closed ($\hat{K}_{\text{nl}} \to \infty$), one for the hole open ($\hat{K}_{\text{nl}} = 0.2$). For both cases, the values of the blowing pressure for which oscillations start ($\gamma_{\text{osc}}^{(c)}, \gamma_{\text{osc}}^{(o)}$) and stop ($\gamma_{\text{ext}}^{(c)}, \gamma_{\text{ext}}^{(o)}$) are noted. Multistability zones are then determined, knowing as an inner-property of reed instruments, that the equilibrium (no sound, noted R0) is stable when $\gamma > 1$ [5].

3.2 Hole openings

From a constant blowing pressure γ, the hole is instantaneously opened. The frequency of p_{in} is computed before the opening of the hole ($f^{(c)}$), and after ($f^{(o)}$). The ratio $f^{(o)}/f^{(c)}$ determines the register obtained. In particular, if $f^{(o)}/f^{(c)} \approx 3$, the second register is played.

For one value of the blowing pressure, $N_o = 200$ hole openings are performed at different times distributed over a time window $T^{(c)} = 1.5/f_1^{(c)}$, where $f_1^{(c)}$ is the first modal frequency for the closed hole. The value of $T^{(c)}$ is chosen to ensure that all limit cycles can be fully sampled. The proportion of the second register obtained for the N_o openings is computed.

Four thresholds are measured through this procedure: $\gamma_{\text{min}}^{(0\%)}, \gamma_{\text{min}}^{(100\%)}, \gamma_{\text{max}}^{(100\%)}, \gamma_{\text{max}}^{(0\%)}$. Thresholds $\gamma_{\text{min}}^{(100\%)}$ and $\gamma_{\text{max}}^{(100\%)}$ denote the minimum and maximum blowing pressures that always lead to the second register (R2) when the hole is opened. $\gamma_{\text{min}}^{(0\%)}$ is the maximum blowing pressure lower than $\gamma_{\text{min}}^{(100\%)}$ that never leads to R2, and $\gamma_{\text{max}}^{(0\%)}$ is the minimum blowing pressure greater than $\gamma_{\text{max}}^{(100\%)}$ that never leads to R2.

To explore if the initial conditions that lead to a specific regime are sensitive to a small perturbation, a random impulsion is added to $\hat{p}_{in}^{+}$ when the hole is opened. Different amplitudes of perturbation are tested, between 0.0 and 0.50.

Table 1. Values of the four thresholds characterizing the probability of playing the second register when opening the hole.

Threshold	$\gamma_{\text{min}}^{(0\%)}$	$\gamma_{\text{min}}^{(100\%)}$	$\gamma_{\text{max}}^{(100\%)}$	$\gamma_{\text{max}}^{(0\%)}$
Value	0.383	0.386	1.32	1.36

4. RESULTS

4.1 Blowing pressure ramps

Figure 2 shows the evolution of the amplitude of the acoustic pressure in the mouthpiece $\hat{p}_{\text{RMS}}$, as the blowing pressure increases linearly from $\gamma = 0$ to $\gamma = 3$ over 20 s. The blue and yellow curves represent the cases with the hole closed and open, respectively. The color mapping corresponds to the oscillation frequency: for the closed hole, the playing frequency is near the first modal frequency $f_1^{(c)}$ (first register R1), while for the open hole, it is close to the second modal frequency $f_2^{(o)}$ (second register R2).

For each case, the minimum ($\gamma_{\text{osc}}^{(c)}, \gamma_{\text{osc}}^{(o)}$) and maximum blowing pressures ($\gamma_{\text{ext}}^{(c)}, \gamma_{\text{ext}}^{(o)}$) that sustain oscillations are measured. The thick black lines at the bottom of the graph indicate values of γ where the equilibrium (no sound, R0) is stable. Note that the values of ($\gamma_{\text{osc}}^{(c)}$ and $\gamma_{\text{osc}}^{(o)}$) are overestimated due to bifurcation delay [23].

For the open hole, when $\gamma \in [1, \gamma_{\text{ext}}^{(o)}]$ R0 and R2 are both stable. In this range, if a musician plays in the first register with the hole closed and then opens the register hole, they may end up in either R2 or R0. The hole opening procedure described in Section 3.2 is used to evaluate how the probability of playing R2 evolves with γ. The four threshold values characterizing this probability are listed in Table 1.

Within the green region, R2 is always reached. In the blue region around $\gamma = 1.3$, the probability of playing R2 depends on the timing of the register hole opening. In the red region, the system always lands on the R0. Hence, the range of γ in which R2 can be played after opening the register hole from R1 is narrower than the range of γ where R2 is stable.

To characterize the transition regions, $\gamma \in [\gamma_{\text{min}}^{(0\%)}, \gamma_{\text{min}}^{(100\%)}]$ and $\gamma \in [\gamma_{\text{max}}^{(100\%)}, \gamma_{\text{max}}^{(0\%)}]$, multiple hole openings at different times are needed to determine which

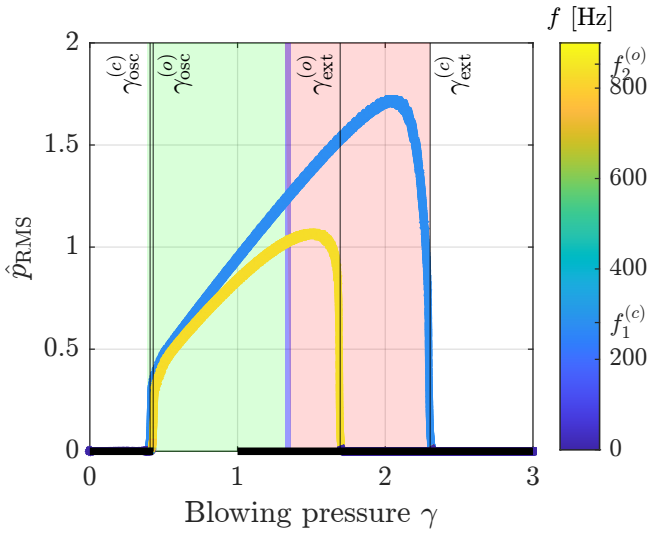

Figure 2. Evolution of the amplitude of the acoustic pressure into the mouthpiece when the blowing pressure γ increases linearly , for a constant embouchure $\zeta = 0.3$. Two *crescendi* are represented: one for the hole closed (blue curve), and one for the hole open (yellow curve). Colored surfaces in the background show the ranges of γ where the second register is reached with a given probability when the hole is opened. Green: 100 %. Blue: between 0 % and 100 %. Red: 0 %.

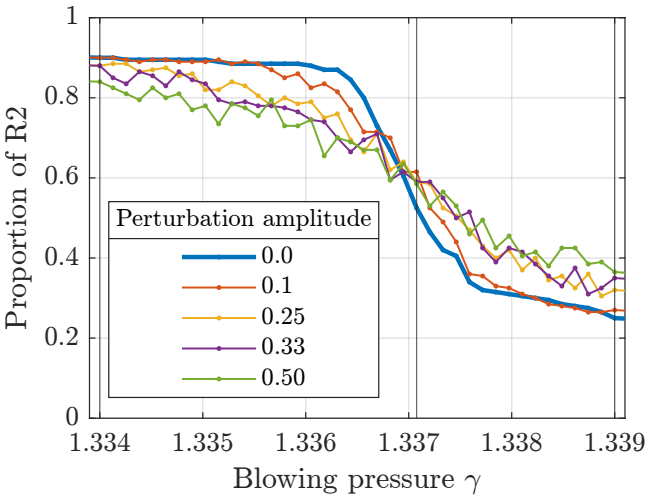

Figure 3. Evolution of the proportion of the second register (R2) when opening the register hole, for $\gamma \in [1.334, 1.339]$. The red, yellow, purple and green curves show the evolution of the proportion of R2 when random perturbations are added to $\hat{p}_{in}^{+}$ when the register hole is opened.

regime the model will predominantly converge to. Compared to the green or red regions, characterizing the blue region requires N_o times more simulations. For instrument makers studying the playability of twelfths in a clarinet model, the narrowness of these transition regions is an encouraging result.

A closer look at the transition from $\gamma_{\max}^{(100\%)}$ to $\gamma_{\max}^{(0\%)}$ is carried out in the next section.

4.2 Evolution of the probability of playing the second register

Figure 3 shows how the probability of playing the second register evolves within $\gamma \in [\gamma_{\max}^{(100\%)}, \gamma_{\max}^{(0\%)}]$. The probability follows negative sigmoid curve: it decreases gradually from 100 % to 90 %, then drops sharply between $\gamma = 1.336$ and $\gamma = 1.338$.

In the projection of the phase space on the variables $(\hat{p}_1, \dot{\hat{p}}_1)$, Figure 4 illustrates how the system converges to either R0 or R2 depending on the position of the initial condition on the R1 limit cycle. For instance, for $\gamma = 1.334$ (top left panel), only initial conditions within a small section of the cycle (around an angle of $3\pi/4$) are attracted to R0 (black dots). Opening the hole at a different time, corresponding to another position on the limit cycle, leads to R2 (red dots). This behavior is an instance of phase-tipping [24], where the result of a transition depends not only on the perturbation but also on the phase at which it is applied. As γ increases and the probability of playing R2 decreases, the set of initial conditions leading to R0 expands.

The top-center panel of Figure 4 shows that the set of initial conditions leading to R0 is not necessarily connected, highlighting the complex structure of the basin of attraction of the equilibrium in the $(\hat{p}_1, \dot{\hat{p}}_1)$ plane. At $\gamma = 1.339$ (top right panel), only a small portion of the limit cycle, around an angle of $-\pi/3$, leads to R2.

This visualization suggests that opening the register hole at the same time in every simulation is not ideal. Within $\gamma \in [\gamma_{\max}^{(100\%)}, \gamma_{\max}^{(0\%)}]$, if the hole were always opened when $(\hat{p}_1, \dot{\hat{p}}_1) \approx (0, -1200)$, the model would consistently produce R2. However, at $\gamma = 1.339$ (top right panel) there are few occurrences of R2.

Introducing a small random perturbation to $\hat{p}_{in}^{+}$ when opening the register hole results in smoother sigmoid curves in Figure 3, indicating that the basins of attraction of R0 and R2 remain stable under perturbations below 0.1. The second row of Figure 4 supports this, revealing additional regions belonging to R2's basin, such as the red dots around $\pi/2$ for $\gamma = 1.339$. Larger perturbations blur the basin boundaries in the $(\hat{p}_1, \dot{\hat{p}}_1)$ plane, as seen in the third row of Figure 4.

To better assess the basin stability of R0 and R2 when opening the register hole, alternative methods could be explored. Since perturbing p_{in}^{+} primarily affects $\dot{\hat{p}}_1$, adding white noise to the blowing pressure γ and the embouchure parameter ζ could provide a more balanced perturbation across the phase space.

5. CONCLUSION

A waveguide model of a clarinet with a register hole is studied. The blowing pressure ranges for which the first and the second registers are stable are determined. In particular, for the open hole configuration, the multistability regions of the second register and the equilibrium are quantified.

Results indicate that within this multistability range, repeatedly opening the register hole from the first register can lead the system to either the equilibrium or the second register. The probability of reaching a given register follows a sigmoid-shaped evolution as the blowing pressure increases. This behavior is reflected in phase space by the structure of the basins of attraction, which progressively enclose the limit cycle of the first register. The shifting probability of convergence to a given regime directly corresponds to changes in the shape of these basins.

Finally, the robustness of the basins of attraction is assessed by introducing random perturbations to the initial conditions. Preliminary results suggest that the basins remain robust under perturbations of p_{in}^{+} smaller than 0.1.

IMAGING-BASED SAXOPHONE REED MODELLING

Diego Tonetti[1*] **Edoardo Piana**[1]

[1] Department of Mechanical Engineering, University of Brescia, Italy

ABSTRACT

Accurate sound synthesis of reed instruments based on physical models is of primary importance in the development and prediction of the sound produced by such devices. Since the sound is produced by reed oscillation, correct modelling of this part is mandatory. Several attempts have been explored in literature both by direct and inverse modelling. Here an imaging-based approach for characterising the reed dynamic behaviour is presented, using a high-speed camera and a Digital Image Correlation technique that allows the measurement of the reed vibrations under exponential sine sweeps pressure excitation signals. The transfer function between the reed and the driving pressure is estimated at different jaw forces using an artificial lip. This approach allows for direct modelling of the reed as a single-degree-of-freedom oscillator that can be implemented in sound synthesis.

Keywords: *reed, computer vision, high-speed camera, saxophone*

1. INTRODUCTION

The saxophone reed is responsible for the sound the instrument generates since its vibration generates a pressure variation over time that the instrument's body amplifies. Its oscillating frequency differs from its natural frequency, and it is imposed by the resonance frequency of the instrument in a feedback mechanism. Modelling the instrument-reed interaction has been first studied for a clarinet-like instrument (such as the saxophone) in [1], where the reed is assumed to behave as a single-degree-of-freedom oscillator, with the oscillations forced by the pressure difference across its surface. The same assumption on the reed dynamics is the most common approach in literature and is used by many authors [2–6]. Others simplify the reed model by assuming that the resonance frequency is much higher than the instrument's one, leading to a quasi-static model of the reed where the displacement is directly proportional to the pressure difference [7, 8]. This simplification is no longer valid as the instrument resonance frequency gets closer to the reed resonance frequency, thus, it is of mandatory importance to estimate its frequency response. Here, the reed transfer function that relates the reed motion to the acoustic pressure is estimated with a high-speed camera and a microphone. Digital Image Correlation is used as an image tracking algorithm to measure the reed displacement. Lip influence is considered, and the transfer function is measured at different biting forces. At last, least-squares optimization is used to fit a numerical model of the reed with experimental data, retrieving the reed stiffness, resonance frequency and damping for each lip force.

2. MATHERIALS AND METHODS

Following the acousto-mechanical modelling of the reed from the literature, the transfer function defined in Eq. (1) that relates the reed displacement $y(t)$ with the acoustic pressure $p(t)$ is estimated to retrieve the resonance frequency ω_r, the stiffness k_r and the damping ξ of the reed.

$$\ddot{y}(t) + 2\xi\omega_r\dot{y}(t) + \omega_r^2 y(t) = \frac{\omega_r^2}{k_r}p(t) \qquad (1)$$

A synthetic reed (Legere 3 tenor saxophone reed) is measured with a high-speed camera Mikrotron Cube7 and

a Bruel & Kjaer 4170 microphone inserted in the mouthpiece via a lateral hole placed 2 mm away from the reed tip. The microphone pressure is acquired with a Bruel & Kjaer Pulse acquisition system. Calibration of the image system is performed with a calibration sheet, which is used to compute the pixel-to-millimeter ratio, while the microphone is calibrated with a pistonphone Bruel & Kjaer type 4228. The chosen reed is made of a synthetic material, allowing us to discard the humidity's effect on the reed's flexibility, leading to more constrained boundary conditions. The reed is mounted on a saxophone mouthpiece, with a speaker connected to the mouthpiece through the hole where the saxophone neck is usually fitted. The effect of the player's lip biting on the reed is simulated with a soft foam of 10mm by 20mm and 5mm thick, with a hanging mass that determines the jaw force applied. The mass is varied from 0g to 1000g with steps of 250g, to simulate different biting forces on the reed. The 0g condition is achieved by removing the artificial lip, which means that the reed is simply clamped to the mouthpiece via the ligature. A constant light source is placed behind the reed, acting as a bright background in the recorded images and allowing for higher contrast in images, which is mandatory for image analysis. The experimental setup is schematized in Figure 1.

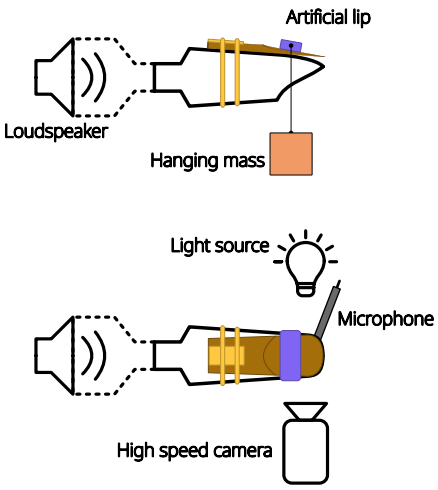

Figure 1. Scheamtic lateral and top view of the experimental setup.

The chosen signal is an exponential sine sweep generated with the plugin Aurora for Audacity [9], which also computes the inverse filter that will be used to remove all the harmonic distortions of the measured signals, allowing the retrieval of the linear response of the reed. For a signal $s(t)$, this is achieved by computing the convolution between the signal and the inverse filter as in Eq. (2):

$$r(t) = s(t) * x^{-1}(t) \tag{2}$$

where $x^{-1}(t)$ is the inverse filter of the exponential sine sweep $x(t)$. Looking at the time series of the convolution result $r(t)$, a series of peaks that correspond to the impulse responses of each harmonic is visible [10]. The linear response is the last impulse response visible in the series and can be isolated by taking a time window around it. An example of the convolution result is presented in Figure 2.

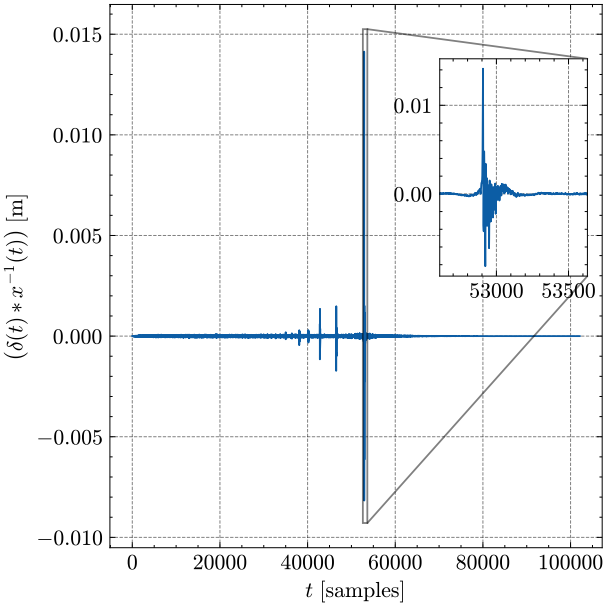

Figure 2. Convolution result of the measured displacement with a load of 0 g. A zoom is performed on the linear response.

Once the linear impulse responses of the pressure and displacement are retrieved, the measured transfer function of the reed $H_m(f)$ is evaluated in Eq. (3) as the ratio of the FFTs of the windowed impulse responses of the displacement $\delta'(t)$ and the pressure $p'(t)$.

$$H_m(f) = \frac{\mathcal{F}(\delta'(t))}{\mathcal{F}(p'(t))} \tag{3}$$

Performing the Laplace transform of Eq. (1) using the operator $s = j\omega = 2j\pi f$ leads to Eq. (4).

$$H(s) = \frac{Y(s)}{P(s)} = \frac{1}{k_r} \frac{\omega_r^2}{s^2 + 2\xi\omega_r s + \omega_r^2} \quad (4)$$

The measured transfer function can then be used to estimate the resonance frequency ω_r, the damping ξ and the elastic coefficient k_r of Eq. (1) by fitting the analytical transfer function $H(s)$ with the experimental transfer function $H_m(f)$. This can be done with least-squares optimization that aims at finding ω_r, ξ and k_r as in Eq. (5).

$$(\omega_r, \xi, k_r) = \arg\min_{\mathbf{b}} \| |H(f, \mathbf{b})| - |H_m(f)| \|, \quad \forall f \quad (5)$$

2.1 Image tracking

Tracking the reed's movement can be trivial, but the choice of image-tracking algorithm is crucial for the correctness of the obtained results. Digital image correlation (DIC) [11] is used here to track the movement of the reed; this procedure allows for computing the image shift between two different frames by computing the cross-correlation function between them, similar to the technique used to calculate the time-lag between two audio signals. The technique can be easily applied due to the image setup constraint, as it is possible to isolate the reed movement entirely from the surrounding ambient, as can be observed in Figure 3, where the only moving object is the reed.

Figure 3. Reed tip acquired by the camera.

The cross-correlation between two images can be computed efficiently with the discrete Fourier transform (DFT) as

$$r = \mathcal{F}^{-1} \left(G_a \circ G_b^* \right) \quad (6)$$

where $\circ$ is the element-wise multiplication of the DFT G_a and G_b of the image I_a at time t and the reference image I_b. The displacement is then equal to the position of the maximum correlation coefficient and can be retrieved as

$$(\Delta x, \Delta y) = \arg\max_{(i,j)}(r) \quad (7)$$

This approach is limited to discrete displacements of 1 pixel, while sub-pixel precision is required due to the small movements of the reed. A straightforward solution is to interpolate the cross-correlation function and find the new maximum given by that interpolation [12], thus achieving sub-pixel accuracy. Here, a 3rd order interpolation is used from the Python [13] library Scipy [14] by performing a zoom with an enlargement factor $Z = 10$, which leads to a sub-pixel accuracy of 0.1 pixel. To save computational costs, interpolation is performed on a small window around the pixel-level peak. The overall displacement due to the pixel displacement plus the sub-pixel displacement is then given by Eq. (8) as

$$(\Delta x, \Delta y) = \arg\max_{(i,j)}(r) + \frac{1}{Z} \arg\max_{(i,j)}(r') \quad (8)$$

where r' is the interpolated cross-correlation. To avoid problems at the borders that could cause aliasing, the images are multiplied by a two-dimensional Hann window. Also, contrast is enhanced via histogram stretching and noise is reduced with a Gaussian blur using OpenCV [15]. The algorithm steps are reported here:

1. Compute the FFT of the reference image multiplied by the Hann window.
2. Compute the FFT of the image at time instant t.
3. Compute the cross-correlation with Eq. (6).
4. Find the pixel-precision displacement with equation 7.
5. Crop the cross-correlation around the peak found in the previous step.
6. Interpolate the cross-correlation and retrieve the sub-pixel displacement again with 7.
7. Scale the sub-pixel displacement by the zoom factor and add it to the pixel-level displacement.

3. RESULTS

All the measurements are performed with a sine sweep that goes from 50 Hz up to 5 kHz with a duration of 5 s, and the sampling frequency is chosen equal to the framerate of the camera, i.e. 10 kHz. The window used around the peak is of 1024 samples, with a sampling frequency of 10 kHz, thus leading to a frequency resolution of 9.77 Hz. The experimental transfer function of the reed measured for all the lip loads is presented in Figure 4, where both the amplitude and the phase are shown.

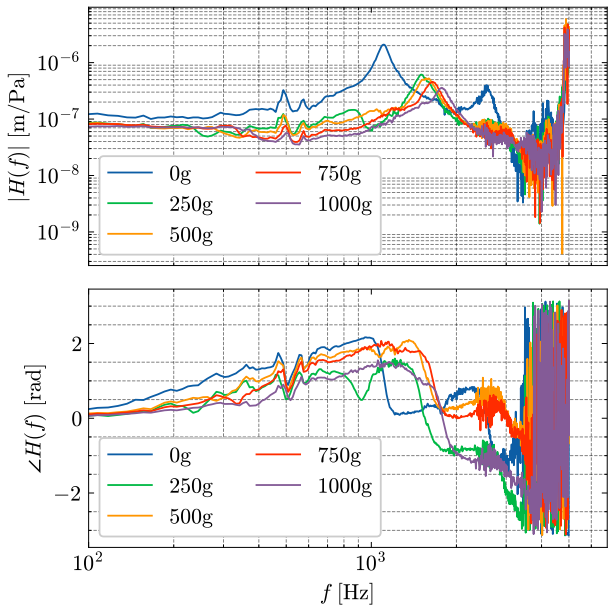

Figure 4. Reed measured transfer functions at different loads.

Comparisons between the measured and least-squares transfer functions are reported for various lip loads in Figure 5. Only the modules of the transfer functions are considered during the least-squares method, as the phase at low frequency presents a drift that makes the single DOF oscillator unfit. Following the control theory of Linear Time Invariant systems in the Laplace domain, the phase shift could be modelled by adding a zero (i.e. a derivative term) at low frequency in the transfer function of Eq.(4), which would increase the phase by 90 deg in agreement with the results, but it would also increase the module by 20 dB/dec which is not visible in the measures. Thus, following the literature, Eq. (4) is considered valid, the phase is discarded, and only the module is used for fitting the transfer function with experimental data. The data is fitted on the frequencies that range from 50 Hz to 2500 Hz to avoid noise at high frequency and at the low frequencies where the reed isn't excited by the ESS.

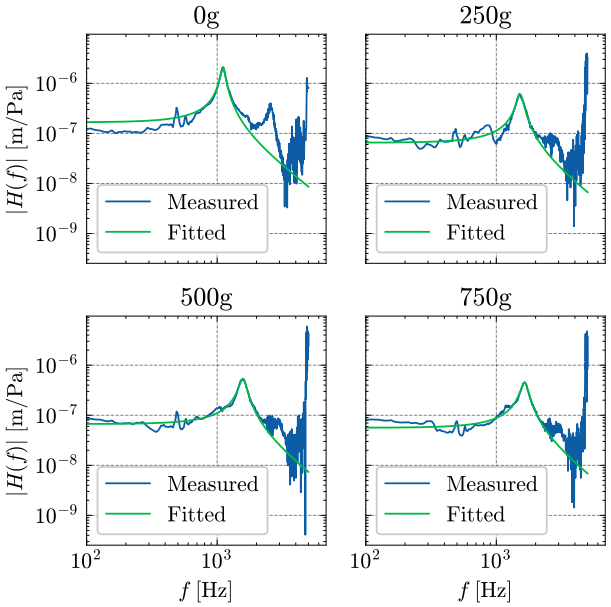

Figure 5. Measured and least-squares optimization results for 4 different lip loads.

The fitted transfer functions are reported in Figure 6, while the estimated coefficients derived from the least-squares optimization are summarized in Table 1.

load [g]	k_r [Pa/m]	ω_r [rad/s]	ξ [1]
0	6.01×10^6	6.97×10^3	3.95×10^{-2}
250	1.54×10^7	9.59×10^3	5.40×10^{-2}
500	1.50×10^7	9.92×10^3	6.24×10^{-2}
750	1.78×10^7	1.04×10^4	6.27×10^{-2}
1000	1.95×10^7	1.12×10^4	7.71×10^{-2}

Table 1. Caption

4. DISCUSSIONS

From the measured reed transfer function with no lip force applied, two resonance peaks are visible, one at 1104 Hz and one at 2549 Hz. The presence of two resonances is not visible when a lip load is applied; this could be a limitation

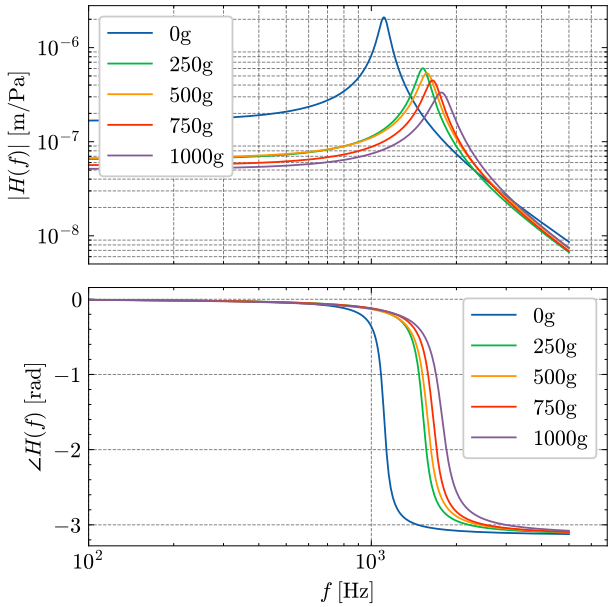

Figure 6. Fitted transfer function of the reeds at all lip loads.

of the experimental setup used, as it presents considerable noise above 3 kHz. A better signal-to-noise ratio can be achieved using a brighter light source, enhancing the image contrast. The reed's first resonance in the absence of lip influence is in agreement with the one measured in [16] for a tenor saxophone cane reed. The first resonance peak is shifted up in frequency as the lip load increases, which is in contrast with the measurements obtained in [5]. This behaviour of the reed increasing its resonance frequency is indirectly observed in [17] and is well known by players, where higher biting forces increase the pitch of the note. In [17], this is justified by stating that the reed is bent against the mouthpiece, thus shortening the reed portion that is allowed to vibrate. The measured resonance frequency and reed stiffness are close to the results obtained by inverse modelling of a clarinet reed in [6], and the reed stiffness is also comparable with the results found for a quasi-static clarinet reed [8]. Significant discrepancies are found with the resonance frequency, stiffness and damping with [18], where inverse modeling similar to [6] was performed on a tenor saxophone reed.

5. CONCLUSIONS

The transfer function of a reed was directly measured at different lip forces via a high-speed camera and Digital Image Correlation. This technique allowed non-contact measures of the reed displacement, representing an alternative to Laser Doppler Vibrometry. The performed measurements were compared with the literature, finding mixed results. These discrepancies could be due to the experimental setups, artificial lips and reed materials. The resonance frequency of the reed is found to be around 20 times greater than the instrument's lowest resonance frequency, while about only 3 times larger than the highest. A quasi-static model of the reed could thus be insufficient to model the reed as the note of interest moves up along the saxophone register.

VOCAL TRACT TURBULENCE AND RECORDER SOUND – A CFD APPROACH

Naomi Nordblom[1*] **Rolf Bader**[1]
[1] Institute for Systematic Musicology, University of Hamburg, Germany

ABSTRACT

Whether it is possible to change the timbre during recorder playing is a much debated question among recorder players. Chen et al. (2007) showed that it is indeed possible to alter the timbre of the recorder as a player. As the underlying mechanism is not clear, a large eddy fluid simulation in two dimensions of four different vocal tract shapes has been carried out. One vocal tract is straight, the second one has a constriction in the back, the third one has a constriction in the front and the last one is a short reference model. The velocities and the pressure point to the hypothesis that turbulence created in the front of the mouth cavity is associated with lesser correlated velocities in the jet region and reduced harmonics.

Keywords: *recorder, flue instrument, turbulence, vocal tract*

1. INTRODUCTION

Although the recorder is present in European culture at least since the middle ages [1], there is still no theoretical framework how to elicit different timbres as a player for a given pitch. Colorful recorder playing has first documented about 70 years ago by Frans Brüggen but until today, players struggle to reproduce this except very few virtuosi. A better understanding of virtuoso recorder techniques could make them accessible for more people. From a physical perspective, the recorder consists of an edge tone which is additionally enslaved by a resonator [2], [3]. This means, that the frequency of the recorder is strongly coupled to the blowing speed which guides the oscillation frequency of the jet [4]. However, there are some loopholes that have the potential to alter the timbre without changing the pitch (for an overview see [5]).

The most researched one sees the windway as the neck of a Helmholtz resonator sitting on the volume of the mouth cavity [6], [7]. This effect has also been examined with fluid simulations on an organ pipe with its chamber [8], [9]. Depending whether the frequency of the Helmholtz resonator is above or below the fundamental of the flue instrument, in-phase or anti-phase oscillations are elicited in the jet. The anti-phase oscillation leads to a more stable tone when the frequency of the Helmholtz is below the fundamental of the instrument [8], [9]. Moreover, possible alterations of the harmonics are discussed [6], [7]. Further in this paper this, will be called the Helmholtz effect. Another mechanism is the production of turbulence in the vocal tract. A spectral analysis revealed different timbres of a virtuoso recorder player when playing the same instrument [10]. After some hypotheses [10] as well as a first fluid simulation [5], it is still unclear, how the turbulence finds its way from the mouth to the sound. This is the scope of this paper.

Transient fluid simulations are well suited as a major contribution to tackle this problem because of their ability to deliver values of all relevant physical quantities at every point in time and space. Due to the 3D nature of turbulence and the different energy cascades [11], a thorough investigation would require several 3D Large-Eddy-Simulations (LES). This would ask for an enormous amount of calculation time and careful selection which data to write out. To facilitate this decision, 2D-simulations have been carried out to develop a qualitative hypothesis for more detailed testing e.g. a possible 3D-simulation.

2. METHOD

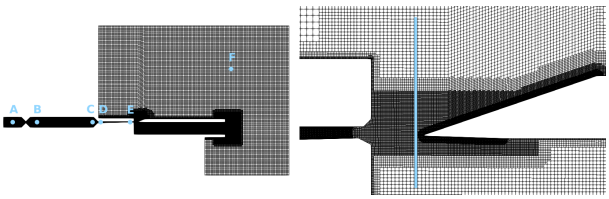

Figure 1: Mesh with sample locations in blue.

To investigate the influence of turbulence in the mouth cavity on the recorder sound, LES-simulations have been carried out. Four different shapes of "mouth cavities" have been tested (fig. 2): The first one is a straight tube. The second one has a constriction in the back and the third one in the front. It is expected, that the flow separates after the constriction to create shear turbulence. Moreover, a short model has been created to distinguish the influence of turbulence from the Helmholtz effect. The dimensions of the mouth cavities are very roughly estimated after [12] with a length of $14.8\,\mathrm{cm}$ and a diameter of $1.63\,\mathrm{cm}$ for the straight vocal tract and the ones with the constrictions in the front. The short vocal tract has the same volume as the front chamber of the mouth cavity with the constriction in the front. The simulations are run with OpenFOAM v2406 and its compressible solver rhoPimpleFoam. The numerics mostly follow [13] because the source code is online and some of his results have been confirmed by experiments [13] and a 3D simulation [14]. The turbulence is modelled with a one-equation-eddy model. The spacial derivatives are discretized with a filtered version of the central differencing scheme to obtain sharp gradients for the jet and suppress oscillations. The temperature is set to $293\,\mathrm{K}$ while the pressure is set to $101\,325\,\mathrm{Pa}$. The boundary conditions consist inter alia of an inlet with constant velocity of $1.17\,\mathrm{m\,s^{-1}}$, acoustically hard walls, a wave transmissive outlet for the pressure combined with an outlet velocity condition with a zero gradient outflow velocity for the air leaving the domain and a calculated inflow velocity for reverse flow into the domain.

The windway and labium of the recorder are built after an f-alto recorder by Johann Pörschmann (about 1680–1757) at the Musikhistorisk Museum in Copenhagen, inventory number CL 417 [15]. The measurements of the chamfers and the position of the labium's tip are lacking in this plan and estimated following the advice of recorder maker Geri Bollinger. The resonator consists of a straight tube with a length of $14.3\,\mathrm{cm}$ and a diameter of $1.93\,\mathrm{cm}$. When creating the mesh, emphasis has been given to a fine grid in the windway, the jet region, around the labium and at the walls (fig. 1). This results in grid sizes between 197 057 cells for the short vocal tract and 219 384 cells for the straight vocal tract. The simulations are run for $0.1\,\mathrm{s}$ with a time-step of $2.5 \times 10^{-6}\,\mathrm{s}$.

3. RESULTS AND DISCUSSION

In this section, we follow the flow from the vocal tract over the windway and the jet to the sound spectra.

3.1 Creation of Turbulence in the Vocal Tract

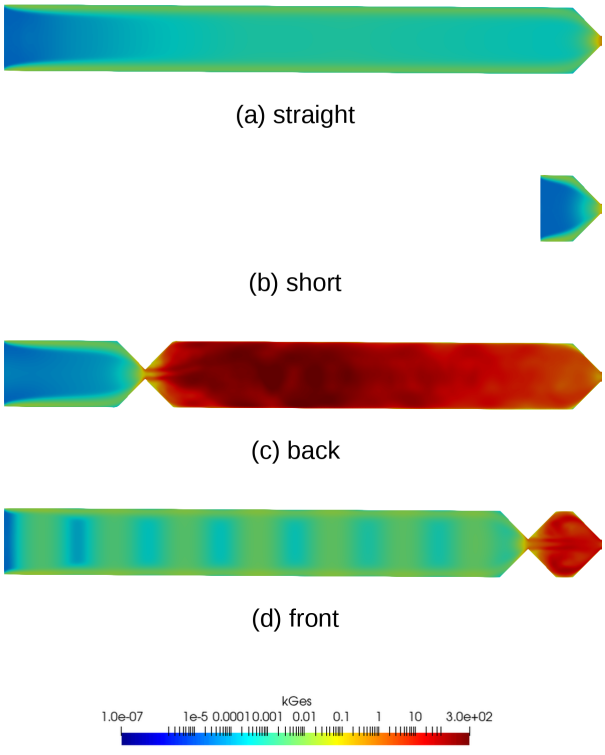

Figure 2: Logarithmically scaled turbulent kinetic energy in the vocal tract after $0.1\,\mathrm{s}$. The constrictions lead to boundary layer separation and create shear turbulence.

As we can see in fig. 2 taken after 0.1 s, the constriction creates shear turbulence by boundary layer separation. The image of the constriction in the back shows the typical growth and the decay of shear turbulence without extra energy supply in the direction of the flow. The energy spectra obtained from the autocorrelation of the velocity component in the mean flow direction show a clear periodicity for the straight and short vocal tracts while there is a typical line at the turbulent locations after the constrictions. The decay of the turbulence of the constriction in the back is also reflected on the spectrum, as harmonic components begin to reappear. This can be seen for example on the energy spectrum of the flow direction velocity in fig. 3 compared to the similar spectra of the straight vocal tract.

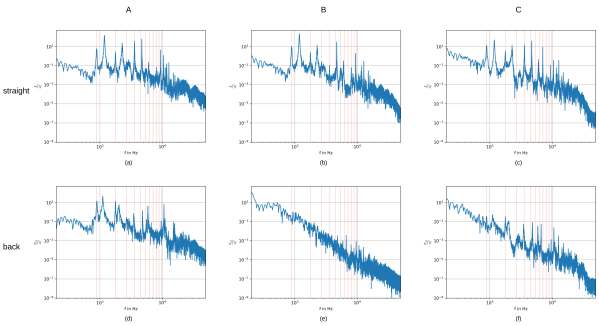

Figure 3: Energy spectra of the velocity fluctuations in the mean flow direction in the vocal tract. The first line shows the straight vocal tract as a comparison while the second line shows the spectra of the constriction in the back before (A), after (B) and long after the constriction (C).

3.2 Turbulence in the Windway

The energy spectrum in the direction along the windway can be seen in fig. 4. The first probe point, D, lies 1.428 57 mm after its entrance while the second probe point is located at 55.98 mm from the entrance, right above the lower chamfer, E (fig. 1). The spectra in fig. 4 show a blend of the acoustic and the flow field. The pink lines show multiples of the fundamental of 891 Hz while the dark red lines show multiples of the resonance frequency of the windway around 2858 Hz up to 10 000 Hz. The gray area shows the minimum eddy frequencies stemming from the turbulence in the windway between 7400 and 60 000 Hz. They are estimated by Taylor's hypothesis with a windway diameter of 9 mm at its entrance and 23 mm at its narrowest point where the flow separates from the lower chamfer to form the jet.

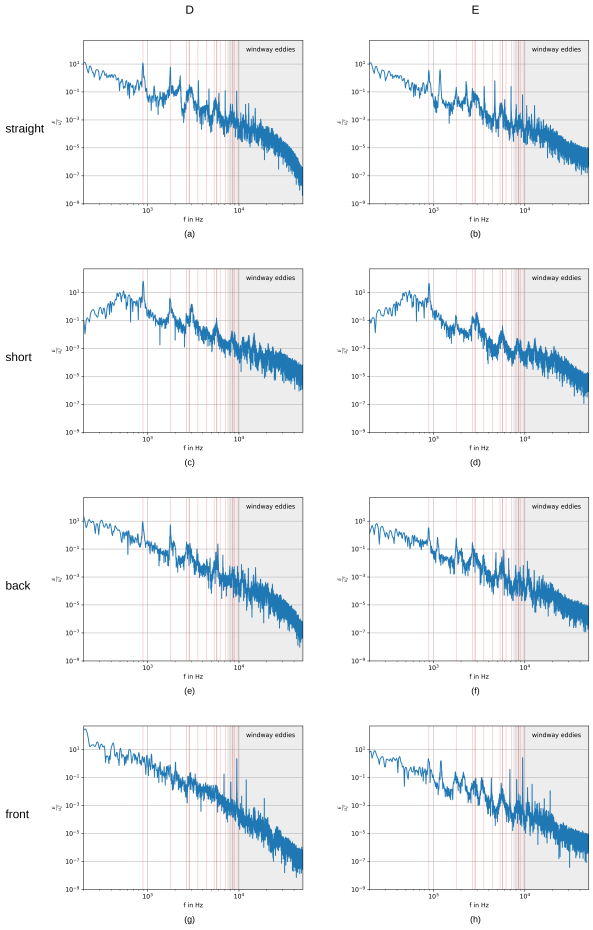

Figure 4: Energy spectrum of the velocity fluctuations in the x-direction from 0.02 to 0.1 s at the windway entrance and at the separation point at its exit.

In general, the spectra show some harmonic peaks associated with the sound field, a more or less logarithmically declining noise floor as well as some inharmonic peaks. Some of them are multiples of the estimated resonance frequency of the windway while others could descend from the flow field as documented by [16] and [9] for the sound pressure levels. The straight vocal tract has the clearest and best aligned harmonics. The spectra of the short vocal tract show less harmonics with broader peaks

and very clear windway resonances. The spectra of constriction in the back shows less aligned higher harmonics than the spectrum of straight vocal tract particularly above 4000 Hz. At the entrance, there are almost no harmonics discernible for the spectrum of the constriction in the front while they reappear with broad peaks and reduced amplitudes at the windway exit. Next, we are looking closer into the gray regions of fig. 4 which would allow for isotropic eddies in the windway. Except for the short vocal tract, all spectra show more energy at these frequencies at the exit of the windway compared to its entrance possibly because of the wall boundary layer of the windway. The reason for the exception of the short vocal tract is not known. The two vocal tracts with constrictions exhibit slightly enhanced amplitudes above 30 000 Hz. All in all, the different geometries show already different turbulence structures when leaving the windway with the straight vocal tract being the most harmonic and the constriction in front showing the most high-frequency peaks. A detailed analysis in this region has to be used with great caution because of the convection in the windway, the different energy cascade between 2D and 3D could play a major role.

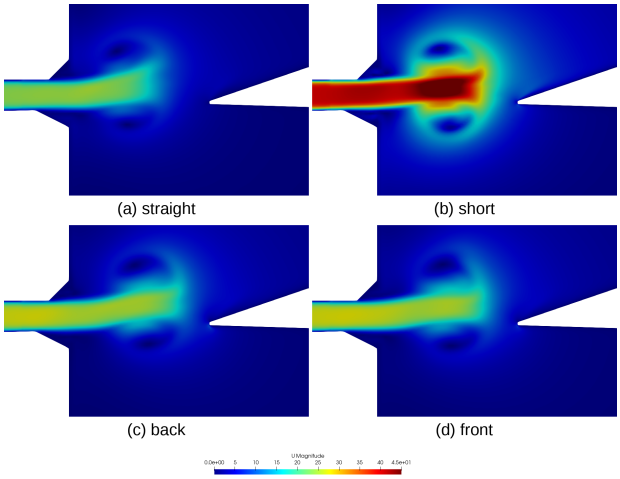

Figure 5: Jet velocity magnitude after 0.001 68 s for the straight, front and back condition and after 0.0008 s for the short vocal tract. The different histories of the jet are amplified by the Kelvin-Helmholtz instability.

3.3 Jet Velocities

The development of the jet velocities can be analyzed in two consecutive time windows. When the flow enters the cutup as a jet for the first time, it is mainly influenced by the Kelvin-Helmholtz instability (KHI) reflecting its aerodynamic history. After the resonator delivers its feedback over the time, interesting correlations of the jet velocities can be spotted and it seems more to behave like a complex system.

3.3.1 Initial Kelvin-Helmholtz Instability

Fig. 5 shows the Kelvin-Helmholtz instability of the velocity magnitude of the jet after 0.001 68 s for the straight, front and back condition and after 0.0008 s for the short vocal tract. At this moment, the initial shockwave [13] has already been reflected on the jet and it might also pertain to the perturbations of the jet amplified by the KHI.

The differences between the images reflect the different histories of the jets before arriving at the cut-up. The straight vocal tract shows the biggest upward bending of the jet. This initial upward-bending is clearly reduced for the short vocal tract due to its higher momentum. This condition shows a higher velocity at this initial stage because the air is more compressed in the mouth cavity before entering the windway due to the proximity of the inlet to the windway entrance. However, this enourmous velocity difference disappears in the steady-state. The constrictions show lower velocity gradients especially when the constriction is in front and thus flatter velocity profiles due to the upstream turbulence in accordance with [17].

3.3.2 Velocity Correlations During the Steady-State

To capture the vertically oscillating jet, a line sample of the velocities has been drawn perpendicularly through it 2.6364 mm away from the windway exit as shown in fig. 1. At this location, the vertical oscillation of the jet is well developed, but it is not yet highly asymmetrical due to the labium. The x-component of the velocity in the mean flow direction shows the position of the jet over time until 0.1 s (fig. 6).

The time development of the jet position is mirrored by the pressure evolution at 17 cm away from the labium above the foot as we can see at the example of the straight vocal tract. At first, an oscillation forms until 0.005 s and grows up to 0.023 s. During the growth, the velocities around the jet align their movement with the jet. The steady-state is temporarily disturbed between 0.042 s and 0.05 s by an exception in the velocities with a simulta-

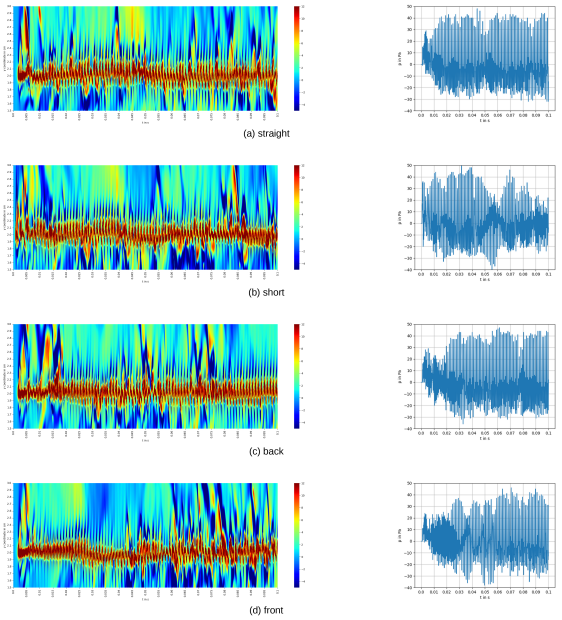

Figure 6: Left: Horizontal velocity component of a sample line perpendicular to the jet plotted over the time until 0.1 s. Right: corresponding pressure amplitudes 17 cm away from the labium above the foot at point F.

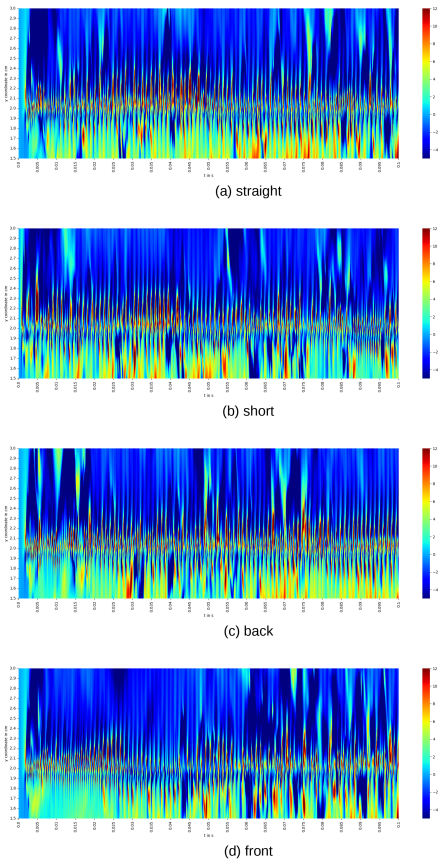

Figure 7: Vertical velocity component of a sample line perpendicular to the jet plotted over the time until 0.1 s.

neous reduction in sound pressure. The short vocal tract has a shorter initial transient and a less stable steady-state. From 0.0885 s and 0.096 s, the recorder overblows. This dependence of the overblowing on the geometry of the vocal tract could hint to [4] who have shown that trained recorder players can enlarge the hysteresis of their instrument with respect to overblowing. The constriction in the back exhibits a longer transient up until 0.038 s. Here, we can also watch the oscillations around the jet and the pressure amplitude grow together. The constriction in the front has a very long transient and growth until 0.028 s with very regular movements although it has some difficulties to take along as much air around the jet as the other conditions. Then, the the jet gets more irregular up to 0.028 s settling into a steady-state with a varying amplitude and surrounded by some quite far-reaching non-periodic velocity fluctuations.

While the x-component reveals the position of the jet, the y-component tells us something about its vertical movement (fig. 7).

During the steady-state, the heatmaps show different levels of variability of the vertical jet movement over time. Moreover, this jet movement influences the air around it up to different distances. To obtain a numerical value associated with these effects, the correlation function of the time evolutions of each sample point with a point in the middle of the jet has been taken. Fig. 8 shows the L1-norm of each correlation function depending on the y-coordinate.

The correlations are the highest inside the resonator. The reflection of the sound waves in this region could support the strong correlation. A second peak can be observed in the jet and a third one above the jet in the cut-up and slightly outside of the instrument. The image shows an

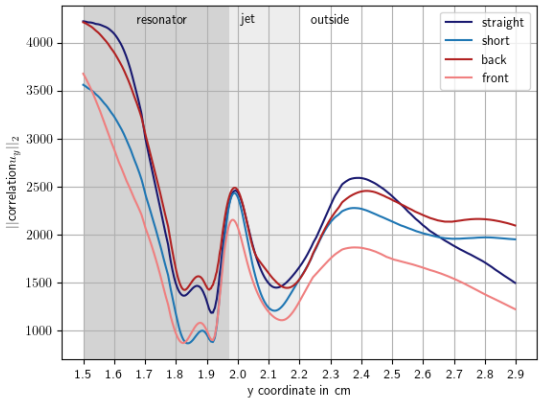

Figure 8: Correlation norm of the time evolution of each sample point with a point in the jet.

interaction between the size of the mouth cavity and the turbulence with enhanced correlations for a larger vocal tract and less turbulence. This is most prominent in in the cut-up peak outside of the jet and the resonator. Moreover, the difference between the front and the short condition suggest a second possibility to alter the sound next to the proposed Helmholtz effect.

3.4 Radiated Sound Spectra

The radiated sound spectra in fig.9 are taken 17 cm away from the labium above the foot from 0.02 to 0.1 s during the quasi-stationary state with a sample rate of 10^5 Hz. This gives a frequency resolution of 12.07 Hz. All the fundamentals are at 891 Hz. The spectrum of the straight vocal tract shows the clearest harmonics with the narrowest peaks. In this, the first and second harmonic are most prominent. In comparison, the spectra of the short vocal tract and the constriction in the back differ slightly while the spectrum in the front shows clear changes. The spectrum of the short vocal tract shows slightly wider peaks and tightened octaves as overtones. The first and second harmonic are a little bit weaker. The sound spectrum of the constriction in the back also displays slightly wider harmonics. In this case, the first and second harmonic are as strong as in the spectrum of the straight vocal tract with weakened third and fourth harmonics. In general, these changes are rather small and it would be interesting if they can be perceived. In contrast, the spectrum with the constriction in the front only shows a strong first harmonic with a weaker second and higher harmonics not discernible from the background. The first and second harmonic are considerably broader. Moreover, it displays some extra energy in the frequencies around the second harmonic and between 6000 and 7000 Hz. This rich fundamental and the enhanced noise floor between 6000 and 7000 Hz match with the virtuoso recorder technique described and recorded by [10] although the slightly enhanced noise could be just by chance. However, they report altering the position of the soft palate, a different body movement that is not necessarily associated with creating shear turbulence, so additional effects such as the Helmholtz effect could also play a role.

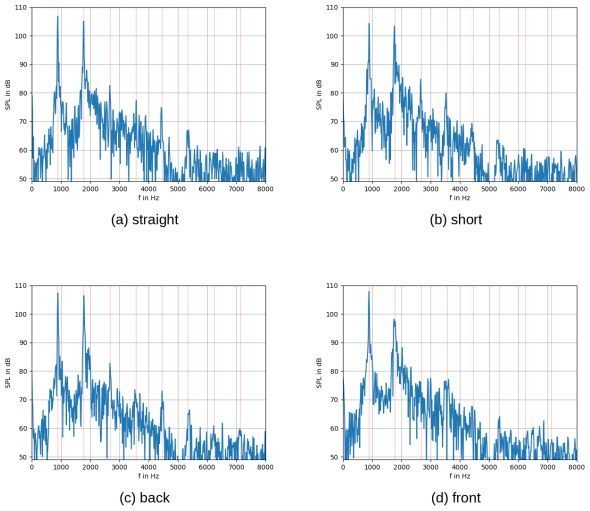

Figure 9: Pressure spectra during the quasi-stationary state from 0.02 to 0.1 s. The constrictions are associated with less clear harmonics in the sound spectrum.

In general, these results raise the questions whether the feedback between the jet and the resonator or the KHI plays the leading role for a timbre change with turbulence in the mouth cavity.

4. CONCLUSION

The results show changes throughout the instrument in the flow and the radiated sound pressure with the geometry in

the vocal tract. The data from the short vocal tract differ clearly from the changes seen in the vocal tract with a constriction in the front. This points to a second possibility to alter the sound for a given pitch next to the Helmholtz effect. We propose that this could work in two steps: First, the shear turbulence in the mouth influences the initial KHI by mostly by aerodynamic effects. In the second step, the instrument behaves like a complex system with the feedback between the jet and the resonator additionally altering resulting sound pressure. Moreover, the comparison between the constrictions in the front and in the back suggest that turbulence might be most efficient to alter the sound when created at the right spot in the mouth. These effects are associated with reduced harmonics when the constriction is in the front. However, this is only a first dip into the mechanism behind a possible vocal tract influence on the sound of a flue instrument. 2D turbulence has a different energy cascade which is also not accounted for by the used turbulence model. Therefore, the results need to be checked with a more resource consuming 3D simulation and experiments now that we have some better idea, which data could be useful to write out. Further simulations would also require a mesh quality study. In the meanwhile, recorder players could test whether this concept and some basic knowledge about turbulence could be artistically useful.

5. ACKNOWLEDGMENTS

Thank you to Dan Laurin and Han Tol for their support from a recorder players' perspective, Jost Fischer for his skillful introduction to openfoam, Bernd Leitl for sharing his knowledge about turbulence and asking good questions, Martin Stieben as an exceptionally motivated HPC admin and the acoustics group of our institute for many helpful discussions. Thank you also to Johann Joachim Quantz for demonstrating the importance of written transmission of flue instrument playing techniques.

ABSTRACT

Self-sustained musical instruments, such as wind or bowed string instruments, are capable of producing sustained sounds from a continuous supply of energy. These instruments exhibit transient regimes when the sound appears and during note changes. In this study, we focus on certain transient behaviors of a soprano trombone around a double Hopf bifurcation, induced by a slide displacement. To numerically study these transients on a model, the input impedance of the instrument is interpolated between different slide positions. Linear stability analysis and time integration are applied to a brass model for this situation. These simulations show that around a double Hopf bifurcation and at constant blowing pressure, it is possible to select the equilibrium or two different periodic regimes by only controlling the slide position.

1. INTRODUCTION

Brass instrument are self-oscillating systems whose functioning regimes depend on the resonator parameters and on the playing parameters, such as the blowing pressure or the lips resonance frequency. In the scope of dynamical systems, the oscillations of a self-sustained musical instrument usually arise from Hopf bifurcations, where a periodic solution appears and the stability of an equilibrium solution changes. The study of the Hopf bifurcations and the dynamics of a brass instrument around these bifurcations is a common approach [1]. In most works concerning this subject, the considered sets of parameters foster one specific periodic regime at a time [2]. Nevertheless, these instruments exhibit double Hopf bifurcations where two Hopf bifurcations appear for the same values of parameters. Around those double Hopf bifurcations, two different periodic regimes may appear which results in rich transients and multistability issues. In this article, we focus on the transient behavior of a soprano trombone around a double Hopf bifurcation. The model is presented in Sec. 2 along with the input impedance interpolation of a slide instrument. Linear Stability Analysis (LSA) and time integration are then applied to the model in Sec. 3 to study a moving slide scenario. Conclusions are drawn in Sec. 4.

2. BRASS INSTRUMENT MODEL

2.1 Equations of the model

We use the same model as in [3]. The lips are represented by a one degree-of-freedom linear oscillator and the resonator by a modal decomposition of its input impedance. The air flow passing through the lips is modeled by the Bernoulli equation. Overall, the the model writes:

$$\begin{cases} \ddot{x} + \frac{\omega_L}{Q_L}\dot{x} + \omega_L^2(x - x_0) = \frac{p_0 - p}{\mu_L}, \\ \dot{p}_n - s_n p_n = Z_c C_n u \quad \forall n \in [1, N_m], \\ p = 2\sum_{n=1}^{N_m} \Re(p_n), \\ u = W\sqrt{\frac{2|p_0 - p|}{\rho}} \cdot \text{sign}(p_0 - p) \cdot \max(x, 0), \end{cases} \tag{1}$$

where x is the lip position, p_n are the modal pressures, u is the air flow and p_0 is the blowing pressure. ω_L, Q_L and μ_L are the angular frequency, the quality factor and the surface mass of the lips. N_m is the number of modes used to describe the input impedance and C_n and s_n are its residues and poles. Z_c is the characteristic impedance at the input of the resonator, W is the width of the lip channel, x_0 is the lip position at rest and ρ is the air density. In the remainder, we set the following parameters:

$$\begin{cases} f_L = 500 \text{ Hz}, \\ \mu_L = 2 \text{ kg.m}^{-2}, \\ Q_L = 4, \\ x_0 = 1 \cdot 10^{-4} \text{ m}, \\ W = 8 \cdot 10^{-3} \text{ m}, \\ Z_c = 1.83 \cdot 10^6 \text{ kg.s}^{-1}.\text{m}^{-4}. \end{cases} \tag{2}$$

2.2 Studying slide instruments

To explore the behavior of a brass instrument around a double Hopf bifurcation, we choose to fix the lip parameters and to vary continuously the resonator modal parameters using a slide. Indeed, it is difficult to control and estimate the lip parameters on an experimental setup whereas it is much easier to do so with a slide position. That is why we study a soprano trombone.

In order to simulate its behavior at any slide position or with a time evolving slide position, we interpolate the modal coefficients (poles C_n and residues s_n) of the input impedance measured at various slide positions. The input impedance is measured at each slide centimeter (the resonator length modification is twice as long as the slide displacement since the pipe is 180° curved) and its modal decomposition is computed with the peak-picking toolbox [4]. As a result, the resonator is entirely described by only one control parameter d_{slide}, which facilitates numerical implementation.

Using the peak-picking toolbox [4], the input impedance can be decomposed with at least $N_m = 11$ modes at any slide position without having spurious modes. However, in the following, we will only keep two of these modes which is sufficient to highlight a double Hopf bifurcation.

3. NUMERICAL ANALYSIS

3.1 Linear Stability Analysis (LSA)

We consider two control parameters (p_0, d_{slide}) since all other parameters are fixed according to (2). Usually, Linear Stability Analysis (LSA) is used to find threshold pressures and fundamental playing frequencies at the onset of the oscillations. This corresponds to finding Hopf bifurcations in the plane (p_0, f_L). Such a representation is given in Fig. 1 for $d_{slide} = 15$ cm. The intersection of two Hopf curves corresponds to a double Hopf bifurcation (marked with stars on Fig. 1, 2 and 3). In the remainder, we keep only modes 5 and 6 which are associated with the two Hopf bifurcations that cross around $f_L = 500$ Hz. The LSA of the two modes model is plotted in Fig. 2. Reducing the model to only two modes slightly changes the location of the Hopf bifurcations, but they still cross around $f_L = 500$ Hz.

Here, we consider a fixed $f_L = 500$ Hz and a variable d_{slide}. Consequently, the Hopf curves are rather plotted with respect to d_{slide} in Fig. 3. We limit the study to $p_0 \in [0, 5]$ kPa and $d_{slide} \in [10, 16]$ cm. In this region of interest, only two periodic solutions exist along with the equilibrium, and they show a double Hopf bifurcation at $p_{0,DH} = 2.8$ kPa and $d_{slide,DH} = 14.6$ cm.

Additionally, we use Manlab and the Hill-Floquet stability analysis [5] to compute the periodic branches and their stability. In this configuration, all Hopf bifurcations are direct. For a given d_{slide}, the first Hopf bifurcation (i.e. with the lowest p_0) leads to a stable regime whereas the second Hopf bifurcation (i.e. with the highest p_0) leads to an unstable regime. For p_0 higher than the second Hopf bifurcation, this second regime becomes stable through a torus bifurcation represented by dashed lines in Fig. 3.

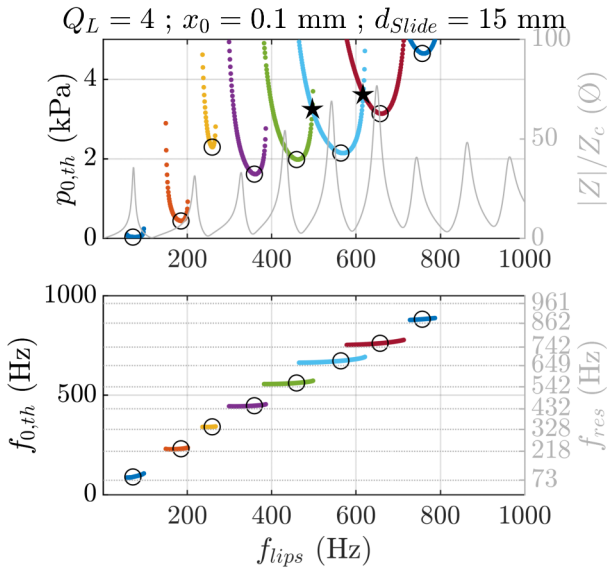

Figure 1: LSA with respect to f_L considering $N_m = 11$ modes. Pressure thresholds (top pane) and playing fundamental frequency at the onset of the oscillations (bottom pane). Double Hopf bifurcations are represented by stars. The dimensionless input impedance modulus is superimposed on the top pane whereas the resonance frequencies are represented as horizontal gray lines on the bottom pane. Each color corresponds to a different playing regime. The local minimum of $p_{0,th}$ are marked with a circle.

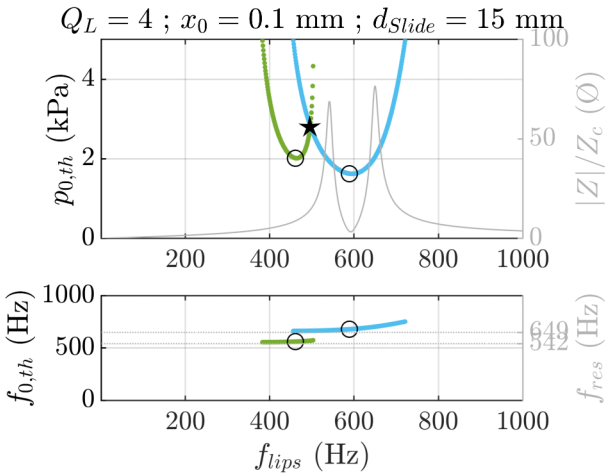

Figure 2: LSA with respect to f_L considering only modes 5 and 6. The double Hopf bifurcation is indicated by a star.

The regions where the second periodic regime is unstable are shaded.

3.2 Time simulation

According to Fig. 3, for p_0 slightly below the double Hopf $p_{0,DH}$, one can switch from one periodic regime to another passing through the equilibrium by varying only the slide position. We study this kind of scenario with time integration. The considered parameter trajectory is drawn in black in Fig. 3, with $p_0 = 2.6$ kPa and $d_{slide} \in [14, 16]$ cm. In Fig. 4, the time evolution of the mouthpiece pressure p computed with time integration is plotted along with the control parameters p_0 and d_{slide}, as well as its spectrogram.

Firstly, the brass model indeed passes through both periodic regimes and the equilibrium. Secondly, the system transients last few seconds after both parameters are fixed. This observation is consistent with the fact that the system is close to its Hopf bifurcations. Indeed, in this region, leading LSA eigenvalues (i.e. with the highest real part) are close to zero, which corresponds to slow exponential growth or decrease and therefore, long transients. Finally, the amplitude of the oscillations decreases for both periodic regimes as the slide position moves toward the double Hopf bifurcation, until oscillations disappear when the system reaches the equilibrium. Since d_{slide} varies dynamically, silence appears with some delay after the slide position crossed the static Hopf bifurcation predicted by LSA [6].

This type of behavior has been observed on preliminary experiments using artificial lips and a controlled air supply which suggests that the real system also exhibits double Hopf bifurcations for some sets of parameters.

4. CONCLUSION

In this short paper, we show that brass instruments may exhibit double Hopf bifurcations for some sets of parameters. Around such a bifurcation, two periodic regimes exist and the system has a rich behavior especially regarding transients. Here, we only focus on one specific

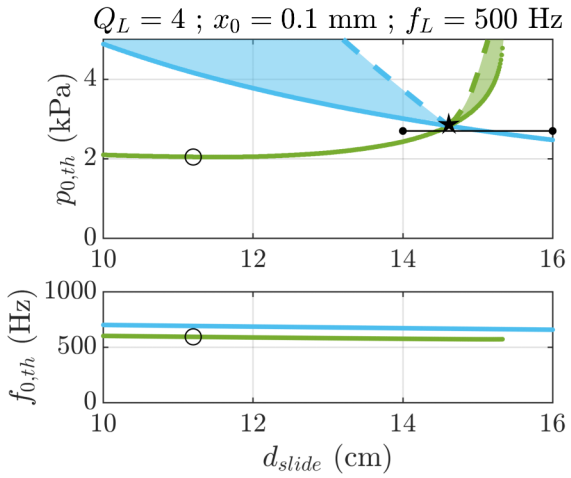

Figure 3: LSA with respect to d_{slide} considering only modes 5 and 6. Continuous lines represent Hopf bifurcations whereas dashed lines represent torus bifurcations. The double Hopf bifurcation is indicated with a star. The solution coming from the second Hopf bifurcation is unstable between its Hopf and its torus bifurcations. This is represented by shaded regions of the corresponding color. The horizontal black line represents the parameter trajectory considered for time integration in Sec. 3.2.

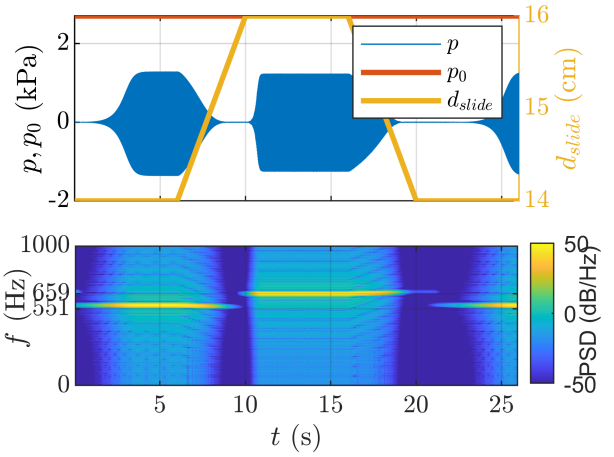

Figure 4: Top pane: time evolution of the control parameters p_0 and d_{slide} and of the resulting mouthpiece pressure p computed with time integration. Bottom pane: Corresponding spectrogram of p in terms of Power Spectral Density (PSD).

scenario where the slide position varies continuously. This scenario highlights the interest of studying the slide position as a bifurcation parameter since it induces interesting behaviors while remaining easy to control and to measure in an experimental context. To compute time integrations with a varying slide position, we propose to describe the input impedance with only one parameter by use of interpolations of the modal parameters. The multistability intrinsic to double Hopf bifurcations, as well as the associated transient behaviors, will be further explored in experimental and numerical studies.

MUSICAL ACOUSTICS STUDENTS FACED WITH THE CHALLENGE OF BUILDING NEW MUSICAL INSTRUMENTS

Ana M. Barbancho* **Isabel Barbancho** **Lorenzo J. Tardón**

ATIC Research Group, ITIS Software, ETSI Telecomunicación,
University of Málaga, 29071 Málaga, Spain

ABSTRACT

One of the most difficult aspects to assess in university students is their level of initiative and creativity: teaching usually focuses on learning techniques for practical problem solving, mostly with systematic solutions. For this reason, in the subject Musical Acoustics, an optional subject in the fourth year of the Degree in Sound and Image Engineering at the School of Telecommunications Engineering of the University of Malaga, since the 2015-2016 academic year, students have been asked to make a new musical instrument as part of the assessment of the subject. The only condition that the instrument must meet is that it must produce three musical sounds of different frequencies. In this article, a brief compilation of all instruments is made in order to focus on the most original and creative ones. It should be noted that over the years, the pupils have made better and more creative instruments.

Keywords: *Musical Acoustics, Creativity, Musical Instruments, Higher Education*

1. INTRODUCTION

Nowadays, the job market is becoming increasingly competitive, and holding a university degree in engineering, while a necessary condition for accessing a qualified job, is no longer sufficient. For this reason, both students and professors must make a significant effort to ensure that the skills acquired during academic studies align with industry demands and provide students with a high degree of versatility. Among these skills, soft skills are gaining increasing importance. One of the most relevant soft skills is creativity. Traditionally associated with humanities and arts-related studies, creativity is now being increasingly recognized as a key competence in engineering education [1]. Furthermore, it is essential to acknowledge that engineering curricula are continuously evolving to adapt to the ever-changing technological landscape and to ensure that students acquire the necessary competencies for the professional world [2].

For this reason, elective courses such as Musical Acoustics [3], offered at the School of Telecommunications Engineering of the University of Málaga (UMA), must be in constant evolution to integrate competencies that are particularly relevant for the job market or that, despite their importance, may not have been adequately covered in other courses within the degree program. Musical Acoustics is a fourth-year elective course (final year of the program) in the Bachelor's Degree in Sound and Image Engineering. Due to the nature of its syllabus, its elective status, and its position in the final year of the degree—where the number of students enrolled is typically lower—it allows for more creative activities compared to mandatory courses from earlier years. For this reason, since the 2015-2016 academic year, the practical component of the course has included the construction and acoustic characterization of a musical instrument. However, since the 2022-2023 academic year, traditional lab practices have been replaced by personal projects, many of which still involve the creation of musical instruments [4]. The only requirement for the musical instrument is that it must be capable of producing at least three dis-

tinct musical sounds. This practical assignment replaced the classical sound characterization practice based on pre-recorded sounds, which did not allow for any form of creativity from students.

This paper presents the various instruments built by students and analyzes the level of creativity demonstrated across different academic years.

The structure of this paper is as follows: Section 2 describes the context in which students engage in this creative activity. Section 3 details the process of constructing and measuring a musical instrument, along with a list of the instruments created in each academic year. Section 4 presents the results of the creativity analysis conducted on students' projects over multiple academic years. Finally, Section 5 outlines the main conclusions drawn from this study.

2. CONTEXT

The University of Málaga has 21 faculties and schools, with an annual student population of approximately 33,000, although this number fluctuates slightly depending on the academic year [5]. Fig. 1 illustrates the evolution of student enrollment at UMA.

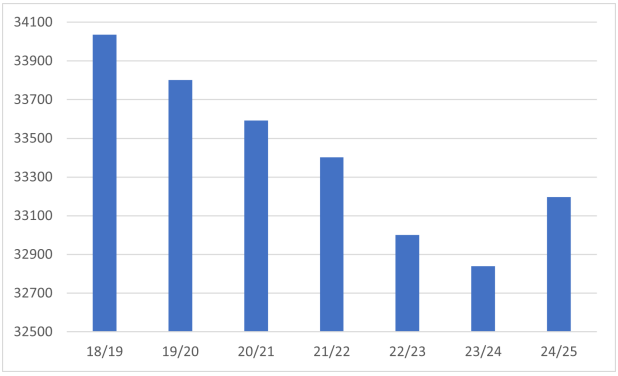

Figure 1. Evolution of the number of student enrolled at the UMA.

The students considered in this study are enrolled in the School of Telecommunications Engineering (ETSIT) within the Bachelor's Degree in Sound and Image Engineering (GISI). Specifically, they are students taking Musical Acoustics, a fourth-year elective course offered in the first semester. This subject has a teaching load of 6 ECTS, equivalent to 60 hours of classroom instruction, distributed as follows: 30 hours of theoretical lectures, 18 hours of laboratory sessions, 6 hours of problem-solving classes, 2 hours of student presentations, and 4 hours dedicated to other activities (such as visits to recording studios and theaters, as well as attendance at conferences). Fig. 2 compares the number of students enrolled at the ETSI of Telecommunications of UMA over the past five years with those enrolled in the Sound and Image Engineering degree. This figure shows that enrollment rates have remained quite stable, although a slight increase in total student numbers can be observed in recent academic years.

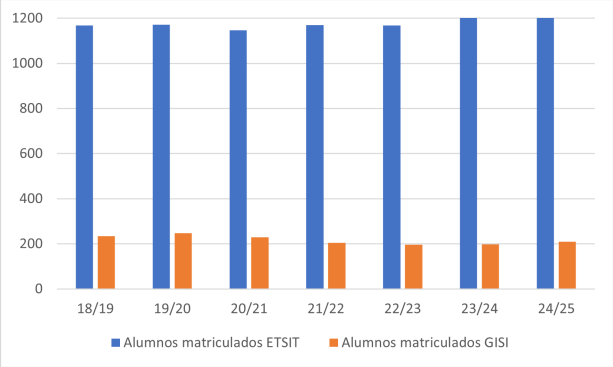

Figure 2. Evolution of student enrolled at the ETSI of Telecommunications of the UMA together with those enrolled in the Sound and Image Engineering degree (GISI).

Fig. 3 presents the evolution of student enrollment in Musical Acoustics, as well as the ratio between students who successfully complete the course and those who drop out. Notably, after the increase in enrollment in the academic year following the COVID-19 pandemic (2020-2021), the number of students taking the course has remained stable. More importantly, the number of students failing the subject has decreased. This suggests that students find the course appealing, both in terms of its description in the official syllabus [3] and through their experiences in class. Considering that overall student enrollment at UMA, and consequently across all degree programs, is declining, the sustained interest in Musical Acoustics, despite being an elective course, can be considered a success. Regarding the gender distribution of enrolled students, the percentage of male and female students is consistent with the average enrollment figures at the ETSI of Telecommunications of UMA [6].

The typical profile of students enrolled in this elec-

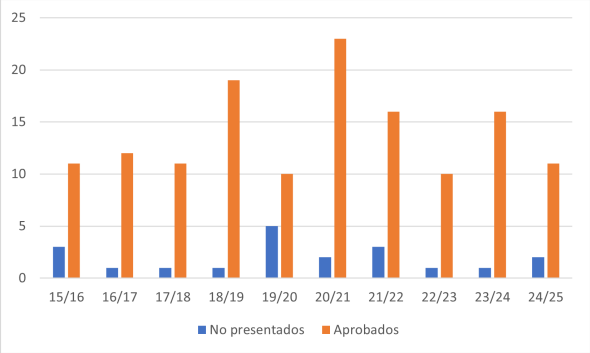

Figure 3. Evolution of students enrolled in Musical Acoustics, as well as the ratio between students who pass and student who drop out of the subject.

tive course includes those with a strong interest in music—either because they have formal conservatory training or because they seek to acquire musical concepts to apply them professionally, given their future careers as sound and image engineers. Additionally, students are often drawn to the course because of its distinctive pedagogical approach [4].

3. MUSICAL INSTRUMENTS DESIGNED IN MUSICAL ACOUSTICS

This section first outlines the required characteristics of the musical instruments to be constructed (subsection 3.1), followed by a summary of the instruments created in each academic year (subsection 3.2).

3.1 Required characteristics of the musical instrument

On the first day of the Musical Acoustics course, students are introduced to the syllabus and the various activities associated with the subject. Among these activities is the practical assignment of constructing a musical instrument, which was incorporated into the curriculum in the 2015-16 academic year. The specifications for this assignment are as follows: students must construct an analog musical instrument capable of producing at least three distinct, tuned musical notes. Additionally, they must record and acoustically characterize these sounds in both the time and frequency domains. A technical report must be submitted detailing the instrument's design, the materials used, the construction process, and the acoustic analysis of the sounds it produces.

Since the 2022-23 academic year, students have been given the option to replace traditional laboratory practices with a personal project. The theme of this personal project must be related to the subject matter of the course and aligned with the student's personal interests and future professional aspirations. Several project ideas are proposed to the students, including the construction of musical instruments, with an emphasis on integrating digital components into their design. The personal project requires the submission of a project report, which may take the form of a direct link to a website or an Instructable [7].

Furthermore, whether students choose to undertake the instrument construction assignment or a personal project, they must deliver an in-class presentation in the format of a masterclass, allowing their peers to learn the fundamental concepts underlying each project. The instrument or personal project may be completed individually or in teams of up to two students, depending on the scope of the work.

3.2 Revision de los instrumentos construidos

Tab. 1 presents a summary of the musical instruments constructed across different academic years. In the first year of implementation (2015-16), the instrument construction activity was highly structured, requiring all students to build an electronic monochord (Fig. 4). This guided workshop proved to be highly successful, leading to the continuation of the activity in subsequent years with greater flexibility granted to students.

In the 2016-17 academic year, students were encouraged to design instruments based on the golden ratio, which led to the development of the UMA-registered Auralófono® [8]. In the following years, students were given complete creative freedom in the design of their instruments (examples of analog instruments created in different academic years are shown in Fig. 5). A review of the constructed instruments reveals that most of them are pan flutes or recorders, although some academic years exhibit a higher degree of creativity than others.

Additionally, the activity has become increasingly consolidated, with a growing number of students incorporating electronic components into their designs. Fig. 6 showcases examples of such electronic instruments. Finally, it is worth noting that with the introduction of personal projects, the number of musical instruments constructed has decreased. However, the quality of the instruments has significantly improved, with most of them

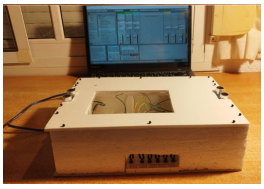
now featuring electronic components.

Conducting an analysis of students' creativity is a complex task, as defining creativity itself is challenging. However, by closely examining the instruments constructed along with the presentations given in class, some key observations can be made.



- Students generally struggle to be creative and to take risks with innovative proposals. Interestingly,

Table 1. List of musical instruments created by academic year

Academic Year	Musical Instruments
2015-16	Electronic Monochord (5 groups)
2016-17	Auralófono® (2 groups) Electric Guitar with Frying Pan
2017-18	8-String Lyre PVC Flute Pipe Organ with Cardboard Tubes
2018-19	Bicycle Spoke Kalimba Irish Flute Xylophone with PVC Tubes Cookie Tin Ukulele PVC Trombone Acoustic Bass
2019-20	Pan Flute PVC Flute 7-String Lyre Xylophone with Copper Pipes

Figure 6. Examples of some of the electronic instruments built by the students of musical acoustics.

the most innovative proposals—precisely because they do not conform to traditional musical instruments—are those suggested by the course instructor (electronic monochord and Auralófono®).

- The level of creativity in the instruments built varies significantly depending on the student group. A noteworthy example is the instruments from the 2018-19 academic year, all of which were distinct and made from novel recycled materials, in contrast to those from the 2019-20 and 2020-21 cohorts, which were more conventional and similar in design. Interestingly, these student groups also differed in terms of academic performance and interpersonal dynamics.
- During the 2020-21 academic year, due to the COVID-19 pandemic, classes were held online, and projects were completed individually. This clearly influenced the students' level of creativity and effort in constructing their musical instruments.
- Although students in the Sound and Image Engineering program have a foundational knowledge of electronics, it is clearly insufficient for them to independently undertake projects requiring circuit construction. Students acknowledge their interest in creating electronically integrated instruments but do not feel adequately prepared to do so.
- The introduction of personal projects has resulted in the creation of instruments with an electronic component and increased complexity in terms of functionality, assembly, and capabilities. These instruments have proven to be more satisfying, even for the students themselves.
- Despite some highly developed instrument proposals, there is still significant progress to be made in fostering students' creativity.

4. CONCLUSIONS

This study has explored the implementation of a creative pedagogical approach within the Musical Acoustics course, an elective in the final year of the Bachelor's Degree in Sound and Image Engineering. The primary objective was to engage students in the construction of musical instruments that generate at least three distinct tuned pitches. The findings derived from this study offer valuable insights into the intersection of engineering education and creative practice:

- The integration of creative tasks within a traditionally technical curriculum is well-received by students, who demonstrate enthusiasm for hands-on, innovative learning experiences beyond conventional laboratory exercises.
- Over the years, as the activity has become institutionalized within the course, the diversity and complexity of the musical instruments produced have increased, reflecting a growing engagement with the creative process.
- The introduction of personal projects has led to fewer instrument constructions overall; however, the complexity, originality, and inclusion of electronic components in these projects have significantly improved. Students report a heightened sense of achievement and deeper conceptual understanding as a result.
- The choice of instrument type, level of innovation, and overall difficulty of construction are strongly influenced by the particular cohort of students. This suggests that group dynamics, peer collaboration, and prior experience play a crucial role in determining creative outcomes.

- A noticeable trend is the recurrence of simpler designs, particularly pan flutes and recorders. These choices are often associated with students who demonstrate lower engagement, possibly due to the abundance of readily available online instructions, reducing the necessity for independent problem-solving and innovation.
- While some students exhibit significant creativity in their projects, many struggle with the concept of innovation. The root causes of this reluctance remain unclear—whether due to a lack of intrinsic creativity, a hesitancy to invest additional effort, or a pervasive fear of failure in an academic setting.
- These findings highlight the urgent need to systematically incorporate creativity-enhancing methodologies within engineering education. By integrating more open-ended, interdisciplinary, and exploratory tasks into curricula, students can be encouraged to develop critical thinking, adaptability, and problem-solving skills essential for their future professional careers.

ABSTRACT

Building permanent bases for human life on both the moon and Mars is one of the greatest challenges facing humanity. All civilisations, from the most ancient to the present, have had their own music. This music has been conditioned, among other factors, by the material means that were naturally available. Moreover, the initial musical instruments of all civilisations have been percussion instruments. Therefore, if in the future humans are to inhabit the moon or Mars, they must be able to make musical instruments with the materials available in their environment. This article presents the design and the acoustic characterisation of bells made from lunar regolith. This will make it possible to analyse the ability to create music with the materials available on the moon and thus to improve the adaptation of humans.

Keywords: *bell, moon sound, lunar regolith, acoustic characterization*

1. INTRODUCTION

The origins of music are closely intertwined with the origins of humanity [1]. Both archaeological excavations and cave paintings depict music in its simplest forms—percussion and wind instruments. Music has always played a vital role in human communication, from warning of dangers to expressing emotions and serving as a form of entertainment.

Among all percussion instruments, bells have been present in every civilization, and they continue to be studied and constructed today, both as instruments for classical orchestras, church carillons, and as auditory signaling elements on ships, among other uses [2], [3].

Therefore, in a future—whether near or distant—where humanity may establish colonies on other planets or even in other galaxies [4], [5], music must remain an essential part of human life. Moreover, humans will need to build musical instruments using the materials available in the places where they live.

This article presents the design and acoustic characterization of bells made from lunar regolith. This will enable an analysis of the potential to create music using materials found on the Moon, thereby improving human adaptation to extraterrestrial environments.

The article is structured as follows. Chapter 2 presents the design of the bells. Chapter 3 details the data acquisition system used for capturing the sounds of the bells. Chapter 4 describes the bell sound database that has been created. Chapters 5 and 6 present the tools used for characterizing the bell sounds and the results obtained from their analysis, respectively. Finally, Chapter 7 provides the conclusions drawn from this study.

2. BELLS DESIGNS

The design of bells has been a task to which considerable time and effort have been devoted over the centuries across numerous civilizations. Through the analysis of bells and percussion instruments from various cultures, such as Japanese wind bells, Tibetan singing bowls, Japanese-style dopamine bells, the town hall bell of Brihuega (Guadalajara, Spain), wind chimes, and others, it was concluded that a cylindrical geometry provides an effective foundation for bell design. Moreover, considering

the nature of the materials to be used, as described in subsection 2.1, the size should be kept compact. Figure 1 presents the dimensioned plans of the bells that were designed and manufactured.

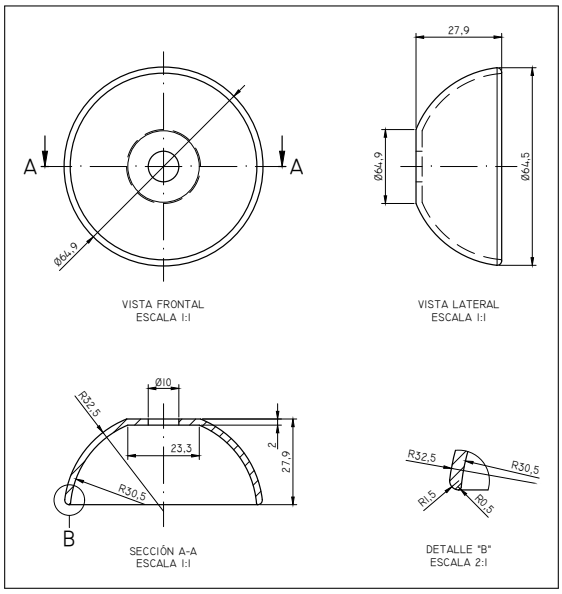

Figure 1: Plan, profile and elevation with dimensions of bells to be measured.

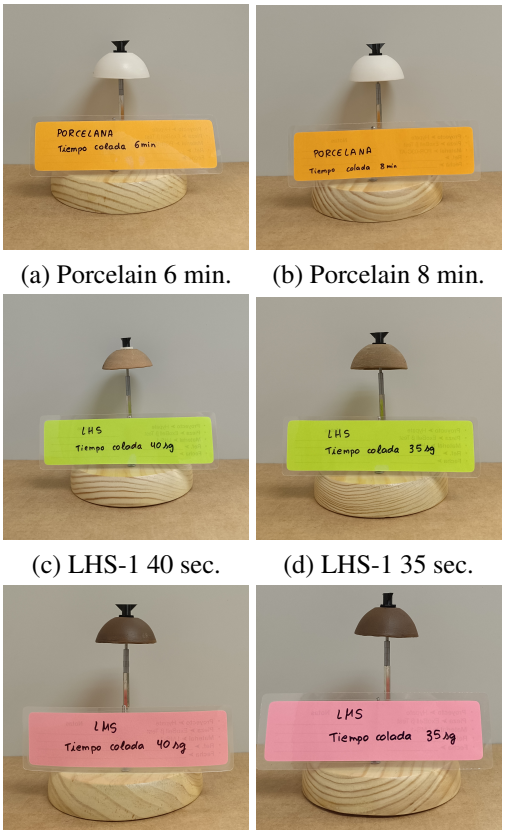

2.1 Bell manufacturing materials

In the present study, the acoustics of bells made from three different materials, each with two casting times, have been measured, resulting in a total of six bells to be measured and characterized. Figure 2 shows the six bells to be acoustically characterized, labeled with their respective material and casting time.

The three materials used are as follows:

- Porcelain (POR-03C-AT): A ceramic made from varying proportions of clay, kaolin, feldspar, and quartz. It is a material with good plasticity, being a casting porcelain suitable for general use [6].
- LHS-1: The Lunar Highlands Simulant (LHS-1) is a high-fidelity, mineral-based simulant designed to represent a generic or average highland location on the Moon. The highlands are considered the "lighter" regions of the Moon's surface, primarily composed of plagioclase, often referred to as Anorthosite. This simulant is not made from a single terrestrial lithology, but accurately replicates the texture of lunar regolith by combining both mineral and rock fragments in precise proportions based on the Apollo mission regolith samples [7].
- LMS-1: Lunar Mare Simulant (LMS-1) simulates the lunar mare regions, which are the darker portions of the Moon's surface. LMS-1 is a high-fidelity, mineral-based analog commonly used for educational and research purposes. This formula was designed based on data from the Apollo Lunar Soil samples [7].

It is noteworthy that due to the fragility and handling difficulties of the materials used, especially the porcelain, the 8-minute porcelain bell presents a small crack on its edge, which could lead to changes in its acoustics.

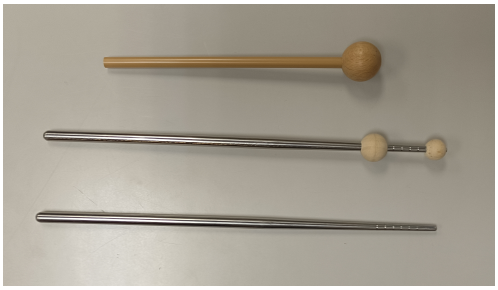
2.2 Bell holders and mallets

In addition to the three types of manufacturing materials, three mallets made of different materials were used: wood, metal with a wooden head, and metal. These were used to assess how the type of mallet affects the sound produced by the bells. Figure 3 shows the three mallets used for the acoustic characterization.



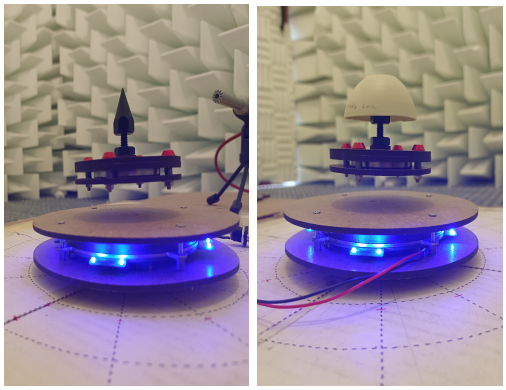


Figure 3: Mallets used for acoustic characterisation, from top to bottom: wooden mallet, metal mallet with shaped head and metal mallet.

Furthermore, to analyze the effect of the bell support, two types of supports were used: a fixed-base support (Fig. 2) and a support using a magnetic levitator (Fig. 4).

(a) Empty (b) With a bell

Figure 4: Magnetic levitator holder. (a) Empty. (b) With 6 min porcelain casting bell.

3. ACOUSTIC DATA ACQUISITION SYSTEM

In order to perform the acoustic characterization of the bells, it is essential to obtain sound recordings that are as pure and clear as possible, minimizing any external noise and interference from the recording environment. To achieve this, the recordings were made in the anechoic chamber at the E.T.S.I. de Telecomunicación, University of Málaga [8]. Figure 5 shows an image of the anechoic chamber at the E.T.S.I. de Telecomunicación, University of Málaga.

The anechoic chamber at the E.T.S.I. de Telecomunicación is specifically designed to eliminate acoustic wave reflections. Both the floor and the interior walls are lined with pyramidal wedges made of sound-absorbing materials, which further enhance the dispersion of any sound that is not absorbed. Additionally, the chamber is fully isolated from external noise sources.

For the recordings, two Behringer ECM8000 microphones [9] were employed. These are ultra-linear condenser microphones with a flat frequency response ranging from 20 Hz to 20 kHz, offering high sound resolution and an omnidirectional pickup pattern, making them ideal for precise acoustic measurements.

The bells were positioned in the center of the anechoic chamber, with the microphones placed at 90° and 180° relative to the striking point, as shown in Figure 6.

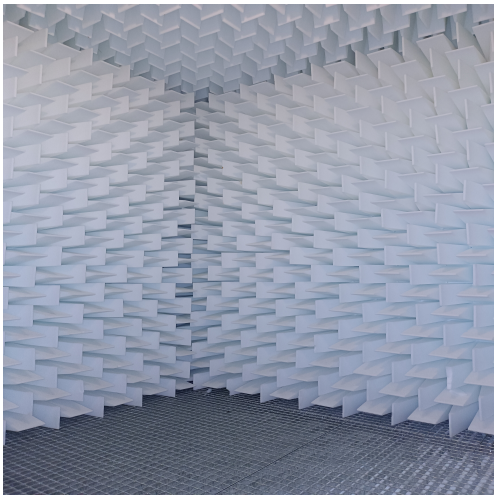

Figure 5: Anechoic chamber of the E.T.S.I. de Telecomunicacion of the University of Malaga [8].

To carry out the recordings, the output signal from the microphones was connected to the Roland QUAD-CAPTURE sound card [10], which allows for the recording of two independent audio channels. The sound card was configured to record at a resolution of 24 bits and a sampling rate of 44.1 kHz.

Regarding the software used, Audacity [11], a free

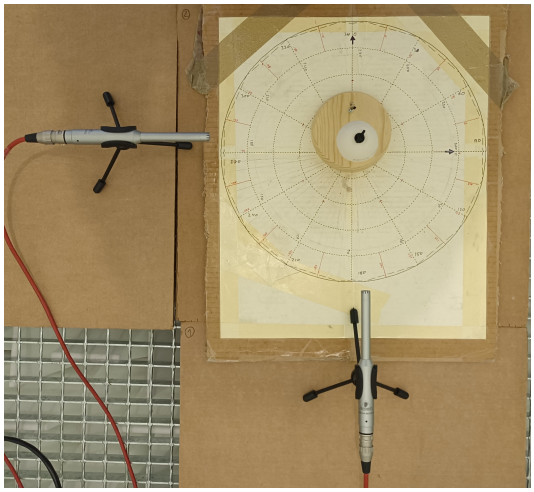

Figure 6: Positioning of the measuring microphones [9] in relation to the bells.

software application for recording and editing audio, was employed for the audio recording. For the analysis and characterization of the recordings, Matlab [12] was utilized due to its computational power and the existing libraries for audio signal processing.

4. DATABASE OF BELLS MADE WITH LUNAR REGOLITH AND PORCELAIN

This study has resulted in a database of bell sounds made from lunar regolith and porcelain. Each of the six bells (Fig. 2) was recorded with both types of supports, fixed and magnetic levitator, using the three types of mallets (Fig. 3), striking the bell twice—once on the lower half and once on the upper half—with two microphones positioned at 90° and 180° relative to the striking point (Fig. 6). This process has generated a database of 144 *.wav files, sampled at 24 bits and 44.1 kHz.

5. TIME AND FREQUENCY TOOLS FOR THE CHARACTERIZATION OF BELL SOUNDS

In this section, the time and frequency tools employed to characterize the bells sounds are described.

5.1 Time domain characterization

The study of the sounds produced by the bells in the time domain aims to determine if there are notable differences in the duration, amplitude, and waveform of the signals between the different bells, so that the influence of the material can be assessed.

A classic parameter for studying the signal in the time domain is the envelope. For this study, the classic envelope model for isolated musical sounds proposed by Jensen [13] will be used. To obtain the envelope, a 5th-order Butterworth filter with a cutoff frequency of 11 Hz was applied. The result was then normalized to a maximum value of 1. The attack time (T_a) is defined as the time between the first sample that exceeds 10% of the maximum value and the first sample that reaches 85% of the maximum amplitude. The release time (T_r) is calculated as the time between the last sample at 70% of the maximum amplitude and the last sample that exceeds 10%. The time between T_a and T_r is called the sustain time (T_s). It is expected that, depending on the material the bell is made from, and under equal excitation conditions, these times will differ.

5.2 Frequency Domain Characterization

To characterize the bell sounds in the frequency domain, both the FFT and the spectrogram will be used. In both cases, the frequency axis will be expressed in MIDI number (eq. 1).

$$MIDI = 69 + 12log_2(f/440) \quad (1)$$

The FFT calculation will be performed using the entire sound length of each recording. For the calculation of the spectrogram, a window size of 1024 will be used, with an overlap of 512, a Hamming window, and a DFT length of 4096. To determine the fundamental frequency, the algorithm proposed by Yin [14] will be employed. Additionally, for the characterization of the harmonic part of the signal relative to the residual, the model presented in [15] will be used.

6. RESULTS

This section characterizes the different bells and analyzes the influence of the supports, mallets used, and striking point, based on the time and frequency characteristics presented in section 5.

6.1 Analysis of the Envelope, Attack Time, and Decay Time

To perform the analysis of the envelope along with its attack and decay times, the first step was to evaluate whether there were significant differences between using recordings made with the microphones at 90° or 180°. As shown in Fig. 9, the envelopes are similar. Therefore, this section will focus on the recordings made with the microphone positioned at 90°.

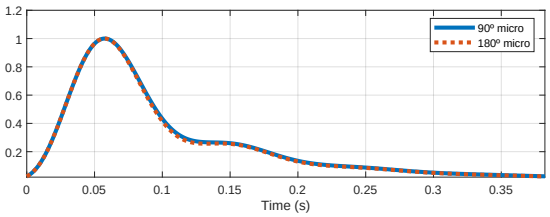

Figure 7: Envelope LHS-35s bell, wooden mallet, low impact and fixed support, for 90º and 180º microphone.

The attack and decay times were calculated as the average of the attack and decay times computed for each bell, with both types of supports, three types of mallets, and two striking positions (12 recordings in total per bell). It is noteworthy that the support and the method of excitation of the bell do not have a significant influence on the attack and decay times.

Table 1: Comparison of bells according to their time attack (T_a) and time release (T_r) (ms) and fundamental frequency ($F0$) in MIDI number and the distance from the fundamental to the first overtone (ΔF) also in MIDI.

Bell type	T_a	T_r	$F0$	ΔF
LHS-35s	31.5 ms	139.2 ms	108	14.80
LHS-40s	31.3 ms	179.0 ms	107	16.02
LMS-35s	30.7 ms	93.9 ms	108	14.18
LMS-40s	31.1 ms	113.9 ms	107	14.64
Por-6min	30.3 ms	81.7 ms	96	19.25
Por-8min	31.6 ms	134.6 ms	101	16.03

Table 1 shows the average attack and release times for each type of bell. The following observations can be made from this table:

- The attack and release times are similar across all bells, showing no significant differences according to the material type.
- The attack times are much shorter than the release times, which aligns with the typical characteristics of small-sized percussion instruments, such as the bells being characterized [16].

Regarding the shape of the envelope, when analyzing all the recordings based on the type of support, mallet, and striking position, it was observed that there are differences depending on whether a fixed support or a levitator support is used (Fig. 8). It was found that the levitator support, which allows the bell to move from its position, causes the envelope to decay uniformly. However, the fixed support, which provides rigid attachment at the top, results in some cases where the envelope does not decay uniformly.

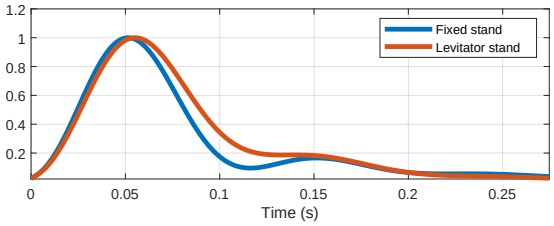

Figure 8: Comparison of envelope between fixed and levitator stand for LMS-40s bell, high stroke with wooden mallet.

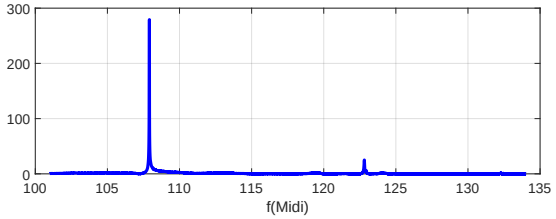
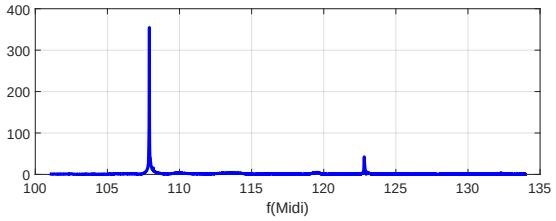


6.2 Analysis of the fundamental frequency

One of the most interesting parameters to study is the fundamental frequency of each bell, as well as the number of overtones they exhibit and the intervals between them.

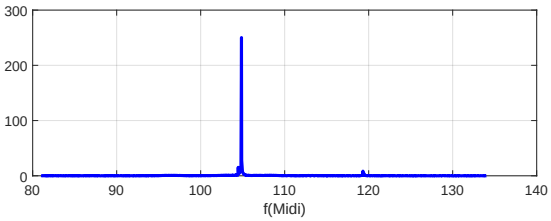


First, it was evaluated whether there were any differences in the frequency analysis when using recordings made with microphones placed at 90º or 18º0 degrees. It was observed that the microphone placement had no significant effect on the analysis, as shown in Fig. **??**. Therefore, it was decided to use the recordings from the microphone placed at 90º degrees.

The fundamental frequency was calculated as the average of the fundamental frequencies calculated for each bell, with both types of supports, the three types of mallets, and the two striking positions (12 recordings in total per bell). It is worth noting that the support type and the excitation method of the sound in the bell do not have a significant influence on the fundamental frequency. Similarly, the difference between the fundamental frequency and the first overtone was also calculated.

Table 1 shows the fundamental frequency of each bell in MIDI number, as well as the distance between the fundamental frequency and the first overtone, in MIDI number. The following observations can be made from this table:

(a) 90º microphone



(b) 180º microphone

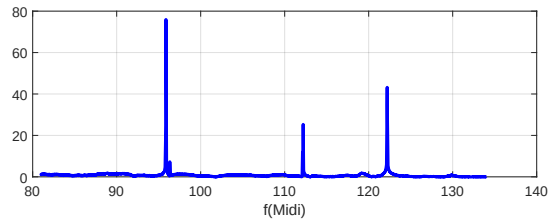


Figure 9: Spectrum of LMS-35s bell, mixed mallet, low stroke, fixed stand for (a) 90º and (b) 180º microphone.

- The fundamental frequencies of the bells made from lunar regolith (LHS and LMS) are higher than those of the porcelain bell.
- The fundamental frequencies of the bells made from lunar regolith are identical for the same pouring time, with those of shorter pouring times being higher. However, for the porcelain bell, the one with the longer pouring time exhibits a higher fundamental frequency.
- The distance between the fundamental frequency and the first overtone is significantly greater for the porcelain bells than for the lunar regolith bells. The harmonic distances in the lunar regolith bells are quite similar, except for the LHS bell with a pouring time of 40s, which shows a greater distance.
- None of the bells exhibit harmonic frequencies, as the distance between the fundamental frequency and the first overtone is not an integer multiple of the fundamental frequency (in Hertz).
- The fundamental frequencies are relatively high, given the small size of the bells.

Another parameter that has been analyzed is the number of overtones present in the recorded sounds of the bells. Upon analyzing all the recorded sounds of the bells, it was observed that the bells made from porcelain exhibit three peaks in the spectrum (fundamental frequency and two overtones), whereas the bells made from lunar regolith only show two peaks (fundamental frequency and one overtone). Clearly, porcelain behaves differently from lunar regolith in this regard. Fig. 10 shows an example of the spectrum of a lunar regolith bell and a porcelain bell, highlighting the difference in the number of overtones. To conduct a more in-depth study of the overtones produced by each material, it would be necessary to manufacture larger bells, as the ones available, having such high fundamental frequencies, result in any additional overtones falling outside the range of human hearing.

(a) LHS-40s bell

(b) Porcelain 6 min bell

Figure 10: Spectrum for (a) LHS-40s bell and (b) porcelain 6 min bell, mixed mallet, low stroke and fixed stand.

6.3 Influence of the type of support and striking location

As outlined in section 2.2, two distinct types of supports were used, fixed and magnetic levitation, to characterize the bell sounds. The magnetic levitation support, being a magnetic system, attracted the metal mallet, which led to the recordings being made with lower-force strikes and very light impacts.

The comparative acoustic evaluation of the recordings made with the fixed support versus the levitation support reveals that the recordings with the fixed support exhibit higher volume and richer tonal quality. This can be attributed to two factors: firstly, with the levitation system, the force applied had to be reduced to prevent excessive movement of the bell, which could cause the levitation point to be lost and the bell to fall. Secondly, because the

bell was levitating, some of the mallet's energy was dissipated in moving the bell and its support off its axis, which does not contribute to sound production.

This evaluation is evident in the calculation of harmonic energy relative to residual energy from the recordings of all the bells, considering the initial 20% of the total sound duration (from the attack time to the onset of the sustain phase). Table 2 displays the mean harmonic energy relative to residual energy for the six bells, across the three mallet types. It is clear that the higher striking point of the bell generates less harmonic richness than the lower striking point, and that the fixed support also contributes to a richer tonal output, as confirmed by the sound evaluation.

Table 2: Harmonic energy with respect to the residual for comparison of bells according to striking location and the type of support (Striking location-type of support): High-Levitator (H-L), High-Fixed (H-F), Low-Levitator (L-Lev) ando Low-Fixed (L-F).

Bell type	H-Lev	H-F	L-Lev	L-F
LHS-35s	1.37	1.81	1.97	2.52
LHS-40s	0.87	2.97	0.60	2.85
LMS-35s	1.60	2.91	1.10	5.12
LMS-40s	0.28	1.30	0.93	1.78
Por-6min	0.27	0.34	0.67	0.42
Por-8min	0.92	3.22	1.61	1.36

6.4 Influence of the type of mallet

As shown in Fig. 3, three different types of mallets were used. The choice of mallet type has been sonically proven to have an impact on the sound. In general, the sounds produced with the wooden mallet were louder and more resonant than those with the mixed mallet, while the metal mallet yielded the most limited volume and sonority. Clearly, more than the material, the larger striking surface of the mallet excites more movement in the bells (note that the wooden mallet has the largest surface, while the metal tip has the smallest).

In Table 3, the average harmonic energy relative to the residual energy is shown (considering the initial 20% of the total sound duration, which includes the attack time and the start of the sustain time) for the six bells, across both supports, both striking positions, and all three types of mallets (wooden, metal, and mixed). It is evident that the wooden mallet produces the greatest sound output of the three, followed by the mixed mallet.

Table 3: Harmonic energy with respect to the residual for comparison of bells according to evaluate the influence of the type of mallet.

Bell type	Wood	Metal	Mixed
LHS-35s	2.98	0.85	1.83
LHS-40s	4.47	0.55	3.68
LMS-35s	3.74	0.84	3.76
LMS-40s	1.79	0.83	0.68
Por-6min	0.76	0.49	0.41
Por-8min	1.40	1.46	2.52

7. CONCLUSIONS

This paper presents a study of the sound produced by bells made from lunar regolith. For this purpose, recordings were made of six different bells: four made from two types of lunar regolith (LHS and LMS), and two made from porcelain. The goal was to assess the differences between bells made from Earth materials. Additionally, three types of mallets and two support types—fixed and levitation—were employed.

The key conclusions drawn from this study are as follows:

- The sound of the bells made from lunar regolith shows strong similarities both among them and with the porcelain bells. Thus, it is possible to obtain instruments with similar tonal qualities even when using different starting materials.
- Due to their small size, the attack and decay times are relatively short. However, this is consistent with all percussion instruments of similar dimensions.
- Similarly, the fundamental frequencies are relatively high (ranging from 96 to 108 in MIDI number), as expected for small bells.
- The envelopes of the bells are similar across all samples, with the type of support having the greatest influence on their shape. The levitation support, by allowing free movement in all directions, results in smoother envelopes. This behavior could be representative of how such instruments would function

in environments with lower gravity than Earth's.

- The harmonic content of bells made from lunar regolith exhibits fewer overtones compared to porcelain bells. This indicates that the ability of lunar material to vibrate is slightly inferior.
- The study of support type and strike point revealed that striking the bell at a higher point produces fewer harmonic overtones than striking it lower. Furthermore, a fixed support produces a richer sound.
- The influence of mallet type showed that the wooden mallet generates the highest sound production, followed by the mixed mallet. It is evident that the size of the striking surface is the most significant factor influencing the sound, as the wooden mallet has the largest striking surface.

Given that the bells manufactured are very small and thus produce very high fundamental frequencies with short sound durations, it would be beneficial to have larger bells to continue advancing in the acoustic characterization of different materials.

In conclusion, this study demonstrates that it is possible to manufacture musical instruments similar to those used on Earth using materials from other celestial bodies. Thus, this research represents a significant step forward in the possibilities of supporting human life on other parts of the universe.

ABSTRACT

This paper presents the design and construction of a homemade sound tube demonstrator that doubles as a functional musical instrument. Developed as a pedagogical tool, the prototype aims to introduce children to fundamental musical concepts such as sound production, pitch, and scales. The design process involved validating the instrument's operation as both an open and closed tube, with special attention given to determining the precise tube lengths required for accurate tuning. The study addresses theoretical challenges, such as material selection and tuning techniques, alongside practical considerations to ensure the prototype is both accessible and durable. Acoustic measurements were conducted to validate the theoretical predictions and ensure accurate tuning of the instrument. To assess its educational impact, the demonstrator was tested in a public educational setting, where children engaged with it through guided activities. The results show that the tool helps inspire musical curiosity and makes learning more engaging through hands-on activities. This work highlights the potential of simple, low-cost instruments as educational resources, contributing to both acoustic design and music. The sound tube demonstrator exemplifies how functional hyper-instruments can bridge science and art, inspiring future generations to explore music and acoustics.

1. INTRODUCTION

From an early age, children develop the ability to quickly identify, differentiate, and reproduce a wide range of sound sequences, including melodies [1]. This is further supported by studies [2–4], which demonstrate that children show a stronger attraction to a more melodic, song-like maternal speech compared to standard speech, showing toddlers to be naturally attracted to music. There is a substantial body of research affirming the importance of musical education in early childhood, highlighting its role in activating essential cognitive processes: music learning engages the mental operations required for young children to perceive and analyze auditory stimuli effectively [5]. It has been shown to enhance memory [6], improve attention and concentration [7], and serve as a powerful means of expression while stimulating imagination in children space [8]. Previous research has demonstrated that rhythmic abilities not only develop rapidly during early childhood but are also closely linked to the development of non-musical skills in cognitive and motor domains [9].

Music has numerous positive effects on a child's development, making it essential to integrate it into their education, with the majority of early childhood educators acknowledging how children prefer music-related activities over non-musical ones [5].

There are many musical instruments suitable for introducing children to the world of music, allowing them to learn in a simple and engaging way. To this end, percussion instruments such as bells, maracas, and triangles are commonly used to teach basic rhythmic patterns, while the recorder (flute) serves as a tool for developing breath control and learning simple melodies.

For this purpose, this work presents a musical instrument designed for children with no prior musical experience. The goal is to introduce them to basic musical concepts such as sound production, scale creation, and

the distinction between low and high-pitched tones. For this purpose, a sound tube demonstrator is designed as a simplified pipe organ with eight tubes spanning the octave from C5 to C6. Its intuitive design ensures that anyone, regardless of their musical background, can easily use it to play and explore musical concepts interactively.

The novelty of this work lies in the integration of acoustic design and music education into a single, accessible instrument. The development process involved studying the fabrication of organ pipes, and selecting suitable materials and tuning system. Once constructed, the demonstrator's performance is evaluated by comparing its acoustic output with theoretical expectations. The effectiveness of the tool was demonstrated through an educational session with toddlers, during which various activities and new concepts were introduced and successfully understood by them.

This approach not only bridges the gap between theoretical and practical knowledge, but also provides an innovative tool that fosters creativity and learning in young children, making it a valuable contribution to music pedagogy and acoustic research.

This manuscript is organized as follows: Sec. 2 provides detailed information on the design and construction of the organ tube-like instrument, including the materials, tools required, and budget. Section 3 evaluates the instrument's performance and describes the educational activity conducted with children, demonstrating its effectiveness as a teaching tool. Finally, Section 4 presents the conclusions derived from this work.

2. DEMONSTRATION SYSTEM CONSTRUCTION

This section outlines the design details, materials, and tools used in construction, along with the budget considerations, as well as the challenges encountered during the process and the measures implemented to overcome them.

2.1 Materials and methods

The demonstrator is inspired by the mechanics of a pipe organ. This type of instrument produces sound by channeling pressurized air, or wind, through organ pipes, with each pipe generating a single pitch, typically controlled by one or more keyboards.

Unlike wind instruments powered by lung capacity, pipe organs require significantly higher air pressure and volume [10]. According to [11], an organ consists of several key components, all enclosed within a chest (resonance box), whose design varies based on historical period, craftsmanship, and register size.

- **Windchest with pipes:** The pipes are arranged by note and timbre. A rank consists of pipes that produce the same timbre across all notes. Each key corresponds to a note and can activate different ranks individually or in combination.
- **Wind system:** This includes the blower (air supply), reservoirs, regulators, and wind ducts that maintain stable airflow to the pipes.
- **Control system:** Comprising the keyboard, action mechanism (tracker, pneumatic, or electric), drawstops, and the pallet box, which connects keys to valves, allowing air to flow into the pipes.

Note that our demonstrator is designed as an educational tool to teach toddlers how sound is produced, using this simplified instrument as an example. Several adaptations have been made to achieve this goal:

- The pipes used in this demonstrator are indirect embouchure pipes. In this design, airflow passes through a narrow windway before striking the edge of the embouchure, ensuring sufficient pressure to produce sound. The demonstrator includes only one rank of eight tubes, covering the C5 to C6 scale. This limited size is intentional to suit toddlers' height and interaction ease. Note that not accidentals notes were considered to ease difficulty.
- The wind system replaces a traditional blower with a large balloon. This choice enhances usability for children while making the instrument visually engaging and intuitive to operate.
- The control system omits the keyboard, eliminating the need for a tracker action. Instead, airflow is managed manually via removable washers and a tap, which allow children to open specific pipes directly, fostering hands-on interaction.
- To enhance its educational value, the instrument does not include a resonance chest, leaving all components visible. This transparency helps young learners observe and understand the mechanisms behind sound production.

For the construction of the instrument, the following materials were considered:

- Polyvinyl chloride (PVC) was chosen for constructing the tubes of the instrument due to its affordability, ease of handling, availability in various diameters and rigidities, and the presence of prefabricated connection pieces further on the market.
- PVC was also used to create custom washers for sealing the tube bezels and fabricating the end caps of each tube with an eva sheet.
- The instrument is mounted on a handmade wooden plank with openings for each tube, enabling easy assembly and disassembly. This design keeps all components visible, enhancing its educational value.
- Recycled cork stoppers were repurposed to address windcap role.
- An adjustable tap was integrated to control the airflow through the tubes.
- A large balloon was employed as the air source to supply the instrument with consistent airflow.

The tools used to work with these materials included a PVC pipe cutter, a drill with a 8mm bit for creating the beveled hole, scissors for trimming the rest of the bevel, and sandpaper to smooth out imperfections and sharpen the beveled edge. Fig. 1 ilustrates the key components considered in the instrument functioning.

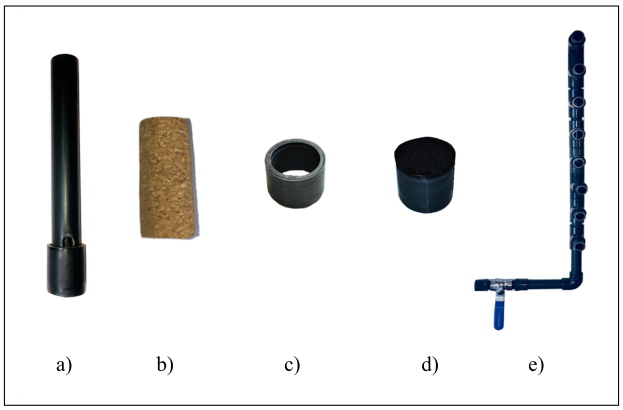

Figure 1. Instrument components, including a tube example (a), cork stopper (b), custom washer (c), tube end cap (d), and wind system with full assembly and tap (e).

When assembled, these parts are configured as depicted in Fig. 2, creating the complete instrument. This setup includes the custom wooden plank, which serves as an "open resonance chest" enabling both structural support and an educationally transparent view of the system.

Figure 2. Organ tube-like demonstrator constructed using the previously presented materials.

Tab. 1 presents a detailed breakdown of the budget required for the construction of the instrument.

Table 1. Detailed budget breakdown for components used in instrument construction

Component	Quantity	Unit price (€)
PVC tube 20mm (3m)	2	2.40
PVC tube 24mm (1m)	1	1.60
L connection	3	0.62
T connection	8	0.62
Nap	1	5.20
Eva rubber	1	0.90
Wood Plank	1	14.00
Balloon	1	2.00
	Total	35.32 €

The affordability of the selected materials and components highlights the accessibility of this solution, ensuring that the demonstrator can be easily reproduced and integrated by educators to introduce musical concepts to children in an engaging and practical manner.

2.2 Instrument Tuning

Pythagorean tuning, attributed to the sixth-century B.C. philosopher Pythagoras, was used as tuning system. It is based solely on the pure fifth (3:2 ratio) found in the harmonic series. This system prioritizes the purity of the fifths, over other intervals, such as seconds and thirds, which become noticeably compromised, which results in harmonically pleasing intervals [12].

To determine the intervals of each note relative to the tonic in Pythagorean tuning, successive additions of pure fifths are calculated within the limits of a single octave. Fig. 3 illustrates the final interval values derived from this method.

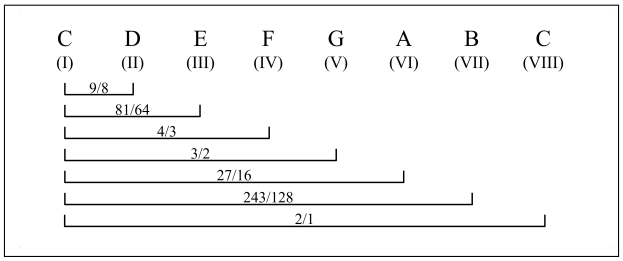

Figure 3. Intervals from each pitch to the tonic in the Pythagorean tuning system.

From this point, using these intervals to the tonic as a reference, the intervals between consecutive pitches are calculated and presented in Fig. 4.

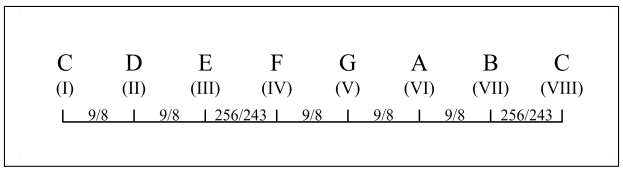

Figure 4. Intervals between consecutive pitches in the Pythagorean tuning system.

This figure illustrates how the Pythagorean scale is constructed using a single type of whole tone (9/8) and a single type of diatonic semitone (256/243).

First, the theoretical frequencies of the eight notes forming the demonstrator were calculated. The chosen system encompasses the octave from C5 to C6, with A5 (880 Hz) serving as the reference point, being the octave above the standard tuning note A4 (440 Hz). Using this reference, the frequency of each remaining tone is determined according to the following (1):

$$f_{\text{note}} = f_{\text{ref}} \cdot \left(\left(\frac{9}{8} \right)^{n_{\text{tones}}} \cdot \left(\frac{256}{243} \right)^{n_{\text{semitones}}} \right) \quad (1)$$

where f_{ref} corresponds to A5 frequency, and n_{tones} and $n_{\text{semitones}}$ represent the number of tones and semitones between the two notes. Note that if the new pitch is lower than A5, both n_{tones} and $n_{\text{semitones}}$ must be negative.

Tab. 2 presents the theoretical frequencies of the notes in the octave from C5 to C6, calculated using the expression outlined earlier.

Table 2. Theoretical frequencies calculated using the Pythagorean tuning system

Tune	Frequency (Hz)	Tune	Frequency (Hz)
C5	521.48	G5	782.22
D5	586.67	A5	880.00
E5	660.00	B5	990.00
F5	695.31	C6	1042.96

Now, tube design is assessed to obtain the target frequencies shown in the previous table. For this purpose, several assumptions are considered [13]:

- The tube diameter is sufficiently large to neglect the effects due to viscosity.
- The tube diameter is small compared to the tube length and the wavelength, λ, produced.
- The surfaces forming the tubes are rigid.

In pipe organs, sound is generated through longitudinal wave motion, where sound waves reflect at the tube ends. The air column is excited by the windway, transferring vibrational energy to the air. The point of excitation is neither a perfect node nor an antinode, leading to a slight inaccuracy in the frequency, which we aimed to adjust through design corrections.

In the tube's length, L, a half wavelength, λ, is produced [14]. The frequency of the harmonic can be calculated knowing the relationship between the frequency of the sound produced, the speed of propagation, and the wavelength using the following expression (2):

$$f_n = \frac{n \cdot c}{2L} \quad (2)$$

where f_n is the frequency of the $n-th$ harmonic, $c = 340m/s$ is the speed of sound in air, and L is the tube length.

Based on this expression, the first sound tube was constructed with a length of 12.7 cm to achieve a frequency of 880 Hz (A5 tune). The tube's length is measured from the end of the bevel to the open end (see Fig. 1.a). Fig. 5 displays the frequency response of the tube when excited.

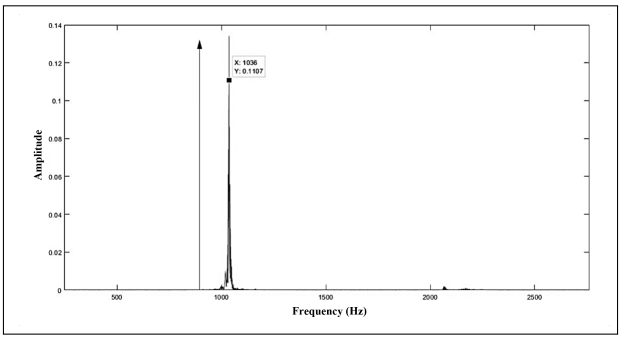

Figure 5. Spectrum obtained from a tube with $L = 12.72$ cm. An arrow is used to indicated the expected frequency of 880 Hz.

In this figure it can be observed the up-cited deviation from the theoretical expected frequency, with an obtained frequency of 1036 Hz when designing the tube to produce a sound of 880 Hz. Therefore, in practice it is observed how tube's length must be slightly lower than the theoretical value computed. This was already assesses in [15] where an approximation of the real length needed L_R is obtained by applying the following expression (3):

$$L_R = L - 3.3r \tag{3}$$

where L is the tube length and r stands for the intern ratio of the tube.

However, an adjustment to the formula is made based on the observed differences. This involves modifying the correction factor in the ratio according to the difference between the measured and expected values, as calculated by the following equations (4)(5):

$$L = \frac{c}{2 \cdot f} \tag{4}$$

$$L - L_R = c_{factor} \cdot r \tag{5}$$

where L is the tube length, L_R is the previously calculated real tube length, r represents the internal ratio of the tube, and c_{factor} is the new correction factor to be applied.

With this in mind, the new corrected tube length L'_R is computed as (6):

$$L'_R = L - 4.6 \cdot r \tag{6}$$

Following the calculations for all the desired frequencies, the resulting length values are presented in Tab. 3.

Table 3. New tube lengths obtained using the fixed equation previously presented.

Tune	Frequency (Hz)	Tube Length L'_R (cm)
C5	521.48	28.90
D5	586.67	25.30
E5	660.00	22.10
F5	695.31	20.80
G5	782.22	18.00
A5	880.00	15.60
B5	990.00	13.50
C6	1042.96	12.60

3. RESULTS AND EVALUATION

This section presents the actual measurements of each of the tubes, providing insight into the performance of the instrument and the details of the educational activity in which the demonstrator was tested with toddlers, illustrating its effectiveness as a pedagogical tool.

3.1 Instrument performance analysis

To test the instrument's alignment with theoretical values, three different types of measurements were considered: individual measurements for each pitch (tube), the intervals with the tonic, and the analysis of the closed tubes (lower octave). For the sound recordings and analysis, MATLAB software [16] was used, with a sampling frequency of 44100 Hz and a bit depth of 16 bits in a mono-channel configuration. Each sound was recorded for approximately 5 seconds to ensure that all relevant details of each sound were captured effectively.

3.1.1 Individual tubes measures

The first set of measurements involved assessing each tube individually to examine their fundamental frequency in relation to their length. This approach aimed to validate the

accuracy of the expression (6). Fig. 6 presents the spectrum obtained from the Fast Fourier Transform of the audio corresponding to the $C5$ tune.

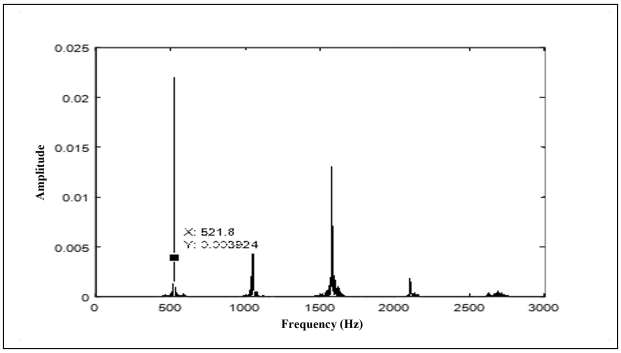

Figure 6. Spectrum obtained from a tube with $L = 28.90$ cm aiming to produce C5 tune ($f = 521.48$ Hz). The fundamental frequency is marked with a pointer.

This figure depicts that the fundamental frequency closely aligns with the theoretical frequency expected. Additionally, three harmonics are present at frequencies of 1044 Hz, 1571 Hz, and 2095 Hz, which correspond approximately to harmonics second to fourth harmonics ($2f$, $3f$ and $4f$). Their amplitudes are significantly lower than that of the fundamental frequency and diminishes as the frequency rises. At higher frequencies, the presence of harmonics becomes more difficult to discern, as expected from a wind instrument.

With this in mind, Tab. 4 presents a comparison between the obtained frequencies and the theoretical values, along with the absolute error in Hertz between them.

Table 4. Theoretical and obtained frequencies comparison, including the frequency error observed.

Tune	Expected frequency (Hz)	Obtained frequency (Hz)	Abs. Error (Hz)
C5	521.48	521.80	0.32
D5	586.67	585.90	0.77
E5	660.00	656.30	3.70
F5	695.31	695.60	0.29
G5	782.22	781.90	0.32
A5	880.00	881.00	1.00
B5	990.00	987.50	2.50
C6	1042.96	1042.00	0.69
		Mean Error	1.23

This table shows that the obtained results closely align with the expected frequencies, with a mean error below 1.25 Hz.

3.1.2 Intervals with tonic measures

The second set of measurements focused on analyzing each interval with the tonic. To present the results, graphs were created to display both the spectrum of the two sounds comprising the interval played simultaneously and each sound individually. This approach seeks to highlight the differences between a chord and the mere addition of two tones. An example is provided in Fig. 7, illustrating the major third interval formed between the notes C5 and E5.

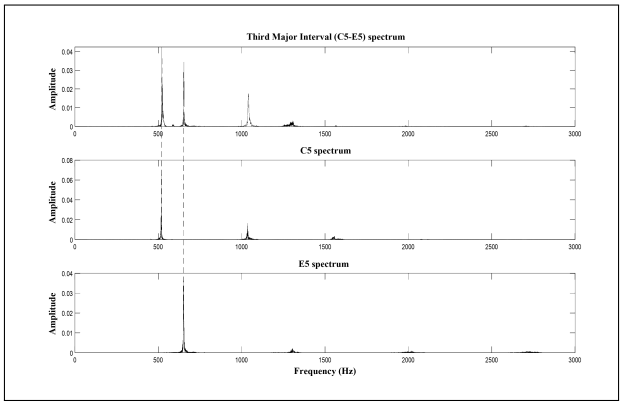

Figure 7. Frequency spectrums of C5 and E5 notes along with the spectrum of the interval formed between them.

The analysis confirms that the excited frequencies correspond to those of each individual tone in the interval. Additionally, alongside the fundamental frequencies, their respective harmonics are also excited. This behavior is consistent across all intervals, showing a similar trend to the findings in the previous section: as frequency increases, the number of generated harmonics decreases.

Furthermore, the spectral analysis reveals that the spectrum of an interval played as a chord is nearly identical to the sum of the spectra of its constituent tones. It was also observed that, depending on the interval, some harmonics of the individual tones may overlap in frequency, resulting in an additive effect. These findings highlight the predictable harmonic structure of the instrument and its intervals.

3.1.3 Closed tubes measures

Unlike open pipes, in a closed pipe, a node is formed at the closed end while an antinode occurs at the open end. Consequently, the wavelength in a closed pipe is twice that of an open pipe [14]. From the relationship between λ and f, the harmonics in a closed pipe are given by expression (7):

$$f_n = \frac{(2n-1)\cdot c}{4L} \tag{7}$$

where c is the speed of sound, L is the length of the pipe, and n represents the harmonic order. Note that only odd harmonics are present in closed pipes due to the boundary conditions at the ends.

However, since the tubes were specifically constructed to meet the design criteria for open pipes, the frequencies obtained through this method deviate significantly (mean value error of 4.85 Hz) from the ideal values, which should correspond to half the fundamental frequencies of the previous measurements (lower octave). Given the instrument's intended use as an educational tool, these deviations in frequency are considered acceptable. To achieve more conclusive results, the tube design would need to be adjusted to align with these new frequency requirements.

3.2 Educational activity

The ultimate purpose of constructing this demonstrator is its pedagogical use. It aims to help children understand how air is transformed into sound and how this sound depends on the size of the tubes. To evaluate its effectiveness, the demonstrator was presented at Colegio Enrique Tierno Galván in La Zubia (Granada) to a group of 5-year-old students.

The demonstration started by discussing musical instrument families—percussion, string, and wind—with examples like a tambourine, guitar, and recorder. Students then categorized other instruments and learned about the musical scale, writing and singing an octave from C5 to C6. Concepts like "low" (thick sound) and "high" (thin sound) were introduced.

The demonstrator was used to show how air turns into sound, starting with inflating a large balloon to capture toddler's attention. Playing the scale on the demonstrator, students observed that lower pitches came from larger tubes and higher pitches from smaller ones. They then took turns playing the demonstrator themselves, reinforcing the relationship between tube size and pitch.

The activity concluded with a recap of the concepts and another group performance of the scale. Fig. 8 shows three students interacting with the demonstrator.

Figure 8. Photograph taken during the musical instrument demonstration, showing students interacting with the demonstrator.

This activity was evaluated by the class tutor, who validated the tool's effectiveness and the achievement of its intended objectives. The demonstration proved its value as an educational resource for introducing young children to the physics of sound.

4. CONCLUSIONS AND DISCUSSION

This work presented a pipe organ demonstrator designed to illustrate sound production in open and closed pipes, enabling the study of vibration modes and the frequencies they produce. A comprehensive analysis of potential materials was undertaken, with PVC ultimately selected for its cost-effectiveness, availability, and recyclability, making the demonstrator an affordable tool for educational use.

The Pythagorean tuning system proved effective in demonstrating harmonic relationships in tuned intervals (2nd, 4th, 5th, and 8th) and inharmonicities in untuned intervals (3rd, 6th, and 7th). Adjustments were made to the tube length formula based on experimental data, improving the design's accuracy.

A thorough validation process was conducted to confirm the instrument's performance, with frequencies aligning closely with expectations for open pipes. While

discrepancies in the closed-pipe configuration were observed, they were deemed acceptable for educational purposes, with a redesign necessary for precise implementation.

The demonstrator's effectiveness as a pedagogical tool was validated through a hands-on activity with 5-year-old students. Despite no prior musical knowledge, students successfully learned the musical scale and the relationship between pitch and pipe size. While the demonstrator could benefit from further refinement in certain areas, it has proven to be an effective and valuable tool for educators to introducing young learners to the basic principles of music and acoustics.

ABSTRACT

This study introduces a novel integration of visual and haptic feedback to improve music perception for Deaf and Hard-of-Hearing (DHH) individuals. The proposed prototype, named MusicTanvas, leverages a touchscreen augmented with electroadhesion-based haptic technology, enabling dynamic overlay of tactile textures on visual content. The system processes pre-recorded audio tracks to extract spectral, harmonic, and rhythmic features, which are mapped to both visual and haptic representations. More in detail, key features such as chroma, Mel-Frequency Cepstral Coefficients (MFCCs), and rhythmic figures, are translated into corresponding visual attributes (e.g., color, shape, and size) and tactile textures. Users can explore music in real-time through these multisensory outputs, which evolve synchronously with the audio playback. A preliminary user assessment demonstrates the system's potential to enhance musical interaction by combining visual-haptic feedback.

1. INTRODUCTION

Music perception for Deaf and Hard-of-Hearing (DHH) subjects is challenging due to the unavoidable involvement of auditory perception. Hence, the reliance on extra-auditory cues is essential to ease music conveyance to DHH listeners. Among those, visual representations [1] and tactile feedback [2] are the most widely adopted ones.

Various visual techniques exist (see [3] for a thorough overview), including color coding (i.e., the association of musical elements such as notes, scales, and chords with specific colors) and graphical notation (i.e., the use of symbols, shapes, and patterns to represent musical concepts such as rhythm, dynamics, and phrasing). Meanwhile, tactile feedback has been provided through wearables (e.g., vibrating wristbands) synchronized with musical events [4], to convey to DHH users the sense of rhythm, beat, and dynamics. Moreover, tactile graphics can be exploited to create representations of musical scores using raised textures or embossed materials, to be explored while listening to a recording of the pieces.

The joint adoption of visual representations and tactile feedback can be supported by programmable touchscreens enhanced with electroadhesion-based haptic technology. Such hardware has already been explored for the conveyance of the notion of "sonic grain", i.e., a form of "tactilization" that allows for a cross-modal connection between the texture of sound and material surfaces, thus bridging tactile and sonic experiences [5].

In this paper, we adopt the TanvasTouch [1] hardware

[1] Tanvas. Surface Haptics. https://tanvas.co/

support to offer a time-varying visual and tactile representation of one or multiple audio tracks [2] constituting a musical piece. Our developed prototype, named MusicTanvas, processes pre-recorded audio files to extract the evolution over time of their spectral characterization in terms of Mel-Frequency Cepstral Coefficients (MFCCs), chromas, spectral bands, entropy, their rhythmical content, and timbral features. Once the pre-processing phase is completed, a mapping between the above-mentioned features and the choice of colors, shapes, luminosity, and haptic textures to be associated to each track is identified and proposed to the listener during the audio reproduction [3] .

Results acquired through a preliminary usage assessment of MusicTanvas by a pool of 20 subjects testify to the usefulness of joint visual-tactile stimuli in enhancing music perception.

The remainder of the paper is organized as follows: Sec. 2 provides a review of the related literature. Sec. 3 introduces the TanvasTouch technology, describing its principles. Sec. 4 describes the characteristics and functionalities of our proposed implementation. The chosen visual and haptic representations are discussed in Sec. 5. The performance assessment of MusicTanvas is discussed in Sec. 6. Finally, Sec. 7 ends the paper.

2. RELATED WORK

2.1 Visual Representations

Visual representations of music play a crucial role in translating auditory information into visual stimuli for DHH individuals. Historically, Aristotle [6], Newton [7], Graves [8], Garner [9], and Kandinsky [10] explored correlations between colors and sounds. These insights have shaped interdisciplinary research, suggesting the use of color and shapes to convey musical tones and rhythmic elements [11]. From these studies, it emerges that the most common approach is to associate pitch or timbre with colors and shapes, whereas the intensity of the sound is often represented through the variation of shapes' sizes.

Smith and Williams [12] introduced a visualization technique in which the velocity of a single tone designates its loudness or softness. Velocity is represented by the relative size of a displayed sphere, with its radius ranging from 0 to 127, reflecting the minimum and maximum MIDI velocity values. Moreover, instruments with similar timbres are grouped and differentiated by color, according to the MIDI specification. Other, more recent options, such as the one proposed by Lima et al. [13], include a visualization prototype called *SongVis* that uses emojis, colors, lines, and shapes to represent different features such as danceability, mood, tempo, music genre, and instrument.

Malandrino et al. [14] proposed *VisualHarmony*, a visualization tool able to represent harmonic structures. It provides a music editor for the composition of 4-voices music with the possibility to highlight the harmonic structure with different colors, based on the circle of fifths. Furthermore, special attention is given to inclusiveness and accessibility, since VisualHarmony gives users the possibility to customize the circle of fifths to be discernible also by people with color perception deficiencies.

Deja et al. [2] introduced *ViTune*, a visualizer prototype built to allow DHH individuals to experience music by displaying a real-time visual representation of the played sound. ViTune performs a harmonic and percussive source separation once users upload their music files. The harmonic part is divided into four ranges, each one visually represented through bars and stars, with size changing based on the signal strength. Conversely, saturation, brightness, and opacity of the visualized components depend on the extracted chromagram. In our prototype, we will leverage a similar approach to visualize either chromagrams or MFCCs.

Another approach to visually representing musical features involves using shapes and sizes: Cruz et al. [15] use polygons, where the number of sides corresponds to different octaves. Higher octaves, representing treble sounds, are associated with polygons with more sides, whereas lower octaves, associated with bass sounds, are associated with polygons having fewer sides. Moreover, the volume (or velocity) of the note affects the size of the polygon: larger polygons indicate higher velocities. Our prototype adopts the same approach to visualize sound loudness.

2.2 Haptic Representations

In recent years, vibrotactile stimuli have gained attention as a method to convey musical elements, such as rhythm and melody, to DHH individuals. Research has increasingly explored how tactile feedback can enhance musical experience by converting audio signals into vibrations per-

technology

[2] A track is a single audio recording that may contain one or multiple musical stems (e.g., vocals, melody, bass, drumset).

[3] A video demonstrating the prototype usage is available on YouTube: https://youtu.be/HEz74yxcOZ8

ceived through the skin. Most research has focused on vibrating stimuli rather than more advanced haptic technologies, such as those based on the variation of electroadhesivity properties of surfaces [16], to create tactile sensations. Our prototype is based on the latter technique.

Furthermore, researchers have investigated how the tactile sense can convey information about a stimulus's roughness. Brown et al. [17] characterized roughness using a sinusoidal stimulus modulated by another signal, demonstrating that increasing the modulation frequency results in a rougher perceived signal. It is worth mentioning that auditory and tactile perceptions have significantly different dynamic ranges [4]. Hearing can perceive a dynamic range of approximately 130 dB, whereas tactile perception can discriminate only about 50 dB. Furthermore, audible sounds for humans range from about 20 to 20,000 Hz, with peak sensitivity between 500 and 4,000 Hz. In contrast, tactile sensitivity ranges from 1 to 1,000 Hz, with peak sensitivity around 200–300 Hz, depending on the body part. Despite these disparities, both auditory and vibrotactile senses exhibit high temporal resolution, enabling accurate perception of rhythm.

Alves Araujo et al. [18] conceived the *Auris System* to enable subjects with hearing loss to experience music through other senses. Musical features such as melody, rhythm, and harmony are reproduced by the combination of two different devices, the *Auris Chair* and the *Auris Bracelet*. Furthermore, Fontana et al. [19] examined how vibrations can be leveraged to experience musical harmony through vibrotactile stimuli.

3. BACKGROUND ON TANVASTOUCH

The TanvasTouch device leverages *electroadhesion* [20], a technique that uses an electric field to create friction between surfaces. It can produce friction at 256 distinct intensity levels, enabling users to feel a wide range of textures on a 2D surface [16] [21].

The TanvasTouch device is composed of two parts: hardware and software [22]. The hardware includes a specialized touchscreen that dynamically adjusts its surface friction in response to user interaction. Custom electronics detects touch input and modifies friction forces in real time, creating tactile sensations as users slide their fingers across the screen.

The software part is composed of the TanvasTouch Engine, which controls the electrostatic forces by interpreting finger movements on the screen and adjusting the electrostatic field to provide tactile feedback. Furthermore, the TanvasTouch API allows developers to develop touch-based applications that simulate various textures and tactile sensations.

When developing an application that utilizes TanvasTouch, developers can align the graphical and haptic representations with the corresponding displayed figures to ensure that tactile feedback is delivered in the correct area of the screen. However, there could be scenarios where haptic feedback is used to offer multiple textures within a single visual representation.

The images used for haptic feedback generation need to be in gray scale with values 0-255 per pixel and in .png file format. Essentially, the Tanvas device lets users perceive different textures through the contrast between black and white images: white areas represent high friction, creating a rough sensation, while black areas represent low friction, resulting in a smooth feel. As users slide their finger across the screen, the differences in friction between the black and white areas allow them to feel varying textures.

4. PROTOTYPE IMPLEMENTATION

Our prototype [4] was created using the C# language, within the Windows Presentation Foundation (WPF) User Interface (UI) framework, part of the .NET framework. To incorporate haptic feedback, we employed the TanvasTouch API from the TanvasTouch Software Development Kit [5]. The WPF framework uses XAML (Extensible Application Markup Language) for the declarative specification of UI components, while C# is used to implement their corresponding functionalities. In our implementation, the XAML script specifies the collection of UI components such as buttons, images, and layout configurations. Conversely, the C# script manages the display state of these UI elements, toggling image visibility, facilitating page navigation, initiating audio playback, extracting audio features, and handling haptic feedback. Within the XAML document, images are integrated using the `Image` tag, and haptic feedback functionality is achieved through the `TSprite` tag, a component of the TanvasTouch API.

Besides managing UI components and haptic feedback, the application also incorporates advanced audio

[4] The source code, along with audio clips, is publicly available in the following GitHub repository: `https://github.com/moeni27/MusicTanvas`

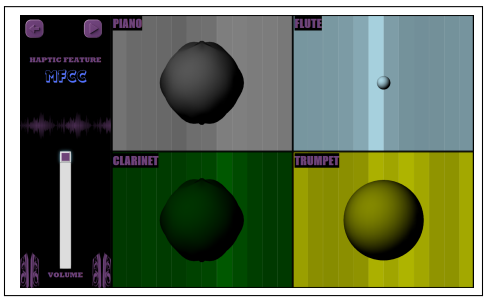

Figure 1: MusicTanvas UI, with 4 sections and MFCC values associated to background stripes.

feature extraction. This functionality is essential for providing meaningful audio analysis and improving user interactions based on audio content. The NAudio library [6], integrated into the .NET framework, facilitates audio playback, stop, and amplitude retrieval across multiple audio files concurrently. Meanwhile, feature extraction is achieved through Python and various libraries such as librosa [7] and numpy, specifically via the pythonnet library [8]. Key features extracted include spectral centroid, MFCCs, chromagram, and onset detection, which are crucial for analysis and interaction with the audio content.

5. VISUAL AND HAPTIC REPRESENTATIONS

5.1 Graphical User Interface Structure

The MusicTanvas UI is structured into up to four distinct sections, each representing a prominent instrument group (see Fig. 1). Users can explore the app in two modes: *Multi-Track Mode* and *Single-Track Mode*. In Multi-Track Mode, the user can upload up to four audio tracks (i.e., files) simultaneously. The UI dynamically adjusts based on the number of tracks uploaded, displaying a distinct section per track. All tracks must have the same duration to be reproduced or stopped simultaneously. Conversely, the Single-Track Mode utilizes Artificial Intelligence (AI) for audio processing. By uploading a single audio track, the app uses *Spleeter* [23] [9] to split it into four stems: vocals, bass, percussion, and other instruments. Different studies [24] [23] evaluated Spleeter's performance by comparing it with other state-of-the-art systems, showcasing its high-quality source separation capabilities.

5.2 Audio Processing Algorithms

To offer meaningful visualization of audio content, our application relies on a number of audio processing algorithms. More in detail, we implemented a window-based extraction procedure for chromagram, MFCC, spectral centroid (a descriptor of the perceived brightness of a sound [25]) and loudness. Such window-based extraction process is applied separately to each track. This ensures that the features are computed independently for each audio source, maintaining the integrity of the individual tracks. Chromagrams, MFCCs, spectral centroids, and onsets are extracted using the *librosa* Python library and stored in NumPy arrays. The extraction uses a window length of 1024 samples with an overlap of 512 samples. Given a sample rate of 44.1 kHz, this setup results in an update time for feature extraction of $512/44100 = 0.0116 \simeq 0.012$ seconds per frame, where each frame represents a brief time interval used for feature extraction and analysis. Furthermore, the application uses the NAudio stream properties to extract the amplitude values from audio segments. Furtermore, the application employs two complementary algorithms: as previously mentioned, in Single-track mode it uses *Spleeter* to segment the audio track into four predefined stems, whereas in Multi-track mode it implements an instrument recognition algorithm. This algorithm leverages a Convolutional Neural Network (CNN) and a K-Nearest Neighbors (KNN) classifier based on MFCCs, chroma, and spectral centroid acoustic features, to identify and categorize the primary musical instrument present in each uploaded audio track [26]. Based on the classification output, each track is then assigned to the corresponding section and color according to the associations proposed by Kandinsky [10] (see Table 1).

Finally, to quantify rhythmic complexity, we use an onset extraction algorithm [27], that starts by transforming the audio signal into a time-frequency representation using the Short-time Fourier Transform (STFT). This process breaks down the audio signal into overlapping frames (with a 50% overlap) and derives the spectral characterization for each frame, capturing the energy distribution of the signal. The overlapping frames are crucial to enhance the temporal resolution of the analysis, as they ensure that each frame shares information with adjacent frames, capturing smooth transitions, preserving temporal relationships in the audio signal, and reducing the influence of

windowing artifacts.

From the STFT output, the spectrogram of the audio track is computed, which represents the magnitude of the audio signal over time. We apply a logarithmic compression to the spectrogram's magnitude, which enhances weak spectral components and simulates human perception, highlighting smaller variations that might otherwise be overlooked. Subsequently, a novelty spectrum is derived from the spectrogram, highlighting abrupt energy changes between consecutive frames. This spectrum is obtained by computing the difference between adjacent columns of the spectrogram: a positive difference indicates significant changes in the audio signal, hinting to potential onsets. The novelty spectrum represents such energy changes and helps detect new events. To enhance detection accuracy and minimize noise, a local average is computed across the spectrum. This smoothing process helps differentiate genuine onsets from minor signal fluctuations. In the final onset detection stage, each spectrum value is adjusted by subtracting its respective local average. Values surpassing a predefined threshold are identified as significant onset indications.

5.3 Mappings of Audio Features to Visual and Haptic Representations

Tab. 2 shows how specific audio features are mapped to their corresponding visual and haptic representation in our interface. More in detail, a sphere (i.e., the shape chosen to represent musical features) is visually represented in the foreground of each section (as in [12]). The sphere's radius dynamically adjusts based on the loudness of the corresponding audio track. This adjustment reflects amplitude variations within the track and is influenced by a volume slider controlling the overall audio output of the application (located on the left side of Fig. 1). If the tracks have different initial audio levels, the application performs normalization to ensure consistent volume output. The sphere's color brightness is linked to the spectral centroid feature. As the spectral centroid shifts across the audio track, the sphere's color brightness dynamically adapts, visually reflecting changes in tonal brightness. Moreover, the output of the onset detection algorithm influences the surface of the sphere, visually accentuating event changes in the audio content (Fig. 2). This representation gives users the possibility of visually appreciating the temporal structure and intensity variation within the musical composition. Spherical representations were chosen for their smooth visual appearance, complemented by dynamic changes to their surfaces to reflect audio characteristics effectively.

Table 2: Mapping of Audio Features to Visual Representations

Audio Feature	Visual Representation	Haptic Representation
MFCC or Chromagram	Color brightness of background stripes	Texture roughness of background stripes
Rhythmic complexity	Sphere's surface	-
Spectral centroid	Sphere's color brightness	-
Loudness	Sphere's radius	-

Regarding the background, inspired by [10], each section is adorned with a specific color palette, chosen according to the instrument automatically detected in the corresponding audio track. Moreover, in each section, the background is divided into several vertical stripes. Each stripe symbolizes either one of the 7 MFCCs derived from the feature extraction process or one of the 12 pitch classes of the chromagram. The choice between 7 and 12 stripes is determined by the feature being represented. The stripes' colors dynamically transition from lighter to darker hues, reflecting the normalized values of the corresponding MFCCs/chromas within a specific temporal context. Besides the visual representation, each

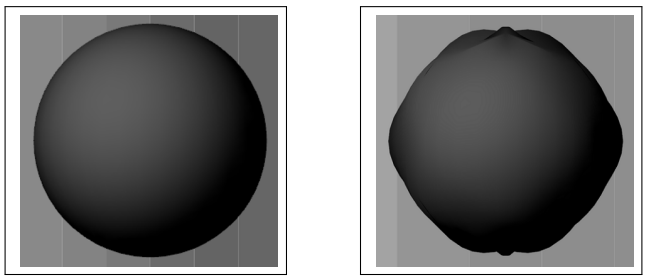

Figure 2: MusicTanvas GUI showing onset detection: smooth surface indicates no onset (left), non-smooth surface indicates onset detection (right).

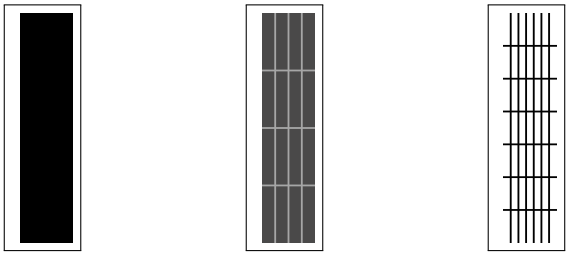

Figure 3: Haptic images representing feature value ranges: $0 \leq x < 0.1$ (left), $0.4 \leq x < 0.5$ (center) and $0.9 \leq x \leq 1$ (right).

stripe also features a corresponding haptic feedback representation. This haptic representation consists of a gradient stripe, transitioning from black to white through various shades of gray. Specifically, ten distinct haptic images are generated, ranging from black to white via 8 intermediate shades of gray.

Furthermore, vertical and horizontal lines are added, forming a grid-like pattern. For darker shades of gray, the grid consists of a few horizontal and vertical lines. As the shade lightens, more lines are progressively added, increasing the density of the grid. This granularity variation enhances the haptic experience, allowing users to better distinguish between different values through tactile feedback. These shades correspond to MFCC/chroma values ranging from 0 to 1. For instance, an MFCC value between 0 and 0.1 triggers a black haptic image, a value between 0.1 and 0.2 triggers a dark gray image, whereas a white image is associated with values between 0.9 and 1 (see Fig. 3). This approach allows users to perceive tactile feedback corresponding to the MFCC/chromagram variations by swiping their fingers over the screen. MFCC and chroma values are generated approximately every 12 milliseconds, but this interval is too brief for users to perceive the tactile feedback effectively. To overcome this issue, the system aggregates the values over a 5-second window and computes their average, thereby smoothing the tactile feedback into a more coherent and perceptible signal.

Table 3: Validation Accuracy vs. Number of Categories.

Number of Categories	2	3	11
Validation Accuracy	90%	75%	60%

Table 4: Processing Times for Feature Extraction and Source Separation

Audio Length (s)	10	40	120
Extraction Time (s)	0.17	0.68	2.17
Separation Time (s)	25.93	31.28	51.60

6. PERFORMANCE ASSESSMENT

The performance assessment of MusicTanvas evaluates instrument recognition accuracy, computational efficiency and user experience.

The IRMAS dataset [28] was used to train and test the instrument recognition model. The dataset includes 6705 audio recordings from 11 instrument classes. The dataset was split into 80% for training and 20% for testing. Moreover, a 5-fold cross-validation approach was performed to ensure robustness evaluation of the model. As shown in Tab. 3, the accuracy drops from 90% when classifying two instruments to 60.70% for 11 categories. This highlights the challenge of distinguishing between instruments with simlar audio features.

The system's computational efficiency was evaluated by measuring processing times for audio feature extraction and source separation on tracks of varying lengths, using *Spleeter*. As summarized in Tab. 4, feature extraction time and source separation time grow approximately linearly with the track length.

Due to the difficulty of recruiting DHH participants, a preliminary user assessment study was conducted with 20 non-impaired participants aged between 20 and 60 (see Tab. 5 for an overview of the participants' musical experience level). To simulate deafness, participants interacted with MusicTanvas without any auditory feedback, and all tasks were evaluated without sound. Participants were given a brief training session before the evaluation.

The user experience assessment evaluated the color-

Table 5: Musical Experience Level (scale from 1 = beginner to 5 = expert)

Experience Level	1	2	3	4	5
Frequency	2	4	10	4	0
Percentage	10%	20%	50%	20%	0%

Table 6: Enjoyment of MusicTanvas (scale from 1 = not enjoyable to 5 = very enjoyable)

Enjoyment	1	2	3	4	5
Frequency	0	0	0	12	8
Percentage	0%	0%	0%	60%	40%

instrument mapping and the impact of tactile and visual feedback on musical perception. Results show that color-instrument associations proposed by participants largely aligned with the MusicTanvas mapping. Furthermore, 85% of users preferred the multi-quadrant display for multi-instrument recognition, citing improved instrument differentiation.

Tactile and visual feedback were appreciated for enhancing the perception of individual musical parts, although the tactile feedback alone received mixed ratings regarding its effectiveness. Moreover, participants reported no negative experiences with tactile feedback, and all of them found the visualization helpful for instrument recognition. MusicTanvas was also appreciated for its ease of use (see Tab. 6). All participants agreed that it has great potential to help DHH subjects.

7. CONCLUSIONS

This paper presented MusicTanvas, a prototype application that utilizes a touchscreen enhanced with electroadhesion haptic technology, which enables the overlay of tactile textures onto displayed content that dynamically changes over time. The prototype incorporates a set of algorithms that pre-process single or multiple pre-recorded audio tracks to extract key spectral, harmonic, and rhythmic elements within set time intervals. These extracted musical features are stored as arrays or lists. During playback, the system retrieves the pre-extracted feature values, ensuring that they evolve synchronously with the audio. These values are then used to control both visual and haptic feedback, to ease music perception for DHH individuals with a multisensory interaction that matches the auditory playback.

As future work, we aim to develop a customizable feature mapping that will allow each user to define the sensory feedback that suits them best to perceive a given musical characteristic. Moreover, enhancing the system to process live audio in real-time would allow users to experience music as it is being performed.

Finally, this technology may prove useful also for blind and visually impaired individuals, if all visual elements are properly replaced with a haptic overlay, thus conveying a wider variety of musical features exclusively via tactile feedback.

MELOPAD, A PORTABLE DEVICE FOR MUSIC COMPOSITION BASED ON THE BELA AUDIO AND INTERACTION PLATFORM

Jasmin Thieme [1*] **Luis Molina-Tanco** [2]
[1] Shure DACH, Eppingen, Germany
[2] Telecommunication Research Institute (TELMA), Universidad de Málaga, Málaga, Spain

ABSTRACT

MeloPad is a prototype of a portable device designed for recording short musical annotations. Portability is key, allowing users to create music in any situation without requiring an external power source. The device includes interchangeable physical covers that simulate different instrument families. *MeloPad* detects the attached cover and dynamically adjusts its menu to offer sounds corresponding to the selected instrument family. It features an OLED display and buttons for selecting options. Users can practice a melody, record it, listen to it through headphones, and store it in the device's memory. When no cover is attached, previously recorded melodies can be accessed. The interaction and audio processing are managed using Bela, an open-source embedded computing platform designed for real-time audio and sensor-based applications. MeloPad is inspired by a MIDI peripheral developed by the French company Joué Play.

Keywords: *portable synth, Bela audio, i2c interface, 3d prototyping*

1. INTRODUCTION

The primary goal of this project, part of a bachelor's degree in Sound and Image Engineering (a four-year program), is to develop *MeloPad*, a fully functional prototype of an interactive electronic device that integrates knowledge in audio signal processing, digital circuit design, programming, and 3D modelling.

MeloPad is designed to capture spontaneous musical ideas anytime, anywhere, without relying on a mobile phone or the limitations of voice recording. Musical inspiration often strikes at inconvenient moments -on a train, while walking, or travelling- when there is no easy way to record a melody. While a phone's notepad or voice recorder can help, humming a tune rarely does justice to how it sounds in one's mind. *MeloPad* provides an intuitive alternative, offering a selection of virtual instruments and adjustable frequency ranges to accurately capture musical ideas. It features interchangeable physical covers called "*sábanas*" (sheets) which mimic different instrument interfaces. The device detects the placed sheet and adjusts its sound accordingly. Users can record, play back, and save their melodies for later use.

MeloPad draws inspiration from the *Joué Play* MIDI controller by the French company *Joué Music Instruments* [1]. Similar to Joué Play, which uses swappable, velocity-sensitive silicone pads to represent different instrument layouts, *MeloPad* employs interchangeable sheets to simulate different instrument interfaces such as a piano, string instrument, or percussion set. This physical interaction enhances the user experience, making the device more intuitive. Unlike Joué Play, which requires external power and must be connected to a tablet or similar device, *MeloPad* is fully autonomous, running on a rechargeable battery. A small OLED screen and three buttons allow for intuitive navigation and selection of options.

MeloPad is built around *Bela* [2], a real-time audio processing platform with low-latency and a user-friendly development environment, designed for musicians and

developers with intermediate programming skills. To keep the device compact and portable, we chose *Bela Mini* [3], a smaller version that retains all essential functionality while reducing the overall size.

2. USE CASE ANALYSIS

To define the functionality of *MeloPad*, we have identified three main use cases that ensure a complete user experience: recording melodies, accessing stored recordings, and transferring them to an external device. Additionally, we analyse the operational context in which users interact with the system, detailing the different modes of operation and the interfaces involved. Finally, we outline the key functional requirements that *MeloPad* must meet to ensure seamless recording, playback, and file transfer, as well as an intuitive and portable user experience.

2.1 Use cases

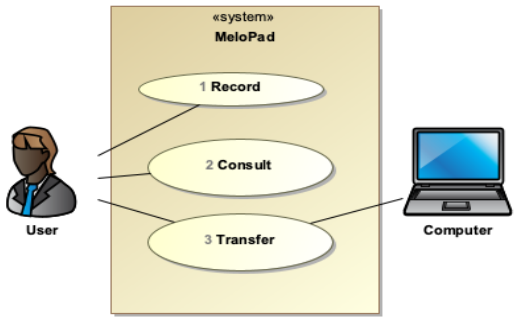

Figure 1. *MeloPad* Use Cases.

The system supports the core use cases shown in Figure 1 and explained as follows:
1. **Record:** The user selects an instrument and an octave range, practices the melody, and starts recording. The system captures the played notes and stores them as a .wav file in *MeloPad*'s memory.
2. **Consult:** Users can access previously stored melodies, play them back through headphones, and delete them if desired.
3. **Transfer:** By connecting *MeloPad* to a computer via USB, users can access the stored .wav files, copy them, and delete them using a file explorer interface.

Each use case has specific preconditions. For recording, a capacitive sheet must be correctly placed, and headphones must be connected. For accessing stored recordings, the sheet must be removed. Transferring files requires a USB connection to a computer.

2.2 Operational Context

MeloPad interacts with the user through various interfaces. The capacitive sheet detects touch input, while buttons allow navigation through menus and function selection. The system provides feedback through an integrated display and audio output via a 3.5mm headphone jack.
Key system interactions include:
• **User inputs**: Touching the capacitive sheet (note input), pressing buttons (navigation and controls), and adjusting the volume potentiometer.
• **System outputs:** Displaying information on the screen, playing audio through headphones, and allowing USB file transfer.
• **External connections:** The system connects to a computer for transferring recordings and supports battery charging via micro-USB.

MeloPad automatically detects whether a capacitive fabric is installed or not. If present, it enters Record Mode, allowing users to generate and record melodies. If no fabric is detected, the system switches to Consult Mode, where users can browse and play stored recordings. When connected to a computer, it enters Transfer Mode, enabling file management via micro-USB.

2.3 Functional and nonfunctional requirements

MeloPad's functionality is defined by the following core requirements:
• R1: **Audio Output** – The system must generate and play sound through headphones.
• R2: **Sound Configuration** – Users should be able to adjust volume (R2.1), select virtual instrument sounds (R2.2), and define a frequency range (R2.3).
• R3: **Portability** – The system must be portable, including a rechargeable battery (R3.1), weighing no more than 1kg (R3.2), and having a maximum dimension of 30 cm (R3.3).
• R4: **Capacitive Sensing** – *MeloPad* must detect user interactions through capacitive sensors.
• R5: **Recording Functionality** – Users should be able to start (R5.1) and stop (R5.2) recordings via button presses.
• R6: **Playback and Management** – The system must support playback (R6.1), deletion of a recent recording (R6.2), browsing stored files (R6.3), and removal of saved recordings (R6.4).
• R7: **Display Interface** – A screen must provide visual feedback and system status information.
• R8: **File Transfer** – *MeloPad* should allow users to transfer recordings to a computer via an integrated file management application.

These requirements have guided the development and verification of the prototype to ensure it meets the needs of the end user.

3. TECHNOLOGY AND DESIGN CHOICES

The *MeloPad*'s functionality is achieved through a combination of hardware components and developed software. The core of the device is the Bela Mini platform, chosen for its low-latency audio processing and compact size. Bela Mini runs Linux and is well-suited for the creation of interactive musical applications. Its development is supported by a user-friendly Integrated Development Environment (IDE) [4] accessible via the web, offering tools for coding, file management, and real-time audio visualization through a virtual oscilloscope.

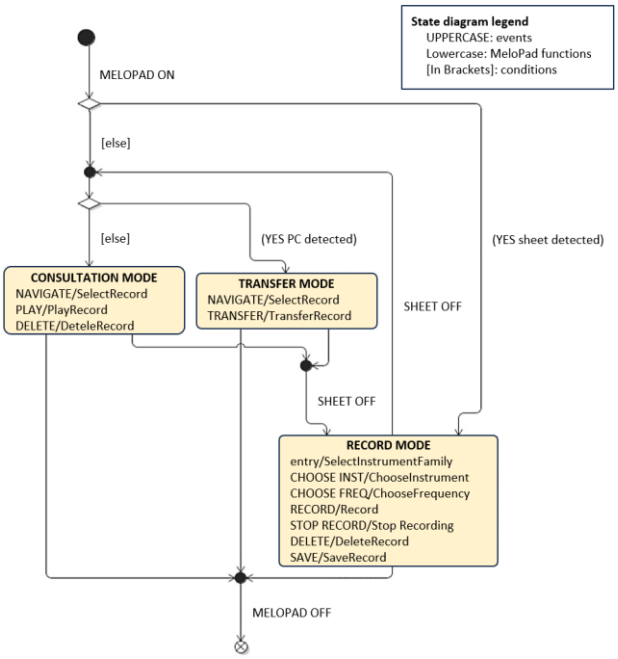

Figure 2. *Melopad*'s state diagram.

The whole hardware and software design was started after completing the first phase of this project, where the use cases and the system states were specified. Based on Figure 2 the next step was to start with the hardware and software design following the chosen requirements.

3.1 Hardware design

For user interaction and sound generation, *MeloPad* utilizes several key hardware elements:

• Trill Craft Sensor: The device employs a Trill Craft capacitive sensor [5]. This sensor, developed by Bela, features thirty inputs, allowing for the connection of conductive materials to detect variations in capacitance caused by touch. In *MeloPad*, this sensor is crucial for interpreting the user's input on the interchangeable "sábanas".
• Interchangeable "sábanas" (Sheets): A key innovative aspect of *MeloPad* is the use of physically interchangeable covers called "sábanas". These sheets are designed to simulate the interfaces of different musical instruments, such as a piano. *MeloPad* can detect the placed sheet through a detector circuit, and the software then offers corresponding instrument sounds in a menu. For example, a "sábanas" simulating an electronic piano was created to validate the concept. The connection of the "sábanas" is detected by the Bela, which then determines the appropriate instrument.
• OLED Screen and Buttons: A small OLED screen is integrated into the device to display basic options related to the placed "sábanas" and general information. Navigation through menus and selection of functions are facilitated by three buttons.
• Potentiometer: A potentiometer is included to allow the user to adjust the volume level of the audio output.
• Audio Output: Audio generated by *MeloPad* is outputted through a 3.5mm mini-jack stereo connector for headphones.

The communication between the Bela Mini and peripherals like the OLED screen and the Trill Craft sensor relies on the I2C (Inter-Integrated Circuit) serial communication protocol. I2C uses only two signal lines (SDA and SCL) for data transmission and synchronization. Each I2C device on the bus has a unique address, allowing the Bela (as the master device) to communicate with each peripheral individually. In *MeloPad*, the OLED screen has an address of 0x3c, and the Trill Craft sensor's address is 0x30.

For the physical design of *MeloPad*, the 3D modelling programme Blender was used to find the appropriate design and create the 3D printable model.

3.2 Software design

On the software side, the project is primarily developed using C++ within the Bela IDE. The software structure follows the standard Bela program flow with setup(), render(), and cleanup() functions. Several Bela-specific libraries are utilized, including:
• Bela.h: Provides access to core audio settings and input/output buffers.

• Trill.h: Enables communication with and control of the Trill Craft sensor.
• AudioFile.h: Facilitates the reading and writing of audio files to the device's memory, using the AudioFileUtilities namespace with functions like load() and write(). The setSamples() function is used for saving the generated melody, and loadMono() is used for reading from memory.

The project incorporates the Synthesis ToolKit (STK) [6], an external C++ library for real-time audio synthesis and processing. STK provides a wide range of virtual instruments, which are utilized in *MeloPad* to generate the different instrument sounds selectable by the user. Integrating STK required installing the library via the Bela's Ethernet connection (on a regular Bela board, as Bela Mini lacks Ethernet) and learning its API. The general structure for using STK involves creating instrument objects, setting their sample rate (Stk::setSampleRate(BelaSampleRate)) and frequency (instrument->setFrequency(frequency)), and using the sound generating functions: noteOn(frequency, amplitude) which generates a note but does no send it to the output; tick() to enable real-time audio production by advancing a sample on each call; and noteOff(amplitude) to turn off the generated note adjusting the fade out.

The software architecture also includes custom-developed classes like Display and Teclado (Keyboard) to organize the code for screen updates and sound generation, respectively. A Debouncer class, adapted from an open-source Bela resource, is used to handle button presses and prevent misreading due to bouncing. The U8g2 library is employed for controlling the OLED display via I2C. The entire software is configured to run automatically upon Bela Mini startup. It is possible to find the whole software on a Github repository[1].

This combination of Bela Mini's real-time audio capabilities, the Trill Craft sensor, interchangeable "sábanas" for varied user interfaces, and the STK library for sound synthesis forms the technological foundation of the *MeloPad* prototype.

4. DEVELOPMENT CHOICES AND PROTOTYPE

This project has involved a major development effort as it is a complete prototype of a software-hardware product. It was inspired by the Joué device [1], the first of the class of synthesisers whose keyboard is not fixed but interchangeable.

[1]Github Repository of *MeloPad*'s Software: https://github.com/JasminThieme/MeloPad

4.1 Mechanical design decisions

To minimize the size of *MeloPad*, the Bela Mini was chosen, which is more compact compared to the standard Bela version (56 x 35 x 21 mm vs. 87 x 54 x 27 mm). The Bela Mini is suitable for this project as no analogue outputs (such as those for speakers) are needed, which are exclusive to the standard Bela.

Initially, a touchscreen was considered for menu navigation, but it was quickly replaced with buttons due to the complexity and cost involved. Nevertheless, a screen was kept to display information and show the options activated by the buttons. After researching various screen sizes, the first version of *MeloPad* was created, which initially featured a small screen around one inch in size. This option would have required many push buttons, which would have made the design bulky. As a result, a design without a screen was proposed, using an LED for each button. However, this idea was soon discarded as one of the goals of the project was to implement a visual interface.
After extensive searching, a suitable 2.42-inch screen was found, leading to the second design version: five buttons with individual functions. Finally, the number of buttons was reduced to three and their functionality would change depending on the options displayed on the screen. This resulted in a complete implementation of both the screen and buttons.

Figure 3. *MeloPad* final 3D-design.

The choice of buttons and the potentiometer was based on a compromise between three factors: usability, space, and design, as the goal was to minimize the size while achieving an elegant, simple and intuitive prototype. After acquiring the chosen screen and buttons, the final design was adjusted as shown in Figure 3. The 3D model created in Blender has

been shared on a Github repository[2] as well to complete the design and for future consultation.

[2]Github Repository of *MeloPad*'s 3D Model:
https://github.com/JasminThieme/MeloPad-3D

4.2 Tests and implementation of "sábanas" (sheets)

The Trill Craft capacitive sensor from Bela was chosen due to its ability to create and customize sensors. With 30 capacitive inputs, it allows for the development of a wide range of projects in various sizes and applications. To ensure the proper operation of *MeloPad*, tests were carried out with different conductive materials, and the best option was to use a wire without the insulating plastic, as it has a bigger conductive surface and would be more sensitive to touch.

Two types of sheets were planned to be created: one to mimic a string instrument and another for a keyboard. The keyboard design was the simpler of the two, requiring one position per note. However, the string instrument design was more complicated due to the number of notes involved. Initially, multiplexing the strings to generate tones based on the combination of cables touched was considered, but it was discarded due to the limited position detection capability of the Trill Craft sensor. Eventually, one idea was to assign each guitar tone to an input on the sensor, this allowed for five frets to be covered with a single sensor, and by combining two sensors, a complete guitar neck could be built. The final test for the guitar sheet was based on three frets and three strings, with the sensitivity adjusted to ensure proper response. Due to time constraints, the guitar sheet implementation was discarded, and only the piano sheet was completed.

For the piano sheet, a simple design was used, with one cable per key to detect the capacitance variations. The software implementation utilized the equal temperament chromatic scale, where each semitone is calculated based on the twelfth root of two to calculate the frequencies of the two octaves of notes as in Eqn. (1):

$$f_n = f_0 * (\sqrt[12]{2})^n \quad (1)$$

where n is the note number relative to the fundamental, f_0.

4.3 Power supply for *MeloPad*

One challenge in designing *MeloPad* was that the same USB-micro connector of Bela Mini would be used for both power and connection to external devices. This means that the rechargeable battery and the USB-micro connector for connecting to a computer needed to share the same USB-micro port on the Bela.

The solution was to implement a sliding switch. In one position, the switch connects the Vcc input of the Bela to the Vcc of the rechargeable battery. In the second position, it connects the Vcc input from the external USB-micro connector, to connect an external device. For data transmission, the cable connected to the Bela needs to have four wires: GND, Vcc, Data+, and Data-, therefore the cable connected to Bela is a 4-wired one. For powering the device, only the first two wires are used as shown in Figure 4.

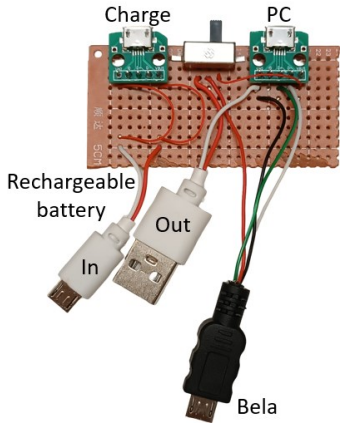

Figure 4. Power and connections piece.

The solution was to implement a power and connection piece which includes two USB-micro female connectors exposed to the outside, one micro-USB male connector with 2 wires for powering the external battery, one with 4 wires to connect the Bela, and a USB-A connector for charging the external battery. This set of components is housed inside the case.

4.4 Implementation of the display

The *MeloPad* features a 2.42-inch OLED display with a resolution of 128x64 pixels, offering a high contrast with white text on a black background. OLED technology provides individual pixel illumination, resulting in clearer visuals compared to LCD screens. The display serves as the main interface for user interaction, where information is displayed, and options are selected.

The screen shows various states depending on the action being performed. For the use case Record these software states include:

- **INITIAL**: Displayed when the device is powered on.

- **CHOOSE_INST**: The user selects an instrument (e.g., Rhodes, Hammond, Wurley) for the piano sheet.
- **CHOOSE_OCT**: The user chooses the octave for the selected instrument, adjusting the frequency range.
- **INFO**: Displays the current settings. Audio output is generated.
- **RECORD**: Activated when the user starts recording their melody.
- **STOP_REC**: Shown after recording ends, with options to save or retry.
- **SAVE_MEL**: Displays a confirmation message when the melody is saved.

In the Consultation use case (when no sheet is detected), the display shows a file list where users can play, navigate, or delete recordings. Screens for this process include:

- **LISTA**: The file list. One file per screen. Options to choose *next*, *play*, *previous*.
- **PLAY**: Displays the playback state. Option to delete the record.
- **ELIMINADO**: Confirms deletion of a recording.

This OLED display is crucial for guiding the user through different interaction stages, ensuring a seamless user experience while maximizing visual clarity.

4.5 Final prototype design

The distribution of the components inside the *MeloPad* case has been challenging as the components almost entirely occupy the available volume of the case, resulting in a very compact space, see **Figure 5**.

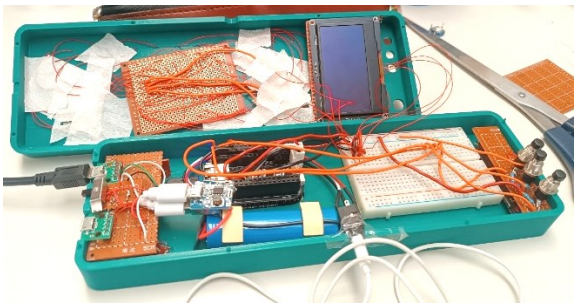

Figure 5. Components distribution in *MeloPad*'s case.

In the upper half of the case, the screen, capacitive sensor, and the cables connected to the sensor are placed. These wires are exposed to the outside through small holes visible in the 3D model, Figure 3. The cables for the sensor needed to be organized in such a way to avoid contact between them and minimize potential interference. The use of rigid cables made the ideal arrangement challenging. However, by maintaining the insulating plastic, interference was kept to a minimum, even when the wires were in contact.

Figure 6. Final look of the *MeloPad* prototype.

The final prototype looked compact and clean as shown in Figure 6. The piano sheet fit on the sensors area and the buttons would let one interact with the menu shown on the screen. Through the headphones the notes would sound when a position is being touched on the piano.

5. RESULTS AND DISCUSSION

5.1 Functionality and performance of the prototype

The *MeloPad* prototype demonstrated satisfactory functionality in its Record and Consultation modes, allowing the generation, recording and playback of sounds through an intuitive screen-based interface and buttons. The portability of the device, thanks to its compact design and rechargeable battery, meets the stated requirements. However, limitations were identified in the file deletion function and data transfer, which led to omitting the implementation of the third use case, Transfer.

5.1.1 Validation of implemented use cases

Verification tests showed that the *MeloPad* prototype largely meets the functional requirements set. In Record mode, the user interface based on the OLED display and buttons allowed an intuitive selection of instruments and octave ranges. Interaction with the capacitive sensors via the piano "sheet" generated accurate sounds and the recording function worked properly, allowing melodies of up to 20 seconds to be captured, played back and stored in Bela's memory.

In Consultation mode, navigation through the list of recordings was seamless, with options for playing and deleting files. However, a limitation was identified in the file deletion function, as files persisted in memory despite confirmation of deletion. This aspect requires improvement of the software.

5.1.2 Performance and Portability

The prototype demonstrated excellent transportability. Its compact (24.5 cm x 8 cm x 3.5 cm) and lightweight (350 grams) design makes it easy to carry and use in different environments. The internal rechargeable battery provides autonomy, eliminating the need for an external power supply.

5.2 Areas of improvement

The *MeloPad* project succeeded in developing a portable, self-standing device with an innovative design, fulfilling the main idea of creating a modular synthesiser with interchangeable "sheets" to simulate different instrument families. The intuitive interface and the ability to record and playback melodies enhance the user experience.

However, areas for improvement and future work were identified:

- **String Sheet**: Study of the layout of the sensors and optimisation of the design to accommodate as many inputs as necessary.
- **Sheet Material**: Explore more durable and tactile materials for the sheets.
- **Hardware Size**: Explore smaller microcontrollers to reduce the volume of the prototype.
- **Internal Cables**: Replace the internal rigid cables with flexible cables to improve durability and avoid disconnections.
- **Safe Shutdown**: Implement a safe shutdown button to protect Bela's operating system, avoiding data corruption.
- **Record Deletion**: Implement a record deletion function that allows users to delete files.
- **Transfer**: Develop a desktop application that allows users to transfer, consult and delete files from *MeloPad*.

5.3 Conclusion

The *MeloPad* project represents a progress in the creation of portable and modular digital musical instruments. Proposed improvements in future work could make *MeloPad* an even more versatile and accessible instrument for musicians and sound experimentation enthusiasts.

ALFONSO AND THERESA: MERGING TRADITIONAL LUTHERIE WITH MODERN ELECTRONICS IN THE DESIGN OF AN EXPANDED LUTE AND CONTRABASS

Celeste Betancur Gutiérrez[1*] **Luna Valentin**[1]
[1] CCRMA, Stanford University, USA

ABSTRACT

This paper details the parallel engineering and building processes for an electric and extended lute (Alfonso) and an electric and extended contrabass (Theresa). We illustrate how the fusion of craftsmanship, acoustic tradition, and modern electronic design can redefine the sonic possibilities of heritage instruments and traditional lutherie. We begin by discussing the initial concept and design phases, where musical and aesthetic considerations guided the instruments' form, function, and ergonomics. This step also relied on acoustical measurements made on a traditional lute from the Stanford collection and a traditional European contrabass. Next, we delve into the woodworking and carving techniques used to shape each instrument's body, discussing the role of material choice in achieving desired tonal and structural properties, and the accessibility of such techniques for novice instrument makers. Finally, we examine our approach to integrating pickup systems of various types, real-time signal processing, and onboard electronics. The instruments can produce a variety of signals that then can be remapped into control, audio, or both, ultimately making them hyperinstruments.

Keywords: *lutherie, expanded instruments, electric instruments*

1. INTRODUCTION

The contrabass originates from the creation of both the Violone and the Violin/Cello, which designs merged during the 16th century into the modern contrabass we know today [1]. In the case of the lute, there are multiple stories and traditions, but the instruments we still call lutes today are from the same era, and were made in Europe too. These two instruments kept their basic shape almost unmodified for centuries.

We found ourselves playing traditional instruments in contemporary ensembles, improvisations, and jams with many other players with different tools, from traditional instruments like ours to modern midi controllers and new instruments. Being computer musicians with knowledge in acoustics, hardware and software development, we felt our practice was fragmented into multiple compartments. On one hand, we were using cutting edge algorithms in our own research for DSP or AI research and on the other hand we were playing traditional instruments, although expanded techniques on the instruments were fully incorporated in our practice already.

2. CONCEPT AND DESIGN

The project of building expanded instruments began as a conversation between the two authors, where we realized that our musical practice could benefit from instruments that combined traditional playing techniques with digital skills like software and hardware design. Luna was exploring archeo-acoustics, and Celeste was taking a graduate course in musical acoustics as part of her research. With guidance from Prof. Marc Rau (Musical Acoustics) and Prof. Sasha Leitman (Physical Interaction Design for Music), we started by measuring a lute made by a Belgian

luthier from the Harry R. Lange Collection of Musical Instruments and Bows at Stanford University.

2.1 The Lute, Celeste

I conducted a two-hour interview with Herbert W. Myers, the collection's curator, to learn more and discuss initial ideas. This conversation helped me choose this particular lute from the collection, which also includes several others. The choice was based on mainly two reasons: the quality and good sound of the selected lute and the more standardized shape that is not a common denominator for this family of instruments.

The design kept the lute's traditional L-shaped head while modifying other aspects for practicality and playability. The scale was shortened early on to accommodate metal strings, which introduced extra tension while maintaining a tuning similar to the original lute. For the body, I chose a more modern, ergonomic shape inspired by electric guitars, balancing tradition with contemporary aesthetics and functionality, also the resonant box was replaced by a solid body architecture.

It is important to note that modern lute construction is relatively rare, as the instrument has largely been replaced in contemporary musical practice. While some luthiers continue to refine traditional techniques and make improvements ([2]), our approach differed in that we aimed to introduce fundamental structural changes rather than merely refine existing methods.

2.2 The Contrabass, Luna

My goal was to design an electric contrabass that preserves key acoustic properties while improving transportability and ergonomics. I wanted to integrate a resonant cavity to maintain the fundamental response of an acoustic instrument, allowing natural amplification while reducing the instrument's physical volume for easier transport.

Unlike most commercial electric and custom upright basses [3], which lack sides and compromise bowing technique and upper-register access, this design includes a detachable side structure for improved ergonomics. Inspired by models like, this custom made bass and the Yamaha electric contrabass [4]—but with a more open, documented approach—this instrument balances classical playability with modular expandability.

The design process began with precise documentation of my own classical contrabass, a versatile instrument built in the 1950s in Southeastern Europe for traditional music playing and reworked for classical performance 15 years ago approximately. Its adaptable design, suited for both classical and jazz settings, served as a foundation for ensuring this new instrument retained traditional playability while enabling extended modifications.

3. CONSTRUCTION

3.1 The Contrabass, Luna

To streamline the process and accommodate my lack of prior luthiery experience, I started with a kit for certain key components, Fig. 1. The neck and fingerboard, both crucial for playability and precision, remained unmodified. The ebony fingerboard, included in the kit, was a cost-effective choice and avoided the challenge of carving a perfectly regular surface. The bridge also came precarved in a rough form, requiring additional thinning and height adjustments.

The hardwoods used for the rest of the instrument pieces were bought in a hardwood store in Oakland, CA, and selected under Dr. Mark Rau's guidance [5].

Please, note the contrabass that served as a model is a 5/8 sized contrabass, fitting my relatively short stature. The resulting electric contrabass is also between 5/8 and 3/4 sized.

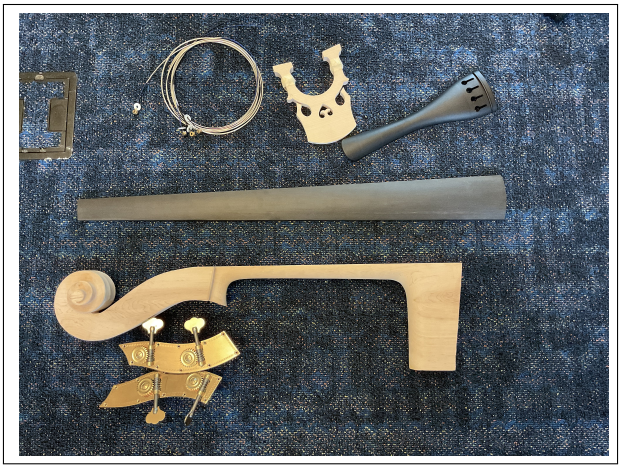

Figure 1. Pieces bought for the construction.

3.1.1 Designing and Carving the Body

The body was built as a minimalist resonant cavity, often designated as "the coffin", see Fig. 2. Its length was reduced to the bare minimum— just enough to maintain

string vibrating length and accommodate a shortened tailpiece. Although my traditional contrabass cavity measures 110 cm, I determined that a functional version could be reduced to 88 cm.

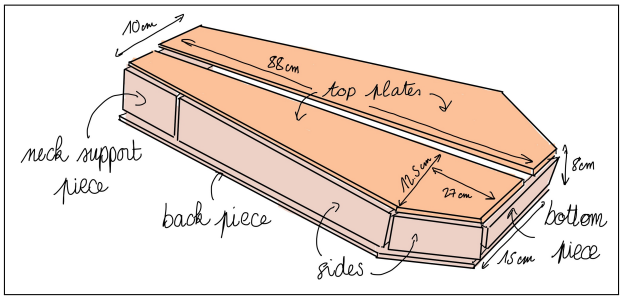

Figure 2. Schematics of the body of the electric contrabass.

I drew the shape of the coffin-looking resonnant cavity by projecting a scaled image of my acoustic contrabass on a piece of paper and then drawing the resonnant cavity, respecting minimum dimension previously calculated. The maximum width of the body is 25 cm, at the height of the bridge (27cm from the bottom of body) and fits the bridge wideness (16cm) plus extra centimeters to allow the top plate to vibrate with the bridge.

Figure 3. Photo of the body of the electric contrabass before final closure.

3.1.2 Neck Attachment

Joining the neck to the body was one of the most delicate steps, see Fig. 5. The neck insert has a highly specific shape, and my design choices reduced the contact area between the neck and body. To compensate, the neck was secured with a thick lag bolt after insertion, see Fig. 4.

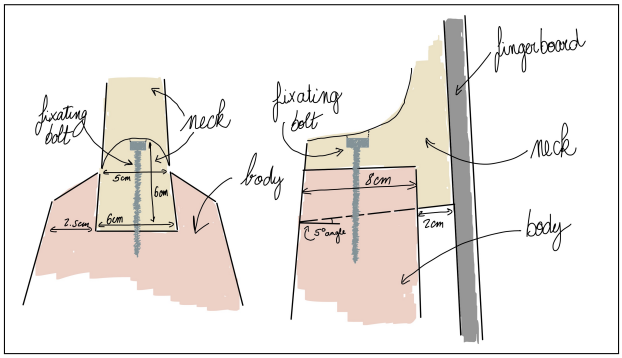

Figure 4. Schematics of the neck attachment.

Figure 5. Photo of the neck attachment hole.

A key structural parameter was the neck angle, critical for achieving the correct fingerboard elevation. Based on measurements from my classical contrabass, I determined that the neck needed a +5° angle between its base and the top plate. This was derived from a 2 cm clearance between the top plate and the fingerboard at its highest point and an 8 cm clearance at the lowest end, ensuring the right setup for bowing and playability. Recarving a hole in the body to create the space for the neck ended up being a complicated task that took over 6 hours to fit the shape of the neck nicely. This process could have been anticipated.

3.1.3 *Crafting the Tailpiece and Sides*

After assembling the main structure, the tailpiece and sides became more of an artistic handcrafting process than strict engineering. The tailpiece, based on my model contrabass but shortened to 14 cm, was hand-carved from zebrawood, repurposed from leftover lute-making materials, Fig. 6. The sides, cut from maple, were designed as a copy of the shape of my acoustic contrabass, in order to maintain ergonomic capacity. Retrospectively, this design poses functional issues and could be improved:

Figure 6. Tailpiece.

- Attachment system: The bolts and inserts are sturdy but impractical for quick assembly/disassembly.
- Weight issues: The maple shoulders are almost as heavy as the entire contrabass, suggesting the need for lighter materials (e.g., carbon fiber) to optimize portability.

These pieces were not the most time consuming but represented 4 days of work including cutting, times of setting for pieces glued together, shaping and sanding.

3.1.4 *Final Assembly and Adjustments*

The last steps—adding tuners, gluing the fingerboard, shaping the bridge, installing the nut, and fitting the endpin support—were relatively straightforward (6 extra days). The wood was finished with shellac varnish. While a professional luthier could refine certain aspects to improve playability, Theresa meets my envisioned design goals, balancing acoustic integrity, transportability, and modularity in my first instrument-making venture, Fig. 7

Figure 7. Final instrument

3.2 The Lute, Celeste

Unlike Luna, who had no experience in luthiery, I had prior knowledge from previous projects, including building electric bass guitars and electric guitars of various scales, shapes, and budgets. Additionally, I had some experience with general woodworking and carpentry, skills I acquired from my grandfather, a master carpenter with over 70 years of experience in Medellín, Colombia. From him, I learned numerous techniques and refined my craftsmanship so much so that I even named the lute in his honor.

3.2.1 *Measurements*

To initiate the process, I carefully measured the dimensions of the reference lute, focusing particularly on its scale length which is the critical distance between the nut and the saddle that determines fret spacing along the neck. The acoustic lute follows an international standard scale of 62 centimeters. Notably, despite its total length of 74 cm, its neck is relatively short, measuring only 24 cm, which allows for just 12 frets. Wanting to accommodate more frets, I opted for a longer neck and a greater neck-to-body ratio, ultimately designing an instrument that could fit 18 fret spacings.

When adapting the instrument to an electric version, I made a deliberate choice to shorten the scale length and reduce the overall dimensions. This decision was primarily influenced by the weight of the solid wood body in an electric lute and the tension of the metal string compared to the gut or nylon ones. Unlike its acoustic counterpart,

the denser construction significantly increases the instrument's mass, making it necessary to shorten the overall length for ergonomic playability.

Table 1. *Comparison between both lutes.*

Measure	*Acoustic*	*Electric*
Scale	$62cm$	$23 - 1/4in$
Tracks	$9(8*2, 1*1)$	$7(5*2, 2*1)$
Frets	12	18
Lenght	$74cm$	$69cm$
Neck	$24cm$	$37cm$
Shape	*Pear*	*Telecaster*

However, despite the reduced scale and total length, the neck of my electric lute extends to 37 cm—longer than that of the acoustic version. This extended neck allows for additional frets, aligning with the design principles commonly found in modern electric guitars.

By extending the fretboard, I aimed to enhance the instrument's versatility and provide a familiar playing experience for musicians accustomed to contemporary electric guitar designs, which is my personal experience although I also play the traditional lute.

3.3 Wood and first cuts

I chose zebra wood for the body, flamed maple for the bridge and fingerboard, mahogany for the head and neck, and ebony for the nut. The hardwoods, sourced from Oakland, CA, were selected with Dr. Mark Rau's guidance, balancing weight, stiffness, aesthetics, and cost.

Since the body wood wasn't the right size, I cut it into four pieces to create a mirrored pattern, planed them down, and hand-finished the seams for symmetry, Fig. 8

For the neck and head, I measured a 19-degree angle to achieve the L-shaped head, cut the pieces with a band saw, and glued them together—taking about two hours for prep and 24 hours for setting. I then routed the truss rod channel and finished with extensive sanding and planing, Fig. 9

3.4 Shaping

Once all the wood pieces were ready, I hand-drew designs directly onto the surface of the body wood, using the natural zebra wood patterns as inspiration. The flowing, wavy lines mirrored my own tattoos, giving the head and body a unique, organic aesthetic. Ultimately, the body shape took

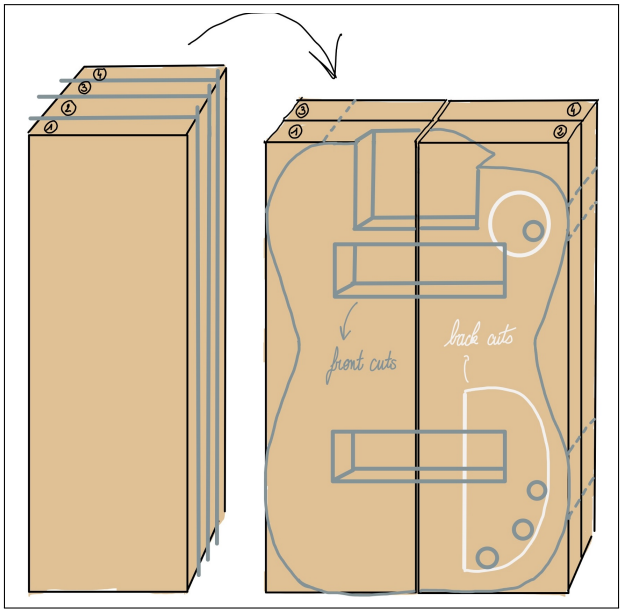

Figure 8. Crafting of Alfonso's body.

on a form reminiscent of Fender Telecasters, blending traditional craftsmanship with a modern touch.

Shaping the instrument required a jigsaw, electric sander, chisel, and hand router, making it the most labor-intensive stage—over 16 hours across four sessions, plus two full days dedicated to carving the neck's back arc. The fingerboard radius was carefully shaped by hand using a 3D-printed template from my instructor and sandpaper, a process that took two continuous hours. The bridge, crafted from flamed maple, was reinforced with epoxy resin due to minor imperfections, while the nut and saddle were shaped with an electric sander, using the same radius template for precision.

3.5 Assembly process and all related to strings

With all components prepared, I routed the channel for the saddle while considering the best way to attach the neck to the body. After weighing the options—adhesive bonding or screws—I chose screws for easier disassembly, making transportation, especially by plane, more practical.

Once this step was complete, I carefully calculated the string positioning, ensuring proper spacing and height relative to the fingerboard. Gradually tuning the strings helped apply the correct tension to the structure, preparing the lute for its final shape Fig. 10.

At this stage, the instrument was not yet fully com-

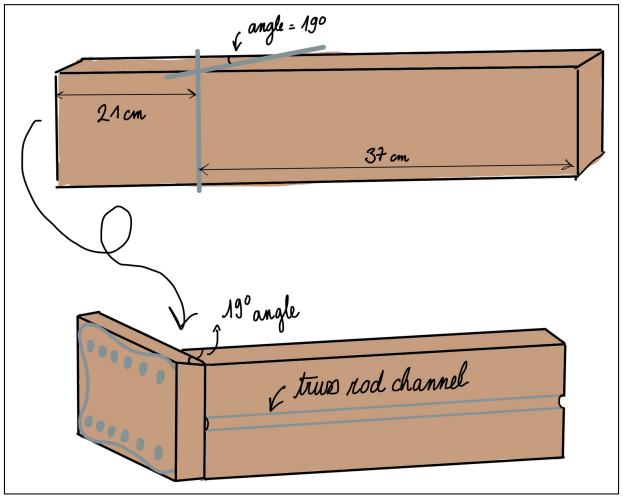

Figure 9. Crafting of Alfonso's body.

Figure 10. Final Lute Instrument

plete; the electromagnetic pickup and other essential components still needed installation, and no finishing had been applied.

4. ELECTRONICS - EXPANDED INSTRUMENTS

4.1 The Contrabass

Theresa was conceived not merely as an electric contrabass, but as an extended instrument—one that expands the performer's expressive and gestural vocabulary by integrating digital sensing and real-time sound processing. While retaining the tactile and acoustic qualities of a traditional instrument, the instrument enables a hybrid mode of performance that merges the physical gestures of instrumental playing with programmable interaction [6], [7], [8].

To support a broad spectrum of sonic characteristics, Theresa is equipped with two complementary pickup systems. An electromagnetic pickup, positioned at the end of the fingerboard, offers a focused, traditional amplified bass tone. In parallel, piezo pickups mounted at the bridge capture a richer dynamic and spectral response. These signals are compatible with standard bass amplification setups. Future iterations may include the addition of a condenser microphone inside the resonant cavity, inspired by systems like the Yamaha Silent Bass, to further recover the instrument's natural resonance and spatial depth.

Beyond this conventional amplification, the instrument integrates a modular electronic system designed to augment performer interaction and sound control. Installed on the left shoulder, the mounting platform hosts a range of swappable sensor modules and microcontrollers, configured to be easily accessed by the performer's right hand during performance (Fig. 11). The platform itself is designed for quick removal and interchangeability, reinforcing the concept of a reconfigurable and adaptive instrument.

The first implementation of this system includes buttons, rotary knobs, capacitive touch sensors, and motion-sensing elements such as accelerometers, gyroscopes, and compasses, all interfaced through an Arduino Uno [9]. These sensors communicate with a Max/MSP patch, allowing real-time mapping of gestural input to a variety of audio processing functions, including filtering, modulation, spatialization, and granular effects. In some cases, control parameters may also drive higher-level compositional structures, enabling a performative blending of instrumental play and live electronics.

This approach positions the instrument within the lineage of extended instruments—tools that transcend traditional definitions by embedding computational and gestural responsiveness within their design. For example, subtle tilts of the instrument can control spatial diffusion, while touch gestures on capacitive sensors may trigger or morph effects such as tremolo, distortion, or grain-based textures, extending the timbral range far beyond what is physically possible on an acoustic contrabass.

Importantly, this modular and expandable architecture supports ongoing development. While currently deployed on a single shoulder, the system is structurally pre-

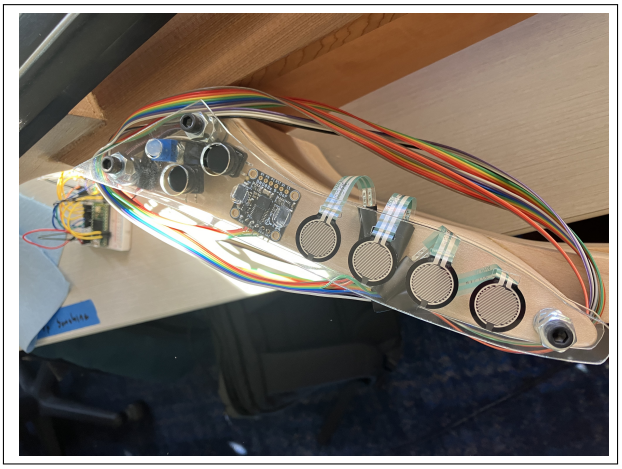

Figure 11. Modular electronics with capacitive touch sensors, an accelerometer, a gyroscope, a compass, knobs, and buttons, interfaced through an Arduino Uno

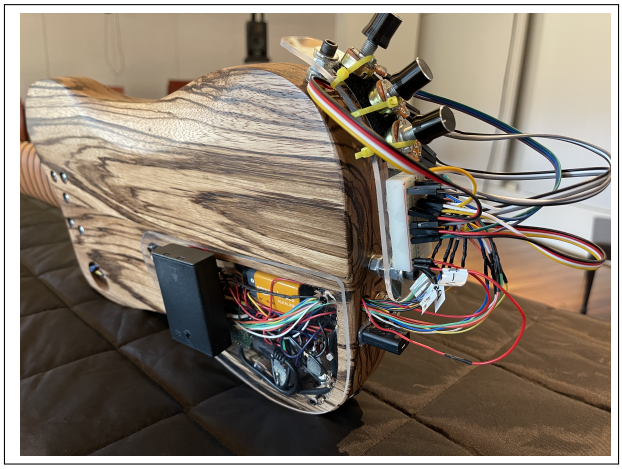

Figure 12. Electronics seen from the back

pared for extension to other parts of the instrument. Potential future additions include wireless communication, more compact or high-resolution sensors, and haptic feedback systems for bidirectional interaction—a feature that could fundamentally reshape the tactile experience of performance. Here, we exemplified an extended instrument paradigm: a hybrid of acoustic tradition and digital innovation, where gesture, sound, and spatial interaction coalesce [10]. It preserves classical technique while radically expanding the instrument's expressive scope, offering performers an adaptable and evolving tool for musical creation.

4.2 The Lute

The lute features an active microphone circuit based on the widely used Fishman Fluence pickup system. This system is designed to effectively capture the sound of the metal strings with high fidelity and minimal coloration. The Fluence circuit does not require any additional signal conditioning or processing within the instrument body: it outputs a clean, high-quality signal directly to a standard 1/4-inch female jack mounted on the instrument's side Fig. 12.

In addition to this, there is a second pickup system installed beneath the bridge. This is a Fishman piezoelectric acoustic pickup, optimized to capture the resonance and body vibrations of the lute. Unlike the Fluence system, the piezo signal is not sent directly to an output jack. Instead, it is routed into an embedded digital signal processor located inside the instrument. This processor runs a series of custom signal processing algorithms, allowing for advanced manipulation of the acoustic input before it is sent to a second 1/4-inch output jack, positioned just above the first one. Like the first, this circuit is also active, meaning it includes preamplification and requires power to operate. Both batteries live inside the circuit cavity inside the lute.

To manage the Fluence system, the instrument includes a pull-up potentiometer for switching between configuration presets, along with two additional rotary potentiometers that control tone, blend (mix), and overall output volume.

For the piezo and signal processing system, control is managed via a modular, custom-designed acrylic interface mounted on the side of the lute. This module houses four dedicated potentiometers, two Bela sensors (which could include touch, pressure, or motion sensors) [11], and a multifunction control board featuring eight general-purpose I/O pins. These I/O pins are directly connected to a Teensy microcontroller board embedded inside the lute [12], allowing for real-time interaction with the signal processing algorithms or for sending control data externally via USB or serial communication protocols.

The first iteration of the system's internal processor came preloaded with several essential audio effects modules: a high-pass filter, a resonant filter, a reverb effect based on the well-known Freeverb algorithm, and a custom-designed digital feedback circuit. These components work together to create a vivid and dynamic sonic

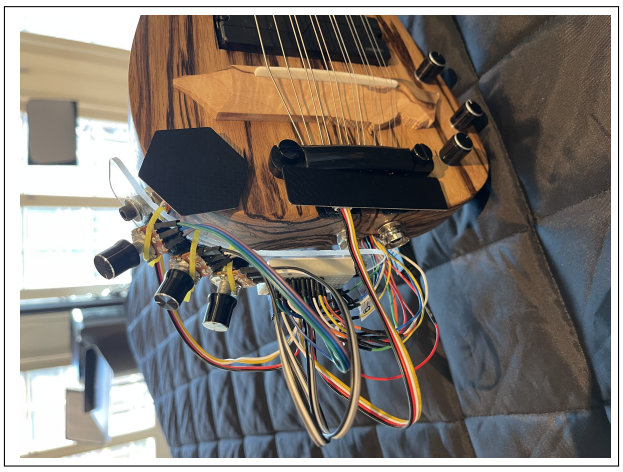

Figure 13. Electronics on the Lute

environment, enabling the performer to shape real-time feedback and texture in musically expressive ways. The digital feedback engine, in particular, is highly sensitive to changes in the input signal and spatial characteristics, making it ideal for gestural control. It is fully responsive to the BELA sensors, allowing the performer to modulate parameters such as filter cutoff, resonance, feedback depth, or reverb size using touch, motion, or pressure.

To enable both system updates and external data communication, a USB female connector is mounted just above the output jacks. This port provides direct access to the Teensy microcontroller, allowing the user to reprogram the internal firmware, upload new processing algorithms, or retrieve real-time digital data generated by the onboard sensors and control interfacesFig. 13.

5. CONCLUSIONS

Designing and building a musical instrument is an intensive, time-consuming, and deeply personal process—one that demands not only technical skill but also emotional endurance. As detailed throughout this paper, the construction of these particular instruments required fluency in a broad range of competencies: the use of hand and power tools, precise measuring, and a strong foundation in electronics, acoustics, and embedded systems. However, beyond the technical challenges, this process also proved to be profoundly gratifying and creatively rewarding.

In Celeste's case, the approach was unapologetically improvisational. Rather than following a strict plan from the outset, Celeste allowed intuition, spontaneity, and situational problem-solving to shape the development path. This wasn't a lack of structure but rather a fluid methodology rooted in her prior experience with instrument design and building. That experience acted as a compass, allowing her to make informed, responsive decisions in real time.

This hybrid of expertise and improvisation extended even to the integration of complex electronics: an active dual-circuit pickup system, real-time digital signal processing, and a rich sensor array. These components were not simply installed: they were curated, adjusted, and adapted according to the needs and affordances of the instrument as it evolved in her hands. From the sculpting of the sound through digital feedback and reverb to the custom interface for expressive control, each element reflects a balance between pragmatism and play.

Luna, by contrast, began with a clear and deliberate vision for both the aesthetic and functional dimensions of the instrument. Her goal was to create a lightweight, transportable electric contrabass that preserved the tactile and acoustic sensibilities of a traditional instrument, while offering modular expandability for live electronic performance. With little prior experience in luthiery, much of the process involved improvising practical solutions to realize that vision—from carving a resonant cavity inspired by classical proportions, to adapting hardware components for ergonomic assembly, and solving unforeseen mechanical issues with hands-on experimentation. The integration of a modular sensor platform and real-time processing system further expanded the instrument's expressive scope, enabling an embodied mode of performance where gesture, space, and sound are intricately linked.

Ultimately, building these instruments was not only about achieving functional tools; it was about crafting living systems, each capable of interaction, surprise, and sonic depth. They stand as reflections of both meticulous labor and creative joy, of structure and improvisation, and of a personal, evolving practice that values both precision and poetic expression.

ULTRASONIC IMAGING FOR QUANTIFYING MICROPLASTIC CONCENTRATIONS IN LIQUIDS

Óscar Martínez-Graullera[1*] **Paula Moreno**[1] **Carlos Pinillos Boralla**[1] **Jorge Huecas**[1]
Ruslan Shaporin[1] **Montserrat Parrilla**[1] **Luis Elvira**[1]
[1] Instituto de Tecnologías Físicas y de la Información (ITEFI), CSIC, Spain

ABSTRACT

In recent decades, the uncontrolled disposal of plastic waste into the environment has caused widespread contamination, infiltrating even the food chain. The issue of microplastics, particularly in oceans, poses significant challenges with negative implications for marine ecosystems, human health, and the economy. Furthermore, emerging contaminants and their interactions with climate change exacerbate these impacts. To address this problem, active monitoring programs are being developed to detect contaminants such as microplastics, antibiotics, and chemicals in coastal waters. Advancing technologies to implement these strategies effectively is essential. This study aims to develop an analytical procedure to quantify microplastic concentrations in liquids (5–50 microns), optimized for onboard instrumentation. A system has been designed to channel the flow through a 1 mm diameter pathway, utilizing high-frequency ultrasonic imaging (20–50 MHz). Ultrasonic image processing enables the measurement of reflected energy to estimate microplastic concentrations. This method is calibrated using controlled monodispersive polystyrene particle concentrations, establishing a relationship between reflected energy and particle concentration. The proposed approach provides a pathway for real-time, accurate microplastic detection, supporting environmental monitoring and mitigation efforts. This paper presents a preliminary study, employing a 20 MHz transducer and an experimental setup with monodispersive polystyrene particles in continuous flow.

Keywords: *microplastic, high frequncy ultrasonic, ultrasonic image*

1. INTRODUCTION

Nowadays, the presence of micro-scale contaminants in the food chain remains a significant uncertainty for human well-being. Studies have detected both chemical and physical pollutants at various points in the chain, with particular concern in the oceans, which serve as humanity's primary food reservoir [1,2]. To assess the severity of this issue, the European Union has launched research initiatives to establish monitoring protocols. These efforts are accompanied by technological developments that could be integrated into early warning systems in critical areas. This study is framed within that context.

Microplastic concentrations (5–50 microns) can be measured using various high-precision optical and spectroscopic methods [3–5]. However, ultrasound offers key advantages: it can detect particles in suspension, enables real-time marker-free detection, and allows for in situ application. These features are essential for developing an autonomous monitoring system. As a first step, this study proposes a measurement procedure using optical methods as a reference. The objective is to obtain an image of the sample—ultrasonic in this case—on which processing can be performed to quantify the number of particles.

Although this procedure does not allow for chemical identification and faces significant challenges, such as nanoparticle detection and the influence of factors like salinity, temperature, and turbidity on the ultrasonic signal, it is nonetheless more robust and applicable than other solutions. Additionally, since certain polymers absorb more ultrasonic energy, it offers some potential for discrimination.

2. EXPERIMENTAL SET-UP

2.1 Image Generation

Given the range of particle sizes to be detected, the decision was made to use high-frequency ultrasound and focused transducers (20 MHz, focal position at 13 mm, beam diameter of .1mm) operating in pulsed wave mode to generate the ultrasonic image. Due to the characteristics of the medium, a peristaltic pump (Watson-Marlow 120U/D1 pump 200rpm) and a 1 mm-section tube were used to create a closed circulating system for the sample. At a specific point, the transducer was integrated into a specially designed device that provides a flat interface with the sample flow. The transducer is positioned at an inclination angle of 30^o to increase the measurement area within the flow, as shown in Figure 1. However, the measurement section is limited to the beam section that covers only part of the tube (see Figure 1 right).

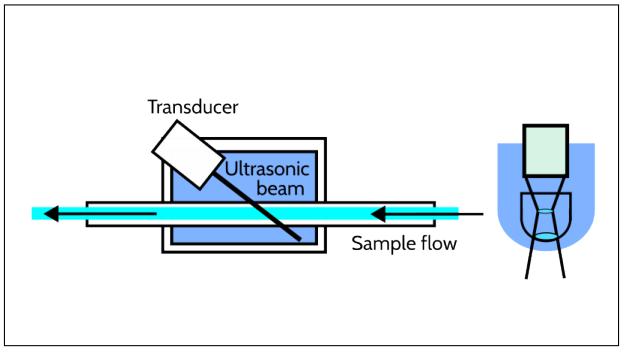

Figure 1. Transducer position in the measurement device.

In this setup, the image is composed by assembling a sequence of consecutive acquisitions. The image size is determined by the acquisition system's ability to maintain a constant data flow to the processing system. In this case, with a sampling rate of 80 MS/s, echoes are captured for 20 microseconds, and the analysis image consists of 5000 consecutive lines acquired every 500 milliseconds.

2.2 Sample Preparation

In order to develop an experimental system for the detection and quantification of particles in water samples, we have generated several calibrated samples based on spherical monodisperse polystyrene particles ranging from 2 to 12 microns in diameter. We calculated the concentrations by counting the particles in a Neubauer chamber under a microscope or using the ImageJ program. In Figure 2, we can see an optical image of the sample.

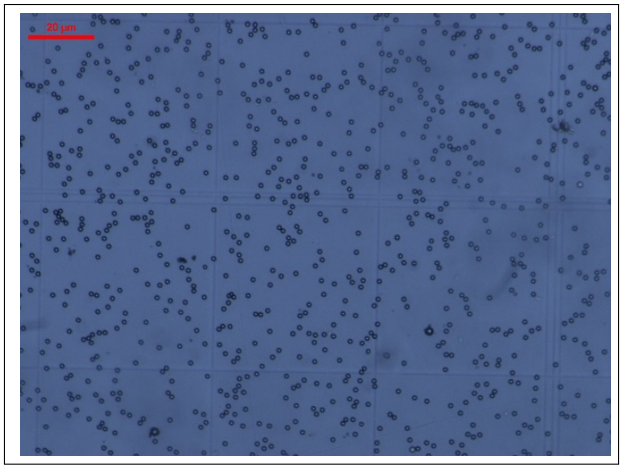

Figure 2. Spherical monodisperse polystyrene particles ranging 10 microns in diameter

To obtain polydisperse samples, with particles of different sizes and irregular shapes, we used polystyrene shavings. In these samples, we used the same methods to determine the concentration, but the irregular shape of the particles makes it difficult to distinguish whether we are observing large particles or several smaller particles agglomerated together (figure 3).

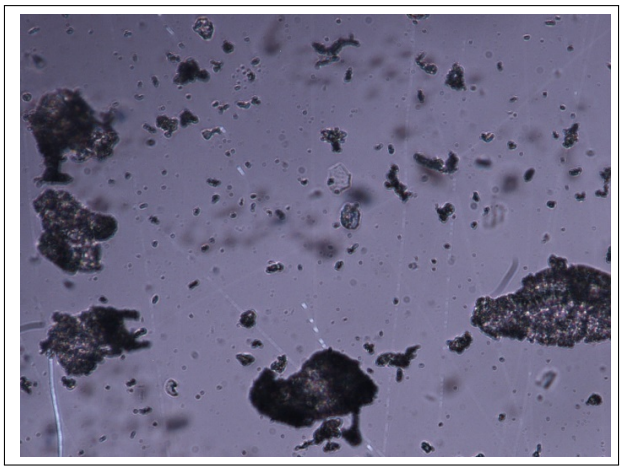

Figure 3. Polydisperse samples

2.3 Measurement Procedure

The measurement system is configured in two stages. The first, instrumental stage consists of the transducer, its support system, and an ultrasonic Difrascope system (DASEL Sistemas S.L.) responsible for signal acquisition. The second stage is a processing stage, at this moment developed in MATLAB, which handles signal preprocessing and reflector counting.

Ultrasonic imaging is composed of the assembly of consecutive A-scan lines (see figure 4). The image shows microplastic particles, artifacts due to multiple reflections in the measurement tube, and thermal noise. With a transducer frequency of 20 MHz, the preprocessing stage includes band-pass filtering and a spatial filter designed to eliminate the effect of multiple reflections within the tube. Once the structural elements are removed, image processing is performed. After applying a two-dimensional low-pass filter to reduce noise, dilation and erosion operations are used to differentiate reflectors from the background, eliminating spurious values. Then, a statistical analysis of the data is conducted to determine the threshold value that enables segmentation and reflector counting.

In the case of monodisperse spherical particles, the reflectors appear in a characteristic pattern as oblique lines following the flow direction (Figure 5). Other shapes, such as arcs and symmetrical forms, also appear, caused by flow variations induced by the peristaltic pump. The periodicity of these artifacts indicates their artificial nature.

Finally, it is important to note that the ultrasonic beam only covers a section of the tube, meaning that the measurement represents a sample-based estimate of the particle concentration. Calibration is necessary to adjust the measurement to the actual concentration value.

3. CALIBRATION

In order to assess the ability to distinguish between concentrations and calibrate the system, three concentration levels were used: 10 particles per μL, 26 particles per μL, and 50 particles per μL (sample composed by spherical monodisperse polystyrene particles ranging 10 microns in diameter). Each concentration was evaluated with the pump operating at different speeds: 4, 8, 12, and 16 rpm.

For each measurement, 3000 images were acquired, each consisting of 5000 lines. The number of circulating particles was counted in each image, and to eliminate outliers, the complete dataset was averaged using a sliding window of 32 samples. This value was empirically determined. Finally, the histogram is calculated to statistically characterize each distribution. Given the nature of the data—positive values with a significant mean—we have chosen the Rice distribution as the basis.

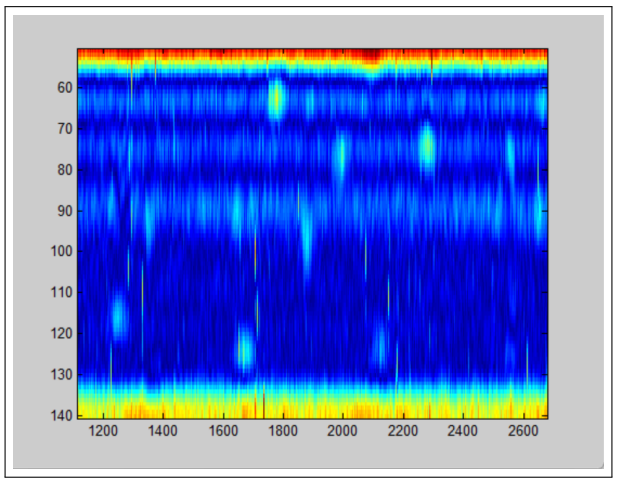

Figure 4. Ultrasonic image obtained at 20 MHz by assembling consecutive A-scan lines.

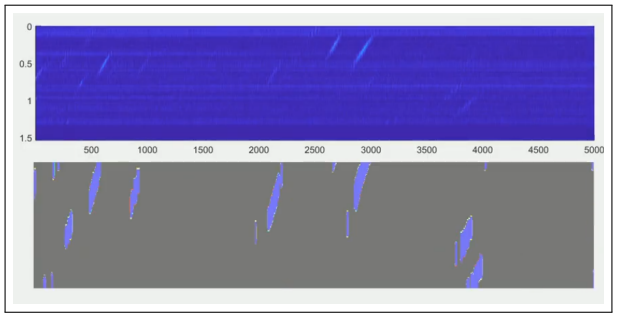

Figure 5. At the top, the ultrasonic image is presented after preprocessing. At the bottom, segmentation shows the reflectors.

To evaluate the results, the histograms of the three concentrations are compared at each speed, and Rice distribuions are estimated.

In Figure 6, we can see the result of circulating the liquid at the lowest speed. The number of detected particles is low, and the results are imprecise for all three concentrations, as the histograms overlap.

In Figure 7, we can see the result of circulating the liquid at speed 8rpm. The number of detected particles is higher, and the highest concentration becomes significant

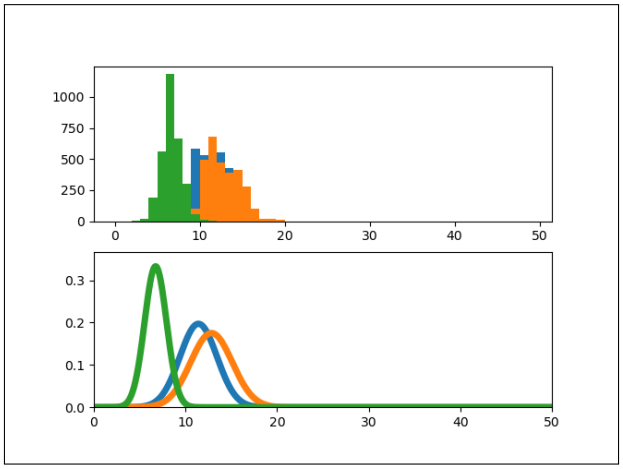

Figure 6. At the top, the histograms of the concentrations of 10 pp/μL (green), 26 pp/μL (blue), and 50 pp/μL (orange) at 4 rpm. At the bottom, the estimated Rice distributions (same color code).

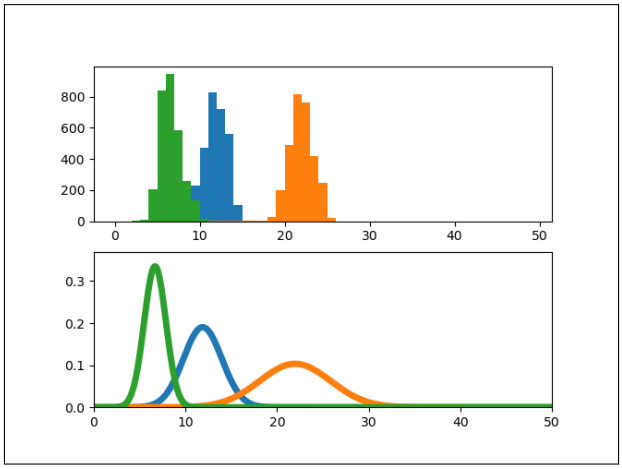

Figure 7. At the top, the histograms of the concentrations of 10 pp/μL (green), 26 pp/μL (blue), and 50 pp/μL (orange) at 8 rpm. At the bottom, the estimated Rice distributions (same color code).

and distinguishable from the other two. The 26 pp/μL and 10 pp/μL concentration remains consistent with the previous measurement.

In Figure 8, we can see the result of circulating the liquid at speed 12rpm. The concentrations can now be distinguished, and we can characterize them using the corresponding distribution functions. Although there is slight overlap between the 50 pp/μL and 26 pp/μL concentrations, the spread of the distributions allows for the calibration of intermediate concentrations.

In Figure 9, we can see the result of circulating the liquid at a speed of 16rpm. At this speed, the number of particles in the image increases, having opposite effects on the particle count. On one hand, the 26 pp/μL concentration increases in value and yields more consistent results, improving detection capability. On the other hand, the 50 pp/μL concentration decreases in value, contrary to expectations. This occurs because, as the number of particles under the beam increases, they cluster in such a way that, during the image binarization process, they may be counted as a single particle when, in reality, they could be two or more. In the case of 10 pp/μL, there is no substantial change in the mean. Despite the increase in speed, the particle density remains low, which means it cannot be ensured that the particles pass directly under the beam.

The results indicate that the pump exhibits an optimal operating speed at which measurement discrimination improves and histogram distributions become more concentrated. However, two key limitations were identified. At high concentrations, discrete particle counting is hindered by clustering effects, which compromise both the accuracy and precision of the measurements. This limitation necessitates the use of complementary descriptors to refine concentration assessment. Conversely, at low concentrations, it becomes essential to control the trajectory of microplastics to ensure their passage through the transducer beam, as their random motion can result in inconsistent or missed detections.

On a positive note, the measurement distributions can be statistically characterized using Rice distributions, which opens the possibility of developing a framework to manage measurement uncertainty based on the likelihood of belonging to a calibrated set of reference distributions.

4. CONCLUSIONS AND FUTURE WORK

This study has demonstrated the viability of using high-frequency ultrasound to quantify the concentration of microplastics in liquid media. The measurement protocol, while exhibiting a degree of flow dependence, has proven to be both reliable and reproducible and incorporates a defined margin to address uncertainty. Current research efforts are directed toward identifying the optimal flow velocity to enhance measurement resolution and extend the detection range toward lower concentrations. In parallel,

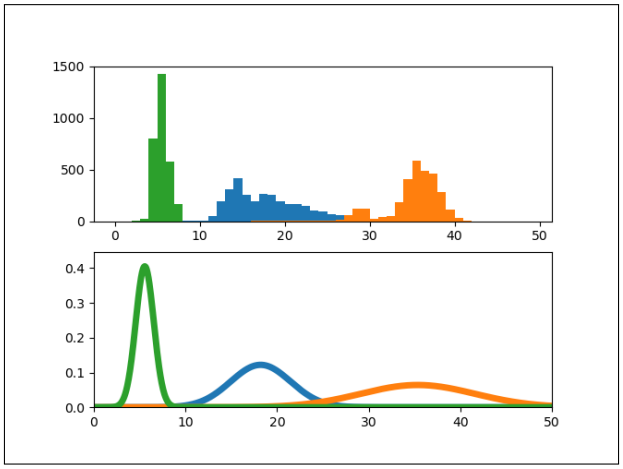

Figure 8. At the top, the histograms of the concentrations of 10 pp/μL (green), 26 pp/μL (blue), and 50 pp/μL (orange) at 12 rpm. At the bottom, the estimated Rice distributions (same color code).

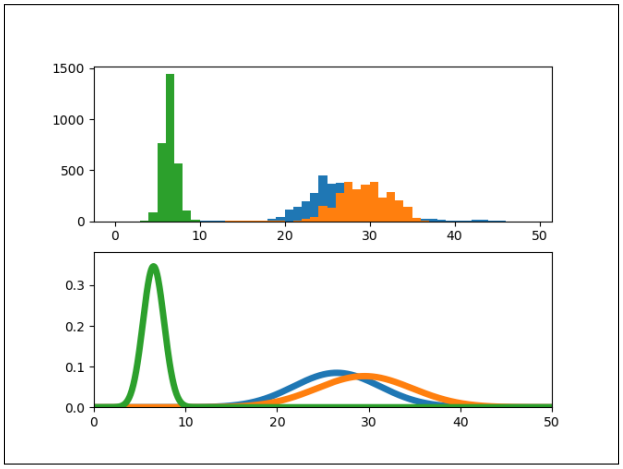

Figure 9. At the top, the histograms of the concentrations of 10 pp/μL (green), 26 pp/μL (blue), and 50 pp/μL (orange) at 16 rpm. At the bottom, the estimated Rice distributions (same color code).

alternative signal descriptors, such as energy density, are being evaluated to complement particle counting, with the aim of improving concentration estimation and resolving ambiguities that arise at elevated flow speeds.

Nonetheless, the methodology has thus far been validated only to a limited extent using polydisperse samples, and the potential impact of naturally occurring microorganisms in water has yet to be addressed. These considerations will introduce future refinements to the signal processing pipeline.

Despite these limitations, the results obtained thus far provide a solid foundation for the development of a next-generation measurement prototype, advancing the system toward eventual deployment on a lightweight computational platform.

ABSTRACT

Ultrasound has a wide range of applications in fields such as medicine, architecture, or chemistry. In particular, ultrasound-intensified reactors (where chemical and/or physical reactions take place) have proven to be more efficient than traditional reactors in multiple situations, offering a benefit to the industry. This is due to the increased control over the conditions in the mixture, helping to accelerate reactions and replace solvents, among other things. Two examples of this are the agri-food and pharmaceutical sectors. In the first case, ultrasound reactors can improve continuous production, product stability, and allergen removal. In the second, issues such as capillary blockages and crystallization treatments can be mitigated through this technology. This paper presents a preliminary design of an ultrasonic reactor aimed at these applications. The device utilizes a long sonotrode to enhance energy transmission to a continuous flow. This sonotrode consists of a solid cylinder with a machined helical groove along its surface, into which a tube is inserted through which the sample to be treated is passed. Analytical and numerical methods have been used for its design, which have subsequently been reflected at the experimental level for the agri-food and pharmaceutical industry applications.

1. INTRODUCTION

Ultrasound technology has emerged as a powerful tool across various scientific and industrial sectors, including medicine, chemistry, and engineering. Its application in reactors, particularly ultrasound-intensified reactors, has shown significant advantages over conventional methods [1,2]. These reactors enhance reaction efficiency by providing precise control over the conditions within the mixture, leading to faster reaction rates and the potential for solvent-free processes. Such benefits have been demonstrated in industries such as agri-food and pharmaceuticals, where ultrasound-assisted techniques improve production stability and mitigate common challenges like crystallization and capillary blockages [1,3].

The synthesis of particles with controlled properties at the nanoscale and microscale has garnered significant attention due to their diverse applications in fields such as adsorption, ceramics, catalysis, and drug delivery [4]. Among various fabrication methods, continuous flow approaches utilizing microreactors have emerged as powerful tools, offering advantages like enhanced mass and heat transfer, precise control over reaction conditions, and improved reproducibility [5]. However, a critical challenge in continuous flow systems, particularly when synthesizing particles or performing crystallization, is the potential for clogging of the microchannels by solid formation, including the aggregation or precipitation of products or by-products [1,3,6].

To address the issue of clogging in continuous flow reactors, several strategies have been explored. These include modifying the wettability of the channel surface, adjusting the viscosity of the solution [7], and employing multiphase flow [1,5,7]. Another promising technique in-

volves the application of ultrasound irradiation within the microreactor [1,2]. Ultrasound has demonstrated its effectiveness in preventing and even removing clogging in capillary systems, attributed to the strong cavitation effects it induces [1,3]. Furthermore, ultrasound can enhance mass transfer rates at gas-liquid or liquid-solid interfaces and promote mixing, which can be particularly beneficial in processes like continuous crystallization and nanoparticle synthesis [3,5,6].

In this context, a significant need exists for robust and scalable continuous flow reactors. Particularly, they can be applied to the agri-food and pharmaceutical industries as they can effectively handle solids and prevent clogging [3]. While continuous flow reactors offer numerous advantages, such as precise control and enhanced mass transfer [4, 6], their widespread adoption is hindered by challenges related to solid handling, including clogging from precipitate formation, solid catalysts, or insoluble byproducts [3].

To address these limitations, the design of a large-scale flow reactor should incorporate strategies for efficient solid management. Ultrasound irradiation emerges as a particularly promising technique for both preventing and clearing blockages in continuous flow capillary systems [3]. Ultrasound can induce cavitation, which provides a mechanical means to disrupt particle aggregation and resuspend settled solids [5, 8].

Notably, even low-power acoustics without cavitation has been shown to effectively unclog and prevent blockages [3].

The fabrication of such a reactor should consider several key aspects. The choice of materials must ensure chemical compatibility with the intended applications in the agri-food and pharmaceutical sectors. For efficient ultrasound transmission, materials such as glass can be advantageous [5]. The reactor design should incorporate optimized sonotrode geometries, such as blade, block, cylindrical, or even helicoidal shapes, to achieve wider and more uniform sonication areas suitable for larger reactor volumes and longer capillary lengths [3]. Acoustic design principles are crucial to ensure that the applied frequency resonates effectively with the reactor system, maximizing the conversion of electrical power into acoustic energy focused on the reaction channels. Finite element analysis (FEA) can be a valuable tool in the design process to simulate and optimize the acoustic field distribution within the reactor [6].

Validation of the large-scale flow reactor will be essential to confirm its efficacy in handling solids and preventing clogging while maintaining process performance. This should include characterizing the hydrodynamics of the reactor using residence time distribution (RTD) measurements to ensure predictable flow behavior, potentially approaching plug flow to minimize dispersion [8]. Techniques like high-speed microscopic imaging can visualize flow patterns and the behavior of solid particles under different operating conditions and with the application of ultrasound [3]. The reactor's ability to handle multiphase flow and maintain suspension of solid catalysts or reagents should be rigorously evaluated [5]. Furthermore, the performance of the reactor should be tested in relevant applications, such as continuous crystallization of pharmaceutical compounds with control over particle size and polymorph [9], and continuous catalytic reactions involving solid catalysts [5], demonstrating sustained, clog-free operation and desired product quality.

By focusing on integrated design, incorporating effective solid handling strategies like ultrasound, and thorough validation, the development of large-scale continuous flow reactors can be significantly advanced for the benefit of the agri-food and pharmaceutical industries. Nonetheless, their widespread adoption is hindered by challenges related to solid handling, including clogging from precipitate formation, solid catalysts, or insoluble byproducts [3].

Thus, ultrasound-intensified flux reactors serve as a tool to study the effects of ultrasound irradiation on substances of interest. Flux reactors, in contrast to ultrasonic batch reactors, allow continuous operation, which is beneficial at the industry level.

The reactors that will be studied consist of a system which contains a Langevin transducer (or two) coupled to a long sonotrode. This sonotrode consists of a solid aluminum cylinder with a helical machining along its surface, into which a tube is inserted through which the sample to be treated is passed by means of a peristaltic pump. The objective of this study is to design, build and experimentally test this kind of reactors.

The first section will be dedicated to the analytical and numerical design of the reactor. The second section will treat the experimental part, in which the experimental setup will be described, as well as the methodology and results.

2. DESIGN OF THE SONOTRODE

The system will consist of a Langevin transducer coupled to a cylindrical sonotrode, which will be an aluminum cylinder with a length of 630 mm, with a machined helical

groove on its surface to locate the tube. The first design was developed considering a 60 W Langevin transducer with two piezoelectric ceramics PZT8. The scheme of the system with its dimensions is shown in Fig. 1.

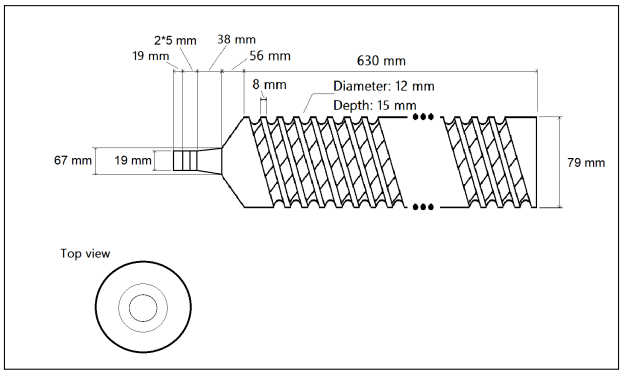

Figure 1. Initial scheme of the system.

Nonetheless, new high-power Langevin transducers were bought (with 4 piezoceramics PZT8), with dimensions different from those of the original Langevin transducer. Thus, the final scheme of the system has a step between the cone and the Langevin transducer, as shown in Fig. 2.

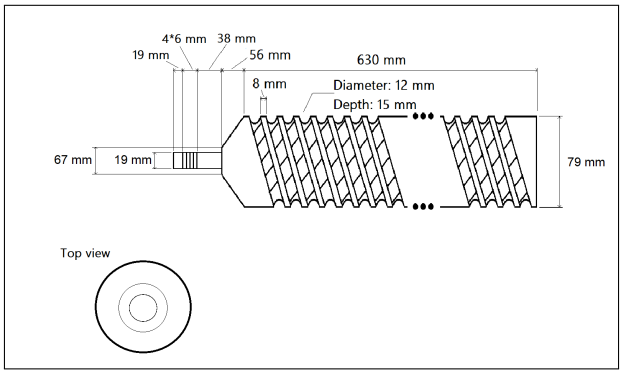

Figure 2. Initial scheme of the system.

2.1 Analytical design

The design of the system was made through the Mason model. The system was modeled to be resonant at 28 kHz. The equivalent circuit of the system can be seen in Fig. 3. An approximation has been used for the analytical solution. It has been considered that there is not a helical slit but a separated transversal ring slit sequence, in a way that there are maximum and minimum radius variations for the section. The part of the circuit corresponding to this ring sequence (the sonotrode) is shown in Fig. 4.

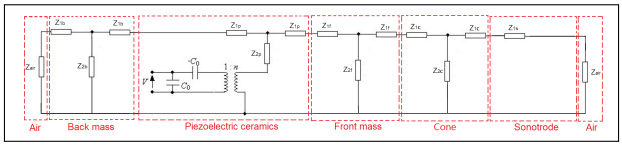

Figure 3. Equivalent circuit for the entire system. The sonotrode part is indicated as an equivalent impedance.

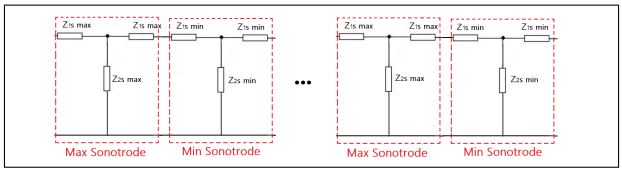

Figure 4. Equivalent circuit for the sonotrode part, where it is considered the sequence of maximum and minimum radius section of the sonotrode as if they were coupled blocks of different sections.

The result of the impedance of the system as a function of the frequency according to this method was solved using Python. The result is shown in Fig. 5, where it can be seen that the resonance of the system is approximately 28 kHz.

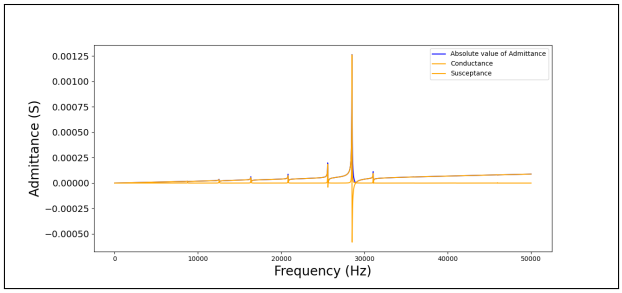

Figure 5. Absolute value of admittance, as well as conductance and susceptance of the system according to Mason model.

2.2 Numerical design

The system has also been numerically simulated in order to obtain the optimum design. The first attempt was to optimize the system at a frequency of 28 kHz. The software COMSOL Multyphysics has been used. The libraries used for this model have been "Solid mechanics", "Electrostatics" and "Piezoelectric effect". The result of this first attempt can be seen in Fig. 6, in which the transducer coupling to the sonotrode has been enlarged for better visualization.

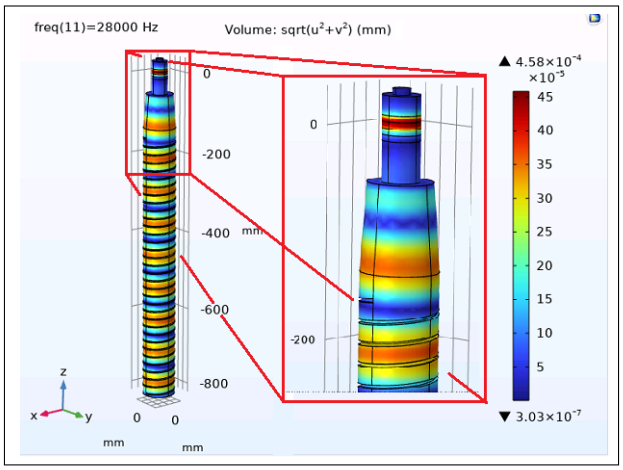

Figure 6. Numerical result of 28 kHz frequency response of the system. The parameters u and v correspond to the displacement on the x-axis and on the y-axis, respectively. Thus, $\sqrt{u^2+v^2}$ gives the total radial displacement of the system.

The absolute value of admittance, the conductance and the susceptance of the system has been computed from the numerical model by COMSOL Multphysics. The result is shown in Fig. 7.

Later, more designs were developed in order to increase the acoustic power. Thus, the new designs were mainly symmetric with two transducers of different resonant frequencies (20 kHz and 28 kHz), one in each side of the cylinder, as shown in Fig. 8, in which the transducer coupling to the sonotrode has also been enlarged for better visualization. Symmetric systems were modeled in 2D axisymmetric because they require less computational power and, due to the symmetry of the problem, the desired vibration modes can be studied in this way. In Fig. 9 the built sonotrodes are shown.

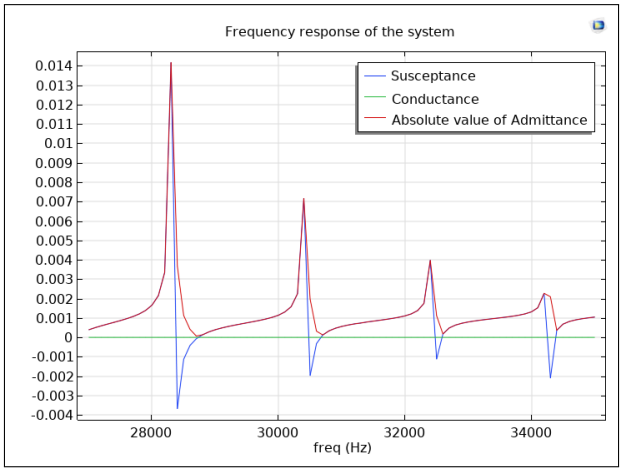

Figure 7. Numerical result of the absolute value of admittance, the conductance and the susceptance of the system. The result is not exactly the same as the one shown in Fig. 5, because that was an approximation.

3. EXPERIMENTS

The scheme of the experimental setup is shown in Fig. 10. The sample is forced to pass through the PFA tube by a peristaltic pump.

In order to control the experimental system, a LabVIEW program has been created. This program consists of a system of 3 tabs, each one in charge of a specific task. In the first tab, frequency sweep is performed in order to find the resonant frequencies of the system experimentally. In the second tab, the emission at the optimum frequencies can be controlled, making it possible to emit only at the desired frequency or at multi-frequency, with a continuous or totally customized pulsed signal. The third tab provides basic control of the pumps and monitoring of the potential pressure sensors and flow meters that can be added to the system.

Once the experimental setup has been completed (Fig. 11), tests can be started. The methodology is the same for all the experiments: the sample is passed through a tube coiled around the sonotrode, driven by a peristaltic pump. The pump flow rate and the type of ultrasound treatment (continuous or pulsed) can be changed depending on the sample and the purpose of the experiment.

In the laboratory, it has only been possible to perform preliminary studies which need to be systematically repeated in order to obtain more accurate and solid conclu-

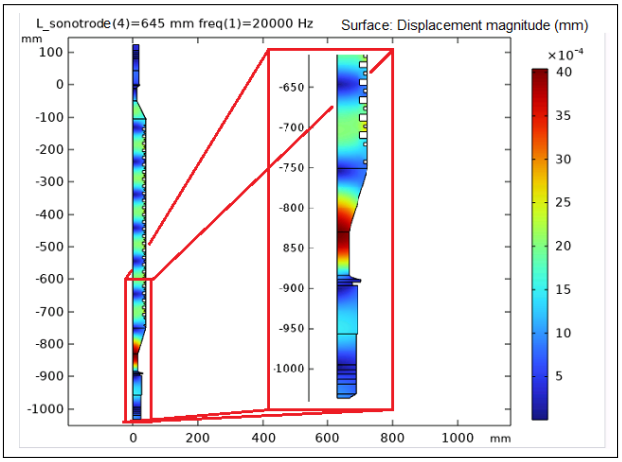

Figure 8. Numerical result of 20 kHz frequency response of the symmetric system.

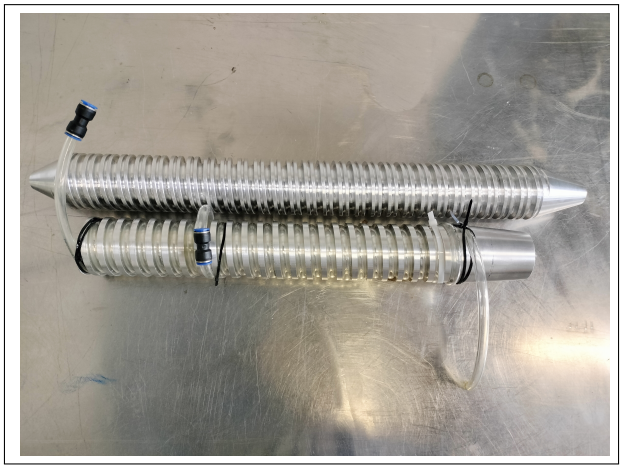

Figure 9. Built sonotrodes.

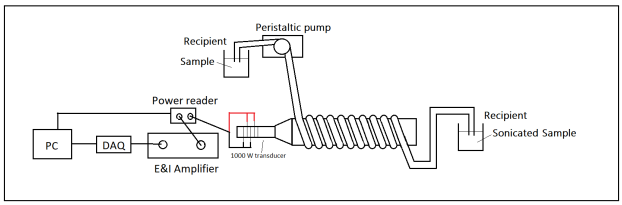

Figure 10. Experimental scheme (not to scale).

sions. Thus, only qualitative results can be summarized in this work.

The experiments performed coincide with the main problems found in continuous production in the industry, which are mentioned earlier. Thus, each experiment is a test to verify if the built device is able to solve the corresponding problem.

3.1 Antifoaming capacity

To check if the system is able to remove the foam, first it has to be generated. To create foam, the sample for the liquid-gas system was beer. When ultrasounds were applied some effects on the bubbles were observed, mainly the reduction of the large ones.

3.2 Unclogging capacity

The purpose of this experiment is to create a clog, and check if the ultrasound application can remove it. The sample for the liquid-solid system was water with sand.

The generation of the clog is made by means of a 3D printed tube reducer. The inner diameter of the tube goes from 2.5 mm to 1 mm in one single step.

When ultrasounds are applied, the effectiveness of removing and preventing clogs was qualitatively observed.

3.3 Homogenization of dispersed systems

The objective of this experiment is to increase the homogeneity of dispersed systems.

The sample for the dispersed system was pineapple juice. When ultrasounds are applied, a slight reduction of the juice pulp was observed.

More experiments are needed in order to prove the actual reduction of the juice dispersion.

3.4 Viscous systems

The objective of this experiment is to reduce the viscosity of the sample, in order to make it easier to transport. This is the case of sauces, for example. The sample in this case was mayonnaise.

When ultrasound is applied, a clear reduction in viscosity (slight liquefaction) was observed.

Another objective of this experiment is to test whether the device is capable of generating stable emulsions. This has not been made yet in the laboratory.

More quantitative, replicable and representative experiments are needed in order to properly test the proposed ultrasonic flux reactor in an industry context.

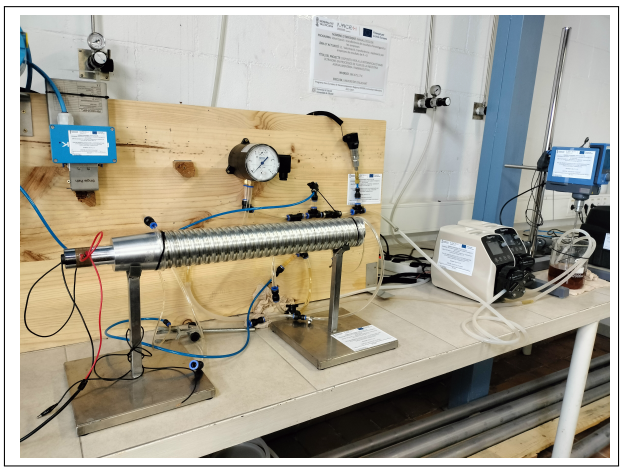

Figure 11. Experimental setup.

4. CONCLUSION

The application of ultrasonic reactors in the agri-food and pharmaceutical industries is explored, highlighting their advantages in enhancing reaction efficiency, preventing clogging, and improving product quality. The study presents the design and testing of a novel ultrasonic reactor, featuring a solid cylindrical sonotrode with helical slit for optimized energy transmission. The potential of the reactor has been experimentally suggested in terms of foam reduction, unclogging capacity, and liquefaction of sauces, although there are limitations in dispersion improvements. The results suggest that ultrasound-assisted reactors could be a valuable tool for industrial processes, offering potential scalable and effective solutions for continuous flow applications.

PRELIMINARY STUDY ON THEORETICAL CORRECTIONS TO THE EQUATION OF STATE IN SINGLE-BUBBLE SONOLUMINESCENCE AND EXTENSION OF THE MINIMUM RADIUS STAGE

Raúl Fernández-Clement[1*] **Pedro Poveda-Martínez**[2] **Roberto Gómez**[1]

[1] Department of Physical Chemistry, University of Alicante, Spain
[2] Department of Physics, Systems Engineering and Signal Theory, University of Alicante, Spain

ABSTRACT

Single bubble sonoluminescence (SBSL) involves the emission of very short flashes of light by bubbles subjected to a periodic ultrasonic acoustic field in a liquid medium, which slowly expand and rapidly contract, emitting light at the minimum radius stage. Several theories have been proposed to model the behavior and thermodynamic conditions inside the bubble, and most of them treat the gas inside as an ideal gas. Nonetheless, the experimental results obtained to date show conditions that deviate from the range of applicability of the ideal gas equation. This paper proposes a first approach to the study of the SBSL phenomenon through the application of an equation of state corresponding to real gases, and even to plasmas, in order to obtain theoretical corrections to the dynamics and thermodynamic conditions (mainly pressure and temperature) inside the bubble. In addition, the possibility of prolonging the minimum radius stage of the bubble by modifying the applied acoustic field will be analyzed, in order to examine whether the thermodynamic conditions inside the bubble vary or not in this case, and whether these conditions are stable in time.

1. INTRODUCTION

Single bubble sonoluminescence (SBSL) refers to the phenomenon in which a gas bubble, when exposed to a periodic ultrasonic acoustic field within a liquid, emits brief but intense flashes of light. This occurs as the bubble undergoes a process of gradual expansion followed by rapid contraction, with the emission of light occurring precisely at the point of minimum bubble radius [1]. The role of the acoustic field is paramount, as the rapid oscillations induced by the ultrasonic waves are critical in driving the bubble dynamics that lead to the high-energy light emission observed during the bubble's collapse. Understanding the acoustics involved is essential, as the precise control of the ultrasonic field influences both the intensity and the characteristics of the emitted sonoluminescent light.

The equation of state (EOS) also plays a crucial role in understanding the extreme conditions reached inside a collapsing bubble in SBSL. During the collapse, the gas within the bubble is subject to rapid compression, leading to extreme temperatures and pressures characteristic of the warm dense matter (WDM) regime. Accurately modeling these conditions is essential for predicting key parameters such as density, temperature, and the subsequent light emission [2].

Different EOS models have been proposed to describe the thermodynamic behavior of the gas inside the bubble. Early approaches relied on the ideal gas law [3], but as experimental and numerical studies revealed significant deviations from ideal behavior [4], more sophisticated models, such as that based on the van der Waals equation [5] and high-complexity real gas models [6], have been introduced. These models incorporate non-ideal gas effects,

phase transitions, and even plasma formation [7] at the final stage of collapse.

The theoretical sensitivity of SBSL light emission to the choice of EOS suggests that sonoluminescence could serve as a unique experimental platform for testing and refining EOS models relevant to WDM physics [2].

On the other hand, the applied acoustic field can be modified in such a way that there is a point in space where a very high pressure is reached. In this context, if the bubble is located in that point, its behavior is different from that of normal SBSL. The bubble collapse is prolonged in time and it loses its stability.

The first section will be dedicated to the corrections to the equation of state for the gas in a sonoluminescing bubble. The main objective of this part is to perform a review of the current models which aim to apply realistic EOS in SBSL.

The second section will treat the conditions and numerical results for the prolongation of bubble collapse. The objective of this part is to find theoretical conditions for the bubble to keep collapsed more time.

2. EQUATION OF STATE FOR THE GAS IN THE BUBBLE

During the collapse, the gas inside the bubble in SBSL undergoes rapid compression, reaching temperatures and pressures characteristic of the warm dense matter (WDM) regime. The choice of EOS directly influences the predicted density, temperature, and light emission behavior, making it a key factor in SBSL modeling [2, 8].

First, it is necessary to define the theoretical model that will be used in order to describe the time evolution of the bubble radius. Rayleigh-Plesset model will be used, for which the time evolution of the bubble radius reads:

$$R\ddot{R} + \frac{3}{2}\dot{R}^2 = \frac{1}{\rho}\left(P - P_\infty - P(t)\right) \tag{1}$$

$$P = p_{\text{gas}} - 4\mu\frac{\dot{R}}{R} - 2\frac{S}{R} \tag{2}$$

where R is the bubble radius; ρ, the liquid density, p_{gas}, the pressure of gas inside the bubble (given by the chosen equation of state); P_∞, the ambient pressure of the liquid; $P(t) = P_A \sin(\omega t)$, the pressure due to the acoustic field of an angular frequency ω and amplitude P_A; μ, the liquid viscosity; S, the surface tension of the liquid; and the dot indicates time derivative. This is an approximation valid up to the order of $\dot{R}/c$ [9].

This section will review the different EOS used to model the gas inside the bubble in SBSL, including considerations of ideal gas behavior, non-ideal gas effects, and plasma formation, which is poorly studied.

2.1 Early Approaches: Ideal Gas Models

The simplest EOS used in SBSL studies is the ideal gas law, which assumes non-interacting particles [10]. It provides a useful first approximation, particularly in non-collapse conditions when the bubble follows an adiabatic process. The mean pressure of the gas is given by:

$$p = \frac{NkT}{V} = \frac{nRT}{V} \tag{3}$$

where N is the number of molecules; k, is the Boltzmann constant; T, the mean temperature of the gas; and V, the total volume occupied by the gas. For the second equation, n is the number of moles of the substance and R is the ideal gas constant.

The collapse of the bubble is very short-lived (thus, the collapse is considered to be adiabatic). Therefore, the bubble is most of the time (almost the whole cycle) outside the collapse range [11]. Thus, in non-collapse conditions, it can be assumed that the gas inside the bubble obeys the ideal gas law, for simplicity and because through this approach it is possible to extract a lot of information, making it a good first approximation for the study of this phenomenon.

The adiabatic equation applied to SBSL in this case reads [12]:

$$P = P_0\left(\frac{R_0}{R}\right)^{3\gamma} \tag{4}$$

where γ is the adiabatic index.

However, as the bubble collapses, pressure and temperature increase significantly [13], leading to ionization and strong deviations from ideal gas behavior [14].

2.2 Moderate Complexity Models: Van der Waals Equation

Real gases deviate from ideal behavior due to intermolecular interactions [15]. The van der Waals equation introduces correction terms:

$$p + \frac{a}{v^2} = \frac{RT}{v - b} \tag{5}$$

where $v = V/n$ is the molar volume of the gas (n is the number of moles of the substance). In this equation,

a and b are two constants, which are characteristic of the particular type of molecules that it describes [5].

This model predicts higher temperatures and pressures than the ideal gas law and provides a better approximation for SBSL conditions [16]. The adiabatic equation for this case is as follows [17]:

$$p = \left(P_0 + \frac{2S}{R_0}\right)\left(\frac{R_0^3 - h^3}{R^3 - h^3}\right)^{\gamma} \tag{6}$$

Where h is the characteristic van der Waals hard-core radius of the gas inside the bubble.

Despite its improvements, this model still falls short under extreme SBSL conditions.

2.3 Higher complexity models for real gases

Despite improving the ideal gas model, the Van der Waals model is also unsuccessful because of the extreme conditions reached in the collapse. Thus, more advanced EOS models, such as the Peng–Robinson equation, have been developed to improve accuracy under high pressures and temperatures [6]. These models refine SBSL predictions but do not fully account for plasma formation.

2.4 Warm Dense Matter regime

Warm dense matter (WDM) is a branch of plasma physics. Its importance lies in its influence in the structure and formation of giant planets and other astrophysical objects, such as brown dwarfs, as well as in the implosion trajectories of proposed laser fusion capsules [18, 19]. It is characterized by pressures of above a million atmospheres (100 GPa), and with temperatures between 1 and 100 eV (where 1 eV = 11600 K) [20], and its density is sufficiently high to render the ions strongly coupled [21].

In the laboratory, WDM can be created through lasers [22, 23], using a magnetic anvil cell [24], employing extreme ultraviolet radiation [25], or even utilizing a pulsed-power driver [26]. It is hard to obtain, so it is difficult to obtain a theoretical model to describe it [27–29]. Many attempts have been done to obtain an equation of state (EOS) for WDM [30–33].

In this context, SBSL is presented as a phenomenon in which it could be possible to generate WDM in a relatively simple way, given the extreme conditions of pressure, density and temperature inside the bubble in the collapse. Therefore, SBSL can be used to test EOS in WDM regime [2].

2.5 Plasma Formation and Ionization: The Role of Plasma in the Collapse

At extreme temperatures, the gas transitions into plasma, requiring a plasma-specific EOS. While early models relied on the Saha equation, experimental data suggest much higher opacity, pointing to strong Coulomb interactions [34]. Some models incorporate magnetohydrodynamic effects to explain plasma behavior during collapse [35].

Despite significant advances, a universally accurate EOS for all SBSL stages remains elusive, highlighting the need for hybrid approaches that combine different models.

3. COLLAPSE PROLONGATION IN SBSL

In SBSL, the final stage of the collapse (the time the bubble remains contracted at its minimum radius) lasts picoseconds [36], as the pulse width of the emitted light. In this context, some questions may arise: is the emitted light directly related to the minimum radius stage? Can the bubble stay contracted for longer? In that case, would the light pulse widths be longer? Would the light emitted have different characteristics?

In this section, the prolongation of the time the bubble remains collapsed will be numerically studied. In order to achieve that, modifications in the applied acoustic field will be analyzed. Specifically, the application of two excitation sources will be numerically studied.

The numerical model is as follows. A parallelepiped container full of water will be considered, with dimensions a = 10 cm, b = 20 cm and c = 30 cm (referring to the x, y and z coordinates respectively). The two sound sources are located on the same face of the container (one centered and one eccentric source) radiating at 25 kHz in phase, as can be seen in Fig. 1 . This simulation has been performed with ANSYS software. The sound pressure level inside the container can be seen in Fig. 2, where the point of maximum pressure is indicated in red, and the point of minimum pressure is indicated in blue.

In this context, a numerical study will be performed to analyze what is the time evolution of the bubble radius, as well as of the pressure and temperature inside the bubble if it is located at the point of maximum pressure level. The numerical model will consist of solving the Raylegih-Plesset equation using Python. In order to achieve that, a change of variable

$$u = \dot{R} \tag{7}$$

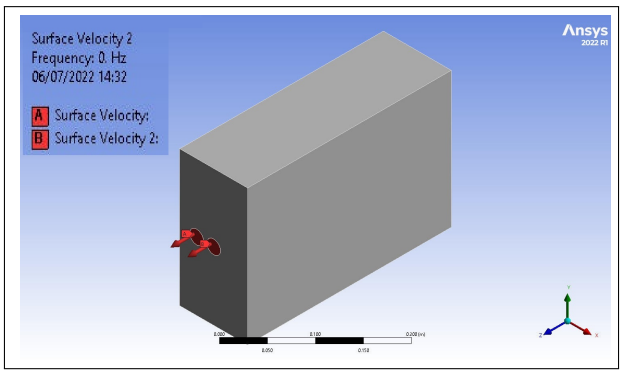

Figure 1. Problem statement of a parallelepiped with two excitation sources.

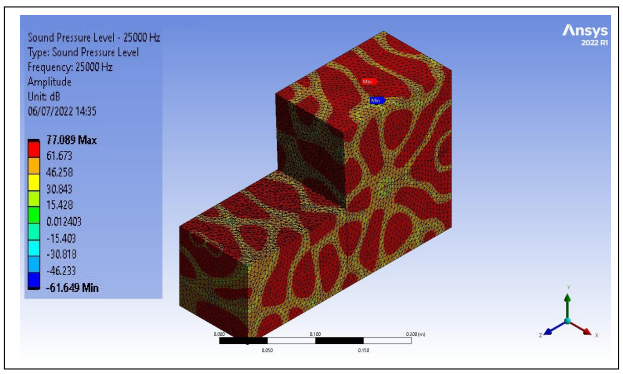

Figure 2. Sound pressure level in a parallelepiped with two excitation sources.

will be used. In this way, it is possible to obtain the following system of equations for the bubble:

$$\left.\begin{aligned} u &= \dot{R} \\ \dot{u} = \tfrac{1}{R\rho}\Big[\Big(P_0 + \tfrac{2\sigma}{R_0} - P_v\Big)\big(\tfrac{R_0}{R}\big)^{3\gamma}\big(1 - \tfrac{3\gamma u}{c}\big) - \\ -\tfrac{2\sigma}{R} - \tfrac{4\mu u}{R} - P_A\sin(\omega t) + \\ +P_v - P_0 - \tfrac{2\sigma}{R_0}\Big] - \tfrac{3u^2}{2R} \end{aligned}\right\} \tag{8}$$

where P_v is the vapor pressure; and σ, the surface (interfacial) tension of water. The pressure and temperature will be modeled as:

$$P(t) = \left(P_0 + \frac{2\sigma}{R_0} - P_v\right)\left(\frac{R_0}{R}\right)^{3\gamma} \tag{9}$$

$$T(t) = T_0\left(\frac{R_0}{R}\right)^{3(\gamma-1)} \tag{10}$$

Numerical results using Python suggest that the radius increases to a disproportionate and meaningless value, as shown in Fig. 3. This means that the movement of the bubble is not stable, i.e. the bubble disappears (explodes). This can also be deduced from the pressure and temperature graphs (Fig. 4), in which their value cancels out after a certain instant. These plots allow us to know the moment when the bubble explodes (from the moment when its value is zero), which is at approximately 20 microseconds. In addition, it should be noted that the pressure and temperature peaks are smoother (the changes are more progressive) than in the case of SBSL, where they are more similar to a Dirac delta, as shown in Figure 5a of [37]. This could mean that, due to the high pressure that the bubble undergoes, it stays longer in the minimum radius stage during the first 20 microseconds.

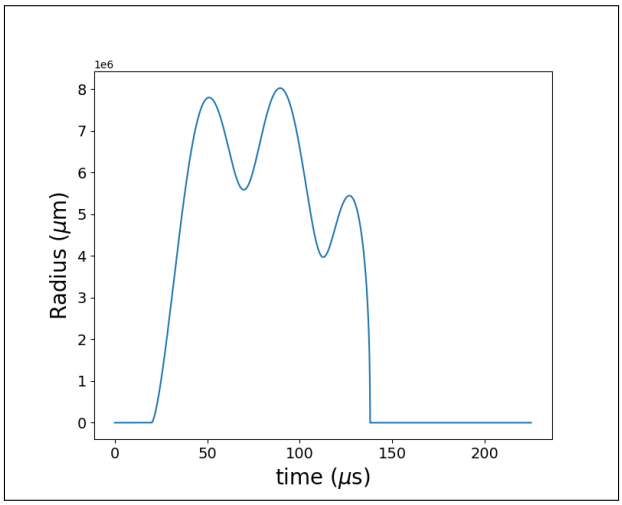

Figure 3. Time evolution of the bubble radius with two excitation sources.

If Fig. 3 is enlarged to see the initial instants, Fig. 5 is obtained, where it can be seen that the bubble remains collapsed almost 20 microseconds. Normal conditions in SBSL experiments show that the bubble collapse lasts a few picoseconds. That means a prolongation of six orders of magnitude for the time in which the bubble remains collapsed.

4. CONCLUSION

Numerical simulations suggest that modifying the acoustic field can prolong the collapse stage six orders of magnitude in time, though this may lead to instability. Addi-

tionally, none of the current theoretical models can explain exactly the experimental observations of SBSL, and one of the properties to be corrected is the considered EOS. The application of an EOS for real gases could more accurately model the thermodynamic properties inside a sonoluminescing bubble. This would lead to improved accuracy in fitting theoretical simulations with experimental data, as well as to a more complete explanation of the phenomenon. Although ideal gas models provide a useful starting point, deviations at high pressures and temperatures necessitate more complex approaches, including van der Waals corrections and plasma-based models. The application of these models, or even a combination of them, should give more accurate results that better fit the experimental data. Thus, the need for hybrid EOS models tailored to different SBSL phases is suggested, and also the possibility of collapse prolongation. The use of an appropriate EOS in SBSL, as well as finding conditions for stable prolongation of bubble collapse, is left for future research.

5. ACKNOWLEDGMENTS

The part of this article dedicated to the time prolongation of bubble collapse was first studied by the author in his Master's Thesis with the help of professors Jaime Ramis Soriano (University of Alicante) and Alessandro Fabbri (University of Valencia). The author thanks them for their help and enlightening comments and explanations. Professors Enrique Segovia and Jaime Ramis are also acknowledged by their work on the definition of the numerical model for the container.

ABSTRACT*

Acoustic Emission (AE) testing is a non-destructive evaluation technique widely used in numerous fields providing ongoing monitoring to detect and track early signs of damage within structures. To ensure an effective interpretation of AE signatures in relation to damage mechanisms, a combination of numerical and experimental approaches is crucial for a comprehensive study of the measurement chain, including excitation sources, propagation mediums, sensors, acquisition systems and signal processing. This study aims to model the AE measurement chain using highly reproducible and reliably characterized emission waves from a piezoelectric sensor. To achieve this, the first step was to calibrate the source using a laser vibrometer. The aperture effect and several parameters of the sensor responses were investigated. Then, 3D models incorporating these source mechanisms within a metallic material were developed simultaneously by experiment and simulation to analyze AE wave propagation and measurement chain effects. Validated results in time and frequency domains showed good agreement, demonstrating the accuracy of the numerical approaches. These findings are crucial for gaining a significant understanding of AE sensors, contributing to sensor calibration processes, modelling of the entire measurement chain to enhance the interpretation of damage mechanisms.

1. INTRODUCTION

Non-Destructive Evaluation (NDE) techniques are widely used in numerous industrial fields to assess structural health and detect early damage without causing permanent harm of components and structures. These techniques provide inspections that are both safe and reliable, while remaining cost-effective and able to be conducted without interrupting ongoing operations. Acoustic Emission (AE) method is one of the most frequently employed NDE methods to detect and track early signs of damage in mechanically loaded structures and components. In such cases, the AE waves are generated by the sudden releasing of energy under the form of elastic waves and propagating in all directions within the material. The source of AE events may come from natural phenomena (earthquakes, rock bursts) [1], deformation

processes [2], crack propagation [3], damage mechanisms in composite structure [4], etc. These AE waves are usually captured by sensors which convert the mechanical disturbance on the contact surface into a voltage-time waveform signal, providing information about the location and characteristics of AE events. The detection process of AE signals is described by the measurement chain illustrated in Figure 1. According to this, an AE signal in time domain S(t) is obtained by the convolution (⊗) of the characteristics of all elements in the measurement chain, from excitation source F(t), propagation medium G(t), coupling conditions C(t) and sensor transfer function H(t), and acquisition system A(t) as Eqn. (1):

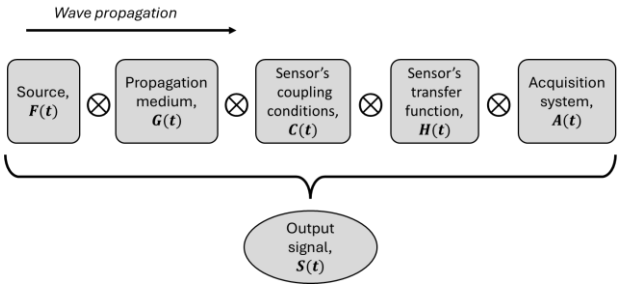

Figure 1. Measurement chain used for detection of AE waves.

$$S(t) = F(t) \otimes G(t) \otimes C(t) \otimes H(t) \otimes A(t) \quad (1)$$

The main scientific obstacles in enhancing our understanding of AE results lies in comprehending how the signal evolves from the excitation source to the obtained signal that highly dependent on the measurement chain configurations, such as excitation source mechanisms [5-6], structure and material properties, observation distance and direction [12-14], and sensors characteristics and its coupling conditions [15]. Piezoelectric sensors are widely used in AE testing due to their high sensitivity and affordability; however, their transfer function varies significantly based on sensor type, structure, and operating frequency [16-17]. These significant influences of the measurement chain configuration lead greater challenges when determining a robust correlation between AE signal characteristics and their respective actual excitation mechanisms. Addressing these challenges requires a well-defined characterization of each element in the measurement chain, which can be achieved through an effective combination of numerical and experimental approaches. For this purpose, studies should be carried out with configurations that include well-defined source mechanisms and propagation medium properties, facilitating a more straightforward analysis of the other elements in the measurement chain. With the rapid advancements in science and technology, numerical simulation tools have become essential and widely used by researchers to analyze the complex interactions and propagation of AE waves. Several mechanisms, simplified from AE events, have been used in simulations involving changes in applied force, displacement, or released energy over a very short excitation time. For instance, pencil-lead breaks sources are used to validate numerical results against experimental data, supporting the modeling of conical sensors, and considering the influence of geometrical specimen on AE signal characteristics [8, 18]. Moreover, glass tube fracture sources have been modeled and applied in research calibration processes for AE sensors [10, 16]. The mechanical impact sources are used to investigate the boundary reflection conditions and sensor characteristics in detecting AE wave propagation [19]. Another AE source mechanism consists of using a laser to generate an ultrasonic excitation that was used to obtain the calibration curve of piezoelectric sensors [20]. Furthermore, an artificial source generated by an AE sensor directly excited by an electrical pulse is also used in numerical research to study the complex behavior of piezoelectric conversion in AE sensors, as well as the influence of factors related to the propagation mediums of AE waves [14, 21]. Compared to other sources, the one generated by transmitting sensors offers higher reproducibility through control of the electrical pulse configuration, while also facilitating a better understanding of the electrical-mechanical conversion process, known as the sensor's response, thus contributing to successful sensor modeling in numerical approaches. The sensor's response is influenced not only by the sensor's geometry and the spatial variations across the sensor surface but also on the operating frequency, known as aperture effect [7, 21-22]. To the best of our knowledge, there has been limited exploration in literature regarding the precise determination of the response of transmitting sensors and its application in numerical studies to examine the influence of the AE measurement chain.

In this study, the source mechanism from AE sensors in terms of the normal velocity response was first characterized by using a laser vibrometer. Two types of sensors were used, including a resonant sensor, R15α, and a wideband sensor, F15α (from Physical Acoustics, USA). The influences of aperture effect on the response

of each sensor were investigated. Next, 3D models incorporating these mechanisms were developed to study the wave propagation and the influence of the measurement chain. The simulation results were validated with experiments to verify the accuracy of the modelling parameters and setup. Finally, the impact of contact surface conditions on the amplitude of the sensor response was taken into account to enhance the accuracy of the simulation results.

2. MEASUREMENT OF THE SENSOR'S RESPONSE

The vibration velocity responses across the active surface of sensors are non-uniform due to the aperture effect. To demonstrate this, a simplified model of the velocity response assumes that the variation across different positions on the sensor surface can be represented by the maximal velocity response usually measured at the center region of the surface, $v_{center}(t)$, multiplied by a k parameter as shown in Eqn. (2) [7].

$$v(t) = \frac{1}{S}\iint_S k(r).v_{center}(t)\,dS \quad (2)$$

Where S denotes the contact surface area of sensor, $k(r)$ is called the aperture effect function of the sensor and is a real number ranging from 0 to 1. This parameter represents the sensitivity of the normal vibration velocity at a position located at radius r, relative to its value at the center region of the sensor surface. In this study, two types of AE sensors were utilized: the narrowband resonance sensor, type R15α, with an operating frequency range from 50 kHz to 400 kHz, and the wideband flat frequency sensor, type F15α, with an operating frequency range from 100 kHz to 450 kHz.

Figure 2 shows the setup of the testing for measuring AE sensor response in terms of normal vibration velocity on its active surface. The acquisition includes an OFV-505 sensor head connected to an OFV-5000 vibrometer controller which was set with a VD-09 decoder board, and bandpass filter from 100 Hz to 1 MHz adapted to AE wave characteristics [1]. Ultrasonic excitation was obtained using a UTC110 system (MISTRAS, France), controlled through the EuroScan V software. AE sensors were fixed on a displacement system by plastic clamping units. The measurements on the active surface of the sensors were conducted along the centerline with a spacing of 200 µm between each point. The experimental data from the tests were processed using MATLAB® with a 4th-order Butterworth low-pass filter as in [18], with a cutoff frequency of 500 kHz adapted to operating frequency ranges of used sensors.

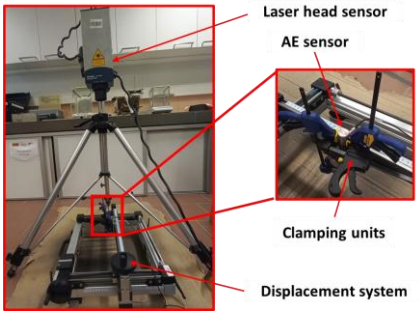

Figure 2. Test layout for measuring sensor's response in term of normal vibration velocity.

3. 3D MODELS OF WAVE PROPAGATION

3D models incorporating source mechanisms generated by transmitting sensors' response were established simultaneously by experiment and simulation as shown in Figure 3 a, and b, respectively. In the case of experiment, the same acquisition system as previous measurements were used to capture normal velocity of AE waves within an aluminum plate of dimensions 500 mm x 500 mm x 2mm. The AE sensor was mounted on the specimen surface by a thin layer of silicon glue. After several tests to determine the optimal excitation parameters, an excitation pulse with 100 volts and a rise time of 700 ns was applied to the AE sensor. The signals were obtained at two positions located at 30 mm and 90 mm as distances from sensors. A finite element approach was conducted by using the software COMSOL Multiphysics® through module "Solid Mechanics (Elastic waves)". The setup includes a 3D aluminum plate dimensioning 250 x 300 x 2 mm with its properties referred to [8]. The low-reflection conditions were applied to minimize the effects of reflected waves adapted to free conditions of wave propagation in larger geometry as experimental condition. The source from transmitting sensors were set on its contact surface using velocity response according to Eqn. (2) based on experimental results. Several tests were performed to determine the convergence of mesh element size and critical timestep. Based on these findings, the element size of 1 mm, corresponding timestep of 0.15 µs were chosen, offering a good compromise with computational time. On the other hand, a linear combination of mass and stiffness matrices were applied considering the attenuation of wave amplitude during propagating. Here, α and β are the mass

and stiffness proportionality coefficients, as known as Rayleigh damping coefficients. Both AE sensors used with operating frequency range less than 500 kHz, so the impact of β (mostly in high frequency) is neglected. Only α is applied (in low frequency), set to 30000, adapting with a damping factor of 0.002 at maximum frequency of 1 MHz based on experimental results.

4. RESULTS AND DISCUSSION

4.1 Sensor surface velocity response and aperture effects

4.1.1 Sensor velocity response of sensors

The results in the response of two sensors at the surface center in terms of normal vibration velocity are illustrated in Figure 4. The normal velocity response varies significantly depending on the sensor type, affecting both waveform and its amplitude. The R15α resonant sensor shows higher sensitivity in peak velocity compared to the F15α wideband sensor, measuring 4.5 mm/s and 3.4 mm/s, respectively. Due to the inherent characteristics of resonant sensors, the R15α can maintain oscillations with minimal excitation energy, resulting in extended signal retention and higher amplitude responses compared to the F15α sensor.

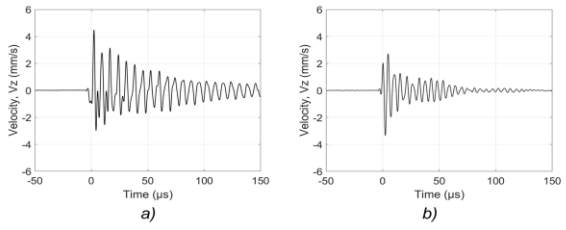

Figure 4. The velocity response measured at the center of surface for R15α (a) and F15α (b) sensors.

4.1.2 Peak velocity response across entire sensor surface

Figure 5 shows the results of peak velocity response across full measured diameter on active surface of both sensors. The standard deviation of peak velocity across 32 consecutive measurements remained below 0.1 mm/s (less than 3% of the max values) in most cases, demonstrating high reliability of tests. It can observe that the obtained peak velocity tends to exhibit symmetry along the centerline of the sensor's active surface. The results indicate that the peak velocity response varies with position on the sensor's contact surface, with higher values at the central region and decreasing towards the edges, depending on the sensor type. This is consistent with previous tests conducted on the μ80 sensor [22]. These findings highlight the influence of the aperture effect on the response of the AE sensors.

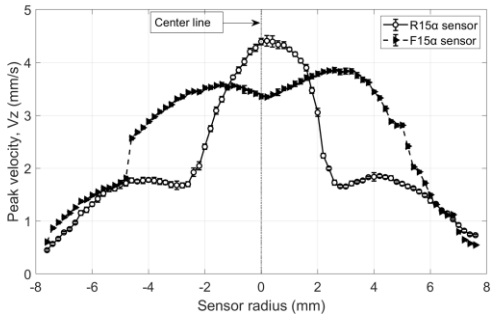

Figure 5. Peak normal velocity of the sensor response measured by laser vibrometer.

4.1.3 Aperture effect function of sensors

The *k(r)* factor, representing the influence of the aperture effect (Eqn. (2)), is illustrated in Figure 6. The analysis focuses on half of the sensor surface, taking into account its symmetrical response along the centerline. Here, the *k(r)* values were determined by normalizing the peak velocity at a given position *r* with respect to the maximum peak velocity response measured at the central region, followed by smoothing using a Savitzky-Golay filter [23]. For the R15α sensor, the highest *k(r)* value was found at the center, gradually decreasing toward edges of the sensor. Conversely, the F15α sensor exhibited a more uniform distribution, with *k(r)* values ranging between 0.93 and 1 over a central region extending up to 4 mm. These findings indicate that the peak amplitude variation across the sensor surface does not follow a simple uniform decay, as previously

assumed [7], but rather depends on both sensor characteristics and radial position *r*. The observed variations can be attributed to the aperture effect, which influences the sensor's transmitting transfer function, with dependencies on spatial positioning and operating frequency [7, 21-22]. This study enhances the understanding of how AE sensors convert electrical excitation into mechanical vibrations, providing valuable insights into source identification using transmitting sensors, contributing directly to accurate numerical sensor modeling, and the characterization of AE sensor transfer functions.

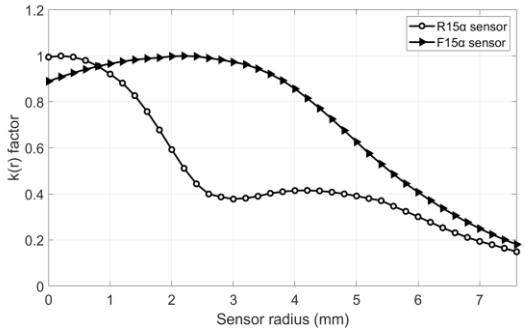

Figure 6. The values of *k(r)* as aperture effect function for both sensors.

4.2 AE wave propagation modelling

4.2.1 Excitation source mechanisms caused by AE sensors

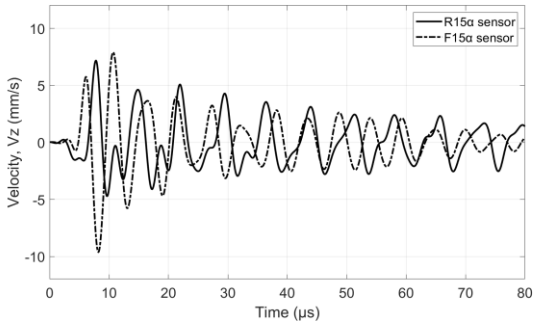

Figure 7. Source mechanisms generated by AE sensor response applying to numerical models.

The excitation source mechanisms generated by the transmitting sensor response for the R15α and F15α sensors are illustrated in Figure 7. These results were calculated using Eqn. (2), considering the sensor response at the center of the surface and its aperture function, which were applied for simulation.

4.2.2 Comparison of experimental and numerical results in both time and frequency domains

To match the configuration of the laser vibrometer in the testing setup, a 4th-order Butterworth bandpass filter (100 Hz – 1 MHz) was applied to the numerical results. Validation was performed by comparing the simulated and experimental normal velocity waveforms in the time domain and their corresponding FFTs, as shown in Figures 8 and 9, respectively, at observation points 30 mm and 90 mm away. Overall, the results show strong agreement across both domains. In order to quantify this agreement, the Pearson's correlation coefficient [24-25] was calculated for the full signal duration, a 30 μs window from the onset (limited between two vertical dash line), and the FFT results, summarized in Table 1. It is noted that a maximum correlation coefficient of 1 indicates a perfect positive correlation, -1 represents a perfect negative correlation, and 0 indicates no correlation. In all cases, the correlation coefficient ranged from 0.61 to 0.8 for the full signal, from 0.56 to 0.78 for the 30 μs window, and remained around 0.85 for the FFT results. These values align well with previous studies on AE wave modeling from pencil-lead breaks [9, 43]. A slight discrepancy in peak velocity was observed for the F15α sensor, with a difference of 1.3 mm/s at 30 mm and 0.3 mm/s at 90 mm, while for R15α sensor it is negligible. In the frequency domain, the R15α sensor results closely matched in both peak frequency and magnitude, while the F15α sensor showed a deviation of approximately 35 kHz and 10 dB, respectively. These differences might be caused by variations in sensor contact conditions during measurements and validation, as previously discussed in [21] and further discussions in the final section. A strong agreement between the experimental and simulation results validated the accuracy of the proposed numerical model, the calibrated excitation source mechanism from the transmitting sensors' responses and its aperture effect, and its application to AE wave propagation.

Table 1. Summary of the correlation coefficients of validated results.

Sensors	R15α		F15α	
Positions	30 mm	90 mm	30 mm	90 mm
Full duration	0.61	0.8	0.63	0.62
Within 30 μs	0.56	0.78	0.73	0.72
FFT	0.86	0.86	0.85	0.84

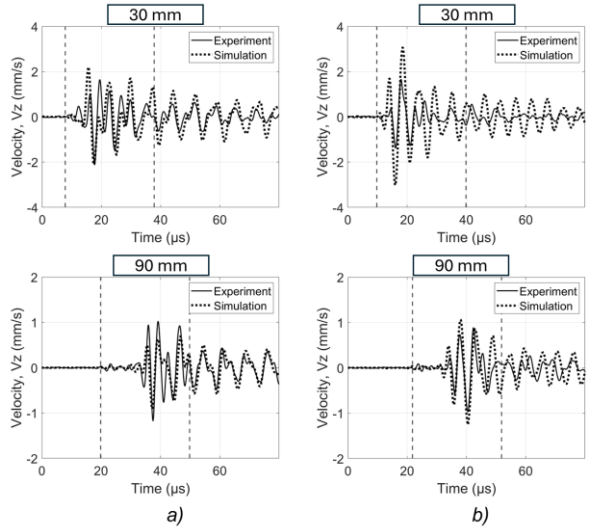

Figure 8. Validated results for the normal velocity of AE wave propagation generated by the response of R15α (a) and F15α (b) sensors.

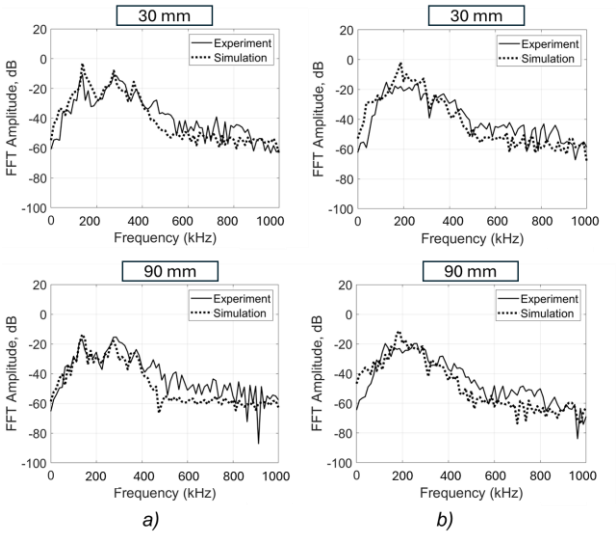

Figure 9. Validated results for FFT transformation of the AE wave propagation generated by response of R15α (a) and F15α (b) sensors. For vertical axis, 0 dB is referenced at 1 V/(mm/s).

4.2.3 . Consideration of the influence of sensor contact conditions

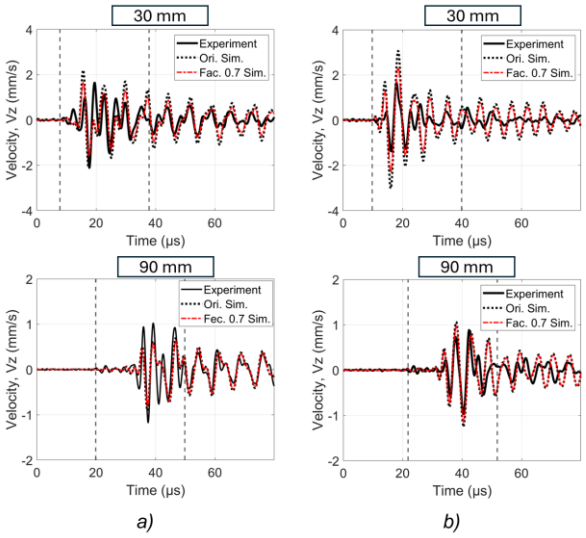

Figure 10. Validated results of normal velocity signals, accounting for the influence of the loss factor due to different sensor surface contact conditions, for R15α (a) and F15α (b) sensors.

As mentioned previously, differences in sensor's contact conditions may explain the slightly higher peak velocity and FFT magnitude observed in the simulation compared to the experiment in the near field. In sensor response measurements, the transmitting sensor's active surface was in free contact with air, whereas in the validation tests, it was in loaded contact with the specimen surface through a thin layer of silicon glue. In free contact conditions, the large impedance mismatch between the sensor and air could lead to increased oscillation energy at the surface, potentially enhancing resonance effects. In contrast, under loaded contact conditions, the smaller impedance mismatch, along with the applied pressure and coupling, resulted in smoother vibrations with lower amplitudes [21]. To account for the reduction in sensor response amplitude due to contact condition changes, a constant correction factor was introduced to improve simulation accuracy. Numerical simulations were conducted to evaluate the impact of different amplitude loss factors on the velocity response of transmitting sensors. The findings indicate that applying a loss factor of 0.7 improves agreement between simulated and experimental results. The damping coefficient α was recalculated and set to 12000 corresponding to the incorporating losing factor and its impact on the excitation

source's maximum amplitude. The final normal velocity signals are presented in Figure 10, comparing the original simulation (black dotted line), the simulation with a 0.7 loss factor (red line), and the experimental results (solid black line). Applying the loss factor improved the alignment between simulation and experiment, with a maximum error below 0.5 mm/s for the F15α sensor, while maintaining similar accuracy for the R15α sensor.

5. CONCLUSION

In this study, the normal velocity response on the active surface of two types of piezoelectric AE sensors was analyzed: the R15α, a narrowband resonant sensor, and the F15α, a wideband sensor with a flat frequency response. Additionally, 3D models were developed to simulate AE wave propagation generated by the response of transmitting sensors within an aluminum plate. To begin with, the results indicated that the normal velocity response is not uniform across the sensor surface and decreases toward the edges of the surface. Resonant sensors exhibited higher energy, with maximum sensitivity concentrated in a small central region of the surface, whereas wideband sensors showed lower energy but distributed peak sensitivity over a broader area. The study further examined *k(r)* as a function of the aperture effect, emphasizing the effects of sensor geometry, spatial variations, and operating frequency in shaping the peak normal velocity response. These findings provide valuable insights into AE sensor behavior, enabling improved sensor modeling in numerical methods without requiring detailed physical geometry. On the other hand, a very good agreement was observed between simulation and experimental results in both time and frequency domains, validating the accuracy of the numerical approach. To address variations in sensor response amplitude due to different coupling conditions, a loss factor was introduced, refining the simulation accuracy by accounting for changes from free contact (air) to loaded contact (specimen surface). These results contribute to a more comprehensive understanding of signal transformation from the source mechanism through wave propagation to the acquisition system, supporting the development of an improved AE measurement framework.

ABSTRACT

Plane Wave Imaging (PWI) with ultrasonic arrays, initially developed for fast medical imaging, is nowadays being applied in Ultrasonic Testing (UT) for Non-Destructive Testing (NDT). In NDT, the Total Focusing Method (TFM) is regarded as the gold standard for image quality. However, TFM requires multiple transmission events (one for each array element), which can be slow for applications demanding very fast image acquisition. Since PWI can generate images of comparable quality with fewer transmissions, it presents a promising solution for such high-speed applications. This study demonstrates how volumetric PWI can be achieved using matrix arrays for testing arbitrarily shaped components, where a coupling medium is required and ultrasound waves are refracted on the component surface. This introduces complexity in calculating the time delays required to generate a plane wave within the component, a process that is straightforward in a single propagation medium scenario. Additionally, since the computation of those delays requires knowledge of the surface shape, we also explore how plane waves can be utilized for fast estimation of the surface shape.

1. INTRODUCTION

Non-Destructive Testing (NDT) plays a crucial role in ensuring the safety and integrity of critical infrastructure. In recent years, Plane Wave Imaging (PWI) has emerged as a promising technique for ultrasonic testing, offering significant advantages over traditional methods in terms of speed and image quality. Originally developed for medical imaging applications [1], PWI has found increasing relevance in industrial NDT scenarios, where rapid inspection and high-resolution imaging are fundamental [2].

In the field of NDT, the Total Focusing Method (TFM) has long been considered the gold standard for image quality [3]. However, TFM's requirement for multiple transmission events—one for each array element—can be a limiting factor in applications that demand very fast image acquisition. This limitation becomes significant when image reconstruction is performed by software and RF signals must be transferred to a computer, creating a bottleneck. Plane Wave Imaging (PWI) addresses this issue by reducing the amount of data that needs to be transferred and processed, generating images of comparable quality to TFM.

The application of PWI in industrial settings, particularly for testing components with complex geometries, presents unique challenges. Unlike medical applications where ultrasound typically propagates through a single medium, industrial NDT often involves coupling media and refraction at component surfaces. This introduces complexity in calculating the time delays required to generate a plane wave within the inspected component, a process that is relatively straightforward in single-medium

scenarios.

These challenges were addressed for the case of linear arrays and 2D imaging by various works [4–6]. In the context of railway inspection, Chang et al. [7] demonstrated a wavenumber-domain PWI technique capable of real-time dynamic imaging in vibrating environments, achieving frame rates of up to 83.3 fps. These developments highlight the potential of PWI to revolutionize NDT practices in the railway industry and beyond.

This study aims to further advance the application PWI using matrix arrays to perform 3D imaging of arbitrarily shaped components. We present a method for computing delay laws in 3D, which introduces additional challenges compared to the 2D case. Furthermore, we explore the use of plane waves for the rapid estimation of surface shape, a crucial step in accurately calculating time delays for wave generation within the component. The proposed methods are demonstrated through an example involving the testing of a cylindrical test piece using a 3 MHz 11x11 array.

2. METHODS

In this section we derive the emission focal laws to generate a three-dimensional plane wave across any given surface using a two-dimensional array. The approach begins by identifying a central ray originating from the array's center and refracting it in the desired plane wave direction, determined via Snell's law. For the remaining array elements, Fermat's principle is employed to compute rays that converge to a far-field focus positioned along the previously calculated central ray. A step-by-step derivation is provided below.

Figure 1 illustrates the geometry involved. A plane wave can be defined by a unit direction vector $\hat{k}$. For each array element E a ray must be found that refracts in the plane wave direction. To this end, the corresponding entry point G must be found (Figure 1.a). Snell's law states that the incident ray, the surface normal $\hat{n}$ at G, and the refracted ray are contained in a plane called the incidence plane. The directions of the incident and refracted rays are given by the unit vectors $\hat{v}_1$ and $\hat{v}_2$ respectively (Figure 1.b). According to Snell's law:

$$c_2 \sin(\theta_1) = c_1 \sin(\theta_2) \tag{1}$$

where θ_1 is the incidence angle, θ_2 the refraction angle, and c_1, c_2 the wave propagation velocities of the two media.

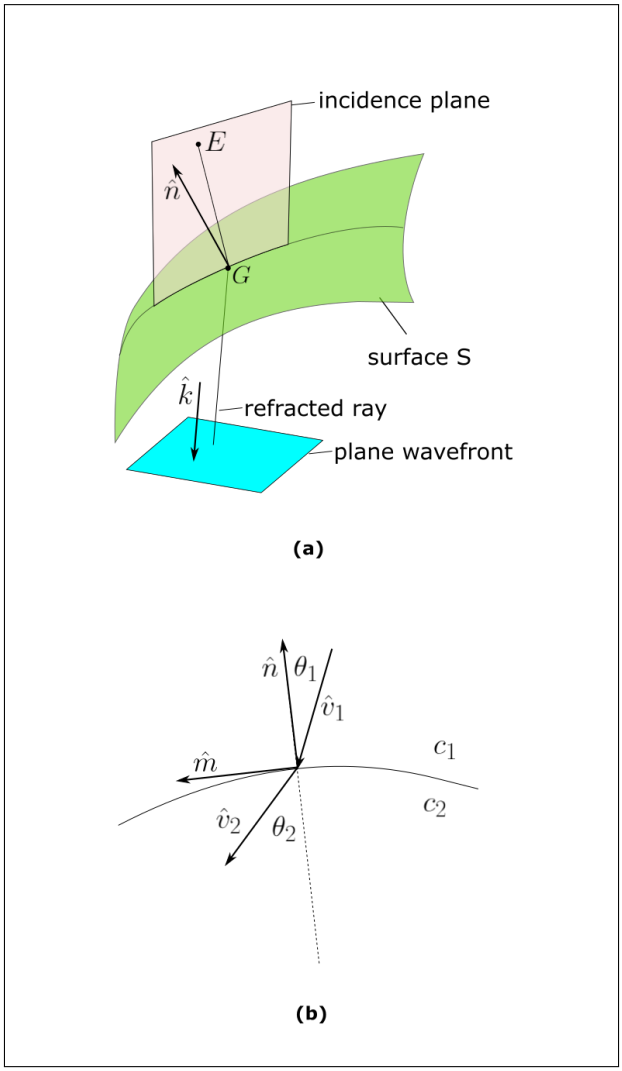

Figure 1. Geometry involved in the generation of a 3D plane wave through refraction. (a) Test piece surface, incidence plane and wavefront. (b) Vectors for Snell's law calculations

Given an element E and an entry point G, the incident unit vector is $\hat{v}_1 = \frac{\overline{EG}}{\|\overline{EG}\|}$. We need to compute $\hat{v}_2$ as a function of G, and solve the equation $\hat{v}_2 = \hat{k}$. From Figure 1.b we can see that:

$$\hat{v}_2 = \sin(\theta_2)\hat{m} - \cos(\theta_2)\hat{n} \tag{2}$$

where $\hat{m}$ is a tangent vector contained in the incidence

plane, which is given by:

$$\hat{m} = \hat{v_1} - \hat{v}_1 \cdot \hat{n} \tag{3}$$

The incidence angle cosine is given by the dot product:

$$\cos(\theta_1) = -\hat{v}_1 \cdot \hat{n} \tag{4}$$

Using equations (1) and (4) we get:

$$\sin(\theta_2) = \frac{c_2}{c_1}\sqrt{1 - (\hat{v}_1 \cdot \hat{n})^2} \tag{5}$$

Equations (2) and (5) along with the relation $\cos(\theta_2) = \sqrt{1 - \sin^2(\theta_2)}$ gives us $\hat{v}_2$ as a function of $\hat{v_1}$ and $\hat{n}$:

$$\hat{v}_2 = \frac{c_2}{c_1}\sqrt{1 - (\hat{v}_1 \cdot \hat{n})^2}\,(\hat{v_1} - \hat{v}_1 \cdot \hat{n}) - \sqrt{1 - \left(\frac{c_2}{c_1}\sqrt{1 - (\hat{v}_1 \cdot \hat{n})^2}\right)^2}\,\hat{n} \tag{6}$$

As was said before, to find the entry point coordinates (x, y, z) we should solve $\hat{v}_2 = \hat{k}$, which is a system of three non-linear equations. However, the z coordinate is a dependent variable. We suppose the surface is represented by a function $z = f(x, y)$. Additionally, vectors $\hat{v}_2$ and $\hat{k}$ have unit norm and thus one of its three coordinates is dependent on the other two. Therefore, we have a system of two equations with the two unknowns (x, y). Equation (6) does not show explicitly the dependence on (x, y). In order to make it explicit we should express the coordinates of $\hat{v_1}$ and $\hat{n}$ in terms of (x, y) as:

$$\hat{v}_1 = \frac{(x - E_x, y - E_y, f(x, y) - E_z)}{\sqrt{(x - E_x)^2 + (y - E_y)^2 + (f(x, y) - E_z)^2}} \tag{7}$$

$$\hat{n} = \frac{(-\frac{\partial f}{\partial x}, -\frac{\partial f}{\partial y}, 1)}{\sqrt{1 + \frac{\partial f}{\partial x}^2 + \frac{\partial f}{\partial y}^2}} \tag{8}$$

where (E_x, E_y, E_z) are the array element coordinates. Replacing (7) and (8) in (6) to solve $\hat{v}_2 = \hat{k}$ results in a complex and cumbersome system of equations with no analytical solution. As in the 2D case, numerical methods are needed to solve it. Newton-Raphson method might be used, but it required the calculation expression (6) partial derivatives which gives lengthy and impractical formulae. Thus, we implemented a brute force grid search approach, which is inefficient but easy to implement. We will call this method of computing the entry point Brute Force Snell (BFS). If it has to be applied to all the array elements, the overall computation time would be very high.

An alternative method for the computations of the entry points can be derived by following this idea: a plane wave emission is equivalent to an emission focused to a point in infinity. This is illustrated in Figure 2.a, where a bunch of rays from array elements is refracted and focused to a point F_{far} very distant to the array and surface. Figure 2.b shows the bunch of rays is close to a bunch of parallel rays. Rays from the array elements to F_{far} can be computed using Fermat's principle. But first we need to find the appropriate F_{far} for a given plane wave direction $\hat{k}$. As show in Figure 2.b, the far away focus must be located on the ray coming from the array center O_P, that is refracted at the point G_P. Thus $\overline{G_P F_{far}} = s\hat{k}$ with $s >> W$, where W is the aperture size ($s = 100 * W$ for example). Entry point G_P must be computed by Snell's law. In our case that was done using BFS, which is a slow algorithm but its only applied once per plane wave.

The emission time delay $\Delta t(E)$ for an array element E is finally computed as:

$$\Delta t(E) = t(E, F_{far}) - t(O_P, F_{far}) \tag{9}$$

where $t(E, A)$ is the TOF from E to a point A. With these delays a plane wave is created such that it goes through the array center at time $t = 0$. The TOF $t_{PW}(\hat{k}, \vec{r})$ of the plane wave to a point A is finally computed as:

$$t_{PW}(\hat{k}, A) = t_{far} + \frac{1}{c_2}\overline{F_{far}A} \cdot \hat{k} \tag{10}$$

$$t_{far} = t(O_P, F_{far}) \tag{11}$$

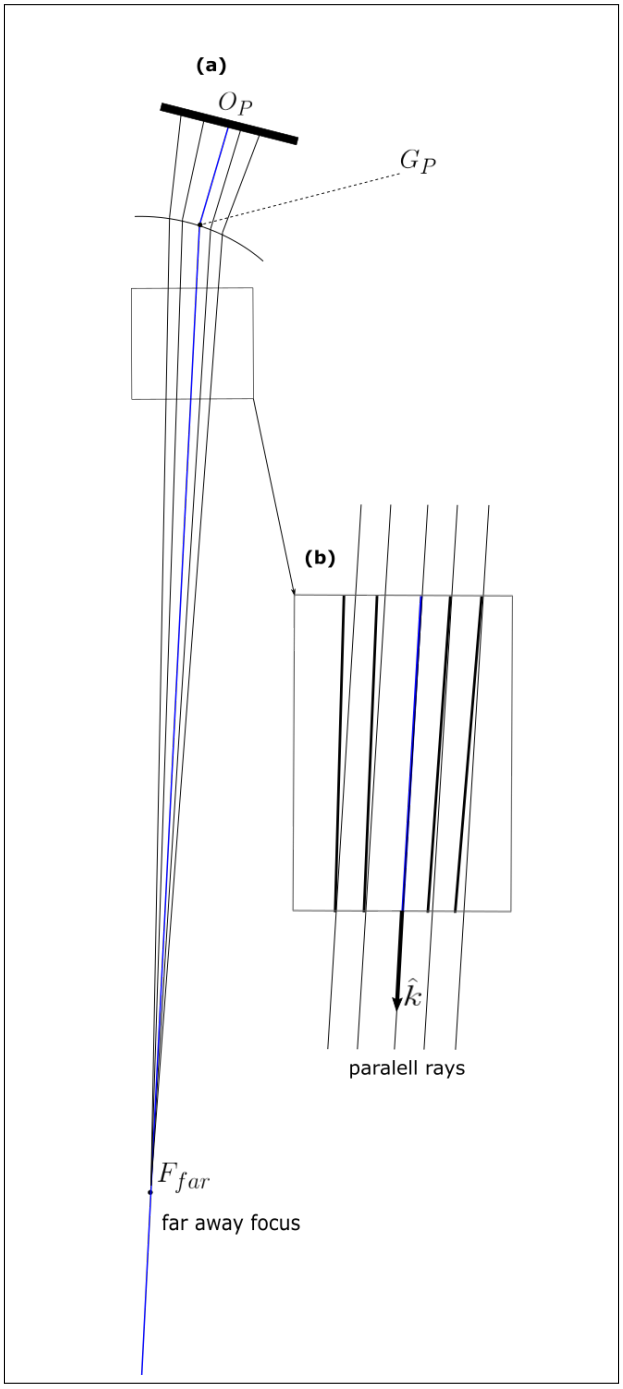

Figure 2. Geometry involved in the generation of a 3D plane wave through refraction. (a) Test piece surface, incidence plane and wavefront. (b) Vectors for Snell's law calculations

To compute the total TOF, we must calculate the ray path from the point $\vec{r}$ to each array element. This process typically requires an iterative calculation using Fermat's principle, which is computationally intensive. To optimize this procedure, we employ the 3D Virtual Array method, which we developed in our previous work [8].

As previously mentioned, TOF computations require a surface representation in the form $z = f(x, y)$. This representation can be obtained using ultrasound echoes reflected from the component's surface. In our previous work [9], we proposed several methods to achieve this for basic geometries, such as cylinders, planes and spheres.

One approach involves using a single plane wave directed along the array normal. This method has the advantage of requiring only a single firing, making it very fast. However, this method may fail if the probe's normal is at a significant angle to the surface, so it is best used in scenarios where such angular deviations are avoided.

For more complex or general geometries, alternative methods should be employed. Techniques such as those described in [10, 11] are promising candidates but would need to be extended to three-dimensional cases, as demonstrated in [12].

3. EXPERIMENTAL VALIDATION

In this section, we present an experimental example using a cylindrical aluminum test component with a 10 mm radius, featuring two Flat Bottom Holes (FBHs) in its midplane. The probe used was a 3 MHz, 11x11 matrix array with a 1 mm pitch. Data acquisition was performed using the SITAU II 128 full-parallel ultrasound system by DASEL S.L. (Spain).

TFM and PWI techniques were applied to generate images within a volume of 88x80x80 voxels. PWI was performed using nine plane waves, with an additional wave dedicated to surface detection. Lateral views of the resulting volumetric images are shown in Figure 3. It is observed in Figures 3 a and b that both methods produce similar results, where the 2 FBHs (H1 and H2 in Figure 3.a) are clearly imaged. A detailed comparison is presented in Figure 3.c, which displays the lateral amplitude profiles of H1 and H2, revealing that the contrast of H1 is slightly better in TFM. However, the acquisition efficiency difference between TFM and PWI is significant. TFM requires 121 individual firings, corresponding to each element in the 11x11 matrix array. In contrast, PWI in this experiment utilizes only 9 plane wave firings. Consequently, the RF signals collected for TFM contain ap-

proximately 14 times more data than those acquired for PWI. This substantial reduction in data volume for PWI highlights its potential for faster acquisition and processing times, which can be crucial in real-time imaging applications.

The main drawback of PWI is the requirement for an additional acquisition step to detect and reconstruct the surface, as well as the need to compute the emission focal laws—tasks that are unnecessary in the Full Matrix Capture (FMC) mode used for TFM, as they don't depend on the surface shape. However, in some cases, surface detection can be accomplished with just a single firing, and the computation of the delays, using the method described in Section 2, is highly efficient. In the example presented, this computation takes approximately 1 millisecond.

Regarding the software beamforming execution time, our current GPU implementation using an Nvidia GeForce RTX 3090 card demonstrates significant performance improvements for PWI compared to TFM: 68 ms for TFM and 15 ms for PWI. This represents more than a 4-fold speed increase for PWI over TFM in terms of image reconstruction. However, the most substantial advantage lies in the reduced data transfer time associated with PWI, coarsely 14 times less data in PWI than in TFM.

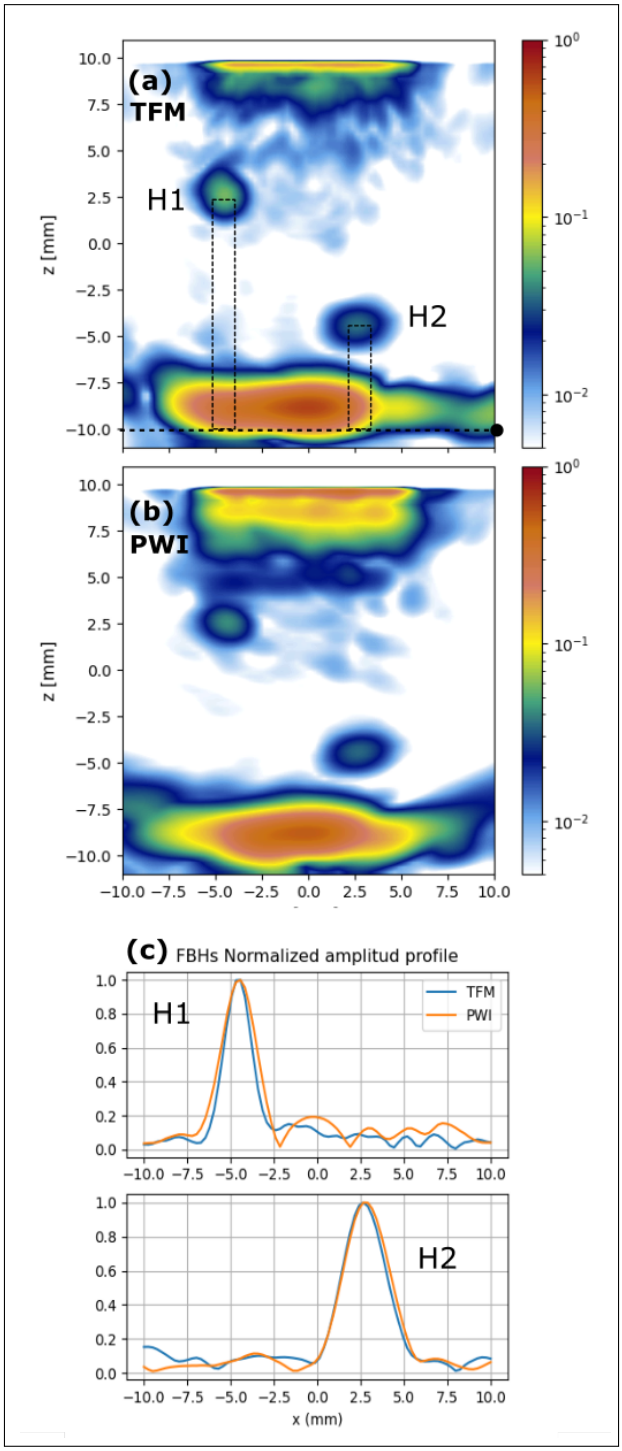

Figure 3. TFM and PWI images (lateral view). The cylinder axis is coincident with the X-axis. (a) TFM image; FBHs are represented by dashed lines in the schematic overlay (b) PWI image with 9 plane waves, (c) Amplitude profiles of the FBHs for the two imaging methods.

4. CONCLUSIONS

This study has demonstrated the feasibility and advantages of using 3D PWI with matrix arrays for non-destructive testing of components with arbitrarily shaped surfaces. By addressing the challenges associated with wave refraction at interfaces, we have presented a method for computing the delay laws required for the generation of plane waves within the inspected component. The use of a surface representation derived from ultrasound echoes makes the proposed method adaptive.

Experimental validation using a cylindrical test component with flat-bottom holes confirmed the effectiveness of the 3D PWI technique. The results demonstrate that PWI can achieve comparable image quality to the Total Focusing Method (TFM) while significantly reducing the number of transmission events.

Future work will focus on refining the surface detection and reconstruction algorithms and conducting comprehensive comparisons with TFM across a wider range of component geometries and defect types. Ultimately, the advancements in 3D PWI presented in this study contribute to the ongoing evolution of NDT techniques, paving the way for more efficient and reliable inspection of critical infrastructure components.

ABSTRACT

The High Flux Reactor at the Laue Langevin Institute produces the most intense neutron flux in the world, with a thermal power of 58 MW. As part of the global non-proliferation initiative, the Laue Langevin Institute aims to convert highly enriched fuel into low enriched uranium. This conversion is a challenging process, requiring strict compliance with safety standards and the preservation of the same performance quality for the new fuel element. During an irradiation cycle of the fuel element, multiple microstructural and physicochemical transformations occur, depending on the specific irradiation history of the fuel element, leading to a swelling phenomenon of the fuel plates and a decrease in the inter-plate distance. The Perseus project therefore aims to develop new evaluation tools, particularly a measurement of the inter-plate distance using an ultrasonic pulse-echo system with a frequency of 100 MHz. In this article, we will present the system developed over the course of three theses, the different solutions implemented to measure the inter-plate distance on an irradiated fuel element. The radiation-resistant transducer, custom-built along with its instrumentation, and the associated signal processing will be detailed to present measurements on irradiated fuel elements.

1. INTRODUCTION

The High-Flux Reactor (RHF) at the Institute Laue Langevin (ILL) generates the world's most intense neutron flux with a thermal power of about 58 MW [1-2]. As part of a global nonproliferation initiative, ILL aims to convert the RHF from high enriched uranium to low enriched uranium, a challenging process that must maintain safety standards and performance quality [3-5].

High Performance Research Reactors (HPRR) produce neutrons for material testing or science through fission in the reactor's fuel. During an irradiation cycle, various micro-structural and physical-chemical transformations occur in the fuel element. Post-irradiation examinations are essential to assess new fuel elements, identify structural modifications, and control irradiation histories [6]. Post-irradiation examinations activities, conducted in highly radioactive environments, require specialized infrastructure such as visual examination, radiography, and ultrasonic testing. Ultrasonic measurements are particularly valuable for nondestructive evaluation in the nuclear industry [7-10].

The Institut Laue Langevin and the University of Montpellier's Institute of Electronics and Systems launched the PERSEUS project to estimate the inter-plate distance within an ILL HPRR spent fuel element, linked to the RHF irradiation history. An ultrasonic device with a double element transducer was engineered and tested in the lab for in-situ measurements [11]. A mechanical system was developed to control the device underwater during testing. The paper discusses experimental constraints, the ultrasonic device and mechanical holder's structure and behavior, the instrumentation, and the time of flight estimation process. Section 4 covers in-laboratory measurement and calibration, and Section 5 presents the main result: an in-situ estimation

of the water-channel profile along 50 cm. The paper concludes with future perspectives.

2. EXPERIMENTAL CONSTRAINTS

To evaluate the irradiation history of the ILL RHF fuel element, several experimental constraints must be considered. First, non-destructive post-irradiation examinations are necessary to ensure the integrity of the fuel element. High precision measurements are required despite the challenging access to the element, which is submerged in a moderating water pool at a depth of 12 meters for cooling after use. Additionally, the fuel plates have involute shapes to maintain a constant nominal inter-plate distance of 1.8 mm, limiting the ultrasonic device's thickness to 1 mm. The desired measurements need micrometric resolution to detect expected microscopic structural modifications of around 25 µm, necessitating high-frequency operation to achieve resolutions of about 1 µm. The ultrasonic device must be carefully designed, as the wavelengths are comparable to its microstructure, significantly affecting the device's ultrasonic response. Finally, since the measurements are conducted in a highly radioactive environment, special attention must be given to the materials used in the ultrasonic device to ensure its performance when introduced into a spent fuel element. The following section details how we addressed these constraints through the design of the ultrasonic device and its integration into a measurement system.

3. EXPERIMENTAL SETUP

3.1 Measurement principle

Nondestructive testing has become crucial in the nuclear industry for assessing the efficiency and safety of nuclear power generation, especially in complex geometries like the High-Flux Reactor (RHF) at the Laue Langevin Institute [12]. Previous research led to the development of a measurement system to estimate the RHF fuel element's water-channel thickness (Fig. 1) [11-15]. This system, requiring expertise in electronics, high-frequency acoustics, and mechanics, has now been optimized to measure the inter-plate distance, known as the water-channel thickness.
The measurement system uses a waterproof dual piezoelectric transducer, which acts as both an emitter and receiver, integrated at the end of a 1 mm steel blade. When the blade is inserted into the nominal 1.8 mm inter-plate distance, (Fig. 2) the transducers are connected to a pulser/receiver to transmit and receive ultrasonic waves. These waves undergo specific signal processing to evaluate the inter-plate distance.

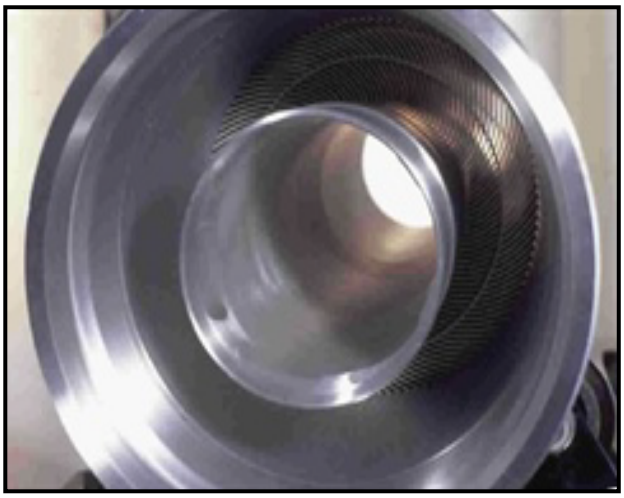

Figure 1. Bottom view of an RHF fuel element.

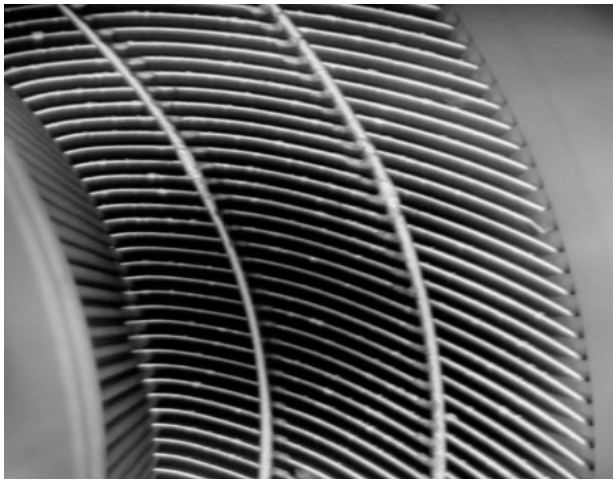

Figure 2. Enlarged top view of the plates of a fuel element with the channels whose distance needs to be measured.

The measurement principle involves two piezoelectric elements bonded to both faces of a silica support, mounted on one end of a 1 mm thick, 10 mm wide, and 1500 mm long stainless-steel blade (Fig. 3). After the blade is introduced into the water channel, the inter-plate distance is measured using ultrasonic waves emitted and received by a

dual transmitter/receiver system. The pulse echo method quantifies the time of flight t between reflections on the silica support and the fuel plates. Based on the ultrasonic velocity c in the propagation medium, the distance d is calculated using the formula in Eqn. (1).

$$d = (c*t) / 2. \quad (1)$$

By summing the distances d_1 and d_2 and adding the thickness d_s of the silica (Fig. 3), the measurement of the water channel thickness d_{wc} can be calculated using the following formula, with d_1 being the distance between the silica and the right plate, d_2 being the distance between the silica and the left plate, and d_s being the thickness of the silica Eqn. (2).

$$d_{wc} = d_1 + ds + d_2. \quad (1)$$

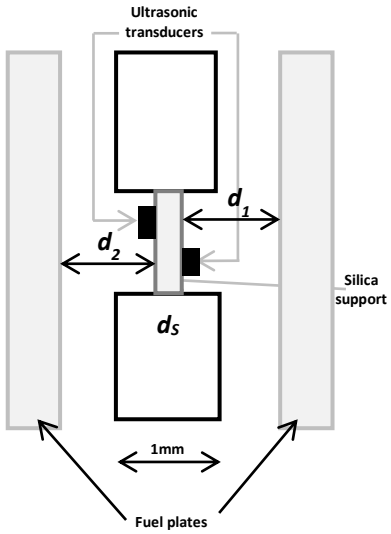

Figure 3. Schematic diagram of the measurement of a channel's thickness.

3.2 High-frequency ultrasonic device

A high-frequency ultrasonic transducer is a multi-layered device comprising a piezoelectric element disk, backing material, matching layer, and coaxial cables for transmission and reception. Fig. 4 illustrates the manufactured transducers. To meet experimental constraints and achieve the desired resolution, LiNbO3 ceramic was chosen for its excellent radiation resistance and vibration properties. The piezoelectric elements were carefully thinned to 35 µm, enabling operating frequencies of around 100 MHz. These elements were then attached to a 400 µm thick high-purity silica support, serving as the delay line. Special care was taken during the bonding process to ensure proper alignment of the transducers [16-17].

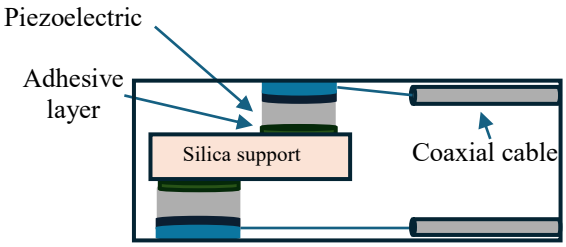

Figure 4. Transducer architecture.

To facilitate the insertion of transducers into the inter-plate distance, they were mounted on one end of a stainless-steel blade, as shown in Figure 5. This blade was meticulously manufactured, adhering to nuclear procedures to ensure material quality, cleanliness, and precise dimensions. The blade used in this study had specific dimensions: 1 mm thickness, 10 mm width, and 1500 mm length. The silica support, including the two active elements, was designed to fit into a hole at the blade's end. Grooves were drilled on both faces of the blade to facilitate cable connections for the transducers. Once mounted, the transducers were connected to a 20 m cable, allowing remote measurements.

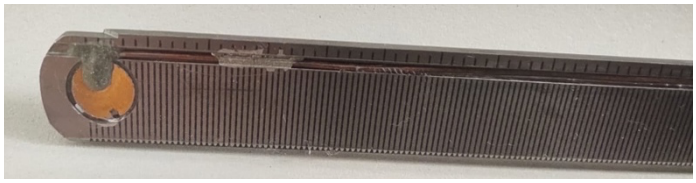

Figure 5. Ultrasonic transducer.

3.3 Instruments

The acquisition system begins with a dual transmitter/receiver electronic board (PXI) designed and manufactured at the University of Montpellier's Institute of Electronics and Systems. This dual pulse generator is optimized to produce high-frequency pulses compatible with transducers operating up to 400 MHz. Additionally, specific electronics enable the excitation of piezoelectric elements after a 20-meter cable.

Electric signals are transmitted through coaxial cables, and the received signals are then sent to a filtering system and a programmable gain amplifier. These signals are captured and converted into digital format using a NI PXIe-5162 acquisition card, chosen for its 2*2.5 GS/s sampling frequency and 10-bit resolution. Subsequently, digital signal processing is performed, with further details provided later.
All electronic board and the control computer are housed in a NI PXI rack, creating a compact and practical system for in-situ measurements. This setup not only ensures convenience but also facilitates procedures required for use in controlled nuclear zones.

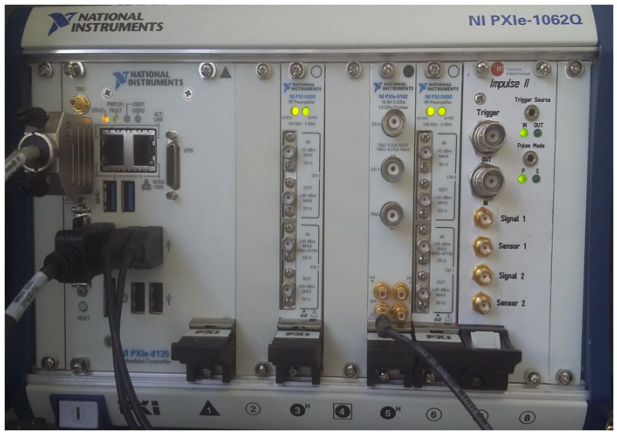

Figure 6. PXI controller with all electronic boards used for the generation, acquisition and processing of high-frequency ultrasonic signals.

3.4 Mechanical holder

Positioning the blade within the water channel is a crucial step in in-situ measurements, especially since the fuel element is stored in a 12-meter deep cooling pool. This experimental constraint necessitates high flexibility in aligning the ultrasonic device. To control and identify the device's position, ILL developed an automatic system. As shown in Fig. 7, this system includes a mechanism that allows translations along two axes to align the ultrasonic device with the fuel plates. It also utilizes motorized reels powered by a variable speed drive to control movement along the z-axis. Additionally, the reel can be operated manually for fine-tuning adjustments and situations requiring manual control.
A wire encoder is also used to determine the vertical position of the blade during measurements. This sensor is directly connected to the PXI rack computer, enabling synchronized ultrasonic measurements with the blade's height in the water channel being measured.

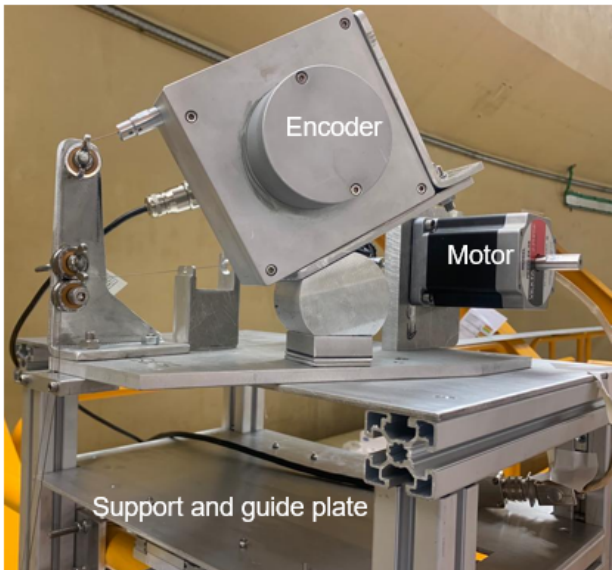

Figure 7. Mechanical holder.

3.5 Measurement principle

The distance measurement is based on a pulse/echo method [18]. The time of flight (ToF) of an ultrasonic wave corresponds to the interval between the emission and reception of an ultrasonic pulse reflected by an object or surface. To determine the distance d to the object, the echo time t is multiplied by the velocity c at which the ultrasonic wave propagates through the medium (Eq. 1).
Due to the transducer structure shown in Fig. 3, two series coexist in the signal. The first series, shown on the left side of the signal in Fig. 8, corresponds to the signature of a transducer positioned in water. This composite signal includes both the electrical excitation of the transducer and the multiple reflections of the initial pulse at the silica/water interface.
The complementary part of this signal is transmitted through the water and received after reflecting off the surface of the fuel plates. The resulting signal corresponds to the right side of the signal in Fig. 8.
To identify the time of flight, an inter-correlation is performed between the two parts of the signal in Fig 8, as indicated in [11]. To achieve this inter-correlation, the two overlapping zones must be separated. This is resolved by

point-by-point subtraction of the first zone with an acquisition made without a plate echo.

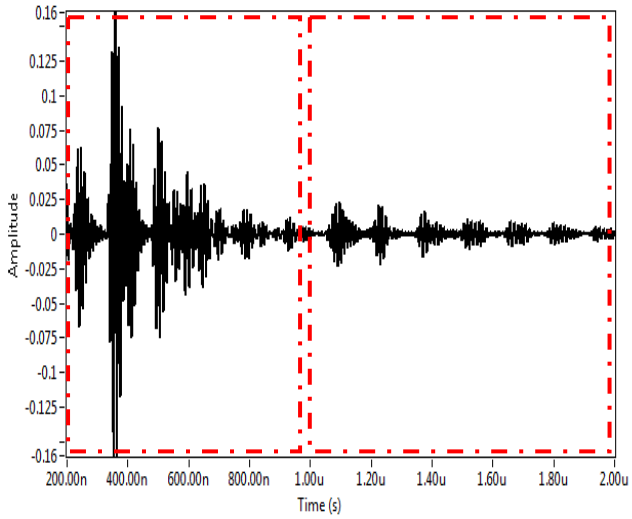

Figure 8. Experimental signal highlighting two series of echoes.

Using a silica delay line that produces multiple reflections allows for inter-correlation with a series of echoes rather than a single echo. This complicates signal processing due to the saturation of the initial echoes but facilitates the detection of the actual time of flight value, as the inter-correlation is performed over a large number of periodic echoes.

The inter-plate distance d_{wc} is then defined by Eq. (2), where d_s is the thickness of the silica layer and d_1 and d_2 are the thicknesses of the water layers on both sides of the blade. A statistical treatment for a given position can also be performed to reduce measurement noise.

4. IN-LAB MEASUREMENT

After introducing the principle of inter-plate distance measurement, we conducted an in-depth evaluation of the complete system to assess the transducer performance and signal processing accuracy for in-situ measurements.

4.1 Experimental bench in the laboratory

We built a motorized test bench with 8 degrees of freedom to ensure parallel motion of the blade to the plates. We first performed tests on a piece of fictitious fuel element, as shown in Figure 9. This allowed us to develop the measurement protocol and verify that the movements measured with the wire encoder, which will be used during on-site measurements, gave satisfactory results.

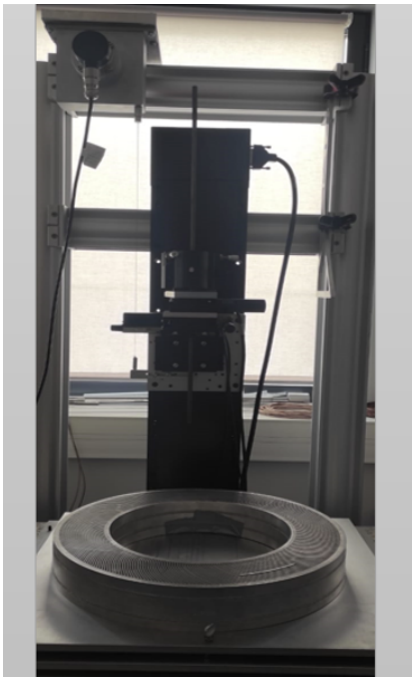

Figure 9. Experimental bench in the laboratory.

4.2 Measurements on a reference sample

This involved creating samples with faces as flat as possible and spaced 1.8 mm apart. To control this inter-plate distance, identical standard shims were machined to micron precision, ensuring the inter-plate distance was as close to 1.8 mm as possible. During a series of measurements, four ascending and descending movements of the device were performed to assess the distance between the plates along the height of this sample. The results of these measurements are displayed in Figure 10, indicating reproducible measurements at each position on a micrometric scale. The average thickness value for the 1.8 mm samples was determined to be 1.82 mm, with local standard deviations of 0.8 µm. There is a global variation of 1.4 µm across the sample's height, attributed to the fabrication process in the laboratory. These laboratory experiments clearly validate the reproducibility and quality of the measurements

performed with the designed devices and allow us to consider in-situ measurements.

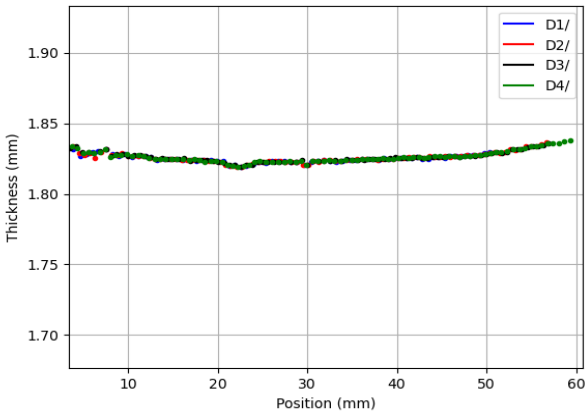

Figure 10. Measurement on a 1.8 mm reference sample.

5. IN-SITU MEASUREMENT

The RHF fuel element at the ILL, produced by CERCA, consists of 280 curved plates welded to two concentric aluminum tubes Fig.11. The fixed distance between two fuel plates, known as the water-channel thickness, is nominally 1.8 mm, allowing cooling water to pass through the reactor structure [19].

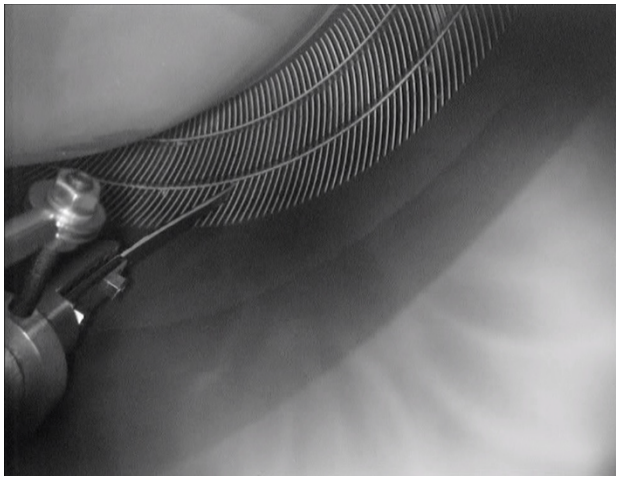

Figure 11. Photo of the insertion of a blade into a channel of the RHF fuel element in the pool.

An in-situ experiment was conducted at the ILL, where a spent fuel element is stored. A radiation-resistant camera was submerged in the pool above the fuel element to observe and control the blade's displacement. The ultrasonic device, equipped with instruments, was attached to a 12-meter support above the water pool. The blade was connected to a supporting system that ensured attachment, alignment, and synchronization with the wire encoder for real-time feedback.

Inter-plate distance measurements were performed on a single channel of the fuel element. Ultrasonic signals were recorded as the blade ascended along the water channel, with signals acquired every 50 ms. Post-treatment extracted high-confidence signals with good SNR from the data, corresponding to accurate estimations of the water-channel thickness. The results, presented in Fig. 12, show thickness estimations over 50 cm along the fuel element depth.

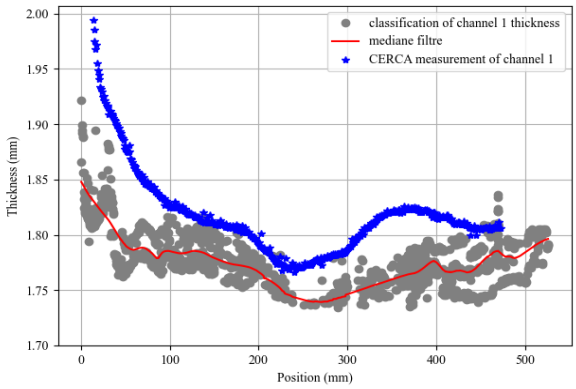

Figure 12. Results of ultrasonic measurements in gray, average in red, and comparison with pre-irradiation measurements conducted by CERCA in blue.

Due to the fuel element's position at the bottom of the cooling pool, alignment of the transducer with the plate surfaces cannot be guaranteed, leading to dispersion in thicknesses. The results, however, provide a good estimation of the water-channel thickness behavior, showing a curved shape with a local minimum between 200 mm and 300 mm.

The thickness estimation is presented as a red straight line along with gray measurement points. This mean behavior confirms a local minimum of 1739 µm in the water-channel thickness at 270 mm from the plate top. Furthermore, the

blue curve represents the measurement values provided by CERCA, estimating the inter-plate distance before irradiation, with an average of about 1796 µm. The global profiles for the two sets of measurements were found to be generally consistent. The mean thickness reduction in the first 50 mm is estimated to be around 40 µm.

6. CONCLUSIONS

To summarize, this extensive study outlined the design and application of a specialized ultrasonic transducer for examining the irradiation history of the RHF fuel element. The non-destructive control system utilized the pulse-echo method, enabling the estimation of the inter-plate distance within a fuel element through time-of-flight measurements.
Following the presentation of the system and the signal processing techniques for ToF estimation, various tests and evaluations were performed to verify the transducer's performance and accuracy in measuring this crucial parameter. These assessments helped validate the ultrasonic device and confirm its dependability for in-situ measurements under challenging access conditions.
A dedicated mechanical system was subsequently developed to efficiently transport and position the ultrasonic device in an underwater environment. This system facilitates flexible and agile movements, allowing the remote insertion of the ultrasonic transducer into water channels at a depth of 12 meters. Developed by ILL, this innovative mechanical system provides a solid foundation for inspections, offering more insights into the integrity of the fuel element and enabling measurements in different water channels of the fuel element.
In an initial experiment demonstrating the device's relevance, measurements were taken in one channel of the RHF fuel element. Post-processing was carried out to select signals with a high signal-to-noise ratio. The results presented in the final section were compared to water-channel thicknesses measured by CERCA prior to irradiation. The strong correlation between the two sets of results in the water-channel shape clearly demonstrates the quality of the proposed ultrasonic device and its suitability for future in-situ remote control in radiative environments.
Additionally, this device provided an initial estimation of one water-channel profile of a spent fuel element along 50 cm from the top of the element. The results indicate an average reduction in water-channel thickness of approximately 40 µm.
Since it is not possible to measure elements before irradiation, and to truly compare the measurements taken by CERCA with the ultrasonic measurements, it is proposed to create a demonstration sample that could be measured by both methods to confirm or refute the existing discrepancy between the two methods. Additionally, a further measurement campaign on other channels, compared with pre-irradiation measurements, could help enrich these conclusions.

7. ACKNOWLEDGMENTS

The authors would like to thank Y. Launay, O. Guillemard and A. Fournier for their strong contribution to the manufacture of the ultrasonic device and the associated mechanical bench and electronics.

ABSTRACT

Ultrasonic imaging based on beamforming relies generally on the precise synchronization of signals within a sensor network. Time shifts in these signals—often caused by sensor clock drifts—can be estimated and corrected during post-processing, prior to applying the backpropagation algorithm, using methods like the Peak Correlation Technique (PCT). However, in certain situations, particularly when defects exhibit anisotropy effects, additional time shifts can distort the backpropagated signals, undermining the accuracy of defect localization. This study focuses on statistically quantifying the impact of anisotropy-induced time shifts the contrast of defect localization images. The analysis is conducted in a thin reverberating plate, where covariance matrices are recorded in Full Matrix Capture (FMC) mode under two conditions: with and without a defect. Numerical simulations using A0 Lamb mode propagation are performed to validate the theoretical predictions.

Keywords: *Ultrasonic imaging, beamforming, Peak Correlation Technique, anisotropy-related shifts.*

1. INTRODUCTION

The demand for monitoring the structural integrity of infrastructures with minimal energy and hardware resources has led to the development of ”passive” imaging techniques. These methods leverage ambient noise to detect defects in reverberant media, eliminating the need for controlled emissions and ensuring substantial energy savings throughout the monitoring process. Studies such as [1, 2] have demonstrated that the Green’s function of a given medium can be reconstructed by cross-correlating ambient noise recordings from a network of sensors.

Structural Health Monitoring (SHM) has recently evolved with the increasing integration of autonomous sensor networks directly into infrastructures [3, 4]. This advancement revolutionizes integrity assessment by enabling continuous, real-time monitoring. Embedded sensors simplify traditional systems while enhancing efficiency, providing precise, instant data that supports swift, informed decisions, reducing failure risks and extending structural lifespan.

The use of autonomous sensor networks for SHM has significantly reduced costs and complexity, but signal resynchronization remains a major challenge. Each sensor relies on its own internal clock, leading to signal drift. Although various synchronization methods have been proposed, the most accurate ones require additional hardware, contradicting the goal of low-resource networks. The Peak Correlation Technique (PCT) [5–7] is a promising method for resynchronization, detecting time shifts by correlating the cross-correlation between signals. However, we have shown in previous works [8, 9] that noise in the measurement process can impair resynchronization and hinder defect localization.

In our previous studies, we assumed that the de-

fect scattered isotropically in all directions (constant scattering amplitude in all directions). However, in a more realistic scenario, the defect may exhibit preferred directions [10–12], which can also introduce shifts that overlap with resynchronization errors, further degrading the accuracy of defect localization. In this paper, we will conduct a statistical study of the shifts related to the anisotropy of the defect to quantify their impact on the contrast of defect localization images.

This work is structured as follows: we begin by theoretically quantifying the impact of shifts induced by defect anisotropy on its detection in elastic reverberating plates. Subsequently, we perform numerical simulations to validate the theoretical results.

2. THEORETICAL DEVELOPMENTS

We consider an array of N sensors placed on the surface of a plate subjected to ambient noise. As explained in [13], detecting a possible defect in a plate consists of calculating the cross-correlations between all pairs of sensors, both in the presence and absence of the defect, and then taking the difference to isolate the signature of the latter. We recall that for a pair n of sensors, in order to compensate for the propagation distance from the first sensor to the defect and then from the defect to the second sensor, we backpropagate the resynchronized differential cross-correlation in post-processing $\Delta C_n^{res+}(\omega)$ by multiplying it by a dispersion compensation term as follows:

$$BPF_n(\omega) = \Delta C_n^{res+}(\omega)\, e^{jk(\omega)d_n}, \tag{1}$$

with $BPF_n(\omega)$ the backpropagation of $\Delta C_n^{res+}(\omega)$ to the pixel corresponding to the position of the defect, $k(\omega)$ the wave number of the bending mode A_0 and d_n the sum of the distances from the first sensor to the defect and from the defect to the second sensor.

The inverse Fourier transform of $BPF_n(\omega)$ allows to find the backpropagated signals on the position of the defect in the time domain. We note that, these backpropagated signals correspond, ideally, to the autocorrelation of the emission signal. In the case of an isotropic defect, and if the signals are perfectly synchronized, the typical shape of these signals is as shown in Fig. 1. However, in the case of an anisotropic defect, the anisotropy influences both the amplitude and the phase of the backpropagated signals. As illustrated in Fig. 2, this results in time shifts and amplitude variations observable in the backpropagated signals.

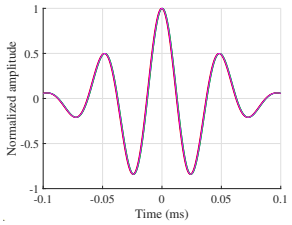

Figure 1. Example of back-propagated signals, on the defect position, in the case of an isotropic defect.

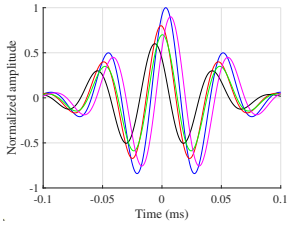

Figure 2. Example of back-propagated signals, on the defect position, in the case of an anisotropic defect ($\mathcal{E}_n = 0$ et $\tau_n \neq 0$).

In the remainder of this paper, we are interested in quantifying the contrast ratio defined in [8] as a function of the standard deviation of the initial shifts due to the phase anisotropy of the defect. To do this, we assume that back-propagated signals are affected both by the initial shifts and by the errors resulting from the imperfect resynchronization. As a result, the resynchronized version of the differential cross-correlation function becomes as follows:

$$\Delta C_n^{res+}(t) = \Delta C_n^{+}(t + \mathcal{E}_n + \tau_n), \tag{2}$$

with τ_n the initial shift due to the anisotropy of the defect and $\mathcal{E}_n$ the resynchronization error.

Which is equivalent, in the frequency domain, to:

$$\Delta C_n^{res+}(\omega) = \Delta C_n^{+}(\omega)\, e^{j\omega\mathcal{E}_n}\, e^{j\omega\tau_n}. \tag{3}$$

In a similar way to [8], we can express $\Delta C_n^{res+}(\omega)$ as follows:

$$\Delta C_n^{res+}(\omega) = f(\theta_n, \omega)\chi_n\, e^{-jk(\omega)d_n}\, U_0(\omega)\, e^{j\omega\mathcal{E}_n}\, e^{j\omega\tau_n}, \tag{4}$$

with $U_0(\omega)$ a term defined in [8].

Substituting Eq. 4 into Eq. 1 we obtain:

$$BPF_n(\omega) = f(\theta_n, \omega)\chi_n \, U_0(\omega) \, e^{j\omega\mathcal{E}_n} \, e^{j\omega\tau_n}. \quad (5)$$

Thus, the sum over the N_c pairs can be written as follows:

$$BPF(\omega) = \sum_{n=1}^{N_c} f(\theta_n, \omega)\chi_n \, U_0(\omega) \, e^{j\omega\mathcal{E}_n} \, e^{j\omega\tau_n}. \quad (6)$$

Returning to time domain and integrating the square of the modulus of $bpf(t)$, the inverse Fourier transform of $BPF(\omega)$, over an interval $[-T_0/2, T_0/2]$ containing the first wave packets, yields the intensity of the pixel corresponding to the defect position as follows:

$$I_{res} = \int_{-\frac{T_0}{2}}^{\frac{T_0}{2}} |bpf(t)|^2 \, \mathrm{d}t. \quad (7)$$

Replacing $bpf(t)$ with its expression (inverse Fourier transform of the Eq. 6) we obtain:

$$I_{res} = \int_{-\frac{T_0}{2}}^{\frac{T_0}{2}} \left(\sum_{n=1}^{N_c} f(\theta_n, \omega)\chi_n \tilde{u}_n(t) \right)^2 \mathrm{d}t, \quad (8)$$

with $\tilde{u}_n(t) = u_0(t + \mathcal{E}_n + \tau_n)$.

Similarly to [8], Eq. 8 becomes:

$$I_{res} = \frac{\sigma_0}{2\pi} \int_{-\frac{T_0}{2}}^{\frac{T_0}{2}} \left[\sum_{n=1}^{N_c} \chi_n^2 u_n^2 + \sum_{n=1}^{N_c} \sum_{m \neq n}^{N_c} \chi_n \chi_m \tilde{u}_n(t) \tilde{u}_m(t) \right] \mathrm{d}t. \quad (9)$$

Which can be written as follows :

$$I_{res} = \frac{\sigma_0}{2\pi} \left[E_0 \sum_{n=1}^{N_c} \chi_n^2 + \sum_{n=1}^{N_c} \sum_{m \neq n}^{N_c} \chi_n \chi_m \int_{-\frac{T_0}{2}}^{\frac{T_0}{2}} \tilde{u}_n(t) \tilde{u}_m(t) \, \mathrm{d}t \right]. \quad (10)$$

with $E_0 = \int_{-\frac{T_0}{2}}^{\frac{T_0}{2}} u_0^2(t) \, \mathrm{d}t$.

Since we are interested in an average behavior of the intensity on the position of the defect, we introduce the statistical average (denoted $\langle . \rangle$) on I_{res} for a set of random realizations on $\mathcal{E}_n$ and τ_n, and knowing that $\tilde{u}_n(t)$ and $\tilde{u}_m(t)$ are independent (because $\mathcal{E}_n$ and τ_n are assumed to be independent for $n \neq m$) we obtain:

$$\langle I_{res} \rangle = \frac{\sigma_0}{2\pi} \left(E_0 \sum_{n=1}^{N_c} \chi_n^2 + E_1 \sum_{n=1}^{N_c} \sum_{m \neq n}^{N_c} \chi_n \chi_m \right), \quad (11)$$

where $E_1 = \int_{-\frac{T_0}{2}}^{\frac{T_0}{2}} \langle \tilde{u}_n(t) \rangle^2 \, \mathrm{d}t$.

Then, Eq. 10 becomes:

$$\langle I_{res} \rangle = \frac{\sigma_0 N_c^2}{2\pi} \left[E_1 \, \bar{\chi}^2 + \frac{E_0 - E_1}{N_c} \bar{\chi^2} \right]. \quad (12)$$

Just like [8,9] , to quantify the degradation of the contrast ratio in the case of imperfect resynchronization, the definition of the contrast ratio consists of dividing the intensity of the Eq. 12 by a reference intensity calculated when the signals are perfectly resynchronized. This reference intensity can be expressed, by replacing E_1 with $E_0^{'}$ in the Eq. 12, as follows:

$$\langle I \rangle = \frac{\sigma_0 N_c^2}{2\pi} \left[E_0^{'} \, \bar{\chi}^2 + \frac{E_0 - E_0^{'}}{N_c} \bar{\chi^2} \right], \quad (13)$$

with $E_0^{'} = \int_{-\frac{T_0}{2}}^{\frac{T_0}{2}} \langle u_0(t + \tau_n) \rangle^2 \, \mathrm{d}t$.

Thus, under the assumption of a circular network around the defect, the contrast ratio defined in [8] can be written :

$$C_r = \frac{E_0 + (N_c - 1)E_1}{E_0 + (N_c - 1)E_0^{'}}. \quad (14)$$

Using Parseval's theorem and the transfer theorem in the same way as in [8], we can show that E_1 can be written:

$$E_1 = 4\pi^2 \int |U_0(\omega)|^2 \, |p_{\mathcal{E}}(\omega)|^2 \, |p_\tau(\omega)|^2 \, \mathrm{d}\omega, \quad (15)$$

with $p_{\mathcal{E}}(\omega)$ and $p_\tau(\omega)$ are the Fourier transforms of the probability density of the resynchronization errors and that of the initial shifts, respectively.

Similarly, we can easily show that:

$$E_0^{'} = 2\pi \int |U_0(\omega)|^2 \, |p_\tau(\omega)|^2 \, \mathrm{d}\omega. \quad (16)$$

As for E_0, its expression can be found in [8].

Finally, the Eq. 14 becomes:

$$C_r = \frac{\int |U_0(\omega)|^2 \, \mathrm{d}\omega + 4\pi^2 (N_c - 1) \int |U_0(\omega)|^2 |p_{\mathcal{E}}(\omega)|^2 |p_\tau(\omega)|^2 \, \mathrm{d}\omega}{\int |U_0(\omega)|^2 \, \mathrm{d}\omega + 2\pi (N_c - 1) \int |U_0(\omega)|^2 |p_\tau(\omega)|^2 \, \mathrm{d}\omega}. \tag{17}$$

This expression, which generalizes the expression developed in [8] for the case where the defect is anisotropic, shows that resynchronization errors affect the numerator of the contrast ratio, while initial shifts influence both the numerator and the denominator of this ratio. We will explore and confirm this relationship through a numerical simulation in the next section.

3. NUMERICAL VALIDATION

To validate the theoretical results obtained in the previous section, a numerical simulation is performed here using a finite element code ELMER. This code models acoustic wave propagation in a finite plate based on the Reissner-Mindlin plate theory.

The configuration tested (see Fig. 3) consists of an aluminum plate of dimensions 1×0.5 m^2 and thickness 3 mm. On the surface of this plate, we place an array of 8 sensors at known positions and a distribution of 600 sources uniformly distributed around the sensors. A defect is modeled by a zero normal displacement imposed at the position (53, 26) cm on the surface of the plate.

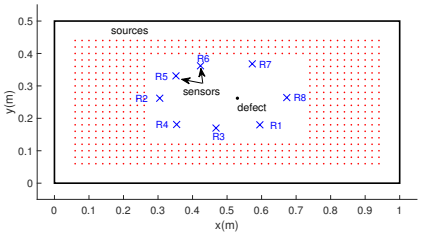

Figure 3. Simulated configuration: aluminum plate 1×0.5 m^2 and 3 mm thick. 8 sensors (blue crosses). 600 sources uniformly distributed around the sensors (red dots). A point defect at position (53, 26) cm.

The emission signal is a Gaussian-windowed sine of frequency $f_0 = 20$ kHz. The sampling frequency is 2.5 MS/s. For each pair of receivers, the summed cross-correlation over all sources is computed.

We whiten the simulated signals between 1 kHz and 30 kHz and then calculate the cross-correlations for all sensor pairs in the cases with and without defects. Next, we introduce initial shifts according to a Gaussian distribution with zero mean and variable standard deviation, denoted σ_τ. For each value of σ_τ, we add to these cross-correlations resynchronization errors modeled by a normal distribution with zero mean and variable standard deviation σ. We then apply the localization algorithm [13] to the obtained cross-correlations. Finally, we calculate the contrast ratio averaged over 100 draws of the initial shifts and 100 draws of the resynchronization errors. This numerical contrast ratio can be compared to the theoretical curve of the Eq. 17.

The curves showing the evolution of the contrast ratio as a function of σ for different values of σ_τ are shown in Fig. 4.

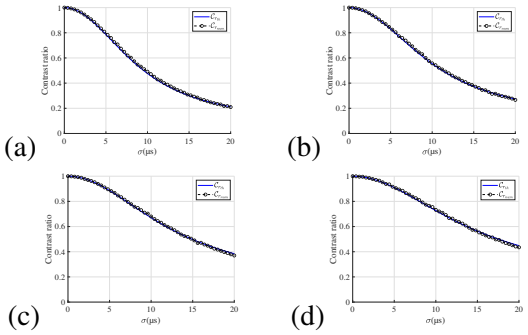

Figure 4. Comparison between the variation of the theoretical (blue line) and numerical (black circles) contrast ratio, as a function of σ, the standard deviation of the resynchronization errors, for different values of the standard deviation of the initial shifts : (a) $\sigma_\tau = 2$ µs, (b) $\sigma_\tau = 6$ µs, (c) $\sigma_\tau = 10$ µs, (d) $\sigma_\tau = 12$ µs.

On the one hand, we observe that the numerical results are in excellent agreement with the theory. On the other hand, it is clear that an increase in σ_τ causes a significant change in the shape of the curves.

4. CONCLUSION

In this paper, we have explored the impact of defect scattering anisotropy on the signals used for localization. We demonstrated that phase anisotropy leads to initial shifts in

the signals. These shifts can overlap with resynchronization errors and significantly affect the contrast in defect localization images. In future works, the results presented in this paper could be used to classify defects by conducting a detailed analysis of the initial shifts. This classification could be further refined by incorporating the defect's scattering cross section into the contrast ratio calculation.

ABSTRACT

The high sensitivity of nonlinear terms in the elastic response of materials to the early appearance of damage has led to the emergence of the so-called NEWS methods (Non-linear Elastic Wave Spectroscopy). These NDE (Non-Destructive Evaluation) methods exploit the increase in the material's nonlinear behaviour as damage increases. In particular, the NIRAS technique (Non-linear Impact Resonance Acoustic Spectroscopy) detects changes in the resonance of a material (frequency, damping factor, etc.) as a function of impact intensity.
In this work, the NIRAS technique has been employed to characterize concrete using different sensing methods (accelerometers and FBG - Fiber Bragg Grating). Additionally, this study presents the conditioning process, along with a viscoelastic model of the Maxwell and Kelvin-Voigt types, to understand the effects of conditioning on the specimens during testing.

Keywords: *nonlinear acoustics, conditioning effect, fiber Bragg grating (FBG), NIRAS technique*

1. INTRODUCTION

Geomaterials—such as rocks, sand, soil, and combinations thereof like concrete—are classified within a specific group known as Non-Linear Mesoscopic Elastic (NME) materials [1]. These materials are characterized by their heterogeneous internal makeup, with a complex non-linear response strongly influenced by various microstructural elements, including micro-cracks, grain contacts, and voids. Compared to traditional atomic elastic materials, this response is significantly more pronounced. Due to these unique properties, the non-linear behavior of NME materials cannot be adequately described by Landau's classical non-linear elasticity theory [2].

One of the most effective methodologies for evaluating damage in concrete and other cementitious materials is the non-destructive technique known as Nonlinear Elastic Wave Spectroscopy (NEWS). This method focuses on analyzing various nonlinear phenomena [3], including the generation of higher-order harmonics, wave cross-modulation, shifts in resonance frequency, and amplitude-dependent attenuation. Despite variations in technique, all NEWS approaches share a common goal: to quantify non-linear material behaviors through dynamic responses.

Concrete degradation has been extensively studied over time, with research highlighting that different deterioration mechanisms alter their dynamic properties in distinct ways [5][6]. Concrete exposed to thermal shock (rapid temperature changes) can suffer significant internal damage due to the differential expansion and contraction of its constituent materials. This abrupt thermal gradient induces high tensile stresses, particularly at the interfaces between aggregates and the cement paste, often leading to microcracking, debonding, and eventual loss of mechanical integrity. Repeated thermal shocks can accelerate degradation, reducing stiffness, strength, and durability over time [7]. Investigations have applied NEWS techniques to evaluate thermal shock effects on concrete across various compositions and number of cycles [8][9] and changes in

acoustic non-linearity under thermal stress [10][11][12] [13].

A notable example is the Non-linear Impact Resonance Acoustic Spectroscopy (NIRAS) technique. NIRAS operates by monitoring how the material's resonance frequency varies with different levels of impact force (see Figure 1), providing insights into internal structural changes.

However, the use of NEWS techniques, and NIRAS in particular, also implies that, under certain conditions, the specimen may undergo a conditioning process as a result of material hysteresis. This leads to observable differences in the results between the first time the material is tested (i.e., non-conditioned state) and subsequent repetitions of the test (conditioned state). This phenomenon can be referred to as discrete memory or material conditioning, and it arises from a combination of slow dynamics and fast dynamics. It is worth noting that the material may or may not return to its relaxed or non-conditioned state over time [4].

In this study, the authors focus on two key aspects. First, they aim to demonstrate the conditioning effect that mortar specimens undergo when subjected to the NIRAS technique. To this end, results from the first (not conditioned status) and second tests (conditioned status) are compared. This conditioning becomes more pronounced in damaged specimens, as non-linear phenomena are more evident in these cases. Therefore, the study specifically considers specimens that have been damaged through thermal shock. Moreover, experiments are conducted using both traditional piezoelectric accelerometers and fiber Bragg grating (FBG) sensors, which are embedded into the specimens during the manufacturing process.

Thanks to the integration of embedded FBG sensors during specimen fabrication, the second objective of this work is to investigate the relaxation behavior of the specimens after being tested. The use of FBG technology allows for internal strain monitoring, offering valuable insight into the time-dependent recovery process that occurs as a result of mechanical conditioning.

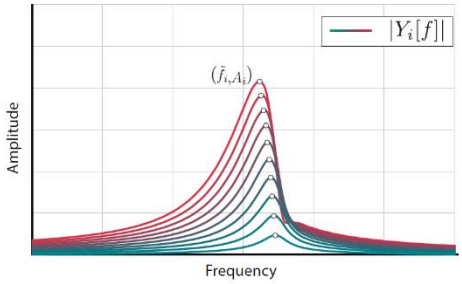

Figure 1. Received frequential response for the different impact levels ($Y_i(f)$)

2. MATHEMATICAL BACKGROUND

NIRAS is a method used for impact assessment and damage detection and involves impacting the material with different strength levels and analyzing the resulting acoustic frequency responses. The different reverberation signals are denoted by $y_i(t)$ where i denotes the different impacts and $Y_i(f)$ is the Fourier Transform of $y_i(t)$ (Figure 1). The non-linear parameters related to the resonance frequency shift α is obtained from a simple linear regression fit (Figure 2):

$$\frac{\tilde{f}_0 - \tilde{f}_i}{\tilde{f}_0} = \alpha \cdot A_i \tag{1}$$

$$A_i = \max|Y_i(f)| \tag{2}$$

$$\tilde{f}_i = \max_f|Y_i(f)| \tag{3}$$

Where A_i is the is the peak amplitude of the spectrum, $\tilde{f}_i$ is the peak frequency and $\tilde{f}_0$ denotes the intersection with y-axis of the linear relationship between the peak amplitudes A_i (x-axis) and the peak frequencies $\tilde{f}_i$ (y-axis).

The NIRAS technique obtains the parameter α_f^{NIRAS}, among others, as an indicator of the no linear behavior of the material: the greater the damage, the greater the no-linear behavior and the greater α_f^{NIRAS}.

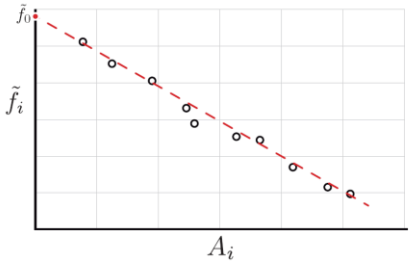

Figure 2. Linear regression from the different resonance signals.

The Maxwell model may be more suitable for describing the dynamic behavior of the specimen during fast mechanical responses, while the Kelvin-Voigt model is more appropriate for representing the slow dynamics effects, such as those associated with conditioning and material relaxation over time. However, experimental observations in this study suggest that both behaviors coexist in the tested specimens. The act of testing itself induces a conditioning state—often referred to as slow dynamics—which subsequently alters the specimen's mechanical response in follow-up impacts, which are governed by fast dynamics.

In this context, the Zener model, derived from a combination or modification of the Maxwell and Voigt models, provides a more comprehensive framework. It effectively captures both the immediate elastic response and the time-dependent relaxation behavior of the tested specimens. Although traditionally used to model fast relaxation phenomena, the results presented in this study and those in [4]demonstrate that damaged specimens, exhibiting stronger non-linear responses, undergo a measurable conditioning process simply as a result of being tested. This effect is clearly reflected in the evolution of the non-linear parameter α reinforcing the connection between mechanical damage, slow dynamics, and non-linear acoustic response.

3. EXPERIMENTAL

3.1 Manufacturing and damage induction of mortar specimens

Three mortar specimens (A, B and C) were prepared by mixing Portland cement (EN 197-1-CEM I 52.5 R) [14], sand (quartz) and water in the 1:3:0.5 ratio. After mixing the components, following the procedure described in UNE-EN 196-1 [15], the fresh mortar was placed in a prismatic mold of 50x60x240 mm size. Because prior to pouring the mortar, several optic fibers were settled according to Figure 4. Due to the fragility of the fibers, the mortar was poured in three layers, avoiding damaging the fibers. For this, the fresh mortar was dropped in a zone free of fiber and then the mold was vibrated (Vibrating Table ToniVIB Tonitechnic) for 30 seconds (vibration frequency 50 Hz, amplitude 1 mm). This procedure was twice repeated and finally the superior part was flattened using a spatula. Additionally, metallic capillary sheath (Figure 3a) was used to protect each optical fiber during the pouring and vibration process and was removed immediately after the surface leveling.

The mold was put in a humid chamber (20 ºC, RH>90%) for 24 hours. After this period, the specimens were carefully demolded and were covered with a plastic film, to avoid water evaporation. The wrapped specimens were stored in the same humid chamber for 46 days, to complete the hydration of the Portland cement.

After 88 days from mixing the mortar components, two of the specimens were subjected to thermal shock (B and C): the specimens were immersed in hot water (80ºC) for 1 hour and then immediately submerged in cold water (4ºC) for 10 minutes, tank of 0.01 m3.

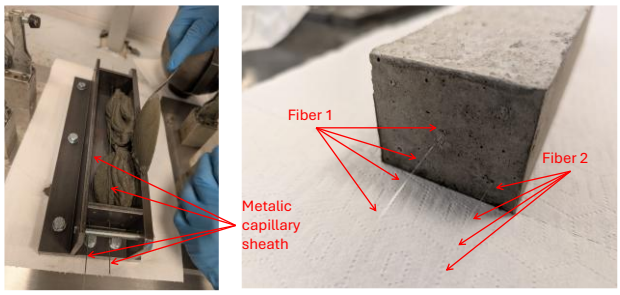

Figure 3. a) Manufacturing process b) Demolded specimen showing the optical fiber emerging from the mortar.

3.2 Embedded Instrumentation

Two of the three specimens (A and B) were internally instrumented during the fabrication process with two optical fibers aligned along the longitudinal axis of the specimen: one positioned at the center and the other near a corner (Figure 4). Each optical fiber contained two integrated Fiber Bragg Gratings (FBGs), which were located at the center and at one end of the fiber.

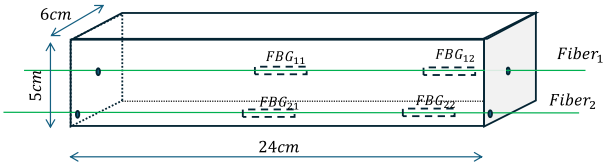

Figure 4. Representación de las fibras embebidas.

The FBGs were primarily tuned to the wavelengths listed in Table 1 and illustrated in Figure 5. Fiber 2 of Mortar A was damaged during the demolding process, therefore no measurements were obtained from this fiber.

3.3 Measurement setup

Two distinct experimental configurations were employed in the development of this study. In the first experimental, multiple impacts were applied to different specimens with the objective of analyzing the mechanical conditioning process induced by repeated excitation.

The second setup was designed to perform long-duration measurements, spanning a period of several days. In this case, the specimen was initially subjected to controlled impacts to induce a conditioned state, after which continuous monitoring was carried out with the aim of evaluating the temporal evolution of the material. The main objective was to observe the potential residual effects of the conditioning, as well as the gradual recovery of the specimen's original state once the excitation had ceased.

Both experiments were structured into three functional stages: an initial excitation phase using impact, a second sensing phase, and finally, a data acquisition system responsible for recording and storing the signals obtained.

In the first experiment, the excitation stage consisted of an instrumented hammer and a clamping system designed to immobilize the specimen during measurements, thereby ensuring consistent conditions for each impact. The hammer's attachment to the support allowed for an almost constant impact force across all repetitions, ensuring the repeatability of the conditioning process.

In the second experiment, aimed at studying the temporal evolution of the material, excitation was carried out solely using a conventional hammer, employed to induce the initial conditioning of the specimen prior to the start of prolonged monitoring. In this case, impact uniformity was not critical, as the primary interest lay in observing the post-conditioning effects over time.

During the sensing phase, two types of sensors were used: accelerometers and optical fibers with embedded Fiber Bragg Gratings (FBGs) within the specimens.

In the first experiment, both types of sensors were employed. One accelerometer was placed on the hammer to capture the impact during striking, and another was mounted on the specimen to monitor the material's dynamic response and evaluate the effect of the conditioning induced by repeated impacts. In addition, FBG optical sensors embedded within the specimen were used to

record both the impacts and the structural changes in the material resulting from the conditioning process.

In the second experiment, only FBG optical sensors were used, as the main objective was to analyze how the specimen, after being conditioned by the impacts, returned to its initial state or, alternatively, experienced a progressive loss of the properties induced by the conditioning. In this context, the use of accelerometers was not necessary, since the focus was on observing the temporal evolution of the material properties under resting conditions following the initial impacts.

The final stage of the experiment corresponds to data acquisition, for which two specific devices were used, each responsible for capturing data from the different sensors.

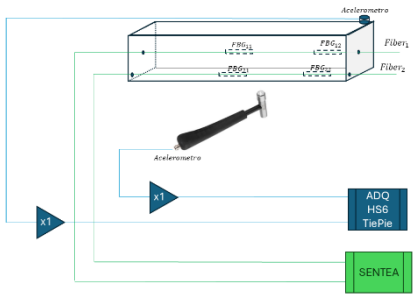

Figure 6. Esquema del montage.

In the first experiment, both devices were used. For the capture of accelerometer data, the TiePie HS6 data acquisition system was employed, which has four input channels. However, in this measurement, only two of these channels were used, dedicating one to each accelerometer (one for the hammer and the other for the specimen).

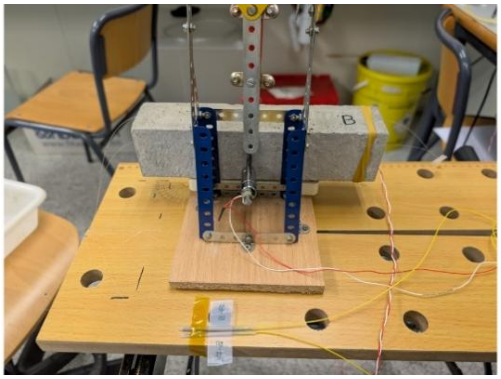

Figure 7. Photograph of the experiment

The second device used was the SENTEA optical interrogator, specifically designed for reading Fiber Bragg Gratings (FBGs). This device also has four channels, allowing for the simultaneous interrogation of multiple FBGs per channel. In the context of this experiment, each channel was used to interrogate a set of FBGs embedded within the specimen, enabling the capture of relevant data on the material's behavior.

In the second experiment, only the SENTEA interrogator was used, as the objective of the measurement focused exclusively on monitoring the FBGs, without the need to record data from the accelerometers.

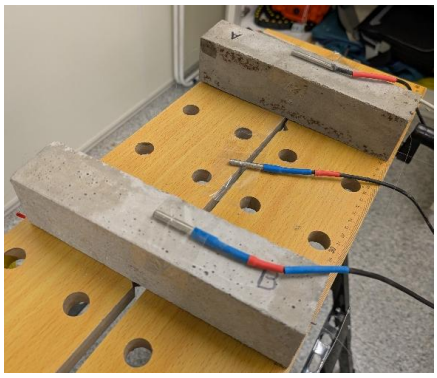

Figure 8. Overview of the long-term experimental setup

In the first experiment, the specimen was placed on a rigid support to prevent any displacement during the measurements (Figure 7). Ten consecutive impacts were applied using the instrumented hammer, with an increasing force in each strike. This process was repeated after the initial ten impacts, allowing for a comparison between measurements obtained under two conditions: one with the specimen in its initial (resting) state, and the other after it had been conditioned by the repeated impacts.

In the second experiment (Figure 8), the specimen was subjected to ten initial impacts in order to induce conditioning. Afterwards, it was left at rest for several days to observe its behavior over time, allowing for the evaluation of whether the specimen gradually returned to its original state or remained in a partially conditioned state. The main objective of this experiment was to analyze the temporal evolution of the material's properties, observing either a return to normality or a progressive loss of the conditioning induced by the impacts.

4. TESTS DESCRIPTION AND RESULTS

As described, two types of tests were conducted on the mortar specimens: the NIRAS acoustic spectroscopy test and the long-term conditioning evolution test. These tests were performed on both undamaged and damaged specimens, using embedded fiber Bragg gratings (FBGs) and piezoelectric accelerometers for strain and vibration measurement. Specifically, three specimens were studied: one undamaged specimen (A) and two thermally shock damaged specimens (B and C). Specimens A and B were instrumented with embedded FBG sensors. The complete experimental matrix is summarized in Table 2.

Table 2. List of damaged and undamaged mortar samples tested with accelerometers and FBGs, non-conditioned (M1) and conditioned (M2) and long-term monitoring

Sample	Status	Acc.		FBG		
		NIRAS				Long-term
		M1	M2	M1	M2	
A	Sound	√	√	√	√	√
	Damage	Reference sample – no damage applied				
B	Sound	√	√	√	√	-
	Damage	√	√	√	√	√
C	Sound	√	√	Not instrumented		
	Damage	√	√			

The first test, the NIRAS procedure, consisted of applying ten controlled impacts to the specimen using an instrumented hammer. The impacts were progressively stronger, modulated by increasing the striking angle. A second identical series of ten impacts was then performed. The first measurement set (M1) corresponds to the non-conditioned state, while the second (M2) corresponds to the conditioned state. This protocol enabled a direct comparison of the specimen's dynamic response before and after conditioning, allowing for the assessment of non-linear and hysteretic behavior resulting from damage. As shown in Figure 9 and Figure 10 the relationship between peak frequency and amplitude, exhibits a consistent variation between the first and second series. While the absolute change may be small, the trend is systematic. Since α is associated with the degree of non-linear behavior, this conditioning effect becomes more evident in the damaged specimens, where non-linearities are more pronounced.

Table 3 and Table 4 summarize the values of both α and f_0 for undamaged and damaged specimens, as well as for the first and second measurement series. For undamaged samples, α is close to zero, indicating an essentially linear material response within the applied impact range (i.e., resonance frequency does not depend on impact amplitude). As damage increases, the absolute value of α also increases, reflecting stronger non-linear behavior. The trend is consistent across both sensing technologies. Additionally, a decrease in f_0 is observed as damage progresses, consistent with a loss of mechanical stiffness. A systematic shift in both α and f_0 is also evident when comparing results from the first impact series (non-conditioned state) with subsequent impacts (conditioned state). This shift is more significant in damaged specimens, which display a more prominent hysteretic response.

Moreover, as shown in Table 3 and Table 4, the parameter α also varies consistently not only between the two damaged specimens but also between the two sensing technologies, reinforcing the robustness of the observed trends.

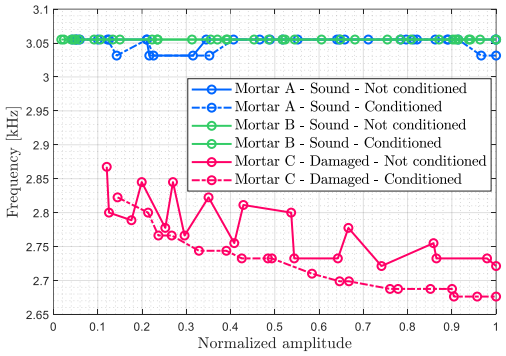

Figure 9. Amplitude vs. frequency curves measured with the accelerometer for conditioned and unconditioned specimens, with and without damage

Table 3. NIRAS parameters (α and f_0) for the samples A, B and C, between "Not conditioned" and "Conditioned" for the accelerometer sensor

Accel.		Not conditioned			Conditioned		
		$-\alpha$	f_0	R^2	$-\alpha$	f_0	R^2
A	Sound	5.77	3.04	0.06	1.14	3.0	0.01
B	Sound	0	3.05	-	0	3.05	-
	Dam.	94	2.78	0.7	106	2.8	0.70
C	Dam.	119	2.8	0.8	148	2.83	0.89

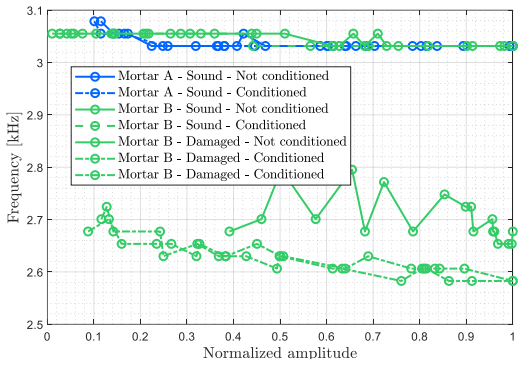

Figure 10. Amplitude vs. frequency curves measured with the FBG for conditioned and unconditioned specimens, with and without damage

Table 4. NIRAS parameters (α and f_0) for the samples A, B and C, between "Not conditioned" and "Conditioned" for one of the FBG sensor

FBG		Not Conditioned			Conditioned		
		$-\alpha$	f_0	R^2	$-\alpha$	f_0	R^2
A	Sound	30.0	3.05	0.37	30.5	3.05	0.38
B	Sound	27	-	0.58	32	3.07	0.77
	Dam.	-	-	-	109	2.68	0.85
C	Dam.	-	-	-	-	-	-

Thanks to the embedded nature of the FBG sensors, it was possible to perform a long-term strain monitoring following the NIRAS impact testing. This second experimental phase involved continuous tracking of the FBG wavelength shift for three days after the initial test. The post-impact wavelength evolution differed significantly between the undamaged and damaged specimens. In the undamaged sample, the wavelength showed a specific temporal trend which correlates with temperature changes, while in the damaged sample, the evolution also followed the temperature changes but with a distinct pattern. This difference can serve as an indicator of two key aspects: the first one the thermal response, since Figure 11 shows that the major wavelength variations coincide with temperature fluctuations; and second one , mechanical relaxation, given that both samples were kept in the same ambient conditions (temperature, humidity, and pressure), allowing the observed trend differences to be attributed to differences of material relaxation dynamics.

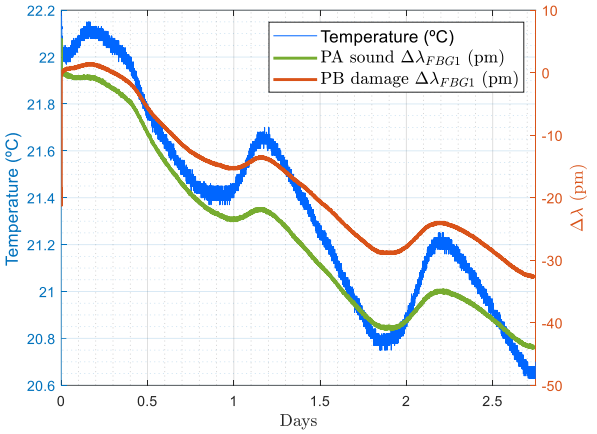

Figure 11. Temperature (blue line), wavelength of sound probe (A) (green line) and wavelength of damaged probe (B) (red line) along several days.

5. CONCLUSIONS

The ability to inspect instrumented specimens, with multiple sensing points along the same fiber, represents a valuable advancement in non-destructive evaluation techniques. The NIRAS technique has proven to be a highly sensitive method for detecting generalized damage. In this study, it was successfully applied to evaluate mortar specimens subjected to thermal shock damage and the comparison between undamaged and damaged samples confirmed the technique's sensitivity.

Furthermore, the study has revealed the presence of a conditioning effect, where specimens exhibit a distinct change in their dynamic response simply as a result of being tested. This was evidenced by systematic differences in the extracted parameters between the first test (non-conditioned state) and subsequent tests (conditioned state). In essence, the material exhibits a form of mechanical memory, which becomes increasingly prominent as damage severity increases.

Two distinct sensing technologies were utilized: traditional piezoelectric accelerometers and embedded fiber Bragg gratings (FBGs). Both demonstrated consistent trends. The accelerometers provided precise results with low variance and high repeatability but required surface attachment. On

the other hand, embedded FBGs, despite being more challenging to measure, allowed for similar results while offering the unique capability of long-term internal monitoring.

Thanks to this capability, the FBG sensors enabled the observation of post-test relaxation behavior, highlighting significant differences in the relaxation dynamics between damaged and undamaged specimens. This suggests that FBGs not only replicate conventional measurements but also provide additional insight into the temporal evolution of mechanical conditioning.

ABSTRACT

The high sensitivity of nonlinear terms in the elastic response of materials to the early appearance of damage has led to the emergence of the so-called NEWS methods (Non-linear Elastic Wave Spectroscopy). These NDE (Non-Destructive Evaluation) methods exploit the increase in the material's nonlinear behaviour as damage increases. In particular, the NIRAS technique (Non-linear Impact Resonance Acoustic Spectroscopy) detects changes in the resonance of a material (frequency, damping factor, etc.) as a function of impact intensity.
In this work, the NIRAS technique was employed to characterize damage in mortar concrete samples embedded with FBG (Fiber Bragg Grating) sensors. The advantage of this technique lies in the fact that these sensors can be integrated during the fabrication process, spatially distributed, share the same optical fiber, and be interrogated remotely.

Keywords: *impact resonance acoustic spectroscopy, thermal shock damage, fiber bragg grating sensors, thermal shock mortar degradation*

1. INTRODUCTION

Geomaterials—such as rocks, sand, soil, and combinations thereof like concrete—are classified within a specific group known as Non-Linear Mesoscopic Elastic (NME) materials [1]. These materials are characterized by their heterogeneous internal makeup, with a complex non-linear response strongly influenced by various microstructural elements, including micro-cracks, grain contacts, and voids. Compared to traditional atomic elastic materials, this response is significantly more pronounced. Due to these unique properties, the non-linear behavior of NME materials cannot be adequately described by Landau's classical non-linear elasticity theory [2].

One of the most effective methodologies for evaluating damage in concrete and other cementitious materials is the non-destructive technique known as Nonlinear Elastic Wave Spectroscopy (NEWS). This method focuses on analyzing various nonlinear phenomena [3], including the generation of higher-order harmonics, wave cross-modulation, shifts in resonance frequency, and amplitude-dependent attenuation. Despite variations in technique, all NEWS approaches share a common goal: to quantify non-linear material behaviors through dynamic responses.

Within the field of NEWS, impact spectroscopy has gained traction due to its straightforward excitation requirements and high sensitivity to non-linear effects. A notable example is the Non-linear Impact Resonance Acoustic Spectroscopy (NIRAS) technique. NIRAS operates by monitoring how the material's resonance frequency varies with different levels of impact force (see Figure 1), providing insights into internal structural changes.

Concrete degradation has been extensively studied over time, with research highlighting that different deterioration mechanisms alter their dynamic properties in distinct ways [4][5]. Concrete exposed to thermal shock (rapid

*Corresponding author: jorgocas@dcom.upv.es

temperature changes) can suffer significant internal damage due to the differential expansion and contraction of its constituent materials. This abrupt thermal gradient induces high tensile stresses, particularly at the interfaces between aggregates and the cement paste, often leading to microcracking, debonding, and eventual loss of mechanical integrity. Repeated thermal shocks can accelerate degradation, reducing stiffness, strength, and durability over time [6]. Investigations have applied NEWS techniques to evaluate thermal shock effects on concrete across various compositions and number of cycles [7][8] and changes in acoustic non-lineartity ybder thermal stress [9][10][11] [12].

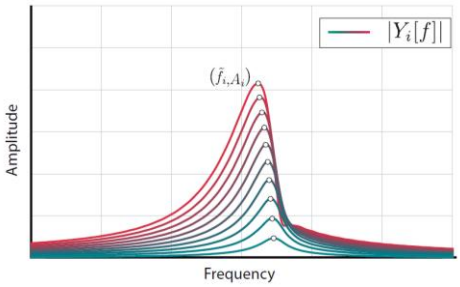

Figure 1. Received frequential response for the different impact levels ($Y_i(f)$)

In this study, the authors focus on the application of the NIRAS technique to evaluate thermal shock damage in mortar specimens, using embedded Fiber Bragg Gratings (FBGs) as sensors during the fabrication process. A key innovation lies in the simultaneous interrogation of multiple spatially separated FBG sensors inscribed along the same optical fiber. The performance of these FBG sensors is compared against that of surface-mounted accelerometers. While accelerometers are effective for measuring acceleration and vibration during impact events, FBGs offer precise strain and displacement measurements. Additionally, FBGs can be embedded within the material for long-term, remote monitoring and allow for the integration of multiple sensing points on a single fiber, enhancing spatial resolution.

2. MATHEMATICAL BACKGROUND

NIRAS is a method used for impact assessment and damage detection and involves impacting the material with different strength levels and analyzing the resulting acoustic frequency responses. The different reverberation signals are denoted by $y_i(t)$ where i denotes the different impacts and $Y_i(f)$ is the Fourier Transform of $y_i(t)$ (Figure 1). The non-linear parameters related to the resonance frequency shift α is obtained from a simple linear regression fit (Figure 2):

$$\frac{\tilde{f}_0 - \tilde{f}_i}{\tilde{f}_0} = \alpha \cdot A_i \quad (1)$$

$$A_i = \max|Y_i(f)| \quad (2)$$

$$\tilde{f}_i = \max_f|Y_i(f)| \quad (3)$$

Where A_i is the is the peak amplitude of the spectrum, $\tilde{f}_i$ is the peak frequency and $\tilde{f}_0$ denotes the intersection with y-axis of the linear relationship between the peak amplitudes A_i (x-axis) and the peak frequencies $\tilde{f}_i$ (y-axis).

The NIRAS technique obtains the parameter α_f^{NIRAS}, among others, as an indicator of the no linear behavior of the material: the greater the damage, the greater the no-linear behavior and the greater α_f^{NIRAS}.

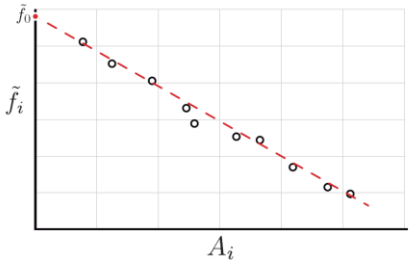

Figure 2. Linear regression from the different resonance signals.

3. EXPERIMENTAL

3.1 Manufacturing and damage induction of mortar specimens

Three mortar specimens (A, B and C) were prepared by mixing Portland cement (EN 197-1-CEM I 52.5 R) [13], sand (quartz) and water in the 1:3:0.5 ratio. After mixing the components, following the procedure described in UNE-EN 196-1 [13], the fresh mortar was placed in a prismatic mold of 50x60x240 mm size. Because prior to pouring the mortar, several optic fibers were settled according to Figure 4. Due to the fragility of the fibers, the mortar was poured in three layers,

avoiding damaging the fibers. For this, the fresh mortar was dropped in a zone free of fiber and then the mold was vibrated (Vibrating Table ToniVIB Tonitechnic) for 30 seconds (vibration frequency 50 Hz, amplitude 1 mm). This procedure was twice repeated and finally the superior part was flattened using a spatula. Additionally, metallic capillary sheath (Figure 3a) was used to protect each optical fiber during the pouring and vibration process and was removed immediately after the surface leveling.

The mold was put in a humid chamber (20 ºC, RH>90%) for 24 hours. After this period, the specimens were carefully demoulded and were covered with a plastic film, to avoid water evaporation. The wrapped specimens were stored in the same humid chamber for 46 days, to complete the hydration of the Portland cement.

After 88 days from mixing the mortar components, two of the specimens were subjected to thermal shock (B and C): the specimens were immersed in hot water (80ºC) for 1 hour and then immediately submerged in cold water (4ºC) for 10 minutes, tank of 0.01 m3.

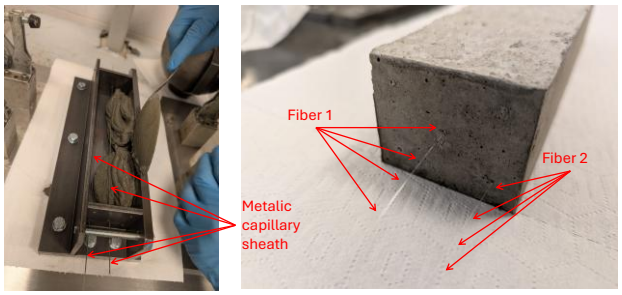

Figure 3. a) Manufacturing process b) Demolded specimen showing the optical fiber emerging from the mortar.

3.2 Embedded Instrumentation

Two of the three specimens (A and B) were internally instrumented during the fabrication process with two optical fibers aligned along the longitudinal axis of the specimen: one positioned at the center and the other near a corner (Figure 4). Each optical fiber contained two integrated Fiber Bragg Gratings (FBGs), which were located at the center and at one end of the fiber.

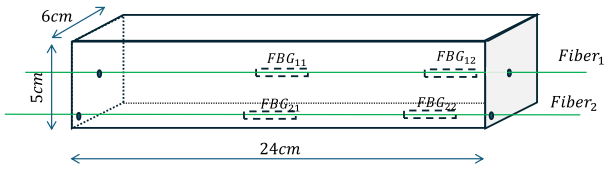

Figure 4. Representación de las fibras embebidas.

The FBGs were primarily tuned to the wavelengths listed in Table 1 and illustrated in Figure 5. Fiber 2 of Mortar A was damaged during the demolding process, therefore no measurements were obtained from this fiber.

Table 1. Wavelengths of the FBGs (nm)

Specimens	$Fiber_1$		$Fiber_2$	
	FBG_{11}	FBG_{12}	FBG_{21}	FBG_{22}
Mortar A	1533.98	1544.05	-	-
Mortar B	1534.07	1543.94	1553.95	1563.80

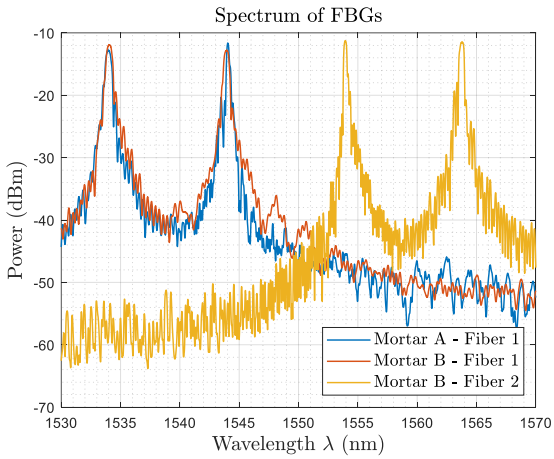

Figure 5. Spectrum of embebed fibers

3.3 Measurement setup

The experimental system employed for the execution of the test comprises three main subsystems: the excitation stage, the sensing stage, and the data acquisition stage.

In the excitation stage, an instrumented hammer was employed to apply controlled impacts to the specimen. The specimen was securely fixed using a custom-designed

support structure. As the hammer remained coupled to the support, multiple measurements could be performed without significant variation in the direction of the impacts, thereby ensuring the repeatability of the excitation conditions.

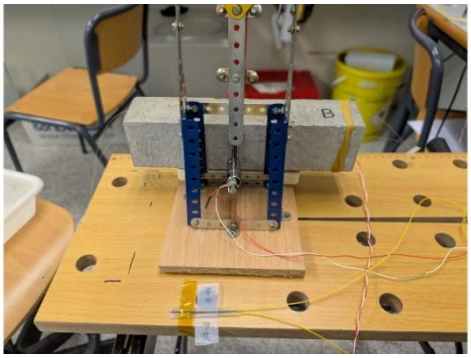

Figure 6. Photograph of the experiment

During the sensing stage, two accelerometers were utilized: one integrated into the instrumented hammer and another attached to the specimen. These devices were employed to record the accelerations induced in both the excitation element (Figure 8 - Column 1) and the tested specimen (Figure 8 - Column 2) . Additionally, two optical fibers were embedded within the specimen. Each fiber contained two Fiber Bragg Gratings (FBGs): one positioned at the center of the embedded section and the other at one of its ends. This configuration enabled the simultaneous monitoring of strain at various critical points of the specimen, with high sensitivity and spatial resolution (Figure 8 - Column 3 and 4). While two optical fibers (fiber 1 and fiber 2) were embedded into the mortar specimens, the present work reports results from only one of them.

The data acquisition stage was performed using two specialized instruments. Accelerometer signals from both the impact hammer and the specimen were recorded using a TiePie HS6 data acquisition system, noted for its high resolution and real-time capture capabilities. For the signals originating from the embedded optical fibers, an optical interrogator manufactured by SENTEA was used. This device features four independent channels and a maximum sampling frequency of 23 kHz. This configuration enabled the simultaneous interrogation of all the Fiber Bragg Gratings (FBGs), with one channel allocated per optical fiber. Each channel allows concurrent reading of multiple FBGs, thereby enabling synchronized acquisition of the two FBGs embedded in each fiber. This is illustrated in Figure 8, where the simultaneous signals from the accelerometers and spatially separated FBGs are plotted.

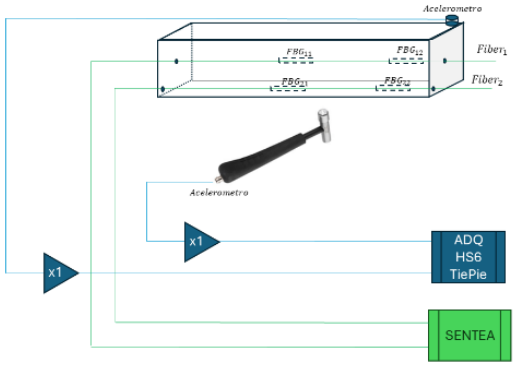

Figure 7. Experimental setup diagram

3.4 Tests description

The tests consisted of applying a series of controlled impacts to the specimen using the instrumented hammer. Each series involved ten consecutive impacts, with increasing force determined by the progressive increase of the striking angle. Upon completion of the first series, the procedure was repeated under similar conditions, applying an additional ten impacts to assess the repeatability of the specimen's dynamic response in its initial (undamaged) state.

As an illustrative example, Figure 8 displays a series of five impacts, showing the signals captured by both the hammer-mounted accelerometer and the surface-mounted accelerometer, as well as the signals recorded by the embedded FBGs in specimen B. The figure clearly shows the proper synchronization and simultaneous acquisition across the different sensor types. The FBG signals exhibit a baseline offset related to the specific wavelength at which each grating is fabricated. This baseline is inherent to the interrogation process itself and this mean value was subtracted from the FBG signals to ensure accurate analysis.

Subsequently, the specimen was subjected to a damage-inducing process via thermal shock. Once its structural properties had been altered, the two-testing series were repeated: ten impacts with the specimen in a non-conditioned state (i.e., without post-damage adjustments), followed by another ten impacts after conditioning. This procedure enabled a comparative analysis of the specimen's

dynamic behavior before and after thermal damage. The experiments are summarized in Table 2.

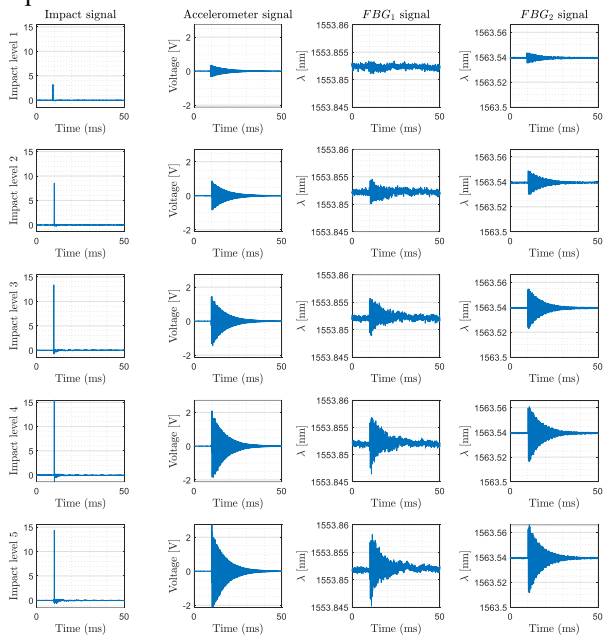

Figure 8. Temporal signals corresponding to different impact levels (displayed in rows) and different sensors (displayed in columns). The signals were acquired from Mortar B - Fiber 2, in its sound state.

Table 2. List of damaged and undamaged mortar samples tested with accelerometers and FBGs.

Sample	Status	Accelerometer	FBG
A	Sound	√	√
	Damage	Reference sample - no damage applied	
B	Sound	√	√
	Damage	√	√
C	Sound	√	No instrumented
	Damage	√	

4. RESULTS

Each experiment comprises ten different impact levels. For each impact signal, a Fourier transform was applied, resulting in a dataset of ten pairs of maximum amplitudes and their corresponding frequencies per experiment.

As an example, Figure 9 presents the normalized amplitudes versus the associated frequencies for specimen B under different conditions (sound and damaged) and using different types of sensors (accelerometers and FBGs). The figure reveals similar trends between the measurements obtained from the accelerometers and the FBGs for the same damage state.

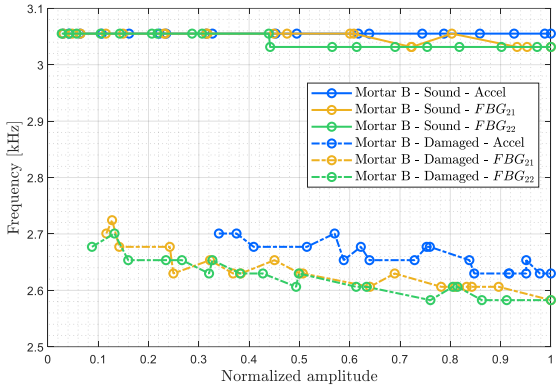

Figure 9. Normalized amplitudes vs frequencies for different conditions (sound and damaged) and different sensor types (accelerometers and embedded sensors FBGs) of specimen B.

From these curves, the NIRAS parameters α_f^{NIRAS} and f_0 were extracted for all the cases, as shown in Table 3. When available, the coefficient of determination R^2 is also reported to assess the goodness of fit. As observed, in the absence of damage, the frequency variation with impact level is negligible, resulting in a very small α parameter as expected for a horizontal line. Additionally, the estimation shows considerable variability, as reflected in the corresponding R^2 values in Table 3.

As damage increases, the nonlinearity in the system's response also increases, which is reflected by a higher α value. In such cases, the linear fit improves significantly. Notably, there is a strong correlation between the results from the accelerometers and the FBG sensors. The advantage of FBGs lies in their ability to accommodate multiple sensing points along the same optical fiber and enable simultaneous interrogation.

In this context, the parameter f_0 serves as a reliable damage indicator because all specimens share the same composition. However, for specimens with different mix proportions (and consequently different f_0 values), the variation in α becomes a more effective indicator of damage presence.

5. CONCLUSIONS

This study highlights the potential of embedded sensor technologies as a reliable and effective approach for structural health monitoring in cement materials. In this case, thermal shock has been applied to mortar samples to generate damaged samples. The results indicate that the obtained values from the embedded Fiber Bragg Gratings (FBGs) sensors are similar to piezoelectric sensors. But embedded sensing systems offer numerous advantages, including real-time monitoring capabilities, high sensitivity to damage evolution, and the possibility of spatial and remote operation over the same optical fiber. Despite these benefits, several challenges remain, including sensor protection during the manufacturing process, ensuring long-term durability of the sensors within harsh environments, and reducing implementation cost.

Overall, embedded sensors represent a promising and evolving solution for advancing the reliability and efficiency of structural health monitoring systems in composite structures.

ABSTRACT

This work deals with the characterization of the adhesion quality and of the adhesive film properties in Titanium/Epoxy adhesive film/3D Composite aeronautical assemblies. Due to the thickness of the adhesive film in the different samples, between 80 µm and 200 µm, the study is carried out with a scanning acoustic microscope (SAM) in pulse-echo mode, at high frequencies (20 and 50 MHz). The difficulties expected and that are challenged are due both to the acoustic impedance contrast between the materials and to the high frequency of the study, which should render the reflected echo at the Epoxy film/Composite undetectable or very low. These conditions mean that the experiment must be carried out carefully and with high accuracy.
Nevertheless, the observation of the low amplitude reflected echo at the adhesive film/Composite interface in the different samples was possible thanks to the good signal-to-noise ratio (SNR) of the experimental set up instrumentation. The properties of the adhesive film are determined using the A-scan method with a planar transducer. Moreover, SAM images are obtained using a focused transducer, confirming the adhesion quantification and providing a fast estimation of the adhesive film thickness.

1. INTRODUCTION

Reducing the weight of aeronautical structures is essential to reduce fuel consumption and emissions. Adhesive bonding, which offers several advantages over traditional methods such as welding or riveting, plays a key role in achieving this weight reduction. Consequently, non-destructive evaluation (NDE) [1, 2] is required to assess the quality of the adhesion in the assemblies. Various NDE techniques are used to detect defects such as porosity or delamination [3]. This study focuses on samples representative of the Leap engine fan blade, provided by Safran Tech, which consists of a titanium alloy TA6V {Ti} bonded to a thick 3D woven Composite {Comp} with a thin layer of Epoxy resin AF191K {Epo} in the range of a hundred microns. The resulting structure is a trilayer stack {Ti/Epo/Comp}. Its properties are given on Table 1. Due to the thickness and properties of the Composite, it is considered as a semi-infinite medium in the frequency range of the study. To achieve effective echo separation, the axial resolution of the selected transducer must be appropriately matched to the adhesive layer thickness, typically ensured by maintaining a sufficient thickness-to-wavelength ratio. As a result, thin adhesive layers require a transducer with a center frequency in the tens of MHz range. Until now, obtaining reliable information on adhesion levels has been challenging, as it is highly dependent on the adhesive thickness and on the acoustic impedance ratios. The difficulty in performing ultrasonic evaluations with a favorable signal-to-noise ratio stems from the significant acoustic impedance contrast between TA6V and the Epoxy resin, and the relatively low contrast between the Epoxy resin and the Composite. This contrast, together with the attenuation introduced by the high frequency of the study, make the detection of the reflected echo at the Epoxy/Composite interface particularly

challenging. It is therefore crucial to find a balance: a frequency high enough to match the wavelength to the adhesive's thickness, but not too high (as the attenuation increases with the frequency) to detect background echoes, particularly the background echo at the Adhesive/Composite interface, with a sufficiently exploitable amplitude. The theoretical energy reflection and transmission coefficients for each interface in the assembly at normal incidence are as follows:

R_1 and T_1 (eq. (1)) correspond to the {Water/Ti} interface, R_2 and T_2 (eq. (2)) to the {Ti/Epoxy} interface, and finally R_3 and T_3 (eq. (3)) to the {Epo/Comp} interface.

$$\begin{cases} R_1 = \left(\dfrac{Z_{Ti} - Z_{Water}}{Z_{Ti} + Z_{Water}} \right)^2 \approx 0.8025 \\ T_1 = \dfrac{4 Z_{Ti} Z_{Water}}{\left(Z_{Ti} + Z_{Water} \right)^2} \approx 0.1975 \end{cases} \quad (1)$$

$$\begin{cases} R_2 = \left(\dfrac{Z_{Epo} - Z_{Ti}}{Z_{Epo} + Z_{Ti}} \right)^2 \approx 0.6393 \\ T_2 = \dfrac{4 Z_{Epo} Z_{Ti}}{\left(Z_{Epo} + Z_{Ti} \right)^2} \approx 0.3607 \end{cases} \quad (2)$$

$$\begin{cases} R_3 = \left(\dfrac{Z_{Comp} - Z_{Epo}}{Z_{Comp} + Z_{Epo}} \right)^2 \approx 0.0452 \\ T_3 = \dfrac{4 Z_{Comp} Z_{Epo}}{\left(Z_{Comp} + Z_{Epo} \right)^2} \approx 0.9548 \end{cases} \quad (3)$$

At the {Water/Ti} interface, approximately 80.25% of the energy is reflected, and only 19.75% is transmitted to the Ti layer. At the {Ti/Epo} interface, 63.93% of T_1 is reflected due to the significant impedance contrast between the two materials, while only 4.52% of the product T_1T_2 is reflected at the {Epo/Comp} interface. As a result, very small quantity of energy reaches the {Epo/Comp} interface, and then the reflection at the {Epo/Comp} interface is very weak due to the low impedance contrast between Epoxy and Composite.

2. EXPERIMENT

2.1 Studied samples

The samples studied are representative of the Leap engine fan blade and were provided by Safran Tech. They consist of three materials: a titanium alloy TA6V {Ti} bonded to a thick 3D woven Composite {Comp} using an Epoxy resin AF191K {Epo}. The Epoxy bonding process involves cleaning the interfaces with ethanol. Strips of the chosen material and specific thickness are then placed along the edges of the surfaces between the two materials to control the Epoxy layer thickness and prevent adhesive leakage during polymerization [1]. The polymerization process is carried out in a pressure-controlled oven, where four calibrated spring clamps apply a constant force of 65 N. Under standard conditions, the bonded sample is fully polymerized at 150°C for 3 h [1]. The adhesive thickness was estimated by in a first-hand simply by measuring the entire assembly with a caliper and subtracting the thickness of the titanium alloy and the Composite, as these are relatively thick. The parameters of the samples are given in Table 1, as supplied by the manufacturer.

Table 1. Properties of the studied trilayer assemblies.

Layer	TA6V	Epoxy	Composite
ρ [kg/m^3]	4430	1300	1590
E [GPa]	113	5.12	10.5
ν	0.34	0.30	0.29
c_L [m/s]	6060	2300	2920
c_T [m/s]	3120	1230	1600
h [µm]	180	80 to 200	13600

ρ [kg/m^3]: density; E [GPa]: Young's modulus; ν: Poisson's ratio; c_L [m/s]: Longitudinal wave velocity; c_T [m/s]: Transversal wave velocity; h [µm]: layer thickness.

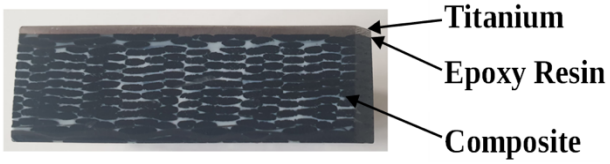

Figure 1. Cross-section view of the studied trilayer.

2.2 Scanning Acoustic Microscope (SAM)

The experimental study uses the PVA TEPLA Scanning Acoustic Microscope (SAM 301 - pulse-echo mode), which is based on the reflection of acoustic waves at interfaces due to changes in acoustic impedance. It is a sequential representation system in which a piezoelectric transducer emits a beam of ultrasonic waves which propagate through a coupling liquid, which is water in this case. The beam is scattered by the sample, and the signal is received by the same transducer [4, 5, 6]. As shown in Figure 2, the SAM consists of three main functional units: the acoustic sensor,

the electronic unit, the mechanical scanning system, and the display unit [7].

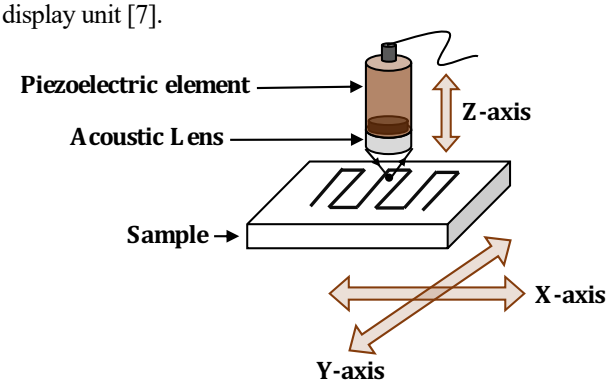

Figure 2. Scanning axes of the SAM.

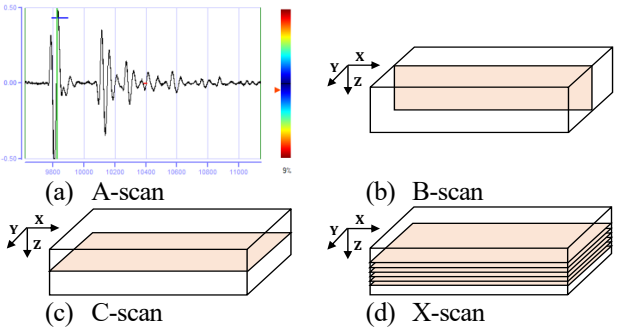

Figure 3. Types of scans for the visualization of ultrasound signals.

It also provides a variety of imaging options, as shown in Figure 3. Different types of scans are available, each offering a unique method of visualizing and assessing the material under examination. The four most commonly used scan types with SAM are A-scan, B-scan, C-scan, and X-scan [8].

3. CHARACTERISATION OF THE SAMPLES

Using the planar and focusing transducers available in the laboratory, background echoes from the adhesive were observed in samples with an Epoxy film thickness of less than 200 µm. This observation aligns with the fact that the adhesive is highly attenuating, and the energy of the echo at the Epoxy-Composite interface decreases with increasing Epoxy thickness. In this study, two samples with significant differences in the Epoxy film are examined: Sample 1 has a significantly thicker Epoxy film compared to Sample 2, as shown in Table 2.

3.1 Axial resolution consideration

The axial resolution (eq. 4) of the selected transducer must be adequate in relation to the thickness of the adhesive film being measured. This requirement is often expressed in terms of the thickness-to-wavelength ratio, which must be sufficient to allow effective echo separation. For a Gaussian echo envelope, the axial resolution is given by [9, 10]:

$$\Delta z_6 = \frac{t_6}{2T_0}\lambda_0 \approx \frac{0.88}{BW_{6,r}}\lambda_0 \qquad (4)$$

where Δz_6, t_6 and $BW_{6,r}$, represent respectively the axial resolution along the propagation axis, the round-trip signal duration, and the bandwidth at −6 dB, λ_0 and T_0 are the wavelength and the time period associated with the center frequency f_0. Consequently, the center frequency f_0 can be chosen so as to satisfy the following criterion:

$$f_0 \geq \frac{0.88}{BW_{6,r}} \max_{1\leq n\leq 3}\left\{\frac{c_{L,n}}{h_n}\right\} \qquad (5)$$

where $c_{L,n}$ is the longitudinal wave velocity and h_n is the thickness of the considered layer indexed n. In the studied case, with an estimated relative bandwidth of the transducer around $BW_{6,r} = 50\%$, the theoretical axial resolution limit at −6 dB is $\Delta z_6 = 1.76\ \lambda_0$. Thus, taking into account the thin adhesive layer into consideration, with a wave velocity of 2300 m/s in the Epoxy and a minimum thickness of 80 µm, eq. (5) gives a minimum center frequency f_0 of the transducer at 50 MHz.

A-scan characterizations are therefore performed using a planar transducer (Olympus V358-SU, SN: 1466080) with a center frequency of 50 MHz. As a result of eq. (4), the axial resolution of the system at 50 MHz is estimated at $\Delta z_6 \approx 81$ µm in the Epoxy layer. As an illustration, Figure 4 shows the A-scans obtained on samples 1 and 2.

3.2 A-scan

As a preliminary step, the caliper measurements of the thicknesses of the three constitutive layers are summarized in the following Table 2:

Table 2. Caliper measurements of thicknesses [µm].

Sample	TA6V	Epoxy	Composite
1	994	135	13540
2	981	86	13610

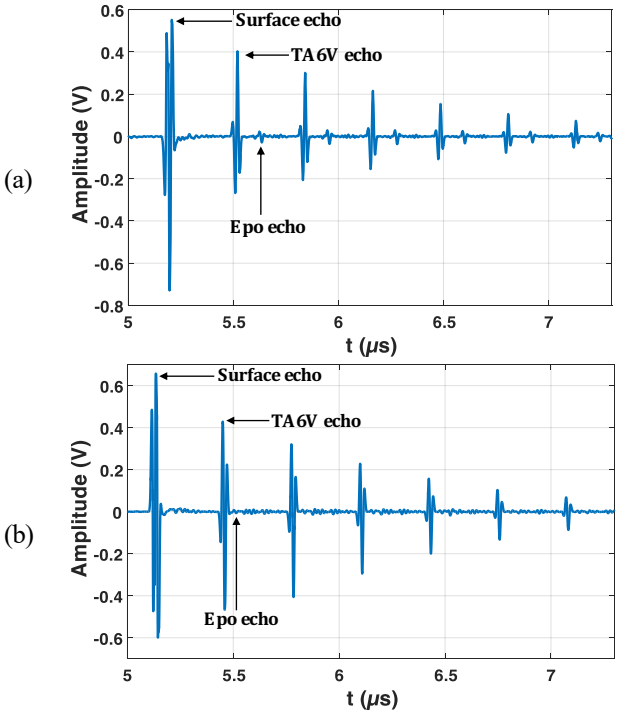

Figure 4. A-scan for 50 MHz center frequency excitation.: (a) Sample 1 and (b) Sample 2.

Upon examining the obtained signals in Fig.4, it can be observed: the echo reflected at the {Water/T} interface (first interface) labelled "Surface echo"; the echo reflected at the {Ti/Epo} film interface (second interface) labelled "TA6V echo"; a very small reflected echo at the {Epo/Comp} interface (third interface) labelled "Epo echo". Then are following periodically delayed multiple reflections from the TA6V layer, *i.e.* the {Ti/Epo} interface (second interface), as well as the associated small echoes from the {Epo/Comp} interface (third interface). The thickness of the adhesive film is then deduced by evaluating the time-of-flight between the background echo of TA6V (labelled "TA6V echo" on Fig.4) and the background echo of the Epoxy resin (labelled "Epo echo" on Fig.4), corresponding to the wave path within the Epoxy resin.

3.3 Determination of the Epoxy film thickness

This time-of-flight is estimated using the cross-correlation [11] between the Hilbert transform (HT) of the considered echoes indexed $n = \{1, 2\}$. The cross-correlation $cor_{e1,e2}(t)$ results from an integral between the envelopes $e_1(t)$ and $e_2(t)$ of the considered echoes $s_1(t)$ and $s_2(t)$, respectively:

$$cor_{e1,e2}(t) = \int_{-\infty}^{+\infty} e_1(\tau).e_2(t-\tau).d\tau \qquad (6)$$

with $$e_n(t) = \left|s_n(t) + i.HT\{s_n(t)\}\right| \qquad (7)$$

This envelope calculation (eq. 7) requires to pay a special attention of the studied echoes, as well as careful identification of the cutting boundaries of the echoes and a smooth windowing. The cross-correlation (eq. 6) shows a maximum at the date Δt_{max} which corresponds to the time-of-flight between the considered echoes $e_1(t)$ and $e_2(t)$.

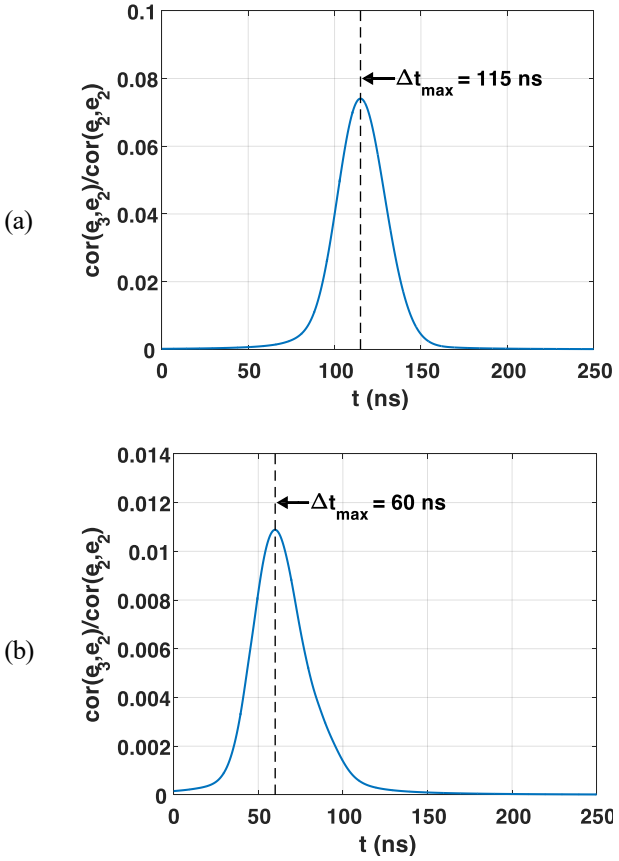

Figure 5. Cross-correlation of the Hilbert envelopes of the considered echoes of TA6V and Epoxy layers: (a) Sample 1 and (b) Sample 2.

As shown in Fig. 5, the calculated cross-correlation (eq. 6) of the Hilbert transform envelopes (eq. 7) of the relevant echoes, gives an evaluated cross-correlation time-of-flight Δt_{max} at 115 and 60 ns for samples 1 and 2, respectively. The thickness of the adhesive layer (Epoxy layer) is therefore estimated from the time-of-flight relationship: $e_{Epoxy} = c_L \times \Delta t_{max}/2$, giving in 132 µm and 69 µm for samples 1 and 2, respectively. These measurements are more accurate and more relevant than the subtraction estimation given in Table 2.

3.4 Hypothesis on the quality of the adhesion

Knowing that the samples were assembled with an Epoxy resin cured under the same conditions, it induces the same attenuation in the adhesive film. It can be seen that the background echo at the {Epo/Comp} interface is significantly higher for the thicker sample (sample 1, 132 µm), whereas the background echo at the {Ti/Epo} interface is almost the same for both samples. This amplitude difference between the two samples is assumed to be related to the quality of the adhesion at the {Epo/Comp} interface: a low level of adhesion in sample 1 leads to low transmission into the Composite and a high reflected echo, whereas a high level of adhesion in sample 2 results in higher transmission into the Composite and a lower reflected echo, as observed for this second sample. A series of C-scans, *i.e.* X-scans (Figure 3), are then performed to confirm this assumption.

3.5 X-scan

Using a 20 MHz focusing transducer, an X-scan is initiated to obtain 2D images (C-scans) reflecting the subsurface condition. Initially, it is essential to configure the experimental conditions, including setting the correct focal distance (with a fixed focus on the Epoxy background echo), calibration, and establishing the protocol for horizontal adjustment. The result will be C-scans at different depths within the sample. In addition, the focus was set on the Epoxy/Composite interface.

For all X-scan in this study, the gate size of each C-scan is 20 ns, corresponding to a distance of 23 µm in the Epoxy and 29.2 µm in the Composite. The axial resolution of the system at 20 MHz is 202 µm in the Epoxy.

A data window was selected and then divided into C-scan windows of 20 ns each. The scan area is 2 cm × 1.5 cm^2 with a pixel resolution of 200 µm/Pixel for sample 1 and 2×2 cm^2, with a pixel resolution of 100 µm/Pixel for Sample 2.

Analysing the images resulting from the X-scan starting from the TA6V-Epoxy interface (Figure 6a) for Sample 1, uniform colours are observed over most of the image, with some contrast at the edges, possibly indicating a slight misalignment of the sample. This colour homogeneity suggests that the medium remains unchanged, meaning we are still within the Epoxy layer. As we progress through the images, we reach C-scan n°7 where we can confirm the transition from the Epoxy to the Composite layer by the presence of carbon fibre bundles. By measuring the time shift between C-scan n°1 and C-scan n°7, corresponding to six windows of 20 ns each, the thickness of the Epoxy layer can be estimated as follows: $e_{epoxy} = 6 \times 23 = 138$ µm.

For Sample 2 (Figure 6b), a similar pattern is observed. The image shows a uniform color distribution, indicating that we are still within the Epoxy layer. As we analyze the successive images, C-scan n°4 shows the presence of carbon fibre bundles in light blue, mixed with the Epoxy in dark blue. This marks the transition from the Epoxy layer to the Composite zone, as the fiber bundles become clearly visible across several image windows. The thickness of the Epoxy layer is then estimated from the time shift between C-scan n°1 and C-scan n°4, corresponding to three windows of 20 ns each: $e_{Epoxy} = 3 \times 23 = 69$ µm.

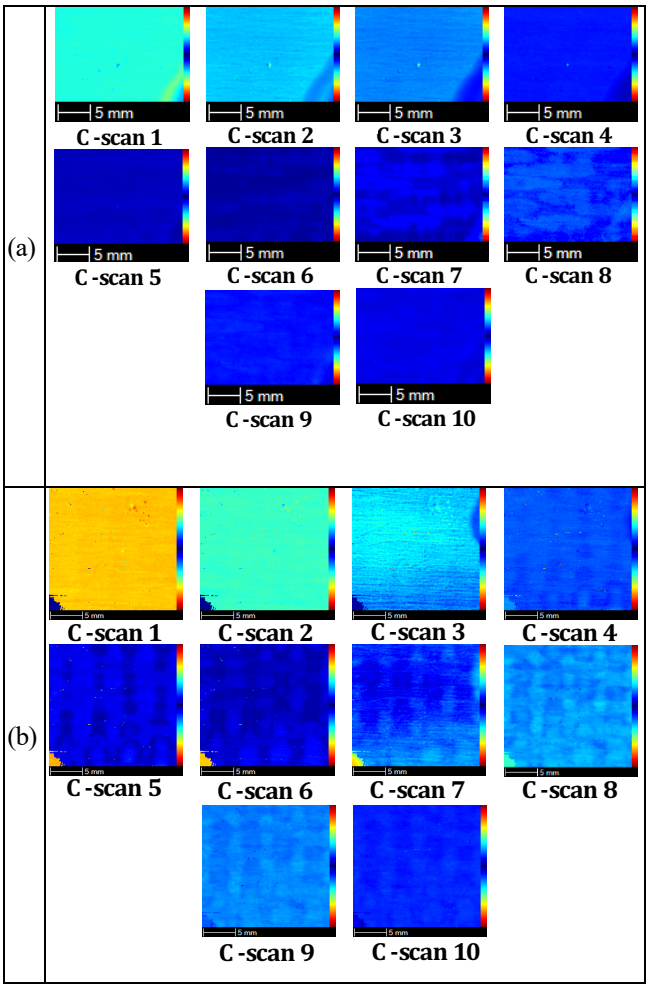

Figure 6. X-scan starting from the TA6V/Epoxy interface: (a) Sample 1 and (b) Sample 2.

Table 3 summarizes the measured thickness of the adhesive film by the three methods: the basic measure by the calipper, by X-Scan and A-Scan.

Table 3. Epoxy film thickness [µm] according to measurement method.

Method	Sample 1	Sample 2
Calliper	135	86
X-scan	138	69
A-scan	132	69

The A-scan measurement estimates it to be 132 µm, while the X-scan imaging gives a thickness of 138 µm. For sample 2, both methods give a thickness of 69 µm for the Epoxy layer. The A-scan method is the most accurate, but the X-scan can provide a quick estimate of the thickness of the Epoxy, although it is highly dependent on the time gate size and its initial starting position.

As shown in Figure 6, in terms of bond quality, the Composite is detected in several X-scan imaging windows of the same duration (20 ns): in sample 2 (spanning six C-scan windows, from C-scan n°4 to n°9). In contrast, it appears in only two X-scan imaging windows for sample 1 (C-scans n°7 and n°8) and is less distinct. These observations show how the transmitted echoes propagate through the Composite and allow the carbon fibers to be distinguished from the Epoxy. The number of detected C-scan images, which reflects the depth of the signal penetration into the Composite, confirms that the adhesion is stronger in Sample 2 than in Sample 1.

4. DISCUSSION

Initially, several samples with different adhesive film thicknesses were tested using either planar or focused transducers. Pulse-echo measurements showed that only samples with an adhesive film thickness of less than 200 µm exhibited round-trip echoes. This finding is consistent with the fact that the adhesive is highly attenuating, causing a further reduction in the energy reaching the {Epo/Comp} interface as its thickness increases. Two samples made of the studied trilayer structure {Ti/Epo/Comp} have been studied (see Table 2).

Accurate precise measurement of the Epoxy film thickness is essential to ensure the mechanical properties of the adhesive. In practice, strips of material placed on the edges of the surfaces between the two materials during the bonding process allow the thickness to be controlled. However, this thickness can change during polymerization. Therefore, the thickness measurement after the bonding operation is only an estimate that must be validated by acoustic methods. The measurement of the Epoxy film thickness for Sample 1 was 132 µm with the A-scan compared to 138 µm with the X-scan. However, for Sample 2, the thickness is 69 µm with A-scan and 69 µm with X-scan, compared to an estimate of 86 µm, indicating that the estimate is inaccurate and that the thickness to be taken into account is that obtained by acoustic method.

In terms of adhesion quality and comparing the results of the two samples, it can be seen that for Sample 2, with an Epoxy film thickness of 69 µm, the background echo amplitude is low. Conversely, for Sample 1, with an Epoxy film thickness of 132 µm, approximately double of that of Sample 2, the background echo amplitude is significant. This difference in amplitude cannot be attributed to the attenuation due to the viscosity of the adhesive but rather to interface conditions. This leads to the hypothesis that the adhesion quality of sample 2 is better than that of sample 1, the cohesive properties of the adhesive being identical.

In X-scan imaging, the Composite fibers are visible in several C-scan windows of the same duration (20 ns). For sample 2, the Composite fibers can be observed in 6 consecutive C-scan windows, whereas for sample 1, they are less visible, appearing in only 2 C-scan windows. This can be interpreted as a better energy transmission from the adhesive film to the Composite, suggesting a degraded adhesion quality in sample 1 compared to sample 2. These observations highlight the energy transmission within the Composite and allow the differentiation of the carbon fibers, with different levels of clarity in the different windows. As a result, the X-scan imaging supports the hypotheses derived from the A-scan analysis regarding adhesion quality.

Thus, regarding the background echo amplitude of the Epoxy film which depends on the {Epo/Comp} interface and the related adhesion quality, it can be concluded that the adhesion quality of Sample 2 is better than that of Sample 1.

5. CONCLUSION

The challenge of the ultrasound investigation lies in the very contrasting impedance discontinuities in the studied trilayer {Ti/Epo/Comp} structure: strong between the titanium and the adhesive, and weak between the adhesive and the Composite. These samples were characterized using the scanning acoustic microscope PVA TEPLA SAM 301. One of the objectives was to evaluate the thickness of the Epoxy film. Quantification using X-scan imaging was also carried out to obtain different C-scans in depth, particularly

from the Epoxy to the Composite, allowing the thickness of the epoxy film to be measured by imaging. The different levels of adhesion in the samples were identified by analyzing the background echo of the Epoxy film relative to its thickness, and by examining the amount of energy transmitted to the Composite layer through the X-scan imaging.

6. ACKNOWLEDGMENTS

ABSTRACT

Layer on substrate structures are often subject to various types of defects, particularly those resulting from manufacturing process during thin-film growth. Currently, one method of inspecting such structures involves the use of IDT transducers for excitation and laser vibrometry for reception. In this work, we propose a complementary approach inspired by passive noise correlation imaging methods initially developed in geophysics. This technique is applied here to image layered structures on substrates by exploiting the correlation of diffuse acoustic waves and the associated principle of passive Green's function reconstruction, enabling the detection and imaging of defects. The analysis was performed using numerical simulations and preliminary experiments on silicon wafers (3 mm thick). IDTs (10-25) MHz were used to generate surface waves, and the resulting displacement field was captured using laser vibrometry. Simulations and measurements were carried out on both defect-free and defect-containing cases. Correlation matrices were calculated on Full Matrix Capture mode. Finally, a beamforming algorithm was applied to localize defects, taking into account silicon's anisotropy.

1. INTRODUCTION

Layer-On-Substrate (LOS) structures are subject to numerous degradations related to: manufacturing defects during thin film growth (thickness gradient), the quality of layer adhesion to the substrate (surface roughness), cracks, and delaminations. For these reasons, the microelectronics industry is increasingly interested in non-destructive evaluation methods, particularly for characterizing bonding quality in wafer assemblies. The work presented here proposes an alternative method based on the correlation of diffuse surface acoustic waves generated by inter-digital transducers (IDTs) operating in the frequency band between 10 and 25 MHz.

Typically, LOS characterization using IDT is performed by emitting a short (broadband) pulse onto the sample to be inspected, whose vibrational displacement amplitudes are then measured by a laser vibrometer. At high frequencies, this procedure must be performed with high precision, making automation a challenge. This so-called active method has yielded very promising results for the characterization of thin layers such as sol-gels [1, 2].

Meanwhile, the acoustic field correlation approach, initially used in geophysical applications [3–6] or in underwater acoustics [7–9], provides a relevant theoretical basis for the passive reconstruction of the medium's impulse response known as the Green's function (GF). Generally, GF estimation by noise correlation is based on the principle that waves emitted by random noise sources, when recorded at two points in the medium, can be used to retrieve the impulse response of the medium between these points sensing. In other words, the cross-correlation $C_{AB}(t)$ of the signals recorded at these two points A and B makes it possible to reconstruct the impulse response of the medium :

$$\frac{\partial}{\partial t} C_{AB}(t) = K\,[G_{AB}(t) - G_{AB}(-t)] + n_{AB}(t) \quad (1)$$

where C_{AB} is the cross-correlation between points A and B of the medium, G_{AB} is the Green's function (GF) between the same points, K is a constant depending on the

properties of the medium and the noise source, and n_{AB} is the residual error of the GF reconstruction.

This method is particularly useful in situations where it is difficult to generate controlled signals, such as in seismology, aeronautics, etc. However, the reconstruction quality is particularly influenced by the way the sources are distributed (localized or not), the number of sources, and the nature of the medium (absorption, attenuation, scattering, reverberation) [10]. In NDT/SHM, this method has been successfully validated at low frequencies (10, 30) kHz (Lamb waves) on aluminum damaged plates (cracks, holes, etc.) [11, 12].

In this work, we propose to extend this method to high frequencies (5-25) MHz by exploiting surface waves to probe microstructures (silicon wafers). Although complex (due to anisotropy), we first propose a simple numerical study to validate the approach on an anisotropic medium, and then it was attempted experimentally by developing suitable instrumentation using IDTs. Although promising, IDTs have rather poor reception capabilities; we therefore propose to use them here as a source of diffuse surface acoustic waves. IDTs are fabricated to focus the energy of surface acoustic waves onto the entire wafer [13]. To take full advantage of this method, optical detection is used and correlation functions are calculated. Figure 1 illustrates this principle.

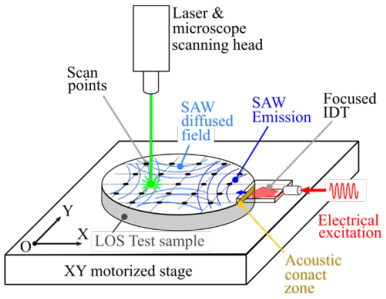

Figure 1. Schematic representation of the proposed characterization method based on the diffuse acoustic wave correlation.

The paper is divided into three parts: Section (1) is dedicated to the imaging in silicon (100); Section (2) is dedicated to numerical validation; and Section (3) is dedicated to the development of the instrumentation and preliminary tests on the GF reconstruction. Finally, a conclusion and perspectives.

2. IMAGING IN ANISOTROPIC MEDIA USING SURFACE WAVES

2.1 SAW propgation in Silicon (100)

Surface Acoustic Waves (SAW) propagate parallel to the surface of an elastic material, and their amplitude decreases rapidly, often exponentially, through the depth of the material. The penetration depth is of the order of the wavelength, providing high sensitivity to surface defects, voids, cracks, coatings, films, and nano/microparticles adhering to the surface. These waves are currently attracting increasing interest, particularly for miniaturization aspects. However, the acoustic propagation of these waves in anisotropic media is complex, where velocities depend on the propagation direction. Several theoretical studies [14, 15] are devoted to determining an analytical formulation of velocity profiles in anisotropic materials. In this paper, the velocities are calculated numerically using the analytical equation proposed by Teransako et al. [16].

On can recall here the Hooke's law extended to anisotropic materials using a tensor formulation that includes orientation:

$$\sigma_{ij} = c_{ijkl}\,\epsilon_{kl}; \quad i,j,k,l = 1,2,3 \tag{2}$$

where σ and ϵ are the stress and strain tensors.

The general case of a fourth-rank tensor requires 81 terms. By exploiting the cubic symmetry properties (silicon (100) has a face-centered diamond cubic crystallographic structure), the anisotropic properties of a cubic crystal can be described with a 6×6 matrix using a simplified tensor notation, which requires only three independent values: $c_{11} = 165.7$ GPa, $c_{12} = 63.9$ GPa, and $c_{44} = 79.56$ GPa.

The physical properties of silicon (100) are: Poisson's ratio $\nu = \frac{c_{12}}{c_{11}+c_{12}} = 0.278$; Young's modulus $E = c_{11} - 2\nu c_{12} = 130$ GPa; density $\rho = 2330$ kg/m^3; and the Zener coefficient $Z = \frac{2c_{44}}{c_{11}-c_{12}} = 1.56$.

In our case, the material under test is considered as a semi-infinite volume. Fig. 2 shows the estimated speed profile.

Two modes are observed for surface waves (regular mode and pseudo-mode) over a velocity range of 4500 to 5500 m/s.

In the following subsection, to perform defect imaging, an interpolation was performed on the two observed modes.

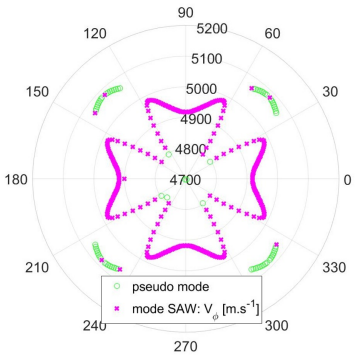

Figure 2. Theoretical (background) and experimental (red dots) velocity profiles.

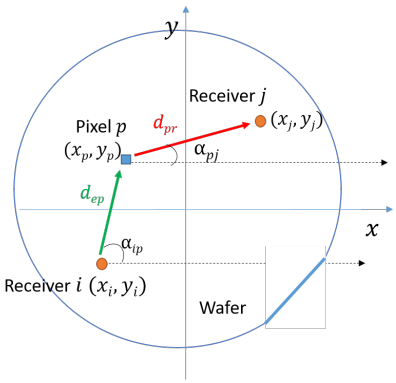

Figure 3. Illustration of the beamforming algorithm in anisotropic medium (backpropagation).

2.2 Imaging in anisotropic material

Considering two receivers R_i and R_j, the cross-correlation of the recorded signals across N_s noise sources can be expressed as follows:

$$C_{ijN_{Ns}}(\omega) = N_s\, D_{ij}(\omega) + n_{ijN_s}(\omega) \tag{3}$$

where D_{ij} represents a deterministic term containing the causal and anti-causal parts of the Green's function between the two receiver positions, and n_{ijN_s} is a term related to the residual noise from the reconstruction of the Green's function. As in [17], we adopt the differential beamforming algorithm to extract the defect signature, i.e., $\Delta\mathbf{C} = \mathbf{C}^{def} - \mathbf{C}^{ref}$, where "def" and "ref" refer to the cases with and without defects, respectively.

The principle consists of taking the image element index (i,j) of the matrix $\Delta\varphi$ and backpropagating it according to the current position of the pixel (x_p, y_p) and for each propagation direction (see Fig. 3). Concretely, this consists of multiplying the differential matrix by a phase function involving the wave number k depending on the surface wave direction, i.e.

$$bpf_{(}x_p, y_p)(\omega) = \sum_{i=1,\, j=1}^{N,N} \Delta\mathbf{C_{ij}}(\omega)\, e^{[+j\, k(\omega,\alpha_{ip})\, d_{ip} + k(\omega,\alpha_{pj})\, d_{pj}]} \tag{4}$$

with $\alpha_{ip} = atan\left|\frac{y_p - y_i}{x_p - x_i}\right|$ and $\alpha_{pj} = \arctan\left|\frac{y_j - y_p}{x_j - x_p}\right|$. The terms d_{ip} and d_{pj} are the distances from receiver i to pixel and from pixel to receiver j, respectively.

After returning to the time domain using an inverse Fourier transform, the pixel intensity is obtained by summing the resulting waveforms for each index value $(i,\, j)$ and calculating the energy of this sum over a time window T_0 (typically the inverse of the bandwidth):

$$I(x,y) = \int_0^{T_0} [bpf_{(x_p,y_p)}(t)]^2, dt, \tag{5}$$

where $bpf(t)$ is the FT of $bpf(\omega)$.

For pixels located on the defect, this amounts to a constructive sum and therefore to a maximum intensity at the defect position.

In Section 3, a numerical validation was proposed.

3. NUMERICAL VALIDATION

To validate the imaging algorithm proposed for anisotropic media, a simplified numerical simulation is proposed.

We consider the propagation of surface waves in an infinite plate without absorption. In the frequency domain, this propagation between a source and a receiver R_i at positions $\vec{r_s}$ and $\vec{r_i}$, respectively, can be modeled in the far field using the propagation function defined as follows:

$$P(\vec{r_s}, \vec{r_i}, \omega) = \frac{1}{\sqrt{(\vec{r_s} - \vec{r_i})}}\, e^{[-j\, k(\omega,\alpha_{ip})\, d_{ip} + k(\omega,\alpha_{pj})\, d_{pj}.]} \tag{6}$$

Therefore, the signal received at R_i can be expressed as follows:

$$u(\vec{r_s}, \vec{r_i}, \omega) = P(\vec{r_s}, \vec{r_i}, \omega)\, u_e(\omega), \quad (7)$$

where $u_e(\omega)$ is the Fourier transform of the transmitted signal.

In the presence of a defect, the signal received at R_i can be written as follows:

$$u_d(\vec{r_s}, \vec{r_i}, \omega) = u(\vec{r_s}, \vec{r_i}, \omega) + \Delta u(\vec{r_s}, \vec{r_i}, \omega), \quad (8)$$

with $\Delta u(\omega) = f_d(\omega)\, P(\omega)\, u(\omega)$. Here f_d represents the defect scattering amplitude and $\vec{r_d}$ is the defect position.

Using the inverse Fourier transform, we return to the time domain to obtain the signals $u_d(t)$ and $u(t)$ received by R_i in both cases: with and without a defect, respectively.

The tested configuration consists of an infinite silicon wafer whose properties are implicitly introduced in the previously estimated dispersion curves. Twelve receivers (crosses) are placed at known positions on its surface. The origin is taken at the low left corner of the wafer. At the center of the imaging array, a defect is modeled by a point scatterer of constant f_d (isotropic scatterer). A set of 361 sources (red dots) are randomly distributed around the receivers.

The transmission signal is a sinusoidal cycle weighted by a Hanning window at a center frequency of 7 MHz. The sampling rate is 300 MS/s. The signals are acquired for 28 μs. For each pair of receivers, the summed cross-correlation across all sources is calculated. The back-propagation-based imaging algorithm discussed above is then applied to the positive-time correlations. The localization image obtained for an area of (45 $\times$ 45) cm2 around the defect is shown in Fig. 4 for active and passive cases.

Pixel intensities are normalized relative to the maximum intensity. As observed, the defect location is correctly localized in passive mode compared to active result.

In what follows, we propose a suitable instrumentation to validate these numerical results.

4. EXPERIMENTAL VALIDATION: ESTIMATION OF GREEN'S FUNCTIONS

Here, we initially focused on studying correlation functions in a "defect-free" case. The experiments were performed on a silicon wafer of 7 cm in diameter and 2 mm thick. Surface acoustic waves were generated using a 7 to 25 MHz IDT transducer designed for this study [13], oriented at 45 degrees to favor the radiation of Rayleigh waves and minimize their conversion into bulk waves radiating into the substrate (cf Fig. 5). Since the transducer aperture is approximately 2 mm, the measurement points were chosen within the IDT's radiation zone. The measurement step size was approximately 10 mm, and a measurement grid of N = 25 points was created. Each Ascan is averaged 350 times and recorded over 2 ms. This corresponds to approximately 1000 times the reverberation time in the wafer.

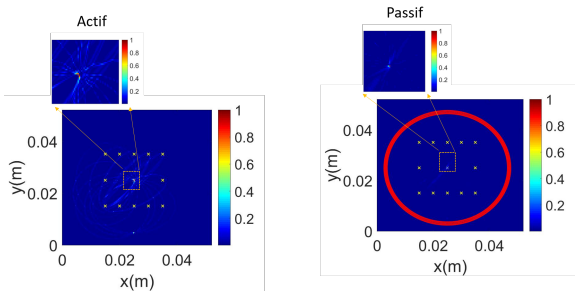

Figure 4. Defect localization image in active (raw signals in FMC mode) and passive (correlation functions, red circles indicate source positions) configurations.

The correlation functions are then calculated, and we obtain N$\times$ N impulse responses. Figure 6 shows a seismogram of cross-correlations between measurement point 3 of the grid and the other points on the same line.

As can be seen, the correlation functions are not symmetrical at zero. This demonstrates poor reconstruction quality of the Green's function (generally, when the correlation function is symmetrical between positive and negative times, it is a good indicator of convergence towards the Green's function). This can be explained by the fact that surface waves are not sufficiently reverberant at these operating frequencies. Another phenomenon may also occur, such as the conversion of surface wave modes into bulk waves. This work is in progress.

5. CONCLUSION

In conclusion, this study has shown the interest of the passive approach by correlation of diffuse waves to image silicon wafers. The results obtained by the numerical simulation are promising and have allowed to validate the

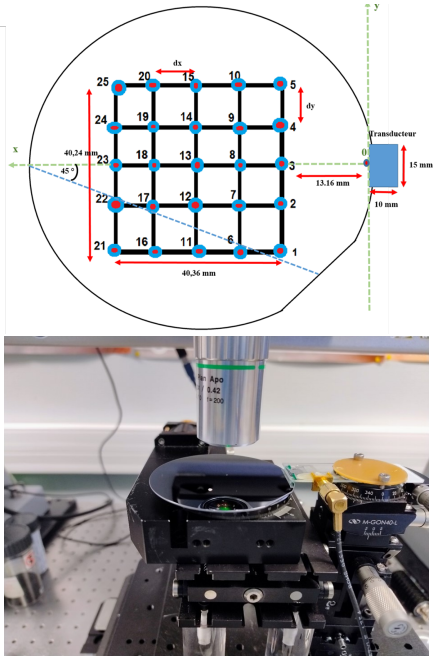

Figure 5. Experimental setup.

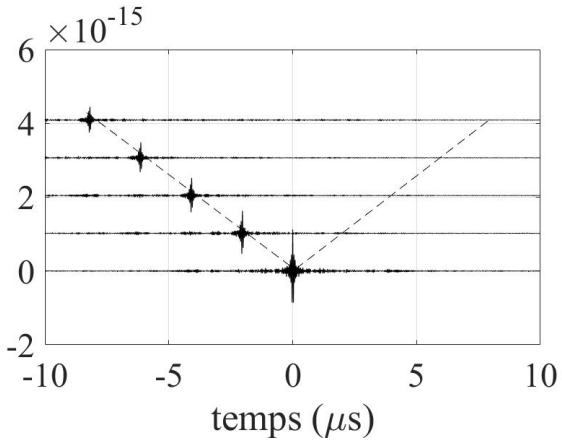

Figure 6. Seismogram of cross-correlations between measurement point 3 and the other points on the same line (see Fig. 5).

imaging algorithm in anisotropic medium. An experimental study was also conducted where an instrumentation adapted to generate a high frequency diffuse field by interdigital transducers was proposed. A preliminary study was first carried out on the estimation of the Green functions on a healthy wafer (without defect). The first results clearly show that surface waves are not very reverberant at these frequency ranges. To image micro-structures it is necessary to consider lower frequencies while remaining at the MHz scale, which can be particularly interesting in particular to image bonding defects in wafers. This approach certainly has a strong potential in the field of microelectronics.

ABSTRACT

Burst wave lithotripsy (BWL) is an ultrasound-based technique used to fragment kidney stones. In this proof-of-concept, we test a novel approach based on acoustic vortices to improve the efficiency of stone fragmentation. Acoustic vortices are wavefronts containing phase dislocations which carry pseudo-orbital angular momentum. These beams can be synthesized and focused by spherical phased-arrays which also enable beam steering and control the topological charge of vortices. Experiments were conducted using real and artificial kidney stones in water using a 128-channel therapeutic ultrasound phased-array transducer with 1.1-MHz central frequency. Sinusoidal-pulsed bursts of 20 cycles at 200-Hz pulse repetition frequency were generated. A confocal 128-element imaging probe monitored stones, while a camera recorded the fragmentation. Conventional BWL and single-topological-charge vortices were compared using same rarefaction pressure and, additionally, same energy. Artificial stones (Bego-stone) and real stones (calcium-oxalate-monohydrate and brushite) were tested. We observe that fragmentation speed is enhanced in a factor of two using vortices in artificial and real stones. Furthermore, vortices are a kind of defocused beams. Therefore, the mechanical index using vortices is lower than using BWL, resulting in a potentially less injurious therapy for surrounding tissues. These results demonstrate that acoustic vortices can enhance fragmentation using low-amplitude focused ultrasound.

Keywords: Acoustic vortices, Burst Wave Lithotripsy, Kidney stones

1. INTRODUCTION

Nephrolithiasis, or kidney stone disease, is a common and recurrent pathology affecting approximately up to a 20% of the population in some regions [1, 2]. It is characterized by the formation of solid crystalline deposits in the renal system [3]. Currently, shock wave lithotripsy (SWL) [4] remains a first-line, non-invasive treatment for renal calculi. SWL is an ultrasound-based technique used to eliminate these calculi based on high-energy acoustic pulses to fragment stones into smaller particles. However, SWL is associated with several limitations, including incomplete stone fragmentation, healthy tissue injury, and reduced efficacy [5, 6].

In recent years, burst wave lithotripsy (BWL) has emerged as a promising alternative to SWL [7]. This ultrasound-based technique, designed to fragment kidney stones using high-intensity and short-duration ultrasound bursts with low pressure amplitudes, improves precision and potentially reduces tissue damage. Preclinical and early clinical studies suggest that BWL may offer enhanced fragmentation efficiency and better patient outcomes compared to SWL [8-10].

Acoustic vortices are wavefronts with phase dislocations that carry pseudo-orbital angular momentum [11-13]. These specialized beams can be synthesized and precisely focused

using spherical phased-array transducers, which also allow beam steering and the control of vortex topological charge.

In this proof-of-concept study, we explore a novel approach to improve conventional BWL which leverages acoustic vortices to enhance fragmentation efficiency [14] as shown in Fig. 1.

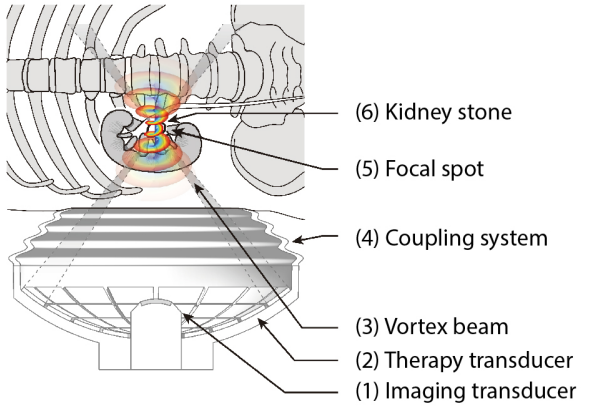

Figure 1. Schematic diagram of the proposed technique.

2. METHODS

Experiments were conducted to evaluate the feasibility of vortex-induced fragmentation using real and artificial kidney stones in a degassed-distilled water tank under controlled conditions. A 128-channel therapeutic ultrasound phased-array transducer, operating at a central frequency of 1.1 MHz, was used to deliver precise acoustic energy. The piezoelectric elements, arranged on a 150-mm diameter and 150-mm aperture bowl, generated sinusoidal pulsed bursts of 20 cycles at a 200-Hz pulse repetition frequency. Lower frequency and pulse repetition frequency are typically used in BWL experiments [15, 16].

A confocal 128-element ultrasound imaging probe enabled real-time monitoring of the stone and its progressive destruction, while a water-proof video camera recorded the fragmentation process enabling us to capture the fragmentation rates and patterns. The video of the experiment, once saved, was used for post-processing, in which the stone was segmented using a binary mask. This allowed us to determine the percentage of remaining stone.
The study compared conventional BWL with BWL enhanced by single-topological-charge acoustic vortices under identical rarefaction pressure conditions (8 MPa for both techniques) and at equal energy levels (8 MPa with vortex and 14 MPa with conventional BWL). Note that, since the focal spot volume is larger when using vortices, at similar energy values the mechanical index is reduced with vortices due to the lower applied pressure.

Artificial kidney stones were fabricated using cylindrical BegoStone [17, 18] samples of 2 mm radius and 10 mm height, with variations in the concrete-to-water ratio to replicate different mechanical properties of real kidney stones [19]. Concentrations of 3:1 and 5:1 were used in the experiments conducted with artificial stones. These two types of concentrations replicate Uric Acid and Calcium Oxalate Monohydrate (COM) real stones respectively. Experiments with real stones included the use of COM and Brushite samples, which were obtained from patients.

Both artificial and real stones were glued to a transparent film, ensuring they remained fixed to a non-rigid surface to enable the correct treatment without the displacement of the stone. This film was placed in 3D-printed structure designed to capture any fragments expelled from the surface of the stones.

3. RESULTS

We observed that acoustic vortices enhance fragmentation speed by a factor of two in artificial kidney stones and most real stones, with some exceptions. Fig. 2 illustrates the average fragmentation speed achieved across all experiments conducted with 3:1 artificial stones, which have similar properties to Uric Acid stones. The blue line represents experiments performed with acoustic vortices, while orange and gray lines correspond to experiments conducted without vortices. The orange line represents cases using the same rarefaction pressure as the vortex experiments. In contrast, gray line represents cases with the same energy levels as the vortex experiments, i.e., a much larger rarefaction pressure. Note that the fragmentation speed using conventional BWL is always slower, both for the same pressure and same energy levels, ensuring that the key factor leading to a more efficient fragmentation is the use of vortices.

In addition to the results presented in this work, similar experiments were conducted with 5:1 artificial stones, as well as with COM and Brushite real stones. Results obtained using real stones show a similar enhancement in fragmentation speed, with some exceptions that

showed no enhancement. These may be attributed to variations in the size and shape of the treated stones, which can influence the fragmentation process. However, for all artificial stones, results remained consistent, doubling the fragmentation speed when using vortices.

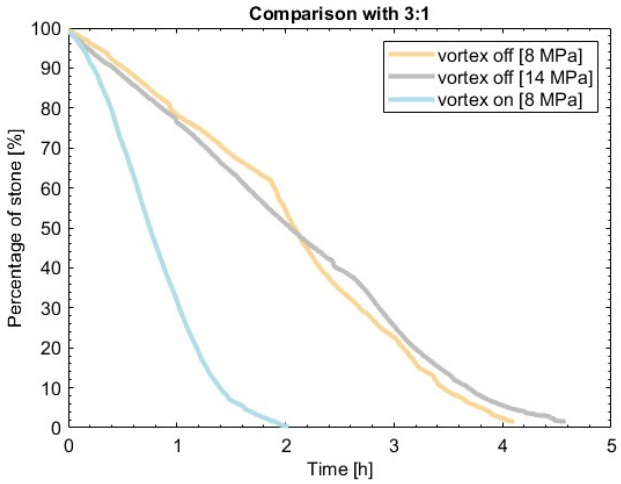

Figure 2. Evolution of the fragmentation as recorded by the video for the artificial stones of concentration 3:1.

4. CONCLUSION

The results indicate that acoustic vortices significantly enhance fragmentation speed, approximately doubling it in artificial kidney stones and in most real kidney stones. Additionally, due to the defocused nature of vortices, the mechanical index is reduced, suggesting potentially safer treatment for surrounding healthy tissue compared to conventional BWL. These findings demonstrate that acoustic vortices can effectively improve kidney stone fragmentation using low-amplitude focused ultrasound, offering a promising avenue for more efficient and less invasive lithotripsy techniques.

ABSTRACT

Focused ultrasound combined with microbubbles can locally and transiently open the blood-brain barrier (BBB) in a non-invasive and safe manner, providing a potential strategy for drug delivery into the brain. The technique is currently being used to test drugs for the treatment of different pathologies; however, the BBB opening dimensions depends on several characteristics of the ultrasonic beam. In this work we characterize the BBB opening in small animals produced by a manufactured transducer operating at frequencies 1.05 MHz (fundamental; $FWHM_{3dB}$ = 1.5 mm | DOF_{3dB} = 6 mm) and 3.25 MHz (first harmonic; $FWHM_{3dB}$ = 0.5 mm | DOF_{3dB} = 2 mm). The transducer has been tested in 11 mice, demonstrating its capability for different BBB opening dimensions with gadolinium (Gd) signal detected in contrast-enhanced T1-weighted MRI.

1. INTRODUCTION

The blood-brain barrier is a highly selective structure that regulates the passage of substances from the blood into the central nervous system (CNS). It is composed mainly of specialized endothelial cells, linked by tight junctions, which limit the diffusion of molecules larger than 400-500 Da and maintain brain homeostasis. However, this protective barrier also restricts the passage of most therapeutic compounds, posing a significant challenge for drug delivery in both preclinical animal models and clinical applications in humans.

Focused ultrasound (FUS) combined with microbubbles has been proven to transiently, non-invasively, and safely open the BBB in a localized manner [1]. This technique has been successfully demonstrated in various species, including rodents [2,3], macaques [4,5], and humans [6,7], enabling targeted drug delivery to the brain. Moreover, BBB opening has been explored for various applications, including enhanced chemotherapy delivery, gene therapy, and the treatment of neurodegenerative disorders [8].

In this study, we will use a manufactured FUS transducer operating at frequencies 1.05 (fundamental) and 3.25 MHz (first harmonic) together with microbubbles to open the

BBB in n = 20 mice. By employing T1-weighted FLASH magnetic resonance imaging (MRI) with gadolinium contrast, we will verify and analyze the openings.

2. MATERIALS AND METHODS

2.1 Acoustic simulation

Acoustic simulation was performed using the k-Wave MATLAB toolbox to model ultrasound wave propagation and quantify pressure distribution, focal spot localization, and transmission efficiency through the skull [9]. The transducer utilized in the simulation was identical to the one employed in the experiment, operating in two modes: at its fundamental frequency of 1.05 MHz and at its first harmonic frequency of 3.25 MHz. It had a diameter of 65 mm, a focal length of 50 mm, an inner aperture of 4 mm and a thickness of 2 mm.

For the acoustic simulations, we used an isotropic numerical grid with a spatial step of Δh = 292 µm for simulations at 1.05 MHz and Δh = 74 µm for simulations at 3.25 MHz, corresponding to a spatial resolution of 6 grid points per wavelength at each frequency. The numerical time step was chosen to ensure a Courant-Friedrichs-Lewy (CFL) number of 0.25. The CT data of the mouse used for the simulation were identical to [10]. The density and speed of sound for each voxel were derived from converting the corresponding Hounsfield Units (HU) to acoustic impedance [11,12]. Acoustic absorption coefficients were obtained from [10] and were 0.0023, 0.4374, and 17.6946 dB/cm for water, brain, and bone, respectively, at 1.05 MHz, and 0.0072, 1.3540, and 54.7469 dB/cm for water, brain, and bone, respectively, at 3.25 MHz.

Figure 1 presents the normalized acoustic fields obtained from simulations, illustrating the acoustic field for both frequencies.

2.2 Acoustic characterization

Acoustic characterization was performed in a water tank filled with degassed water to characterize the ultrasound field parameters. The transducer was positioned using a motorized stage (15 µm resolution, PI miCos GmbH, Germany) to ensure precise alignment. A calibrated hydrophone (HNA-400, Onda Corporation, USA) with a preamplifier (AG-2010, Onda Corporation, USA) was used to measure pressure waveforms at various spatial locations inside the skull cavity. The experimental measurements taken in the pool were compared with the simulations to verify the consistency and validity of the results (Figure 1 Bottom subplots).

Measurements performed in the water tank using ex vivo tissue revealed that the attenuation of the mouse skull was 21% at 1.05 MHz and 52% at 3.25 MHz. At 1.05 MHz, an input signal of 150 mV was required to obtain a pressure of 0.5 MPa, while at 3.25 MHz, an input signal of 315 mV was required to achieve a pressure of 0.6 MPa. For all measurements, the exact system used in the in vivo experiments was employed (Figure 2).

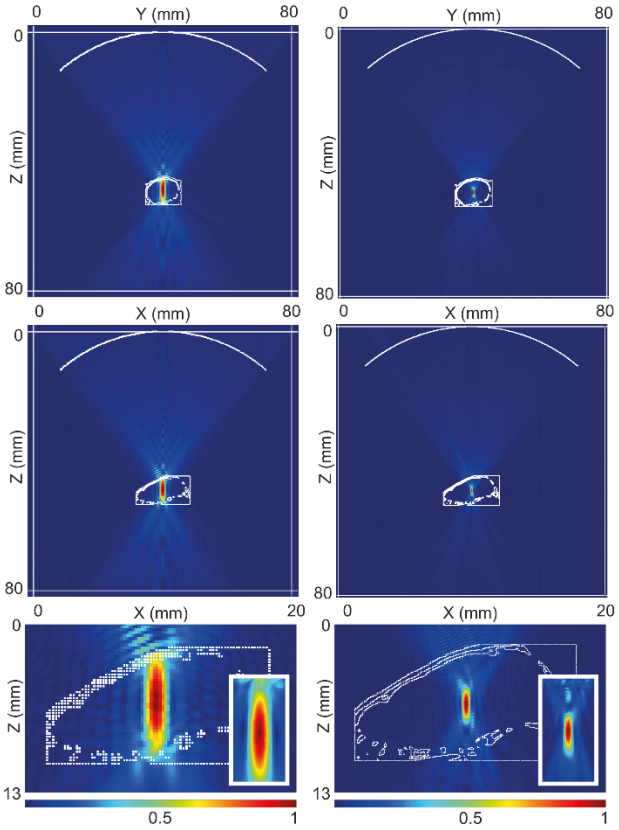

Figure 1. Ultrasound field simulated at 1.05 MHz (left), and 3.25 MHz (right). Images at the bottom show a zoom view of the focal point along with a subplot with the experimental results.

2.3 Animals

A total of 20 female swiss mice (age: 8 weeks, weight: 20 g) (SN-SWISS-F, JANVIER LABS, France) were used in this study. The animals were housed in standard conditions with a 12-hour light/dark cycle, temperature between 20 and 24°C and ad libitum access to food and water. When needed during the experiment, mice were anesthetized with 1-2% isoflurane and their body temperature was maintained at 37°C using a heating pad.

All procedures were conducted in accordance with European Directive 2010/63/EU on the protection of animals used for scientific purposes and approved by the Conselleria de Agricultura, Ganadería y Pesca of the Generalitat Valenciana (Approval ID: 2022 VSC PEA 0254 tipo 2).

2.4 Sonication

The sonication was performed using a custom ultrasound system based on a piezoelectric focal bowl, an arbitrary waveform generator (Red Pitaya 125-14, Red Pitaya US, USA) and an amplifier (OPAMP PA119, Apex Microtechnology, USA) specifically designed for the experiment (Figure 2). Prior to sonification, the animal was shaved in the head area and placed on the stretcher. Intravenous 1 µl/g microbubble injection (Definity, Lantheus Medical, USA) was administered immediately before the sonification.

Two sonification protocols were applied. The first involved f = 1.05 MHz, P = 0.5 MPa, PRF = 5 Hz, DC = 3%, and t = 120 s, and was applied to 10 mice. The second utilized f = 3.25 MHz, P = 0.6 MPa, PRF = 5 Hz, DC = 3%, and t = 120 s, and was applied to 10 mice. Following the sonification, an intraperitoneal injection of 200 µl Gd (Dotarem, Guerbet, France) was administered.

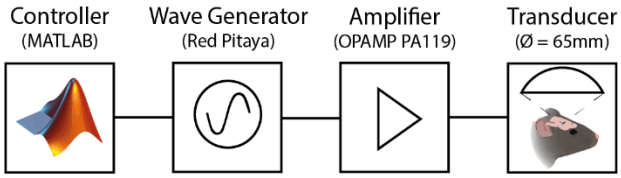

Figure 2. Ultrasound system diagram.

2.5 MRI

Mice were transferred to the MRI (BioSpec 70/30, Bruker, Germany) and anesthetized with isoflurane. A contrast-enhanced T1-weighted FLASH scan (TR/TE of 230/3.3 ms, flip angle of 70°, number of excitations of 18, inplane resolution of 85 µm × 85 µm, slice thickness of 500 µm and receiver bandwidth of 50 kHz.) was acquired 60 minutes after gadolinium injection. Scans were performed in both coronal and horizontal planes (Figure 3).

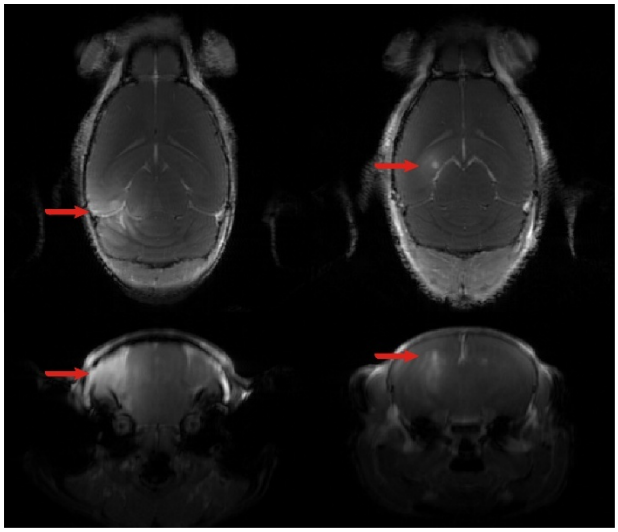

Figure 3. T1-weighted MRI images showing gadolinium due to blood-brain barrier opening. On the left, images obtained with the first protocol (f = 1.05 MHz), and on the right, with the second (f = 3.25 MHz).

2.6 BBB opening analysis

The analysis of the Gd signal in the T1-weighted MRI images aimed to obtain the centroid coordinates and the total volume of the BBB openings. For this analysis, *SAMson* was used to automatically segment the brain from the surrounding tissue in coronal planes [13]. Once isolated, all brains were segmented with *MATLAB* [14] using the same intensity threshold, resulting in a binary matrix. The *regionprops* function was then applied, which considers only the nonzero values in the matrix to extract the centroid coordinates (y and z coordinates). Additionally, the *nnz* function was used to count all nonzero voxels in the matrix. The total volume was then obtained by multiplying this

voxel count by the dimensions of a single voxel (85 µm × 85 µm × 500 µm). Since the *SAMson* tool is only applicable to coronal MRI studies, an additional manual segmentation was performed using *ITK-SNAP* [15] on the horizontal plane MRI study to obtain the *x* coordinates.

Finally, the centroid coordinates of each opening were referenced to the center of the generated matrix, as the matrix size had been adjusted to match the exact dimensions of the brain. This reference is robust across our different MRI studies, allowing for a reliable comparison of the locations of the openings.

3. RESULTS

Successful BBB opening was achieved in 11 mice. 9 mice did not show any opening. All of them had difficulty injecting the microbubbles. BBB disruption was observed in 6 mice using the 1.05 MHz protocol and in 5 mice using the 3.25 MHz protocol. For the first 7 openings (6 at 1.05 MHz and one at 3.25 MHz), the transducer was positioned in a specific brain region and kept fixed while the animals were placed accordingly to evaluate targeting precision. Subsequently, the transducer was shifted 3 mm forward to perform the remaining four openings at 3.25 MHz. The average BBB opening volume was 19.85 ± 6.20 mm³ for the 1.05 MHz condition and 12.41 ± 3.66 mm³ for the 3.25 MHz condition.

Regarding targeting precision, the displacement of the centroid of the BBB opening respect to the mean value per sonication event was 0.23 ± 0.18 mm, 0.20 ± 0.11 mm, and 0.07 ± 0.03 mm along the X, Y, and Z axes, respectively, for 1.05 MHz, and 0.08 ± 0.05 mm, 0.16 ± 0.13 mm, and 0.12 ± 0.06 mm along the X, Y, and Z axes, respectively, for 3.25 MHz (Figure 4). The total displacement of the centroid of all the BBB openings was 0.18 ± 0.16 mm, 0.17 ± 0.12 mm, and 0.11 ± 0.08 mm along the X, Y, and Z axes, respectively.

For the 1.05 MHz frequency, the positional analysis included all 6 mice with successful BBB openings. However, for the 3.25 MHz case, only three mice were considered for positional analysis. One of the remaining two was sonicated at the same location as the 1.05 MHz condition to confirm successful opening, while the other exhibited an opening significantly displaced from the intended area due to an animal positioning error. For the total displacement error, all BBB openings were included except the one with positioning error.

Additionally, for the 3.25 MHz case, all three openings were performed by physically shifting the target 3 mm forward to assess the system's targeting precision. The measured distances between these openings and the previous ones resulted in an average separation of 3.16 ± 0.11 mm.

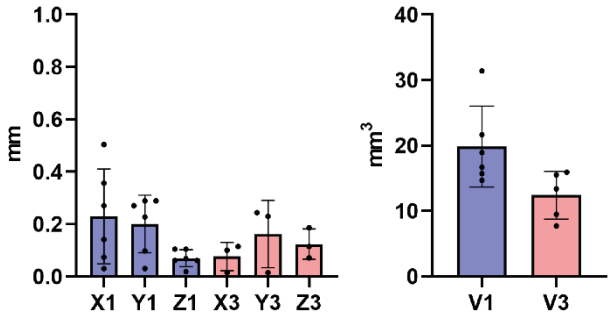

Figure 4. (Left) Mean and standard deviation of the absolute centroid displacement of the BBB opening along the X, Y, and Z axes. (Right) Mean and standard deviation of the volume of the BBB opening. Blue bars represent data acquired at 1.05 MHz, while red bars correspond to 3.25 MHz.

4. CONCLUSIONS

Twenty BBB opening procedures have been performed in mice using two different protocols in order to evaluate the capability of an FUS system to perform precise openings.

The average BBB opening volume was larger for the 1.05 MHz condition (19.85 ± 6.20 mm³) compared to the 3.25 MHz condition (12.41 ± 3.66 mm³), indicating a frequency-dependent effect on opening dimensions. Targeting precision analysis showed small centroid displacements per sonication event, with mean deviations of 0.23 ± 0.18 mm, 0.20 ± 0.11 mm, and 0.07 ± 0.03 mm along the X, Y, and Z axes, respectively, for 1.05 MHz, and 0.08 ± 0.05 mm, 0.16 ± 0.13 mm, and 0.12 ± 0.06 mm along the X, Y, and Z axes, respectively for 3.25 MHz. These results obtained are consistent and reliable, as they align with those described in

similar studies [10,16] and suggest that the manufactured transducer can achieve precise and reproducible targeting.

Furthermore, for the 3.25 MHz condition, the physical shift of the sonication target by 3 mm resulted in an observed average displacement of 3.16 ± 0.11 mm, confirming the system's targeting accuracy. This level of precision is particularly relevant for procedures requiring multiple BBB openings at different locations within the same experiment.

However, a significant portion of the variability in both volume and spatial distribution can be attributed to the initial target placement. Since the first sonications were performed at a randomly assigned location within the cerebellum due to errors in mice positioning, the irregular and smaller geometry of this brain region (compared to the hemispheres) led to Gd leakage spreading beyond the intended area, resulting in less well-defined openings. Quality of microbubble injections also played a crucial role in defining BBB opening volume, as incomplete administration of the microbubble dose frequently led to reduced opening sizes. Additionally, one case of significant displacement due to positioning error highlights the importance of accurate animal alignment in sonication experiments to ensure reproducibility and precise targeting across multiple sonication sites.

These findings demonstrate the feasibility of using the manufactured transducer for frequency-dependent BBB opening in small animals, providing valuable insights for future preclinical applications in drug delivery studies.

ABSTRACT

Carotid plaque rupture causes most ischemic strokes, yet current diagnostics focus on arterial stenosis, overlooking 80–90% of vulnerable plaques. This highlights the need for affordable, precise, and non-invasive imaging to assess plaque vulnerability. To address this, we developed a low-cost, dual Ultrasound/Photoacoustic system integrating a Vermon L7.5-MHz ultrasound probe, a 128-channel programmable phased array Ultrasound scanner (Dasel, Spain), and pannels of pulsed semiconductor lasers diodes of 5W emitting 100 ns pulses at 447 nm. Synchronization was managed via external pulse generators, with laser light delivered through optical fibers. Validation utilised phantoms of black nylon threads. GPU-accelerated delay-and-sum beamforming was used for image recontruction. The system achieved 530 μm lateral and 360 μm axial resolution. This system offers a cost-effective, non-invasive approach for high-resolution multiparametric tissue characterization. Future aims will be to improve in vivo assessment of plaque vulnerability.

1. INTRODUCTION

Stroke causes over 11.6% of all deaths, with ischaemic stroke alone responsible for more than 6 million deaths annually, making it the second leading cause of death worldwide. It is primarily triggered by plaques in the carotid artery—mainly composed of lipids, blood, and collagen—that obstruct blood flow and rupture suddenly. While our understanding of plaque evolution has advanced, current diagnostics still focus mainly on detecting arterial stenosis. This approach only identifies 10-20% of cases, thereby missing crucial indicators of plaque vulnerability [1]. Consequently, there is an urgent need for non-invasive, simple, and low-cost imaging techniques that can assess carotid plaques' composition, stability and vulnerability.

Photoacoustic imaging (PAI) is a promising technique that combines the contrast and spectral benefits of optical imaging with the deep penetration and high spatial resolution of ultrasound, taking advantage of the low scattering of ultrasound in biological tissue and relying on the photoacoustic (PA) effect [2]. This effect is produced by illuminating the tissue with pulsed light of very short duration (around a few nanoseconds), which causes the molecules present, whether endogenous or exogenous (such as haemoglobin or melanin), to absorb the incident energy. This absorption generates a local increase in temperature and pressure, which in turn causes a thermoelastic expansion of the tissue, giving rise to acoustic waves that propagate and are picked up by ultrasound transducers. In this way, the technique complements ultrasound information by providing functional data on tissue oxygenation and vascular dynamics. The study aims to characterize a low-cost, portable ultrasound-photoacoustic system using semiconductor laser diodes, which are more affordable and portable than traditional lasers.

2. METHODOLOGY

2.1 System description

We developed a low-cost, non-invasive dual Ultrasound/Photoacoustic system. This system consists of a clinical ultrasound probe (Vermon L7.5 MHz) with 128 elements, a centre frequency of 7.5 MHz and a bandwidth of 60%. For the photoacoustic part, the system consists of two panels of five pulsed semiconductor laser diodes (SLD) with a wavelength of 447 nm and 5W of power, placed on each side of the clinical probe. The illumination from each diode is delivered uniformly to the transducer's acquisition plane via optical fibers attached to each diode on the panels (Fig. 1). The delivered pulse width is 100 ns with a pulse repetition rate of 1 kHz. This pulse generated by the diodes is regulated by an Arduino signal generator (Arduino Uno) and a controller (SLD Picolas LDP-V 240-100 V3.3 Driver) that is responsible for activating and synchronising the illumination and ultrasound detection. The images are acquired by a programmable ultrasound scanner provided by the company Dasel (Spain), with a sampling frequency of 62.5 MHz and 128 transmission and reception channels. This scanner can perform multiple acquisitions, allowing the use of different types of averaging to minimise the noise characteristic of photoacoustic images. The acquired photoacoustic images have a depth of 20 mm, since this depth marks the practical limit of imaging in the current photoacoustic configuration, since from that point the intensity of the fluence is 20% lower than its maximum value.

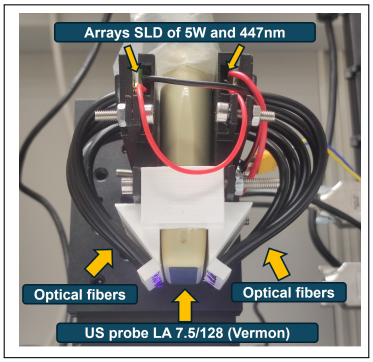

Figure 1. Photoacoustic system that combines a clinical ultrasound probe with two arrays of five 5W SLD (447 nm). These diodes are attached to the sides of the probe, and their light is delivered to the transducer's acquisition plane through optical fibers.

2.2 Image reconstruction

After the photoacoustic signal is captured by the ultrasound detectors, reconstruction algorithms are employed to convert the temporal variations in pressure into final photoacoustic images. Numerous reconstruction methods are now available to achieve this, and the GPU-accelerated delay and summation (DAS) method was used in this study [3].

2.3 Lateral and axial resolution

To evaluate spatial resolution, a home-made phantom of 0.26 mm diameter black nylon threads spaced 4 mm apart both laterally and axially (Fig 3A.), immersed in water, was scanned with our experimental setup. The following expressions were used to calculate the theoretical and lateral resolution [4]:

$$R_l = 0.71 \cdot \frac{c_0}{NA \cdot f_0} \qquad R_a = 0.88 \cdot \frac{c_0}{\Delta f} \tag{1}$$

with c_0 the velocity of sound in the medium, NA is the numerical acoustic aperture, f_0 and Δf the centre frequency and bandwidth of the transducer signal, respectively. To characterise the spatial resolution of our system we reconstructed the image of a point target, in this case

the black nylon thread, and used the Point Spread Function (PSF) method [4]. The Full Width at Half Maximum (FWHM) of the PSF determines our experimental spatial resolution.

2.4 Signal-to-noise ratio (SNR) and amplitude correction map

Several photoacoustic image acquisitions were performed to test the dependence of signal-to-noise ratio (SNR) on the number of averaged signals. Finally, an amplitude correction of the reconstructed PA image with DAS of the black nylon phantom was performed. For this purpose, the reconstructed image was divided into blocks and, for each block, the maximum amplitude value is extracted. This generates a 'correction map' representing the local variation of the signal in the image. This map is used to normalise the original image by dividing the reconstructed image by the correction map, thus compensating for acoustic and optical attenuations and local variations in amplitude, resulting in a more homogeneous representation of the signal. Finally, a median filter was applied, reducing residual noise and improving the visual quality of the corrected image.

3. RESULTS

3.1 Lateral and axial resolution evaluation

The theoretical lateral and axial resolution of the system were obtained to be 0.23 mm and 0.29 mm, respectively. However, these theoretical resolutions are not taking into account in their expressions the characteristics of the piezoelectric elements of the transducer such as kerf or pitch. On the other hand, Fig. 2B shows the photoacoustic image reconstructed with the delay-and-sum algorithm of the black nylon thread (Fig. 2A) immersed in water. From the PSF method, we extracted the FWHM of the reconstructed signal, previously performing a Gaussian fit to it and establishing that if the signal did not exceed a threshold of -6 dB then the system is not able to correctly resolve the point object. By analysing both the lateral and axial profiles of the signal, we obtained a lateral resolution of $R_L = 0.53$ mm and an axial resolution of $R_A = 0.36$ mm (Fig. 2C).

3.2 SNR vs number of signal averages and correction amplitude of the reconstructed images

To determine the optimal number of image averages for our acquisitions, we analyzed the SNR as a function of

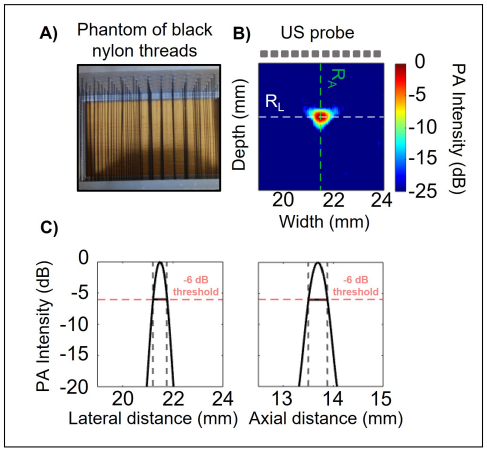

Figure 2. A) A phantom with 0.26 mm diameter black nylon threads spaced 4 mm apart laterally and axially. B) A PA image of the threads is reconstructed using DAS to assess the lateral and axial signal profiles. C) The lateral and axial resolutions are determined via the PSF method, using a -6 dB threshold as the resolvability limit.

the number of averaged frames. As shown in Fig. 3, the SNR progressively improves with the number of acquisitions. A noticeable increase is observed around 3000 averages, where the SNR reaches approximately 54%, indicating a significant enhancement in signal clarity. At 5000 and 10000 averages, the SNR further improves by roughly 30%. Based on these results, we selected 5000 averages as a suitable trade-off, providing a robust SNR of 72% while keeping the acquisition time within 5 seconds, making the system more suitable for time-sensitive applications.

Finally, a photoacoustic image of the phantom composed of black nylon threads was reconstructed using the DAS algorithm (Fig. 4A). An amplitude correction was subsequently applied to account for signal attenuation with depth and laterally (Fig. 4B). As illustrated in Fig. 4C, the corresponding amplitude profiles show a marked improvement, exhibiting a more homogeneous signal distribution across all the image. This indicates that the amplitude correction effectively compensates for intensity decay, enhancing the overall image uniformity and interpretability.

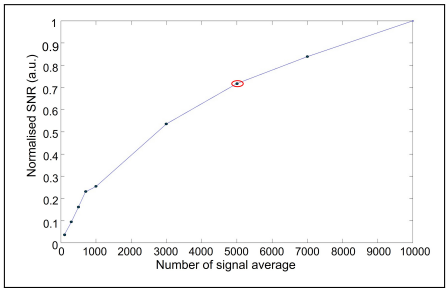

Figure 3. Normalised Signal-to-noise ratio (SNR) as a function of the number of signal averages. The red circle indicates the averaged signal number we chose to perform the rest of the measurements, since it represents 0.72 SNR, indicating a good signal-to-noise ratio.

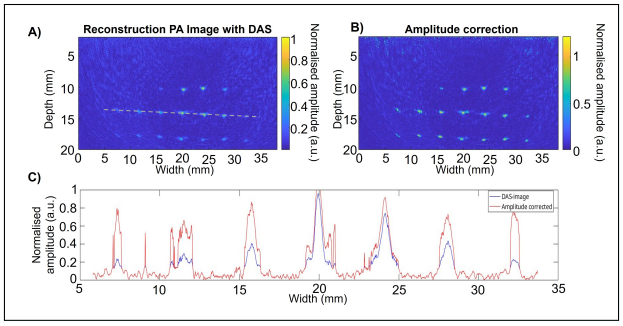

Figure 4. A) Normalized PA image of the black nylon threads phantom reconstructed with DAS. B) The image after amplitude correction. C) Amplitude profiles showing the original image in blue and the corrected image in red, with the dotted line indicating the DAS-extracted profile.

4. CONCLUSIONS AND FUTURE WORK

We developed a low-cost, non-invasive dual ultrasound/photoacoustic imaging system capable of delivering high-quality imaging performance, validated using black-wire phantom experiments. The system achieved a lateral resolution of 0.53 mm and an axial resolution of 0.36 mm, with a signal-to-noise ratio (SNR) of 0.72 obtained from 5000 averaged acquisitions. These results confirm the system's robustness and suitability for high-contrast, depth-resolved imaging.

Future work will focus on the ex vivo characterization of resected human atherosclerotic plaques under the ethical approval PI-6157 (La Paz University Hospital of Madrid, Spain). This next step aims to assess the system's ability to differentiate plaque composition and support the identification of features related to vulnerability, ultimately advancing its potential for clinical vascular imaging applications.

ABSTRACT

Photoacoustic (PA) microscopy provides high-resolution images with optical-selective contrast at greater depths than conventional optical techniques by detecting acoustic waves generated from the absorption of pulsed light. To increase the applicability of the technique, cost-effective, compact laser diodes (LDs) have emerged as a promising alternative to expensive and bulky solid-state lasers (SSLs). Due to their low peak power, widened temporal pulses are generally used to obtain more pulse energy and achieve acceptable PA signal levels. Additionally, the multimode, low-quality beams emitted by LDs hinder the focusing capabilities, resulting in larger focal spots, i.e., lower image lateral resolutions. The generated signal characteristics will thus differ from the well-known broadband photoacoustic waves of several MHz produced by SSL-based systems. In this work, we conducted an experimental study to analyze the impact of the pulse duration, pulse shape, and focal spot size on the generated PA signals, using a laser diode-based photoacoustic microscope. The analysis shows that the pulse durations and focal spot sizes of LDs produce narrowband PA signals shifted towards lower frequencies. This is important for improving the design of efficient transducers, which will eventually allow the implementation of cost-effective photoacoustic imaging systems in clinical practice.

1. INTRODUCTION

Biomedical photoacoustic (PA) imaging combines optical and ultrasound technologies to offer high-resolution, non-invasive images with enhanced penetration and contrast. It relies on the photoacoustic effect, where endogenous chromophores such as melanin or haemoglobin absorb laser pulses, generating ultrasound waves that can be detected and used to reconstruct the absorption distribution [1].

The generation of PA pressure waves is based on the compliance of both stress and thermal confinements. This means that the excitation pulse duration must be shorter than the time that acoustic waves and heat require to travel through the excited volume [2]. Consequently, short pulses of a few nanoseconds coming from high-quality solid-state lasers (SSLs) are the preferred choice to efficiently generate PA signals. Moreover, the emitted acoustic waveform is proportional to the first derivative of the laser intensity temporal profile [2], [3]. Hence, short pulses generate sharp, bipolar pressure waves, allowing for high-contrast and high-resolution acoustic imaging [4].

The utilization of cost-effective laser diodes (LDs) in photoacoustic imaging (PAI) is gaining attention due to their affordability and compact size, which make them an attractive alternative to bulky and costly SSLs [5], [6]. However, these low-cost sources typically emit low-energy, low-quality laser beams, hindering their use in clinical-oriented systems [7]. The current drivers that pulse the LDs grant these sources with pulse tuning capabilities. For this reason, usually widened pulses are chosen to increase the per-pulse energy and, therefore, the image signal-to-noise ratio (SNR). However, longer pulses generate narrowband PA signals shifted to lower frequencies, which highly affects the image resolution [8], [9]. Moreover, stress confinement may be violated if the excited absorber is too small, reducing the generation efficiency.

Here, an experimental study has been carried out to study the impact of the pulse duration, pulse shape and source size in the generation of PA signals using a low-cost laser. With this work, we aim to offer novel and useful information about the generated frequency spectrum, which will eventually help the optimization of cost-effective PAI systems, aiding its implantation in clinical practice.

2. MATERIALS AND METHODS

2.1 Photoacoustic microscopy system

In this study, we used a custom photoacoustic microscope based on a cost-effective pulsed laser diode (905D2S3JT09X, Laser Components, Germany), which emits 235 W laser pulses at a PRF of up to 10 kHz in the NIR range (905 nm). The low-quality laser beam emitted by the PLD is reshaped and homogenized by coupling it into a multimode fiber. This fiber-coupled configuration allows to vary the focal spot size by simply placing a spatial filter, or pinhole, at the fiber output without decreasing the laser fluence or working distance. The current pulses are delivered by a pulse current driver (LDP-V 80–100, PicoLAS GmbH, Germany) controlled by a programmable pulse generator (Stemlab 125, RedPitaya). A commercial spherically focused sensor (focal length of 64 mm) made of polyvinylidene difluoride (PVdF) was aligned with the excitation in reflection mode with a 60º angle (Y-107, Sonic Concepts, USA), ensuring high sensitivity detection within 0.01-15 MHz. The detected PA waves are pre-amplified (ZFL-500LN, MiniCircuits, USA) and digitalized at a sampling rate of 150 MHz (ADQ14, Teledyne SP Devices, Sweden).

2.2 Experimental set-up

In optical-resolution photoacoustic microscopy, a tightly focused laser spot is used as the excitation beam, thus generating point-like acoustic sources. In this study, a USAF resolution target (R3L3S1P, Thorlabs, USA) made of a 120 nm-thin chromium film was used as absorber. To analyze the impact of the acoustic source size on the generated PA spectrum, tests were made without and with a 50 µm pinhole, having two focal spots of 150 and 50 µm, respectively. For each case, PA signals were acquired using laser pulse widths of 15, 35, 60, 80 and 100 ns, measured at their Full Width at Half Maximum. It is worth noting that low-cost pulse drivers usually generate asymmetric pulses with long rise times, which can affect the generated signals. To compensate for the poor SNR with shortened pulses, 5000 averages were done for fair comparison between cases.

3. RESULTS

The results are depicted in Figure 1. First (Fig. 1a), the larger source generates PA frequency spectra concentrated below 10 MHz, centered between 4-5 MHz depending on the pulse width. As expected, longer pulse widths result in less high frequency content in comparison with the shorter pulse, indicated by the 18 and 10 dB difference between the 10-15 MHz range and the main lobe, respectively. Similarly, for the smaller source of 50 µm (Fig. 1b), longer pulses generate PA signals with a reduced frequency content than the shorter ones. However, the small source size critically contributes to enlarging the bandwidth. While the 100 ns pulse generates PA signals with differences of around 10 dB in the 10-15 MHz range with respect to the main lobe, the 15 ns pulse generates a wideband signal, with differences below 6 dB in the 1-16 MHz range. In this case, the amplitude decrease beyond 15 MHz can also be influenced by the limited detection bandwidth of the ultrasound detector.

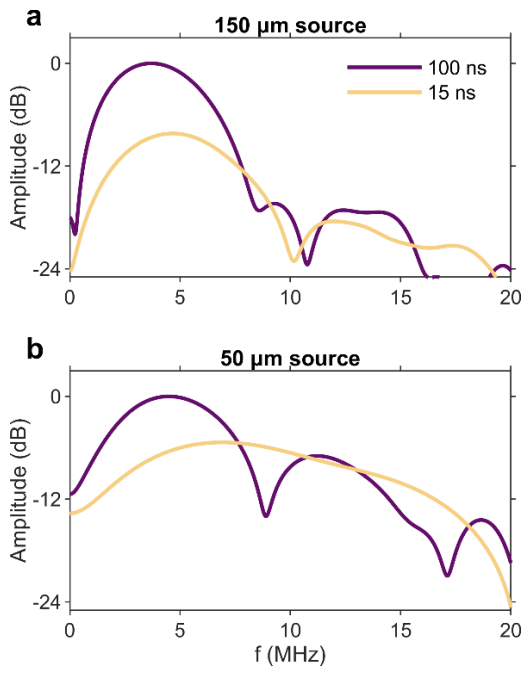

Figure 1. Comparison of the generated PA signal spectrum using pulse widths of 15 and 100 ns, for both (a) 150 µm and (b) 50 µm laser focal spots. Amplitude is normalized for each source size.

A more exhaustive analysis for all the laser pulse widths is shown in Figure 2. For the larger source of 150 µm (Fig. 2(a)), the generated PA amplitude increases with optical energy, which is proportional to the pulse width. However, for the smaller source of 50 µm (Fig. 2(b)),

that trend is not observed. This discrepancy is explained by considering the confinement time, estimated to be around 33 ns for the latter. In this way, shorter pulses (60 ns) produce higher amplitude signals than wider ones (100 ns), despite having 55% less optical energy. Hence, within this range, the effects of higher PA conversion efficiency and optical energy deposition are combined.

It is noteworthy how the asymmetric laser pulse, due to the slow rise time of the low-cost current driver, induces a different PA signal morphology compared with the well-known N-shaped waveform generated with a short laser pulse with fast and symmetric flanks. In this case, the slow rise time generates a short positive lobe, followed by a sharp negative lobe coming from the fast-falling edge of the laser pulse, which highlights the influence of the selected pulse driver and the excitation pulse shape.

Regarding the generated spectrum, center frequency and bandwidth at -6 dB was calculated for each case (Fig. 2 (a, b)). As observed, both source sizes show a similar tendency, reducing the bandwidth and center frequency as the pulse size increases. However, it is visible how these variations are more noticeable for the smaller source, which shows a clearly broader spectrum for the shorter pulses.

4. CONCLUSION

An experimental study to evaluate the impact of the spatiotemporal excitation parameters (pulse width, shape, and source size) on the generated photoacoustic spectrum has been carried out. By varying the pulse width from 15 to 100 ns, with two different excitation source sizes of 150 and 50 µm, we showed that the pulse width is highly correlated with the generated PA spectrum, and that this impact is also strongly dependent on the excited absorber size, i.e., the laser spot size in an optical-resolution photoacoustic microscopy system as the one used in this study. The experimental spectra show how typical LD excitation generates narrower bandwidths, shifted to central frequencies around 5 to 10 MHz, which highly differs from the PA signals generated with high-quality SSLs. Moreover, we have provided experimental evidence of the stress confinement time violation, indicated by the reduced amplitude of PA signals generated with longer pulse widths that, despite having more energy, result in a less efficient conversion. These results show the relevance of considering both the source size and the pulse width for selecting an appropriate detection bandwidth. Also, they highlight the necessary compromise between optical pulse energy and conversion efficiency in LD-based photoacoustic microscopy systems, associated with a plausible violation of the stress confinement time.

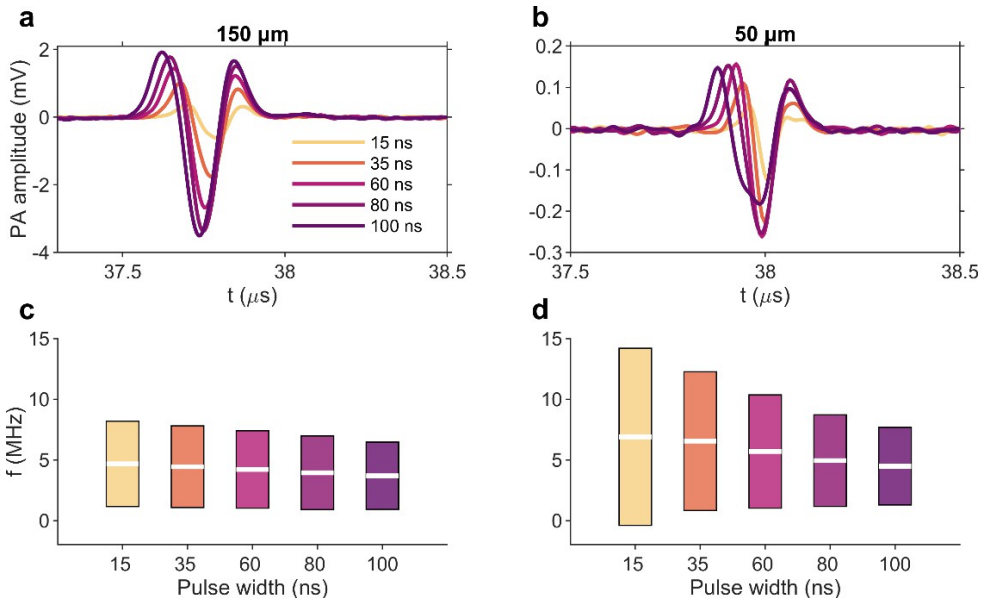

Figure 2. Experimental PA signals and their frequency content spread (center frequency and bandwidth at -6 dB) using laser pulse widths from 15 to 100 ns, for laser spots of 150 µm (a,c) and 50 µm (b,d).

We believe that these findings can provide useful insights to develop optimized PAI systems using low-cost components, thereby facilitating their integration into clinical practice.

ABSTRACT

Acoustic holograms are used in transcranial ultrasound to tailor the acoustic wavefront generated by a single-element transducer compensating skull aberrations and focusing the beam over brain structures. However, current hologram design relies on full-wave simulations where acoustic properties are known by computed tomography (CT). Since exposing patients to ionizing radiation is undesirable, we propose the use of zero echo time (ZTE) magnetic resonance images (MRI) to construct the patient-specific lens. This MRI sequence enables the visualization of tissues with short T2 values, such as bone. By establishing a linear correlation between CT Hounsfield Units (HU) and ZTE intensity values, pseudo-CT images are generated. Furthermore, transducer positioning has been optimised. Temporal bone window is established as a suitable surface for propagating acoustic waves, due to its reduced thickness and flat morphology. Results show that peak pressure at the focus is reduced by 5.38% when using pseudo-CT holograms respect to CT-holograms. The obtained treated volumes considering acoustic properties of the pseudo-CT and those of the CT show a difference of 0.18%. This approach can be applied in holographic wearable devices for transcranial ultrasound therapies such as blood-brain barrier opening or neuromodulation to avoid the use of ionising radiation during the therapeutic treatment.

Keywords: *therapeutic ultrasound, magnetic resonance imaging, neuromodulation, acoustic holograms, transtemporal window.*

1. INTRODUCTION

Therapeutic ultrasound is an emerging modality to treat diseases affecting the central nervous system. It represents a minimally invasive technique with high spatial resolution, which allows targeting even the innermost structures of the brain [1-3]. In those therapies, precise targeting accuracy is required to focus ultrasound energy on the desired structures inside the brain. However, the skull bones present high acoustic impedance, absorption, heterogeneity, and irregular thickness. These produce aberrations and defocusing of the acoustic beam due to strong scattering, reflection, refraction and attenuation effects [2,3]. To

[*] ***Corresponding author***: *aerosim@i3m.upv.es.*

mitigate these effects, acoustic holograms were proposed [4-6]. Acoustic holograms are passive lenses, commonly 3D printed, placed over a single-element transducer surface. They locally modulate the phase of the ultrasound beam, correcting skull aberrations and enabling the focalization over the desired structures inside the brain.

To design a lens for transcranial applications, full-wave acoustic simulations are performed, modelling wave propagation through the different media constituting the human head. These simulations require the acoustic properties of both soft tissues and cranial bones, which are commonly obtained from computed tomography (CT) images [7]. However, exposing patients to ionizing radiation is undesirable.

In this study, we propose the use of zero echo time (ZTE) magnetic resonance images (MRI) to avoid the use of X-ray CT images for hologram design. This imaging protocol enables the visualization of tissues with short T2 values, such as bone. Previous studies have obtained different linear correlations that enable ZTE intensity values conversion into Hounsfield Units (HU) measured on CT images. As a result, pseudo-CT images are obtained [8-11]. In addition, these pseudo-CT are used to optimize transducer location over the temporal bone window. With this approach, its flat morphology and reduced thickness are exploited, enabling higher pressure values at the focus, while reducing the remaining pressure over the skull [12,13]. This contributes to the optimal sonication of the desired structures inside the brain, allowing the generalisation and reproducibility of patient-specific positioning. It can be implemented in holographic wearable devices used in transcranial ultrasound therapies, eliminating the need for ionizing radiation.

2. METHODS

2.1 CT and ZTE Images

CT and ZTE images used in this work were obtained and provided by the Centro Integral de Neurociencias A.C. (HM CINAC) in Hospital Universitario HM Puerta del Sur and all patients provided written consent for data collection. The co-registration of both images is performed using 3DSlicer software. Density and sound velocity of hard and soft tissues are obtained from CT image values and the linear relationship between X-ray attenuation values.

2.1.1 Pseudo-CT Generation

To generate the pseudo-CT images, we have followed the steps presented by Miscouridou *et al.* [11]. ZTE images undergo a bias-field correction filter. Analysing the histogram of the resulting intensity values, two peaks can be identified. The first one, placed at lower intensity values, corresponds to the backward noise of the image. The second one, at higher intensity values, belongs to head soft tissues. Regarding this last peak, all voxel intensities are normalized to the soft tissue peak value. Intensity values between these two peaks are considered skull. By applying a threshold to the normalised ZTE image, a binary mask identifying the skull is generated. Morphological operations are used to fill the generated binary mask. Finally, the linear model defined in Eq. (1) is used in the voxels defined as skull, converting ZTE intensities values into HU [11].

$$CT = -2085\, ZTE + 2329. \qquad (1)$$

Fig. 1 shows the original HU values from the CT image and the HU values obtained from the transformation of the ZTE image into pseudo-CT for the same patient.

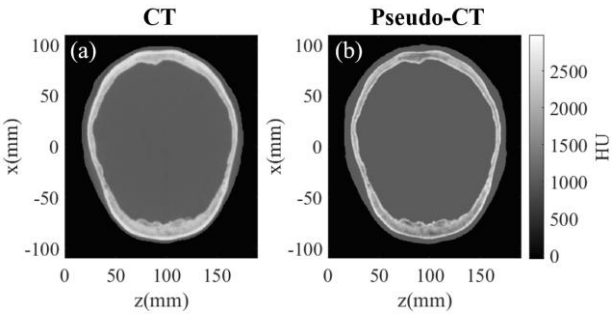

Figure 1. Representation of the HU values defined in (a) CT image, and the equivalent values obtained in (b) pseudo-CT.

2.2 Temporal Bone Window Positioning

An optimization algorithm has been developed to automate the positioning of the ultrasound transducer over the area of minimum thickness in the temporal window using the pseudo-CT [12,13]. In the sagittal view analysis of the generated skull mask, a local maximum in thickness can be identified in the temporomandibular joint (TMJ). Using the TMJ as a reference point, the algorithm automatically positions the transducer over the area of minimum thickness. To achieve normal orientation of the transducer with respect to the skin surface, it is necessary to ensure that there is no overlap with the ear structure [13].

2.3 Acoustic simulations

A flat transducer, with a diameter of 65 mm, excited at a central frequency of 650 kHz, is used. Skull, soft tissues and the transducer are considered to be immersed in water at a temperature of 37º C. Different acoustic simulations are performed in the time domain using MATLAB k-wave toolbox. It implements a pseudo-spectral method in k-space that allows the propagation of ultrasound in heterogeneous media to be modelled, considering the attenuation of the biological tissues considered. The defined workspace corresponds to a homogeneous medium, water, characterized as a cubic grid with a resolution of λ/6, where λ = 2.3 mm is the wavelength in water at the central frequency.

The holographic lens is designed performing a time-reversal simulation, known as *backward* simulation. A virtual source is placed at the centre of the therapeutic structure targeted for neuromodulation, the ventralis intermedius nucleus (Vim) of the thalamus. The segmented structure is corregistered for each analyzed patient. The virtual source emits a train of 100-cycle sinusoidal pulses at the central frequency. As the wavefront propagates through the skull, it is distorted due to differences in sound speed, density and attenuation, relative to those of soft tissues. The resulting wavefront is recorded over the holographic plane to design the geometry of the acoustic lens. Two different backward simulations are performed. The first one uses acoustic properties obtained from the CT image, while in the second one, the acoustic properties are extracted from the pseudo-CT image. As a result, two sets of holographic acoustic lenses are designed for each patient. An example of the recorded phase distribution over the holographic plane used to construct them is shown in Fig. 2.

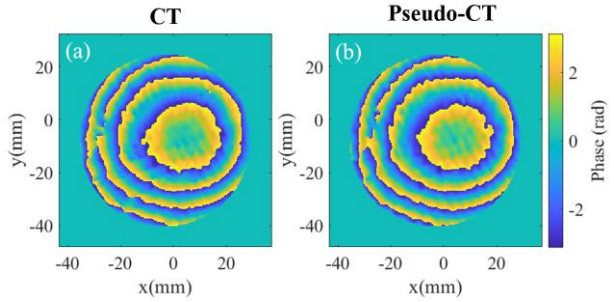

Figure 2. Phase distribution of the wavefront recorded in the holographic plane coming from the virtual source, taking into account the acoustic properties of (a) the CT image and (b) the pseudo-CT image.

In the numerical model, the material used for constructing the lens is a photoreactive resin Clear (Formlabs, USA) with the following acoustic properties: c_L = 2599.31 m/s, ρ_L = 1185.78 kg/m^3. The absorption value was set at α_L = 3.13 dB/(cm·MHz^y) at 650kHz, where y = 1.3, in agreement with values reported for photopolymers with similar properties [4].

A second acoustic simulation is then conducted, known as *forward* simulation. The same acoustic pulse is now emitted from the previously defined transducer. The wave passes through the holographic lens, which modulates it in phase, then through the skull, enabling the focalization over the desired structure. The maximum pressure acoustic field in the volume of interest is recorded for analysis. Three different situations are considered. First, the holographic lens designed using CT-derived acoustic properties is evaluated under matching conditions (CT-CT). Second, pseudo-CT based lens is measured under consistent acoustic conditions (pCT-pCT). Third, the pseudo-CT based lens performance is evaluated under CT acoustic properties in an effort to approximate the most realistic clinical scenario (pCT-CT).

3. RESULTS

The acoustic fields simulated under the specified conditions are evaluated in 5 anonymised patients. The differences between the resulting acoustic fields are quantified in terms of variations in focal position, volume of the sonicated therapeutic target, and peak pressures. In Fig. 3, the resulting acoustic fields obtained in the different considered situations are analysed, being (a) and (b) XZ and YZ planes for CT-CT, respectively, (c) and (d) for pCT-pCT, (e) and (f) for pCT-CT.

Fig. 4. (a) illustrates the deviation along the axial axis with respect to the coordinates of the virtual source defined for the holographic lens design, establishing that there is no significant difference between simulation conditions. A deviation of (-0.31 ± 1.80) mm along the beam propagation axis is observed between the pCT-CT and pCT-pCT simulations, while the deviation respect to CT-CT simulations is (1.02 ± 1.97) mm. Along the lateral axes, the deviation is not significantly distinguishable.

With respect to the sonicated target volume, the mean volume of the therapeutic target is (371.46 ± 5.20) mm^3. The results of the simulated fields show a reduction of 0.17% in the sonicated target volume when comparing the

pCT-CT to the pCT-pCT field. When comparing the treated volume between pCT-CT and CT-CT, the reduction is 0.18%.

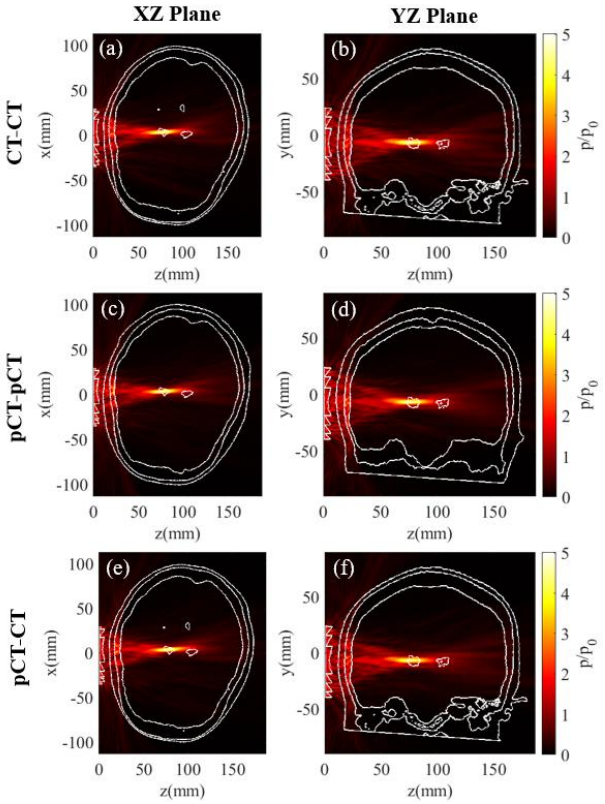

Figure 3. XY and YZ planes amplitude distribution of the acoustic field. (a) and (b) for the CT-CT simulation conditions, (c) and (d) for pCT-pCT conditions and (e) and (f) for the pCT-CT simulation conditions.

Regarding pressure values, a decrease of 3.74% in the maximum focal pressure is observed in pCT-CT field compared to the pCT-pCT field. When this same parameter is compared to the CT-CT field, the reduction reaches 5.38%. Fig. 4. (b) presents the mean maximum pressure measured at the focus for the 5 analysed patients under each simulation condition. Furthermore, the mean pressure over the analysed target volume is also evaluated. In the pCT-CT field, a decrease of 5.47% is measured relative to the pCT-pCT field, while a 5.57% reduction is observed when compared to CT-CT field. When optimizing transducer positioning, the remaining pressure over the skull is minimized. It can be seen that the maximum pressure on the skull in the pCT-CT field is reduced by 0.31%, yielding equivalent values to those obtained in the CT-CT field.

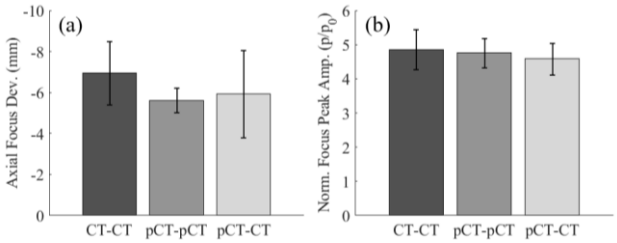

Figure 4. (a) Mean focus deviation in the beam propagation axis. (b) Mean normalized peak pressure measured at the beam focus. Kolmogorov-Smirnov test ($p>0.05$), establishes that there is no significant difference between pCT-pCT and pCT-CT, neither between CT-CT and pCT-CT.

4. CONCLUSION

By employing ZTE images, we generate pseudo-CT images that enable accurate estimation of skull acoustic properties. This study demonstrates that such images can be used as a suitable substitute for CT images in the design and fabrication of holographic lenses. They also allow the precise positioning over the temporal bone window.

Comparative analyses between the generated acoustic fields obtained using CT-based and pseudo-CT-based holographic lenses revealed that the treated volume remains constant. However, although not significant, differences in focal positioning and a reduction in the maximum pressure are observed. Future research will focus on correcting these variations by analyzing the potential underestimation of the skull HU values in pseudo-CT images.

These findings support the use of ZTE images as a non-ionizing alternative for the development of patient-specific acoustic holograms. Their integration into wearable transcranial ultrasound therapy devices opens a new path for non-invasive clinical applications, including neuromodulation and blood-brain barrier opening, while ensuring patient safety and the precision of the treatment.

ABSTRACT

Transcranial focused ultrasound has proven to be an effective method for the treatment of neurological disorders, offering a non-invasive and highly precise approach for the targeting of specific brain regions. In this context, ultrasound holograms have been shown to be capable of focusing through the human skull using low-cost 3D-printed acoustic holographic lenses, where a wavefront is encoded into the height of the pixels of a lens. When the coding is performed at the holographic plane, i.e., a planar surface in front of the transducer, the reconstructed wavefront is approximated by a hyperbolic phase profile in the thin lens approximation. However, as the thickness of the physical lens is beyond the thin lens approximation, this results in aberrations. In this work, a new strategy is proposed matching the phase of the field produced at the exit of the lens to the target phase in a whole holographic volume. The method is validated using analytic and simulations techniques. Results show that this phase-matching approach provides better focusing performance over traditional methods and, therefore, might be used for accurate hologram synthesis in practical applications.

1. INTRODUCTION

Acoustic holograms are intricate lenses designed to encode customized phase distributions onto their surface, enabling the formation of specific acoustic pressure patterns within a medium [1]. Essentially, an acoustic hologram produces a three-dimensional acoustic field, providing precise control over pressure waves at a target region [1, 2]. It operates on the principles of interference and diffraction, akin to optical holograms, but adapted for sound waves. This technology has gained prominence for its versatility, finding applications in many fields such as in acoustics [3, 4], biomedical ultrasound [5, 6] and advanced techniques such as contactless micromanipulation or biofabrication [7, 8].

In particular, acoustic holograms hold significant promise in ultrasound therapy, particularly in transcranial ultrasound [6], where they have demonstrated great potential to enhance treatment effectiveness. Applications include improving hyperthermia treatments [9, 10], facilitating targeted drug delivery by opening the blood-brain barrier [11, 12], neuromodulation [5, 13] or the creation of customized cavitation patterns [14]. Beyond therapy, acoustic holograms can also be utilized for imaging and monitoring therapeutic ultrasound treatments [15].

Current holographic methods are based on the recording of a phase and/or amplitude of the desired wavefront [1]. In particular, phase-only acoustic holograms aim to build a *holographic lens* that allows the phase of the wavefront coming out of the lens to match that of the recorded wavefront. However, existing lens design methods fail to precisely encode the target phase distribution, primarily

due to the complex topology of these lenses, which introduces intricate wave physics often overlooked in the design process [16]. As a result, physical lenses generate suboptimal acoustic images. In this work, we propose a method for designing acoustic holograms and lenses that accurately reproduce a desired target field. This approach uses a *phase-matching* strategy to ensure that the phase of the field produced at the exit of the lens matches the target phase across the entire holographic volume. We validate this method through analytical and simulation techniques, demonstrating its superior performance in focusing acoustic waves compared to traditional methods.

2. METHODS

In current hologram design methods, the target field is defined in a transverse plane and it is assumed that the lens produces a phase shift at the transverse plane location [6]. This results in a simple linear relationship between the lens height and the phase of the field. However, this approach assumes plane wave propagation, and thus, does not account for other wave phenomena such as refraction and diffraction at discontinuities. To address these limitations, we propose a *phase-matching* strategy to match the field at the exit of the lens to better match that of the target field.

In contrast with conventional single plane methods, where the phase of the field is matched at a holographic plane at a set distance from the transducer, our proposed phase-matching method matches the phase of the field produced at the exit of the lens to the target phase in a whole holographic volume, that is, in successive planes parallel from the transducer location up to a desired distance. The height of each pixel in the lens is determined such that its transmission coefficient phase aligns with the recorded phase originating from the virtual sources at some point in the holographic volume.

The proposed method is validated through analytical mean and simulations using a 1.1-MHz circular 50-mm aperture transducer. Simulations were performed using k-Wave toolbox (MATLAB) for simulating acoustic wave propagation [17]. The transducer was modeled as a circular piston with a Gaussian distribution of the amplitude and a uniform phase distribution. Simulation are performed in a uniform water medium at a temperature of 25 °C with a resolution of $\lambda/6$, where $\lambda \approx 1.4\,\mathrm{mm}$ is the wavelength water at the working frequency; in which the lens is placed on top of the planar source.

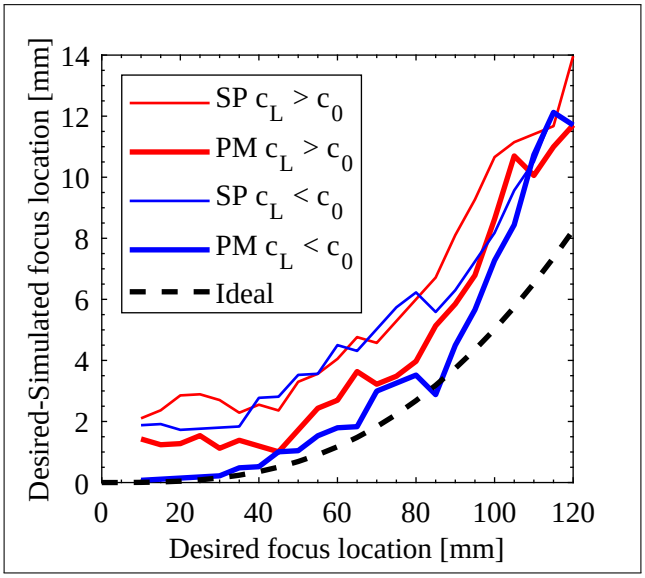

Figure 1. Simulated focus for single plane (SP) and phase matching (PM) lenses for rigid and soft materials.

The performance of the phase-matching approach is compared to traditional methods, comparing its focusing capabilities at multiple distances and its hability to create complex acoustic images at different depths via the estimation of their structural similarity index measure (SSIM) of the obtained acoustic fields for MNIST number images one to five [1]. The fields obtained via propagation through the lens will be compared againts the ideal pattern obtained via the Rayleigh-Sommerfeld integral using a back and forth propagation of the original MNIST images.

3. RESULTS

Simulation results in Fig. 1 in which both methods were compared against an ideal focused transducer. It can be observed that phase-matching hologram lenses outperform traditional methods for both rigid ($c_L > c_0$) and soft ($c_L < c_0$) lenses, producing focal spots closer to the ideal case for all studied focal distances. In particular, soft

[1] The SSIM index is a perceptual metric that quantifies the similarity between two images, ranging from 0 to 1, with 1 indicating perfect similarity [18].

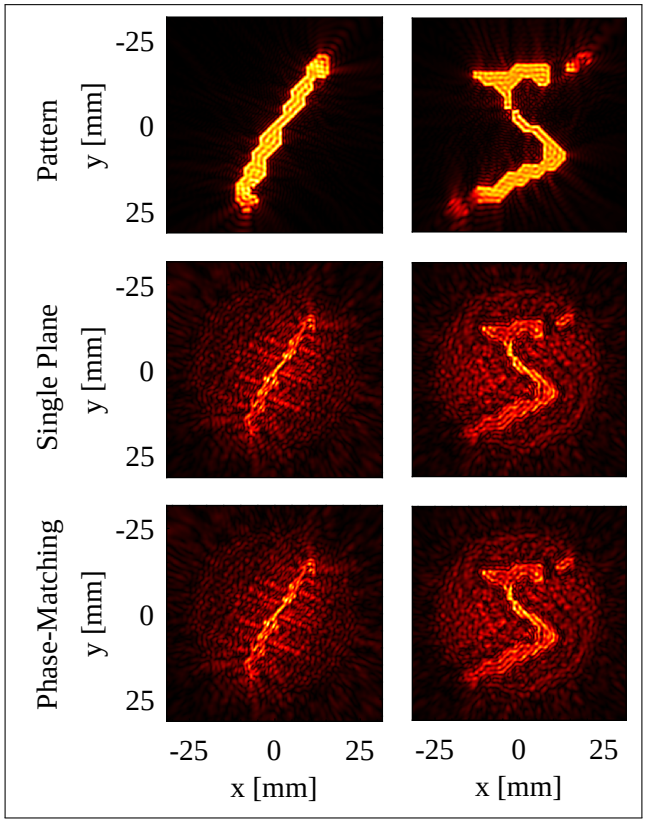

Figure 2. Acoustic patterns for MNIST iamges one and five obtained through Rayleigh-Sommerfeld propagation, traditional and phase-matching methods.

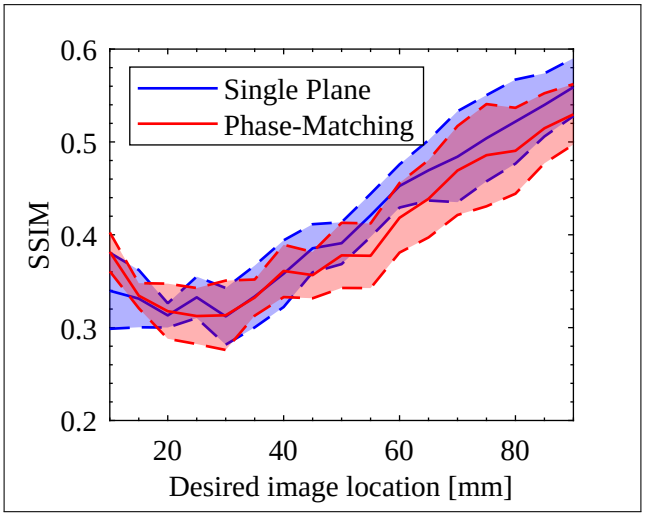

Figure 3. Average Structural Similarity Index Method (SSIM) for MNIST number images one to five obtained through traditional and phase-matching methods.

phase matching lenses appear to perform very close to an ideal focused transducer for nearer focus locations.

To study the performance of the phase-matching approach in creating complex acoustic images, we generated holograms to get the acoustic patterns for numbers one to five from the MNIST dataset. Due to the excelent focusing capabilities shown for soft lenses in Fig. 1 we have decided to work with soft lenses for this trial. An extract of theses images are shown in Fig. 2 for a focal distance of 15 mm. Since the prevalence of one method over the other cannot be easily ruled out, we evaluated the performance of these holograms at different focusing distances ranging from 10 to 90 mm in 5-mm steps using the Structural Similarity Index Method (SSIM), as shown in Fig. 3. The shaded error plot shows that both methods are pretty similar for this application, although we believe this may be to the existance of a critical angle that hinder the performance of the phase-matching approach. Still, for low focusing distances we can observe that the phase matching approach seems to outperform traditional methods.

4. CONCLUSIONS

In this work, we proposed a novel phase-matching approach for designing acoustic holograms that accurately reproduce the desired target field. This method aligns the phase of the field produced at the exit of the lens with the target phase across the entire holographic volume, resulting in superior focusing performance compared to traditional methods. We validated this approach through analytical and simulation techniques, demonstrating its effectiveness in focusing acoustic waves and creating complex acoustic images. Via simulations, we demonstrated that our approach outperfermorms traditional methods in terms of focusing capabilities at multiple distances, specially for soft lenses. The method also shows promise in generating complex acoustic images, with a slight advantage over traditional methods at lower focusing distances.

ABSTRACT

In the last decade, plane-wave-based volumetric ultrasonic imaging has become a promising research tool in preclinical neuroscience. Its high-speed imaging capability at a high operating frequency allows the observation of microvascular structures and the acquisition of functional ultrasound (fUS) images. However, achieving high-quality 3D super-resolution images requires fully functional full apertures supported by many independent channels, as well as high data transmission rates and processing capacity. Based on current technology, which emulates full array performance through multiplexing, this technique is far from reaching full maturity. This study investigates the potential of sparse arrays to achieve a trade-off in designing 3D imaging systems for fUS. Starting with a 32x32-element aperture, sparse array configurations with up to 256 elements for transmission and reception are explored. The study examines the requirements and opportunities of this approach during pre-beamforming and beamforming stages, focusing on system architecture.

Keywords: *plane wave, sparse array, ultrasonic imaging, volumetric imaging.*

1. INTRODUCTION

The plane-wave imaging technique involves emitting a plane wavefront and forming the image during reception by compensating for both the distance to the receivers and the distance traveled by the wavefront during transmission [1, 2]. Because the imaging region is very close to the aperture, the plane wave itself—during its formation process—primarily generates the acoustic noise responsible for the artifacts. Although this technique produces significant sidelobes and lower-quality images, it offers the advantage of very fast acquisition, thereby enabling new applications such as functional imaging [3,4]. To improve image quality, multiple images acquired at different transmission angles are combined. The diversity in the sidelobe distribution leads to their cancellation when combined, enhancing the overall image quality. In this way, a balance between image quality and acquisition speed can be sought.

In linear arrays, the number of angles used varies depending on the required image quality, with typical values ranging from 3 to 30 angles [1]. For two-dimensional arrays, these values range from 5×5 to 11×11 angles [2]. Determining the optimal number of angles requires prior experimental validation or a simulation model to balance image quality and acquisition complexity.

Volumetric imaging remains a technological challenge [5, 6]. One major limitation is the difficulty in achieving apertures with sufficient dimensions to provide high resolution. Current models in the literature typically assume a (32×32) element array (1024 elements) with inter-element spacing exceeding $\lambda/2$. Another critical challenge is the parallel control of a large number of elements. Only recently have systems been developed that support up to 256 elements in parallel, often relying on complex setups with multiple systems to reach that number.

The quality of plane-wave imaging is achieved through diversity. A set of images where the prevalence

of reflectors against a background of varying noise from image to image enhances their presence and smooths out the sidelobes. This always occurs within a space primarily limited to the projection of the aperture—the region insonified by the plane wave—where the main contribution to the image comes from the 0-degree angle transmission, while the remaining angles provide diversity.

From the system's perspective, the ability to generate high-speed imaging depends not only on the time of flight but also on how quickly the acquisition buffers become available again (i.e., the time required to transmit the data to the storage unit). This time depends on the communication interface, for example, for an acquisition time of 14 microseconds and 256 parallel channels, it can be 150 microseconds (with a high-speed 3GBps interface) or 6.4 milliseconds (with a more common Gigabit Ethernet interface).

2. SPARSE ARRAYS FOR PLANEWAVE

For this work, we take as a reference the problem of operating a two-dimensional aperture of 1024 elements (32×32) spaced at λ at a central frequency of 15 MHz, using no more than 256 elements. This represents a 4-to-1 reduction, which can be implemented in various ways. However, when designing a sparse aperture, it is necessary to take into account the constraints imposed by the associated imaging modality. The volumetric imaging space considered ranges from 3 to 7 mm in depth, with a maximum size of 4 mm per side.

Therefore, it is important to analyze how the transmitted wavefront contributes to the generation of sidelobes in the near-field region of the aperture [7]. Figure 1 shows a representation of the wavefront generated by our reference aperture at $Z = 6mm$ in the fully populated case. The projection of the array, which is the area where the image is intended to be obtained, is marked by the two black lines. The complexity of the global wavefront pattern arises from the two-dimensional distribution of the elements, which leads to the formation of multiple secondary wavefronts, resulting in imaging artifacts. One way to mitigate these interfering wavefronts is by deactivating the outer elements.

In this case, the aperture is reduced to 256 elements—specifically, by limiting the emitting aperture to the central (16×16) elements. However, secondary lobes remain high due to the boxcar aperture shape. To reduce them, we can apply an apodization scheme based on element distribution.

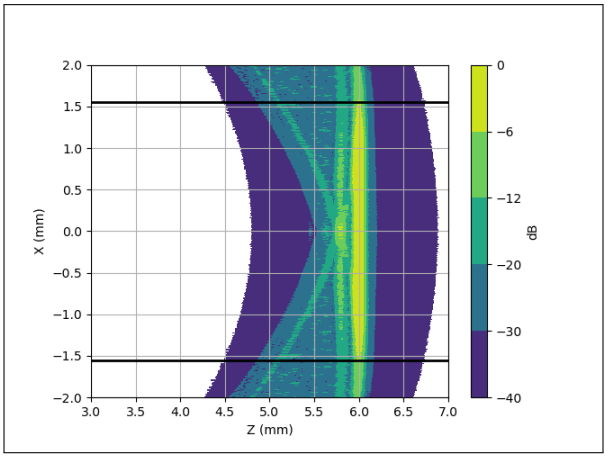

Figure 1. Emission waveform in $Y = 0$, fully populated case.

If we consider a sparse element distribution, such as a binned array, configured using a density scheme that implements a low-sidelobe window (in this case, a Taylor window), it is possible—at the cost of reducing the main wavefront size to one-third of that of the fully populated aperture—to suppress the main secondary wavefronts and reduce parasitic wavefronts to an irregular structure with very low intensity (figure 2). It is worth to mention that this apodization scheme avoids changing the emission voltage for each array element, a feature that is not available in all ultrasound systems.

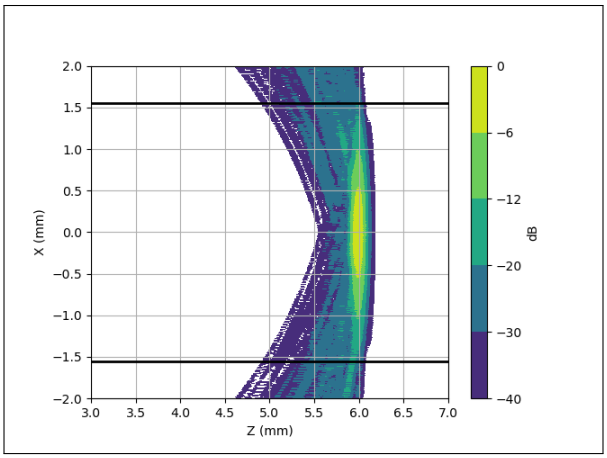

Figure 2. Emission waveform in $Y = 0$, 256 sparse case following a density apodization based on Taylor window

In reception, on the other hand, it is necessary to choose a solution that implements narrow beams to provide high-resolution imaging. In this regard, we have opted for a ring-shaped distribution. In both cases, we start by dividing the aperture into 4×4 bins, allowing us to select between 1 and 16 active elements per bin, depending on the desired density function across the aperture. In each transmission-reception process, both apertures are randomly selected according to their respective density function, thereby increasing the diversity of the diffraction pattern. Figure 3 presents an example of the solutions adopted for transmission (left) and reception (right) and the corresponding element density distributions.

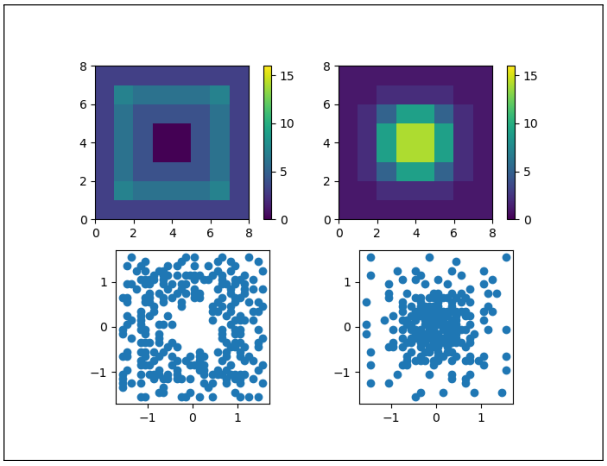

Figure 3. The 256 sparse array distribution. Top: In the left, element density for reception aperture. In the right, element density for transmission aperture. Bottom: In the left, example of reception aperture. In the right, example of transmission aperture.

For analyzing the process of generating an image for a single deflection angle (0^o) and compare the image from the full array with the one obtained using the sparse aperture, we have simulated the position of a line of scatterers along the Z-axis, separated by $0.25mm$. To assess the effect caused by diffraction, no white noise has been introduced into the model.

In Figure 4, we present the result of the full aperture. The image exhibits a large number of lobes and artifacts. To generate the final image, this image is combined with others obtained at different transmission angles, thereby reducing the interference pattern.

In Figure 5, we present the result of the sparse aperture. The image exhibits a significant reduction in artifacts, a lateral resolution comparable to that of the full aperture, and a secondary lobe pattern characteristic of the ring-shaped aperture.

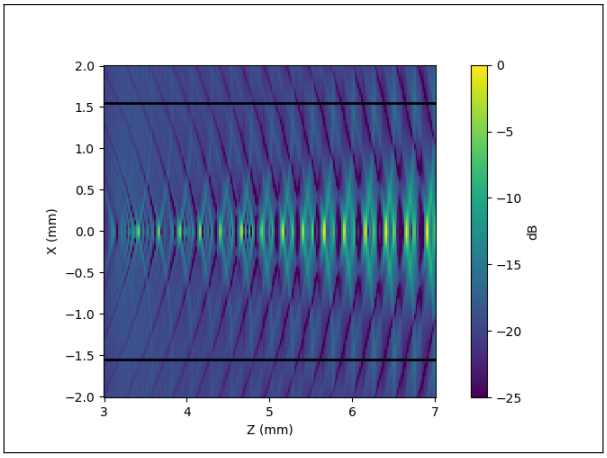

Figure 4. Image produced in the plane of interest ($Y = 0$) by the full aperture.

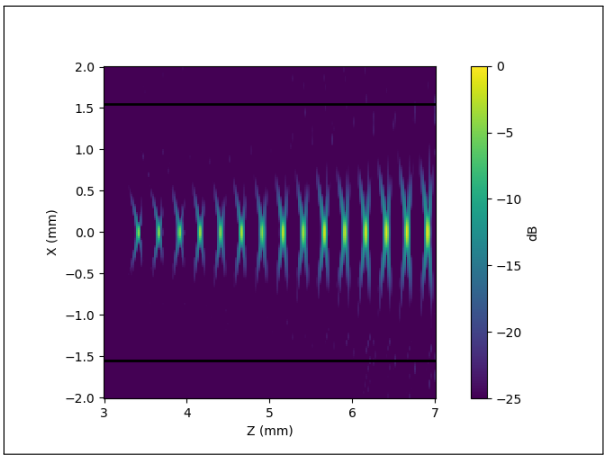

Figure 5. Image produced in the plane of interest ($Y = 0$) by the sparse aperture configuration.

To understand how the complete process works, we designed a sampling scheme with up to 32 emission shots, oriented to cover the entire reference volume. The scanning strategy follows a Fermat distribution based on the golden angle [8]. For the conventional plane-wave image, where emission superposition occurs in the illuminated scene, the final image is obtained by averaging the

32 steered images. To evaluate this process, we considered a more complex scene composed of a set of reflectors distributed in the XZ plane, maintaining the distribution along Z and a constant angular distribution along X. Figure 6 illustrates this in the case of a full aperture. The image can capture the presence of the reflectors but exhibits very low contrast.

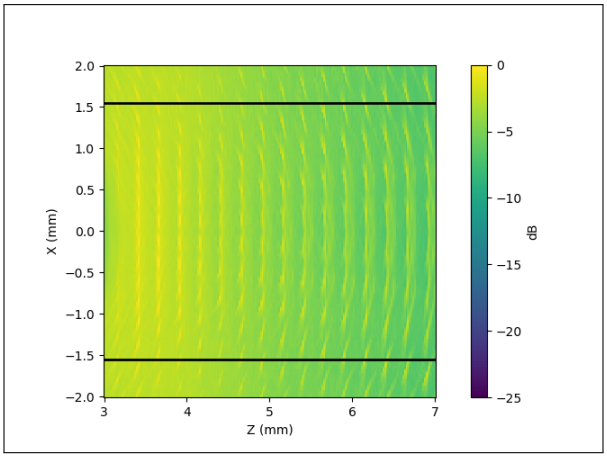

Figure 6. Image produced in the plane of interest ($Y = 0$) by the full aperture.

In the case of the proposed technique based on sparse apodized apertures, averaging between images cannot be applied since the emission beams are narrower and the images have minimal overlap. Therefore, the contribution of each image must be weighted according to the degree of influence that the emission beam has on the point under study. As explained earlier, while maintaining each aperture's respective density function for each shot, two new apertures are randomly generated—one for transmission and one for reception.

This operating approach, using sparse apertures and plane waves, offers an interesting alternative for integrating signal averaging. For a given angle, once a reception aperture has been selected, we could perform multiple consecutive transmissions with different sparse transmission apertures. By maintaining the same transmit lens and the same reception aperture, the signals can be directly averaged in the acquisition buffer.

By considering multiple sparse apertures for transmission that share the same main wavefront but produce different interfering secondary wavefronts, we can reinforce the main wavefront while generating destructive interference for the secondary wavefronts, thus minimizing their contribution to image artifacts (see figure 7). By adjusting the interference based on the relationship between transmission timing and time-of-flight, it is possible to make these variations "transparent" to the system, especially if a dual-buffer system is implemented.

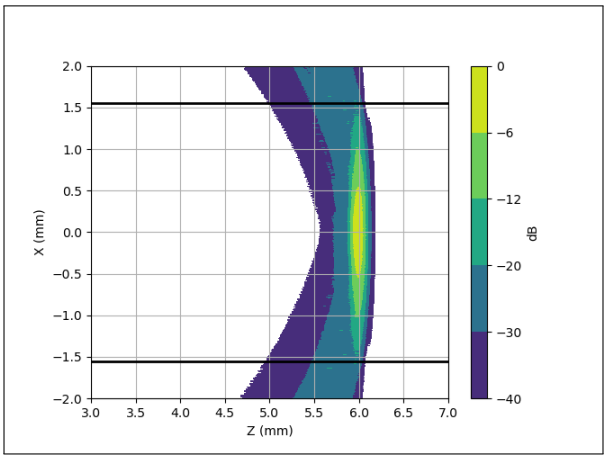

Figure 7. Emission waveform in $Y = 0$ averaged by 16 sparse apertures with 256 elements, following a density apodization based on Taylor window

Therefore, during the emission time of 32 shots required to obtain these 32 images, a total of 544 dispersed apertures were generated (32 for reception and 32×16 for transmission). The image produced by this configuration for the proposed imaging region is shown in Figure 8. Compared to the full-aperture image, the sparse array image improves contrast while maintaining lateral resolution. Residual secondary lobes are still present, but they are not significant enough to degrade image quality.

2.1 Volumetric imaging

We now consider a three-dimensional scene in which the reflectors are distributed along a spiral cone, with its vertex located at the center of the aperture. In this configuration, the reflectors are positioned at varying angles in both elevation and azimuth, as well as at different radial distances within the scanning volume. This setup allows us to compare the imaging performance of a full array versus a sparse array. In both apertures, the 32-angle sampling strategy based on the Fermat spiral was used. The figures display isosurfaces at -12 dB levels. To enhance the interpretability of the scene, the maximum intensities have been projected onto the XY, XZ, and YZ planes.

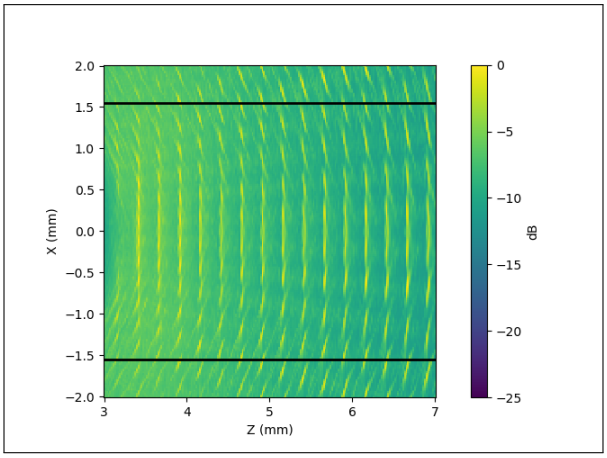

Figure 8. Image produced by the sparse aperture in the plane of interest ($Y = 0$). 16 averaged emissions performed.

The image obtained using the full aperture (Figure 9) exhibits limited dynamic range and resolution, indicating that the proposed scan is not sufficiently dense to produce a high-quality image. In contrast, the image generated using the sparse aperture—by introducing averaging and performing 16 transmissions (each with a different sparse emission aperture) per reception aperture—shows a significant improvement in dynamic range, along with a slight enhancement in lateral resolution compared to the non-averaged approach (Figure 10).

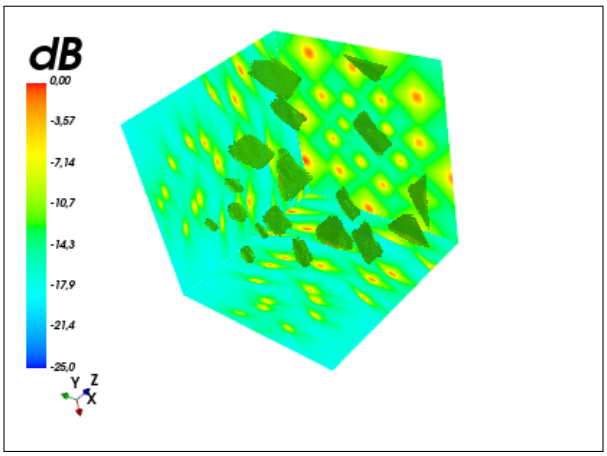

Figure 9. Volumetric image produced by the Full aperture.

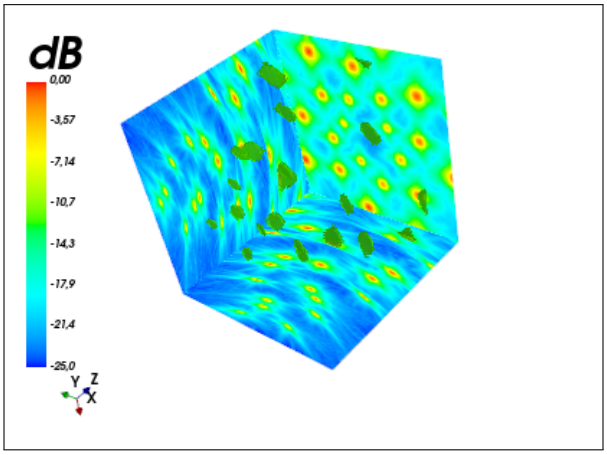

Figure 10. Volumetric image produced by the sparse aperture. 16 averaged emissions performed

The comparison between both apertures demonstrates that, when properly organized, sparsity can be effectively exploited to enhance near-field aperture performance and yield high-quality images. Averaging over the acquisition channels enables this process without incurring additional data flow costs. Furthermore, if the system supports double buffering for acquisitions and allows synchronization of the averaging transmissions with the transmit timing, the process can be rendered effectively transparent in terms of acquisition time. Within this imaging range and under plane wave illumination, the full aperture introduces a substantial number of artifacts and requires greater angular diversity and a higher number of transmissions to achieve comparable image quality.

3. CONCLUSIONS AND FUTURE WORK

The work has proposed a strategy for using sparse apertures in a plane-wave imaging system. Instead of proposing an exhaustive search for a solution, an open approach has been taken, where dozens of apertures are utilized to exploit the diversity they offer in order to improve the overall image result, according to a spatial distribution pattern designed to achieve a specific apodization response. In a way, the apodization used narrows the beam during emission, which nonetheless remains wide enough to allow for a sweep with a narrow beam during reception, generating a type of multi-beam focusing. It has been demonstrated how we can use several sparse apertures in transmission for the same reception to improve the signal-

to-noise ratio, and it has been suggested how this process can be integrated into the system as an averaging operation, parallelizing its activity with data transmission to maintain the acquisition rate at the desired values.

To evaluate this, three possible scenarios were designed in which we could compare the improvement relative to the flat aperture case. On one hand, the reduction of the artifact pattern caused by multiple wavefronts generated in the near field. On the other hand, the improvement in dynamic range when the interfering pattern becomes more complicated due to the regularity of the reflectors. And finally, when the volumetric image as a whole is considered. In all of these scenarios, the sparse aperture image has maintained an excellent response in terms of lateral resolution, even improving upon that of the full aperture.

The proposal is aligned with the objectives of the project, which seek to enhance the detection of microstructures using plane wave high-frame-rate imaging, while simultaneously reducing computational complexity and adapting the sensor to the available hardware resources. The forthcoming development of this work is directed toward the experimental phase, with the aim of assessing the performance of this technique when applied to functional imaging.

ABSTRACT

Ultrasound 3D imaging with arrays usually requires hardware systems with more active channels than for conventional 2D imaging, which increases systems complexity. Furthermore, it increases the beamforming difficulty, as more image lines have to be generated (3D volume) using more acquired raw signals (A-Scans). Typical approaches to this problem can be divided in hardware and software solutions. In the first, the beamforming process is carried out by a specialized hardware (FPGA, ASIC's, etc.), with lower power consumption, but also with lower flexibility. On the other hand, software beamformers are very flexible in terms of programming, but they require a much larger bandwidth with the acquisition system. This work presents a modular and flexible hardware architecture for 2D and 3D ultrasound imaging, which combines hardware beamforming capabilities with high-speed links with a processing computer. This approach enables to work with both hardware and software beamformers, taking full advantage of each one of them. A description of the architecture is given, along with the expected performance in terms of hardware processing power and data transfer rate. Finally, application examples are given: Total Focusing Method imaging in non-destructive-testing, and functional ultrasound imaging in the brain for pre-clinical models.

Keywords: *ultrasound, beamforming, 3D imaging*

1. INTRODUCTION

Ultrasound systems have evolved in the last years from hardware processing with highly specialized electronics, to software beamforming by high capacity computers, mainly because of the availability of powerful Graphical Processor Units (GPU), which are very efficient for the implementation of typical ultrasound imaging algorithms, and are easy to develop with than hardware architectures. Nevertheless, the software approach has limitations with regard to power consumption and integration for the development of industrial and medical devices, which prevents to completely abandon the specialized hardware approach.

This work presents a flexible and modular architecture able to fulfill the requirements of both, hardware and software beamformers. The idea behind that is to provide a platform were new developments can be performed faster and at lower cost by software programming, mainly oriented to scientific research and early stages of final product R&D, while it still have the capacity of implementing the more demanding parts in hardware, at higher processing rates with less power consumption, for final deployment.

A description of the architecture is presented, along with practical examples in two application fields: pre-clinical imaging and non-destructive-testing.

2. HARDWARE ARCHITECTURE

The philosophy of this system is a flexible architecture to work in two different scenarios:

1. Hardware beamforming (HWBF): Whole beamforming and post-procesing is performed by the ultrasonic system and the host PC just displays the image.
2. Software beamforming (SWBF): System sends in real time the raw acquisition data in order to be processed by a high performance computer.

The architecture of the system is scalable, in order to build systems from 32 channels to 512 active channels, keeping the ability of real time beamforming the image in real time.

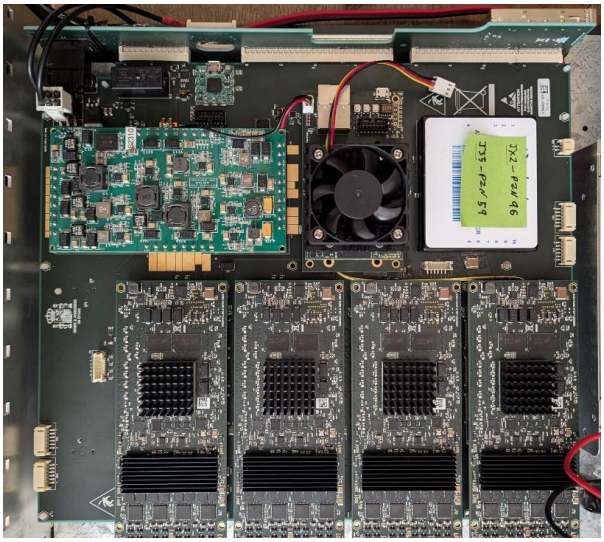

Figure 1. Motherboard of a 128 channels system, with 4x32 channels USMOD32 modules and FPGA SoC control unit.

2.1 System architecture

The control of the emission circuits, the digitalization of the received signals and the beamforming of the image are carried out in a distributed way in the system's FPGAs, transferring the final image to a host computer. The system also has the enough output bandwidth to send raw data to a remote system to be processed in real time. An FPGA SoC with embedded ARM processors performs the control of the system, and also implements the algorithms that are not too intensive but whose execution on the host PC can be a disadvantage due to larger latency.

The main design goals of the architecture are scalability, distributed processing and flexibility. Scalability is important to cover applications that require different numbers of channels, which is common in NDT. On the other hand, distributed processing is essential to handle the large volume of generated data. The third goal is flexibility, i.e. to be able to easily implement different imaging techniques, which is not only achieved by the reprogrammable nature of the FPGAs, but also by being able to evacuate the raw data in real time to an external processing system, e.g. a high-performance PC with GPUs.

The system is based on modules (USMOD32) capable of controlling, digitalizing and processing 32 ultrasound channels. The modules are connected together via a high-speed segmented bus to make possible systems with any number of channels in blocks of 32. **Figure 1** shows an implementation with 128-channels. Each module contains the pulsers, protection circuits and analog front-end (amplifier, filter and A/D converter) for 32 channels and 1 GB of DDR memory to store the beamforming results or the received signals. The selected FPGA is the XC7K160T, from Advanced Micro Devices (AMD, formerly Xilinx) Kintex series. The footprint is fully compatible with the higher-capacity XC7K325T and XC7K410T models for systems that require more hardware processing power.

Two segmented buses connect the FPGAs of the processing modules. The first, based on 10 LVDS pairs (1 Gb/s per pair), is used for programming acquisition and processing parameters and sending the images already conformed to the FPGA-SoC, which can carry out additional processing prior to sending them to the host PC.

The second bus is based on AMD GTX 7-series transceivers, which provide up to 10 Gbps full duplex communication in each direction. The FPGAs integrate 8 GTX transceivers, that are used to connect each module with the previous one with 4 GTX and to the next module with the remaining 4. Thus, closing the circuit (**Figure 2**) results in two circular buses of 40 Gbps each, with data flowing in opposite directions, allowing data transfer between any two FPGAs in the system at 80 Gb/s if both directions are used. This high-speed bus is used to transmit the partially beamformed images between the FPGAs of the modules, since each image line requires information from all channels.

In the HWBF mode, each module beamforms the image lines with the information acquired by its 32 channels, and sends them over one of the two 40 Gbps buses to the next FPGA. This one adds the results of beamforming its own channels with the data received from the previous one and sends the result to the next module.

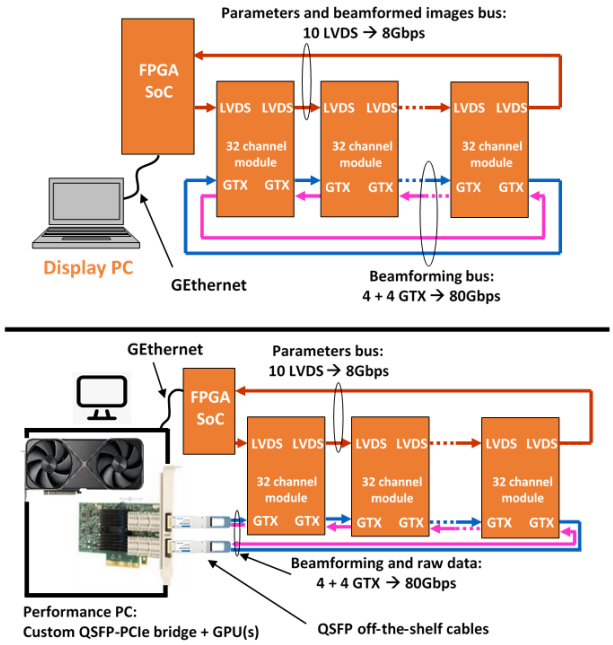

Figure 2. *Top*: configuration for hardware FPGA beamforming, host PC only for display. *Bottom*: configuration with a high performance PC, where beamforming process can be done by software.

When the data has travelled through all the FPGAs, the image is fully formed.

The image is stored in the dynamic memory (DDR), and it is divided into as many parts as USMOD32 are present in the system. This leverages not only the processing power of all the FPGAs, but also the memory bandwidth of all the modules, making the system a high-speed distributed processing architecture. This is the main difference with regard to previously proposed centralized architectures, where a central node requires a large memory bandwidth to store the result. This is particularly important in TFM and PWI image modes, since this kind of image modes have to sum many sub-images obtained with different emission, previous results has to be loaded from memory, summed with current ones and stored back to memory.

For the SWBF, the high bandwidth bus is used to send raw acquisition previously stored in the DDR of the USMOD32 through 2 QSFP cables. These cables are connected to a custom FPGA design implemented in a FPGA based PCIe board with 2 QSFP sockets, mounted in 8-lane PCIe 3.0 slot in a PC. The data from ultrasound system is stored in the PCI board DDR, and then is sent via DMA to PC main memory for the software processing of the ultrasonic data.

2.2 FPGA architecture

Figure 3 shows the representation of the receiving datapath. Other necessary subsystems, such as the emission beamformer, have been omitted in the figure for clarity. In general, the connections shown in this image follow the AXI4-Stream protocol, except for the connection to the DDR which is AXI4 and the 'register access bus' which is a 'custom' register access protocol similar to AXI4-Lite [1]. For the sake of clarity, the data width and operating frequencies of the buses have not been made explicit, but as a guide, they have been drawn with the width in relation to the total bus capacity. For example, the wider buses are capable simultaneously acquiring 32 signals and transmitting the beamforming result, therefore, they have a capacity of at least 28Gb/s. The narrower busses are sized to be transmitted over the LVDS links and, therefore, they have a maximum capacity of 8 Gbps (typically 32 bits at 250 MHz). The element named 'AXI-infrastructure' in Figure 3 consists of several elements of varying complexity such as multiplexers, DMAs, switches, clock domain changes, to name a few.

The datapath starts with the signals of the 32 channels being amplified, filtered and digitalized by the Analog Front End (AFE). Once inside the FPGA, the signals are filtered with a symmetrical FIR filter with 63 coefficients, followed by optional decimation. Afterwards, an adder with a high-capacity FIFO can perform averaging of up to 16 acquisitions. At this point, the acquisition can take two paths: it can either go into the beamformer or it can be stored in the module's DDR as raw data.

In the case of a remote PC performs the beamforming, the connection shown in red is used to dump the data from the DDR to the QSFP links. The protocol used to connect both the FPGAs to each other and the FPGAs to the PCIe card is the AURORA 64/66 protocol [2].

In case of hardware beamforming, the acquired signals can be input directly from the output of the averaged signals or can be loaded from the DDR memory. This is particularly useful if the same acquisition is to be beamformed several times by modifying the parameters (Multi-beamforming).

The beamformed data is summed with that of the precedent FPGAs, which are received from the GTX links. The sum is forwarded to the next FPGA, however, part of this sum has to be accumulated to the previous sub-images. Each FPGA is allocated a part of the image, in order to distribute the memory bandwidth usage among all modules.

2.3 Hardware beamforming

The beamforming operation is performed by a delay sum beamformer with a novel architecture previously developed

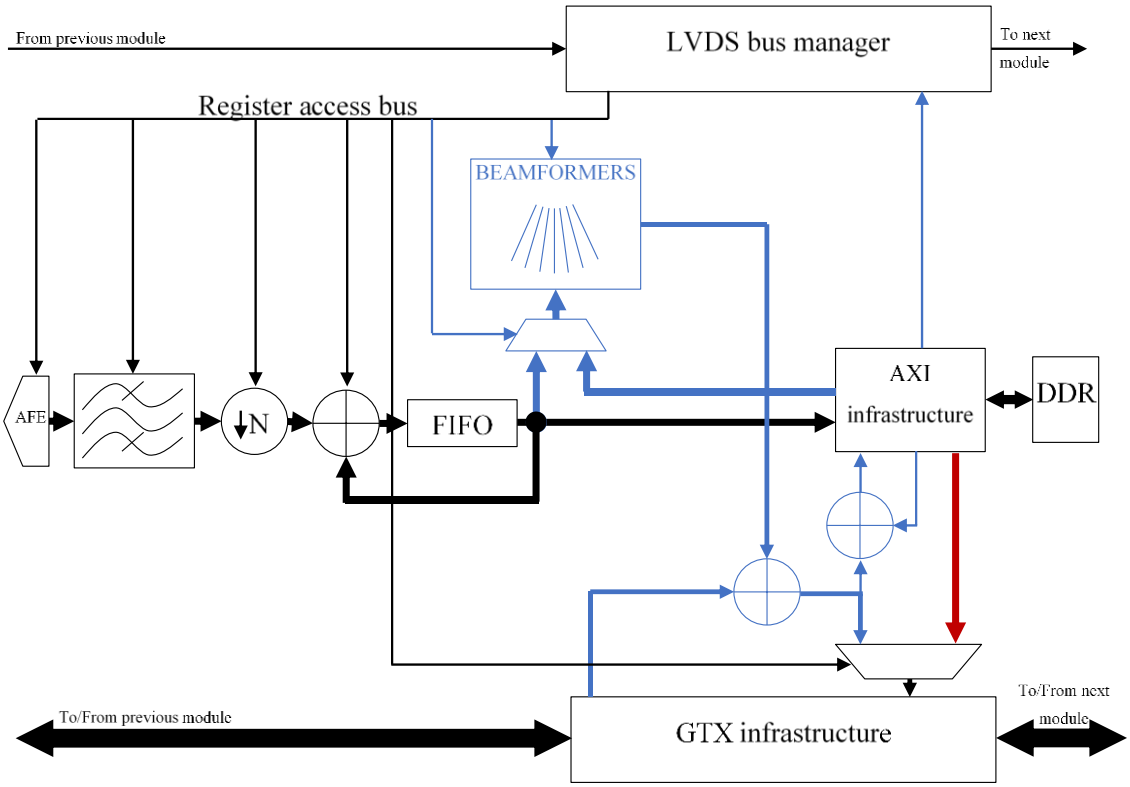

Figure 3. Schematic representation of the datapath inside each FPGA. Elements in black are utilized in both hardware and software beamforming. Blue elements are necessary for hardware beamforming while red connection is only used to dump raw acquisitions to the PC for a software beamforming.

by our group [3]. The delays are performed by using fractional delay filters [4] in order to get time resolution above the sampling frequency [5]. This design features a systolic and parallel architecture for interpolation and beamforming where fractional filtering and the process of sum are imbricated in the same hardware. Besides, this architecture makes an extensive use of the DSP tiles present in FPGAs [6]. These tiles are "hardwired" inside FPGA and therefore are less power consuming and can switch at higher frequencies than circuits implemented with regular FPGA resources, allowing time-multiplexing of these resources. Another key of the design are the delay calculators. Unlike other beamformers [7] where the delays are pre-calculated and loaded in FPGA memory, this beamformers uses a circuit to calculate iteratively the time delay that only needs parameters with a total of 80 bits wide. The delay calculator circuit is a pipelined version of the presented in [8] and a key part of the patent [9]. The pipelining, allows this logic switch at 250MHz using FPGA fabric resources.

Figure 4 shows the schematic of the beamformer. The samples coming from ADCs are stored in a 16 bit wide, 2048 deep circular buffer (one 32Kb Block RAM per channel). Simultaneously, the delay calculator output is used in this way: the integer part of the delay corresponds to index of the sample that is the input of the fractional filter, and the fractional part of the delay, chooses the set of coefficients used to apply the desired fractional delay (0, 1/4, 2/4 or 3/4). The delayed sample is automatically summed to the delayed sample of the other channels since delay filters are cascaded. Whole structure switches at 250MHz, so, we can time multiplex it in order to calculate more than one scan line at once. For example, with a broadband array of 15MHz center frequency where the sampling frequency can be 62.5 MHz, 4 scan lines can be obtained in parallel, while, in a 3MHz center frequency with 15.125MHz sampling frequency, 16 scan lines can simultaneously obtained. This can be useful in the conventional phased array technique if the emission focus is broad enough to beamform multiple scan lines of the image

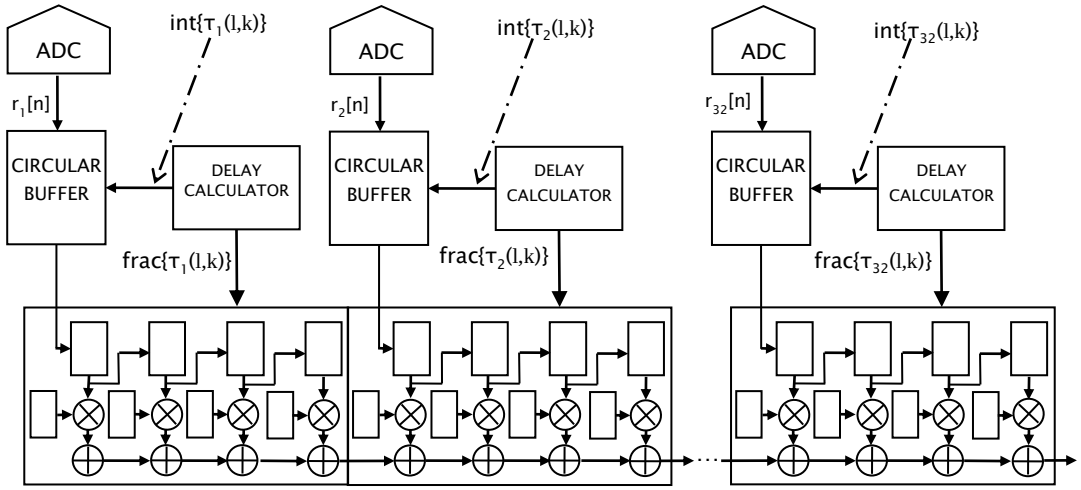

Figure 4. Beamformer architecture: fractional delay and the sum are performed by same FPGA resources, the DSP tiles.

in every emission. But is even much more interesting in plane wave image (PWI) or total focussing method (TFM) where emission is unfocussed and whole image have to be beamformed after every emission event (sometimes called "sub-image"). The ability of implement PWI or TFM in real time depends in the capacity to beamform all scan lines of the sub-image before next emission event. In this work we want to analyze three examples:

A PWI for functional ultrasound (fUS) for rat brain: c=1.5 mm/us, 15MHz center frequency (F_s=62.5 MSPS), L=128 lines of d=15mm depth, 500 beamformed images per second, each one compounded by 7 plane waves (PRF=3500Hz).

B Total Focusing Method: steel c=6.25 mm/us, 3MHz center frequency (15.125MSPS), 128 lines of 50mm depth, 25 images/s compounded by 128 sub-images, one per array element (PRF=1920Hz).

C 3D Total Focusing Method: 16x16 array (256 elements), steel c=6.25 mm/us, 5MHz center frequency (31.25MSPS), 256 lines of 50mm depth, 25 volumes/s compounded by 256 sub volumes, one per array element (PRF=6400Hz).

To determinate if the hardware is able to implement these examples in real time we have to define the next figures: $\mathbf{T_{PRF}}$ (1 / PRF) is the between different acquisitions. $\mathbf{T_A}$ is the time it takes acquiring necessary samples for the image, **L** is number of image lines, **M** is the relationship between switching frequency of the beamformer and acquisition sampling frequency and defines the number of lines in parallel can process in the acquisition time ($\mathbf{T_a}$). **N** is Number of beamformers (the structure shown in Figure 3 can be replicated inside FPGA). **R** is the times the beamformers have to reprocess the same acquisition data in order to beamform all the L lines of the image.

$$R = \left\lceil \frac{L}{M \cdot N} \right\rceil$$

Furthermore, to operate in strict real time, the time that takes to beamform the image (or sub-image) has to be lower than the time between different acquisitions:

$$R_{MAX} = \left\lfloor \frac{T_{PRF}}{T_A} \right\rfloor$$

Using these definitions, **Table 1** shows the number of beamformers needed for the three examples presented, employing this equation:

$$N = \left\lceil \frac{L}{M \cdot R_{MAX}} \right\rceil = \left\lceil \frac{L}{M \cdot \lfloor T_{PRF}/T_A \rfloor} \right\rceil$$

As **Table 1** reveals, the more exigent image mode, the more beamformer structures that have to fit in the FPGA to operate in real time. **Table 2** shows the resource used for the beamforming, taking into account that there are also other subsystems that have to fit in FPGA. Furthermore, the total resource consumption should be below 80% in some critical resources (LUTs

particularly) in order to allow place-and-route tool to reach timing closure.

Table 2~~2~~1. Number of beamformers needed for each acquisition mode

	A	B	C
c (mm/µs)	1,5	6,25	6,25
D (mm)	15	50	50
Ta (µs)	20	16	16
L (lines)	128	128	256
M (lines/beamformer)	4	16	8
FPS (images/s)	500	25	25
Sub-images (angles or elements)	7	128	256
PRF (Hz)	3500	3200	6400
T_{PRF} (µs)	285,71	312,50	156,25
Rmax	15	19	9
N (beamformers)	**3**	**1**	**4**

As can be appreciated with **Table 1** and **Table 2**, the mid-range FPGA XC7K160 can implement complex types of image like example B, but is unable to perform fUS in real time (example A)[10]. However, a system which features high range FPGAs can perform fUS or 3D TFM in strict real time without need a powerful external computer. Despite high-end FPGAs have a higher cost, their lower power consumption and size than a solution based on an external PC, could justify their use for industrial developments.

3. RESULTS

Three application examples with a 128 channels system developed with the proposed architecture are presented. **Figure 5** shows a functional ultrasound image of a rat brain, obtained with a 15 MHZ phased-array transducer, while a visual stimulus is applied to the animal. The Doppler image was generated by the ultrafast plane-wave technique [10] with 5 angles between -6º and 6º, 2 emitted pulses, 8 kHz PRF, 4 averages and a total of 8.000 consecutive images (20 seconds continuous acquisition). The output trigger of the system was received by the visual stimulus system and delayed 10 seconds before emitting a vertical lines pattern to the right eye of the mouse. This way, a base-line reference of 10 seconds can be compared with a stimulus of 10 seconds to detect the activated brain zones. The experiment was repeated 10 times and the response was averaged for better signal-to-noise ratio. Figure 8 shows the functional image in color, overprinted on a single Doppler image in black and white. The activated zone corresponds with that expected for the given stimulus, and the spatial resolution and SNR are in accordance with the experiment set-up.

A second experiment is presented, in this case, for a non-destructive-testing application (**Figure 6**). An 11x11 matrix array of 3.5 MHz was used for imaging inside a calibration block with several flat-bottom holes at different depths. The virtual array method was used [11] to obtain, in real time, the focusing delays inside the material, accounting for the refraction at the interface. The high-speed links were used to transfer data to a PC with an NVidia RTX4080 GPU, where the beamforming algorithms achieved an imaging rate of 10 volumes per second, automatically detecting the component surface location and shape (3D auto-focus).

Figure 7 shows the HWBF performance of the system, by acquiring a TFM image with a 15 MHz 128 elements array, in real-time. The beamformed region is 36mm wide (probe has an aperture of 32 mm) and 50mm depth. The beamformed image size has 256 lines wide and 700 points per line depth. With this configuration, it took 230ms to generate that image (4 frames per second). The system used for this experiment ships the smallest compatible FPGA (XC7K160), so this frame rate can be multiplied by 4 using higher range FPGAs.

Table 3~~3~~2. Number of beamformers that can fit in the 3 different pin compatible FPGAs. In bold, the limiting resource.

	one beamformer	XC7K160		XC7K325		XC7K410	
# BEAMFORMERS	1	2		4		8

Figure ~~5~~57. Hardware beamformed TFM with imasonic 128 elements 15MHz center frequency, 0.25 pitch probe, 36x50mm, 256 x 750pixels.

4. CONCLUSION

This work presents a high-end flexible and scalable hardware architecture for ultrasound imaging systems, able to operate in real-time by hardware beamforming, or transferring the raw data to a high-end processing computer for software beamforming. A 128 channel was built and tested in three demanding applications: Pre-clinical functional ultrasound brain imaging, 3D autofocused imaging in non-destructive testing, and real-time inspection with TFM technique. Future work includes extending the system channel count in a new prototype, able to work with 1024 elements matrix arrays for 3D functional ultrasound.

ABSTRACT

Photoacoustic Imaging (PAI) combines optical excitation with ultrasound detection to produce high-quality molecular images of intact biological tissues. Conventional systems rely on Class IV [1] pulsed lasers, which limits clinical translation. This work explores the use of pulsed semiconductor diodes for their portability, versatility, and low-cost. However, their lower peak power decreases PAI signal amplitude. Implementing deep learning techniques trained with realistic synthetic data is a promising technique to increase PAI image quality [2]. Here we create a framework which simulates real scenarios taking into account acoustics and optical properties, ultrasound transducer characteristics and fiber bundles features, crucial to optimize reconstruction performance with a Neural Network. The simulated experimental setup included an array of optical fibers connected to semiconductor diodes parallel to a 128-element transducer array which registers the signal generated by the absorbed light. Optical properties were simulated in MCX Monte Carlo software using GPU parallelization. k-Wave software was used for acoustic simulations and Time-Reversal (TR) image reconstruction. Finally, a Neural Network model implemented using Tensorflow enhanced the reconstruction, recovering up to 3 cm depth and 200 µm of resolution, delivering exceptional vascular imaging quality.

1. INTRODUCTION

Photoacoustic imaging (PAI) is an emerging biomedical imaging modality that combines optical excitation and ultrasound detection to generate high-contrast structural and molecular images of biological tissues. Its underlying mechanism relies on the thermo-acoustic effect, mathematically represented by:

$$p_0 = \Gamma \mu_a \phi, \tag{1}$$

Where p_0 is the initial pressure rise, Γ is the

Grüneisen parameter, μ_a is the tissue absorption coefficient, and ϕ is the local optical fluence.

State-of-the-art PAI systems typically utilize Class IV pulsed lasers, which, despite providing sufficient optical power, present substantial drawbacks such as high costs, large size, and significant regulatory restrictions, limiting clinical translation. To overcome these challenges, semiconductor diode lasers have emerged as a compact and cost-effective alternative. However, their lower optical output power substantially reduces fluence, negatively impacting image quality and clinical applicability.

Recent advances in computational imaging, specifically deep learning techniques integrated with conventional reconstruction algorithms, offer promising pathways to compensate for reduced fluence and improve reconstruction accuracy. In this study, we develop and evaluate a neural network model trained using realistic numerical simulations of our experimental setup, meticulously accounting for relevant acoustic and optical properties of biological tissues. By improving image reconstruction quality, this approach aims to mitigate the intrinsic limitations associated with diode-based illumination, thereby enabling the development of clinically viable, handheld PAI systems.

2. METHODOLOGY

Training neural networks effectively requires extensive datasets. To meet this requirement, we developed a computational framework to generate realistic synthetic data closely replicating our experimental setup. This framework integrates acoustic and optical simulations using accurate physical parameters, thereby producing synthetic pressure distributions that closely mimic real-world scenarios. The resulting data is subsequently used to enhance the quality and effectiveness of signal post-processing and reconstruction.

2.1 Optical simulations

An array comprising five semiconductor diodes is arranged to uniformly illuminate the acoustic transducer acquisition plane, as illustrated in Fig. 1A. Optical simulations were conducted using MCX Monte Carlo software [3] to calculate the two-dimensional fluence distribution at the transducer acquisition plane. The simulated medium was water, selected due to its low scattering and absorption coefficients [4], facilitating clear evaluation of the optical fluence pattern.

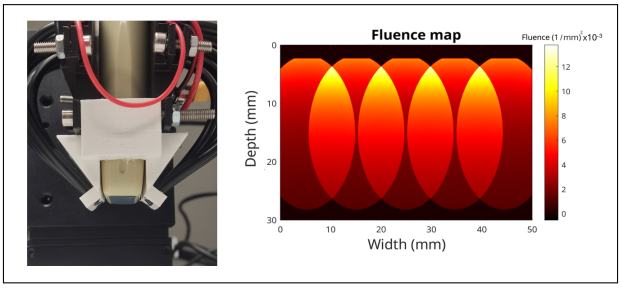

Figure 1. a) Experimental setup simulated. b) Fluence map in the transducer plane corresponding to the acquisition area.

2.2 Phantom generation

Phantoms with realistic vessel structures were generated using a 3D stochastic algorithm informed by real vessel data from coronary arteries [5]. Three distinct projections were created for each generated phantom, producing a comprehensive set of 2D images. By applying various geometric transformations and deformations, a diverse dataset comprising 2000 phantom images was compiled. Each phantom image was subsequently combined with the simulated fluence map to yield the corresponding initial pressure distribution. The ground truth used for neural network training was defined by an ideal, uniform fluence map, representing optimal illumination conditions with a perfectly homogeneous light source.

2.3 Acoustic simulations

Acoustic simulations were conducted using the k-Wave software [6], which addresses both the forward and inverse acoustic propagation problems. The forward simulation involved propagating the initial pressure distribution through water by solving the acoustic wave propagation equation. Signals were captured using a simulated 128-element ultrasound transducer array with a central frequency of 7.5 MHz, considering the acoustic properties of the medium and the geometric arrangement of the transducer elements [7].

Subsequently, the inverse acoustic problem was solved using the classical Time-Reversal (TR) reconstruction algorithm. This method reconstructs the initial pressure distribution by temporally reversing and re-emitting the recorded signals from each transducer element, effectively back-propagating the acoustic waves to their original spatial locations.

2.4 Neural network

The neural network framework developed for this study employs two distinct architectures, as depicted in Fig. 2. The first network is a U-Net designed to process the raw signals simulated with k-Wave under realistic fluence conditions and output signals corresponding to an ideal uniform fluence scenario. This step effectively corrects for fluence heterogeneities inherent in diode illumination.

Subsequently, a Y-Net architecture is utilized, receiving as inputs both the fluence-corrected signals from the U-Net and the initial reconstruction produced by the TR algorithm. The Y-Net generates an enhanced reconstructed image by combining the preliminary reconstruction information (TR) with additional data contained in the fluence-corrected signals, capturing potentially lost details during the initial reconstruction phase. All pressure maps and signals were normalized to their respective maximum values before neural network processing to ensure consistent training conditions and optimize network performance.

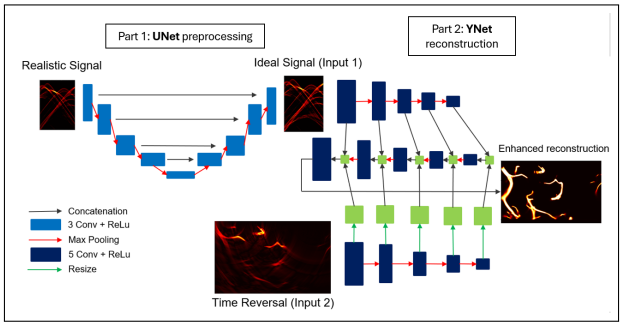

Figure 2. Neural Network workflow scheme.

3. RESULTS

3.1 Image reconstruction

The semiconductor diode illumination setup generates a non-uniform fluence distribution, as depicted in Fig.1, achieving a maximum imaging depth of approximately 30 mm. This depth represents the practical imaging limit for the current photoacoustic configuration, beyond which the fluence intensity decreases by 20% compared to the maximum. When comparing reconstruction techniques, the TR algorithm achieves effective reconstruction only up to approximately 20 mm, beyond which the image quality significantly deteriorates due to insufficient fluence and limitations in the algorithm, with the reconstruction pressure dropping to less than 20% of the maximum peak. In contrast, the combined approach utilizing the TR algorithm followed by the neural network (TR + Neural Network) successfully reconstructs images across the entire depth range enabled by the fluence distribution, demonstrating superior capability in compensating for the non-uniform illumination inherent in diode-based setups.

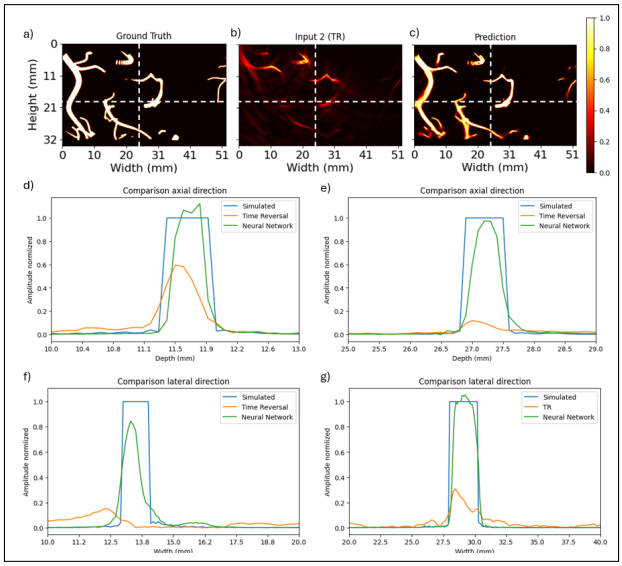

Figure 3. Enhanced image analysis. a) Ground truth. b) TR reconstruction. c) Neural Network reconstruction. d,e) Axial profiles. f,g) Lateral profiles.

3.2 Image enhancement and artifact reduction

Further evaluation of axial and lateral profiles in the reconstructed images provides insights into the effectiveness of signal recovery and artifact mitigation, as illustrated in Fig. 3. Axial profiles demonstrate the neural network's capability to compensate for fluence-induced signal loss at increased depths, effectively maintaining higher contrast compared to the TR reconstruction (Figs. 3d and 3e). Lateral profiles highlight the neural network's proficiency in reducing limited-view artifacts present in the TR method, which typically manifest as data loss along axial vessel structures. The neural network enhances the contrast and clarity of these structures, significantly improving overall image quality (Figs. 3f and 3g).

However, despite notable improvements, the neural network occasionally reconstructs vessel-like structures

absent from the ground truth, introducing artifacts. This phenomenon likely arises from model overfitting due to limited variability in the training dataset. Expanding the training set size and diversifying case scenarios could mitigate such artifacts and further enhance reconstruction accuracy.

4. CONCLUSIONS

The integration of classical reconstruction algorithms with neural network-based approaches demonstrates significant potential for improving the image quality of low-cost, handheld photoacoustic imaging systems. This combined methodology effectively compensates for the inherent limitations of semiconductor diode-based illumination, such as reduced and non-uniform fluence, by enhancing both image depth and contrast. Crucially, accurate and realistic simulation environments are essential for the successful training and performance optimization of neural networks. By employing meticulously characterized synthetic datasets that closely replicate experimental conditions, neural networks can achieve reliable reconstruction capabilities, leading to improved clinical viability and diagnostic utility of compact photoacoustic devices. Future efforts should focus on expanding the variability and size of training datasets, addressing artifacts introduced during reconstruction, and validating performance against experimental data to ensure robust clinical translation.

TOWARDS BROADBAND LATERAL BAW EXCITATION IN A LOW-VELOCITY ANISOTROPIC SUBSTRATE

Konstantin B. Yushkov[1*] **Natalya F. Naumenko**[1] **Vladimir Ya. Molchanov**[1]
[1] Acousto-Optical Research Center, University MISIS, 119049 Moscow, Russia

ABSTRACT

We investigate a novel transducer structure that combines the thin plate lithium niobate (LN) and interdigital transducer (IDT) technologies. We simulated an anisotropic LN-on-TeO_2 structure with an IDT atop, in which shear horizontal (SH) bulk acoustic wave (BAW) excitation was considered. X-cut LN plate is bonded to the substrate, and the IDT electrodes are aligned with $Z + 41°$ direction of pure SH displacement. The transducer was aligned with (110) plane of the TeO_2 substrate having the SH BAW velocity in the range from 0.62 to 0.80 km/s depending on the cut angle α. Frequency dependencies of the resulting BAW polarization in the substrate were retrieved and analyzed. With a fixed-pitch IDT, SH BAW excitation can be achieved in the relative bandwidth of $\sim 20\%$ at various central frequencies depending on the LN plate thickness. At the boundaries of the excitation band, we observed transformation of the BAW mode from SH to longitudinal polarization. Owing to periodic IDT structure, the beam steering effect is observed for the excited SH BAW in TeO_2 that helps to extend the bandwidth of light-to-ultrasound coupling in photonic applications.

Keywords: *acousto-optics, beam steering, interdigital transducer, anisotropic multilayer structure*

1. INTRODUCTION

Broadband excitation of bulk acoustic waves (BAWs) is of great demand in various applications including acousto-optics and photonic integrated circuits. The golden standard of BAW transducers up to 1 GHz is thin plate lithium niobate (LN), which allows for longitudinal/shear mode excitation in solids with high electromechanical coupling. Interdigital transducer (IDT) technology is an effective method for surface and hybrid wave launching, but its applications in BAW domain are still limited. Commonly, leakage of acoustic waves into bulk modes is considered as a drawback and a source of undesired losses in high-frequency ultrasonic devices. To eliminate leakage, high-velocity substrates or membrane structures are commonly used in sufrace acoustic wave devices.

We analyze the possibility of applying IDT techniques for purposeful shear horizontal (SH) BAW excitation in a low-velocity TeO_2 crystal substrate (Fig. 1). Periodical out-of-phase excitation of ultrasound enables the effect of beam steering in the substrate crystal, which can be used to extend the phase-matching band of acousto-optic deflectors and tunable filters [1]. Radiation pattern of a periodically poled transducer depends on the ultrasound frequency that results in effective wavefront tilt and readjustment of acousto-optic phase matching. In this report, we numerically analyze excitation bandwidth and acoustic modal structure created by the said transducer.

2. METHODS

The proposed transducer structure combines the thin plate LN and IDT technologies. We simulated an anisotropic LN-on-TeO_2 structure with an IDT atop, in which SH BAW excitation was considered (panel A in Fig. 2). X-cut LN plate is bonded to the substrate, and the IDT electrodes are aligned with $Z + 41°$ direction of pure SH displacement. The transducer was aligned with (110) plane of the TeO_2 substrate having the SH BAW velocity in the range from 0.62 to 0.80 km/s depending on the cut angle α.

The transducer's performance was modelled with a semi-analytical SDA-FEM-SDA method developed for arbitrary anisotropic multilayered structures excited by an IDT: plane wave decomposition (spectral domain analysis, SDA) is used in homogeneous layers and finite-elements-method (FEM) is used in the electrode layer [2]. Periodic boundary conditions are applied. Frequency dependencies of the resulting BAW polarization in the substrate were retrieved and analyzed.

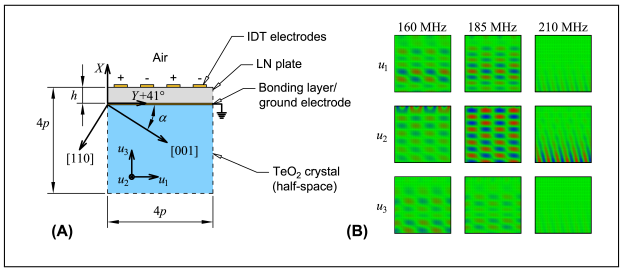

Figure 2. Numerical modelling of the piezoelectric transducer: (A) elementary cell for SDA-FEM-SDA modelling; (B) BAW structure (u_1, u_2 and u_3 mode amplitudes) at various frequencies.

3. RESULTS AND DISCUSSION

The transducer structure (Fig. 1) has several independent parameters, each of them affecting the performance and mode structure of the BAW fields in the substrate. In our simulations, the thickness and the fill factor of the IDT electrodes were fixed. The LN plate orientation corresponded to a standard homogeneous SH BAW transducer (see Fig. 2, A).

The TeO_2 substrate cut angle was $\alpha = 6°$ in $(1\bar{1}0)$ plane, which is a typical crystal orientation for acousto-optic deflectors and filters using slow SH BAW. The optimal IDT pitch $d = 58$ μm was derived from acousto-optic phase matching conditions for a broadband tunable filter design [1].

Admittance of the transducer was computed for different LN plate thickness values. With a fixed-pitch IDT, SH BAW excitation can be achieved in the relative bandwidth of $\sim 20\%$ at various central frequencies depending on the LN plate thickness h. At the boundaries of the excitation band, we observed transformation of the BAW mode from SH to longitudinal polarization. Simulated displacement maps are shown in Fig. 2 (B) for the IDT pitch of $2p = 58$ μm and LN thickness of $h = 5.6$ μm. The SH mode corresponds to u_2 component of the acoustic displacement vector. Owing to periodic IDT structure, the beam steering effect is observed for the excited BAW in TeO_2 that helps to extend the bandwidth of light-to-ultrasound coupling in photonic applications.

From the modelling results we concluded that the optimal LN thickness of h is much smaller than that for a homogeneous SH BAW transducer at the same resonance frequency. That proves a different mechanism of BAW excitation with an IDT: a plate mode is excited in the top layer of the substrate, which is converted into a non-homogeneous BAW mode owing to effective leakage to the low-velocity substrate.

4. CONCLUSIONS

Numerical modelling demonstrated that IDT-on-LN transducer structures are capable of effective excitation of SH BAW in TeO_2 crystal for acousto-optic applications. Resonance frequency can be adjusted by choosing a proper LN plate thickness h provided the IDT pitch d is fixed. Extension of the excitation bandwidth can be achieved using s stair-step LN plate with several segments corresponding to different resonance frequencies.

UNCERTAINTY RELATIONS FOR BROADBAND ULTRASONIC WAVEFORMS: THE CASE OF ACOUSTO-OPTIC FEMTOSECOND LASER PULSE SHAPING

Konstantin B. Yushkov[1*] **Vladimir Ya. Molchanov**[1]
[1] Acousto-Optical Research Center, University MISIS, 119049 Moscow, Russia

ABSTRACT

Broadband acoustic waveforms with phase modulation and complex-valued spectra are widely used for femtosecond laser pulse shaping in acousto-optic dispersive delay lines (AODDLs). Arbitrary transmission functions of quasi-collinear AODDLs can be achieved using the method of dispersive Fourier synthesis (DFS). Being a fast and efficient tool for generation different transmission functions with both phase-and-amplitude spectral modulation, the DFS method also provides the insight on fundamental limitations ultrasound signal performances. In particular, we demonstrate that there is an uncertainty relation between spectral resolution and modulation contrast for chirped ultrasonic waveforms with finite time window. More precisely, the product of spectral resolution by contrast is maximized when total frequency bandwidth equals twofold carrier frequency modulation range of the chirped ultrasonic signal. Experimental validation of the uncertainty principle is demonstrated with a high-resolution AODDL and 12 fs laser pulses at 800 nm. The applications of the DFS method with optimized parameters include programmable generation of arbitrary ultrashort pulse trains.

1. INTRODUCTION

Ultrasonic digital waveform synthesis has become a powerful tool for providing arbitrary transmission functions of acousto-optic tunable filters [1]. It enables creating the complex-valued transmission functions with predefined dispersion that is necessary for compression of ultrashort laser pulses [2]. Optimal parameters for synthesis of acoustic waveforms were investigated in this research.

2. ANALYSIS

To compute a chirped ultrasound waveform with given spectrum $S_{\mathrm{ac}}(\omega)$, we use the Fresnel transform:

$$S(t) = \mathrm{FT}_{(\omega,t)}\left\{S_{\mathrm{ac}}(\omega)\exp\left[iD_2(\omega-\omega_0)^2\right]\right\}, \quad (1)$$

where D_2 in the second order dispersion coefficient, and FT is the Fourier transform operator in (ω, t) domain. The resulting waveform duration T_{eff} is proportional to the frequency modulation band $\Delta\omega$:

$$T_{\mathrm{eff}} = D_2\Delta\omega. \quad (2)$$

A chirped waveform (1) can be decomposed as a sum of elementary signals each having a duration of τ. According to Gabor's uncertainty relation [3], the required bandwidth $\delta\omega$ is reciprocal to τ. Thus, we can define $\delta\omega = 4\pi\rho/\tau$, where the dimensionless parameter ρ that determines the signal contrast. Full bandwidth that is required for a chirped modulated signal is

$$B_\omega = \Delta\omega + 4\pi\rho/\tau, \quad (3)$$

the first term being the frequency modulation band.

The number of resolvable elements in the waveform defined as

$$N = T_{\mathrm{eff}}/\tau = D_2\Delta\omega/\tau. \quad (4)$$

Thus we can derive the information capacity of the chirped ultrasonic waveform as

$$N\rho = \frac{D_2}{4\pi}\Delta\omega(B_\omega - \Delta\omega) \le \frac{D_2\Delta\omega^2}{4\pi} \qquad (5)$$

The quantity $N\rho$ is maximized when $B_\omega = 2\Delta\omega$ that corresponds to the optimal signal bandwidth. This inequality represents the uncertainty principle for chirped pulses with arbitrary spectral modulation [4], which is illustrated in Fig. 1.

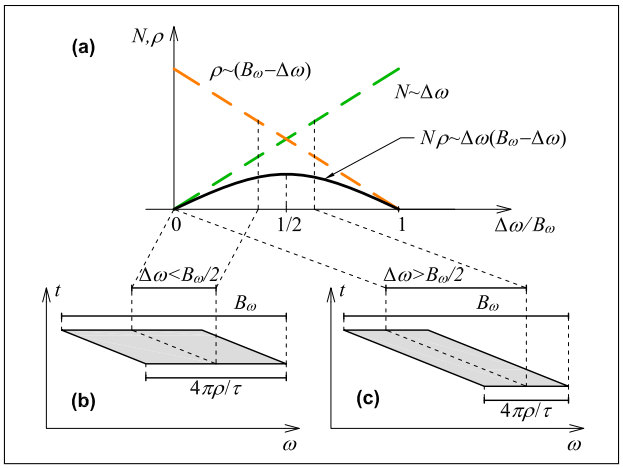

Figure 1. Graphical representation of the uncertainty relations for chirped pulses: (a) number of channels N and available channel bandwidth ρ; (b,c) spectrograms of a chirped pulse.

In the case of acousto-optic pulse shaping and synthesis of arbitrary transmission functions, the frequency modulation band $\Delta\omega$ is defined by the instantaneous bandwidth of processed light, and the full waveform duration is limited by the time aperture of the acousto-optic filter T_a. This allows one to find the optimal acoustic second order dispersion coefficient used in the Fresnel transform (1):

$$D_2 = T_\mathrm{a}/(4\Delta\omega). \qquad (6)$$

3. RESULTS AND DISCUSSION

The effect of optimal bandwidth selection was verified experimentally. The spectrum $S_\mathrm{ac}(\omega)$ was defined as a meander with the full width $\Delta\omega/2\pi = 20$ MHz and modulation period of 0.2 MHz; the waveforms were calculated with the signal's time aperture $T_\mathrm{a} = 50$ μs. The resulting spectra in Fig. 2 illustrate two cases: (a) in the case of minimum bandwidth $B_\omega = \Delta\omega$ the effective waveform duration is $T_\mathrm{eff} = T_\mathrm{a}$; (b) in the case of optimal bandwidth $B_\omega = 2\Delta\omega$ the effective waveform duration is $T_\mathrm{eff} = 0.5T_\mathrm{a}$, and 6 dB enhancement in modulation contrast is observed.

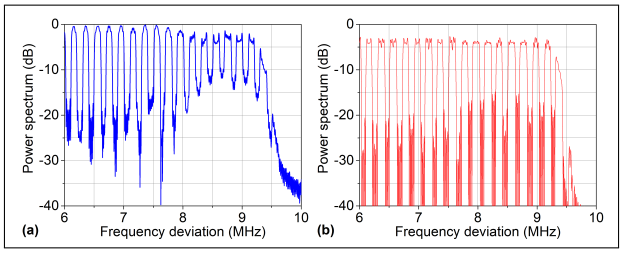

Figure 2. Numerical experiment on binary modulated chirped pulse spectrum: (a) minimal bandwidth $B_\omega = \Delta\omega$ causes contrast degradation near the window boundaries; (b) optimal bandwidth $B_\omega = 2\Delta\omega$ results in maximized contrast.

Similar contrast enhancement was obtained experimentally using broadband femtosecond laser radiation as a probe for arbitrary transmission function of a high-resolution quasi-collinear acousto-optic filter [4]. An original software package based on the Fresnel transform with optimized parameters was developed for controlling programmable acousto-optic filters [2].

ABSTRACT

Optoelectronic oscillators (OEO) - the class of physical systems characterized by the presence of a nonlinear element and feedback loop (FL). Feedback allows controlling the nonlinear element operation and makes it possible to implement various OEO operating regimes - from stationary to chaotic. The presence of a FL time delay is fundamental. We present the results of OEO operation characterization, when the nonlinear element is the collinear acousto-optic (AO) filter. The AO filter provides the time delay existence due to the acoustic wave propagation time through the AO crystal. The fulfilled experiments have shown that the collinear AO filter OEO gives the possibility to adjust the time delay between input and output optical pulses by changing the FL gain. It was also found that changing the electrical signal phase shift in the FL allows OEO multistable states observation, characterized by a difference in the amplitude and frequency of the electrical signal in the FL and, accordingly, the intensity and structure of the light beam at the system optical output.

Keywords: *acousto-optics, feedback, time delay, collinear diffraction*

1. INTRODUCTION

This paper represents the results of the acousto-optic (AO) system with hybrid feedback the examination. The system is operating above the self-excitation threshold, we investigate the feedback loop (FL) parameters influence on its time characteristics and operation frequency.

The examined system is based on the collinear AO diffraction implemented with $CaMoO_4$ AO tunable filter (AOTF) [1]. The hybrid FL connects the AOTF optical output and its piezoelectric transducer [2–8].

The system may be attributed to the so-called optoelectronic oscillators (OEO) [9] - the class of optoelectronic systems that combine the nonlinear element with FL that controls the operating parameters of this nonlinear element. Here the role of a nonlinear element is assigned to the collinear AOTF [7, 8, 10, 11]. The FL is hybrid as it implements the conversion of the part of AOTF output optical signal into an electrical one and controls the parameters of the AO diffraction.

As the examined system operates above the self-excitation threshold, it does not require an external RF generator to arouse ultrasound in the AOTF, and can be treated as AO generator, providing both optical and RF output signals [12, 13].

It is known that the behavior of AO systems that include FL is extremely diverse as well as other OEOs architectures. Various types of oscillations may be observed in such systems, including harmonic, self-modulation, multistable and chaotic [4]. The multistable operation is characterized by the existence of several stable states differing in amplitude, frequency, and direction of diffracted light waves propagation [3, 6, 14].

It is shown that the FL gain variation allows to control the time delay between the optical seeding input optical pulse and the system output optical pulse. It is also shown that the FL time delay and phase shift variation allow one to manage the system operation frequency and,

consequently, the output optical beam intensity and transmission function.

2. EXAMINED SYSTEM DESCRIPTION

The scheme of the examined AO OEO is shown in Fig.1. The collinear AOTF [1], placed between polarizers (α, β, γ), and providing 4 cm AO interaction length, is the main element. The FL operation is based on the AO heterodyning effect implemented with collinear AO diffraction optical radiation polarization peculiarities [15]. The interference between diffracted and non-diffracted optical beams after the output polarizer β makes it possible to obtain the optical radiation amplitude modulation with the frequency of ultrasound aroused in the AOTF for a certain mutual orientation of the input α and output β polarizers polarization planes [15] (α should be along Z or Y $CaMoO_4$ crystallographic planes and angle between α and β should be $45°$).

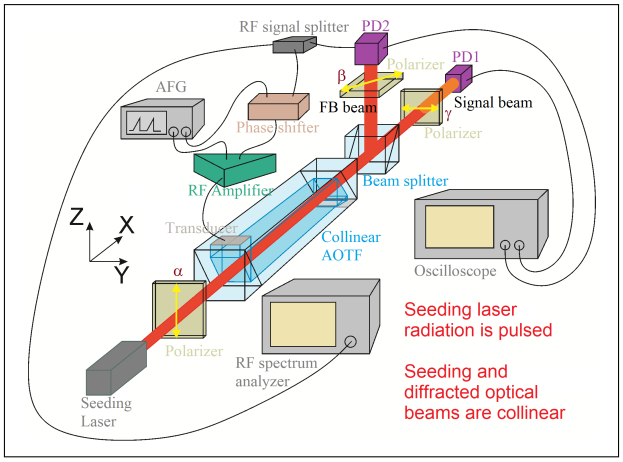

Figure 1. The examined AO OEO scheme.

The amplitude modulation is registered with the photodetector (PD2) that forms the FL input signal. The RF signal in the FL is amplified and phase shifted. Both amplifier gain and phase shifter operation are controlled by bias voltage fed from arbitrary function generator (AFG). The RF signal in FL is analyzed in time domain with a digital oscilloscope and in frequency domain - by the RF signal spectrum analyzer. The FL output feeds into the AOTF piezoelectric transducer.

The AO OEO optical output is organized as follows. The beam splitter is displaced at the AOTF output. It splits the output optical radiation (containing orthogonally polarized incident and diffracted light) into two beams - feedback beam and signal beam. The feedback beam passes through β polarizer and goes to PD2. The signal beam passes through γ polarizer with polarization plane orthogonal to α. This polarizer transmits only diffracted optical radiation. The signal beam intensity is registered by PD1 connected to the oscilloscope.

3. SYSTEM TIME DELAY DEFINITION

By the delay time τ_d we mean the time between the appearance of a laser pulse at the optical input of the system and the registration of diffracted optical pulse by the PD1. There is also another delay time characterized by the signal propagation time throughout the system τ_{fb}, including the FL and the propagation time of the acoustic wave along the entire length of the AOTF. Further, we will show that the τ_d delay time for high FL gain tends to the τ_{fb}.

Figure 2 represents the diffracted pulse intensity on time measurements obtained for FL gain μ values varying from 650 to 100 and optical seeding pulse with 1.3 ms duration.

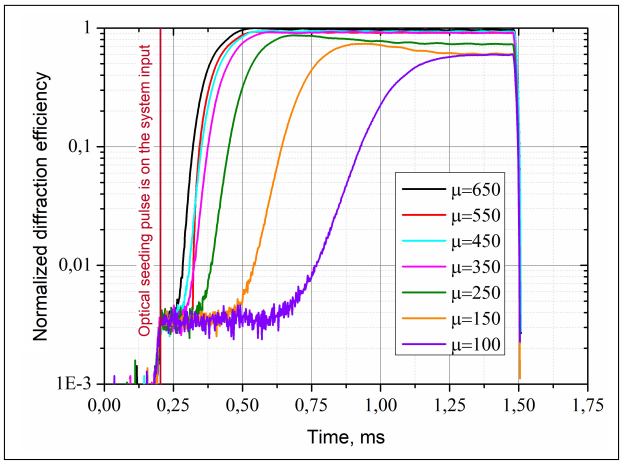

Figure 2. System response for 1.3 ms optical seeding pulse, observed for various FL gain μ magnitudes.

The analysis of the dependencies represented in Fig.2 allows to determine AO OEO time characteristics and follow the AO diffraction efficiency dependence on FL gain.

The obtained results show that the delay time τ_d depends on μ strongly. For the gain variation from 100 to 700, the τ_d decreases from 70 μs to 12 μs while the system time delay $\tau_{fb} \approx 14$ ms. The signal beam AO diffraction efficiency increases by 40%. The minimum τ_d value

is close to the acoustic wave propagation time along the entire AO cell, which seems to be a natural result.

Thus, we have shown that tuning the FL parameters allows one to vary the time characteristics of the examined system in a broad range.

Further we will show that FL phase shift variation, implemented by changing the phase shifter bias voltage, makes it possible to control the AO OEO operating frequency f and, consequently, the output signal beam intensity.

4. MULTISTABILITY OBSERVATION

Another feature of the examined system is the dependence of its operation on the phase shift χ introduced by the phase shifter. The χ magnitude is controlled by bias voltage fed from the AFG.

Figure 4 illustrates the dependence of the signal beam intensity I_s registered by PD1 on the AFG signal magnitude. It can be seen that the intensity (PD1 signal) variation has a rather complex shape. The reason for this is the dependence of the system operating frequency f on phase shift χ magnitude.

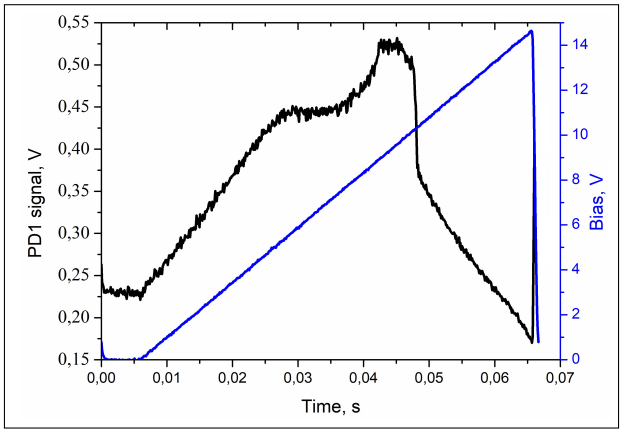

Figure 3. PD1 signal variation in time for varying phase shifter bias voltage.

To obtain the $I_s(\chi)$ dependence in explicit form, it is necessary to measure the χ dependence introduced by the phase shifter on the bias voltage for the AO OEO operating frequency (about 43.5 MHz). This dependence is shown in Fig.4a. It shows that the bias voltage variation from 0 to 15 V provides the χ/π variation from 0.2 to -0.9. It is interesting that the maximum absolute value is achieved for the bias voltage of about 12 V. Thus, the bias voltage variation may be limited by the range 0–12 V.

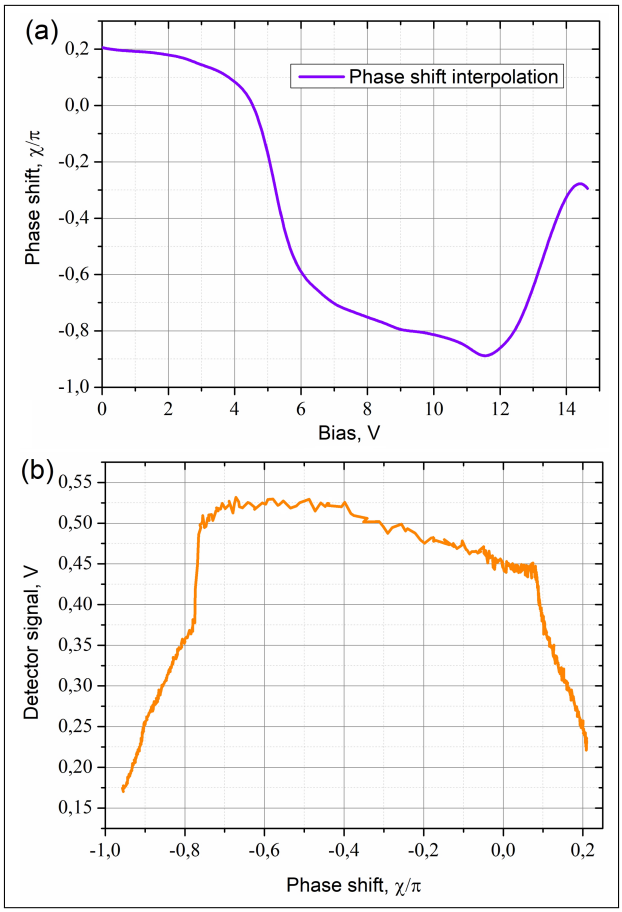

Figure 4. The dependence of normalized phase shift introduced by FL on bias voltage (a) and signal beam intensity dependence on the normalized phase shift magnitude (b).

Finally, the $I_s(\chi)$ dependence (in the form of PD1 signal magnitude) is shown in Fig.4b. It can be divided into three areas: 1 – signal growth between -0.95 and -0.75; 2 – a sharp leap and the second area where the signal beam intensity does not change much ($-0.75 < \chi/\pi < 0.1$); 3 – another leap follows and the third area is observed where the intensity drops significantly ($\chi/\pi > 0.1$).

The I_s variation is caused by the f tuning . Therefore, the leaps in intensity correspond to the frequency ones, and the slow intensity variation is caused by its smooth change.

The mechanism of f tuning with χ variation was considered previously [16]. It is based on the phase balance condition for the examined AO OEO, acting in conjunction with the amplitude balance condition - the frequency dependence of the system transmission coefficient (the feedback beam AO diffraction efficiency dependence on the ultrasound frequency).

The broadest band of f tuning may achieve 200 kHz, while the tuning band for the case shown in Fig. 4 is approximately 100 kHz.

5. CONCLUSION

We have examined the influence of FL parameters (introduced phase shift, time delay,gain) on the collinear AOTF OEO functioning.

The FL phase shift variation may cause a smooth change in the operating frequency and the output radiation intensity and the abrupt one. The operating frequency variation magnitude may exceed 200 kHz.

It was discovered that the FL gain variation allows one to control the AO OEO delay time. In the studied range of gain magnitudes, the delay time varies by about 6 times. It was found that the minimum delay time approximately equals the time required for an acoustic wave to propagate along the entire length of the AO cell.

ACOUSTO-OPTIC SPATIAL FREQUENCY FILTER WITH PHASE CONTROL FOR RECONFIGURABLE DARK OPTICAL TRAPS

Vladimir Ya. Molchanov[1]* **Alexander I. Chizhikov**[1] **Dmitry V. Obydennov**[1]
Konstantin B. Yushkov[1]
[1] Acousto-Optical Research Center, University MISIS, 119049 Moscow, Russia

ABSTRACT

We have developed an original acousto-optic spatial filter (AOSF) of laser beam angular frequencies for dynamically forming cylindrical laser beams with two walls advanced optical trap configurations. To expand the functionality of AOSFs, independent phase control should be added to frequency control, thereby transforming the filter's two-dimensional transfer function (2DTF) from a function of one variable into a function of two independent variables. The 2DTF is controlled by a variable phase of radio-frequency signal at a constant frequency. The peculiarity of the AOSF with phase control is based on the tilt of the acoustic wave front, which compensates for the asymmetry of the two-dimensional transfer function and makes it possible to create pairs of concentric intensity maxima separated by a dark region. An experimental AOSF on paratellurite has been designed and fabricated. This modification of the filter's annular 2DTF has made it possible for the first time to create double cylindrical beams ("thermos beams") that have direct application for optical trapping and microparticle manipulation. This configuration of the laser potential is in demand in dark optical traps, in which resonant particles are repulsed by the laser field and their trapping occurs in areas with minimum field intensity.

1. METHODS

Acousto-optic filters are tunable photonic devices based on anisotropic Bragg diffraction, which are used in spectroscopy, hyperspectral imaging, phase imaging, femtosecond pulse shaping, and laser beam shaping (LBS). The latter application utilizes angular dependence of phase matching, which enables direct filtering of the angular spectrum. Accurate analysis of the AOSF's two-dimensional transfer function can be performed using the curvature tensor of the acousto-optic crystal's refractive index surface [1].

In this work, we report design and fabrication of two AOSF prototypes and their commissioning in LBS systems and optical traps. The basic setup for bottle beam generation is shown in Fig. 1. A laser beam is focused onto the AOSF so that different components of its angular spectrum are diffracted with different efficiencies. The diffracted beam (p-polarization) is polarized orthogonally to the input one (s-polarization), and the first diffraction order is selected by a polarizer at the AOSF output. Relay optics is used for scaling the beam size, and the second Fourier lens converts a conical beam into a bottle beam in its back focal plane.

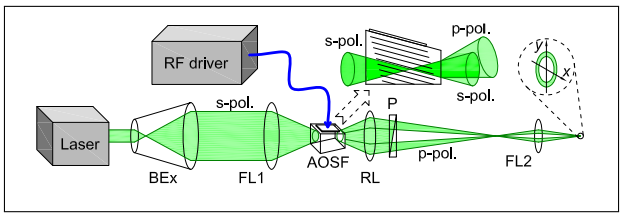

Figure 1. Schematic LBS setup based on an AOSF: BEx — beam expander; FL1, FL2 — Fourier lenses; RL – relay lens; P — polarizer.

The AOSF of configuration #1 was a single-transducer AOSF, which was driven by a radio-frequency (RF) arbitrary waveform generator either in single-frequency or in multi-frequency mode. This AOSF was commissioned with monochromatic radiation at the wavelength of 532 nm and femtosecond radiation at the wavelength near 800 nm. The AOSF of configuration #2 was a dual-transducer AOSF, which was driven by a two channel RF generator with programmable phase delay between the channels [2].

2. RESULTS

Various LBS modes are demonstrated in Fig. 2. Simple annular beam shaping is obtained with monochromatic light and single-frequency RF signal [3]. The phase matching locus is a ring whose radius changes with ultrasound frequency, Fig. 2 (a), that allows creating dynamic annular traps for dielectric particles. In the multi-frequency operation mode, different components of the laser beam's angular spectrum can be diffracted simultaneously with different efficiencies that enables beam profile tailoring. A flat-top beam obtained from a Gaussian beam is shown in Fig. 2 (b). In the case of multi-wavelength laser beam, each spectral component can be controlled independently. Fig. 2 (c) shows a two-color beam obtained from a femtosecond Ti:sapphire laser [4]. The central spot has the wavelength of 800 nm and the outer ring of the laser field has the wavelength of 790 nm.

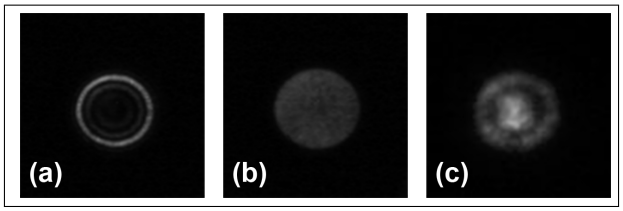

Figure 2. Experimental measurement of laser field distributions at the AOSF #1 output: (a) annular beam shaping of monochromatic light; (b) flat-top beam shaping at multifrequency AOSF operation; (c) multi-color femtosecond beam shaping by AOSF.

Figure 3 demonstrates operation of the phase-controlled AOSF #2 [2]. The RF signal in this case has two independent parameters, the frequency and the phase delay between two channels, which are both used to adjust the transfer function parameters. Owing to the effect of acoustic beam steering, splitting of the transfer function can be achieved. Two-dimensional transfer functions of this type can be used for creating dark optical traps, i.e. volumes with low laser beam intensity enclosed within volumes with higher intensity.

TAILORED ULTRASOUND FIELDS FOR ACOUSTO-OPTIC LIGHT CONTROL DIRECTLY WITHIN A SAMPLE

Jordi Torres-Durall[1*] **Martí Duocastella**[1,2]

[2] Institut de Nanociència i Nanotecnologia (IN2UB), Barcelona, Spain

ABSTRACT

One of the main challenges in optics is to rapidly deflect, focus or guide light directly inside a sample. As of today, the only widely accepted method to achieve this is using endoscopes, that is, optical fibers that are inserted into the sample. However, this approach is intrinsically invasive and highly sample dependent. A recently developed strategy consists of using ultrasound for light control. The idea is to exploit the acousto-optic effect to generate virtual ultrasonic endoscopes, allowing fast and targeted deep light delivery while remaining non-invasive. Nonetheless, realistic applications of this technique still require further research on the optimal acoustic generation process and the subsequent light-coupling. Here, we discuss different hybrid ultrasound-light implementations designed for light control inside samples, highlighting optimal design features and current challenges. In particular, we present the development of a piezoelectric transducer that obviates the need for acoustic cavities and provides micrometric light guiding at MHz frequencies. We also show how ultrasound can be used to enhance imaging depth in a two-photon microscope.

Keywords: *acousto-optics, ultrasound transducer, remote scanning, scattering mitigation, two-photon microscopy*

1. INTRODUCTION

Light control technologies are a key tool for our society, enabling a wide range of medical and industrial applications such as confocal microscopy [1], optical topography [2] or laser surgery [3]. A paramount challenge in modern optics is to non-invasively extend current light-based techniques to deeper within scattering samples, such as biological tissue, as this would allow a paradigm change in light-based biomedical methods. One of the main ways to tackle this challenge is by controlling light directly within the samples.

Traditionally, light control within samples is achieved by inserting optical fibers [4] into the sample, as in traditional endoscopies [5]. Despite allowing operation at arbitrary depths, these methods are invasive and can produce relevant damage to the studied samples or tissues, and thus are not possible or not optimal for many applications. A promising non-invasive alternative is to generate acoustic lenses or waveguides within these samples [6], allowing fast light control while re-directing scattered photons to target locations. Previous studies show the applicability of this method to enhance a range of optical techniques. Despite these promising results, further research is still needed to circumvent geometrical constraints of current ultrasound generation implementations, and to prove the applicability of these methods in real world scenarios.

Here, we propose the use of acousto-optic scattering mitigation for Two-photon excitation fluorescence microscopy (TPEF). We also present the development of an ultrasound transducer geometry that allows the generation of an acoustic lens without the need of an acoustic cavity, circumventing a key restriction of most current implementations. We expect these advances to be a step forward in acousto-optic light control within samples and scattering-mitigation within biological tissues.

2. ACOUSTO-OPTIC DEEP LIGHT CONTROL

Light control within a sample is usually restricted by its absorption and scattering. While in deep light techniques light absorption is usually minimized by selecting a proper wavelength, scattering remains the main challenge that prevents controlling and focusing deep within samples. This scattering is caused by micrometric inhomogeneities within samples, that cause it to lose its initial phase and direction. Intensity I of not-scattered light (ballistic photons) within a sample can be expressed as: [7]

$$I = I_0(z)\cdot e^{-\mu z} = I_0(z)\cdot e^{-\tau}, \quad (1)$$

where $I_0(z)$ is the intensity expected in free propagation, z is the propagation distance within the sample and μ is the scattering coefficient of the sample. The total amount of scattering can be measured through the optical thickness τ, a dimensionless magnitude that can be interpreted as the average number of scattering events that photons have experienced to reach depth z.

The acousto-optic effect allows us to control light through pressure waves [8]. This is because a local change in pressure $\Delta P(\mathbf{r},t)$ leads to a local change in density, causing a local change in refractive index $\Delta n(\mathbf{r},t)$. For water-based materials, at pressure differences below 100 MPa, the acousto-optic effect can be expressed as: [9]

$$\Delta n(\mathbf{r},t) = C_{PO}\cdot \Delta P(\mathbf{r},t), \quad (2)$$

where C_{PO} is the piezo-optic constant of water, at room temperature $C_{PO} = 1.51\cdot 10^{-4}$ MPa^{-1}. This change in refractive index creates a change in light phase, allowing us to remotely focus or redirect light. Thus, exploiting this effect we can generate an acoustic lens within a sample, redirecting scattered photons to desired locations and thus enhancing light-based methods that require light to reach deep within scattering tissues or materials. Using this same principle, we can redirect light to focus it on target locations, allowing fast and dynamic light delivery within samples. [10]

3. ACOUSTIC CAVITIES FOR ACOUSTO-OPTIC SCATTERING MITIGATION

Recent advances in acousto-optics have described how to create acoustic lenses within samples, enabling scattering mitigation by redirecting scattered photons [11]. The usual method to create these acoustic lenses inside a sample is by placing the sample inside a cylindrical piezoelectric transducer, which acts as an acoustic cavity. Using this implementation, past work has shown applications in direct point-scanning imaging [6], light-pattern formation for imaging [12] and virtual waveguide creation for direct imaging [10].

Here, we propose that acousto-optic scattering mitigation can be used to enhance Two-photon excitation fluorescence microscopy (TPEF), synergically combining two state-of-the-art techniques for deep imaging within samples. In TPEF microscopy, the obtained image signal depends on the focal intensity squared. Thus, signal enhancement obtained using acousto-optic scattering mitigation becomes quadratically more relevant when combining it with TPEF microscopy. We exemplify this synergy in Fig. 1, using a waveguide generated with an acoustic cavity at 2.2 MHz frequency and 2 MPa peak pressure. Furthermore, TPEF microscopy usually relies on a near-infrared wavelength for excitation light, minimizing absorption and scattering in biological tissues and thus enhancing imaging depth.

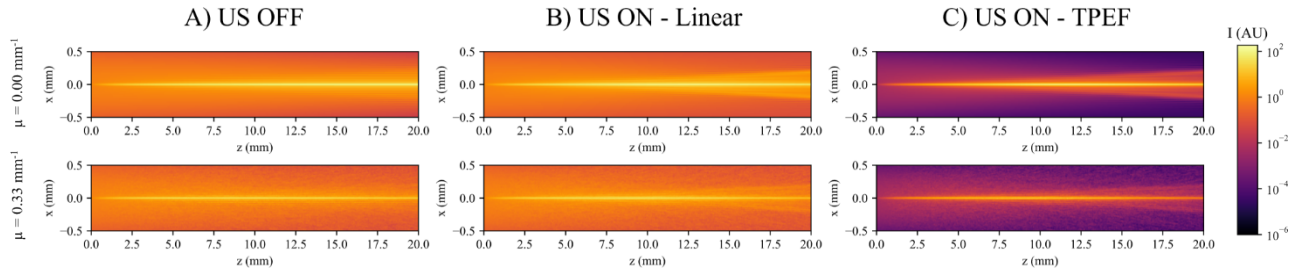

Figure 1. Signal intensity when using a Bessel Beam in different scenarios. (A) Simulated intensity of a Bessel beam, in a homogeneous or scattering medium. (B) Simulated intensity when using the same beam in conjunction with an ultrasound (US) waveguide within a cylindrical acoustic cavity. (C) Simulated intensity when using two photon excitation fluorescence microscopy (TPEF) combined with the same ultrasound waveguide, normalized to show the same peak intensity as (B). As TPEF signal depends on the intensity squared, ultrasound-induced intensity enhancements become quadratically more relevant in the proposed experiment. Note that thresholding effects have not been included in (C), despite potentially offering a substantial increase in resolution.

4. BEYOND ACOUSTIC CAVITIES

Despite generating an acoustic pressure profile optimal for light focusing and scattering mitigation, cylindrical piezoelectric transducers present the great disadvantage that the sample must be confined inside of them for direct deep light control. This means that big samples, including many relevant biological tissues, should be cut for the method to be applied, compromising the non-invasiveness of these techniques. Thus, this restriction often limits the applicability of these methods to phantom samples, far from real-world problems. For this reason, recent research is focusing on finding cavity-free ultrasound generation methods that allow direct deep light control. To this end, past studies have proposed using the photoacoustic-effect [13], two flat transducers [10], or acoustic holograms [14]. However, these implementations can be quite complex and often produce acoustic pressure profiles not optimal for direct light control within samples.

There are two main features that make the acoustic field generated by cylindrical transducers optimal for internal light control. First, it features highly focalized peak pressures, which maximize the change in refractive index. Second, it allows phase differences suffered by light to accumulate over the transducer's length, thus maximizing light focusing (see Fig. 2 A-C). In our recent research [15], we propose to use the angular section of a cylindrical transducer instead (see Fig. 2 D-E). This geometry maintains the key features needed for direct deep light control while allowing the generation of a cavity-free acoustic lens, obviating the need of confining the sample inside an acoustic cavity and thus expanding the applicability of acousto-optic lenses for direct light control within samples.

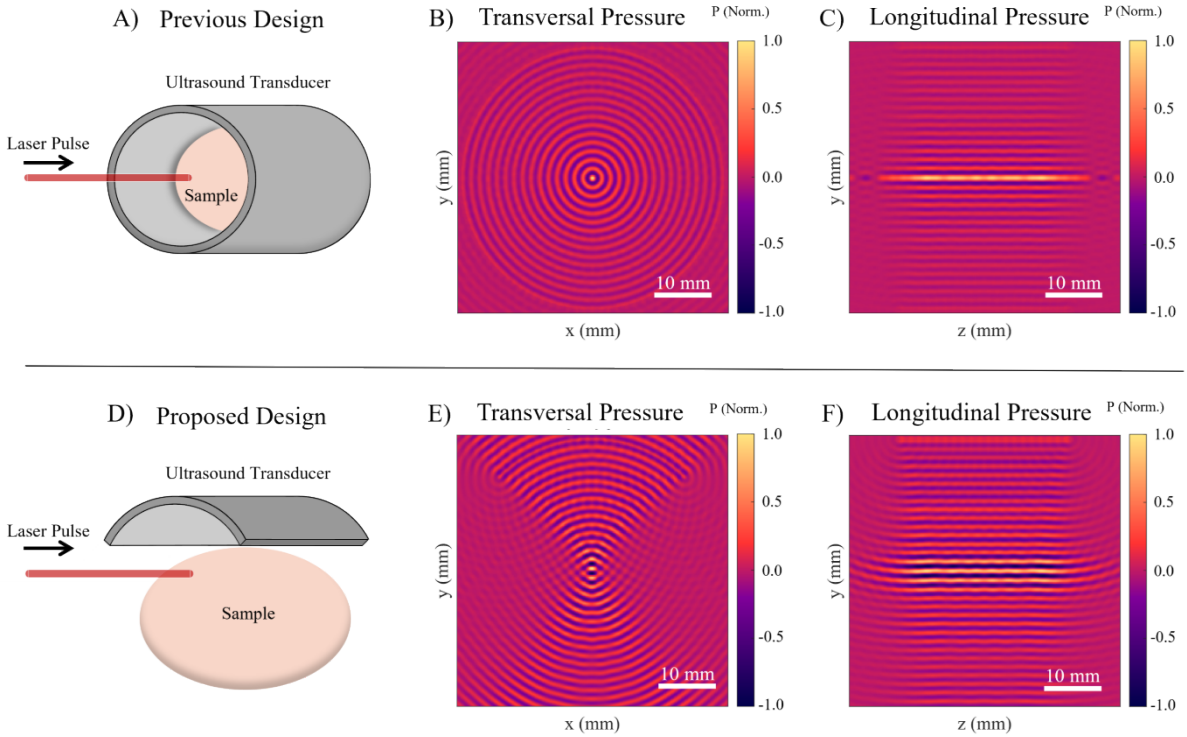

Figure 2. Comparison between acoustic field generation with a cylindrical piezoelectric transducer and our proposed geometry. (A) Scheme of a cylindrical transducer and corresponding simulated transversal (B) and longitudinal (C) normalized instantaneous pressure profiles at 1 MHz (transducer radius 23 mm). (D) Scheme of our proposed 90° cylindrical angular section transducer and simulated transversal (E) and longitudinal (F) instantaneous pressure profiles at 1 MHz. Our design is much less restrictive regarding sample geometry, while maintaining a highly intense elongated acoustic focus.

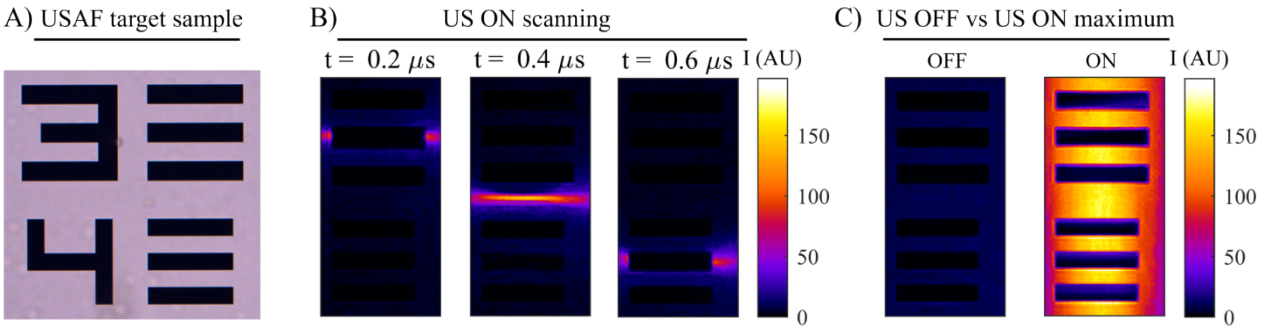

Figure 1. Fast light scanning using an ultrasound-induced lens. (A) Optical microscopy image of the USAF target elements imaged. (B) Captured image when ultrasound is applied, at different time delays between the ultrasound and the light pulse. (C) Maximum intensity detected at each pixel when scanning the light pulse across the whole sample.

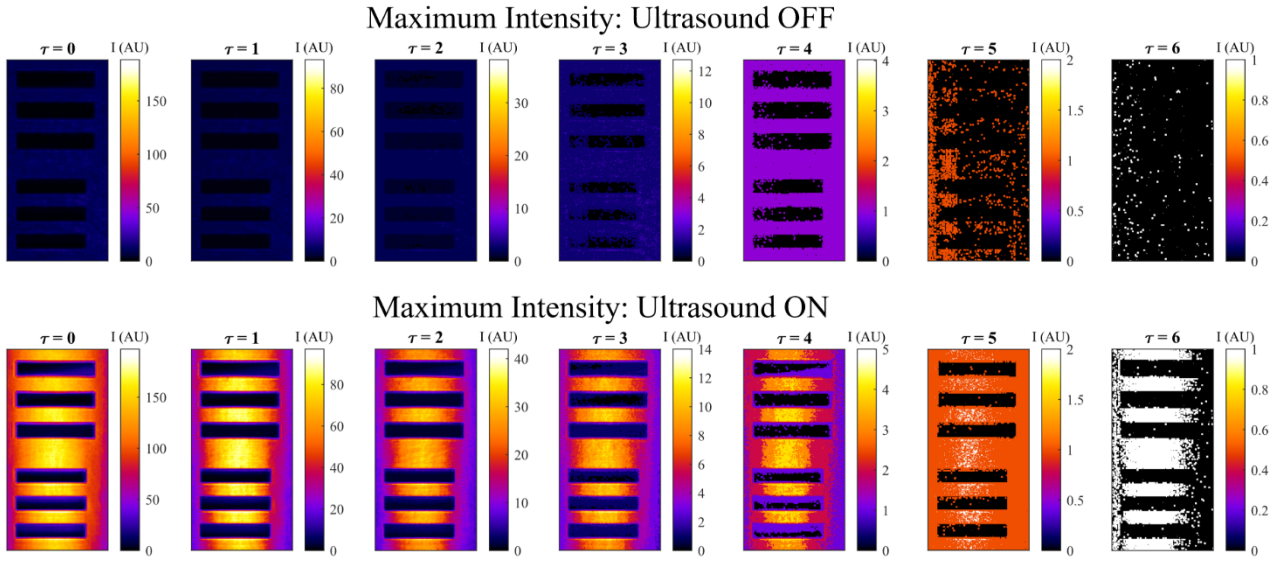

Figure 4. Maximum intensity detected at each pixel with and without ultrasound. We show the maximum intensity detected at each pixel in a 2000 frames video with and without scanning ultrasound. We can observe a huge increase in maximum intensity when using the ultrasound.

By using the proposed transducer geometry and a pulsed laser light source, a focal light line could be rapidly scanned through the sample, allowing fast targeted light delivery at MHz frequency rates over a millimetric region (See Fig. 3). By exploiting the stroboscopic effect, a sample was scanned for different scattering conditions, showing a factor 10 enhancement in light intensity when the ultrasound lens was used. Note that this allowed to reconstruct the sample structure even at scattering conditions where without the acoustic lens, only noise was detected (see Fig. 4). Furthermore, a single photon detector could be used to measure the transmitted intensity profiles, allowing to obtain a 1D profile of the 1.2 mm long sample in just 0.8 μs.

5. CONCLUSIONS

The acousto-optic effect can be used to control light directly within samples, enabling scattering mitigation for deep microscopy and fast light delivery to target locations. As our simulations demonstrate, the combination of Two-photon microscopy and acousto-optic scattering mitigation shows great potential for deep microscopy within scattering samples. Meanwhile, using a piezoelectric transducer consisting in the angular section of a cylinder allows to generate an acoustic profile substantially optimal for internal light control without the need of an acoustic cavity. The proposed geometry can remotely generate an acoustic lens that can be embedded inside a sample non-invasively, allowing targeted light delivery even in the case of large samples. We anticipate that these results will be a step towards non-invasive acousto-optic light control within a variety of materials, including biological tissues.

ENHANCING EYE IMAGING MODALITIES WITH ACOUSTO-OPTIC INTERACTION

Ireneusz Grulkowski[1*] **Daniel Ruminski**[1]
[1] Institute of Physics, Faculty of Physics, Astronomy and Informatics, Nicolaus Copernicus University, Toruń, Poland

ABSTRACT

Optical imaging of the eye is a common clinical procedure in the diagnosis and management of the ocular disorders. Rapid advances in photonics technologies enabled development of optical modalities for diagnostics and management of ocular pathologies. Confocal Scanning Laser Ophthalmoscopy (cSLO) is a confocal microscope modality for visualization of the fundus of the eye. Optical coherence tomography (OCT) is a non-invasive imaging modality enabling generation of micrometer resolution, two-dimensional cross-sectional images and three-dimensional volumetric data presenting internal structure of ocular structures. Acousto-optic interaction facilitates ultrafast manipulation of the optical beam through precise shaping (modulation) of the wavefront. In particular, focus tunable lenses are active optical components that enable engineering of light delivery in optical imaging systems. Acousto-optic devices allow for enhancement of the performance of eye imaging instrumentation. Integration of acousto-optic lenses into OCT and cSLO systems enable improved in vivo imaging of the human eye.

1. INTRODUCTION

Acousto-optics is a branch of physics devoted to fundamental and applied studies of interaction of light with ultrasound. When an acoustic wave travels through an optically transparent material, periodic variations in the refractive index are generated—a phenomenon known as the photoelastic effect. This modulation appears as a dynamic diffraction grating, allowing the light to be modulated, deflected, or shifted in frequency depending on the acoustic signal. By leveraging the interaction between acoustic waves and light within a medium, acousto-optic devices such as modulators (AOMs), deflectors (AODs), tunable filters (AOTFs) and tunable lenses (AOLs) can dynamically alter the intensity, frequency, and direction of light beams in real time with high speed and precision [1]. Those components are currently widely used in imaging, telecommunications, spectroscopy, and laser systems. The advantages of acousto-optic technologies such as non-mechanical operation and rapid response times, make them especially valuable in modern optical and biomedical applications [2].

Eye imaging has become a standard procedure in modern ophthalmic diagnostics, offering visualization of ocular structures essential for early disease detection and monitoring. Advances of optical imaging modalities observed in last few decades provided tools for non-invasive and high-resolution assessment of subtle changes in tissue architecture and functionality, which are crucial for early diagnosis of the conditions like glaucoma, cataract, diabetic retinopathy, macular degeneration, and retinal vascular diseases.

As an important family of photonics industry, acousto-optic devices have been employed in ophthalmology related techniques, offering precise, high-speed control of light. Although we concentrate on imaging modalities, non-imaging applications of acousto-optics in ophthalmology

include also modulation of the intensity and duration of laser pulses, thus enabling precise targeting of ocular tissue during laser surgical procedures while minimizing damage to surrounding healthy structures.

2. ACOUSTO-OPTICS IN OPTICAL COHERENCE TOMOGRAPHY

Optical Coherence Tomography (OCT) is an interferometric modality that detects light that is back-scattered or back-reflected from the internal structures of the object. High-sensitivity and high axial resolution independent on numerical aperture of the objective lens enable OCT to generate cross-sectional or three-dimensional (volumetric) images of the semi-transparent objects such as ocular tissues. OCT has become an indispensable tool in ophthalmology, particularly for high-resolution imaging of the retina and the anterior segment. In recent years, the incorporation of acousto-optic (AO) technology into OCT systems has introduced substantial improvements in imaging speed, precision, and system adaptability.

One of the key contributions of acousto-optics to OCT is the implementation of acousto-optic deflectors (AODs). These devices allow for fast, inertialess beam steering by changing the frequency of the acoustic wave propagating through the crystal. In contrast to traditional mechanical scanning systems, AODs provide high-speed lateral beam scanning across the eye without moving parts. This non-mechanical approach significantly reduces motion artifacts through minimization of the examination time, which translates into improvement of patient comfort during imaging procedures [3].

Furthermore, acousto-optic tunable filters (AOTFs) are widely used in swept-source OCT systems, where rapid and precise wavelength selection is required in wavelength-tunable laser technology [4, 5]. AOTFs enable dynamic control over the central wavelength and bandwidth of the swept laser, facilitating fast tuning speeds (and high axial scan rates) essential for real-time imaging. Additionally, the flexibility of AOTFs supports advanced imaging techniques such as spectroscopic OCT, where wavelength-dependent tissue contrast can provide further diagnostic insights.

The integration of acousto-optic modulation also improves signal processing in OCT systems. For example, acousto-optic modulators (AOMs) can be employed for frequency shifting in interferometric detection schemes, helping to separate signal from noise and enhancing image contrast. This is particularly useful when the tissue is characterized by low scatter.

In addition, acousto-optics facilities enhancement of OCT image quality in terms of scan depth. Acousto-optic lenses enable fast focus tuning. When a series of OCT images is acquired at instances corresponding to different focusing depths, appropriate averaging of OCT scans results in effective extension of the depth of focus of scanning beam, which in turn improves signal in OCT image [6].

3. ACOUSTO-OPTICS IN CONFOCAL SCANNING LASER OPHTHALMOSCOPY

Confocal Scanning Laser Ophthalmoscopy (cSLO) constitutes another retinal imaging technique that enables high-resolution, real-time visualization of the retina and optic nerve head. Unlike traditional fundus photography, which captures a wide-field static image, cSLO uses a focused laser beam that scans across the retina. Like in confocal microscopy, a confocal pinhole is used to block out-of-focus light, allowing for sharp and high-contrast images of specific retinal layers. cSLO is widely used in ophthalmology for diagnosing and monitoring diseases such as glaucoma, macular degeneration, and diabetic retinopathy. Confocal SLO systems can be integrated with acousto-optic lenses to enable high-speed, inertialess axial scanning (z-scanning). Those approaches allow for rapid volumetric imaging of ocular structures.

4. CONCLUSIONS

Overall, acousto-optic technologies have contributed to the development of more compact, faster, and more stable OCT systems for ophthalmic applications. The advantages of acousto-optic devices allow for elimination of mechanical components, facilitate better image quality by high-speed scanning and support real-time visualization of ocular structures. As research advances, further integration of acousto-optic components is expected to enable even more powerful imaging systems.

Recording neuronal activity in 3D using calcium and voltage genetically encoded indicators

Walther Akemann[1] **Joséphine Morizet**[1] **Laurent Bourdieu**[1*]
[1] IBENS, CNRS UMR 8197, INSERM U1024, Ecole Normale Supérieure, Paris.

ABSTRACT

We have developed a non-linear optical microscope for recording 3D neuronal activity in a cortical column, from awake head fixed behaving mice, with unrivalled temporal resolution. This new technique, called Custom-Address Serial Holography (CASH), uses acousto-optic deflectors (AODs) synchronized with a regenerative amplifier operating at 40 kHz. In this configuration, we have shown that the AODs function as ultrafast phase and amplitude modulators, enabling each laser pulse to be spatially shaped at 40kHz. Spatial modulation of laser pulses enables digital holography of extended volumes in the microscope's focal plane for fluorescence excitation. We will demonstrate the possibility of recording the activity of neurons labeled with Genetically Encoded Calcium Indicators (GECIs) such as GCaMP6f with holographic volumes covering their cell bodies. Using holographic volumes covering only cell membranes, we will demonstrate the possibility of using Genetically Encoded Voltage Indicators (GEVIs) to record the activity of 3D neuronal networks. By updating aberration and diffusion correction synchronously with the scanning, we have also performed trans-cranial imaging over fields of view that go beyond the scattering memory effect. Finally, we will discuss the implementation of temporal focusing to improve the optical sectioning of the 3D-CASH holographic microscope.

1. INTRODUCTION

The brain is a complex 3D meshwork of circuits, neurons and micron-scale neuronal processes, which processes information in a distributed way within milliseconds. Understanding brain function therefore requires, ideally, to be able to record brain activity in 3D, at high spatial and temporal resolution. Optical methods, which allow to target neurons in a flexible and minimally-invasive way, offer bright promises and have considerably developed in the last decades. However, recording large numbers of neurons at millisecond temporal resolution, with micron-scale spatial resolution in depth and 3D access remains an unmet challenge.

Non-linear microscopy permits submicron resolution over a depth of a millimeter in the brain. However, because of the need to concentrate light spatially to achieve non-linear effects, it is fundamentally a sequential method, in which the signal arising from a single focal excitation volume (voxel) is collected at each time-point. This imparts a trade-off between the dwell-time (D_t) at each voxel, the number of voxels recorded (N_v) and the frame rate (R) of the recording ($R=1/N_vD_t$). The dwell-time itself determines the total number of photons collected by voxel (N_p) and thus the signal to noise ratio of the recording, at best $\sqrt{N_p}$ when reaching shot noise limit. The total number of photons per time unit is really what matters to discriminate a change in signal in a given object.

A solution to the signal/frame rate trade-off is to keep the dwell-time high but to reduce the number of apparent pixels. While a typical image contains from 250 to 1000 kilo-pixels, the number of identifiable neurons or neuronal parts in the field of view is generally 3 orders of magnitude lower, less than a thousand. Pointing each laser pulse only at one of these objects of interest and recording the signal produced would therefore constitute the optimal solution to record at both high temporal resolution and high signal levels. This "Random-Access" strategy cannot be implemented efficiently with mechanical scanning devices

such as mirrors, because their inertia imparts millisecond-scale switch times between random voxels in the field of view. A technique allowing fast addressing of cells of interest in 3D, with millisecond sampling rate is thus needed. This Random-Access technique should also be compatible with in vivo recordings in head-fixed animal, where brain motion due to breathing, heart beat and muscle contraction will prevent stable recording if not severely mitigated.

2. METHODS

Random-Access scanning has been pioneered in the late 90s by the team of Peter Saggau using Acousto-Optic Deflectors (AODs) [1]. In their standard application as angular deflectors, an AOD used in the Bragg mode efficiently deflects light into the first diffraction order at an angle θ given by :

$$\theta = \lambda.F/v \qquad \text{Eq. 1}$$

where λ is the wavelength of the light, F (~100MHz) the acoustic frequency and v (~650m/s) the velocity of the steady-state acoustic wave inside the crystal. An AOD is working at a central frequency F_0 over a bandwidth $+/-\Delta F/2$ (15 to 20 MHz). The maximum scan angle $\Delta\theta$ is given by $\Delta\theta = \lambda.\Delta F/v$ (~40mrad). The use of an AOD with femtosecond lasers having a broad spectrum $\delta\lambda$ (~10-15nm) raises however issues of temporal and spatial dispersion, that can be compensated at the center of the FOV using diffractive elements [2,3,4]. A crossed AOD pair allows then Random-Access sampling of the FOV at an unmatched speed. The time to establish an acoustic wave in an AOD is given by t_s=L/v, where L is the AOD active aperture. Using large AOD with 13mm aperture to achieve larger FOV give t_s= 20µs. As the dwell time $D_t \sim t_s$, sampling of up 50 000 objects per second (or 50 per ms) can be implemented.

AODs have initially been used as pure deflectors, where the same acoustic frequency occupies the whole profile of the laser beam and where all light is thus deflected to a given angle with a flat wavefront (Eq. 1). However, an AOD can also be used in a non-steady state mode, where it acts as single axis wavefront shapers. We have shown that an AOD that is filled with an ultrasonic pattern of frequency $f_{AOD}(x)$ and amplitude $a_{AOD}(x)$ at a position x in the AOD provides a complex spatial modulation consisting of an amplitude modulation $T(a_{AOD}(x))$, where T is the characteristic amplitude transfer function of the AOD, and a phase modulation $\varphi_{AOD}(x)$, which is related to the frequency modulation $f_{AOD}(x)$ [5]. This shows that an AOD is more than just a deflector, but is in fact a real beam shaping device, acting both as a simultaneous amplitude and phase modulator. Therefore tilt (2D scan) and defocus (3D scan) stands as straightforward applications, while more complex 2D beam spatial modulations can also be achieved and used e.g. in microscopy for digital holography applications.

However, this hides a major difficulty and subtlety. Indeed, a spatially-varying frequency pattern in the AOD cannot be established in a steady-state mode, as an ultrasonic wave is a propagating wave. As the repetition rate of standard lasers in non-linear microscopy (~100MHz) is 3 orders of magnitude larger than the refresh rate of an AOD (~100kHz), consecutive laser pulses interact thus each with different wave patterns in the AOD. To solve this issue, we proposed to use AODs in a "synchronous mode", where the laser pulses are synchronized with the AODs using a low-repetition rate laser, such that the propagating ultrasound pattern is somehow frozen [5]. In this mode, complex phase and amplitude patterns can be generated by the AODs. It includes defocus modulation to achieve fast 3D scans. It allows also to generate complex intensity patterns in the FOV using digital holography [6,7].

3. RESULTS

We have developed a non-linear optical microscope for recording 3D neuronal activity in a cortical column, from awake head fixed behaving mice, with unrivalled temporal resolution. It can indeed address typically 20 cells at 1 kHz or 200 cells at 100Hz. This new optical technique, called Custom-Address Serial Holography (CASH), uses acousto-optic deflectors (AODs) with a regenerative amplifier operating at 40 kHz in the synchronous mode described above. In this configuration, we took advantage of the fact that the AODs function as ultrafast phase and amplitude modulators, to spatially shaped at 40kHz each laser pulse. Spatial modulation of laser pulses enables 3D addressing of neurons but also synchronous digital holography of extended volumes in the microscope's image plane for fluorescence excitation. Whereas defocus modulation allows thus fast 3D scanning at kHz sampling rate, complex shaping of the microscope PSF by wavefront modulation provide 3 key features : 1) it allows to maximize the fluorescence signal by collecting it from an extended cell volume and preventing fluorescence saturation in a diffraction limited spot; 2) it minimizes accordingly photobleaching and photodamage; 3) it allows to minimize motion artifacts. We have generated a library of 2D patterns consisting of 2D arrays of diffraction limited spots or of short segments. To this aim, we have designed different algorithms to determine optimal phase only or complex

patterns in the AODs to achieve the desired intensity patterns in the microscope FOV. These patterns can be adapted to the recording type as e.g. the cell dimension or the amplitude of the motion artifacts that is e.g. larger at large imaging depth. They are also adapted to the cell labeling. In the case of Genetically Encoded Calcium Indicators (GECIs), 2D square arrays of spots were optimal, while 2 line of spots positioned next to the cells can be used to estimate the neuropil contamination. In the case of Genetically Encoded Voltage Indicators (GEVIs), patterns consisting of several small parallel segments positioned near the plasma membrane on each side of the cell were found optimal in terms of SNR and motion artifact mitigation.

3D-CASH recordings of GCaMP6f expressing neurons in layer 2/3 and 5 of mouse primary visual cortex in response to moving contrast gratings reveal the layered organization of the cortex, in the structure of the neuron pairwise correlation matrix. 3D-CASH provides also the possibility of using Genetically Encoded Voltage Indicators (GEVIs) to record the activity of 3D neuronal networks at millisecond timescale, taking advantage of the most recent GEVIs optimized for spike detection. 3D-CASH also allows performing trans-cranial imaging over fields of view that go beyond the scattering memory effect by updating aberration and diffusion correction synchronously with the scanning, Finally, 3D-CASH is limited currently to samples sparsely labeled due to the reduced optical sectioning associated to the holographic illumination, an effect that we aim at reducing by implementing temporal focusing.

ABSTRACT

Acousto-Optic Tunable Filters (AOTF) are versatile devices with a range of applications in modern optics. Their technology has reached a mature industrialability. They are particularly valuable in fields requiring precise wavelength selection and fast switching capabilities, making them essential tools in various applications. The generalisation of their use has led to new applications still requiring specific developments.
We present the design and validation of an AOTF for spectro-polarimetry analysis which provides a constant spectral resolution over a wide spectral band. The variation of the spectral resolution is made possible by the manufacture of a transducer divided into multiple electrodes allowing to play on the interaction length easily by activating and deactivating the electrodes. In addition, the power distribution supplying the electrodes can be modulated, which offers the possibility of finely controlling the spectral template.
The device developed has an acoustic cut of 5°, operating from 450 to 800 nm. We opted for a transducer equipped with 5 electrodes. This strategy makes it possible, depending on the power supply conditions, to modulate the selectivity of the filter by a factor of 4 for a given wavelength and to maintain a constant selectivity of the order of 10 nm over the entire operating range.

Keywords: *AOTF, multi-electrodes, spectro-polarimetry.*

1. INTRODUCTION

Optical filters are essential components in various applications, including telecommunications, sensing, imaging, and spectroscopy [1]. Among these technologies, AOTF have emerged as an useful tool, allowing for precise control over the spectral characteristics of light [2]. Those devices have attracted a great interest, for example, the use of AOTF in imaging applications is under constant development [3-7].
Like all acousto-optic components, the design of the filters is subject to compromise depending on the intended use. For example, some applications require a large angular aperture, others require a large spectral band, while others require large rejection. The optical spectral filter function of an AOTF is a cardinal sine: it has a main lobe and adjacent secondary lobes. The side lobes reduce the performance of the filters by creating diaphony. This is a secondary aspect when filtering monochromatic signals, but it becomes an issue when we are in the presence of a wide spectral band signal. In this case, when tuning the filter for a given wavelength, it is possible to achieve a diffraction efficiency for a neighboring wavelength of up to 10%. In imaging, these secondary lobes are unwanted because they make the image blurry [6]. It is then necessary to reduce the adjacent lobes by implementing an apodization technique. Also, emerging applications drive advancements developments in spectro-polarimetry optical technologies. Spectro-polarimetry combines spectral and polarization information and becomes essential for various scientific fields, including materials science, biology, and remote sensing. The ability to tune the

filter dynamically, as offered by acousto-optic technologies, enhances the versatility and efficiency of spectro-polarimetric measurements, allowing for real-time analysis of complex samples.
This study centers on the development of an apodised AOTF specifically tailored for spectro-polarimetry applications. We present the development of the AOTF, detailing the operational principle, the design parameters and the experimental validation.

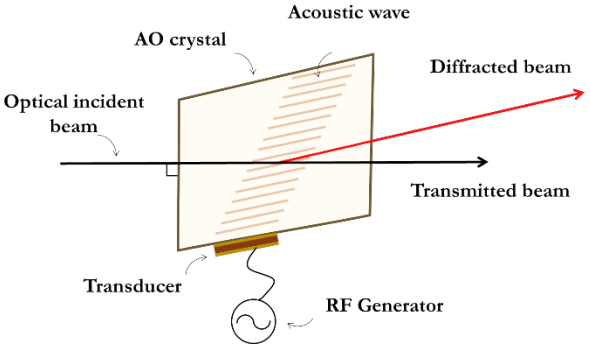

Figure 1. AOTF cell schematic view.

2. AOTF DESIGN

AOTFs are compact and efficient devices able to filter specific optical wavelengths with precision by the application of an appropriate Radio-Frequency (RF) signal that is tuned to satisfy the Bragg matching conditions for diffraction. In order to operate the AOTF, a piezoelectric transducer is mounted onto the side of a photoelastic crystal, such as in our case Tellurium Dioxide (TeO_2), figure 1. This transducer operates by converting RF signals into corresponding sound waves. By applying the appropriate frequency and power level to the transducer, the Bragg matching condition can be successfully satisfied: two first-order diffracted light beams are then separated at the output of the crystal for light with a precisely defined optical wavelength.

2.1 Bragg diffraction

Under Bragg phase matching conditions, the incident and diffracted optical wave vectors (k_i, k_d) and the acoustic wavevector (K) satisfy the exact momentum conservation:

$$\overrightarrow{k_d} = \vec{K} + \overrightarrow{k_i} \quad (1)$$

When the conditions exit the exact conditions (figure 2), a phase mismatch appears, it corresponds to a momentum offset Δk_d:

$$\overrightarrow{k_d} = \vec{K} + \overrightarrow{k_i} + \overrightarrow{\Delta k_d} \quad (2)$$

The study of these conditions allows to obtain information on the angles (incident and diffracted), the wavelength and the acoustic frequency of the interaction, since these parameters are related. With $\Delta\Phi = \Delta k_d . W_{eff}$ the phase mismatch and W_{eff} the effective interaction length that is given by:

$$W_{eff} = \frac{W\cos(\psi)}{\cos(\psi - \theta_i + \theta_a)} \quad (3)$$

Phase mismatch can come from several parameters: a variation in the wavelength $\Delta\lambda$ (spectral bandwidth); a variation in frequency Δf (frequency bandwidth); a variation of the incident angle (angular acceptance): $\Delta\theta$.

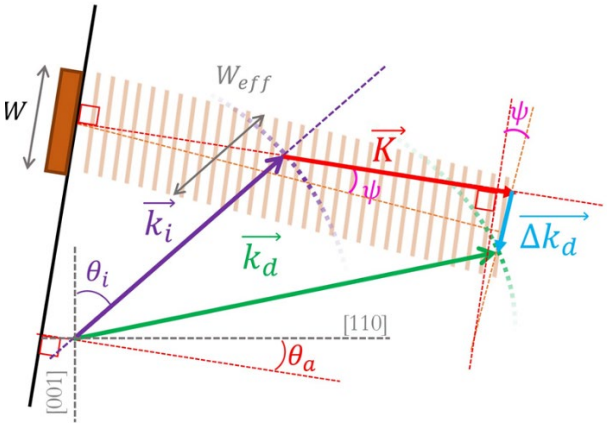

Figure 2. Wave vector diagram.

2.2 AOTF diffraction efficiency

The diffraction efficiency η of an acousto-optic component is expressed by:

$$\eta = \frac{P}{P_0}\frac{\sin^2\left(\frac{\pi}{2}\sqrt{\frac{P}{P_0}+\left(\frac{\Delta\Phi}{\pi}\right)^2}\right)}{\frac{P}{P_0}+\left(\frac{\Delta\Phi}{\pi}\right)^2} \quad (4)$$

The efficiency depends on the sound power P and the phase mismatch $\Delta\Phi$. As we are talking about a filter here, we are interested in the impact of the parameters on the filter optical spectral characteristics.
The analysis of the evolution of the diffraction efficiency as a function of wavelength, angle of incidence or acoustic frequency makes it possible to determine, respectively: an optical (or spectral), angular or acoustic bandwidth (Figure 3). The secondary lobes that characterize the rise in diffraction efficiency on either side of the main lobe can be determined in each of these cases.

An example of the typical diffraction efficiency evolution is shown in Fig. 3.

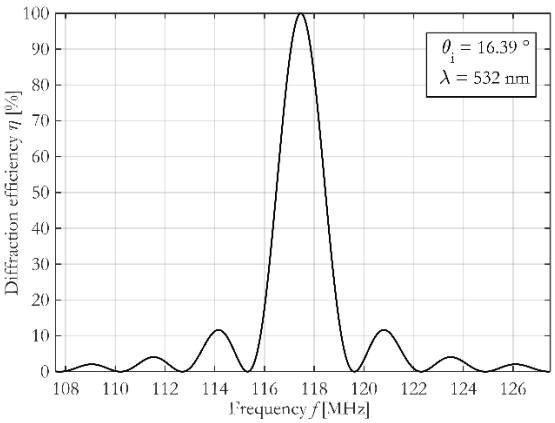

Figure 3. AOTF diffraction efficiency as a function of acoustic frequency.

The diffraction efficiency curves have a recognizable profile: a main lobe and side lobes for representation as a function of acoustic frequency or optical wavelength.
By exploiting the vector relation, it is possible to determine the expression of the acoustic frequency. If the interaction is from ordinary to extraordinary mode, it is expressed by [3]:

$$f_S = \frac{V}{\lambda}\sigma\left(n_i(\theta_i)\sin(\theta_i - \theta_a) - \sqrt{{n_d}^2(\theta_d) - {n_i}^2(\theta_i)\cos^2(\theta_i - \theta_a)}\right) \quad (5)$$

The frequency equation is a function of the parameters of the component and the interaction configuration: angle of incidence θ_i, acoustic cut θ_a, optical wavelength λ, acoustic velocity V, refractive indices ${n_i}^2$ and ${n_d}^2$.

It can be seen in Figure 4, which shows the different acoustic frequencies for extraordinary to ordinary (e-o) and ordinary to extraordinary (o-e) cases as a function of the angle of incidence, that the interaction frequency has some interesting particularities:
-It increases non-linearly if the wavelength decreases; -the two curves intercept.
-There is an incident angle for each frequency curve for which the variation around that angle does not cause a large frequency variation. This angle is the angle necessary to be in a particular case: the case of parallel tangents.
-The curves representing the two modes of interaction intersect at a single point, this is the point of the double interaction, where 100% of the polarizations are diffracted.
Also, it should be noted that the coordinate of the double interaction increases if the acoustic cut increases.

2.3 Apodisation of AOTF transfer function

Figure 3 clearly demonstrates that secondary lobes can be a limiting factor when monochromaticity of the filter is required. This is particularly relevant in the field of spectral imaging [6]. An interesting technic consists in the fabrication of a phased array transducer to control the acousto-optic transfer function [8, 9].
The principle of apodization in AOTFs with arrayed transducers involves the shaping of the acoustic wave's amplitude distribution to influence the diffraction pattern of light. By feeding the array transducer with a Gaussian power distribution, the acoustic wave's intensity generated tapers off gradually towards the edges, reducing abrupt transitions that cause side lobes in the optical output. Indeed, the acoustic wave generates the modulation of the refractive index of the medium, which acts as a diffraction grating for the incident light. The Gaussian power distribution across the transducers ensures that the acoustic wave's amplitude decreases symmetrically from the centre to the edges, so does the diffraction grating strength, minimizing the side lobes in the resulting optical transmission function.
There is of course a tradeoff between system complexity and the achievable filtering characteristics: using a large number of elements allows for a finely tuned filter transfer function with significant side lobe reduction, but it requires a more complex radiofrequency generator capable of producing as many radiofrequency tones as there are elements. We have established that even three elements can enhance the filtering characteristics of an AOTF [10]. To further improve these characteristics while keeping system complexity at an acceptable level, we have developed a device with five transducer elements.
The 5 electrodes can be activated independently, which allows the interaction length W_{eff} to be varied and therefore the optical spectral resolution $\Delta\lambda$ to be varied. This also allows for an apodization functionality.
To design the filter, it is useful to understand how the spectral and frequency bandwidths vary with different parameters. These variations depend on the acoustic cut, which is the first element we examine.

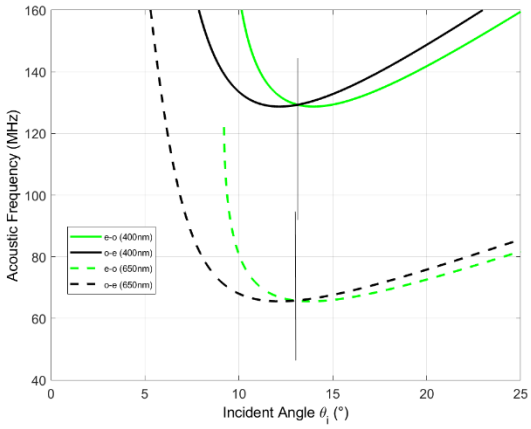

Figure 4. Evolution of the acoustic frequency at synchronism as a function of incident angle (acoustic cut considered for illustration: 6°).

3. DESIGN OF THE AOTF

Here, we present the design considerations for an AOTF operating in the visible light range, hence targeting an operational bandwidth from 400 nm to 900 nm at the design stage. Due to its high efficiency, paratellurite is chosen as the acousto-optic material.

3.1 Analysis of AOTF parameters

Figure 5 shows the variation of acoustic frequency across the reference spectral band for several acoustic cuts ranging from 3° to 9°. It can be observed that the frequency decreases as the wavelength increases, and this effect becomes more pronounced with larger acoustic cuts. High acoustic cuts necessitate higher radiofrequency operation, while low acoustic cuts are known to be more susceptible to unwanted gyrotropy effects [11].

Spectral resolution is a key criterion when selecting the acoustic cut for an AOTF. Figure 6 illustrates how spectral resolution varies with wavelength for several acoustic cut angles, assuming an effective acoustic column width of 7 mm. As can be seen, higher acoustic cuts result in lower spectral resolution. Moreover, a strong variation in spectral resolution is observed for small acoustic cuts; therefore, cuts of 4° or less were excluded, as they correspond to filters with optical resolution profiles that can reach up to 35 nm. However, a filter that would be too selective would result in low diffracted power. Hence, the higher cuts are neither favorable.

We have selected a 5° acoustic cut, which is sufficient to prevent gyrotropy effects while keeping the radiofrequency range confined within a single octave for a practical operation range from 450 nm to 800 nm and offer acceptable spectral resolution.

Then the choice of the number and the width of the electrodes should be considered. We first consider a single electrode of width comprised between 2 to 11 mm. Figure 7 illustrates the variation of spectral resolution with wavelength for various transducer lengths W. It can be observed that this electrode width enable a spectral resolution of approximately 10 nm across the entire operating band, with operation ranging from a 2 mm electrode at 450 nm to an 11 mm electrode at 800 nm. Since the number of electrodes is limited to five to enable spectral tunability while keeping system complexity at an acceptable level, we selected a central electrode larger than the others: 3 mm compared to 2 mm for the rest. This configuration allows, by activating adjacent electrodes, the formation of total transducer lengths of 2, 3, 4, 5, 7, 9, and 11 mm. By selecting, for example, only the 3 to 11 mm configurations, the spectral resolution varies by just a few nanometers across the entire optical band, ranging from approximately 8 to 11 nm, resulting in a variation factor of only 1.4 between the highest and lowest wavelengths.

Finally, considering the double operation point, an incident angle of 10.83° is required. A picture of the device is shown figure 8 and the parameters are summarized in table 1.

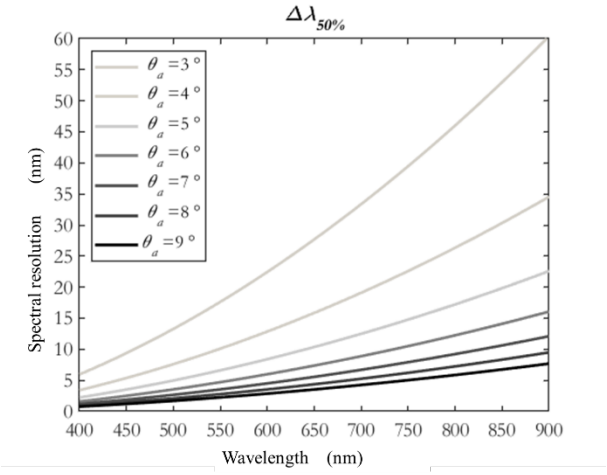

Figure 6. Evolution of AOTF spectral resolution as a function of wavelength for different acoustic cuts.

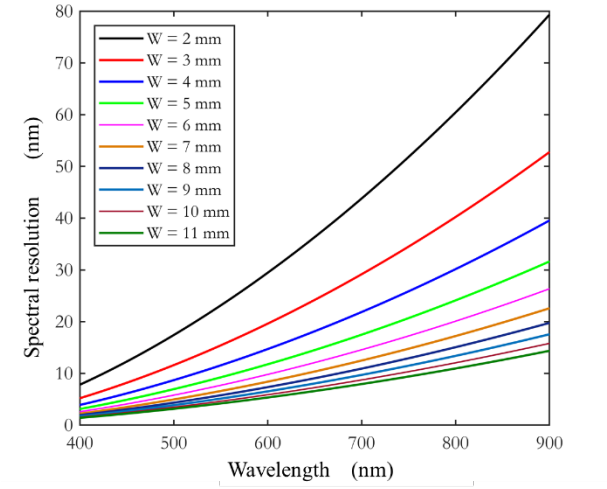

Figure 7. Evolution of spectral resolution for various transducer length.

Table 1. AOTF parameters.

Variable	Value	Unit
Acoustic cut θ_a	5	Degrees
Incident angle θ_i	10.83	Degrees
Transducer length	2 to 11	mm
Transducer number	5	

3.2 AOTF experimental validation

An experimental characterization of the AOTF was performed using the 514 nm line from an argon-ion laser. The same RF signal is coupled to all electrodes. Note that a phase shifter is introduced on the central electrode to compensate for its different behavior, due to its wider width compared to the other transducers. The AOTF's transfer function was estimated by scanning the RF signal across the Bragg frequency, a method known to approximate the optical transfer function shape. Figure 9 shows the relative efficiency of the AOTF for electrode widths ranging from 3 to 11 mm. As expected, a longer grating results in a reduced spectral bandwidth.
The apodization capability was then tested using a 5-channel RF generator developed in house, and an illustration of the apodized filter response is shown in Figure 10.

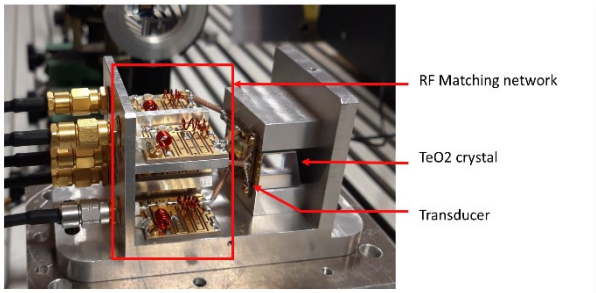

Figure 8. View of the AOTF.

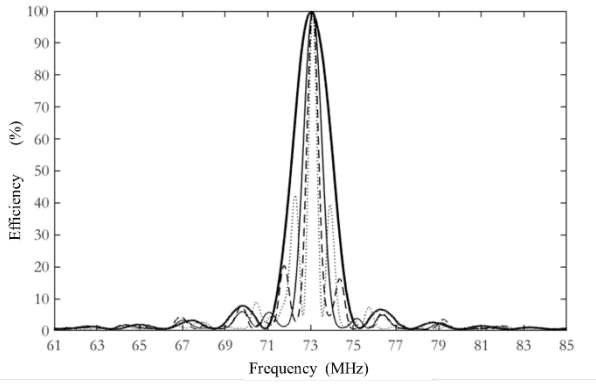

Figure 9. AOTF relative efficiency measured at 514 nm as a function of rf frequency for transducer width activated from 3 to 11 mm.

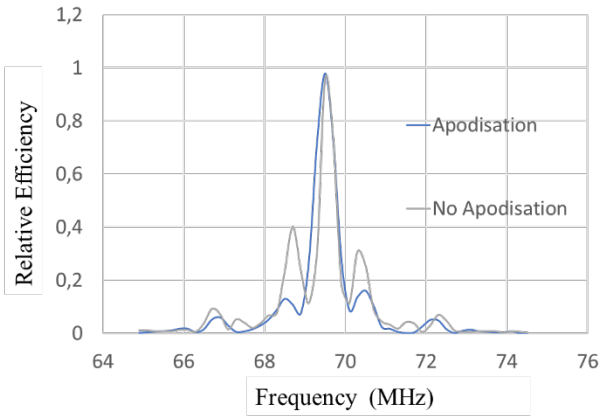

Figure 10. Test of apodisation capability at 532 nm.

During the apodization test, the power distribution across the five electrodes follows a Gaussian-like pattern, while the relative phase between the electrodes is adjusted to compensate for differences between the channels.

4. CONCLUSIONS

In this paper, we have outlined the key steps involved in the design and validation of an acousto-optic tunable filter capable of functioning as a spectropolarimeter. Simulation results were analysed to assess efficiency variations as a function of several parameters. Based on this analysis, an AOTF was designed and implemented to operate within the visible spectrum, from 450 nm to 800 nm. The device features five electrodes, enabling control of spectral resolution as a function of wavelength to achieve a nearly constant resolution across the entire operating range. Characterization and validation confirmed that the component met performance expectations, demonstrating that spectral resolution can be easily adjusted by activating multiple electrodes. With a resolution of approximately 10 nm, the system can distinguish up to 35 discrete spectral bands.

ABSTRACT

One of the main challenges for users applying an AOTF as a commercial off-the-shelf component for optical wavelength filtering, is the lack of detailed manufacturing information on critical parameters. Information such as diffraction angles, the precise RF driving frequencies required for momentum-matching conditions, as well as the data for each wavelength across a certain optical spectrum is not always easily available. To obtain this information, users must perform physical tests to configure the optimal frequencies, diffraction angles, and incidence angles for each wavelength of interest which is labor-intensive and costly.
This research uses an optimization algorithm applied to an analytical model which can characterize key angles related to the AOTF's crystallographic axis, such as the crystallographic axis angle θ_c, the tilt-angle α, as well as facet inclination angles β and γ. First, diffraction testing on an AOTF is done, by recording both output ray angles and the momentum-matching frequency. Then the optimization algorithm is chosen and applied to the analytical model to determine the optimal parameters for θ_c, α, γ, and β. With these parameters, the AOTF's behavior can be extrapolated to multiple wavelengths, which not only saves time, but also enables more versatile planning of optical setups..

Keywords: *AOTF, optimization model, analytical model.*

1. INTRODUCTION

Acousto-Optic Tunable Filters (AOTFs) make use of acoustic waves to manipulate the diffraction of light within a transparent crystal. These versatile devices are employed in various fields, such as ground- and space-based spectroscopy [1, 2] and network applications [3]. AOTFs are compact solid-state devices that filter desired optical wavelengths by applying an appropriate Radio-Frequency (RF) signal. Their compactness, robustness and quick tunability enables fast, efficient, and precise control over the spectral properties of light. AOTFs allow for the selective transmission or blocking of specific optical wavelengths, which makes them particularly appealing for space-based missions [4].
To operate AOTFs and regulate light diffraction at a specific optical wavelength, a transducer is mounted to the side of a transparent crystal, such as TeO_2 or quartz. This transducer converts RF signals of a designated frequency and power into sound waves [5]. Applying the appropriate frequency and power level, the Bragg matching condition can be satisfied, enabling two first-order diffracted light beams emitting at the crystal's output [6].
Using commercial off-the-shelf (COTS) AOTFs in an optical setup comes with certain challenges. Mostly the information provided on critical parameters in order to have an optimal functioning AOTF, is limited.
The aim of this paper is to present an optimization algorithm, using an analytical model, in order to characterize the AOTF's crystallographic axis angle θ_c, the tilt-angle α, as well as facet inclination angles β and γ (Fig. 1). Therefore, first a diffraction testing is done using

a COTS AOTF working in the optical visible domain. Both output ray angles are recorded, together with the momentum-matching frequency. Additionally, a developed optimization algorithm is applied to the analytical model, providing the parameters θ_c, α, γ, and β.

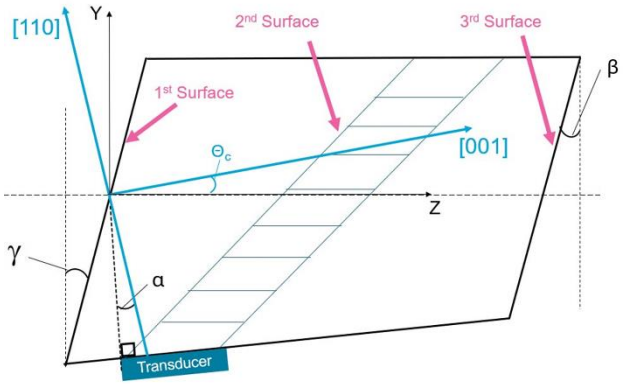

Figure 1. AOTF setup and positioning of the global (black) and crystallographic (blue) coordinate systems.

2. AOTF PARAMETER CHARACTERIZATION APPROACH

The optimization algorithm requires the analytical model's outputs in order to find optimal values that can characterize the main AOTF angles.. First, this model is briefly explained, followed by experimental diffraction tests. Consequently, the algorithm is applied to the model and the AOTF characterization parameters are obtained.

2.1 Analytical model

The goal of the analytical model is to provide as an output the undiffracted ray's optical path through the AOTF, as well as ray tracing of the diffracted ray, accompanied with the frequency signal required for the momentum-matching condition.

The model is based on the approach proposed by Zhao et al. [7], where the AOTF is split into three different surfaces, namely the AOTF entrance surface, the acoustic field and the exit surface (see Fig. 1). Using Directional Cosine Matrices (DCM) in 3D provides the baseline for the Python-based analytical model used in this research. This model has been broken down into more substages and uses adapted mathematical expressions in comparison to Zhao et al. [7], allowing a broad range of optical wavelengths in which the model is applicable.

2.2 Experimental diffraction tests

In this section, diffraction testing on a TeO_2 COTS AOTF (550 – 1000 nm) was carried out by recording both output ray angles, the rotational angle of the AOTF and the momentum-matching frequency. A vertically polarized 635 nm laser light is applied to the AOTF via a polarizer and an iris (Fig. 2). The diffraction occurred only when a vertically polarized light was shone, using a 145 MHz RF signal applied to the AOTF transducer. This RF signal was generated using a lab RF generator and amplifier setup.

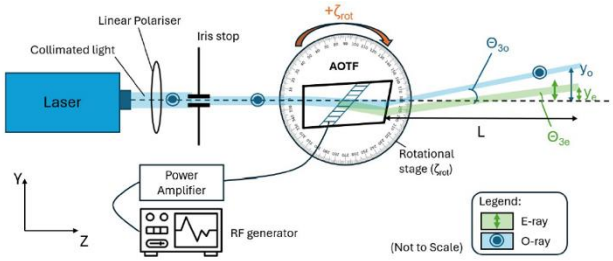

Figure 2. AOTF diffraction test setup with ζ_{rot} is the rotational angle, θ_{3o} is the ordinary undiffracted ray angle and θ_{3e} is the extraordinary diffracted ray.

An example of this diffraction is shown in Fig. 3, where the diffracted light appears faint to the left of the undiffracted light. The dimness of the diffracted light is due to the RF power being set at 100 mW.

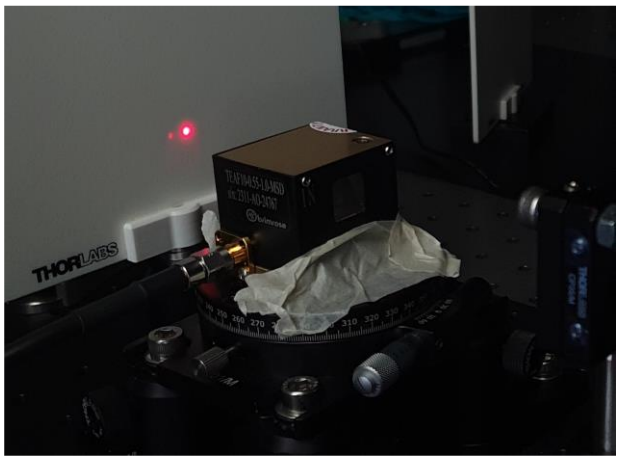

Figure 3. AOTF diffraction when a vertically polarised light is shone onto the AOTF.

The momentum-matching frequency was determined, by rotating the AOTF over a limited range (from -2 degrees

to 8 degrees, compared to the incoming light beam) using the rotational stage (Fig. 2 and 3). The accompanying diffracted and undiffracted rays angles θ_{3o} and θ_{3e} were also recorded by detecting the peak diffracted ray intensity.

2.3 Algorithm selection

To integrate the developed analytical model with an optimization algorithm, the first step was to identify a suitable algorithm. The approach involved selecting an existing method and adapt the analytical model accordingly. Given that the model was implemented in Python and involved multiple variables influencing the results, the selection was limited to multi-variable optimization algorithms available in SciPy. The "L-BFGS-B" algorithm (Limited-memory Broyden-Fletcher-Goldfarb-Shanno) was chosen due to its suitability for multi-variable nonlinear problems and its computational efficiency compared to other quasi-Newton methods [8]. Moreover, this algorithm supports box constraints, allowing for straightforward boundary conditions on variables (θ_c, α, γ, β).

Quasi-Newton methods aim to find a local minimum by approximating the curvature of the objective function, focusing on values where the function approaches a local minimum [8]. To determine the curvatures for each search variable, these methods typically rely on an inverse Hessian matrix [9], containing the second-order partial derivatives. However, calculating a full Hessian becomes increasingly time-consuming as the number of variables (n) grows [10]. To address this, the limited-memory approach estimates the Hessian matrix using only recent search iterations, rather than each time recalculating it from scratch [10]. A detailed mathematical explanation of how this algorithm works is beyond the scope of this research. The primary reason for selecting this algorithm is its computational efficiency in solving multi-variable problems and its ease of implementation in Python through the SciPy library, which also supports simplified variable constraints. Furthermore, the algorithm is relatively effective in finding a global minimum (optimal value) of the objective function [10].

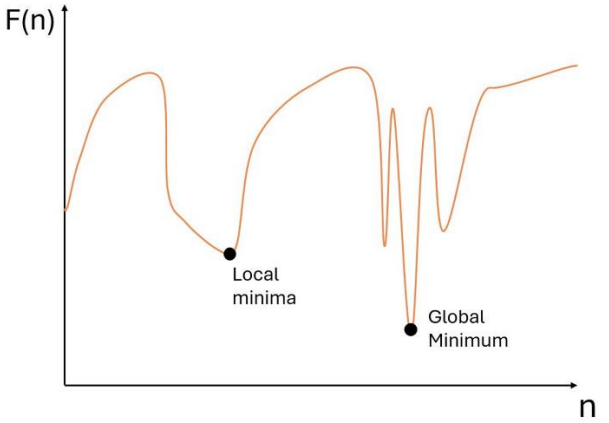

Figure 4. Simplified multimodal example where finding global minimum is challenging for Newton methods.

However, L-BFGS-B can become trapped in local minima, as shown in Fig. 4. This is an example of an objective function with a single variable n demonstrating this limitation [10]. To address this, running the algorithm multiple times with different initial guesses can improve the chances of finding the global minimum.

In contrast, genetic algorithms are generally more effective at locating the global minimum in such cases. Nevertheless, they are more complex to implement, requiring constraints within the objective function, and often come with higher computational costs [11, 12]. Due to these factors, genetic algorithms were not considered in this study but are recommended for future research.

2.4 Objective function and bounds selection

With the L-BFGS-B algorithm selected, the next step is to define its input for optimization. The primary input is the objective function — a scalar function that the algorithm seeks to minimize [10]. The objective is to reduce the discrepancy between the experimental measurements from the COTS AOTF diffraction testing and the predictions from the analytical model. This discrepancy is quantified as a total error, formulated in Eqn. 1 as the objective function. This represents the sum of squared errors for momentum-matching frequency and diffracted/undiffracted angles.

$$E_{tot} = E_{freq} + E_{diff} + E_{undiff} \quad (1)$$

Where each term is defined as follows:

$$E_{freq} = \sum_{i=1}^{n} \left(f_i^{exp} - f_i^{sim} \right)^2 \quad (2)$$

$$E_{diff} = \sum_{i=1}^{n} \left(\theta_{e,i}^{exp} - \theta_{e,i}^{sim}\right)^2 \quad (3)$$

$$E_{undiff} = \sum_{i=1}^{n} \left(\theta_{o,i}^{exp} - \theta_{o,i}^{sim}\right)^2 \quad (4)$$

In Eqn. 2, 3 and 4, *n* represents the number of data points in the experimental results array f^{exp} (momentum-matching frequency), obtained from the diffraction testing, with each point corresponding to a different ζ_{rot} angle. f^{sim} represents the simulated values of the momentum-matching frequency generated by the optimization algorithm. The squared difference is selected because it assigns greater weight to larger errors, ensuring the optimization algorithm to prioritize reducing significant discrepancies.

During each iteration, the algorithm tests different configurations of the variables θ_c, α, γ and β, aiming to minimize the cumulative error across all three equations, thus optimizing the objective function.

To ensure the search remains within realistic AOTF parameter ranges, bounds were set for θ_c, α, γ and β. The selected bounds for the COTS AOTF are listed in Tab. 1, where the left is the lower bound, and the right is the upper bound.

Table 1. Optimization variables and their bounds.

Variable	Bounds	Unit
θ_c	[10; 55]	Degrees
α	[5; 16]	Degrees
γ	[-0.1; 0.1]	Degrees
β	[5; 12]	Degrees

3. EVALUATION OF THE OPTIMIZATION RESULTS

After setting the objective function and bounds for the L-BFGS algorithm, the optimization was executed multiple times with varying initial guesses to avoid the algorithm from becoming stuck in a local minimum. Each optimization run converged to the optimized parameters listed in Tab. 2.

Table 2. Optimized parameters.

Variable	Optimized value	Unit
θ_c	25.92	Degrees
α	11.97	Degrees
γ	-0.1	Degrees
β	7.2	Degrees

The optimized values were subsequently applied to the analytical model. A frequency matching graph is shown in Fig. 5, indicating the match between the predictions (in green) and the experimentally obtained data (in blue). It can be seen that the frequency remains relatively consistent as the rotational angle increases.

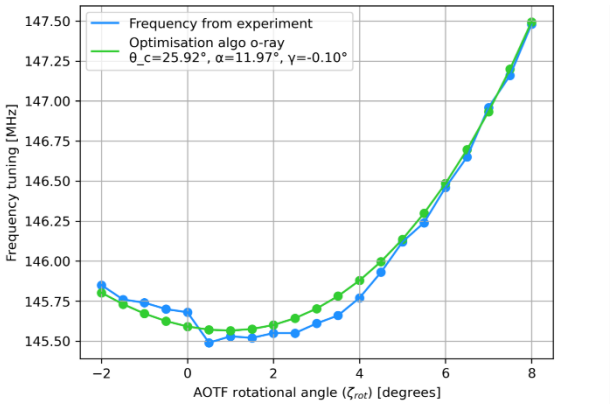

Figure 5. Momentum-matching frequencies as a function of AOTF rotational angle for the ordinary ray diffraction test.

The undiffracted and diffracted angle results are considered together. For the undiffracted rays presented in Fig. 6, in which β plays a key role, the optimization algorithm slightly overestimates the experimental curve.

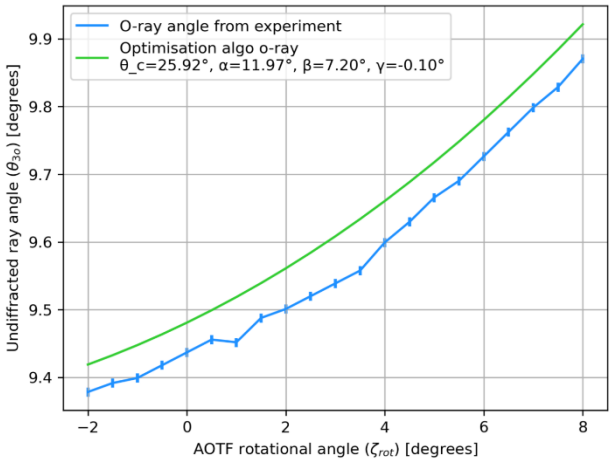

Figure 6. Undiffracted ray angles (θ_{3o}) as a function of AOTF rotational angle for the o-ray diffraction test.

Notably, the angles of the diffracted rays remain extremely stable for this AOTF, consistently ranging between 2.65° and 2.70° (Fig. 7). This stability is an advantage for the optical design, enabling precise predictions of the diffracted ray's path and accurate CCD placement. However, this stability also creates a challenge for the optimization algorithm. When the algorithm attempts to reduce the simulated undiffracted angle by lowering β, it inadvertently shifts the diffracted angle values downward, which penalizes the algorithm if β is reduced too much.

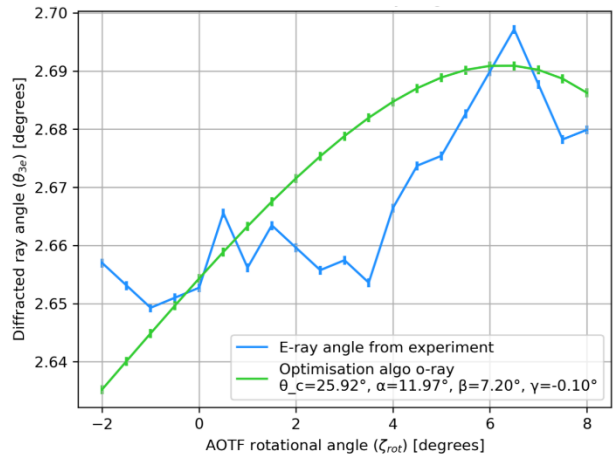

Figure 7. Diffracted ray angles (θ_{3e}) as a function of AOTF rotational angle for the o-ray diffraction test.

In general, the optimization algorithm shows good results, with all simulation curves aligning closely with the experimental data with a discrepancy between experimental and calculated values below 0,02° (Fig. 7). These frequency mismatches could arise from small deviations in the crystal's material properties, such as the acoustic velocity or refractive indices, compared to the values used in the analytical model.

4. CONCLUSIONS

In this research, a dedicated optimization algorithm is explored, in combination with an analytical model. The goal is to find characterization parameters linked to the practical build of the AOTF. The results show that the unknown parameters θ_c, α, γ, and β can be determined.
The L-BFGS optimization algorithm was selected due to its efficiency in handling multiple variables, its computational speed, and its enhanced capability in locating global minima compared to simpler optimization methods. To direct the optimization, an objective function was defined in order to minimize the difference between the simulated and measured values. Additionally, search bounds were set for the AOTF parameters θ_c, α, γ, and β, constraining the algorithm's variable adjustments within these limits.
The optimized values for these four parameters generated curves that closely matched the experimental results. Further improvements could be achieved by either adjusting the penalty in the objective function to refine frequency-matching curves or by incorporating additional variables, such as the material's acoustic velocity. These changes would increase computational time due to the added search variables, but could enhance the characterization process.

ABSTRACT

Optical microscopy is a key tool for investigating the structure and dynamics of biological systems at sub-cellular resolution. However, most conventional microscopy setups are designed to capture two-dimensional (2D) data from moderately thin samples labeled with fluorophores. Due to limitations imposed by light scattering and the need for mechanical focus adjustments, these systems struggle with deep tissue penetration and label-free imaging, making them insufficient for non-invasively studying biological complexity in medium-sized organisms such as organoids. Here, we survey our efforts to address these challenges and achieve label-free sub-millisecond imaging at potential depths of up to millimeters. Our approach leverages the acousto-optic effect – specifically, ultrasound-induced refractive index gradients – to focus, modulate, and guide light. The unique interaction between light and ultrasound enables rapid 3D control of light, making it ideal for developing inertia-free microscopes with no moving parts while achieving label-free imaging at hundreds of frames per second. Additionally, shaped ultrasound waves in a medium can act as an instantaneous waveguide, redirecting light toward a focus deeper than conventional optics. The synergistic integration of acousto-optics with advanced microscopy paves the way for an unprecedented in-situ characterization of dynamic processes.

1. INTRODUCTION

A key frontier in optical microscopy is achieving non-invasive, real-time, label-free imaging of biological samples at sub-cellular resolution. However, current microscopes are primarily optimized for acquiring 2D images at tens of frames per second from fluorescently labeled samples that are only a few hundred microns thick [*1*]. Deeper imaging, which is central for studying complex biological specimens such as organoids, remains limited by light scattering to depths of less than 1 mm [*2*]. Similarly, enhancing image contrast and specificity typically requires fluorescent dyes, introducing additional complexity and potential invasiveness to microscopy systems.

Several strategies have been developed to address these issues and advance toward deeper, faster, and label-free microscopes. Among them, exploiting the acousto-optic effect has proved effective in achieving unprecedented control of light outside and inside biological samples [*3*]. In this short paper, we present an overview of our work in this area. Specifically, we highlight the use of acousto-optics in two important microscopy scenarios: rapid axial focus control in quantitative phase imaging [*4*], and light guiding to enhance deep imaging [*5*].

2. PRINCIPLE OF ACOUSTO-OPTICS

The essence of the acousto-optic effect is to induce refractive index gradients within a medium using ultrasound. By sending ultrasound waves (pressure waves) within a medium, it is possible to locally and rapidly modify its density – and consequently, its refractive index. This enables dynamic control of the medium's optical properties, allowing light to be split, focused, or even guided on microsecond time scales. While acousto-optics has long been used in traditional microscopy – particularly

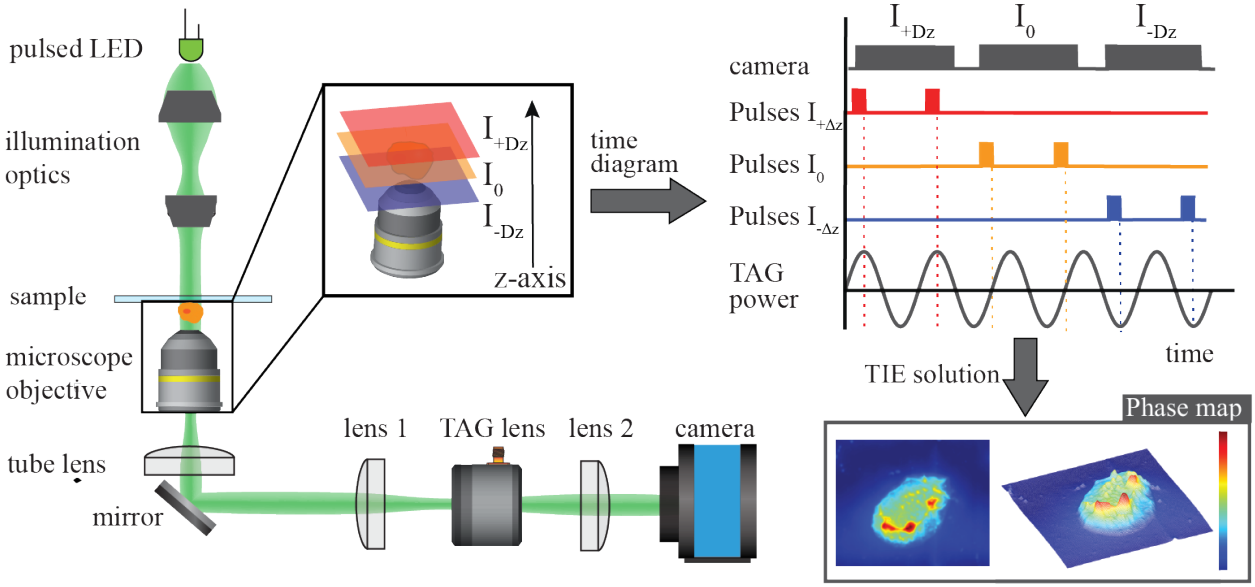

Figure 1. Schematic of the setup for rapid label-free imaging using acousto-optics. An acousto-optic liquid lens (TAG lens), synchronized with pulsed illumination, enables rapid selection of the three focal planes required to solve the Transport of Intensity Equation and retrieve a phase map of the sample. Quantitative phase imaging is thus be achieved at rates only limited by the camera frame rate.

through acousto-optic modulators and deflectors for beam conditioning – our focus here is on two more recent implementations. They have in common the use of non-traditional ultrasound geometries, which have opened new avenues for advancing microscopy.

3. QUANTITATIVE PHASE IMAGING WITH RAPID FOCUS CONROL

The use of fluorescent dyes for high-contrast microscopy can be obviated by measuring the phase shifts that light undergoes as it passes through a specimen – a technique known as phase imaging. Traditionally used as a qualitative method for contrast enhancement, phase imaging has evolved over recent decades into a quantitative approach. This advancement, known as Quantitative Phase Imaging (QPI), not only enhances contrast but also enables the extraction of physical properties such as the refractive index and thickness of the sample [*6*]. Among the various QPI techniques, the Transport of Intensity Equation (TIE) stands out for its simplicity and non-interferometric nature [*7*]. In fact, only two or three brightfield images acquired at known, distinct focal planes are sufficient to retrieve phase information. Unfortunately, precise axial movement of the sample relative to the microscope – often requiring fine adjustments for each specimen – is typically implemented with mechanical actuators, drastically reducing imaging speed in practice.

A promising solution toward real-time TIE imaging is the use of an acousto-optics liquid lens known as the TAG lens [*8*, *9*]. When synchronized with pulsed illumination, it enables remote focus control without any mechanically moving parts. This inertia-free approach allows for microsecond-scale focusing [*10*]. As shown in Figure 1, the sequential capture of three images – each at a different time delay relative to the TAG lens oscillation – allows for the retrieval of a phase map at a speed only limited by the camera's frame rate [*4*]. This high speed enables phase imaging of dynamic events. and, when combined with image stitching, facilitates large field-of-view imaging. This capability is particularly important for the label-free characterization of histopathology samples

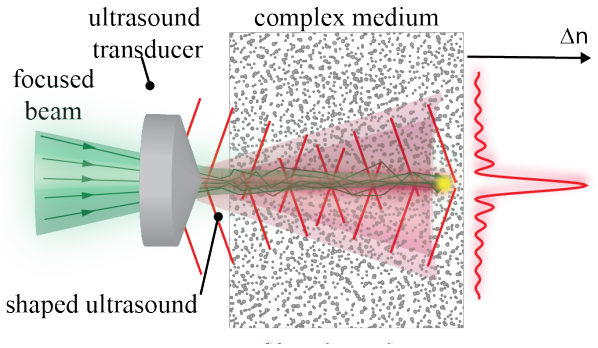

Figure 2. Principle of acousto-optic light guiding within scattering (complex) media. The refractive-index gradients induced by ultrasound act as an embedded waveguide directly inside the medium, helping light reach a deeper focus in analogy to an endoscope.

4. ULTRASONIC ENDOSCOPES

The acousto-optic effect has recently emerged as an effective strategy for mitigating light-scattering inside inhomogeneous media such as biological tissue [*5*, *11–13*]. In this case, shaped ultrasound – ultrasound waves with tailored spatial profiles – are directly sent into the medium of interest. The so-induced refractive index gradients act as effective lenses or waveguides embedded within the medium, helping light reach a deeper focus. In other words, ultrasound acts as a virtual endoscope, as shown in Figure 2. While promising, most implementations primarily rely on resonant acoustic cavities, which require the sample to be placed within the cavity – making the method inherently invasive.

Recent efforts to eliminate the need for resonant cavities include using specially designed ultrasound transducers [*14*, *15]* and specific geometries [*16*]. These methods have reached significant enhancements in the amount of light delivered within scattering media. For example, in samples with an optical thickness of 2.5 – where light is scattered an average of 2.5 times within the medium – the use of two parallel piezoelectric plates resulted in a 700% gain in delivered light [*16*]. This impressive result can be transformative for microscopy applications that rely on light delivery over large areas, such as photoacoustic microscopy.

5. CONCLUSIONS

Acousto-optics offers a promising path toward rapid, deep, and label-free microscopy. By combining innovative ultrasound geometries with new concepts – such as using ultrasonic endoscopes – there has been a recent surge in the potential applications of acousto-optics. We believe that ongoing progress in this area will significantly transform the microscopy landscape, bringing us closer to the coveted goal of a real-time, non-invasive, and deep optical tool.

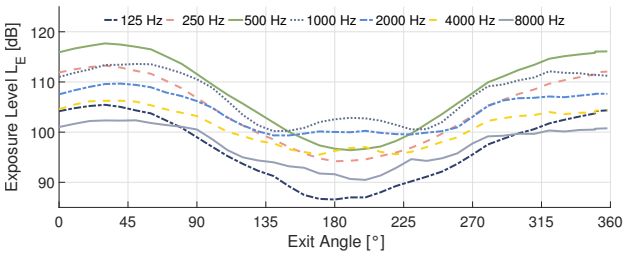
TWO HYBRID DIRECTIVITY MODELS OF MUZZLE BLASTS TO DESCRIBE THE FREQUENCY AND DISTANCE DEPENDENCY

Philipp Bechtel* **Christian Kleinhenrich** **Karl-Wilhelm Hirsch**
Cervus Consult GmbH, Germany

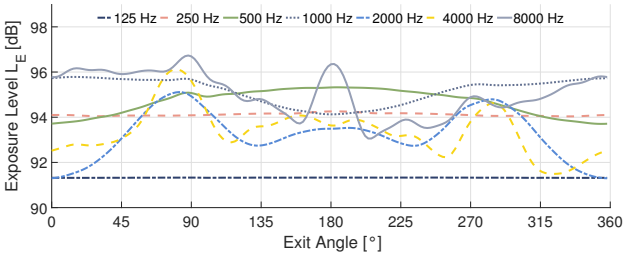
ABSTRACT

The muzzle blast is an auditory risk if the shooter or other personnel are exposed close to the weapon. To evaluate the risk, the signature of the blast must be measured or synthesized for simulation purposes. Muzzle blasts are highly directional. A common approach for simulation is to assume a source model with scalar directivity. This approach neglects the angle- and distance-dependent changes in the frequency spectrum of the blast. Hence, significant discrepancies occur between synthesized and measured shooting signals. This paper presents two alternative approaches to describe the distance- and frequency-dependent directivity of a muzzle blast. The first approach is based on the ANX model by Salomons. In contrast to the scalar directivity of the latter, here a separate source energy is determined for each exit angle using cosine transformation. This model synthesizes the blasts with only a few parameters. For the second model, a transfer function is given by the ANX model and a spherical harmonic source describes the angle and frequency dependency of the blast signature. Depending on the input data, this model provides very detailed reconstructions of measured muzzle blasts even close to the muzzle.



Keywords: *Muzzle blasts, nonlinear, directivity, ANX*

1 INTRODUCTION



The hearing load of the shooter when firing handguns is primarily caused by the muzzle blast. The decisive input variable of models for assessing the exposure and the risk of hearing damage is the sound pressure time curve at the ear. For the investigation of such exposure models, reliable source models of the muzzle blast are required, which provide the sound pressure time signal. In addition to the pronounced frequency-dependent directivity of the muzzle blast, nonlinear effects in sound propagation must be taken into account in the near field of the weapon.

2 FUNDAMENTELS: DIRECTIVITY OF A MUZZLE BLAST

First, the special features of the directivity of a muzzle blast are discussed.

(a) Gun muzzle blast

(b) Loudspeaker

Figure 1: Level of octave bands as a function of the exit angle in the transversal plane for a gun muzzle blast and a loudspeaker (Genelec 8020c)

The level deviations of the octave bands over the azimuth

angle in the transversal plane of a rifle muzzle blast and a loudspeaker are shown in Figure 1. Measurement data from the Genelec 8020c from the BRAS project was used for the loudspeaker directivity[1]. The following aspects become clear from the comparison of the level deviations of the octave bands.

- The octave band-dependent level deviation of the muzzle blast is up to 20 dB depending on the angle of exit and is therefore many times greater than that of the loudspeaker
- The eccentricity - the level difference between the front (firing direction) and the rear - of the muzzle blast is most pronounced in the low frequency bands of 125 Hz to 500 Hz and decreases towards high frequencies from approximate 20 dB to 10 dB
- Most of the energy of this rifle is emitted between 500 Hz and 1 kHz

The propellant gases escaping from the tube during the muzzle blast resemble a massively deformed sphere, as indicated in the schlieren photography from Figure 2.

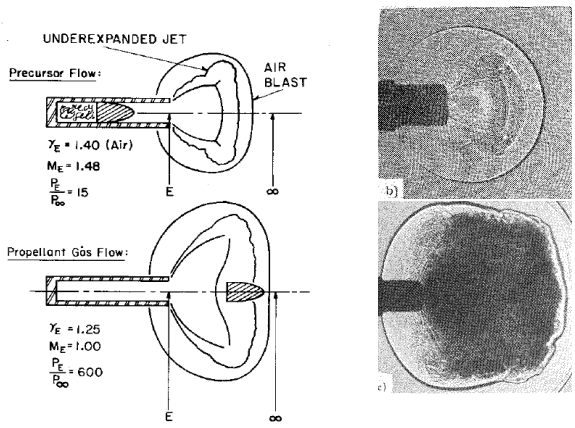

Figure 2: Flows occurring during the muzzle blast[2]

The first spherical sound front recognizable in the schlieren photography is the so-called *precursor*, which originates from the air pushed out by the projectile at supersonic speed. The actual muzzle blast is formed by the propellant gases behind the projectile. These also emerge from the pipe at supersonic speed and flow into the still air. This forms a so-called Mach plate, a well-known phenomenon in fluid dynamics[2]. The muzzle blast is therefore emitted neither from the muzzle itself nor from a sphere around it, but from a disk[3]. This explains why the directional effect is also directed forwards at longer wavelengths, while it tends to remain round at shorter wavelengths.

3 RAW AND REFERENCE DATA

In Figure 3 the 36 measuring points are outlined in the horizontal plane.

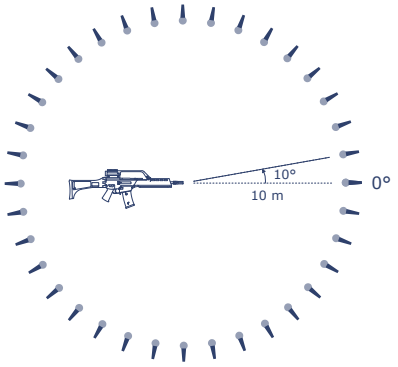

Figure 3: Sketch of the 360° measurement

There are three recorded shot signals per measuring point. The distance between the microphones and the muzzle is 10 m. The weapon used is a rifle on a fixture with a muzzle brake [1] . Both the muzzle and the respective measuring points are positioned 2 m above the approximately reverberant grass ground. This means that the ground reflection hits approximate 2.1 ms after the direct sound. For the investigations presented here, only the direct sound component windowed out using Hamming windows is considered. The full metal jacket ammunition corresponds to the caliber 5.56 mm × 45 mm. In the calculations, an exit velocity $v_0 = 1200\ m/s$ and a projectile mass $m_p = 3.7$ g were assumed for this ammunition.

A total of six additional measurement points from another measurement campaign were used to investigate the propagation models. There, the same rifle type with identical ammunition was measured on an open shooting range. In contrast to the 360° measurement, the ground here consisted of gravel and a shooter was used instead of a fixture. Four of the six reference points are outlined in Figure 4.

[1] According to the current state of the investigation, the muzzle brake influences the emitted sound from an angle of ≈ 140°, so that no clean blast is measured there.

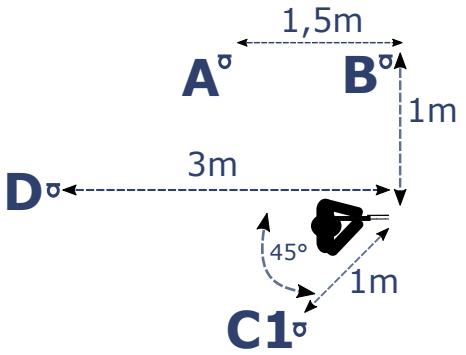

Figure 4: Sketch of reference measuring points

The two remaining measuring points C5 and C10 are in the propagation path of measuring point C1 at a distance of 5 m and 10 m from the muzzle.

4 ANX SOURCE MODEL

This model was introduced in 2024 by Salomons[4] under the title: *Analytical model for sound of explosives and firearms (ANX)*. It is based on a Friedlander blast[5], which has two characteristic values with the peak sound pressure P and the positive transit time T. The characteristic values and the resulting sound pressure time curve are sketched in Figure 5.

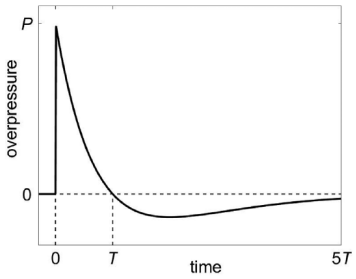

Figure 5: Friedlander waveform, with peak sound pressure P and positive transit time T[4]

The special feature of the ANX model is the nonlinear sound propagation. Here, the peak sound pressure $P(r)$ and the duration of the positive N-wave flank $T(r)$ are distance-dependent variables that are determined according to Equations (2) and (3). As the spectral energy of a signal moves increasingly towards low frequencies with increasing $T(r)$, a blast becomes more low-frequency with increasing distance from the muzzle according to the ANX model.

Table 1: Relevant constants and reference values

K	β	ρ	c	t_0	p_0
0.38	1.2	1.2 kg/m^3	340 m/s	1 s	20 µPa

The auxiliary variable r_*, which depends on the source energy E, limits the application range of the model with $r > 1.6\,r_*$ and can be determined according to Equation (4) with the values from Table 1. The source energy of handguns is usually less than 20 kJ which corresponds to a maximum r_* of 367 mm. This means that the model is suitable for most handguns from a distance of approximately 0.6 m applicable.

$$p(t) = P(r)\left(1 - \frac{t}{T(r)}\right) e^{-t/T(r)} \tag{1}$$

$$P(r) = K\rho c^2 \frac{r_*}{r}\sqrt{\frac{1}{\ln(r/r_*)}} \tag{2}$$

$$T(r) = K\beta \frac{r_*}{c}\sqrt{\ln(\frac{r}{r_*})} \tag{3}$$

$$r_* = 0.7\sqrt[3]{\frac{E}{\rho c^2}} \tag{4}$$

4.1 Scalar directivity

Salomons[4] uses a scalar approach with the directivity D. This value can be calculated with the reference quantity $m_0 = 75$ g according to Equation (5). For small arms, the propellant mass m is only a few grams, so that $m \ll m_0$ applies and the directivity is approximately 17.5 dB. The directional correction term C_{dir} can be determined according to Equation (6) and is for $m \ll m_0$ approximately 11 dB.

The scalar, exit angle-dependent correction level $\Delta L(\phi)$ thus results in Equation (7).

$$D = \frac{17.5}{1 + (m/m_0)^{1.5}} \tag{5}$$

$$C_{\text{dir}} = 10 \log \left(\frac{10}{D} \frac{10^{D/10}}{\ln(10)} \left[1 - 10^{-D/10} \right] \right) \quad (6)$$

$$\Delta L(\phi) = D \left(1 - \frac{\phi}{180} \right) - C_{\text{dir}} \quad (7)$$

For the rifle considered here, the source energy $E = 2500\,\text{J}$ is assumed.

4.2 Source energy-dependent directivity by cosine transformation

In this approach, an angle-dependent source energy $E(\phi)$ is determined. Using the coefficients of a rifle of 5.56 mm × 45 mm caliber from Table 2, the angle-dependent source energy can be determined by cosine transformation according to Equation (8). The angle-dependent source energy can then be used to calculate the distance-dependent signal parameters according to Equations (2) and (3) from which the final signals at the receiver result.

Table 2: Coefficients for determining the direction-dependent source energy of a rifle muzzle blast using the 5th order cosine transformation

Index i	1	2	3	4	5
c_i / J	2521	1908	557	79	52

$$E(\phi) = \sum_{i=1}^{N} c_i \cdot cos(\phi \cdot (i-1)) \quad (8)$$

5 SPHERICAL HARMONICS (SH) SOURCE

As a further source model, a transformation of the measurement data into the spherical frequency domain is considered. This was carried out with a 15th order spherical harmonics decomposition, resulting in 256 complex coefficients for each frequency support point. The method is described in more detail by Williams[6], among others. The reconstructed signals of this source model naturally only represent this type of rifle with the corresponding ammunition.

6 PROPAGATION MODELS

This chapter deals with two different propagation models. Both deal exclusively with distance-dependent attenuation. For example, atmospheric attenuation components that also occur during sound propagation are not taken into account in these models.

The reference distance r_0 was used for the spherical harmonics 10 m, as the data used for the decomposition was available at this distance. For the ANX source model, $r_0 = 1\,\text{m}$ was selected as the reference distance.

6.1 Linear sound propagation model

The linear propagation model uses the $1/r$ approach commonly used in acoustics. The calculation of the sound pressure time curve $p_r(t, \phi)$ at a distance r is shown in Equation (9), neglecting the phase and other attenuation effects.

$$p_r(t, \phi) = p_{r_0}(t, \phi) \cdot \frac{r_0}{r} \quad (9)$$

6.2 Nonlinear sound propagation model

This model describes the nonlinear sound propagation of an N-wave with spherical expansion in a homogeneous environment according to Pierce[7] [2]. The implementation of this model is based on the ANX model according to Section 4.

To determine the distance-dependent transfer function, the angle-dependent energy $E(\phi)$ of the sound source is first required. If this is not available, but for example sound pressure time curves at the known source distance r, the energy of these signals can be estimated. To do this, the exposure level L_E of the signal must be calculated. From this level, the auxiliary variable r_* can then be estimated according to Equation (10) [3]. With the constants and reference quantities from Table 1, the source energy can finally be determined with Equation (11).

$$L_E = 10 \log \left(\frac{\pi K^3 \beta \rho^2 c^3 r_*^3}{p_0^2 r_0^2 t_0} \frac{r_0^2}{4\pi r^2} \sqrt{\frac{1}{\ln(r/r_*)}} \right) \quad (10)$$

[2] Chapter 11.9

[3] According to Salomons[4], the deviation is less than 1 dB

$$E = \rho c^2 \left(\frac{r_*}{0.7}\right)^3 \tag{11}$$

In the next step, the creation of the transfer function is outlined. The angle-dependent source energy $E(\phi)$ is used to generate an ANX signal $p_{r_0}(t, \phi)$ for the reference distance r_0 and a second signal $p_r(t, \phi)$ for the desired source distance r. Using Fourier transformation, these two signals are transferred to the frequency domain and the quotient is formed, which corresponds to the transfer function.

By multiplying the source signal, which has also been transformed into the frequency domain, with the transfer function, the frequency response of the signal at a distance r at the angle of exit ϕ can be determined. The back transformation into the time domain results in the shot signal at the observation point with nonlinear sound propagation.

7 INVESTIGATION

In this section, the source models presented are examined with regard to their applicability in the vicinity of the muzzle. For this purpose, the predicted hearing load as well as the sound pressure time curves and frequency responses are considered.

Table 3: Nomenclature of the abbreviations

Scalar Directivity	scalar directivity according to Section 4.1
Cosine Trans.	energetic directivity according to Section 4.2
Linear	linear propagation model according to Section 6.1
NL	nonlinear propagation according to Section 6.2

The abbreviations used in the following can be taken from Table 3.

7.1 Predicted hearing load

The AHAAH model[8] used to determine the hearing load was developed explicitly for shooting noise. It is an appropriate hearing damage prediction method and is currently used by the US military[9], among others. The AHAAH settings unwarned, no hearing protection and frontal sound incidence were used consistently for all calculations.

The following statements can be derived from the hearing loads presented in Figure 6 over the angle of exit at a distance of 10 m.

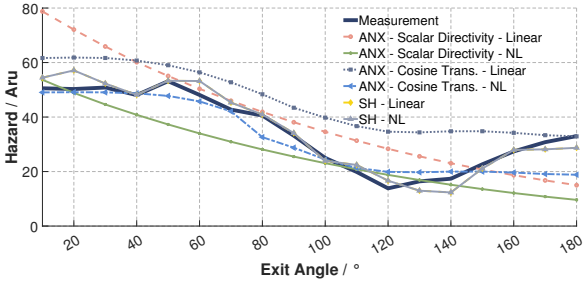

Figure 6: Hearing load over the angle of exit in 10 m muzzle distance

- The predicted hearing load of the measurement signals decreases with increasing angle until the influence of the muzzle brake from $\approx 140°$ causes it to increase again
- The curves of the spherical harmonics reconstructions with linear and nonlinear sound propagation are identical due to the reference distance $r_0 = 10\,\text{m}$ and deviate only slightly from the target values
- The hearing loads according to the ANX models with scalar directivity decrease approximately linearly over the angle of exit. As expected, the values are higher with the linear propagation model, as both the stronger additional level drop and the shift in the spectrum are neglected. The correlation with the values of the measurement are only low for the ANX source models with scalar directivity
- The ANX source model with cosine transformation directivity significantly overestimates the target values in a linear propagation calculation. In combination with the nonlinear propagation model, the method provides appropriate hearing exposure predictions for angles $< 140°$

Next, the models are analysed on the reference data according to Figure 4. For this purpose, Figure 7 shows the hearing loads at the reference measuring points removed in 1 m to 10 m and the following statements can be derived.

- The predicted hearing load of the measurement signals tends to decrease with increasing distance to the muzzle
- At the measurement points B and C1 near the muzzle, the spherical harmonics values deviate significantly from each other depending on which propagation

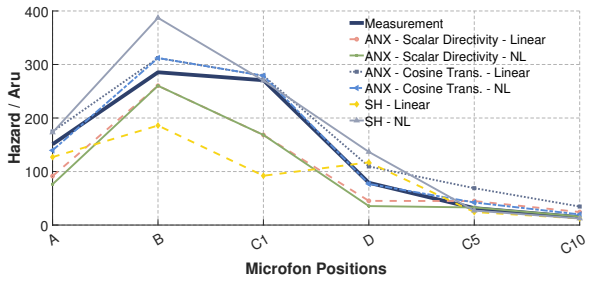

Figure 7: Hearing load at the reference measuring points according to Figure 4

method was used. The deviations with the nonlinear propagation model are significantly lower compared to the target values

- The ANX model with scalar directivity significantly underestimates the actual hearing load for the most part, regardless of the propagation model
- The ANX source model with the cosine transformation directivity and nonlinear sound propagation provides almost identical hearing damage risk as the measurement data When using the linear propagation model, the overestimation of the hearing load increases with the distance to the muzzle

7.2 Reconstructed shot signals

For further investigation, the measured and reconstructed signals at two measuring points on the circle after Figure 3 as well as two relevant positions at 1 m muzzle distance are considered in more detail.

In Figures 8 and 9 the sound pressure time curves and frequency responses at two representative measurement points of the circular measurement are discussed. This shows that, as expected, the spherical harmonics signals are identical to each other and show hardly any deviations from the measurement signals. The ANX approaches with linear sound propagation significantly overestimate the peak levels, in some cases by more than 6 dB. With the nonlinear propagation model, the differences to the target values are significantly smaller. With regard to the frequency responses, all the source models considered provide reasonable reconstructions.

In Figures 10 and 11 the sound pressure time curves and frequency responses are discussed in 1 m distance at different exit angles. For the spherical harmonics signals, the

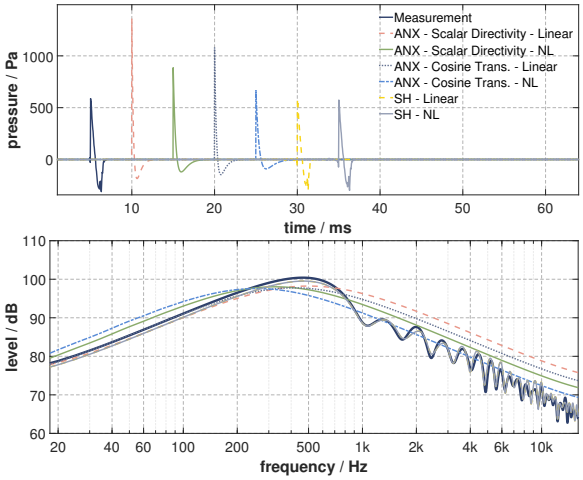

Figure 8: Sound pressure time curve and frequency response under 10° at 10 m distance

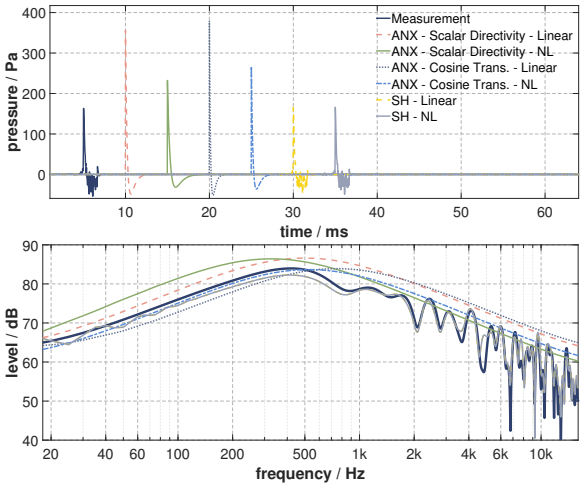

Figure 9: Sound pressure time curve and frequency response under 130° at 10 m distance

difference between them is 3 dB to 4 dB. The sound pressure time curves with nonlinear propagation tend to show higher similarities with the measured data. For the spectra, the model with nonlinear sound propagation also depicts the frequency responses above approx. 500 Hz better. Due to the short useful signal length of 7 ms, the curves below 500 Hz are only partially reliable.

As expected, the ANX source models show no differences at this distance with regard to the sound propagation method. In terms of directivity, the peak levels of the

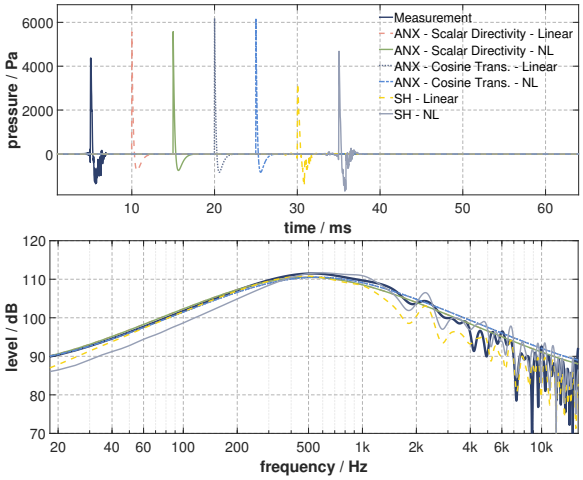

Figure 10: Sound pressure time curve and frequency response under 90° at 1 m distance (reference measuring point B)

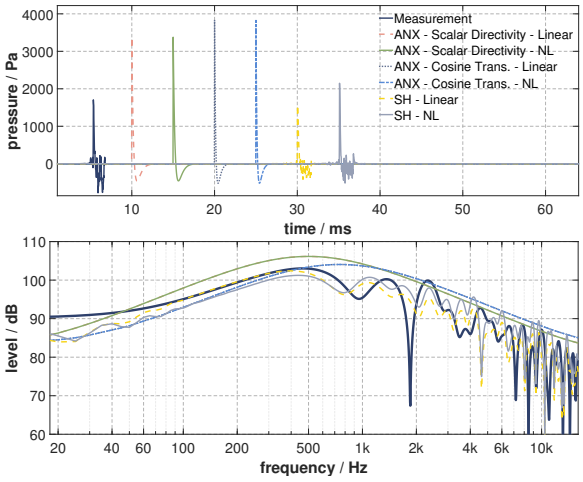

Figure 11: Sound pressure time curve and frequency response under 135° at 1 m distance (reference measuring point C1)

cosine transform method are slightly higher than those of the scalar approach. In addition, the spectra of the scalar ANX model are lower-frequency than those of the cosine transformation. Both ANX source models overestimate the peak level of the measurement signals with 3 dB to 8 dB, in some cases enormously. On closer inspection of the spectra, this difference results primarily from the overestimation of the frequency components above ≈ 3 kHz. The sound pressure time curves at measurement point B shown in Figure 12 were filtered low-pass [4] at 4 kHz for illustration purposes. A comparison with Figure 10 shows that the peak level differences of the ANX models compared to the measurement signal have fallen from above 3 dB to less than 1 dB.

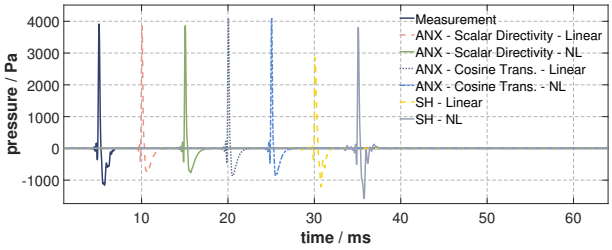

Figure 12: Low-pass [4] filtered sound pressure time curve under 90° at 1 m distance (reference measuring point B)

This aspect explains the high agreement of the AHAAH hearing damage predictions by the ANX model with cosine transformation and nonlinear propagation, despite the marked level differences. The reason for this lies in the way the AHAAH model works. This model calculates the auditory risk units for individual bark bands, whereby the maximum value is decisive. For the gunshot signals analysed here, the maximum ARU value is always in the frequency range between 1 kHz to 2.5 kHz. The lower and higher frequency signal components are therefore less significant when predicting the risk of hearing damage. Regardless of this, the ANX model tends to overestimate the energy of the high-frequency signal components of this gun muzzle blast, which requires further investigation.

8 CONCLUSION

It was shown that the ANX source model with cosine transformation as the directivity generates more realistic signals than the scalar approach, particularly with regard to the predicted hearing load. The reason for this lies in the oversimplified modelling approach of the frequency-dependent directivity of a muzzle blast. The attempt to model this with a single scalar factor logically results in higher deviations than with the more complex cosine transformation approach.

It also became clear that the quality of the shot signals generated close to the muzzle increases when nonlinear transfer functions are used instead of linear sound propa-

[4] 10th order Butterworth filter with 4 kHz cut-off frequency

gation. For example, the ANX model with cosine transform directivity and nonlinear propagation can be used to properly predict the hearing load of the direct sound component of the rifle muzzle blast, considered here as a function of both the angle of exit and the muzzle distance.

The results presented here are subject to some limitations. For example, only the direct sound components of gun blasts were considered. Investigations into the quality of the source and propagation models in combination with multiple reflections in closed systems are still pending. The fact that only one gun was considered here represents a further limitation. For further evaluation, the methods must be applied to other weapons and validated. As an alternative to the methods considered here, the Weber model is another source model to which the nonlinear sound propagation can be applied as a transfer function. Initial investigations into this appear promising.

ABSTRACT*

Earplugs are widely used to prevent noise-induced hearing loss, but discomfort can reduce their effectiveness by affecting their consistent and proper use. Earplug comfort can be described by four dimensions: physical (biomechanical and thermal interactions with the earcanal), acoustical (noise/useful sound perception), functional (usability and efficiency), and psychological (well-being and satisfaction). (Dis)comfort results from the interplay within the user/earplug/work environment triad. The components of this triad and their interactions across multiple phases, ultimately shape the comfort judgment and are defined by various physical and psychological characteristics that must be assessed to fully understand comfort. This paper targets acoustical characteristics of both disposable and reusable earplugs when inserted in the earcanal, focusing on indicators such as sound attenuation and occlusion effect. It presents a synthesis of various acoustic comfort testers developed by the authors' research team to assess these characteristics. Virtual and physical truncated realistic artificial ears and whole head are explored. This research aims to provide manufacturers with comfort-driven design methods for earplugs.

1. INTRODUCTION

Earplugs are commonly used to prevent noise-induced hearing loss, but their effectiveness can be compromised by discomfort, which affects consistent and proper usage. Comfort is a complex concept that encompasses multiple dimensions, including physical (biomechanical and thermal interactions), acoustical (related to noise perception), functional (usability and efficiency), and psychological (well-being and satisfaction) aspects [1].

The perceived (dis)comfort of earplugs results from the interplay between the user, the earplug, and the work environment—an interaction framework known as the "triad" [2]. Various intrinsic physical and psychological characteristics associated with each triad component, interact across several phases (fitting, interaction, internal human body effects, and perceived effects), ultimately shaping the comfort judgment [3]. Examples of physical factors include the earplug's design parameters (shape and material properties), the user's earcanal (EC) morphology, hand dominance and hearing loss condition, and the work environmental conditions. Examples of psychological characteristics involve the earplug's attractiveness or aesthetic design, the user's sex, age and prior experience with earplugs, as well as the nature of the work environment and required physical activity. During the interaction phase of the comfort model, the earplug interacts with the user's EC, leading to additional physical characteristics of the EC/earplug system, that can influence comfort [4]. Examples of such characteristics are the static mechanical pressure exerted by the earplug on the EC and the sound pressure field in the EC.

Understanding these physical and psychosocial influences is essential for enhancing earplug effectiveness in noise

protection. Incorporating comfort considerations into earplug design and selection can help ensure better compliance and protection for individual workers in different occupational settings. However, measuring comfort-related characteristics presents challenges, as objective and quantifiable indicators must be established for laboratory and field assessments.

This paper specifically explores the acoustical comfort of earplugs, focusing on the determination of key physical characteristics of the "EC/earplug" system in the interaction phase.

Acoustical discomfort from earplugs is primarily characterized by two conceptual acoustic sub-dimensions associated with the perception of “External Noises” (i.e. intelligibility of useful sounds) and “Internal Noises” (i.e. occlusion effect) [5]. Physical objective characteristics of the system “EC/earplug” that can impact these two sub-dimensions are the sound attenuation and the occlusion effect (OE) of the earplug [6,7]. The sound attenuation refers to the ability to block the incident noise and can be quantified by the insertion loss (IL). The OE is often described as an amplified and distorted perception of physiological noises, such as one’s own voice, which may sound boomy or cavernous, particularly at low frequencies, when the EC entrance is obstructed. This effect results from both an increase in sound transmission through tissues (skin, cartilage, bone), primarily at frequencies below 1 kHz, and a decrease in air-conducted sound transmission due to the presence of the occlusion device. The OE can be objectively measured by calculating the difference between the sound pressure levels in the open ear and the ear occluded by the earplug when stimulated by tissue conduction, either through physiological noises or a bone conduction transducer.

The sound attenuation and OE can be measured directly on human subjects or using original laboratory tools, called "comfort testers". These testers are intended to help manufacturers improve the comfort of their earplugs by knowing the objective characteristics that influence comfort, but by freeing themselves from participants. This is similar to what is done to estimate the acoustic performance of the protector by measuring its acoustic attenuation in the laboratory on artificial heads (also called ATF for "Acoustic Test Fixture" in English), equipped with an ear simulator. These earplug comfort testers can operate in the real world using physical sensors — we then speak of an "experimental" tester — or in an idealization of the real world using virtual sensors — we then speak of a "virtual" tester. In the latter case, we refer to an analytical or numerical model capable of predicting the physical characteristics of interest. A virtual tester can be useful to (i) better understand the physical mechanisms involved in the triad, (ii) study the effect of various factors on the quantity of interest (acoustic or mechanical), (iii) help design real-world testers.

Commercially available ATFs fail to assess key physical characteristics related to acoustic comfort, as they do not account for essential features such as realistic EC geometry and various tissue conduction paths that influence the sound pressure field in the EC induced by external or internal sound sources [8,9]. As a result, they are unable to capture intra- and inter-individual variability in these characteristics. These reasons make them unsuitable for evaluating sound attenuation and OE from a comfort perspective [10]. Therefore, developing more realistic testers is crucial to accurately replicating the EC/earplug system under both acoustic and mechanical excitations.

This paper provides a comprehensive synthesis of various virtual and experimental testers developed by the authors’ research team to assess sound attenuation and OE, both of which could influence acoustical comfort. These testers can be classified into two categories, distinguished by the level of geometric simplification they consider: (i) truncated ears of various anatomical complexity that consider a region of tissues surrounding a simplified or realistically shaped EC, including or not the pinna and (ii) whole head.

The synthesis presents key principles, selected example results, and limitations of each comfort testing method, starting with experimental and virtual testers for sound attenuation and followed by an analysis of those for the OE.

2. EXPERIMENTAL AND VIRTUAL TESTERS FOR SOUND ATTENUATION

2.1 Realistic truncated ears (Fig.1(a), (b) and (c))

The first tester, shown in Fig.1(a), includes an experimental version and its virtual counterpart. It features a realistic EC and surrounding tissues [11] reconstructed from medical images of a participant. The synthetic materials were selected for their mechanical properties, close to those of biological tissues. The experimental tester, manufactured by a company specializing in anatomical phantoms, includes an embedded microphone positioned at the eardrum but lacks an eardrum simulator. The tester evaluation was based on comparing the predictions provided by the virtual tester with those obtained using the associated experimental tester, both in the open ear and in the ear occluded by a cylindrical steel earplug. The latter has the advantage of being non-deformable and having well-characterized mechanical properties. Although the numerical model generally reproduces the trends observed experimentally,

particularly in terms of pressure levels in the open and occluded ear as well as attenuation (not shown here), some differences persist in certain frequency bands. A calibration of the material properties in the finite element model could improve this correspondence. Furthermore, the steel earplug poses challenges related to the contact conditions with the surrounding tissues. The use of a more conventional earplug, such as a molded silicone earplug, could facilitate the evaluation of the tester. Finally, the simulated IL follows a similar evolution to the attenuation curves measured on human subjects: an increase in attenuation up to the resonance frequency of the open canal, followed by a decrease.

The experimental tester was also evaluated against a reference participant who served as a model of the artificial ear and a commercial ATF. Attenuation measurements for 2 types of earplugs were conducted using the 3M E-A-Rfit system at 3 insertion depths. Results (not shown here) show that the artificial ear better replicate attenuation for roll-down foam earplugs than commercial ATF. However, for push-to-fit earplugs this remains challenging for both. Discrepancies between the virtual tester, the experimental tester, and participant measurements may be attributed to several issues with the experimental tester. These include: (i) material defects—such as degradation of the soft-tissue analogs in the EC due to overly thin walls and irregular surface conditions—that can induce acoustic leaks (ii) insufficient self-IL of the artificial ear, (iii) the fact that synthetic materials at room temperature mimic biological tissues at body temperature, leading to potential deviations (iv) the absence of a heating system which may affect the earplug's behavior and the lack of a eardrum simulator.

To circumvent some of the issues associated with the previous truncated artificial ear (manufacturing defects and self-IL), a simplified version, devoid of cartilage was considered (see Fig.1(c)). It was designed based on a different participant and manufactured at the ICAR laboratory using 3D printing and a soft tissue molding technique. This artificial ear is integrated into a cylindrical metal housing, simulating an artificial head, to limit parasitic transmissions through the side and rear walls of the artificial ear. Preliminary results (see Fig.2) show that the attenuation of the earplugs measured with the artificial ear is lower at low frequencies than that observed on the corresponding human participant, regardless of the insertion depth. At higher frequencies, the results are closer but may be higher or lower depending on the insertion depth. These discrepancies may arise from (i) an overestimation of tissue conduction due to the use of a single homogeneous, overly soft material to represent soft tissues, (ii) the absence of a heating system, (iii) the fact that artificial materials at room temperature mimic biological tissues at body temperature, and (iv) the lack of cartilage and an eardrum simulator.

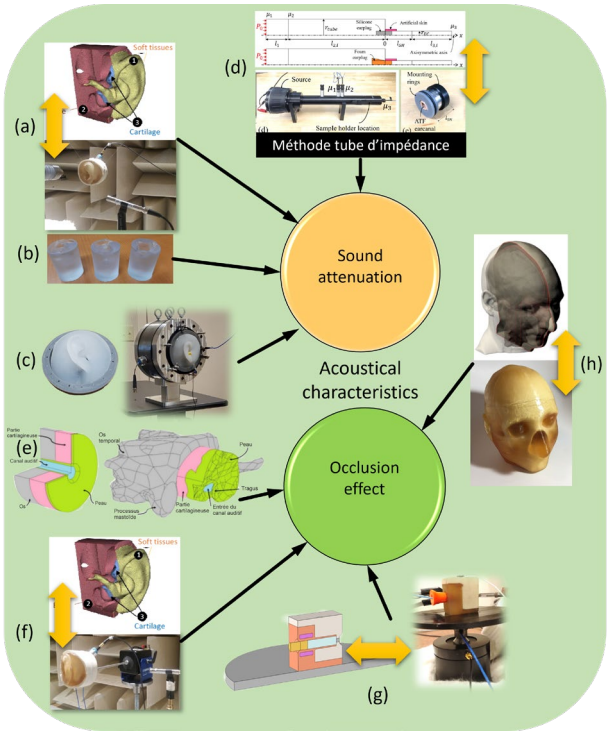

Figure 1. Experimental and virtual testers to assess acoustical physical characteristics of the coupled system EC/earplug

The testers of Fig.1(a) and (c) replicate the artificial ear of a specific individual. In contrast, the experimental tester in Fig.1(b) was designed to incorporate multiple artificial ears with realistic EC geometries but a simplified anatomical structure, adapted to the measurement of sound attenuation and representative of a sample of workers. An anthropometric analysis of a sample of ECs made it possible to identify three groups characterized by distinct morphologies [12]. For each group, the EC closest to the barycenter was selected as a representative model. Three artificial ears were thus manufactured using 3D printing, using a soft elastic resin of Shore 00 = 90 at room temperature. Heated to 37 ° C, these ears were evaluated for several earplugs using the 3M E-A-Rfit system, comparing them to measurements taken on participants during field training sessions. For each earplug, eight measurements were made, with insertions varying between standard depth and deeper insertion. The results (not displayed here) show that the ranking of sound attenuation obtained with these artificial ears is generally consistent with that observed in

participants. However, while these testers satisfactorily represent the attenuation variability measured for pre-molded earplugs, they have limitations for roll-down foam earplugs and pre-molded foam with stems, where significant amplitude differences occur. These differences could be attributed to the excessive rigidity of the artificial tissue, the absence of cartilage and artificial eardrum, and potential parasitic transmissions through the lateral and rear sides of the truncated ears.

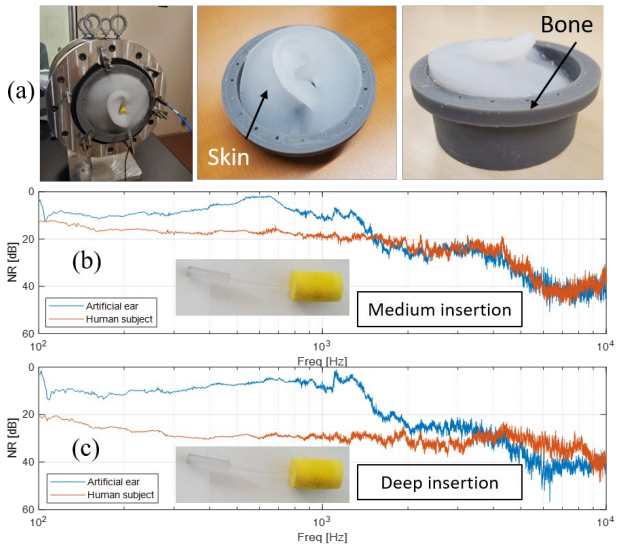

Figure 2. (a) Zoom on tester, noise reduction of a surrogate roll-down foam earplug measured with artificial ear and participant for (b) medium and (c) deep insertion.

2.2 Simplified truncated ear and the use of an impedance tube (Fig.1(d))

Although commercial ATFs are useful for assessing the sound attenuation of earplugs, they have drawbacks. They are costly and require expensive and bulky experimental setups, such as reverberation or anechoic chambers; they typically use a single-size EC, which does not account for variations in EC morphology between individuals and can result in significant differences in personal attenuation. Finally, commercial ATF measurements provide limited understanding of how the intrinsic acoustic properties of earplugs influence attenuation.

To address these challenges, a method for estimating earplug sound attenuation has been developed along with an associated experimental tester [13]. The technique allows to determine the acoustic properties of an earplug (transmission and reflection) inserted in a simplified truncated ear, consisting of a cylindrical artificial EC with a skin layer, all placed in an impedance tube. These acoustic properties are obtained from acoustic measurements upstream and downstream of the truncated ear, as well as using two separate acoustic loads. The measured earplug acoustic properties are then used as inputs to a one-dimensional analytical model to calculate the IL of the earplug. The latter is decomposed into two terms: the transmission loss (TL), which depends only on the physical objective characteristics of the "EC/earplug" system namely, mechanical properties of the inserted earplug and surrounding soft tissues as well as insertion depth, and a correction term, which depends on the reflection coefficients of the earplug medial face, the entrance to the EC and the medial termination of the EC.

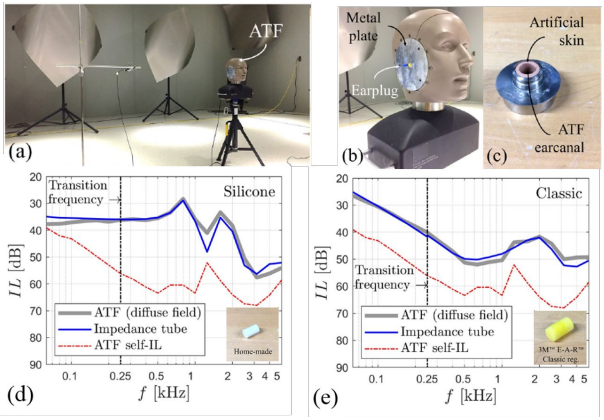

Figure 3. (a) ATF placed in the reverberant room, (b) zoomed-in view of the ATF, (c) ATF EC, Third octave band IL measured on ATF and estimated using the proposed impedance tube method for a silicone earplug (d) and roll-down foam earplug (e). The self-IL of the ATF is also displayed.

In parallel, two virtual testers (not shown here), based on numerical FE models of the experimental tester and an ATF, were developed to test the approach. The first simulated measurements to estimate the earplug's acoustic properties, which were then used in the one-dimensional analytical model to calculate the IL. The second simulated the IL on the ATF, allowing numerical evaluation of how the excitation field (normal incidence plane wave versus diffuse field) affects sound attenuation. The one-dimensional analytical model used to calculate the IL from the acoustic properties of the earplug was verified using the results provided by the previous virtual tester, which acted as a reference. The results obtained with the two testers agree and indicate that the attenuation of an earplug obtained in the tube is representative of that measured in a more realistic acoustic field. Furthermore, experimental

comparisons, on various types of earplugs, between the results obtained with the proposed measurement technique and those from a commercial ATF (see Fig.3) further validates the method. The main limitation of the method concerns its working frequency range determined by the tube diameter (about 6.5 kHz for a diameter of 29mm).
This impedance tube method offers several advantages over ATFs: (i) the technique uses a commercially available impedance tube, thus eliminating the need for an ATF (including the ear simulator) and an acoustic chamber, (ii) the method allows easy integration of different EC geometries using different sample holders, (iii) the method decomposes the earplug's IL into two a TL and a factor influenced by the acoustical characteristics of both open and occluded ear canals, providing deeper insight into sound attenuation and enabling more effective control, and (iv) the method enables the direct incorporation of eardrum impedance variability during post-processing by allowing the calculation of earplug attenuation for any tympanic acoustic impedance once its transmission and reflection properties have been determined.

3. EXPERIMENTAL AND VIRTUAL TESTERS FOR THE OCCLUSION EFFECT

3.1 Truncated ears (Fig.1 (e-g))

Virtual truncated ear testers, shown in Fig.1(e) and consisting of both lumped and FE models, were used to gain deeper insight into the fundamental physical phenomena underlying OE. These two modeling approaches are complementary. FE models supply input parameters for lumped models, while the latter offer a practical framework for interpreting FE simulations. For the FE testers, the set of mechanical boundary conditions and applied excitations was adjusted to reproduce a plausible vibration pattern of the EC wall [14] or to obtain simulation results consistent with experimental data from the literature on OE measured on groups of human subjects [15,16]. The virtual testers showed that OE occurs because blocking the EC creates a closed air cavity between the occlusion device and the eardrum, making it harder for the EC walls to compress it, which increases the acoustic pressure generated in the occluded EC. These models also allowed to revisit and clarify the interpretation commonly adopted in the literature of the OE—notably the influence of the high-pass filter of the open EC and the way in which this effect is modified by its occlusion—an interpretation which, although widespread, suffers from several ambiguities [17]. The first 3D numerical models of truncated cadaveric ears made it possible to highlight the influence of the vibration distribution of the EC wall on the OE [14]. The spatial distribution of the normal vibration of the open EC was characterized, at low frequencies, by the position of its barycenter along the curvilinear axis of the EC [18]. The axisymmetric 2D FE models then made it possible to study the mechanisms of contribution of earplugs to the OE [15,16]. Two mechanisms were highlighted: (i) a Poisson effect induced by the normal component of the parietal vibration of the EC and (ii) a longitudinal movement caused by the tangential component of this vibration.

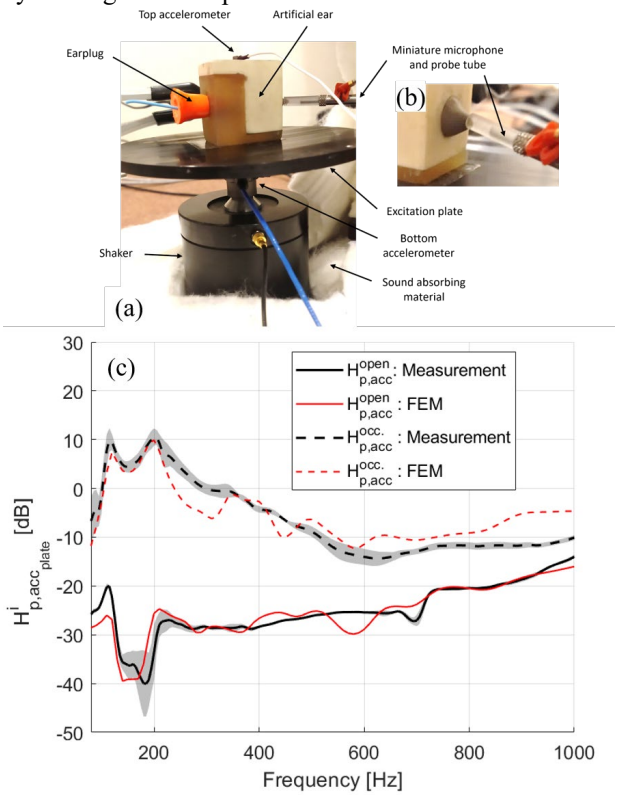

Figure 4. (a) View of tester of Fig.1(g), (b) rear view of the tester, (c) comparison between virtual and experimental tester - transfer functions between eardrum sound pressure and acceleration of excitation plate for open and occluded ears

The virtual tester presented in Fig.1(f) has been partially validated against its experimental counterpart [8,16] in the case of the steel earplug also used in section 2.1. The simulation of the objective OE approximately reproduces the slope of the measured data. However, significant deviations remain in some frequency bands. These discrepancies are attributed to differences in material properties, boundary conditions, coupling conditions or applied loads, between the experimental setup and the

simulation. For other types of earplugs, the validation of the virtual tester was not successful. Furthermore, the evaluations of the experimental tester against groups of participants did not give satisfactory results. Finally, the experimental tester was not directly confronted with the human subject from which it was designed.

To address the challenges associated with the tester shown in Fig.1(f), a new tester based on it and illustrated in Fig.1(g) was designed to simplify the validation process [9]. A virtual tester was developed first, followed by the manufacturing of its experimental counterpart (without artificial eardrum and heating system). The ear canal was reshaped into a straight cylinder with a circular cross-section, and the external boundaries of the truncated ear were modified into a parallelepiped form. The proportions of soft tissue, bone, and cartilage volumes were preserved relative to the realistic 3D artificial ear. Careful material selection and precise manufacturing ensured the faithful reproduction of key features essential for studying the OE. It also integrates excitation and boundary conditions that are more easily mimicked in the virtual tester. Its parallelepiped shape also facilitates experimental manipulations.

After rigorous calibration, the virtual tester was successfully validated against the experimental tester, in particular by comparing the transfer functions between eardrum sound pressure and acceleration of excitation plate for open ear and ear occluded by a silicone earplug (see Fig.4 (c)). The experimental tester was also successfully evaluated against measurements made on a group of participants. This device was shown to reproduce the main effects observed in OE measurements of several earplug types on participants, including (i) significant OE at low frequencies, decreasing with increasing frequency, (ii) reduced OE for deeper earplug insertion, and (iii) differences in OE between earplug types, particularly marked for deep versus shallow insertions. A numerical study also highlighted that the absence of cartilage significantly amplifies OE at low frequencies. Furthermore, the position of the cartilage influences OE, particularly when the artificial ear upper part is fixed. This tester was notably used to validate an innovative metamaterial earplug with reduced OE [19,20] which was then tested regarding perception and comfort judgment on human subjects [7].

The main limitations of this tester are the presence of parasitic structural resonances, which are not representative of what happens in a real head and the dominance of the air-conducted path over the bone conducted one when the EC is open in some frequency bands, potentially leading to an underestimation of OE compared to measurements on participants using a bone transducer.

3.2 Whole head (Fig.1 (h))

Two virtual testers based on the FE method and one experimental tester were developed from magnetic resonance images and computed tomography scans of a participant's entire head. The medical images were segmented using image processing software to reconstruct various anatomical structures of the head, namely soft tissues, auricular cartilage, bone, brain and cerebrospinal fluid, excluding middle and inner ears.

The first virtual tester, representing the participant (Virtual Participant), integrates tissue properties based on scientific literature and accounts for the acoustic effect of the middle and inner ear via an acoustic impedance boundary condition at the eardrum. The second, called Virtual AP-ATF is the counterpart to an experimental tester called augmented physical ATF (AP-ATF) made of artificial materials of known mechanical properties that mimic biological tissues. Unlike the Virtual Participant, neither the Virtual AP-ATF nor the experimental AP-ATF account for the acoustic effect of the middle and inner ear. Based on these testers, rigorous calibration and validation of the FE models used to simulate the physics are possible, as the simulations can be compared to measurements performed on the corresponding participant and on the associated AP-ATF [16].

The Virtual Participant tester was validated against experimental data from the literature on participant groups, as well as measurements on the participant used for its development (see Fig.5). It satisfactorily reproduces known effects, such as the reduction of OE with increasing earplug insertion depth and the influence of the earplug type on OE, particularly for deep insertions.

The Virtual AP-ATF tester was validated by comparing the simulated results with experimental data from the AP-ATF (see Fig.6). Although both testers were not calibrated, comparisons showed generally satisfactory results, with deviations of less than 5 dB. However, the results obtained with the AP-ATF show discrepancies compared to the measurements made on the participant. These differences could be due to the inadequacy of the synthetic materials used to reproduce biological tissues.

During the development of the virtual testers, several significant advances in modeling have been made [21,22] (i) the use of a perfectly matched layer improves the agreement of simulated results with experimental data, compared to a classical radiation impedance condition, (ii) the boundary conditions at the base of the head mainly influence the OE at very low frequencies (< 0.25 kHz), and (iii) modeling the external fluid and tympanic membrane's influence on the EC acoustic field using an impedance condition requires adaptation to account for the global

motion of both the EC entrance and the tympanic membrane. Otherwise, errors in the eardrum sound pressure can occur, especially when the EC is occluded.

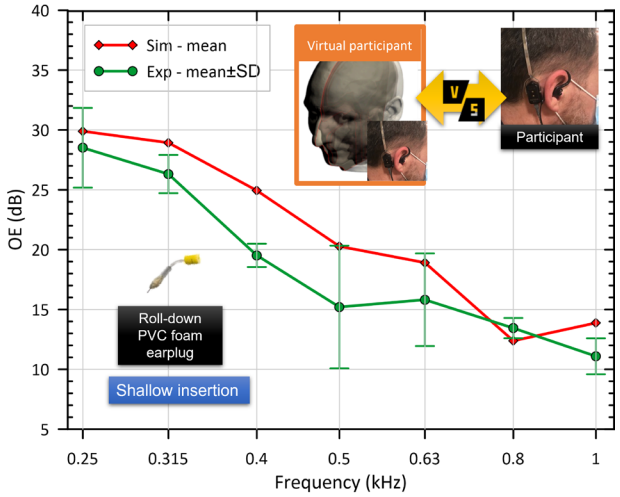

Figure 5. OE simulated using the Virtual participant and measured on the participant

The Virtual Participant tester was used to examine the effect of uncertainties related to several factors on the OE at low frequencies [21]:

• Position of stimulation on the head: the OE is not very sensitive to the global position of the stimulation (ipsilateral mastoid, contralateral mastoid, forehead). However, subtle variations in the stimulation position on the ipsilateral mastoid can contribute to the variability of the OE.

• Position of the measurement point in the EC: OE is little influenced by the exact position of the measurement point in the EC, especially for common earplug insertion depths. Differences between assessments performed at the medial surface of the earplug and at the eardrum are minimal, especially for medium or deep insertions. From an experimental point of view, these results suggest that OE, which is often measured at the medial surface of the earplug for safety and comfort reasons, is a good approximation of measurements performed at the eardrum.

• Mechanical properties of tissues: The stiffness of soft tissues and cartilage is a major factor influencing OE. This effect depends on the frequency band studied, with OE being more affected by the mechanical properties of soft tissues than by those of cartilage. At low frequencies, OE is sensitive to the skull bone Young's modulus, while the soft tissues Poisson's ratio also plays a key role.

Whole-head virtual testers provide more realistic FE simulations of EC vibration and sound pressure field than truncated ear models by accounting for full-head tissue conduction and eliminating boundary condition issues. Unlike other artificial ears used to assess the OE of earplugs [9], the whole-head tester allows for OE evaluation across different stimulation positions and can also be used for other hearing protection devices like earmuffs. However, the initial experimental prototype requires further refinement to better match participants' measurements.

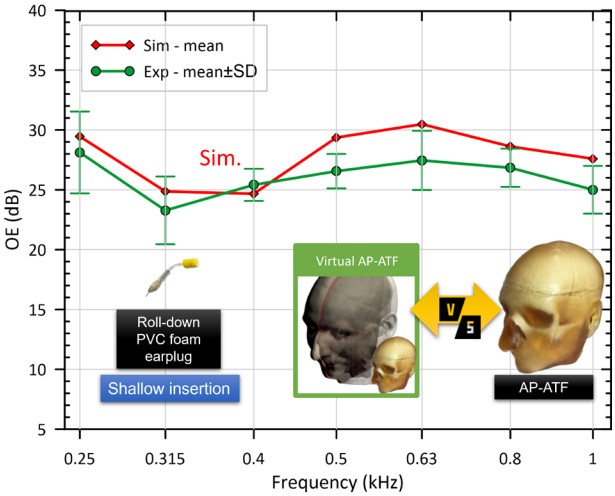

Figure 6. OE simulated using the Virtual AP-ATF and measured on the AP-ATF

4. CONCLUSIONS

This paper presented a synthesis of various virtual and experimental acoustic comfort testers developed by the authors' research team, designed to assess the sound attenuation and the OE of earplugs. While some testers are more advanced than others, they have collectively yielded promising results. Future work will focus on (i) optimizing synthetic materials to better replicate the EC/earplug interactions and tissue conduction, (ii) systematically integrating instrumentation (microphones, heating system and eardrum simulator), (iii) improve the knowledge about tissues and earplugs material properties, (iv) calibrating and validating sound attenuation and OE virtual testers, accounting for uncertainties, (v) incorporating inter-individual variability into both experimental setups and models and (vi) use whole-head virtual testers including middle and inner components to predict the differential intracochlear pressure and the subjective OE.

AUDITORY DAMAGE RISK DUE TO INDOOR AND OUTDOOR SHOOTING

Frits van der Eerden* **Elisabeth van Pruissen** **Erik Salomons**
Paul de Krom **Ad van Heijningen**
TNO - Defense, Safety & Security, The Hague, The Netherlands

ABSTRACT

Many different weapons can be used for military training. For a safe working environment, the maximum permissible exposure needs to be predicted, taking into account the use of hearing protection. In the ISO 17201 standard part 6, 'Sound pressure measurements close to the source for determining exposure to sound', it is described how to capture the time history of the sound pressure at locations of interest, such as for an instructor or shooter. This time-history is the basis for further assessment, like the calculation of an auditory damage risk criterium. The objective of this research is to compare the measurement results using the ISO standard without a person present, with measurements using a microphone close to the head of the shooter or instructor. The A-weighted sound exposure is calculated (ASEL) as well as the Auditory Risk Unit (ARU) using the AHAAH model. Both indoor and outdoor measurement have been conducted for several small fire arms. It was seen that the tail of the time history has a large effect on the results for the ARUs. In addition, tests were carried out with small portable sound absorbing screens to reduce the muzzle blast towards the shooter, instructor and the environment.

Keywords: *shooting noise measurements, auditory damage risk, muzzle blast mitigation*

1. INTRODUCTION

To determine the auditory damage risk for shooting noise during military training, sound pressure measurements are needed close to the muzzle blast. Based on the time history of the sound pressure, the risk can be determined by applying an assessment method. This can be done by using the peak and time duration, the energy (such as the A-weighted sound exposure level: ASEL), or a physical model of the ear (such as the electroacoustic AHAAH model [2]). Each method yields different exposure variables, such as ASEL or Auditory Risk Units (ARU from the AHAAH model) [3].

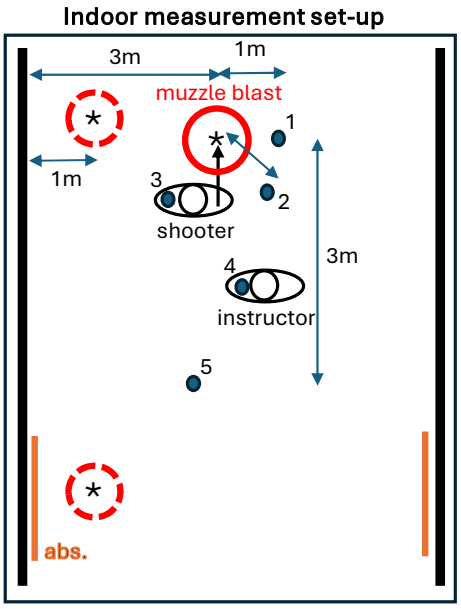

Figure 1. Measurement set-up using 5 microphones (blue markers) near the muzzle blast using 3 different firing positions (red circles).

In this paper measurement results are presented for different small caliber weapons, in an indoor and outdoor setting. The aim of these measurements is to compare the results for two different set-ups; one with a shooter present and one without a shooter; instead a weapon fixture is used. For the latter case the ISO 17201-6:2022 standard [1] is followed, in order to obtain measurements that are less dependent on the influences of the shooter and the microphone position close to the head of the shooter or instructor.

In Section 2 the ISO standard is introduced and in Section 3 the indoor and outdoor measurements are described. Section 4 discusses the results, with and without a shooter, using ASEL and AHAAH results.

Additional outdoor measurements were done, introducing two portable lightweight and sound absorbing screens, to reduce the muzzle blast exposure towards the environment and towards the shooter and instructor. The results for several positions of these screens are presented in Section 5.

2. ISO 17201-6 ON MEASUREMENTS

The ISO 17201 series 'Noise from shooting ranges' consist of 6 parts. The first part of ISO 17201 describes the measurement method to obtain the sound source energy and directivity of the muzzle blast or an explosive charge. The spectral levels can be used for the prediction of sound levels around shooting ranges (this is described in *part 3*). The standard is applicable to calibers of less than 20 mm or an explosive weight of less than 50 g TNT equivalent.

An important aspect for *part 1* of this standard is that the microphones are located at a distance where the peak levels are lower than 154 dB, so that the calculation of the source strength can be done with linear acoustic sound propagation models. As a result this standard cannot be used to determine the sound exposure levels close to the weapon (this is addressed in part 6).

ISO 17201 *part 6* is titled "Sound pressure measurements close to the source for determining exposure to sound" [1]. This part was added to the series to allow for sound exposure measurements at a short distance. It describes how to capture the time history of the sound pressure at the locations of interest, such as for an instructor or shooter. This time history is the basis for further assessment. The assessment itself is not within the scope of the standard.

The standard describes the requirements for a measurement system and the measurement set-up. A special case is described for the microphone position at the center of the head of the shooter. For a better reproducibility and comparison, the shooter should be removed and a weapons fixture should be used. The fixture shall be constructed in a way that minimizes reflections.

For part 6 the measured peak sound pressure levels can be higher than 154 dB, in contrast to the requirement for microphone positions used in *part 1* of ISO 17201, as (non-linear) propagation of the shockwave is not used in *part 6*.

Figure 2. Measurement set-up using 5 microphones close to hard walls (upper) and absorbing walls & ceiling (lower).

3. MEASUREMENT SET-UP

For the measurements, five microphones were used near the muzzle, see Figure 1. Microphones 1 and 2 are at 1 meter distance at the same height as the muzzle, at 90 and 135 degrees with respect to the firing direction. Microphone 3 and 4 are near the ear of the shooter and instructor,

respectively, or at the center of the head when there is no person present. Microphone 5 is at 3 meters distance to the back and was added for a comparison with German measurements.

Figure 1 shows the set-up for the position in the center of the indoor shooting range. It also shows two other positions: close to the reflecting walls and close to the absorbing walls and ceiling.

Figure 3. Outdoor measurement set-up using 5 microphones.

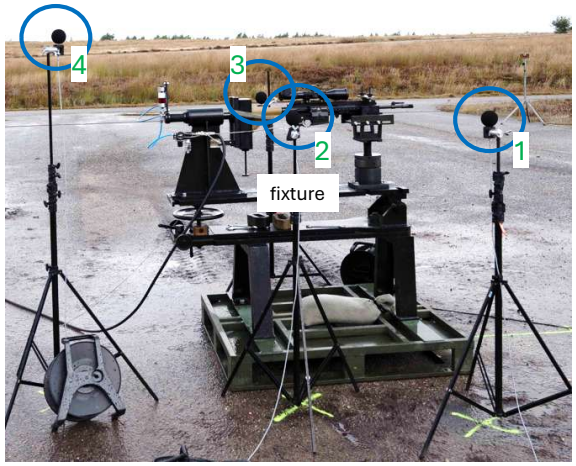

Figure 4. Outdoor measurement using a weapon fixture.

The photos in Figure 2, 3 and 4 give an impression of the indoor and outdoor measurements. Figure 2 shows two shooting positions: near the reflecting walls and ceiling as well as near the absorbing walls and ceiling. Figure 3 shows the outdoor set-up for a standing shooter (a prone position was also used), while Figure 4 shows the rifle in the weapons fixture. In this case the rifle was operated from a distance using a rope.

For the indoor measurements a 5.56 and 8.6 mm caliber rifle was used. For the outdoor measurements an additional 7.62 mm rifle was used. Standing and prone position were measured for both the 5.56 and 7.62 mm rifles. The 8.6 mm rifle was only used in a prone position. Also, a second shooter was included for 5.56 mm to capture possible differences.

At each position a series of 12 shots was measured. The average of these shots are presented in the next section.

4. RESULTS & COMPARISON

4.1 Indoor shooting

Figure 5 shows the (unweighted) sound exposure levels in octave bands for the 5.56 mm rifle, at the 5 microphone positions and for 4 different positions: 1) in the center of the indoor range using a shooter, 2) idem, using a fixture, 3) close to the fully reflecting walls using a shooter, and 4) close to the absorbing walls using a shooter.

Comparing the results for using a shooter (black line) and a fixture (blue line) shows that there is not a significant difference for the sound levels.

When moving the muzzle closer to the hard walls the sound levels are about the same, compared to the center position. The main difference can be seen in the interference pattern (due to the reflection) around 32 and 63 Hz. This can be seen best for the microphone at the shooter position (mic 3).

As expected, by using absorbing walls and ceiling the sound levels are reduced; the multiple reflections are damped. The largest reductions are for the instructor position and the microphone position that is 3 m to the back (mic 5).

On the right-hand side of the figures the results from the AHAAH model are given (in ARU). The results are calculated for 23 frequency bands and the maximum value is reported as the auditory risk. For microphones 3 and 4, at the shooter and instructor positions, a maximum value around 1500 ARU is obtained. Note that a dose above 500 ARU is unsafe, and that a daily limit of 200 ARU is recommended. In that case no temporary threshold shift is expected.

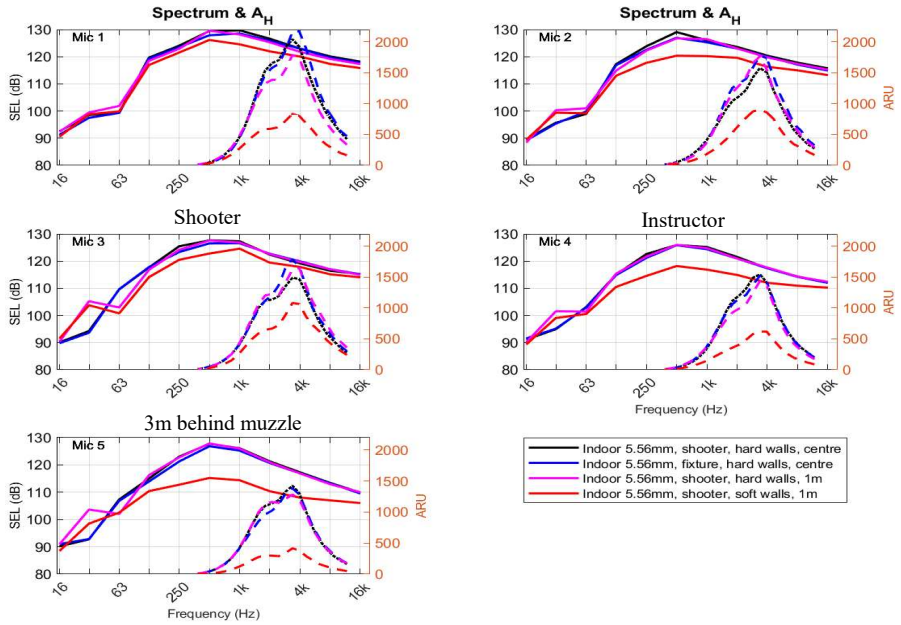

Figure 5. Indoor measurement results for a 5.56 mm rifle at 5 microphone positions and 4 different situations (see legend).

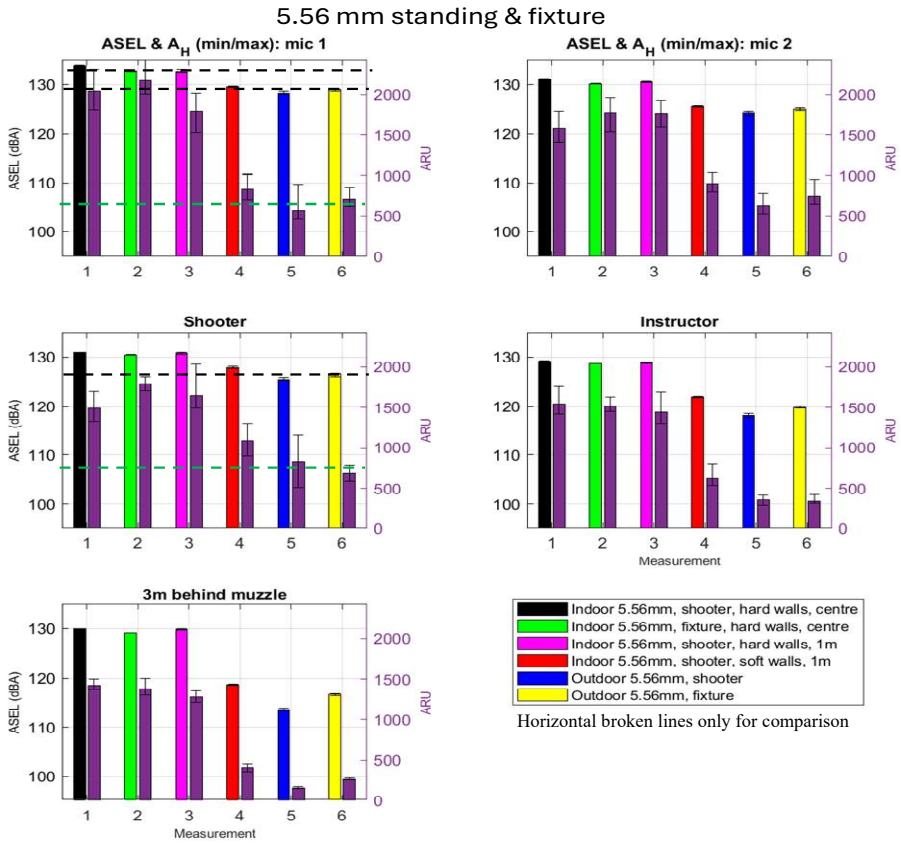

Figure 6. Indoor (& outdoor) measurement results for a 5.56 mm rifle at 5 microphone positions and 6 situations (see legend).

Comparing the ARU for the shooter position (mic 3) with and without a shooter shows a difference of about 200 ARU, while for the instructor position the difference is very small. Remember that the difference in sound levels is small when comparing the shooter and fixture (mic 3).

Figure 6 shows the single value results for the 5.56 mm rifle: the A-weighted sound exposure levels ASEL in dB(A) and the AHAAH (or A_H) results in ARU. Also included are the results for the outdoor measurements (blue & yellow bars), which only include the direct muzzle blast and the ground reflection.

For both the ASEL and ARU also the maximum and minimum values within a series are shown in black. Especially for the ARU the variation can be more than 20%. The ASEL variations are much smaller than 1 dB(A) (note that 1 dB = 26%).

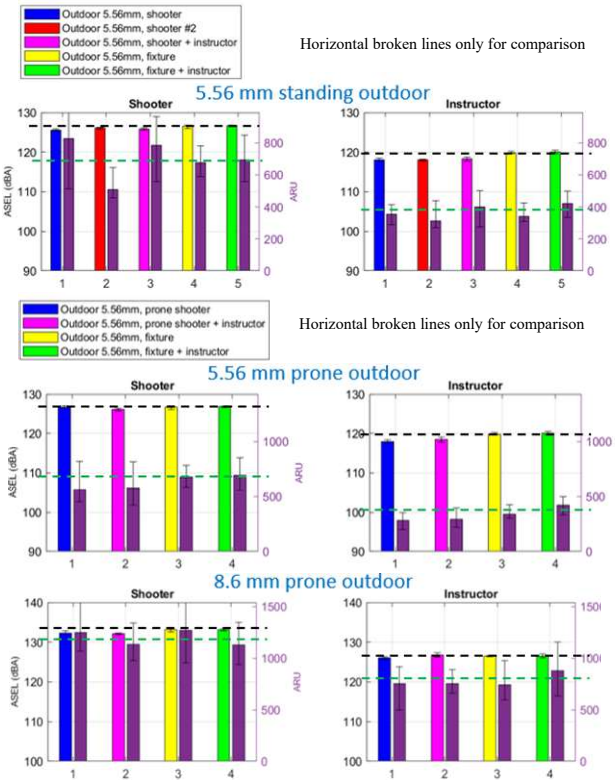

Figure 7. Outdoor measurements results for 5.56 and 8.6 mm weapons at shooter & instructor positions and for different situations (see legends).

The difference in dB(A) between using a shooter or a fixture is small. The ARU results are also in the same range; they can be higher, compared to a fixture, but also lower.

The indoor sound levels are around 6 dB(A) higher compared to outdoors (factor of 4). The ARU results can be up to 3 times higher, compared to outdoors.

4.2 Outdoor shooting

A selection of the outdoor results is given in Figure 7, at the shooter and instructor positions. In the upper figure there are five situations given for the 5.56 mm rifle: 1) with a shooter and no instructor present, 2) with another shooter (smaller), 3) with an instructor present, 4) with a fixture, and 5) with a fixture and an instructor present. It can be seen that the sound levels are within 1 dB(A), while the ARU show larger differences; 100 ARU or more. It is remarkable that for shooter #2 the ARU is substantially lower.

When using the prone position the differences when using a fixture (with a larger muzzle height) are small. The ARU results are a bit lower when using a shooter. The variation within a series is larger when using a shooter compared to using a fixture.

For the 8.6 mm rifle, used in the prone position, the results are similar, when comparing the shooter with the fixture.

4.3 Conclusions

To summarize the results for the indoor and outdoor measurements:

- Using a fixture instead of a shooter gives the same results in dB(A).
- The prone position gives slightly lower levels in dB(A) compared to using a fixture, around 1 dB(A).
- Within a series of 12 shots the ARU can differ up to a factor of two.
- The ARU results when using a shooter or a fixture are in the same range:
  - They can be higher, compared to a fixture, but also lower.
  - For the 7.62 mm standing position only, the ARU results with a shooter are more than a factor of 2 higher compared to using a fixture.

4.4 ARU growth as a function of time

With the AHAAH model one can visualize the ARU growth as a function of time, for example to see the differences between two situations. This is shown in Figure 8 for the 5.56 mm rifle, near the hard and near the absorbing walls, displaying a 1000 ms signal length. Figure 9 shows the corresponding time-pressure history, only for the first 30 ms. This shows that the reflections in the tail of the signal from the hard walls results in an ARU that is three times higher compared to the absorbing walls, where these reflections are much smaller (indicated with the green ellipse).

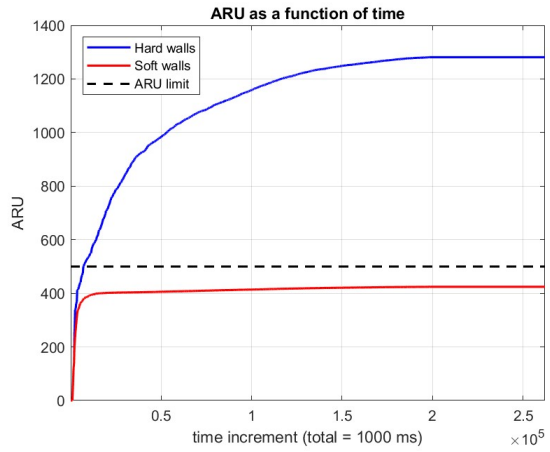

Figure 8. Growth of ARU as a function of time.

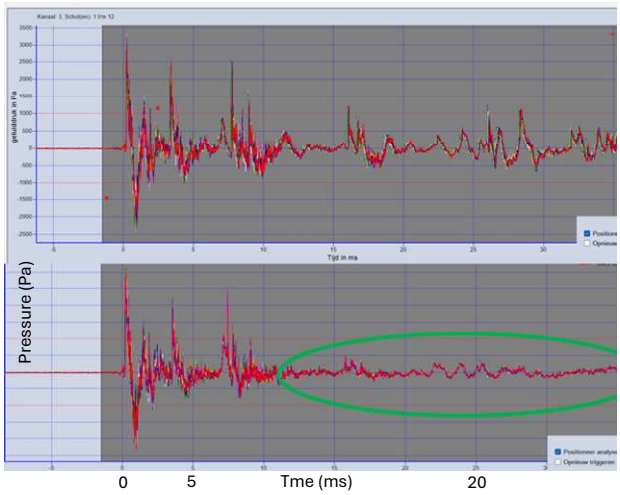

Figure 9. Muzzle blast and reflections (5.56 mm) for hard walls (upper) and absorbing walls & ceiling (lower).

5. OUTDOOR ABSORBING SCREENS

To reduce the contributions of the muzzle blast towards the environment, the performance of closely positioned screens was investigated. The screens are lightweight, so easy to move, and have absorbing panels on the side facing the muzzle blast. In addition the sound levels and auditory risk for the shooter and instructor were measured and compared to the situations without screens.

Two different rifles were used, with a 7.62 and 12.7 mm caliber. The 7.62 mm was used in kneeling and prone position. The 12.7 mm produces a very strong muzzle blast. It was seen that the thin surface layer covering the absorbing material did not remain intact when used close to the muzzle.

The absorbing panels (60 x 120 cm) consist of glass fiber core with a thickness of 5 cm. The are covered by a polyester film, so no gunpowder residue can penetrate the material.

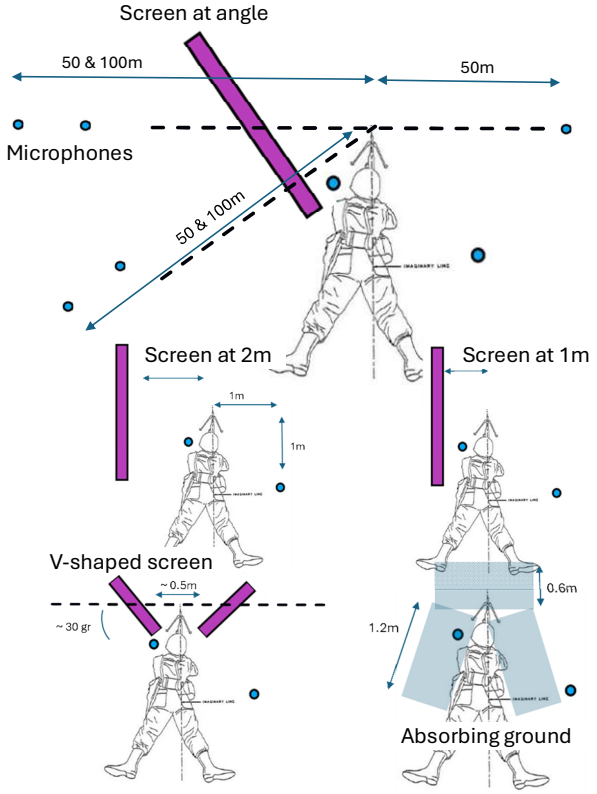

Figure 10. Four different positions of the absorbing screens and absorbing panels (in purple). One position with absorbing panels on the ground (in gray).

5.1 Measurement set-up

Figure 10 shows four positions for the absorbing screens. In fact, there are two screens each with a height of 180 cm and 120 cm wide. The upper figure shows the screen with an angle of 30 degrees w.r.t. the firing direction. The middle figures shows the screen at a distance of 2 and 1 meter from the muzzle. The lower figure shows the two screens in a V-shape (left) and using only the absorbing panels on the ground (right), to suppress the ground reflection. The photos in Figure 11 and Figure 12 further illustrate these set-ups.

Figure 11. Absorbing screen at 2m distance (upper) and at 1m distance (lower).

Figure 12. V-shaped absorbing screens.

As indicated in Figure 10, seven microphones were used: two for the shooter and instructor positions, four behind the screen at 50 and 100 meter from the muzzle (right-hand side, and one in the opposite direction (left-hand side).

5.2 Results

Single value results in dB(A) for the 7.62 mm caliber rifle in prone position are presented in Figure 13. The black bar results are for the situation without a screen and the colored ones for using a screen or an absorbing ground. The upper picture is for the shooter and instructor microphones, and also show the ARU results. It can be seen that using a screen has a small effect in dB(A), while the ARU can either be higher or lower (see also Table 1).

The middle picture shows the microphone position 50 m to the right, where a contribution due to a reflection may exist. This is not the case, the levels are the same or lower (especially for the V-shaped screens, shown in red)

For the microphones behind the screens larger reductions can be seen up to 10 dB(A).

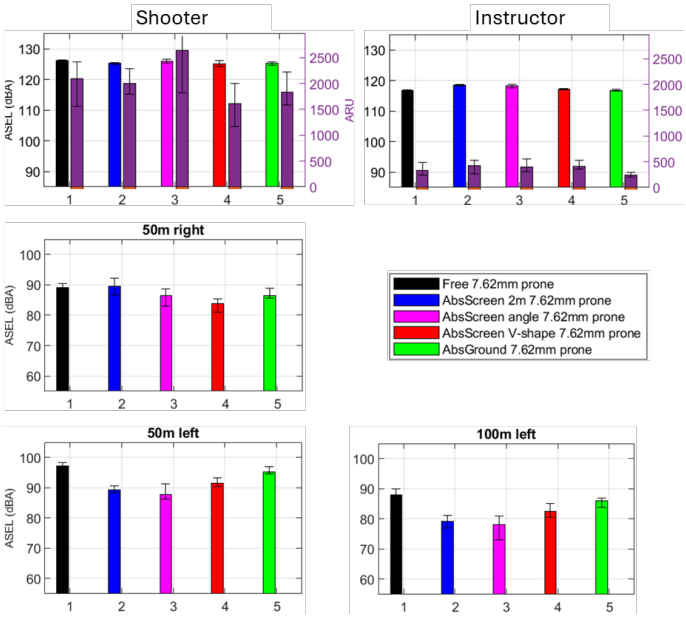

Figure 13. Measurement results in dB(A) and ARU without (black) and with absorbing screen/panels (color).

The differences, compared to the situation without a screen, are summarized in Table 1. The upper section lists the results in ARU for the shooter and instructor positions. The lower sections is in dB(A) for the microphones at 50 and 100 meters distance. When there is an increase the values are shaded in red.

The ARUs show quite a mixed result. For the shooter with a 7.62 mm rifle the results are positive, in general. While for the 12.7 mm rifle it is more negative in general. The instructor results are mostly negative as well. This is a bit surprising, as the other persons that were present behind the weapon observed a noticeable reduction, especially for the 12.7 mm rifle. Further investigation of these results is ongoing.

The reductions in dB(A) for the environment are more consistent. At 50 and 100 meter to the left, the reduction with a screen at 2 or 1 meter ranges between 6 to 10 dB for the 240 cm long and 180 cm high screen, both for the 7.62 and 12.7 mm rifles. While the reflection to the opposite side is between 0 and 1 dB.

The V-shaped barrier also provides a reduction to the left-hand side, between 5 and 6 dB.

The use of absorbing panels on the ground can reduce both the auditory risk in ARU and the sound exposure in dB(A). Only for the 12.7 mm rifle at the instructor an increase in ARU is measured, but this caliber produces a too strong muzzle blast for the absorbing panels to last.

Table 1. Reduction in ARU and dB(A) compared to the unscreened situation. Increase is shown in red.

Reduction w.r.t. unscreened				
Person (ARU)	Shooter	Instructor	Shooter	Instructor
	7.62mm	7.62mm	12.7mm	12.7mm
Abs. screen at 2m	94	-100	62	-229
Abs. screen at 1m	150	-96	-747	-155
Abs. screen at angle	-545	-73	-439	-134
V-shape screen	485	-83	-407	30
V-shape screen (hard)			-698	-90
Abs. ground	260	87	670	-167
Environment (dB(A))	50m right	50 & 100m left	50m right	50 & 100m left
	7.62mm		12.7mm	
Abs. screen at 2m	-1	8, 9	-1	8, 6
Abs. screen at 1m	0	8, 9	-1	9, 7
Abs. screen at angle	2	9, 10	0	9, 7
V-shape screen	5	5	6	8, 7
V-shape screen (hard)			2	5, 5
Abs. ground	2	2	1	1, 0

6. DISCUSSION AND CONCLUSIONS

Sound pressure measurements close to the muzzle blast of small caliber weapons have been carried out for an indoor and outdoor shooting range. The A-weighted sound exposure and the auditory risk units (ARU) from the AHAAH model have been calculated. A comparison of measurements with a shooter and with a weapon fixture have been made, showing a good correspondence for the sound exposure levels in dB(A). For the ARU results larger variations were seen though. The AHAAH model shows a sensitivity for variations in the pressure-time history that is not seen for the A-weighted sound exposure level. Note that a similar observation was made for the measured dose-response relation functions in tactical training environments; for the $L_{Aeq,8h}$ levels a better prediction for the temporary threshold shifts (TTS) was found then when using the AHAAH model [4].

In addition, tests were carried out with small portable sound absorbing screens to reduce the muzzle blast towards the shooter, instructor and the environment. For the environment reductions up to 10 dB(A) were obtained, behind the screen. For the opposite direction the contribution due to reflection is between 0 and 1 dB(A). Again, the ARU results show large variations, with either a reduction or an increase for the shooter and instructor positions.

ABSTRACT

Combat noise exposure poses significant risks to auditory health, including high-frequency sensorineural hearing loss, synaptopathy, and central auditory processing deficits. However, sometimes, combat noise acoustic trauma results in undetectable damage using standard audiometric evaluations. Such impairments, frequently caused by blast-related injuries, may manifest as difficulty in understanding speech in noise, tinnitus, or other auditory complaints, even when conventional audiograms indicate normal thresholds. This work emphasizes the need for comprehensive audiological protocol designed to address these diagnostic limitations. The protocol should integrate conventional and extended high-frequency audiometry, otoacoustic emissions, speech-in-noise testing, and immittance measures while incorporating patient-reported outcomes and detailed noise exposure histories. Utilizing a multifaceted approach, this protocol aims to identify subtle auditory dysfunctions and provide clinicians with robust tools for early diagnosis and targeted management. Clinical examples highlight the necessity of each of these auditory tests. The diagnostic protocol should emphasize the clinical importance of thorough auditory evaluations. It should enable the detection of subclinical impairment and supports tailored rehabilitation strategies. It also highlights the need for continuous monitoring of at-risk populations. These suggestions advocate for a shift in the clinical perspective in evaluating and caring for individuals exposed to combat, with implications for clinical and operational settings.

INTRODUCTION

Combat noise exposure, particularly from blasts, firearms, and explosions, is a distinct form of acoustic trauma that can result in complex and multifactorial auditory damage. Unlike continuous industrial or environmental noise, combat noise often involves short-duration, high-intensity pressure waves that may lead to both peripheral and central auditory injuries. These include, cochlear damage, disruptions at the level of the auditory nerve or brainstem, and if blast is involved tympanic membrane perforation and ossicular chain disarticulation [1]. Additionally, exposure to blast waves may also result in vestibular dysfunction and

concomitant mild traumatic brain injury (mTBI), further complicating the clinical presentation [2–4].
Individuals exposed to such noise frequently report a range of auditory symptoms: tinnitus, hyperacusis, decreased sound tolerance, auditory fatigue, and difficulty understanding speech in noisy environments. While some may present with measurable hearing loss, others show normal audiograms despite persistent functional difficulties. This has given rise to the concept of "hidden hearing loss," referring to synaptic or neural damage undetected by standard pure-tone testing [5,6]. Understanding the full range of potential auditory pathologies resulting from combat noise is essential to developing appropriate diagnostic and rehabilitation strategies.

CLINICAL GAP AND DIAGNOSTIC CHALLENGE

Current clinical practices remain heavily reliant on pure-tone audiometry as the primary diagnostic tool. This creates a substantial gap in care: individuals who report persistent auditory difficulties, such as difficulty understanding speech in noise, sensitivity to sound, or auditory fatigue, are told their hearing is "normal" based solely on standard thresholds. As a result, they are often left without diagnosis, treatment, or acknowledgment of their difficulties [3,4].
This diagnostic limitation has important clinical implications. In current practice, medical treatment for acoustic auditory trauma and the subsequent eligibility for treatment and compensation, is typically contingent upon the demonstration of hearing loss in standard audiometry [7,8]. However, individuals who report significant auditory symptoms following combat noise exposure, such as difficulty hearing in noise or tinnitus, may show normal pure-tone thresholds [9,10]. As a result, these individuals are often not diagnosed with hearing damage and do not receive appropriate treatment or rehabilitation services. This reliance on the audiogram as the primary diagnostic criterion creates a gap in care for patients with functional auditory impairments that remain "invisible" to conventional testing.
A shift in clinical perspective is urgently needed. Rather than relying exclusively on audiometric thresholds, clinicians should adopt a more functional, patient-centered approach that validates subjective complaints and incorporates a broader range of diagnostic tools. Only by acknowledging the limitations of conventional testing can we begin to close the gap between patient auditory complaints and clinical action.

TOWARD A STRUCTURED ASSESSMENT APPROACH

To effectively identify and manage the spectrum of auditory dysfunctions associated with combat noise exposure, a more comprehensive and structured assessment protocol is needed. While pure-tone audiometry provides valuable information about threshold sensitivity, it fails to detect many of the suprathreshold deficits that impact real-world communication, particularly in noisy or cognitively demanding environments. Clinical evidence supports the need for advanced diagnostic tools such as extended high-frequency audiometry (EHF), speech-in-noise tests and distortion product otoacoustic emissions (DPOAEs) which offer critical insights into auditory integrity.
An essential component of such protocols is the use of a dedicated case history (structured auditory anamnesis) designed specifically for individuals exposed to combat noise. Unlike general intake forms, this targeted anamnesis includes questions about the acoustic characteristics of the exposure (e.g., blast proximity, use of hearing protection), timing and progression of symptoms, co-occurring complaints such as tinnitus or sound intolerance, and contextual factors like post-exposure stress or cognitive fatigue. It also considers prior auditory health and service-related functional impairments. This information is vital for tailoring the diagnostic approach and for differentiating between peripheral, central, and non-auditory contributors to the patient's complaints.
This suggested protocol integrates traditional and advanced audiological measures, along with the dedicated anamnesis, in a tiered manner. It guides clinicians through the diagnostic process while validating patient complaints that may otherwise be overlooked. Importantly, the protocol is designed not only to improve diagnostic accuracy but also to inform rehabilitative planning, ensuring that patients with normal audiograms but real functional deficits receive appropriate care.
Implementing such models represents a critical evolution in clinical audiology—one that aligns diagnostic strategies with the complexity of auditory trauma and bridges the longstanding gap between subjective experience and objective findings.

SQUAD-LEVEL OPERATIONAL PERFORMANCE UNDER VARYING HEARING PROTECTION DEVICES AND SIMULATED HEARING LOSS

Benjamin Sheffield[1,2*] **Rebecca E. Bieber**[2] **Stephanie Turcios**[2] **Douglas Brungart**[2]

ABSTRACT

Noise-induced hearing loss continues to be an issue for military personnel, who rely on their hearing to maintain situational awareness and maximize operational effectiveness. Methodological advancements in measuring performance in dismounted combat are paving the way to examine the impact of hearing in these complex environments. In this study, squads from the US Army's 4th Infantry Division conducted standard combat training exercises under different hearing conditions using hearing protection devices (HPDs; passive, active) and hearing loss simulation (normal hearing, moderate-to-severe loss) while outfitted with audiovisual recorders, GPS trackers, laser engagement systems and inertial measurement units on the helmet and weapon. This allowed all squad movement, communication, and engagements to be captured. In addition, performance ratings were collected from observer-controllers (OCs) and participating Soldiers after each drill. Results show a clear advantage of active HPDs compared to the other conditions tested for both Soldier and OC ratings of squad performance. Soldiers also reported low frustration while wearing active HPDs and suffered less casualties on average, whereas a moderate-to-severe hearing loss resulted in higher mental demand and frustration and the highest number of casualties incurred. These findings can help inform Military leaders of the importance of wearing effective hearing protection in combat.

1. INTRODUCTION

A Warfighter's hearing is critical for combat effectiveness, particularly in dismounted combat operations where Soldiers rely on their hearing to detect enemy movements, identify threats, and coordinate with their unit. In environments with limited visibility, such as dense forests or urban battlefields, auditory cues like distant gunfire, footsteps, or radio transmissions provide critical information for survival. The ability to process these sounds quickly allows soldiers to react effectively, enhancing their situational awareness (SA) and tactical decision-making.

Unfortunately, the battlefield is also filled with hazardous noise (e.g. explosions, gunfire, aircraft, vehicle engines) that can cause temporary or permanent hearing damage (e.g. hearing loss, tinnitus) and auditory fatigue. Even brief exposure to these sounds without protection can impair a soldier's ability to detect threats, potentially reducing combat effectiveness in both the short and long term.

Despite these risks, many soldiers are reluctant to wear traditional hearing protection because they fear it will diminish their SA. Standard passive earplugs or earmuffs can muffle critical battlefield sounds, making it harder to detect enemy movements or communicate effectively with teammates. In high-stakes combat situations, soldiers may prioritize immediate survival and effectiveness over long-term health, leading them to forgo hearing protection altogether.

To address this challenge, advanced HPDs have been developed that can both safeguard hearing and enhance

communication [1]. Modern tactical headsets and electronic earplugs filter out harmful noise levels while amplifying essential sounds, such as voices and quiet enemy movements. These devices can allow soldiers to maintain SA without sacrificing their hearing health. Ultimately, Soldiers must balance the tradeoff between hearing protection and SA. While advanced devices offer significant improvements, they are not always available or practical in every situation. Troops often have to decide whether to risk hearing damage for enhanced SA or rely on protection that may slightly reduce their ability to perceive battlefield cues. As technology continues to evolve, finding the optimal balance between hearing safety and operational effectiveness remains a crucial challenge for modern militaries.

In battlefield environments, degraded hearing can occur as a result of hearing protector use, but it can also occur as a result of acute hearing impairment from unprotected exposures during the current engagement or chronic hearing loss from a lifetime of noise exposure prior to the current engagement. In order to make decisions about when, how, and what kind of hearing protection to wear in combat, and also about who might have an acute or chronic hearing loss that is severe enough to interfere with combat operations, it would be extremely helpful to collect information that might allow a prediction of the impacts that different levels of hearing impairment might have on operational performance, regardless of the source.

Traditionally, testing the impacts of hearing loss or HPDs on combat operations has been limited to laboratory measures or carefully controlled field studies that focus on isolated tasks. However, the battlefield is a dynamic environment and the factors that influence combat effectiveness are extremely complex, so it has been difficult to translate these findings to lethality, survivability, or mission success in actual operational environments. Some studies have begun to examine the impact of hearing acuity on combat performance in more comprehensive environments using simulated sound sources [2] or realistic sound sources combined with hearing loss simulation [3-5]. However, in the infantry realm, this has been limited to the individual or fire team level, whereas the fundamental fighting element is the infantry squad.

Beyond logistical considerations, one challenge of expanding to the squad-level has been the lack of validated measures of operational performance in dismounted combat. Thankfully, recent methodological advancements in measuring performance in these environments [6-7] provide a framework to now explore the impact of hearing acuity at the squad level. Interestingly, the initial findings from those studies indicate that the most important contributing factor to combat performance is effective communication within the squad, further emphasizing the need to better understand this issue [7].

In the present study, we utilized the methodologies mentioned above for measuring/analyzing squad performance while varying each squad's hearing acuity across drills using hearing loss simulators and HPDs to examine their impact on performance, providing critical information for our Warfighters.

2. MATERIALS AND METHODS

2.1 Combat Exercise

The combat exercise used for the study was closely modeled after Battle Drill 2A: Conduct a Squad Assault, which is a fundamental infantry exercise that trains soldiers to close upon and destroy an enemy position through coordinated fire and movement. The drill involves a squad maneuvering against an opposition force (OPFOR), typically starting with suppressive fire to fix the enemy in place while an assaulting element moves forward to secure an objective. Soldiers execute bounding movements, alternating between providing covering fire and advancing under protection. The exercise emphasizes teamwork, communication, and aggressive action to overwhelm the enemy.

Data collection took place at a designated training area in Ft. Carson, CO consisting of primarily wooded terrain and grassland with slight elevation changes incorporating hills, meadows, and gulches. There were two Situational Training Exercise (STX) lanes setup on the range, each with differing movements toward their objective. In both cases, the primary objective was to secure a bunker manned by two members of the OPFOR. A third OPFOR member served as a Listening Post/Observation Post (LPOP) a few hundred yards forward of the bunker, where he was concealed in the brush to provide a surprise attack element. Each member of the OPFOR was outfitted with an M4 Carbine rifle.

2.2 Participants and Squad Composition

A total of 86 Soldiers, all male, aged 18-34 years, were recruited from the US Army's 4th Infantry Division to participate as part of their Squad Table III training

program. They ranged in rank from E-1 to E-6 and were assigned to remain within their normal squad and role for the duration of the exercises. Each 9 to 11-man squad consisted of a Squad Leader, a two-man gun team (Gunner and Assistant Gunner), and two fire teams (Alpha and Bravo). Each fire team consisted of 3-4 members depending on the squad size. Each had a Fire Team Leader, an Automatic Rifleman, and either a Grenadier or Rifleman (or in some cases both). The Gunner was outfitted with an M240 machine gun, the Automatic Rifleman with an M249 SAW (Squad Automatic Weapon), and the Grenadier with an M203 grenade launcher mounted on an M4 Carbine rifle. All other squad positions carried M4 Carbine rifles and all weapons were loaded with blank ammunition.

Table 1. Audiogram used for the Simulated Hearing Loss Condition.

Frequency (kHz)	0.25	0.5	1	2	4	8
Level (dB)	50	50	55	65	85	95

2.3 Hearing Conditions

Four hearing conditions were tested in the study, including two HPD conditions and two hearing simulation conditions. The active HPD (Peltor condition) tested was the Peltor ComTac XIII (3M Corp.), which encompasses downleads for participants outfitted with radio communications (Squad Leader and Fire Team Leaders). The other HPD tested was a standard foam earplug (Foam condition), which differed depending on the size for each participant, as determined by an audiologist (3M EAR Classic SuperFit 30 and 33 for small and large, respectively, and Sound Guard 2-color for medium). The two hearing simulation conditions were administered via a custom-designed helmet-mounted hearing loss simulator known as the HL Sims (Sensimetrics Corp.). The HL uses earphones outfitted with small microphones to pass through sound unfiltered when in the normal hearing setting (Simulated Open Ear condition). To simulate hearing loss, a combination of attenuation from the earplug and additive masking noise elevates the detection thresholds at certain frequencies, depending on the audiogram simulated (see [5] for more details). For this study, we chose a moderate-to-severe hearing loss using the values shown in Tab. 1 (Simulated Hearing Loss condition). The Simulated Open Ear condition served as a stand-in control condition since operating with a truly open ear would put the participants at risk of hearing damage from weapons fire.

2.4 Additional Equipment and Measurements

In addition to donning hearing loss simulators and HPDs, participants were outfitted with digital audio recorders (Evida Corp.) and GoPro cameras (GoPro, Inc) to capture communication. Soldiers' helmets and weapons were also equipped with inertial measurement units (IMUs; ADPM, Inc) to track acceleration, angular movement, and orientation of the head and weapon, and to count the number of rounds fired by each participant. Their weapons were also equipped with the Instrumentable-Multiple Integrated Laser Engagement System (I-MILES) lasers and they wore vests and halos with I-MILES sensors. Fig. 1 shows an example of a fully-equipped Soldier.

Figure 1. Fully equipped Soldier with red circles highlighting from left to right: helmet IMU, audio recorder mounted on the HL Sim, GoPro, and weapon IMU.

I-MILES data were routed to a central control tower using a body worn radio frequency transmitter that doubled as a Global Positioning System (GPS) tracker as part of the Homestation Instrumentation Training System. This system allows all movement and engagements to be captured for visualization in real time and to be saved for after action reporting and data analysis (Fig. 2).

2.5 Procedures

In total, there were six squads that each ran through four drills of the exercise alternating between the two STX lanes (two drills per lane) for a total of 24 drills. Each drill was conducted with all squad members in one of the four hearing conditions and conditions were switched between drills to achieve a balance within each squad.

Figure 2. Homestation Instrumentation Training System screenshot showing Bravo team engaging with OPFOR while Alpha team flanks left to assault. The red line indicates a pairing line between the OPFOR and Gunner and the red hat indicates the OPFOR as the shooter. The LPOP can be seen in the bottom left corner.

Before the start of the exercise, participants completed a hearing exam and filled out an intake questionnaire about their demographics, military and combat history, and experience using HPDs. They were also fit with appropriately-sized hearing protection and trained on how to operate the Peltors. After each drill, Soldiers rated their own performance and communication ability and completed the NASA Taskload Index (TLX) [8] via a tablet PC running a custom TabSINT [9] protocol. In addition, unit commanders (Platoon and Company) acted as OCs throughout the exercise and provided ratings of squad performance on two scales assessing Battle Drill task steps and tactical performance principles

2.6 Data Analysis

2.6.1 Observer-Controller Ratings

OC ratings were modeled using linear mixed effects regression in R version 4.4.1 [10]; the buildmer package version 2.11 [11] was used for model selection, using backwards selection and likelihood ratio testing to compare nested models; the effects package was used for visualization of model fitted values. The maximal fixed effects structure evaluated included two-way interactions between condition and each of the following squad-level measures: drill number (4 levels), mean years of service among squad members, mean length of time since the most recent live fire event, the mode value for length of time with the current squad, and mode value for the number of squad leaders during their current assignments, as well as non-interacting fixed effects of platoon (3 levels), lane (2 levels), and mean squad member age (continuous). The maximal random effects structure evaluated included interacting by-OC intercepts and slopes for condition and lane, as well as a random intercept of drill.

2.6.2 NASA Taskload Index

Responses to the NASA TLX were modeled using linear mixed effects regression using the methods described in the above section. The maximal fixed effects structure evaluated included an interaction of TLX subscale (categorical; 6 levels) and condition (categorical; 4 levels), along with non-interacting fixed effects of drill number (categorical; 4 levels), number of years of military service (continuous), age (continuous), and duration of time since the most recent live fire event (continuous). The maximum random effects structure evaluated included by-participant intercepts and slopes for condition and drill number, as well as a random intercept of date.

3. RESULTS

3.1 Observer-Controller Ratings

The final model selected included non-interacting main effects of condition and drill number, as well as a random intercept of OC grader. The main effect of condition is visualized in Fig. 3 and shows that performance was consistently rated higher when squad members were in the Peltor condition as compared to the Foam plugs (b=-12.56, SE=4.89, t=-2.57, p=.01) and Simulated Hearing Loss conditions (b=-19.2, SE=5.26, t=-3.65, p=.001). OC ratings did not differ significantly between Peltor and Simulated Open Ear conditions (b=-10.13, SE=5.2, t=-1.95, p=.06).

The non-interacting fixed effect of drill number indicates a pattern of improved ratings over the course of four drills. Ratings for Drill 4 were significantly higher than those for Drill 1 (b=17.7, SE=5.07, t=3.49, p=.001) and Drill 2 (b=11.97, SE=4.87, t=2.46, p=.02). Ratings did not differ between Drills 1 and 2 (b=5.73, SE=4.89,

t=1.17, p=.25) nor between Drills 3 and 4 (b=4.41, SE=5.12, t=-.86, p=.39).

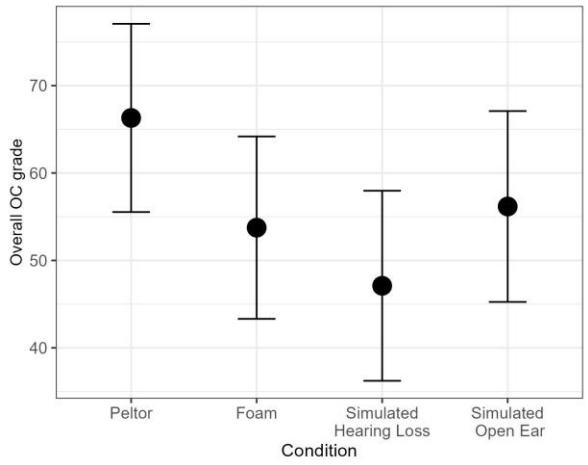

Figure 3. Model-fitted values for OC grade visualized as a function of hearing condition. Error bars reflect the 95% confidence interval. Higher values reflect better performance.

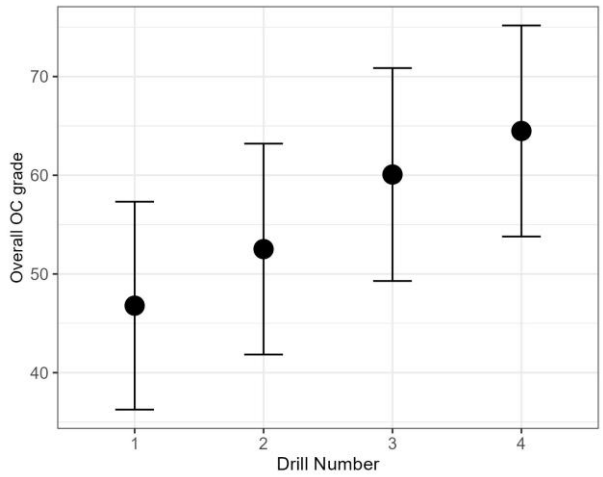

Figure 4. Model-fitted values for OC grade visualized as a function of hearing condition. Error bars reflect the 95% confidence interval. Higher values reflect better performance.

3.2 NASA Taskload Index

The final model selected to describe the NASA TLX data included an interaction of TLX subscale and condition, a non-interacting fixed effect of age, and a by-participant slope and intercept of condition. Significant interactions were examined by re-leveling and re-fitting the model to obtain estimates at all levels; see Fig 5.

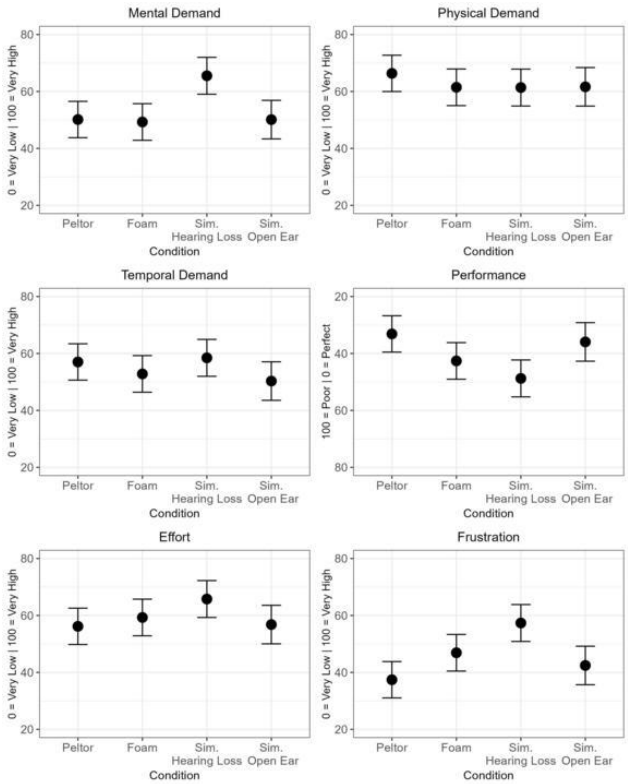

Figure 5. Model-fitted values for NASA Taskload Index subscales visualized as a function of hearing condition. Error bars reflect the 95% confidence interval.

Examination of the significant interaction between hearing condition and TLX subscale reveals the following: When rating levels of Mental Demand, Performance, Effort, and Frustration, participants consistently gave poorer ratings to the Simulated Hearing Loss condition as compared to all other conditions (p<.05, all comparisons). There were no significant differences between Simulated Hearing Loss and any of the other hearing conditions for ratings of Physical Demand or Temporal demand. Ratings of Frustration were significantly lower when using Peltors than either Foam plugs (b=9.48, SE=4.05, t=2.34, p=.02) or Simulated Hearing Loss (b=19.94, SE=4.37, t=270.92, p<.001), and were similar between Peltors and the Simulated Open Ear condition (b=5.02, SE=4.03,

t=1.24, *p*=.21). The same pattern was found for ratings of Performance (Peltor vs Foam: *b*=9.48, SE=4.05, *t*=2.34, *p*=.02; Peltor vs Simulated Hearing Loss: *b*=15.63, SE=4.36, *t*=3.58, *p*<.001; Peltor vs Simulated Open Ear: *b*=2.81, SE=4.04, *t*=0.7, *p*=.49).

3.3 I-MILES Engagement

Preliminary analysis of the I-MILES engagement data indicates no significant effect of hearing condition. However, squads did suffer the highest number of Blue Force (BLUFOR; i.e., friendly or allied forces) casualties on average when operating with a moderate-to-severe hearing loss and the least amount when operating with the Peltors (Fig. 6). Note that all participants were resurrected in HITS by the training operators any time they were indicated as killed until the Squad conducted their final assault on the bunker to maximize the training and keep everyone in play, which is why the number of casualties often exceeds the size of the squad. Fig. 6 also illustrates that the data collected to date are highly underpowered for this analysis with only 6 observations for each condition.

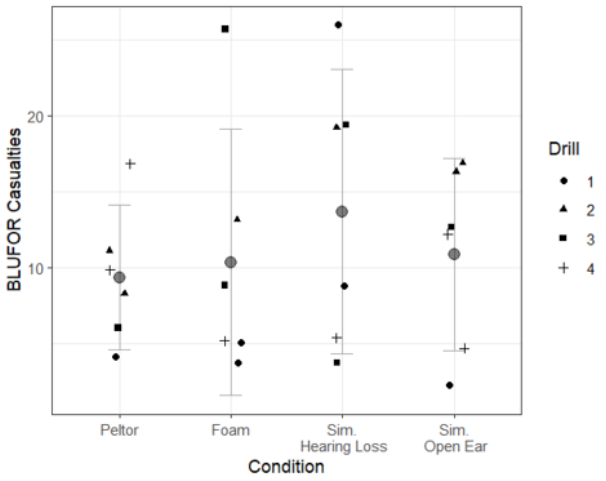

Figure 6. BLUFOR casualties as a function of hearing condition for each drill number. Large circles indicate mean casualties and error bars represent standard error of the mean.

3.4 Inertial Measurement Unit and GPS Analysis

Preliminary analysis of the IMU and GPS data is ongoing, but the early indications are that squads moved faster and spent less time in contact on average when operating with the Peltors and moved slower and spent more time in contact when operating with a moderate-to-severe hearing loss. However, these trends are not statistically significant and the data are currently underpowered for drill-level analyses.

4. DISCUSSION

4.1 Summary of Findings

The findings from this study highlight the operational advantages of advanced hearing protection devices for Soldiers in combat environments. Results indicate that Soldiers perform more effectively when equipped with these devices compared to passive foam earplugs. This underscores the critical importance of providing Soldiers with advanced hearing protection technology to enhance battlefield effectiveness.

Furthermore, the fact that the Peltor condition resulted in numerically higher OC ratings of performance than the Simulated Open Ear condition (though not statistically significant) and that Soldiers' self-ratings of performance were similar across both conditions suggests that wearing advanced hearing protection does not impose a performance cost. These findings may help alleviate concerns about potential trade-offs between hearing protection and operational effectiveness when wearing these types of advanced HPDs.

The study also demonstrates that simulated moderate-to-severe hearing loss significantly degrades performance while increasing mental demand, frustration, and effort. These factors indicate the potential for critical errors in complex operational environments if Soldiers are operating with a hearing impairment. This, too, highlights the importance of wearing effective hearing protection in combat to prevent temporary or permanent hearing loss.

Lastly, squad performance improved over time, reinforcing the effectiveness of the training exercises and underlining value of continued training and adaptation in dynamic combat scenarios.

4.2 Limitations and Future Directions

While these results provide valuable insights, several limitations should be acknowledged. This study represents the initial phase of data collection. Future research will expand the sample size to improve statistical power which will allow for a formal analysis of engagement data (e.g., casualties suffered). However, engagement data alone may

not capture the full scope of objective performance differences, warranting a more in-depth analysis of IMU and GPS data as conducted in [6]. Furthermore, communication data analysis has yet to be conducted, and given the importance of verbal coordination in combat operations, this will be a critical area for further investigation.

A key limitation is the impracticality of blinding the OCs or participants to the hearing condition, which may have introduced bias in performance evaluations. Another limitation is the inability to test a truly open ear condition due to ethical considerations from the risk of hearing damage to the participants, which may impact some of the comparisons involving the Simulated Open Ear condition. Also, the present results evaluate only one type of advanced HPD and only one type of hearing loss. Future research will incorporate other devices and investigate some of the subtleties related to hearing impairment to provide a more comprehensive understanding of the impact of hearing acuity on Soldier performance.

5. CONCLUSIONS

The findings from this study can help inform Military leaders of the importance of wearing effective HPDs in combat to preserve the hearing of our Warfighters, who rely on their hearing to maintain SA and maximize operational effectiveness. The methods employed can be replicated to provide a standardized and ecologically valid assessment of other advanced HPDs and their impact on the Warfighter performance.

6. ACKNOWLEDGMENTS

The authors would like to thank Andrea Brzuska, Briana Biel, Jessica Lanning-Baker, Tammie Taylor, Julianna Voelker, and CPT Dooho Kim for their assistance with data collection; COL Jillyen Curry-Mathis for coordination with the 4th ID; 3M for loaning us the Peltor Comtac XIIIs; and members of the 4th ID for their participation in the study. This study was partially-funded by a grant from the Military Operational Medicine Research Program.

ABSTRACT

Acoustic Test Fixtures (ATFs) are physical substitutes designed to evaluate the attenuation provided by Hearing Protection Devices (HPD). These devices are particularly useful for measurements, where human testing is not feasible, such as high-level impulse noises exposure. However, challenges arise in integrating the mechanical elements required to mimic the response of the human head. The material properties of commercially available ATFs vary, potentially leading to different coupling with HPDs. This study aims to investigate the behavior of a rigid earplug and the resulting acoustic pressure in the ear canal when the stiffness of the ATF ear is modified. An experimental setup was developed, involving a custom laboratory-developed ATF to estimate a rigid earplug attenuation for three simplified ear materials of increasing stiffness. Additionally, a time-domain numerical model using finite element method was created to study the wave propagation in the simplified ATF ear. This study shows experimentally and numerically that the stiffness of the ATF ear significantly influences earplug attenuation measurements by modifying the contribution of tissular conduction in the wave propagation behind the protector. This study paves the way for improving ATF biofidelity by more accurately accounting for the behavior of the human outer ear mechanical properties.

1. INTRODUCTION

Impulse noises are characterized by a high amplitude, a sudden onset, and a brief duration [1]. These noises can be encountered on the battlefield, where soldiers are exposed to impulsive noise levels ranging from 145 dB-peak to 190 dB-peak [1-2]. To ensure adequate protection, it is necessary to accurately assess the performance of Hearing Protection Devices (HPD). Acoustic Test Fixtures (ATF) are commonly used to estimate the attenuation allowed by HPD facing very high-level impulse noises. Nevertheless, the ATF correspond only to an approximation of the human auditory system, whether it concerns the eardrum, the Ear Canal (EC) anatomy, or the material properties [3]. More specifically, the interactions between the very high-level impulse wave and the HPD, as well as the transmission paths through the outer ear's tissues and the HPD, still need to be fully assessed for the current ATF. These transmissions strongly depend on the materials used in the ATF [4], but a clear relationship is not yet fully understood and requires further investigation.
This paper aims to investigate the relation between artificial ear material properties and earplug sound attenuation. An experimental setup was developed, involving a custom laboratory-developed ATF to estimate a rigid earplug attenuation for three geometrically simplified ear materials of increasing stiffness. Additionally, a time-domain numerical model using finite element method was created to study the wave propagation in the simplified ATF ear.

2. EXPERIMENTAL STUDY

2.1 Material and method

The laboratory-designed ATF used in this study, shown in Figure 1, is a modification of the ISL standard ATF that complies with the S.12.42 standard [5]. This laboratory-developed artificial head incorporates the electronics and measuring devices of the standard ISL head. It is modified to allow the installation of an ear flange (diameter 100 mm, thickness 8.5 mm) made from a single homogeneous material. This ear is held in position on the artificial head by an aluminum ring secured by 6 screws.

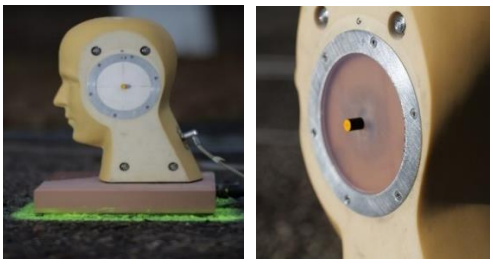

Figure 1 : View of the custom-made ATF (left) and a close-up of the ear flange (right).

For this study, three different ear materials of variable stiffness were considered. Their mechanical properties were measured through a compression test compliant with ASTM D575 and are shown in Table 1. The RTV 3325 ear was produced by molding. The other two ears were fabricated using 3D printing (Formlabs Form 3L).

Table 1. Average mechanical properties of the ears tested in the study with standard deviations.

Name	Young modulus [MPa]	Density [g/m^3]	Poisson's ratio [-]
RTV 3325	0.71 ± 0.02	1.21 ± 0.01	0.38 ± 0.03
Formlabs 50A	4.76 ± 0.16	1.09 ± 0.01	0.47 ± 0.01
Formlabs Draft	(1.40 ± 0.06) ×10^3	1.19 ± 0.01	0.47 ± 0.01

The measurements were conducted in an anechoic chamber. The source of impulsive noise was a laboratory shock tube [6] placed 4 meters from the ATF. A reference microphone was positioned at equidistance from the source to measure the external pressure (Brüel & Kjær ½"). The pressure in the EC was recorded by an ear simulator compliant with IEC 60318-3 standard. In this configuration, the head was subjected in a reproducible manner to an impulse noise of 136 ± 1 dB-peak.

The tests presented in this paper were carried out at normal incidence to the ear. The earplugs used are 3D printed with a cylindrical shape (diameter: 8 mm, length 20 mm) and are made of Acrylonitrile Butadiene Styrene (ABS). They were inserted 10 mm into the ears. The external pressure and the pressure under the earplug were recorded simultaneously with a TEAC LX10 data recorder. Measurements on each ear were conducted five times, to verify the repeatability.

2.2 Results

The average acoustic pressure history measured inside the occluded EC is shown in Figure 2.

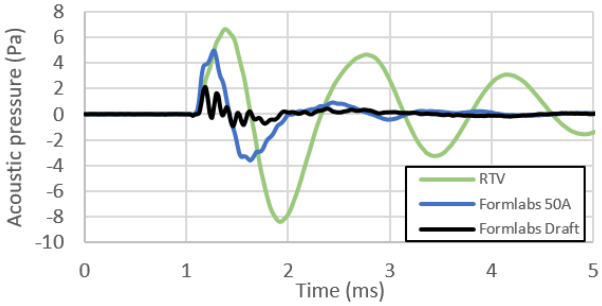

Figure 2. Average acoustic pressure measured inside the occluded EC.

Noise reduction (NR), i.e., the difference in peak levels between the pressure in front of the ear and the pressure in the occluded EC, has been determined for each configuration and is presented in Table 2.

Table 2. NR for the three ear materials tested.

Name	NR peak [dB]
RTV 3325	23.6
Formlabs 50A	28.7
Formlabs Draft	36.3

As shown in Table 2, peak noise reduction decreases with increasing rigidity of the ear flange. The three ears Insertion Losses (IL) were determined for the previously described impulse stimulation. From 100 to 400 Hz, an increase in IL of 12.9 dB per octave and 13.6 dB per octave was observed for the Formlabs 50A and Draft ears, respectively. From 200 Hz to 1 kHz, insertion loss was higher with increasing rigidity. In particular, at 700 Hz, we observe the largest deviations in IL. At this frequency, the IL was 17 dB, 30 dB, and 42 dB for the ear made of RTV, Formlabs 50A, and Draft, respectively. After 1 kHz, there are no marked differences between the different flanges.

3. NUMERICAL MODEL

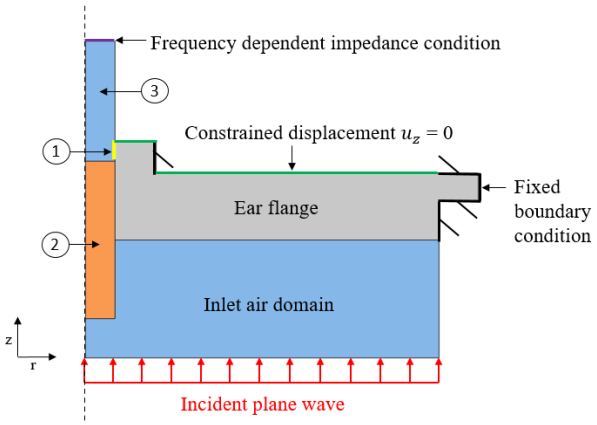
To complete the experimental study, a numerical model of the laboratory-developed artificial head described in section 2.1 was developed. It allows for a more comprehensive analysis by estimating, in addition, the displacements of the protector and ear canal walls or the effect of potential micro-leaks. This time-domain finite element model is solved using COMSOL Multiphysics® (Stockholm, Sweden).

3.1 Methods

The 2D-axisymmetric numerical model developed comply with the ear flange geometry and is composed of four domains, represented in Figure 3. The earplug (labelled 2 in Fig. 3) and ear flange are considered as elastic solid materials, while the external air domain and the air in the EC (labelled 3 in Fig. 3) are modeled as fluid domains, satisfying the lossless Helmholtz equation. The mechanical properties applied to the three ear flanges correspond to the data determined experimentally in Table 1. The air fluid is defined by a density of 1.2 kg/m^3 and a sound speed of 343 m/s at 20°C. The earplug is made of ABS with a Young's modulus of 2200 MPa, a Poisson's ratio of 0.35 and a density of 1040 kg/m^3 [6]. No damping is applied in the solid domains.

The averaged incident sound pressure measured experimentally is used as input to a plane wave radiation condition applied at the bottom of the inlet air domain. The lateral sides of the ear flange are fixed boundary conditions (black lines in Fig.3) and constrained displacement conditions (green lines in Fig.3). These conditions were chosen based on practical insights into the integration of the ear flange with the ATF. An ear simulator consists of a main cavity and two slits to simulate the impedance of the middle ear. To evaluate the acoustic pressure at the ATF microphone position, the main cavity of the coupler has been represented along its entire length. The equivalent impedance of the two slits has been applied by a frequency-dependent impedance condition [7] at the ATF microphone position (purple line in Fig. 3). A fluid-structural coupling exists between EC and ear flange (yellow line labelled 1 in Fig. 3).

The equations in the air and solid domains are solved using at least five quadratic elements per wavelength (maximal resolution frequency was set to 10 kHz) ensuring solution convergence. The time-stepping method generalized-alpha is used to solve the problem. Both acoustic pressure in the EC and inlet air domain, as well as earplug and ear structural displacement fields are computed.



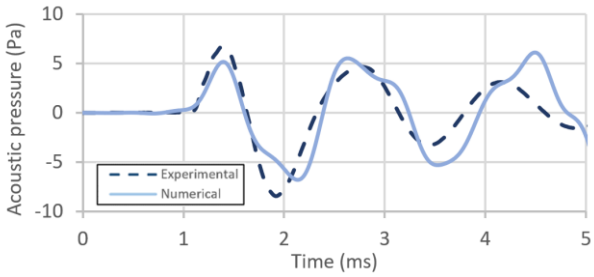


Figure 3. Geometry and boundary conditions of the FE model. The symmetry axis is shown as a dotted line. (1) interface between EC air domain and the ear flange, (2) earplug, (3) EC air domain.

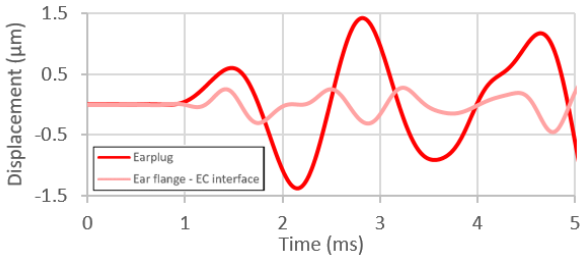

3.2 Results

Figure 4 shows the comparison between experimentally and numerically evaluated acoustic pressure time history in the occluded EC for the RTV ear. The numerical model yields a good pressure estimate, but exhibits undamped oscillations and combined contribution effects. Comparisons of the numerical simulations with the experimental results for the Formlabs 50A and Draft ear (not shown here for the sake of conciseness) indicate notably the presence of leakage during the experiment.

The displacement time history of the earplug (labelled 2 in Fig. 3) in longitudinal direction and of the EC air domain/ear flange interface (boundary 1 in Fig. 3) in radial direction are also represented. These undamped oscillating displacements present a first peak amplitude of 0.60 µm and 0.25 µm for the earplug and the ear canal/ear flange interface, respectively.

(a) Average acoustic pressure in the EC, (3) in Fig.3

Figure 4. Average acoustic pressure and displacements for the artificial ear in RTV.

4. DISCUSSION

The mechanical properties of the artificial ear significantly influence the attenuation provided by earplugs. Specifically, the peak noise reduction is enhanced as the stiffness of the outer ear increases. A previous experimental study has demonstrated the impact of outer ear hardness on the earplug "piston effect" [4]. This effect is characterized by a resonant, back-and-forth rigid body motion of the earplug coupled with the external auditory canal wall, typically occurring at frequencies below 2 kHz. The piston effect may account for some of the discrepancies observed at low-frequency for the earplug insertion loss among the three tested ears.

Analytically, the contribution of the piston effect to variations in ear canal sound pressure can be estimated by considering the relative equivalent occluded ear canal volume change and the adiabatic bulk modulus of air. Estimations based on numerically determined displacements reveal that for the softer ear made with RTV, 63% of the first peak acoustic pressure is attributable to the piston effect and 37% to the ear canal wall vibrations. For higher hardness (displacements curves omitted in this article), this second contribution rises to 38% for the Formlabs 50A ear and 44% for the Draft ear. Thus, the earplug piston effect contribution is predominant for the three ears tested but decreases with the ear's stiffness. The relative importance of these contributions to the human ear remains to be clarified.

Besides, stiffer materials induce additional effects. A low IL can be observed at lower frequencies, especially for the Formlabs 50A and the Formlabs Draft, indicating leakage during experimental measurements. These leakages can be attributed to improper seals between earplugs and EC walls due to the surface's conditions. Indeed, slight grooves could be seen on the earplug (3D printed) and EC surfaces.

5. CONCLUSION

Experimental measurements have quantified the impact of a modification in the stiffness of the ear on the attenuation of a protector. Specifically, peak noise reduction increases with ear stiffness. For the various ear materials, the protector and the EC wall displacements have been estimated numerically and discussed. This study shows that the earplug displacement is the main contribution to the pressure in the EC. The vibration of the interface EC / ear flange has a non-negligible effect, with a contribution increasing with ear stiffness. Finally, these results pave the way for improving ATFs by better reproducing the behavior of earplugs in human ears.

SOUND ATTENUATION WITH DOUBLE HEARING PROTECTION: A COMPARISON OF REAL-EAR AND BEHAVIORAL HEARING THRESHOLD MEASUREMENTS

Hauptman Alon[1*] **Chordekar Shai**[1] **Dirks Coral**[2] **Fostick Leah**[3] **Fink Nir**[1]

ABSTRACT

This study explores the relationship between objective sound measurements and subjective hearing thresholds under double hearing protection. Both Real-Ear Measurement (REM) and subjective testing were used to examine attenuation with EasyView Otoblock earplugs and Optime 105 earmuff. Stimuli were delivered from a fixed frontal source (0° azimuth) across a frequency range of 500 to 12,000 Hz, allowing observation of attenuation patterns at both low and high frequencies.

Descriptive analysis suggested consistent trends across participants. At higher frequencies (above 4 kHz), subjective results indicated more attenuation than objective REM values, whereas the opposite was observed at lower frequencies (below 4 kHz), where REM showed more attenuation. These patterns may reflect the contribution of bone conduction (BC) when air conduction (AC) is significantly reduced.

While the sample size limits statistical generalization, the findings highlight the value of integrating subjective data alongside objective measurements in evaluating hearing protection performance. The use of a realistic protection configuration and fixed sound direction offers practical insights into how auditory information is transmitted under high-attenuation conditions. These insights may support the development of more effective hearing protection devices for environments with hazardous noise exposure.

Keywords: *hearing protection devices, bone conduction, sound attenuation, real-ear measurements*

1. INTRODUCTION

1.1 Air Conduction and Bone Conduction Hearing

Hearing occurs through air conduction (AC), bone conduction (BC), and to a lesser extent, body conduction - which is often considered a subset of BC due to its indistinct boundaries [1]. AC is the dominant auditory pathway, transmitting sound via the ear canal, eardrum, and ossicles to the cochlea. In contrast, BC transmits sound through skull vibrations directly to the cochlea, bypassing the outer and middle ear entirely [2-3]. Under typical listening conditions, AC predominates, but when AC is obstructed,such as through the use of double hearing protection when combining insert earplugs and an earmuff,BC becomes increasingly relevant in auditory perception [4].

The AC pathway depends on the integrity and openness of the outer and middle ear structures. When these are sealed off by hearing protection, the transmission of sound via AC is significantly reduced. BC, however, is relatively unaffected by such occlusion and can become the primary pathway through which sound is perceived, particularly at lower frequencies (<1 kHz). This increased contribution of BC under occluded conditions is known as the occlusion effect, and it leads to measurable differences between physical (objective) and perceptual (subjective) assessments of sound attenuation [5].

*Corresponding author: Alonha@ariel.ac.il.

Copyright: ©2025 Hauptman et al. This is an open-access article distributed under the terms of the Creative Commons Attribution 3.0 Unported License, which permits unrestricted use, distribution, and reproduction in any medium, provided the original author and source are credited

These discrepancies are especially evident when comparing results from Real-Ear Measurement (REM) systems, used to objectively quantify sound levels in the ear canal, with behavioral threshold testing, which reflects the listener's perceptual experience. Under double hearing protection, where the AC path is highly attenuated, REM results tend to overestimate attenuation at low frequencies, while subjective tests reveal residual perception via BC [6].
In this study, we examine sound attenuation under a single, fixed condition of double hearing protection, using EasyView Otoblock earplugs in combination with Optime 105 earmuff. All sound stimuli were presented from the frontal direction (0° azimuth) to ensure consistent spatial input and to eliminate directional variability. This controlled setup allows us to focus specifically on how sound is conducted and perceived under maximum realistic occlusion, providing insight into the interplay between AC and BC under these conditions.
By understanding how the auditory system responds when AC is relatively blocked and BC dominates, especially in the context of real-world double hearing protection,we can better interpret the limitations of standard objective testing and develop more effective hearing protection strategies for high-noise environments.

AC is the most commonly utilized hearing pathway but is significantly reduced when hearing protection is applied. BC offers an alternative route, transmitting sound through bone and soft tissue [2]. Under double hearing protection, where both earplugs and earmuff are used, the attenuation of AC is high, and thus, the relative contribution of BC becomes more prominent. Understanding this shift in auditory pathways is essential for interpreting attenuation outcomes under such conditions.

1.2 Sound Attenuation Under Double Hearing Protection

Earplugs and earmuffs have different frequency-specific attenuation profiles, and their combination (i.e., double hearing protection) increases overall attenuation, particularly in the mid-to-high frequencies. However, the gains in attenuation are limited at low frequencies due to BC transmission, typically plateauing around 40–60 dB [4]. In this study, only the double protection configuration was evaluated using both objective and subjective measurements to assess how AC and BC interact under realistic high-attenuation conditions.
Subjective tests, which are based on perceptual thresholds, provide insight into the listener's experience and are influenced by BC. In contrast, objective methods such as REM offer consistent measurement of sound pressure levels in the ear canal but may underestimate BC effects [5]. This study compares both approaches to provide a more comprehensive eexplanation of attenuation under double protection.

1.3 Objective vs. Subjective Measures

Objective measures (e.g., REM) quantify sound levels in the ear canal using probe microphones, offering repeatable data that reflects the performance of the protection device [7]. However, they overlook the contribution of BC. Subjective thresholds, while more variable across individuals, are sensitive to BC influence. This study integrates both methods to evaluate the perceptual and physical aspects of attenuation under double protection and frontal sound presentation (0°).

1.4 Current Study Focus

This study investigates how double hearing protection affects auditory thresholds via both AC and BC, using a combination of objective (REM) and subjective (behavioral threshold of hearing) methods. The goal is to clarify the extent to which BC contributes to residual auditory perception when AC is substantially attenuated.
By focusing on a realistic protection configuration, earplugs combined with earmuff, the study enables a controlled and focused evaluation of auditory processing under high-attenuation conditions. This approach reduces variability related to directional hearing and protection level, allowing for a detailed analysis of the interaction between frequency, measurement modality, and the dominance of BC versus AC.
Through this design, the study aims to assess how effectively current measurement techniques capture attenuation, and to provide practical insights into the real-world performance of double hearing protection in high-noise environments.

1.5 Research Questions

1. How do objective real-ear measurements compare with subjective behavioral hearing thresholds when attenuation is assessed under double hearing protection?
2. Does the discrepancy between objective and subjective attenuation vary across frequencies?

1.6 Hypotheses

1. Subjective hearing thresholds will demonstrate less attenuation than objective REM measurements at low frequencies due to the contribution of BC pathways.
2. The gap between the subjective level of attenuation and the objective one will be most pronounced at low frequencies and will decrease at higher frequencies.

2. METHODS

2.1 Participants

Ten participants (6 female, 4 male), aged 18 to 28, with confirmed normal hearing, took part in the study. Testing was conducted at the Acoustics and Noise Research Laboratory at Ariel University. Inclusion criteria was air-conduction hearing thresholds of ≤20 dB HL between 500 and 8000 Hz. Exclusion criteria included any history of hearing loss, prolonged exposure to loud noise, or the use of ototoxic medications. The research protocol was approved by the university's ethical review board. All participants signed an informed consent before beginning the experiment.

2.2 Stimuli and Equipment

All measurements were conducted using the Interacoustics Affinity Compact system.

Objective measurements were carried out using Real-Ear Measurement (REM) module with 90 dB SPL pure-tone sweeps ranging from 250 Hz to 16,000 Hz. Sound pressure levels were recorded at the eardrum using a probe tube microphone.

Subjective hearing thresholds were obtained with the audiometer module using warble tones at 500, 1000, 2000, and 4000 Hz, as well as 1/12-octave intervals from 4000 to 12,000 Hz. Participants responded by pressing a button.

Calibration of all equipment was performed using a Brüel & Kjær Type 2250 Sound Level Meter.

All testing was performed in unoccluded condition and under double hearing protection, consisting of EasyView Otoblock earplugs and Optime 105 earmuff (see Figure 1).
Attenuation was calculated by comparing the protected condition to an unoccluded baseline for each participant, using both objective and subjective data.

Figure 1. EasyView Otoblocks by PHONAK, used as insert earplugs (left side), and Optime 105 earmuff by 3M (right side), comprising the double hearing protection configuration evaluated in the study.

2.3 Procedure

Participants completed both objective and subjective tests in a single session lasting approximately 1.5 to 2 hours. REM measurements were passive and required no response from the participant. During subjective testing, participants responded when they heard a tone, and thresholds were established using a manual audiometry protocol.
All stimuli for both objective and subjective tests were presented from a fixed sound source at 0° azimuth, positioned 50 cm infront of the participant's head.
Only the right ear was tested, while in the subjective testing, the left ear was masked at 50 dB HL using narrowband noise to eliminate cross-hearing.

2.4 Data Analysis

Due to the limited sample size, only descriptive statistical analysis was conducted. Attenuation (in dB) was examined across frequency and measurement method (objective vs. subjective). The analysis focused on identifying trends and patterns reflecting the contribution of BC under conditions of significant AC attenuation.

3. RESULTS

Mean attenuation values were analyzed across the tested frequency range, comparing objective measurements obtained through REM with subjective auditory hearing thresholds. The results depicted in Figure 2 revealed clear frequency-dependent patterns in both measurement methods, as well as systematic differences between them. Objective attenuation measurements peaked at approximately 36 dB near 3000 Hz, then gradually declined with increasing frequency, reaching a minimum of 18 dB at 12,000 Hz. Subjective attenuation showed a slightly deeper peak of around 38 dB near 4000 Hz, followed by a decrease

in attenuation to 33-40 dB at the upper end of the frequency range. At frequencies below 3000 Hz, objective attenuation exceeded subjective attenuation, whereas at higher frequencies, this pattern reversed, and subjective attenuation became greater.
This crossover pattern suggests that while objective measurements capture the attenuation of AC sound effectively, they may underestimate the perceptual influence of BC sound, particularly at higher frequencies. The divergence in attenuation levels between methods above 3000 Hz likely reflects the perceptual contributions of BC and the interaction with individual auditory sensitivity and occlusion effects.

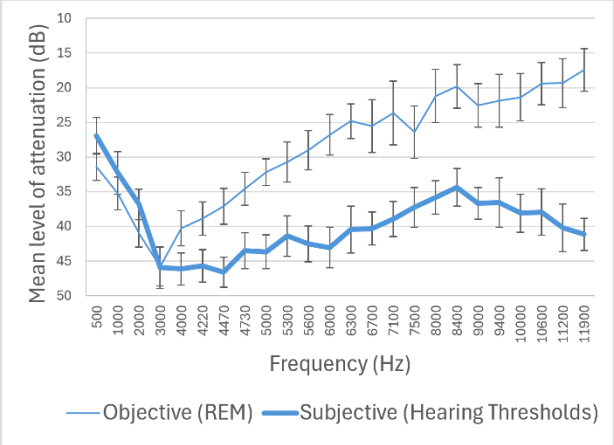

Figure 2. Mean attenuation (in dB) across frequencies, comparing objective REM (thin line) and subjective hearing thresholds (thick line). Measurements were conducted under double hearing protection. Error bars represent standard errors of the mean for each data point. (n=10)

4. DISCUSSION

The results of this study demonstrate clear differences between objective and subjective measurements of sound attenuation, with distinct frequency-dependent patterns. Objective attenuation levels peaked around 3000 Hz and decreased at higher frequencies, while subjective attenuation remained elevated beyond that frequency. This crossover at 3000 Hz may reflect the combined contributions of AC and BC to auditory perception under occluded conditions and aligns with earlier findings [4] showing that the limits of attenuation are set by the BC pathway even under maximal occlusion.

4.1 Dominant Sound Conduction Pathway

In conditions of high attenuation, such as those created by double hearing protection, the AC pathway is substantially reduced, allowing BC to play a more dominant role in perception. While objective REM primarily capture sound pressure levels in the ear canal and are largely AC-dependent [7], subjective thresholds reflect the listener's full perceptual experience, including the effects of BC transmission [23-]. The relatively higher objective attenuation at low frequencies, as compared to the lower subjective thresholds, supports the interpretation that BC continues to transmit sound effectively in this range. These findings are consistent with previous work showing that sound transmission via BC becomes the primary pathway under occluded conditions [3]. At higher frequencies, where subjective attenuation surpasses objective values, individual variability in skull vibration transmission or the auditory system's non-linear characteristics may contribute to perceptual differences not captured by physical measurements [2].
Moreover, it is well established that REM may underestimate BC influence, particularly under conditions involving strong occlusion and internal physiological noise [5]. This limitation underscores the value of using both objective and subjective measures to fully characterize hearing protection performance.

4.2 Stimulus Type Effects

The observed discrepancies between measurement modalities may also stem from differences in stimulus characteristics. Warble tones, used for subjective testing, minimize standing wave formation and provide a more perceptually stable signal, whereas the pure-tone frequency sweeps used in REM are more prone to standing waves and acoustic leakage artifacts [6]. These differences may partly explain the crossover effect between objective and subjective data observed in the present study.
Similar concerns have been raised in clinical hearing aid studies, where REM did not always predict perceptual performance, particularly when complex acoustic interactions were present [7]. Aligning the acoustic properties of the stimuli used in both measurement methods could help isolate the effect of stimulus type on attenuation results and improve the comparability between modalities in future work.

4.3 Limitations and Future Work

As a preliminary study, several limitations should be acknowledged. The sample size was modest, limiting the generalizability of the findings. Additionally, while the study design intentionally focused on a single hearing protection configuration and a fixed sound source direction to allow for controlled analysis, this necessarily reduced ecological variability. Future research should expand the sample population, explore additional hearing protection configurations, and investigate multiple azimuth angles to better simulate real-world listening environments. It is also recommended to further investigate the separate contributions of AC and BC. Finally, standardizing the stimulus type across both objective and subjective measurements could reduce methodological variance and improve the comparability of findings across modalities.

5. CONCLUSION

This study demonstrated clear, frequency-dependent differences between objective (REM) and subjective (threshold-based) measurements of sound attenuation under occluded conditions. A crossover pattern was observed around 3000 Hz, where objective attenuation peaked and then declined, while subjective attenuation remained elevated. These findings highlight the dominant role of bone conduction when air conduction is suppressed and underscore the limitations of relying solely on objective physical measures. Differences in stimulus type also contributed to the divergence between methods, reinforcing the need for methodological alignment. Overall, the integration of both objective and subjective assessments is essential for accurately evaluating hearing protection performance in high-attenuation environments.

6. ACKNOWLEDGMENTS

We extend our gratitude to the undergraduate students from the Department of Communication Disorders at Ariel University for their dedication and effort in data collection.

ABSTRACT

Noise-induced hearing loss (NIHL) poses a serious risk to individuals exposed to high-intensity sounds, particularly military personnel and industrial workers. While hearing protection devices (HPDs) like foam earplugs mitigate NIHL, they often impair sound localization and speech intelligibility. This study investigates the sound-enhancing-connection-tube (SECT), a prototype perforated tube connected to the opening of two vented earplugs, designed to adjust attenuation across frequencies for improving sound localization while preserving protective benefits. Using head-related transfer functions (HRTF) to measure sound pressure at the position of the eardrum, the study evaluated SECT effects on the 1–4 kHz range, critical for speech and environmental sounds.

The research involved three experiments: HRTF-based optimization of SECT design using a head-and-torso-simulator (HATS) and two human trials to assess localization performance. HATS results demonstrated up to 15 dB less attenuation for frequencies above 800 Hz when the SECT was used with vented earplugs compared to just earplugs. However, human trials showed no significant localization improvement. Differences may stem from how the human brain processes complex auditory cues, bone and tissue conduction effects absent in HATS, and potential sound loss through SECT connectors. Future research should prioritize live-subject guided training to address these limitations.

1. INTRODUCTION

Noise-induced hearing loss (NIHL) results from exposure to high-intensity sound, with prolonged noise above 85 dB posing significant risks [1]. Military personnel are especially vulnerable due to exposure to loud engine noise, gunfire, and explosions [2; 3]. Other at-risk populations include construction workers and factory laborers. NIHL can develop gradually, impairing communication and necessitating assistive devices like hearing aids [4; 5].

Hearing protection devices (HPDs) help mitigate NIHL by attenuating harmful noise levels. Linear HPDs, such as foam earplugs, reduce sound evenly across frequencies but may impair speech intelligibility and sound localization [6; 7]. Non-linear HPDs, in contrast, adjust attenuation based on intensity, allowing softer sounds to pass through while blocking louder noises [8]. However, even non-linear HPDs can interfere with localization cues by altering ear acoustics or blocking pinna effects, leading to degraded spatial hearing and increased cognitive effort for speech comprehension [9; 10; 11].

To address these limitations, this study examines a prototype sound-enhancing connection tube (SECT), designed to improve localization while maintaining noise attenuation. The SECT consists of a perforated tube

integrated with non-linear earplugs, allowing controlled attenuation similar to a woodwind instrument. Pilot studies [12; 13; 14] suggest SECT may improve speech intelligibility while retaining noise-blocking properties, though optimal design parameters remain unclear.

A head-related transfer function (HRTF) was used to assess how SECT impacts sound transmission. Initial HRTF measurements on a head and torso simulator (HATS) established baseline effects of occlusion. This study aims to determine SECT parameters that minimize attenuation in the 1-4 kHz range, critical for speech and firearm sounds.

This study's objectives were:

1. To determine which combination of SECT parameters, such as the number and spacing of perforations, leads to a significant difference in the HRTF with an earplug with the tube compared to an earplug without the tube.
2. To test whether individuals demonstrate improved sound localization when using the SECT with a non-linear HPD compared to using the non-linear HPD alone.

We hypothesized that

1. The HRTF measurements for ears occluded with the SECT will show less attenuation in the 1-4 kHz range compared to the occluded condition without the SECT.
2. Individuals using the SECT in combination with two perforated earplugs will show improved sound localization compared to the perforated earplugs alone but will still perform worse than in the unoccluded condition.

Study Overview

The research consists of three experiments:

- Experiment 1: HRTF measurements to analyze SECT design variations.
- Experiment 2: Wideband sound localization tests.
- Experiment 3: Narrowband sound localization tests.

Results will be discussed with implications for future HPD development.

2. EXPERIMENT 1

2.1 Introduction

A HATS is a system designed to replicate the acoustic properties of the human head, torso, and ear canals. It consists of an artificial head and torso with microphones embedded at the eardrum position, allowing researchers to analyze how sound is perceived in different conditions. HATS are widely used in audio research, particularly for testing hearing protection devices (HPDs) [15].

This experiment aimed to optimize the design of the SECT by identifying a configuration that minimizes attenuation in the critical 1-4 kHz frequency range. This range is important for speech perception and identifying key sounds such as rifle fire. Using a HATS setup, we tested various SECT designs to determine the combination of perforation spacing that would allow the best preservation of these frequencies.

2.2 Method

2.2.1 Tools

The experiment was conducted using a GRAS 45BC KEMAR HATS equipped with GRAS 46BD ¼" microphones at the ear canal positions. The HATS was powered by a GRAS 12AX 4-Channel CCP Power Module. Sound was generated using Sinus Samurai software and transmitted through an RCF Ayra 5 monitor, while measurements were analyzed using the same software. A GRAS 146AE rugged ½" reference microphone was placed near the tragus to record the original signal before it reached the ear.

2.2.2 Process

A pure tone sweep (100-12,800 Hz) was played from a monitor positioned 1 meter in front of the HATS at 0° azimuth. The sound level was set to 54 dB[A] at the reference microphone. The sound pressure level (SPL) recorded by the eardrum microphones was compared to the reference microphone to calculate the HRTF. This process was repeated using different SECT designs, with variations in perforation spacing, until a configuration was identified that minimized attenuation in the 1-4 kHz range. The setup we used for this stage of the study can be seen in Figure 1.

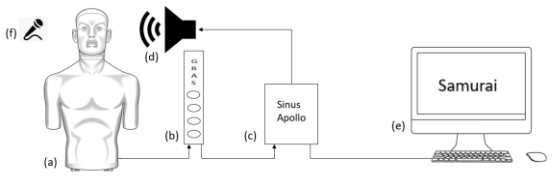

Figure 1. The setup used in Experiment One consisted of (a) KEMAR HATS with embedded microphones in ear canals, (b) Power module (c) Sinus Apollo Light, (d) monitor, (e) laptop with Sinus Samurai software, (f) reference microphone.

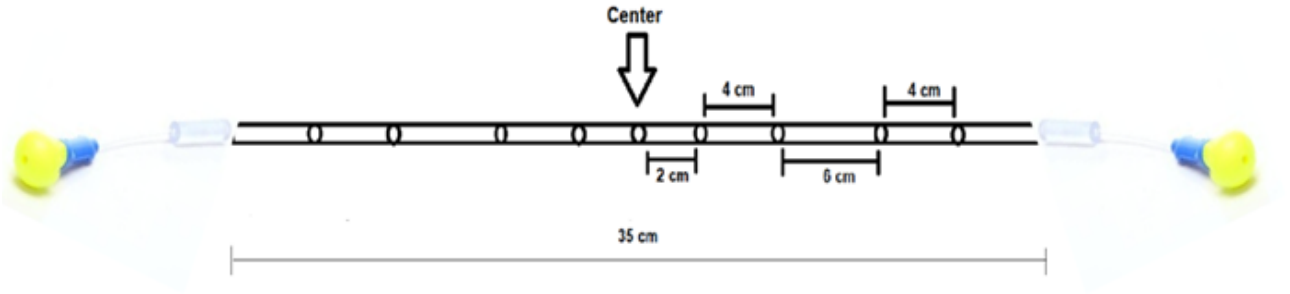

Figure 2. An illustration of the dimensions of the final SECT design used in this study. Earplugs are attached to either side of the SECT

2.3 Results

The optimal SECT design was determined by evaluating the effects of perforation spacing across three prototype tubes (2 cm, 4 cm, and 6 cm spacing). Each design produced frequency-specific attenuation reductions, with the 6 cm spacing showing the least attenuation at 1200 Hz, the 4 cm spacing at 2000 Hz, and the 2 cm spacing at 3000 and 5000 Hz. To incorporate the benefits of all three designs, a final SECT model was developed with perforations at progressively increasing distances from the tube's center (2 cm, 4 cm, and 6 cm), as seen in Figure 2.

2.4 Discussion

The results indicate that incorporating a perforated tube into earplugs alters the HRTF in a way that may enhance sound localization. By reducing attenuation in the 1-4 kHz range, the SECT allows more auditory cues to reach the ear, potentially improving the perception of speech and other critical sounds. This suggests that a properly configured SECT could provide a balance between hearing protection and environmental awareness. This hypothesis was further tested in subsequent human experiments, which assessed whether these modifications led to actual improvements in sound localization performance.

Figure 3. The SECT affixed to a helmet and connected to earplugs.

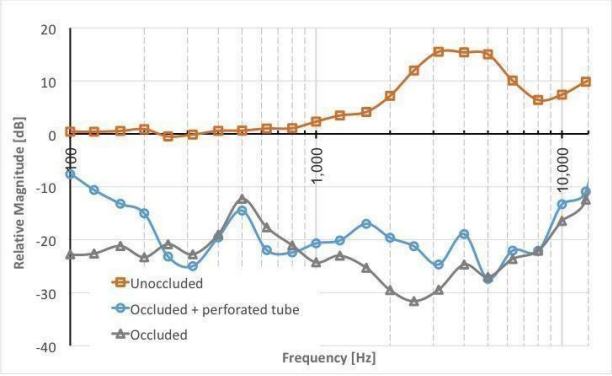

Figure 4. HRTF of the unoccluded condition (orange squares), the occluded condition (gray triangles) and the occluded + perforated tube (blue circles) condition.

3. EXPERIMENT 2

3.1 Introduction

Following the selection of the final SECT design, the next phase of the study tested its effect on human sound localization ability. Soldiers frequently report avoiding the use of HPDs in combat due to their negative impact on localizing sounds such as gunfire and spoken commands [16; 17]. To address this issue, we assessed localization performance using stimuli relevant to combat scenarios. It was hypothesized that the SECT would improve localization compared to standard push-in earplugs but would still perform worse than an unoccluded condition.

3.2 Method

3.2.1 Participants

Fourteen university-aged participants (9 female, 5 male; aged 21–29, mean = 23.9) took part in the study. All had normal hearing and no history of learning or attention disorders. Participants were compensated either monetarily or with course credit.

3.2.2 Tools

Sound stimuli were presented through eight RCF Ayra 5 monitors arranged in a circle around a central chair at a 1.8-meter radius. The speakers were positioned at azimuths of 22.5º, 67.5º, 112.5º, 157.5º, 202.5º, 247.5º, 292.5º, and 337.5º, with 0º representing directly in front of the participant. Responses were recorded via a touchscreen tablet displaying a circular interface, where participants tapped their perceived sound source location. More information about the tools can be found in Fostick and Fink (2021) [10].

3.2.3 Stimuli

Four stimuli were used: the Hebrew word “esh” (fire), a pink noise burst, a single M16 rifle shot, and three M16 shots fired in quick succession. All stimuli were presented at 75 dB SPL.

3.2.4 Procedure

Each participant sat in the center of the speaker array with a tablet on their lap. Each stimulus was presented ten times per speaker for a total of 320 trials (4 stimuli × 8 speakers × 10 repetitions). Stimulus order and speaker presentation were randomized. Each participant completed the experiment under three conditions:

1. Unoccluded (no HPD)
2. Occluded (3M™ E-A-R™ Push-Ins™ Earplugs)
3. SECT condition (SECT attached to 3M™ E-A-R™ Push-Ins™ Probed Test Plugs)

The order of conditions was randomized to prevent fatigue or learning effects. After each stimulus, participants tapped on the tablet to indicate the perceived sound source location. Regular breaks were provided. The research protocol was approved by the university’s ethical review board. All participants signed an informed consent before beginning the experiment.

3.3 Results

Root Mean Square Error (RMSE) was used to assess localization accuracy by measuring the difference between perceived and actual sound azimuths. A three-way ANOVA revealed a significant main effect for condition (unoccluded, occluded, occluded + SECT) ($F(2, 26) = 27.06$, $p < 0.001$, $\eta^2 = 0.675$), stimulus type ($F(3, 39) = 3.38$, $p = 0.028$, $\eta^2 = 0.206$), and speaker position ($F(1.49, 19.33) = 21.06$, $p < 0.001$, $\eta^2 = 0.618$).

Post hoc comparisons revealed that localization accuracy was best in the unoccluded condition, followed by the occluded condition, with the SECT condition yielding the highest RMSE (poorest localization). No significant differences were found between stimuli. RMSE was highest for stimuli from the rear (157.5° and 202.5°) and lowest for front-hemifield locations (22.5° and 337.5°).

A significant interaction was found for condition × speaker position ($F(14, 182) = 8.518$, $p < 0.001$, $\eta^2 = 0.396$) (Figure 5), but no significant interactions were observed for condition × stimulus ($p = 0.072$) or stimulus × speaker ($p = 0.179$).

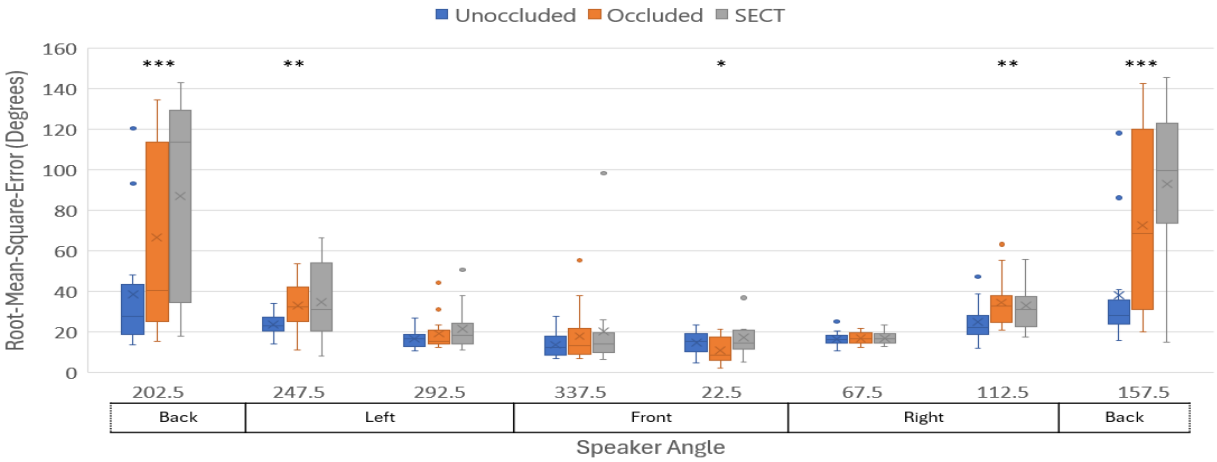

Figure 5. Interaction between condition and speaker angle for RMSE. *p<0.05 between (unoccluded, occluded); (occluded, SECT). **p<0.05 between (unoccluded, occluded); (unoccluded, SECT). ***p<0.05 between (unoccluded, occluded); (unoccluded, SECT); (occluded, SECT).

3.4 Discussion

After testing 14 participants, data analysis revealed no localization advantage for the SECT over standard occluded conditions. While speaker angle effects were consistent with previous findings [10], the SECT failed to enhance localization across the tested stimuli.

One possible explanation is the complexity of the stimuli's frequency content. The SECT was designed to reduce attenuation in the 100–250 Hz and 900–5000 Hz ranges, but its performance was initially measured at a 0° angle. Given that the localization task involved stimuli from multiple angles, SECT's effectiveness may not have translated across all directions, leading to its underperformance compared to expectations.

4. EXPERIMENT 3

4.1 Introduction

Experiment 3 aimed to simplify the stimuli from Experiment 2 in order to more accurately assess the SECT's effectiveness. Additional HRTF measurements were taken from a wider range of sound source angles (22.5°, 67.5°, 112.5°, and 157.5°) to identify which frequencies would most benefit from the SECT apparatus. Based on these measurements, two narrow-band stimuli were selected: a low-frequency stimulus (500-600 Hz) and a higher-frequency stimulus (1200-1600 Hz). These new stimuli are represented visually in Figure 6. The hypothesis was that the SECT would improve sound localization performance for the higher-frequency stimulus, but not for the lower-frequency stimulus. It was also expected that the unoccluded condition would outperform the other conditions for both stimuli.

4.2 Methods

4.2.1 *Participants*

Twenty participants (10 female, 10 male, aged 21-32, mean age 25.7) were recruited for this experiment, with inclusion and exclusion criteria identical to Experiment 2.

4.2.2 *Tools*

The same equipment used in Experiment 2 was employed for this stage of the study.

4.2.3 *Stimuli*

Two narrow-band noise bursts were used as stimuli: a low-frequency stimulus (500-600 Hz) and a high-frequency stimulus (1200-1600 Hz). Each burst lasted 250 ms and was presented at 75 dB SPL. The stimuli were delivered from 8 speakers at randomized positions around the participant.

4.2.4 *Procedure*

The experiment followed the same procedure as Experiment 2, with participants seated in front of 8 monitors. Each stimulus was presented 10 times from each speaker, totalling 160 presentations. The experiment

included the same three conditions: unoccluded, occluded, and SECT. The research protocol was approved by the university's ethical review board. All participants signed an informed consent before beginning the experiment.

4.2.5 *Data Analysis*

A three-way ANOVA was performed to assess the effects of condition, stimulus, and speaker on Root Mean Square Error (RMSE). Main effects and interactions were analyzed to determine how these variables influenced sound localization accuracy.

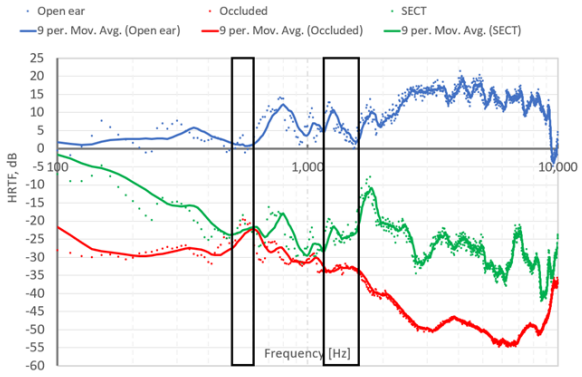

Figure 6. HRTF measurements averaged for stimuli presented from angles of 22.5º, 67.5º, 112.5º, and 157.5º for the unoccluded (blue), occluded (orange), and occluded with SECT (green) conditions. The areas encompassed by the black rectangles indicate the frequency ranges contained in the low-frequency narrow-band stimulus (500-600 Hz) and the high-frequency narrow-band stimulus (1200-1600 Hz) that were used to derive the two narrow sound burst stimuli for Experiment 3.

4.3 Results

A three-way ANOVA revealed significant main effects for both the condition ($F(2, 38) = 42.3$, $p < 0.001$, $\eta^2 = 0.69$) and speaker ($F(1.8, 34.18) = 41.14$, $p < 0.001$, $\eta^2 = 0.684$). There were also significant interactions between condition and stimulus ($F(2, 38) = 4.493$, $p = 0.018$, $\eta^2 = 0.191$), condition and speaker ($F(3.442, 65.39) = 10.867$, $p < 0.001$, $\eta^2 = 0.364$) (Figure 7), and stimulus and speaker ($F(3.905, 74.187) = 2.906$, $p = 0.028$, $\eta^2 = 0.133$). These results highlight that the experimental condition, speaker position, and stimulus type all influenced the RMSE in sound localization accuracy.

4.4 Discussion

The results from Experiment 3 showed that altering the stimuli to focus on low- and high-frequency ranges did not improve performance with the SECT, as hypothesized. While the high-frequency stimulus was expected to benefit from the SECT, no significant difference was found between the SECT and occluded conditions. These findings diverged from those of Villian & Cement (2020) [12], who observed better localization performance with SECT designs compared to standard earplugs. The discrepancy may be due to differences in earplug types used between the two studies (3M Ear Classic vs. 3M™ E-A-R™ Push-In™), and the different methods of performance analysis (RMSE vs. average angle error).

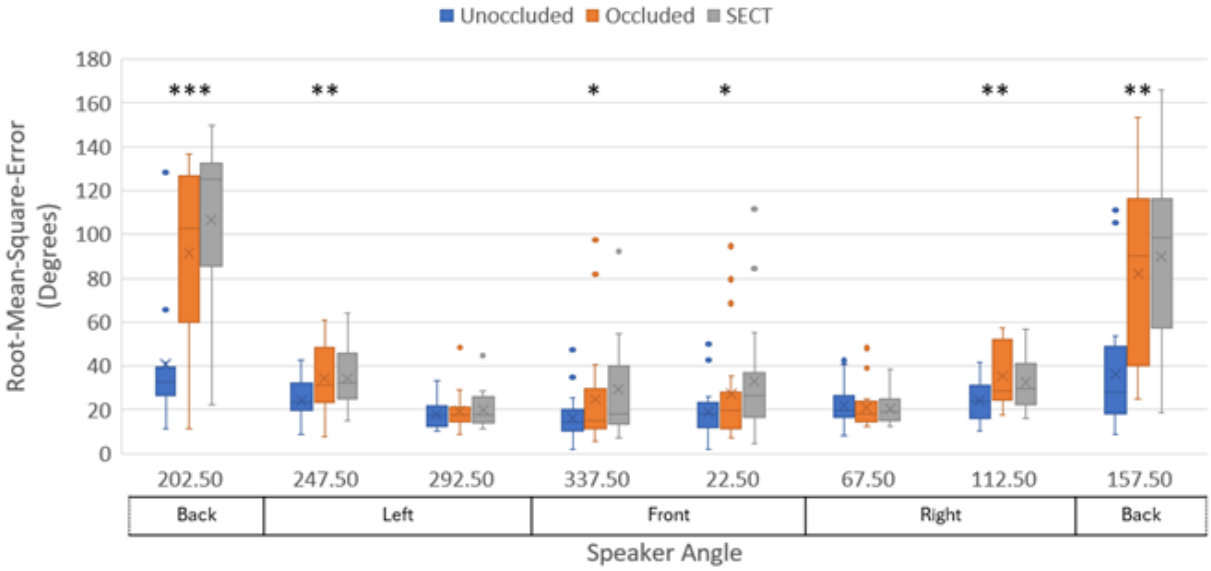

Figure 7. Interaction between condition and speaker angle for RMSE. *p<0.05 between (unoccluded, SECT). **p<0.05 between (unoccluded, occluded); (unoccluded, SECT). ***p<0.05 between (unoccluded, occluded); (unoccluded, SECT); (occluded, SECT).

5. GENERAL DISCUSSION

This study was conducted to create the SECT, a perforated air tube connected to two non-linear perforated earplugs, that would allow for improved sound localization abilities when compared to standard Push-Ins earplugs. HRTF measurements were performed on a HATS to determine which tube parameters allowed for the least amount of attenuation at the 1-4 kHz frequency range, chosen for its inclusion in spoken language as well as dominance in gunfire sound. This design was then tested on human subjects in a sound localization task. Upon analyzing the results, we found no significant statistical difference between the occluded condition and the SECT condition, contrary to our hypothesis. However, as predicted, the unoccluded condition displayed better performance than both occluded conditions.

There are several possible explanations for the discrepancy between the HATS results and the results received in experiments with human subjects. One possibility is based on how the human brain processes and interprets incoming stimuli. Whereas none of these occur within the HATS, typically, the brain processes two sound signals, one reaching each ear, and uses the interaural time and intensity differences to aid in localization, as well as acoustic factors such as the pinna effect [18]. However, the addition of the SECT introduces numerous sound signals to both ears through each of the perforations along the length of the SECT. The arrival of multiple similar stimuli simultaneously may inhibit the brain's ability to differentiate between them effectively [19]. Supervised training using the SECT followed by retesting the sound localization capabilities may lead to improved results. Indeed, Casali & Robinette (2015) [20] showed that training sessions can lead to improved performance in sound source localization tasks while wearing HPDs.

It is also possible that the passage of sound waves through the T-connectors and into the thinner probe tubes located within the perforated ear plugs may weaken sound levels at certain frequencies that would otherwise provide critical information.

Another possible cause for this study's results is the impact of bone and tissue conduction (BTC). The HRTF measurements obtained in the first stage of this study possess only air conduction pathway capabilities. However, the human cochlea also receives sound waves that propagate to the cochlea through the subject's body tissues and bones, which are not measured on the HATS. When HPDs are used, such as those used in conjunction with the SECT, sounds arriving through air conduction are attenuated, thus allowing BTC sounds to dominate the auditory experience. Thus, it may be necessary to

reconsider the way in which the SECT's final design was created. Instead of using a HATS, the HRTF measurements should be performed on a human subject so that the influence of the BTC can be taken into consideration.

6. CONCLUSIONS, LIMITATIONS AND FURTHER RESEARCH

In conclusion, this study explored the potential of the SECT, a perforated air tube connected to non-linear earplugs, to improve sound localization while providing adequate noise attenuation. The SECT design was based on HRTF measurements obtained from a HATS, with the goal of preserving frequencies essential for speech recognition and sound localization in the 1-4 kHz range. However, human trials did not confirm a significant improvement in localization with the SECT compared to standard occluded conditions, despite successful attenuation characteristics in HATS testing. This suggests that while the SECT concept is feasible, the current design may require further optimization to align with natural hearing cues and individual auditory processing mechanisms.

A few limitations may have influenced these outcomes. The study relied on HATS for initial HRTF measurements, which, while precise for acoustic modeling, cannot fully replicate the nuances of human auditory processing. Specifically, the HATS cannot simulate binaural processing and other brain functions that aid in sound localization, such as interaural time differences and the pinna effect. Moreover, the SECT design might introduce competing sound signals due to its perforations, potentially causing interference that limits sound source differentiation. Another important factor is the effect of BTC on hearing perception, which the HATS model does not capture. Human listeners experience BTC in conjunction with air-conducted sound, and the lack of BTC in testing could mean that significant aspects of sound transmission and localization were overlooked.

Future research could benefit from HRTF measurements conducted directly on human subjects to incorporate BTC effects, as well as from additional training protocols to help participants adapt to the SECT's unique signal presentation. These adaptations may enhance the SECT's effectiveness and provide clearer insights into its potential benefits for hearing protection and sound localization.

DESIGN AND ANALYSIS OF MOBILE MICROPHONE ARRAYS FOR ACOUSTIC DRONE TRACKING

Martin Blass* **Franz Graf**
JOANNEUM RESEARCH Forschungsgesellschaft mbH
DIGITAL – Institute for Digital Technologies

ABSTRACT

The growing security threat posed by hostile drones (UAVs) highlights the urgent need for effective detection systems. Besides optical, radar or radio frequency systems, the acoustic domain offers significant but underutilized capabilities. Since human hearing is inherently limited in detecting and localizing weak or high-frequency sounds in noisy or dynamic environments, microphone arrays represent a significant improvement in tracking drone noise. In the literature, most of the existing acoustic systems are stationary and focus on the detection or localization of individual drones. The integration of mobile microphone arrays on vehicle roofs or soldier helmets can enhance military capabilities by enabling real-time tracking of drones in diverse and challenging scenarios. In this paper, we present the design criteria and development of a practical microphone array system capable of detecting and tracking multiple drones. First, we describe the implementation of a hemispherical array of 32 microphones. Then, we consider possible adaptations, e.g. in terms of reducing the number of microphones by selecting subarrays to address low-power consumption considerations and real-time processing for sound source localization. Finally, we show experimental results of a dataset recorded in a fixed and mobile scenario where the microphone array was mounted on a vehicle roof.

1. INTRODUCTION

Within the recent years, drones and other UAVs have become an established technology in the fields of industrial surveillance, disaster management, public safety, logistics, agriculture and smart cities, to name a few. As commercial drones are available at low cost and do not require explicit expertise, they can also easily be used to intentionally or accidentally violate privacy, cause public nuisance through noise, or even pose a threat to society or public institutions when used as a means of attack. Recent military conflicts, such as those in Ukraine and the Middle East, along with increasing drone-related incidents, highlight the need for effective countermeasures against UAV threats. To enhance civilian security and military defense, numerous research projects and counter-UAV technologies have emerged, employing multi-sensor approaches that integrate radar, computer vision, radio frequency, and acoustic detection [1,2]. While often overlooked due to range limitations, acoustic sensing provides a cost-effective and essential tool for UAV detection, especially in scenarios where other modalities face challenges. Microphone arrays, in particular, offer a practical and low-cost solution for determining the incident angles of sound sources, e.g. drones, within a limited range and hemispheric coverage [3].

In order to localize drone sounds in terms of their incident direction, microphone arrays enable the use of direction-of-arrival estimation (DOAE) and beamforming (BF) methods [4]. In addition, sound source tracking algorithms may be applied to process frame-based DOA estimates and to reconstruct movements of multiple sound sources. In [5] a large microphone array with 64 microphones and 4 m diameter was placed on the ground and used to compare three DOAE algorithms: GCC-PHAT, conventional delay-and-sum BF and differential evolu-

tion. Successful localization results were obtained within 80 m. In [6] a 16-channel L-shaped array was chosen together with MUSIC as DOAE method for narrowband, broadband and proposed harmonic focus (2-6 kHz) scenarios. The authors of [7] investigated DOAE using incoherent and proposed coherent BF performed with a 64-channel MEMS microphone array in simulations and outdoor experiments within a range of 200 m. Similar contributions were published in [8, 9].

There is only a limited amount of publications combining both detection and localization to address the sound source association problem to successfully track UAVs while rejecting other sound sources. One promising example is described [10], where UAV noise recorded with a spherical microphone array is used to train a so called *BeamLearning-ID* network to mimic the BF process. Another joint detection and localization approach is described in [11]. In our previous works [12, 13] we presented a framework that enables the joint detection and localization of sound emitted by multiple UAVs in real-time. Similar to [11] we proposed a track-before-detect approach, where multiple hypotheses are generated using a GMM-based sound source tracking algorithm together with a classical ML model relying on drone specific audio features. To the best of our knowledge, our latest paper [13] is one of the first to address mobile UAV tracking, which is of great importance for military applications in view of the global geopolitical situation.

Wearable microphone arrays have been explored for various applications, including sniper detection, situational awareness, and sound event localization. [14] developed a helmet-mounted array for sniper detection, capable of real-time localization by analyzing Mach and muzzle waves from rifle shots. Their system demonstrated robust performance in urban environments with low false alarm rates. [15] presents a similar system with focus on determining the optimum number and position of microphones on a helmet by taking into account diffraction paths and intensity differences. [16] introduced a conformal helmet-mounted array designed to enhance auditory situational awareness while providing hearing protection. Their system integrates BF with head-related transfer functions to maintain spatial hearing and natural localization of sound sources despite protective headgear. [17] focused on a wearable sound event localization and detection (SELD) dataset, using 24 microphones placed on head-worn accessories like glasses and earphones. They evaluated deep learning-based SELD methods, showing that microphone positioning significantly impacts localization accuracy.

In this paper, we want to explore ways to enhance the efficiency of acoustic drone tracking for mobile applications in terms of reducing energy and computational requirements by tuning the number of sensors and the geometry of microphone arrays. First, we present the design and development of *JR-IcoDome32*, a hemispherical 32-channel microphone array that can be deployed in fixed or mobile scenarios, e.g. on vehicle roofs. Second, we analyze a scaled version that could be suitable as a human-worn sensor, e.g. integrated into a soldier's helmet. Then, we derive sub-arrays from the *JR-IcoDome32* to compare their DOAE performance. Finally, we evaluate these array configurations using a dataset collected during measurement campaigns for a fixed and a mobile scenario where the microphone array was placed on the ground and mounted on the roof of a vehicle.

The remainder of this paper is organized as follows: Section 2 explains the microphone array design process including sub-array configurations and the methods used for DOAE and sound source tracking, Section 3 describes the sensor system development and hardware integration, Section 4 presents the experimental setup and results, and Section 5 concludes the work with a future outlook.

2. METHODOLOGY

2.1 Microphone Array Design

Based on the existing knowledge of typical drone sounds and the requirements for mobile application [12, 13], we designed a microphone array suitable for the task of UAV localization: The array should have a rotationally symmetrical directional characteristic, be rigid, lightweight and weatherproof. In addition, a high directivity in the frequency range below 3 kHz and an attenuation of noise below the array in mobile operation (e.g. car engine, rolling noise) should be achieved, which led to a 3D geometry in the design process. The result is a geodesic dome of the type *Icosahedron V2* with a diameter d of 1 m and 26 microphones. By adding 6 more sensors in the base plane, 5 as a pentagon and one in the center, we obtain a 32-channel configuration, of which 16 sensors are placed in 2D and 3D, respectively. In the following we refer to this microphone array as *JR-IcoDome32*. Figure 1 shows the proposed array geometry with microphone positions as connected icosahedron edges and Figure 2 the resulting simulated spatial response given as point spread functions (PSF) for selected octave-band center frequencies and summed over the total frequency range up to 16 kHz.

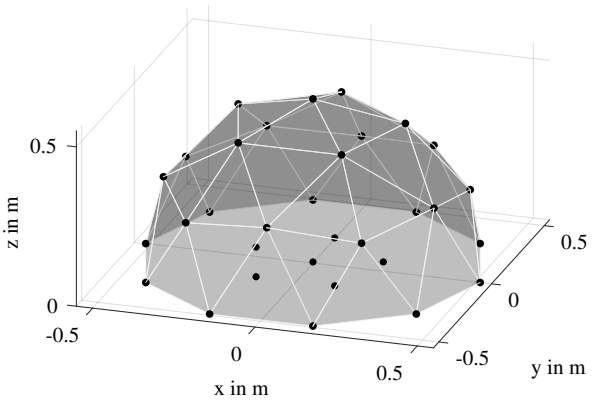

Figure 1: Array geometry of *JR-IcoDome32*.

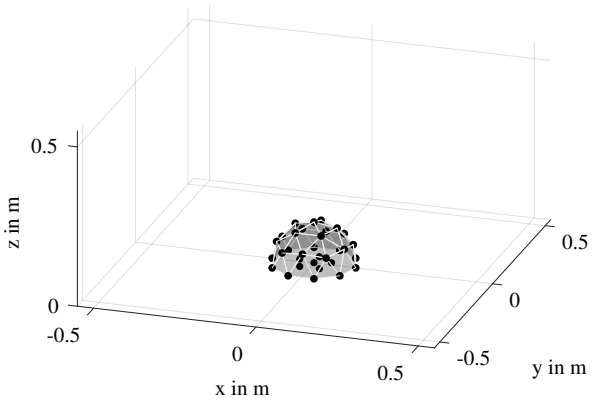

Figure 3: Array geometry of *JR-IcoDome32S*.

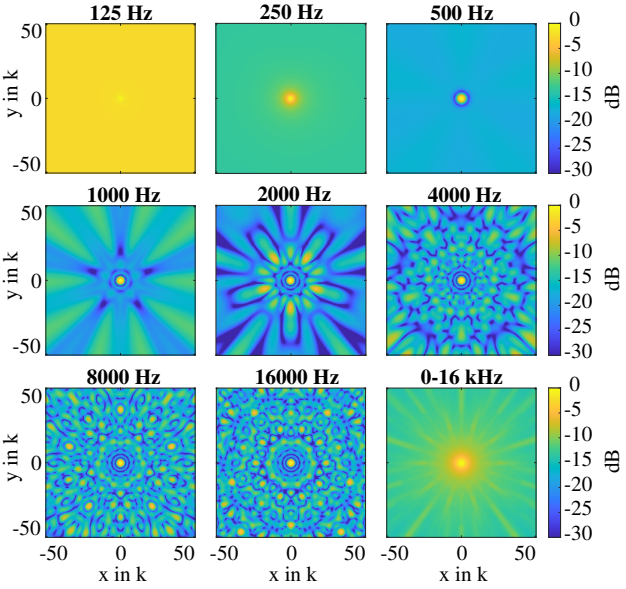

Figure 2: Spatial response as point spread function (PSF) of *JR-IcoDome32* for selected frequencies.

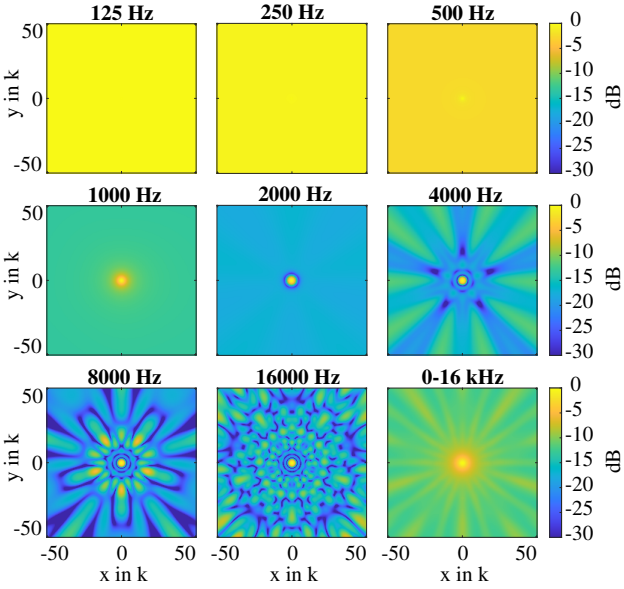

Figure 4: Spatial response of *JR-IcoDome32S* as a scaled version of *JR-IcoDome32* by a factor of 1/4.

In order to visually focus on the inspection of sidelobe levels while maintaining a constant mainlobe width, spatial grids of the simulated beam patterns are normalized by the wavenumber k, defined as $k = 2\pi/\lambda$, where λ denotes the wavelength. We choose a grid size of $k = 100$ in the scanned xy-plane at $z = d/2$, i.e. 0.5 m, over the array for evaluated frequencies. This leads to effective elevation angles of 1° and 71° for 125 Hz and 16 kHz, respectively.

Since we are not only interested in mobile applications for vehicles but also in portable and wearable sensor solutions, e.g. helmet arrays, we explore the spatial characteristics of a smaller scaled version of the *JR-IcoDome32*. For this purpose, we scale the array by a factor of 1/4 to obtain an aperture of $d = 0.25$ m, *JR-IcoDome32S*, which fulfills the requirements of being easily portable and fitting on a helmet. To make a fair com-

parison, we leave the geometry as it is and do not remove the six sensors inside the dome structure, which would be necessary when mounting the array on a helmet. Figures 3 and 4 show the geometry and spatial response results of *JR-IcoDome32S* for the same frequencies as shown for the original array configuration in Figure 2. Due to the scaling process, we observe that the same PSF patterns reappear at four times the frequency compared to *JR-IcoDome32*.

The rotational symmetry of the array allows us to easily derive sub-arrays from the original *JR-IcoDome32* geometry, called *dome32* for short: *base16* (2D) and *dome06*, *dome11*, *dome16* (3D). These configurations are shown in Figure 6 and are evaluated in terms of common array performance metrics in Table 1: f_{min} and f_{max} denote the theoretical, aliasing-free frequency range based on $\lambda/2$, HPBW is the half-power beamwidth, MSL and ASL are the maximum and average sidelobe levels, resp., and DI stands for the directivity index [4]. For this evaluation we use 201x201 points in k and average metrics over third-octave band center frequencies in 100-20000 Hz.

Table 1: Array metrics of *JR-IcoDome32* sub-arrays averaged over third-octave band center frequencies.

Metric	*dome06*	*dome11*	*dome16*	*base16*	*dome32*
f_{min} (Hz)	333	206	191	167	167
f_{max} (kHz)	2.80	3.68	5.28	7.21	19.73
HPBW (°)	25.94	21.49	22.89	21.13	21.80
MSL (dB)	-3.02	-3.95	-5.54	-7.95	-7.86
ASL (dB)	-5.53	-7.94	-9.64	-11.96	-13.02
DI (dB)	6.24	8.56	9.88	10.04	12.25

2.2 Direction-of-Arrival Estimation

As a DOAE algorithm we adapted a Gaussian Mixture Model (GMM)-based approach for clustering steered response power (SRP) estimates of a delay-and-sum beamformer with custom FFT frequency and spatial scanning grid settings as proposed in our previous work [12]. This enables probabilistic modeling, tracking of an unknown number of sound sources and source extraction using masked BF signal outputs. The algorithm provides good localization accuracy even with coarse scanning grids and the computational load enables real-time application. Details about the original algorithm can be found in [18].

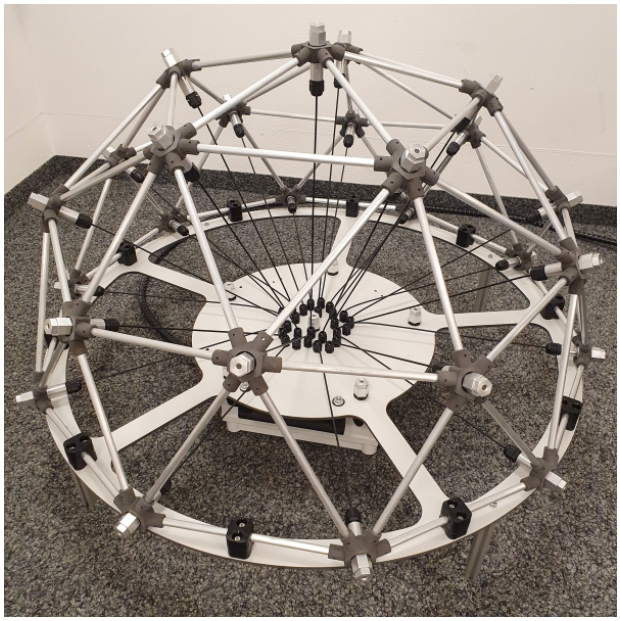
2.3 Sound Source Tracking

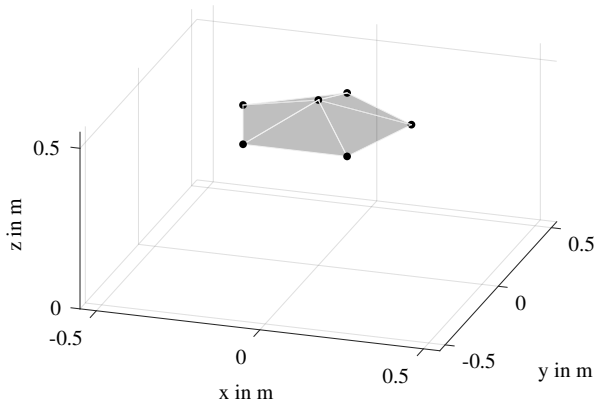
To track potential sound source candidates based on DOA estimates, we use a simple but effective tracking approach to propagate GMM parameters over time as described in [18]: Since the number of active sources may change from frame to frame, each source candidate is assigned a time-to-live (TTL) as soon as it appears. The tracking algorithm then handles the three cases of birth, update and death of up to Q active sources. The birth of a source is controlled by a predefined source confidence threshold γ derived from the GMM parameters $\mathbf{\Sigma}$ and P, as well as by the shrink threshold Υ, i.e. the minimum angular separation between two sources. By using an age-token-based temporal smoothing method, the source locations $\hat{\boldsymbol{\theta}}$, the covariances $\mathbf{\Sigma}$ and the weights P are updated over time.

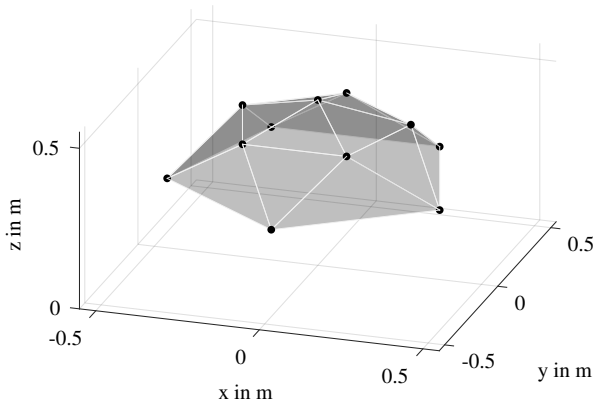
3. SENSOR SYSTEM

3.1 Microphone Array and Audio Hardware

The implementation of the array design *JR-IcoDome32* as described in Section 2 uses a rigid construction with a 6 mm solid plastic base plate and aluminum struts with 3D-printed corner connectors. ICP electret microphones with suitable signal conditioning and A/D converters were preferred over MEMS microphones due to better signal quality and less development effort in the hardware design. All components provide an IP67-rating to protect the sensors from water and dust. Figure 1 shows the final implementation of *JR-IcoDome32*.







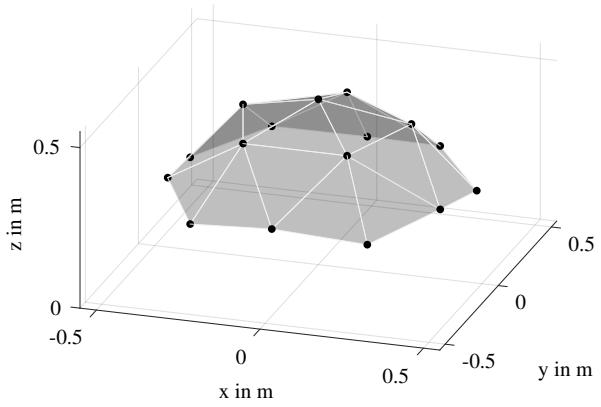


Figure 5: 3D microphone array *JR-IcoDome32*.

(b) Sub-array geometry of *dome11*.

(c) Sub-array geometry of *dome16*.

(d) Sub-array geometry of *base16*.

Figure 6: Sub-array configurations derived from *JR-IcoDome32*.

3.2 Position and Orientation Sensors

The mobile use of a microphone array makes it necessary to determine the sensor position (GNSS) and orientation (IMU). This information is needed to transform DOA estimates from a relative to an absolute coordinate system in order to evaluate DOAE w.r.t. the position reference of a UAV. The following commercial sensors were procured:

- GNSS: *u-blox NEO-6M* with integrated antenna ,
- IMU: *Adafruit ADA2472* with *Bosch BNO055*.

The fusion and integration of these sensors was carried out using an *ESP32* micro-controller and a Python module as a serial interface with real-time data processing.

3.3 Vehicle Integration and Processing Hardware

The complete system consists of the *JR-IcoDome32* with spherical windshields, a suspension system of wire rope springs for a roof rack mount to dampen vibrations, the GNSS-IMU module mounted on the array base plate and an in-vehicle hardware rack. 32 BNC cables are routed as three DB-25 cables via a cable pass-through into the vehicle interior where they are connected to a rack containing USB audio interfaces synchronized via an AVB network and an *Intel NUC7i5DNK* processing unit. The system is powered using a portable power station and consumes approximately 120 W in operation. The integration into a vehicle is shown in Figure 7.

Figure 7: *JR-IcoDome32* with GNSS-IMU module mounted onto the rack roof of a car for mobile use.

Figure 8: Multicopter UAVs used for measurements.

Dataset	UAVs	Runs	Patterns	Duration
Fixed	3	11	3	1.5 h
Mobile	3	31	4	1.0 h

Table 2: Recordings of UAV flights conducted with *JR-IcoDome32* and resulting datasets for evaluation.

4. RESULTS

4.1 Experimental Setup

Audio data was recorded at 48 kHz sampling rate and 24 bit together with GNSS-IMU data logs for fixed and mobile setups at *UMFC Stocking* airfield in 2023. Three UAVs (*DJI Mini 2 SE*, *DJI Mavic 2 Pro*, *twinFOLD KAT*) were chosen for both scenarios, representing small, medium and large multicopters as shown in Figure 8. For the fixed setup, the *JR-IcoDome32* was placed on the ground, while the UAVs flew programmed and manual patterns (*hover*, *circle*, *free*) in distances up to 500 m from the array. In the mobile setup, the array was mounted on the car (Figure 7) and the UAVs performed manually controlled patterns (*hover*, *approach*, *follow*, *circle*) while the car drove at different speeds (10, 20, 30 km/h) in fixed gear on a dirt road. Each UAV was flown separately. Table 3 summarizes the recordings of fixed and mobile datasets.

4.2 System Parameters

For STFT processing, we resample the recorded audio signals to 24 kHz and set the window (Hann) and the FFT size to 2048, with a frame overlap of 50%. Considering the predominant characteristics of drone sound and the array metrics, we choose a frequency range of [300 2300] Hz resulting in 171 processed FFT bins. For the DOA scanning grid we choose a unit hemisphere of 200 quasi-uniformly distributed points [19]. The number of initial sound sources in each frame is 3. For source tracking we limit the maximum number of sources to 16 and set an initial and a maximum TTL for each source of 1.5 s, the minimum angular separation $\Upsilon = 30°$, the confidence threshold $\gamma = 0.3$ and specify an exponential smoothing constant of 0.9 corresponding to a time constant of 0.4 s.

4.3 Performance Evaluation

We present the DOAE results in terms of an exemplary run and a statistical evaluation of the DOAE error for all sub-array configurations. For each run and dataset, we compare the DOA estimates of three sound source tracks (SRC1-3) against the position reference (TRUE) obtained from GPS as azimuth and elevation angles. The opacity of each track represents the confidence output of the algorithm. Figures 9 and 10 show the results of a flight of *DJI Mavic Pro 2* in the fixed scenario for *dome06* and *dome32*, resp. In this run, the UAV took off next to the array and

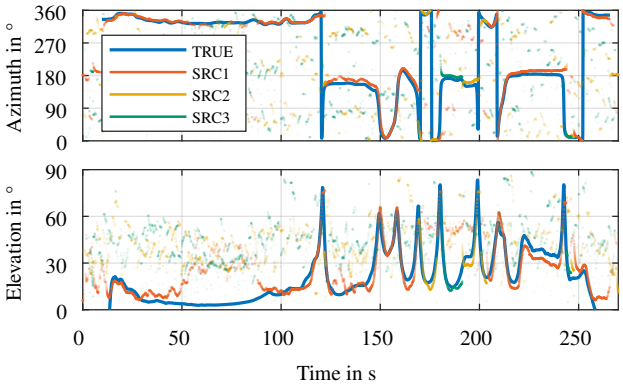

Figure 9: DOAE example with sub-array *dome06*.

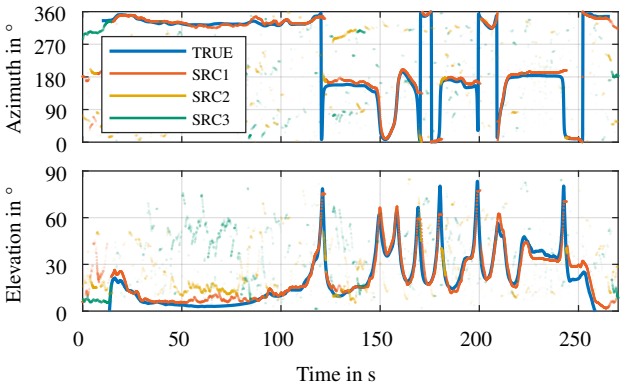

Figure 10: DOAE example with baseline *dome32*.

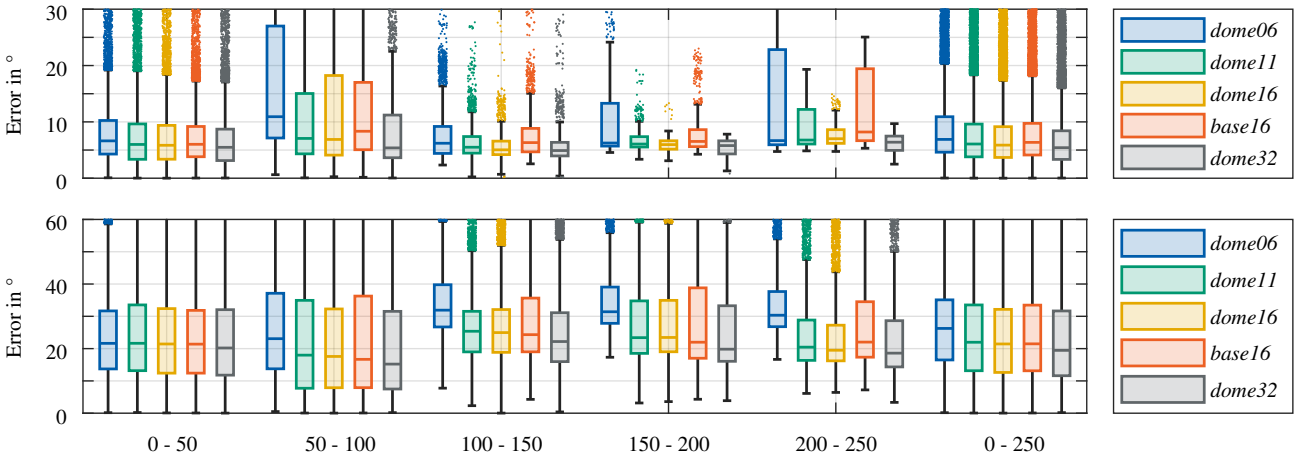

Figure 11: Absolute DOAE error over distance ranges for sub-arrays in fixed (top) and mobile (bottom) setup.

reached a distance of 100 m after 45 s and 260 m after 55 s. It then approached the array and passed 100 m at 90 s and 40 m at 100 s. For the rest of the run, the UAV flew within 80 m and performed overflights. It can be seen that *dome06* lost the UAV from 55-90 s, while *dome32* was able to keep the track (SRC1). In addition, this track is more stable, i.e. fewer changes between track hypotheses.

For each sub-array configuration, we assess the DOAE performance in terms of the absolute angle error for distance ranges in blocks of 50 m and up to 250 m in total. To provide a meaningful summary, we use boxplots to examine the median and interquartile ranges for each sub-array and dataset. Figure 11 presents median errors lower than 10° and 30°, except for *dome06*, for fixed and mobile datasets, respectively. It must be noted that GPS/IMU data may be inaccurate, as we use commercial systems without any enhancement, e.g. DGPS or RTK.

5. CONCLUSION

In this paper, we have presented a 3D microphone array design with possible sub-array configurations and experimental results for acoustic UAV tracking in a fixed and a mobile scenario. Our evaluations show similar results for sub-arrays with 11 or more sensors compared to the 32-channel baseline with 5° and 20° median DOAE error, resp. We argue that *JR-IcoDome32* is a suitable geometry for UAV tracking that also provides good accuracy in elevation. With sufficient drone noise content in the 1-4 kHz range, the proposed scaled version *JR-IcoDome32S* could provide similar performance. Possible future work lies in improving the DOAE and tracking algorithms, e.g. considering SRP amplitudes for weighted GMMs as proposed in [20], JIPDAF with Kalman filters [21], together with extensive evaluations using larger datasets.

ABSTRACT

This study presents a detailed analysis of how acoustic signals generated by drones are perceived by humans compared to their detection by advanced microphone-based systems. The research includes various types of drones and employs a psychoacoustic model to evaluate the perceptual sound power of these signals. This model is used to estimate the maximum distance at which UAV noise remains audible, as a function of frequency. Additionally, a detection system incorporating machine learning techniques and the YAMNet neural network is implemented to investigate how drone acoustic signals are influenced by factors such as distance, frequency, and surface reflections during propagation. The results show that even the most basic acoustic detection systems significantly outperform human hearing in identifying drones. These findings underscore the effectiveness and versatility of such systems, highlighting their potential as valuable tools for enhancing security and surveillance in real-world scenarios.

Keywords: UAV, drone audibility, psyschoacoustic model, distance, masking threshold, comparison

1. INTRODUCTION

The acoustic detection and localization of drones might initially seem ineffective due to the low signal-to-noise ratio (SNR) typically associated with the sound emitted by small unmanned aerial vehicles (UAVs) at the receiver. Additionally, it is sometimes assumed that an acoustic surveillance system cannot outperform the human auditory system. In response to these assumptions, this study investigates the limits of the human auditory system's ability to detect drones, using MPEG Psychoacoustic Model 1 [1], originally developed for audio encoding. The goal is to determine the maximum distance at which a drone remains perceptible to the human ear and to compare this threshold with the detection capabilities of existing automated systems.

In the field of environmental acoustics, several works have evaluated the perceptual impact of drone noise using psychoacoustic sound quality metrics (SQMs), such as loudness, sharpness, and fluctuation strength. For instance, the study in [2] analyzes the perceived annoyance of UAV noise under varying altitudes and flight conditions, concluding that heavier drones flying at low altitudes generate greater discomfort, with loudness emerging as the dominant factor. Similarly, the authors of [3] compare the sounds of drones, helicopters, and lawnmowers, again identifying loudness as the main predictor of annoyance. In a related study [4], multirotor drones are reported to be more annoying than civil aircraft, with sharpness and fluctuation strength playing a key role in perceived disturbance.

However, there is still a lack of systematic analysis regarding the maximum distance at which drone sound remains perceptible to humans. This paper aims to address that gap by estimating the distance beyond which drone sound becomes fully masked by environmental noise and, therefore, no longer causes audible annoyance, or can be detected by humans beings. The analysis is carried out using the MPEG Psychoacoustic Model 1, which enables

the calculation of individual and global masking thresholds, to determine the audibility of signals emitted at a given distance from the listener and affected by propagation losses. This study also reinforces the relevance of acoustic localization and detection systems, demonstrating their ability to detect drones even at distances beyond human auditory capabilities.

To contextualize the comparison, a state-of-the-art acoustic detection system is used as a benchmark. Many modern detection systems rely on machine learning (ML) and deep learning (DL) methods applied to features such as the short-time Fourier transform (STFT) or Mel-frequency cepstral coefficients (MFCC) extracted from drone-specific acoustic patterns. These techniques have shown high classification accuracy and effective range under certain conditions [5–7]. Among these, the YAMNet neural network, used in a previous study by the authors [8], serves here as a reference to evaluate the performance of an automatic system. Rather than providing a detailed assessment of detection systems, this paper focuses on quantifying the audibility of drone noise using a perceptual model, and comparing it with the response of an automatic classifier.

This paper is structured as follows. Section 2 presents the theoretical background of the psychoacoustic model and describes the acoustic characteristics of sound produced by drones. Section 3 analyzes the audibility of a drone at varying distances and compares these findings with the performance of the YAMNet-based detection system. Finally, Section 4 presents the main conclusions of the study.

2. THEORETICAL BACKGROUND

This section introduces the main concepts about psychoacoustics and signal characteristics relevant to the perceptual analysis of UAV sound.

2.1 Psychoacoustic Model

A psychoacoustic model is a quantitative framework that approximates the behavior of the human auditory system [9]. It computes the global masking threshold, which defines the sound pressure level below which acoustic signals are no longer perceived by the human ear. This threshold varies dynamically across both frequency and level, depending on the energy distribution in adjacent spectral components [10].

Human auditory perception is primarily determined by the threshold in quiet and by masking effects produced

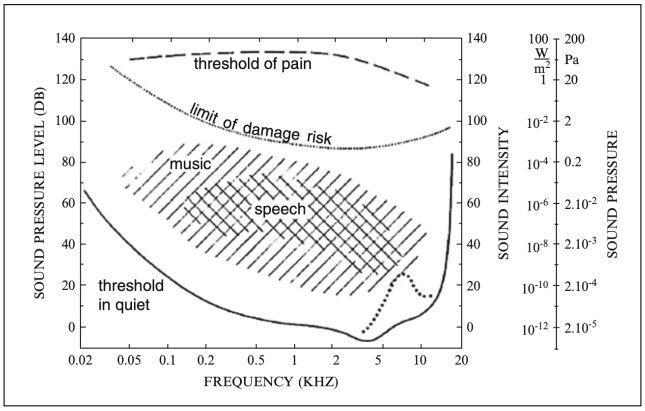

Figure 1: Hearing range [11].

by other sounds. The threshold in quiet refers to the minimum sound pressure level required to detect a pure tone in the absence of any background noise. This threshold is illustrated in Fig. 1, which shows the human hearing range using Sound Pressure Level (SPL) curves. As shown, human hearing ranges from approximately 20 Hz to nearly 20 kHz, with frequency-dependent thresholds for both hearing and pain. The threshold in quiet can be approximated by the frequency-dependent function provided in Eqn. (1).

$$T_Q(f) = 3.64\left(\frac{f}{1000}\right)^{-0.8} - 6.5 \cdot \exp\left[-0.6\left(\frac{f}{1000} - 3.3\right)^2\right] + 10^{-3}\left(\frac{f}{1000}\right)^4 \quad (1)$$

Masking effects at a given frequency depend solely on the signal energy within a limited bandwidth surrounding that frequency [12]. Due to the structure of the cochlea, which converts frequency information into spatial displacement along the basilar membrane, each position on the membrane responds to a specific range of frequencies. As a result, the peripheral auditory system functions as a spectral analyzer and can be modeled as a bank of partially overlapping band-pass filters. The audible range, approximately from 20 Hz to 16 kHz, is divided into 24 non-overlapping critical bands, each corresponding to a unit known as the Bark. Given the nonlinear distribution of resonant frequencies along the membrane, the bandwidths of these critical bands are not uniform and vary with frequency [9]. An analytical expression derived from experimental data is used to approximate the critical bandwidth

Δf as a function of the center frequency f_c:

$$\Delta f = 25 + 75 \left(1 + 1.4 \left(\frac{f_c}{1000}\right)^2\right)^{0.69} \quad (2)$$

The concept of critical bandwidth around a masker defines the frequency region in which masking effects are most pronounced. Consequently, the perception of a sound depends not only on its own frequency and intensity, but also on the presence of nearby spectral components. Masking phenomena are typically classified as either simultaneous or non-simultaneous. Simultaneous masking occurs when a sound becomes inaudible due to the concurrent presence of another sound with nearby frequencies, which raises the auditory threshold in that band. This can occur under several conditions: when narrowband noise masks tones within the same critical band, when tones mask other tones, or when narrowband noise masks other narrowband noise components within the same critical band. In contrast, non-simultaneous masking refers to the phenomenon where the audibility of a sound is affected by a masker that occurs immediately before or after it in time, due to the temporal dynamics of auditory masking.

In this work, perceptual analysis is based on Model 1 of the ISO/IEC MPEG-1 Audio Standard [1, 13]. This model divides the audio signal into subbands that approximate critical bands and estimates the masking threshold, to be used to quantize each subband signal according to the audibility of quantization noise [12].

To apply Model 1, the following steps are carried out:

1. Computation of the FFT and the SPL in each subband.
2. Determination of the absolute threshold of hearing.
3. Identification of tonal and non-tonal components in the input signal.
4. Decimation of invalid tonal and non-tonal maskers.
5. Calculation of individual masking thresholds.
6. Determination of the global masking threshold.
7. Estimation of the minimum masking threshold in each subband.
8. Calculation of the Signal-to-Mask Ratio (SMR).

In the final step, the SMR is computed as the difference between the signal level and the corresponding masking threshold. This value indicates, for each subband or frequency bin, whether a given sound is perceptible or masked by other components. If the SMR is low (i.e., negative in dB), the human ear cannot perceive the sound, even though it is physically present in the signal.

2.2 UAV signal Characterization

The acoustic signal generated by a drone originates primarily from the rotation of its propellers and motors, resulting in a sound with harmonic content when the rotational speed remains constant. However, during flight, this speed continuously varies in response to aerodynamic forces and control adjustments, leading to a non-stationary signal in the time domain. Consequently, frequency-domain analysis is more suitable, as the signal exhibits a spectral pattern characterized by peaks and valleys (as shown in Fig. 2), with energy concentrated in specific frequency bands associated with the rotational speeds of different components.

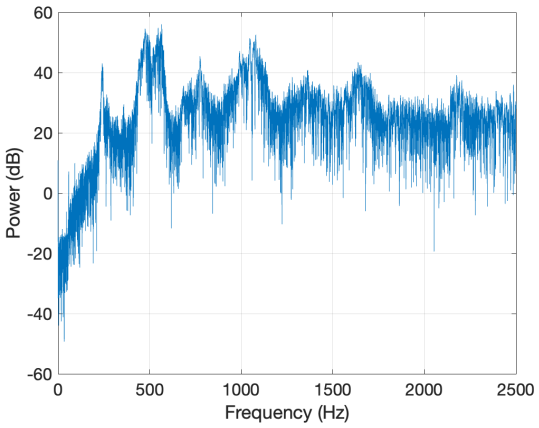

Figure 2: Power Spectrum of Hobbyking FPV250 drone.

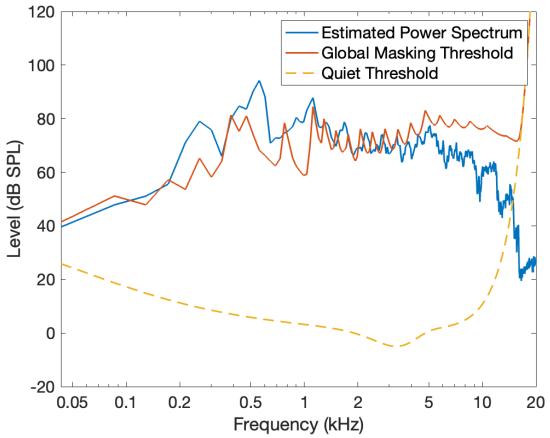
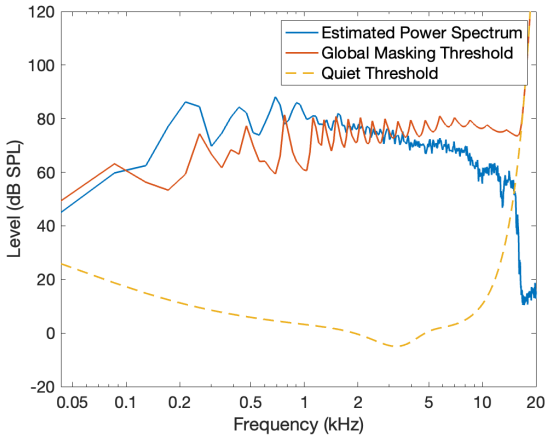


In particular, drone acoustic signals contain tonal components in the low-frequency range, corresponding to the blade pass frequency (BPF) and its harmonics [14]. These tonal components are linked to variations in rotor speed and are clearly reflected in Fig. 2. According to the study by Torija et al. [15], drones exhibit an average tonality of 0.36 tonality units (tu), indicating a moderately prominent tonal component in their acoustic signature. This characteristic has the potential to influence auditory masking effects and, therefore, human perception. These spectral characteristics highlight the suitability of drone noise for perceptual analysis based on auditory masking principles, which will be explored in the next section.

3. RESULTS



This section presents the results of the psychoacoustic analysis applied to UAV acoustic signals using the MPEG Psychoacoustic Model 1. The goal is to determine the maximum distance at which drone noise remains perceptible to the human ear, considering both ideal conditions and more realistic scenarios with propagation losses and environmental noise. In addition, results are also compared against a state-of-the-art detection system to highlight the limitations of human hearing.

As a first step, the analysis was performed on an in-flight recording of the Hobbyking FPV250 quadcopter. This UAV was selected as a representative example of a small and lightweight drone, typically classified in the C0 or C1 category according to current UAV classification standards. To complement this analysis, the DJI Phantom 3 was also evaluated, representing a larger and more robust drone classified within the C2 category. These two UAVs differ significantly in weight, physical dimensions, and structural design, providing a broader perspective on how human auditory perception responds to UAVs with different spectral and operational characteristics. Although some variations are expected between drones, most quadcopters share common tonal and non-tonal features in their acoustic signatures. Therefore, the perceptual results presented here are expected to generalize well to similar UAV configurations.

The initial analysis was conducted at a reference distance of 1 meter, without considering attenuation or background noise. Fig. 3 shows the estimated power spectrum, the global masking threshold calculated using the MPEG model, and the absolute threshold of hearing, for both UAV models. In both cases, the drone signals exhibit prominent energy in the low-frequency range, especially around the BPF and its harmonics. These tonal components result in masking thresholds that closely follow the spectrum shape, particularly where tonal maskers dominate. However, it can be observed that above approximately 1 kHz, the power spectrum begins to fall below the global masking threshold due to the progressive decline in signal energy with increasing frequency, combined with the accumulation of masking contributions from lower-frequency components. As a result, the perceptual significance of high-frequency components is reduced, and only the lower-frequency bands of the signal remain clearly audible. As observed in Fig. 3, both UAVs exhibit comparable spectral distributions and global masking thresholds under ideal conditions, with the signal remaining well above the masking threshold for frequencies below approximately 2 kHz. This confirms that both drones are clearly audible in quiet scenarios, although high-frequency information appears to be imperceptible. Given the similarity of their acoustic profiles, only the results of one of the two UAVs are presented in this paper for the subsequent analyses involving distance-based attenuation and ambient noise.

(a) Hobbyking FPV250

(b) DJI Phantom 3

Figure 3: Estimated power spectrum and masking threshold without considering noise or attenuation.

To evaluate auditory perception as a function of distance, an attenuation model was applied to estimate the frequency-dependent degradation of the acoustic signal over propagation. For this purpose, the standardized mod-

els defined in ISO 9613-1 [16] and ISO 9613-2 [17] were used, which account for effects such as atmospheric absorption or geometric spreading to simulate realistic propagation losses across different frequency bands. Based on this model, the next scenario considers the effect of distance alone, without introducing ambient noise.

As shown in Fig. 4, which corresponds to the DJI Phantom 3 at a distance of 100 meters, the signal spectrum shows a noticeable overall attenuation, particularly at high frequencies. This behaviour is expected due to the frequency-dependent nature of atmospheric absorption. However, in the frequency range where the signal was previously audible—primarily below 1 kHz—the spectral shape remains largely preserved, but with a lower dependence on the energy level. As a result, the masking threshold maintains the shape of the signal spectrum, and the signal-to-mask ratio (SMR) remains positive across most of the low-frequency bands. This indicates that, in the absence of ambient noise, increasing distance alone has the effect of reducing the signal power, but the SMR in the dominant low-frequency range remains almost unchanged.

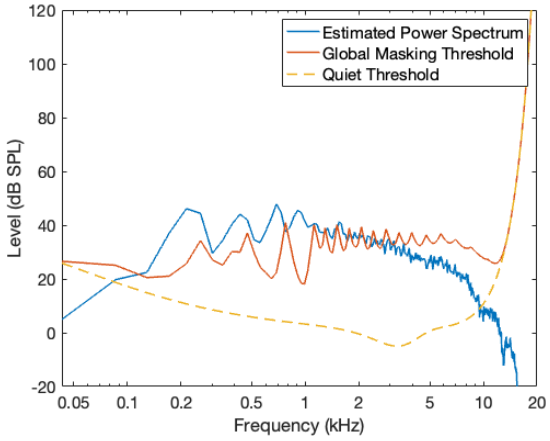


Figure 4: Estimated power spectrum and masking threshold at 100 meters without noise.

To assess the impact of environmental noise on auditory perception, an additional analysis was conducted by introducing Additive White Gaussian Noise (AWGN) at a level of 40 dB SPL. Fig. 5 shows the resulting power spectrum and global masking threshold for the DJI Phantom 3 at a distance of 100 meters under these conditions. Compared to the previous case, the masking threshold is significantly elevated across the entire spectrum, particularly in the mid and high-frequency bands due to the effect of noise.

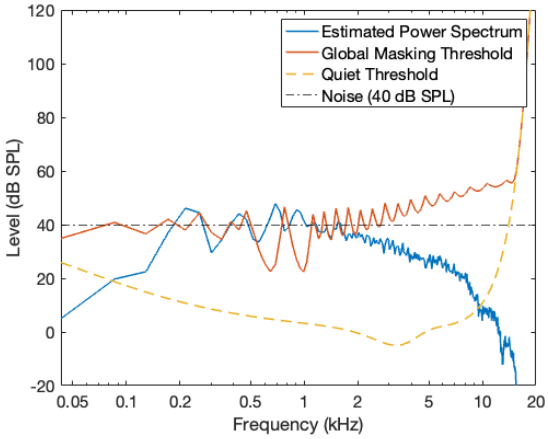

Figure 5: Estimated power spectrum and masking threshold at 100 meters with 40 dB SPL noise.

In this scenario, the estimated power spectrum of the drone signal falls below the masking threshold in most frequency regions, including parts of the low-frequency range. This is mainly due to the combined effects of attenuation and background noise, which increases the masking contributions and reduces the SMR. While a few low-frequency components—particularly some between approximately 100-1000 Hz—may remain marginally audible, their perceptibility is highly uncertain and depends on the local contribution of noise and the local masking level.

Fig. 6 shows the average Signal to Mask Ratio computed for the first 13 Bark bands, plotted at the center frequency of each band. This analysis was performed to assess how far the drone signal remains perceptible under varying propagation conditions. Two horizontal reference lines are included at 0 dB and 3 dB SMR. While an SMR above 0 dB indicates that the signal's spectral energy surpasses the global masking threshold, suggesting potential audibility, a margin of at least 3 dB is commonly adopted to ensure robust perceptual detection. The figure includes SMR curves obtained for multiple distances ranging from 1 meter to 500 meters for the DJI Phantom 3. The analysis is limited to the first 13 Bark bands (approximately up to 2 kHz), since previous results have shown that signal components beyond this frequency range are completely masked and thus perceptually irrelevant.

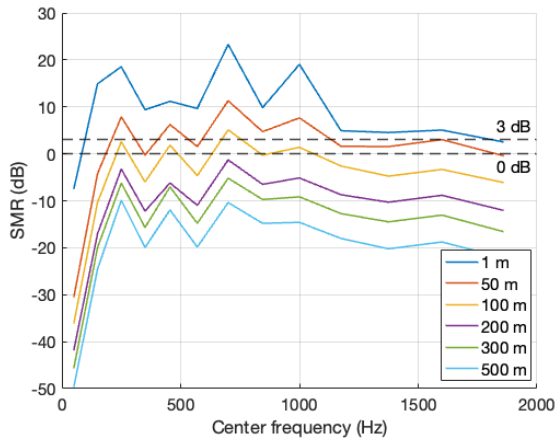

Figure 6: SMR degradation with distance across the first 13 Bark bands.

As illustrated, the drone signal is clearly audible at 1 meter, with all SMR values in the analyzed frequency range exceeding the 3 dB threshold. At 50 meters, the SMR remains above 0 dB in all bark bands, and although several bands still exceed the 3 dB margin, the perceptibility of the signal begins to decrease. At 100 meters, only a few low-frequency bands remain above the 0 dB threshold, while the majority of the spectrum falls below it, indicating that the signal is becoming increasingly masked. Beyond this distance, the SMR continues to decrease, confirming that drone audibility deteriorates rapidly due to the combined effects of frequency-dependent attenuation and ambient noise. Consequently, auditory detection by a human observer becomes extremely limited, or even entirely unfeasible, at distances exceeding 100 meters under typical outdoor conditions.

While the SMR-based analysis illustrates the limitations of human hearing, the following evaluation examines the capabilities of an automatic system under the same acoustic conditions. To compare the human auditory perception with a state-of-the-art acoustic detection system, the YAMNet neural network was evaluated under the same conditions used in the perceptual analysis, that is, with an ambient noise level of 40 dB SPL and propagation-induced attenuation applied according to outdoor transmission models. This deep learning architecture, specifically designed for audio event classification, was previously analyzed by the authors in [8], and the results are reused here to enable a direct comparison between human and machine-based detection performance.

Fig. 7 shows the Receiver Operating Characteristic (ROC) curves obtained for distances ranging from 1 to 500 meters. These curves represent the probability of detection (P_D) vs. the probability of false alarm (P_{FA}), serving as a standard performance metric in detection theory. In general, a larger area under the ROC curve indicates a more reliable detector. As shown, YAMNet maintains high detection performance even at 500 meters, significantly outperforming human auditory capabilities under the same acoustic conditions. These findings reinforce the importance of automated systems for reliable UAV detection over long distances.

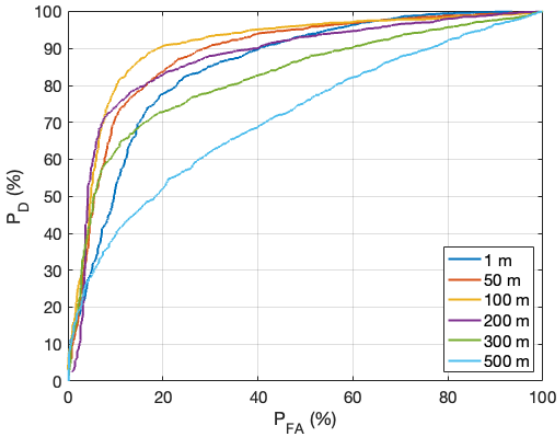

Figure 7: ROC curve for the YAMNet-based detector, at different distances [8].

As demonstrated in the previous analysis, human auditory perception of drone noise significantly deteriorates beyond 100 meters, mainly due to propagation losses and ambient noise. In contrast, state-of-the-art acoustic systems, such as the YAMNet-based model evaluated, can reliably detect drones at distances up to 500 meters. This highlights the critical importance of automated detection technologies, especially in surveillance and security applications, where relying on human hearing alone would severely limit detection capabilities and operational effectiveness. Furthermore, in line with findings from the literature on psychoacoustic sound quality metrics, it can be inferred that in order to avoid any perceptual disturbance to the population, drones should ideally operate at distances of at least 100 meters from inhabited areas, ensuring that their acoustic signature remains below the threshold of audibility and therefore does not cause annoyance.

4. CONCLUSION

In this work, the audibility of UAV noise was evaluated using the MPEG Psychoacoustic Model 1, with the objective of estimating the maximum distance at which a drone can be perceived by a human listener. Under ideal conditions, the acoustic signature of the drone remains clearly audible up to several hundred meters. However, when more realistic scenarios are considered, including propagation-induced attenuation and a moderate ambient noise level of 40 dB SPL, audibility declines significantly, becoming nearly null beyond 100 meters.

The analysis of the global masking threshold and the power spectrum revealed that the perceptible content of the drone signal is mainly concentrated in low-frequency components, particularly below 1 kHz. By calculating the Signal-to-Mask Ratio (SMR) across Bark bands and examining its variation with distance, it was observed that beyond 100 meters, the signal becomes largely masked by environmental conditions, resulting imperceptible to the human auditory system. This threshold naturally depends on ambient noise levels, and more adverse conditions would further reduce detectability.

In contrast, an automatic detection system based on the YAMNet neural network demonstrated robust performance under the same acoustic conditions, achieving reliable drone detection at distances up to 500 meters. These results highlight both the limitations of human auditory perception and the practical viability of acoustic detection systems for surveillance, security, and environmental monitoring applications, even in scenarios characterized by low signal-to-noise ratios.

Finally, the findings are consistent with prior research on psychoacoustic annoyance and support the recommendation that small UAVs should operate at least 100 meters away from populated areas under these conditions. At this range, the acoustic signature remains below the threshold of audibility, minimizing both detectability and potential disturbance.

INVESTIGATING THE IMPACTS OF COCKPIT NOISE EXPOSURE ON HUMAN DECISION-MAKING

Elizabeth L. Fox[1*] **Ashley D. Cook**[1] **Frank Mobley**[1]

ABSTRACT

A large amount of research focuses on protecting military personnel from over exposure to noise, but little research has focused on the cognitive impacts. As such, Air Force Research Laboratory researchers have conducted a study to explore how cockpit noise influences decision-making. Fifteen participants were placed within a chamber with communication ear plugs (daily attenuation collected) and exposed to noise previously recorded within the cockpit of a fifth-generation fighter jet generated at levels of L_A= 60, 70 and 80 dB under protection. Participants completed a series of auditory working memory and visual search tasks in both single- and dual-task paradigms. Performance changes were observed across individual participants depending on differing noise level and task difficulty; additionally, individual fit variances led to differences in room (full body) sound pressure levels that require further investigating. Overall, the results of this study offer a better understanding of how high-level cockpit noise impacts multitasking and working memory performance involved in decision-making. From this work, recommendations can be made on how to manage cognitive load in these complex military operations.

1. INTRODUCTION

Several studies have reliably captured cross-modal demand effects and have found task difficulty modulates the cross-modal impact on performance. More specifically, in a dual-task context, the task load in a primary task of one modality influences the performance on a second task presented in a different modality [1, 2]. However, the literature linking the deleterious effect of prolonged and continuous environmental acoustic noise on intra- or cross-modal attentional resources and cognitive functioning is limited. This is especially true when considering key mechanisms such as working memory (e.g., phonological loop) and higher-order executive functioning (e.g., multitask management). Limited studies have shown that acoustic noise can either enhance or degrade performance. For example, Awada and colleagues demonstrated that incorporation of low levels of white noise improved performance in creative tasks, but increased levels of noise only improved working memory tasks [3]. Overall level of noise influences some aspects of cognitive performance, but some studies have demonstrated that other characteristics (features) of the noise may also be critical indicators [4–6].

In a within-subjects experiment, we systematically investigated the relationship between the level (amplitude) of aircraft noise that F-35 pilots are exposed to and the cognitive processes most relevant for them to achieve mission success. We tested working memory through a standard auditory n-back task and decision-making through a visual multi-object search task. While many environmental stressors exist, this research focused on the impact of acoustic stressors, specifically the level of noise, on cognitive processing and decision-making under various

single- and dual-task loads. We factorially manipulated single- (n-back OR decision-task) and dual-tasks, 3 levels of n-back difficulty (n-back), and F-35 cockpit noise recordings presented at 4 A-weighted levels (quiet, L_A = 60, 70, and 80 dB as measured under hearing protection [UHP]). We assessed response times and accuracy to respond to task stimuli, mathematical modeling coefficients (efficiency cost of multitasking [2]), subjective assessments of affect and arousal (HAAS, [7]), and how one's sensitivity to noise (Noise Sensitivity Scale [NSS]; [8]) impacts performance in, and subjective assessments of, different levels of steady-state F-35 cockpit noise.

Unique to our lab task, participants placed hearing protection on before undergoing a measurement of hearing protection fit, which was used to individualize the external level of sound and properly control noise dose UHP. This was completed immediately prior to all three sessions where noise was administered. As such, the variation within- and between-people using communication earplugs (CEPs) will be reported. In addition to our primary research questions described above (and hypotheses below), these data are also useful for evaluating operational guidelines for use of CEPs as a form of hearing protection in the field.

1.1 Hypotheses

We have three hypotheses in regards to research questions of interest.

Hypothesis 1 (H1). Performance and efficiency will decrease when multitasking compared to isolated completion, and higher decrements will be observed with increasing working memory load.

Hypothesis 2 (H2). Performance and efficiency will decrease under noise, compared to quiet, and more decrements will be observed as the level of noise increases.

Hypothesis 3 (H3). Higher noise exposure will result in higher negative affect and lower positive affect in post session affect state assessment, compared to pre session assessment, moderated by the individuals' degree of noise sensitivity.

2. METHOD

2.1 Participants

Participants included 18 (N = 15 after exclusions) US citizens, 60/40 split between female/male, recruited from the Dayton, Ohio area, who received monetary compensation (20 USD/hour) for their time. All participants completed the task in a controlled laboratory setting on Wright-Patterson Air Force Base.

2.2 Surveys

Noise sensitivity is generally defined as "an individual's internal state which increases their degree of reactivity to noise [9]." It is measured using a 6-item noise sensitivity scale (NSS), where participants agree/disagree with each statement [8]. We measured participants' noise sensitivity prior to the experiment.

The Hedonic Arousal Affect Scale (HAAS) is a survey based on the valence-arousal model of affect. Valence is the hedonic tone or (dis)pleasure of the situation, and arousal is the amount of activation associated with their personal state [10]. The abbreviated 12-item HAAS [7] is well-suited for repeated measure designs, such as the experiment described here, and can be summarized to capture overall positive/negative effects of each noise level on one's relative change in valence and arousal. Participants rated each adjective (e.g., Active, Calm, Irritable, Tired) on a scale from 1 (very slight/not at all) to 5 (extremely) before and after each session. For noise sessions (2-4), participants completed the post-session survey after all trials were complete, but prior to terminating the room noise to obtain a reflection of their state in noise.

2.3 Procedure

Participants completed 4 sessions (each 2.5 hours; total time 10 hours) in the Voice Communication Research and Evaluation System (VOCRES) facility, which is a acoustically diffuse room (down to 500 Hz) and capable of continuous 125 dB A-weighted sound pressure level (SPL) w/ bandwidth 20-20k Hz. Session 1 was the quiet day and required participants to complete the informed consent, the NSS, an Ishihara Color Blindness test, and a baseline hearing assessment. Additionally, prior to and post sessions 1-4, the participant completed the HAAS survey. For sessions 2-4, participants completed daily attenuation measurements for their CEPs using the Michael & Associates FitCheck Solo System. Individuals' attenuation results were used to adaptively filter the noise in octave bands to control for any variance in fit across participants and sessions (noise level was randomized after session 1; noise exposure $<$ 2 hrs/session). Next, participants were tasked with completing the visual search (VS), the working memory (WM), or dual-task, depending on the assigned order. All conditions were completed in each session; participants completed practice trials each session.

Participants were given mandatory 30 second breaks approximately every 5 minutes. After the completion of all conditions and surveys, participants completed a post session hearing assessment to check for any threshold shifts (noise sessions) then were thanked and paid for their time (all sessions).

2.4 Tasks

Order of task presentation was pseudo-randomized. Session 1 required participants to complete the VS and WM tasks in isolation prior to completing the dual-task. All other sessions had randomized order of tasks.

2.4.1 Visual Search Task

Participants were asked to complete a visual discrimination task that had two simultaneous 2-alternative-forced-choice (2AFC) responses, where participants had to decide between two response options in each (see Figure 1 for stimuli). The first 2AFC was to determine whether a dog (left arrow key) or lion (right arrow key) was presented on screen; the second was to determine whether a car was present (up arrow key) or not (down arrow key) – each trial demanded two key presses; participants used their right hand to complete this task.

Six fixations were presented in a half-circle (above center), and one in the center for 500 ms at the start of each trial. Following a short, 0-300 ms blank screen, each fixation was replaced with either a target or distractor icon. The center fixation did not remain. Either a dog/lion was present every trial. On car present and absent trials, four and five distractors filled in the remaining locations, respectively. Stimuli were presented for 1000 ms, and participants had 3000 ms (from the onset of stimuli) to make both the animal and car responses.

Each participant completed a minimum of 15 practice trials (dependent on their understanding of the task) before moving onto data collection. Trials lasted 4600 ms for a total of 336 trials across 6 blocks which amounted to 56 trials/block. The task was presented in isolation and a dual-task context, both of which were completed with the participant at a 60 cm viewing distance from the screen.

2.4.2 Auditory Working Memory Task

Participants were also instructed to complete an auditory working memory task, in this case, an n-back task [11, 12] of varying difficulty (1, 2, 3-back). Responses were given in a Go/No-Go format, meaning that participants pressed a key (F; left hand) when the spoken letters matched the

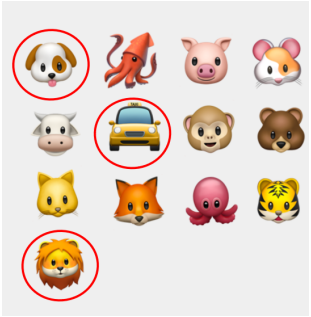

Figure 1. All possible visual stimuli. The red circle represents the target stimuli; all others served as distractors.

letter presented N-ago and withheld a response if the letters did not match, see Figure 2. Letters were prerecorded and took approximately 500 ms to transit aurally via the CEPs; letters C, H, and X were excluded due to idiosyncratic details for this particular experimental design. All letters were presented 6 dB above the level of noise under hearing protection (66, 76, and 86 dB, respectively) to ensure adequate intelligibility (via pilot testing); in the quiet condition, stimuli were presented at 66 dB.

Each participant completed a minimum of 16 practice trials at each difficulty level (dependent on task understanding) before moving onto data collection. Trials lasted 2300 ms with a 1500 ms response window for a total of 672 trials across 6 blocks, which amounted to 112 trials/block. The task was presented in isolation prior to a dual-task context in the first session.

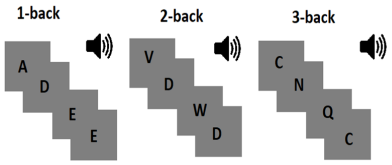

Figure 2. Example of how the n-back task was presented to participants. For these examples, the participant should press the 'F' key following the most recent letter (E, D, C, respectively).

2.4.3 *Dual-Task*

The dual-task consisted of all combinations of n-back paired with the search task. To maintain pacing, there were 2 auditory trials (2300 ms/trial) per 1 visual trial (4600 ms/trial). Each participant completed a minimum of 16 practice trials at each working memory difficulty before moving onto data collection.

2.5 Equipment

Participants used a desktop computer and the Michael & Associates FitCheck Solo System to collect attenuation data; the experimenter used the same computer to administer aircraft noise at the desired level for the duration of the experiment. Participants used a 10.5in Microsoft Surface Go 3 to complete the experiment (fixed location). Participants used CEP 508-SR w/ comply tips (Memory Foam P-Series) to both hear the audio stimuli and as hearing protection in the experiment, see Figure 3. Hearing threshold measurements were conducted using an AudioStar Pro.

Figure 3. Example of CEPs used by participants for noise protection and presentation of audio task.

3. RESULTS

3.1 Data Cleaning

For the visual search task, reaction times (RTs) quicker than 100 ms were removed to eliminate anticipatory responses. Three participants were removed due to any of the following: lack of responses within an isolated task, less than 60% accuracy when completing the visual task, or willingly excluding themselves from the experiment. Two auditory blocks, each in different sessions, were removed from one participant due to a lack of responses. Block one of the visual search task in isolation was removed due to training effects for all participants.

3.2 Auditory Health

Auditory thresholds, noted as hearing level (dB HL), were measured across nine frequencies in each ear (e.g., 125, 250, 500, 1k, 2k, 3k, 4k, 6k, 8k Hz). Baseline thresholds were taken during session 1 and any participant that had $>= 25$ dB HL in two+ frequencies in one ear were excluded, $M = 2.98$ dB HL, $Max = 25$ dB HL. No participants presented with greater than a 10 dB HL threshold shift averaging across 2-4k Hz after noise exposure (Threshold shift: $M = 1.05$ dB HL, $Max = 10$ dB HL) collected less than 5 minutes post-noise exposure.

Due to individual differences in inserting the CEPs, participants had changes in personal attenuation rating (PAR) each session. Nonetheless, due to the adaptive filtering used, the UHP levels remained balanced across participants. However, this necessitated different external room levels based on the individual fit differences, see Table 1.

Table 1. A table summarizing auditory differences among participants across noise levels.

	Desired Noise Exposure	$M(SD)$
CEP Fit	60	30.66 (3.88)
	70	31.85 (4.95)
	80	31.64 (4.08)
Room Levels	60	94.86 (3.86)
	70	107.24 (3.48)
	80	114.34 (3.28)
UHP Levels	60	58.35 (0.53)
	70	68.72 (0.59)
	80	78.15 (0.99)

3.3 Performance

To test H1 and H2, we assessed how VS and WM (n-back) task accuracy and efficiency changed as a function of WM task load and single- v. dual-task (H1), and as a function of noise (H2). We applied z-score and t-tests to assess post hoc differences between conditions for accuracy and Cost, respectively. We applied a Bonferroni p-value correction for all post hoc analyses.

3.3.1 *Accuracy*

First, we used two repeated-measured ANOVAs to assess the accuracy of the VS and WM tasks across single- and

dual-task conditions, and various WM loads and noise levels. z-score statistics are presented for single test or a [range] to summarize multiple tests.

VS task. We found significant main effects of WM load, $F(3, 38309) = 25.06$, $p < 0.05$ (supporting H1) and noise level, $F(3, 38309) = 2.82$, $p < 0.05$ (supporting H2), and their interaction, $F(9, 38309) = 2.71$, $p < 0.05$, on VS accuracy. Post hoc assessments revealed that the isolated VS task in 60 dB, $M = 98.84\%$, $SD = 10.72\%$ and 70 dB, $M = 98.52\%$, $SD = 12.08\%$, were more accurate than the VS task paired with the 3-back in 60 dB, $M = 96.78\%$, $SD = 17.65\%$, $z = 5.22$, $p < 0.05$ and 70 dB, $M = 97.30\%$, $SD = 16.22\%$, $z = 3.29$, $p < 0.05$, respectively. Lastly, the isolated VS task in 80 dB, $M = 99.11\%$, $SD = 9.38\%$, was more accurate than the VS task paired with the 2-back in 80 dB, $M = 96.53\%$, $SD = 18.30\%$, $z = 6.69$, $p < 0.05$. Alternative to our hypothesis, the isolated VS task in quiet, $M = 98.14\%$, $SD = 13.52\%$, is less accurate than the isolated VS task in 80 dB, $z = -3.64$, $p < 0.05$.

WM task. We found significant main effects of context (single- v. dual-tasking), $F(1, 19012) = 111.37$, $p < 0.05$, WM load (n-back), $F(2, 19012) = 1089.44$, $p < 0.05$, supporting H1, and noise level $F(3, 19012) = 11.16$, $p < 0.05$, supporting H2, on WM task hit rate. Additionally, there was an interaction between noise level and WM load on the WM task (n-back) hit rate, $F(6, 19012) = 10.51$, $p < 0.05$. Post hoc assessments revealed that in all noise levels, the 1-back, $M = [92.88\%, 93.85\%]$, $SD = [24.02\%, 25.72\%]$, was more accurate than the 2-back, $M = [83.21\%, 87.93\%]$, $SD = [32.59\%, 37.39\%]$, $z = [4.35, 7.56]$, $p < 0.05$, and the 3-back, $M = [57.47\%, 68.55\%]$, $SD = [46.45\%, 49.46\%], z = [19.38, 28.14]$, $p < 0.05$. In all noise conditions, participants had higher accuracy in the 2-back condition than the 3-back, $z = [13.83, 22.27]$, $p < 0.05$, collapsed across single- and dual-tasking. Participants' 2-back accuracy was higher in 70 dB noise, $M = 87.93\%$, $SD = 32.59\%$, compared to 80 dB, $M = 83.21\%$, $SD = 37.39\%$, $z = 3.62$, $p < 0.05$, partially supporting H2. Alternative to H2, the 3-back in quiet had lower accuracy than when completed in any noise level, $z = [-8.47, -6.22]$, $p < 0.05$.

3.3.2 Multitasking Cost

As a reminder, cost controls for how well individuals perform the task in an "unlimited capacity" environment (i.e., no second task, desired noise level). For each individual, a baseline (single-task) performance was collected in each noise level. These baselines were then compared to their dual-task performance in each level of noise, respectively. If the resulting cost score is equal to 0 and thus unlimited, processing efficiency remains consistent, while a score < 0 denotes a limited capacity and slower processing efficiency, and a score of > 0 demonstrates an increase in processing efficiency and super capacity (for reference see [2, 13]).

VS task. There was a main effect of WM load on VS cost, $F(2, 154) = 11.81$, $p < .05$ (see Figure 4). Specifically, VS paired with the auditory 1-back, $M_{cost} = -0.13$, $SD_{cost} = 3.49$, was more efficient than with 2-back, $M_{cost} = -1.91$, $SD_{cost} = 3.68$; $t(154) = 3.49$, $p < 0.05$, and 3-back, $M_{cost} = -2.51$, $SD_{cost} = 3.87$; $t(154) = 4.67$, $p < 0.05$, supporting H1. Additionally, there was a main effect of noise level on VS cost, $F(3, 154) = 11.66, p < .05$ (see Figure 4). Specifically, VS cost in quiet, $M_{cost} = 0.60$, $SD_{cost} = 4.30$, was higher (i.e., more efficient) than in 60 dB, $M_{cost} = -2.02$, $SD_{cost} = 4.17$; $t(154) = 4.46$, $p < 0.05$, 70 dB, $M_{cost} = -2.24$, $SD_{cost} = 3.16$; $t(154) = 4.83$, $p < 0.05$, and 80 dB, $M_{cost} = -2.41$, $SD_{cost} = 2.57$; $t(154) = 5.12$, $p < 0.05$, partially supporting H2.

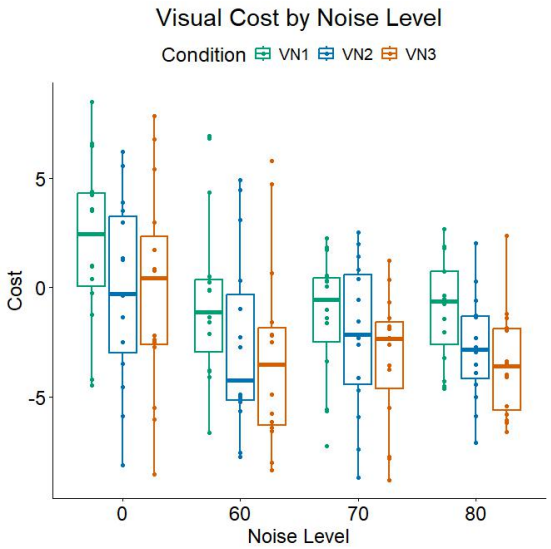

Figure 4. Visual search (VS) cost by noise level and condition. VN1 is an auditory 1-back, VN2 is 2-back, and VN3 is 3-back. All were paired with the VS task.

WM task. There were no main effects of difficulty

(n-back) or noise level (quiet, 60, 70, 80 dB), or their interaction, on WM task cost.

3.4 Survey Analyses

NSS scores were computed from individuals' survey answers at the start of the experiment. HAAS surveys were filled out prior to and after completion of tasks in each session; the difference in the scores was used to detect changes in affect due to the noise level, see Table 2.

NSS and HAAS. Using a simple linear regression model, we found a significant main effect of NSS score on degree of change in negative affect, $F(1, 13) = 6.08$, $p < 0.05$, see Figure 5. Post hoc simple slopes analyses revealed that the greater one's NSS score, the more their negative affect increased due to quiet, $t(32.57) = 2.47$, $p < 0.05$, and 70 dB noise, $t(32.57) = 2.34$, $p < 0.05$, partially supporting H3.

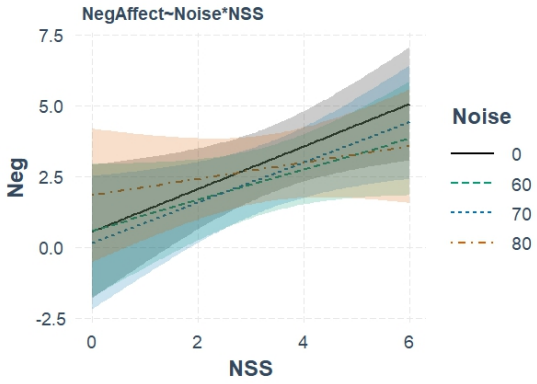

Figure 5. Change in negative affect (NegAffect) by noise level and Noise Sensitivity Scale (NSS) score.

Table 2. Means (standard deviations) for changes (Δ) in positive (Pos) and negative (Neg) affect across noise levels.

Noise Level	Δ Pos	Δ Neg
0	-3.6 (3.70)	3.07 (2.81)
60	-3.00 (2.59)	2.40 (2.47)
70	-2.33 (2.29)	2.53 (2.74)
80	-3.13 (2.77)	2.80 (1.78)

We found no significant main effect of Noise and NSS, or their interaction, to predict changes in positive affect.

VS task. Our results indicated a significant interaction between NSS score and noise level on VS task cost, $F(3, 159) = 3.48$, $p < 0.05$, see Figure 6, partially supporting H3. Post hoc paired-samples analyses revealed that for both low and moderate NSS scores, peoples' VS task efficiency decreased in all noise levels compared to quiet, $t(159) = [-5.42, -3.21]$, $p < 0.05$. Alternatively, those with high NSS scores are only less efficient in 60 dB noise, $t(159) = -2.91$, $p < 0.05$, compared to quiet.

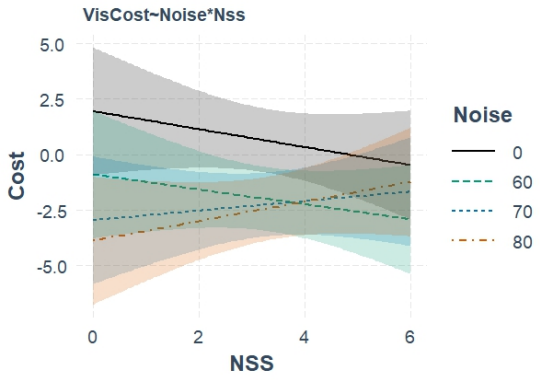

Figure 6. Visual search task cost (VisCost) by noise level and Noise Sensitivity Scale (NSS) score.

WM task. Our results indicated a significant interaction between NSS score and noise level on WM task cost, $F(3, 339) = 7.42$, $p < 0.05$, see Figure 7, partially supporting H3. Specifically, post hoc paired-samples analyses revealed that when participants had a lower NSS score, they were more efficient in the WM task in 60 dB noise, $t(339) = 3.13$, $p < 0.05$, compared to quiet. Alternatively, participants with a higher NSS score had lower efficiency in the WM task in 60 dB, $t(339) = -2.35$, $p < 0.05$, compared to quiet.

4. DISCUSSION

We investigated the relationship of three levels of steady-state F-35 noise and performance in concurrent VS and auditory WM tasks of varying difficulty levels. Importantly, we found no notable shifts in auditory thresholds due to noise exposure and CEP fit improved across session.

First, we found multitasking and WM load influenced performance in both tasks, supporting H1. In particular, VS task accuracy decreased due to multitasking and

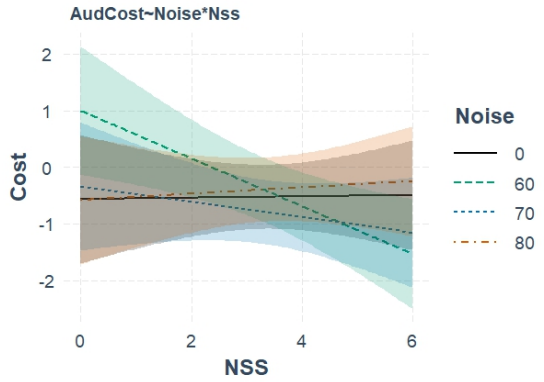

Figure 7. Working memory (WM) task cost (AudCost) by noise level and Noise Sensitivity Scale (NSS) score.

cross-modal WM load. In addition, participants' accuracy in both tasks significantly differed as a function of noise condition, partially supporting H2. Contrary to H2, 80 dB noise increased single VS accuracy; all noise levels led to higher WM accuracy when multitasking under a high load. Lastly, we found multitask efficiency (VS but not WM) decreased in noise, providing partial support for H2.

To investigate how one's sensitivity and emotional response to noise moderates our findings, we first assessed if one's noise sensitivity, as measured by a 6-item scale [8], predicted their degree of change (Δ) in positive and negative affect, as measured by a 12-item scale [7] after noise exposure. We found those with higher sensitivity to noise experienced significantly more negative affect following the quiet and the 70 dB noise conditions. However, no significant differences were found after 60 or 80 dB noise, and no shifts in positive affect were observed for any of the noise levels.

Then, we assessed noise sensitivity as a moderator of our findings and found those with low and moderate sensitivity performed the VS with an unlimited capacity in quiet, but with a limited capacity when exposed to any level of noise. Alternatively, those with high sensitivity to noise performed with an unlimited capacity in quiet, or 70 dB and 80 dB noise, but with a limited capacity in 60 dB noise. Interestingly, those with low sensitivity performed the WM task more efficiently with 60 dB noise than quiet, but those with high sensitivity performed with a more limited capacity in 60 dB noise.

These data suggest that one's degree of noise sensitivity plays a role in the degree of impact and type of interference that steady-state F-35 cockpit noise has on negative affect, and visual (VS task) and auditory (WM task) efficiency, when attempting to multitask. Our study results may indicate that those who are highly sensitive to noise actively work to ignore the noise and focus on maintaining adequate performance in a task of another modality (visual). Alternatively, those with low sensitivity had a within-modality (auditory) boost from the low level of noise, while highly sensitive individuals performed worse in the auditory (WM) task with the same 60 dB noise. Interestingly, those with high sensitivity performed the worst in both tasks when exposed to the low level of noise.

4.1 Limitations and future research

This research has its limitations, but these serve to highlight the importance of future work. First, we chose to control for the level of noise exposure UHP, which necessarily made the level of noise in the room vary across people. The room level may change the degree to which one receives aural information via bone conduction, and the degree to which the sound vibrations may alter effects of physical and cognitive fatigue. Future work should investigate the impact of room level on cognitive performance and use a type of hearing protection that has little variability in the degree of protection between people.

We also chose that Session 1 would always be quiet to mitigate potential harm should participants unknowingly engage in risky behavior (e.g., adjusting their CEPs mid-session). However, future work should fully randomize session order to validate our results.

Our tasks jointly differed in modality and cognitive resource demands so the two cannot be disentangled regarding the impact of noise on cognitive processes. Future work should replicate this study and systematically manipulate perceptual and cognitive resources. While [14] found that distractions that cause higher executive and WM load impacts real-world VS performance, regardless of the source, future research should investigate the moderator of noise sensitivity.

Lastly, we necessarily chose a single source of steady-state aircraft noise, and controlled for the potential effects of fatigue from extended noise exposure. Future work should investigate how variable noise and other types of noise sources may differentially impact cognitive processing and decision-making of single- and multitask demands, and the effects of prolonged exposures that often occur in operational environments [4].

5. CONCLUSIONS

This study provides valuable insights into the effects of aircraft noise on cognitive processes involved in multitasking contexts. We found that noise exposure led to shifts in visual and auditory task performance, especially in multitasking contexts. Additionally, noise sensitivity influenced peoples' cognitive efficiency and emotional impact of noise exposure. Overall, these results underscore the importance of considering individual noise sensitivity when assessing the impact of noise on cognitive and emotional functioning, especially in environments where multitasking is prevalent, such as in aviation or other high-stress operational settings. Future research should build on these findings to further explore how different noise types and individual differences in sensitivity influence cognitive performance across various task demands.

Comparison of REAT and insertion loss measurements using headphone audiometry

Zimpfer Véronique[1*] **Hamery Pascal**[1] **Blondé-Weinmann Cyril**[1]
[1] French-German Research Institut of Saint-Louis (ISL), France

ABSTRACT

Under the current standard, hearing protector performance is assessed using the REAT (Real-Ear Attenuation at Threshold) method. This method involves measuring hearing thresholds with and without hearing protection in free-field conditions. The insertion loss of the hearing protection corresponds to the difference between these thresholds. REAT requires a highly sound-isolated audiometry room with minimal background noise and a diffuse field to ensure that both ears receive identical sound exposure. This study aims to compare REAT results with those obtained through headphone audiometry. Unlike REAT, headphone audiometry measures thresholds separately for each ear, allowing the detection of minor asymmetry between ears. Furthermore, this technique requires only an isolated cabin rather than a free-field environment. This study measured the insertion loss of two different types of earplugs on 13 subjects: a foam earplug and a custom-molded earplug in hard acrylic. These values show some differences between the two methods, with small variations at high frequency for foam earplugs and slightly greater variation at low frequency for custom molded earplugs. In addition, the standard deviation is significantly higher, especially for custom-molded earplugs.

Keywords: Earplug performance, REAT, Headphone audiometry.

1. INTRODUCTION

Every day, we are exposed to continuous and/or impulsive noise that can damage our hearing. In Europe, legislation prescribes a maximum noise exposure level of 87 dB(A) for 8 hours with hearing protection [1]. The best-known solution is using individual Hearing Protection Devices (HPDs), as it is often complicated to reduce the noise level of the sound sources. Adequate protection requires accurate knowledge of the HPD's performances.

Currently, the European and American industries consider the REAT (Real-Ear Attenuation at Threshold) method as the reference for assessing the performance of hearing protectors worn by an individual [2-5]. The REAT method corresponds to a hearing threshold evaluation performed in a diffuse sound field, with and without an HPD. Although the ANSI/ASA S12.6 and ISO 4869 standards describe a detailed protocol to measure the attenuation provided by a given device, the described procedure is generally uneasy to implement on a large scale.
Key difficulties include:

- Acoustic environment: Requires a very well-insulated anechoic room with low background noise and a diffuse sound field so that the two ears perceive the same sound.
- Participant hearing symmetry: participants must have symmetrical hearing in both ears, as threshold is measured with both ears together.
- An additionnnal issue is that Brueck (2009) has shown that the actual attenuation performance of earplugs is often different from that claimed by the manufacturer [8], which limits the relevance of this subjective method.

Alternatively, an objective method is also described in the ANSI Standard [6]. This method is based on the estimation of the HPD insertion loss using a microphone inserted in

the ear canal: it is the MIRE (Microphone In Real Ear) method. Installing a microphone in earplugs is difficult as it could damage them or create an acoustic leak. A study by Berger [7] showed that it is possible to use this method with earplugs specially designed for insertion of a microphone probe, but these earplugs can only be used to measure attenuation.

In this context, fit-test systems have been developed to measure the effectiveness of HPDs in situ. These systems have been used in the literature to measure the attenuation of earplugs [9,10].The aim of this study is to find a method for estimating the effectiveness of earplugs in the laboratory that is easier to implement than the REAT method and less intrusive than the MIRE method. We therefore propose to estimate insertion loss by measuring hearing thresholds with and without earplugs using headphone audiometry. Measuring threshold with headphones rather than in the open field has a number of advantages:

- the headphones isolate the subject, which simplifies the environmental conditions of the measurement,
- participants can present auditory asymmetry between the two ears as each ear is measured separately,
- there are two attenuation values for each subject (one for each ear).

2. MATERIAL AND METHOD

In this study, we performed a comparison between the results obtained with headphone audiometry and data provided by the earplug manufacturers, which were obtained by the approved laboratories using the REAT method.

2.1 Earplugs used

Two different earplugs have been evaluated (Figure 1) :

- A custom earplug in Crylit® manufactured by 3D printing, with a specific geometry for each ear tested,
- A classic foam earplug.

Figure 1. Photographs of the two earplugs used.

2.2 Headphone audiometry

The audiometer used was an Otometrics audiometer with TDH39 headphones. We used the Békésy method at fixed frequencies to measure hearing thresholds. With our equipment, we were able to measure the center frequency of octaves from 125 Hz to 8 kHz. The audiometer cannot measure frequencies below 125 Hz.

2.3 Participants

Thirteen voluntary subjects (nine males and four females) participated in the tests. Each participant has their custom earplug with the same filter from the same manufacturer.

2.4 Measurement protocol

Each participant sat in an audiometry booth in front of the audiometer. They each performed 4 audiometry, each time starting with the left ear:

- the first without an earplug;
- the second with the custom earplug;
- the third with the foam earplug;
- the fourth without the earplug.

The last test was used to check whether the participants were still focused. The measurements were validated if the difference between the first and last measurements did not exceed 5 dB for each frequency tested. The test lasted no longer than 20 minutes.

2.5 Estimated acoustic quantities

We determined the average attenuation per central octave frequency for each earplug between 125 Hz and 8 kHz over the 26 measurements (13 participants times 2 ears). For each frequency, the Assumed Protection Value (APV) was calculated. This APV corresponds to the mean value minus one standard deviation.

To calculate the SNR (Single Number Rating as described in ISO 4869-2 [5]) and the H, M, and L values, the earplug's attenuation at 63 Hz had to be estimated. It is proposed that the attenuation at 63 Hz be taken as the attenuation at 125 Hz minus 1 dB. The standard deviation is the same as at 125 Hz.

3. RESULTS

Figure 2 shows the average insertion loss values obtained for the 26 ears for the two types of earplug. These values are compared with the data provided by the earplug manufacturers. There was little difference except for the results at 125 Hz for the custom earplugs.

Figure 3 shows the APVs for the two types of earplugs. For the foam earplugs, there was a good correlation between our results and those provided by the manufacturer.

On the other hand, for the custom earplugs, where the standard deviation was significant, the APVs were lower than the manufacturer's data, especially at low frequencies. This discrepancy, caused by a very high standard deviation at low frequencies, cannot be explained at present.

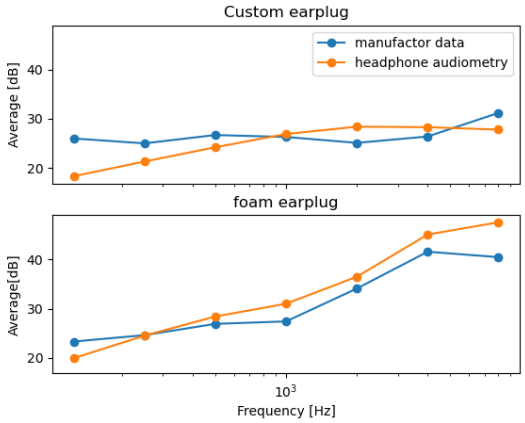

Figure 2. Average insertion loss for the two earplug.

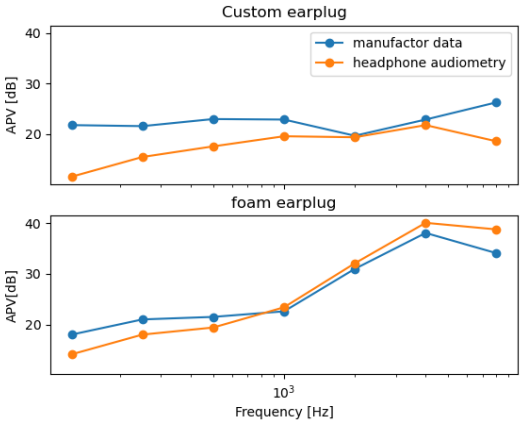

Figure 3. APV for the two earplugs.

Table 1 gives the two earplugs' SNR, H, M, and L values. As with the APV measurements for the foam earplug, the values for the custom earplugs are equivalent but slightly lower.

Table 1. SNR, H, M and L values for each earplug in dB.

	Custom earplug			
	SNR	H	M	L
Manufacturers data	27,7	30	24	22
Headphone audiometry	27	31	23	19
	Foam earplugs			
	SNR	H	M	L
Manufacturers data	23	21	22	22
Headphone audiometry	21	20	19	17

4. DISCUSSION

A method of assessing HPD that is simpler to implement than the REAT and MIRE methods was investigated. This approach consists of determining hearing thresholds with and without hearing protection using headphone audiometry.

In this preliminary assessment, the method gave promising results for foam earplugs, showing good agreement with the manufacturer's data. However, for custom earplugs, the method gave lower insertion loss and APV estimates than the manufacturer's data, especially at low frequencies.

One hypothesis to explain this difference could be that the static pressure exerted by the helmet on the auricle slightly affects the positioning of the protector, possibly reducing its performance. Indeed, the performance of custom earplugs can be more easily affected by deformation of the hearing canal than that of foam earplugs.

5. CONCLUSION & PESPECTIVE

Headphone audiometry method gives results that are consistent with the manufacturer's REAT measurements for foam earplugs. Nevertheless, this method warrants further study to verify whether the observations made with custom earplugs are valid. Given the difficulty of implementing this method, it could be used to verify whether or not the performance of earplugs is stable during prolonged wear. Indeed, Gong et al (2023) [10] reported a very slight loss after two hours of use. This new method could therefore be extended to assess changes in the performance of protectors over time, without the biases of conventional methods.

6. ACKNOWLEDGMENTS

We thank all the volunteers who participated in this test.

THE RELATIONSHIP BETWEEN DAMAGE RISK CRITERIA FOR IMPULSE NOISE EXPLAINED BY SIMPLE ACOUSTICAL DESCRIPTORS

Marian Weger*
French-German Research Institute of Saint-Louis (ISL), Saint-Louis, France

ABSTRACT

Hazardous impulse noise is still a major problem for personnel in industry and construction work, and particularly in the military. The allowed maximum permissible exposures per day for a certain combination of noise and hearing protection differ across countries, depending on the applicable criterion for predicting auditory hazard. Such Damage Risk Criteria (DRC) for impulse noise may take into account signal extrema, zero-crossings, amplitude/energy statistics, or physical ear models. Consequently their reactions to environmental and source characteristics diverge. We evaluated the differences between DRC and their correlations with acoustical descriptors. Most of the variance between hazard predictions by DRC could be explained by linear regression using only a few descriptors that cover certain key sound characteristics or peculiarities of the hearing system. This relationship allows us to better understand how certain sound characteristics translate to the risk of hearing damage and contributes to the ongoing discussion on future DRC standards. As the data comprised only a subset of soldiers' noise exposure, follow-up studies should include larger caliber weapons and complex noise combined with hearing protection, in order to draw more general conclusions.

Keywords: *impulse noise, damage risk criteria, weapon noise, auditory hazard, hearing injury*

1. INTRODUCTION

Despite all efforts and advances in noise control and Hearing Protection Devices (HPD), loud impulse noise still constitutes a major health risk for personnel in industry, construction work, and within the military. Especially during military training, noise exposures from firearms can induce hearing injury among soldiers. In order to quantify a soldier's individual risk of hearing injury, several objective Damage Risk Criteria (DRC) have been proposed. Their predictions, however, diverge, especially for ecologically valid scenarios comprising both continuous noise (from vehicles) and impulse noise (from weapon systems). Even within the EU, several national standards are in use; e.g., Pfander criterion in Germany, LAeq in France, or the Auditory Hazard Assessment Algorithm for Humans (AHAAH) in The Netherlands, and also the thresholds for the maximum admissible daily noise dose vary. At the time of writing, no currently available standard is sufficiently validated in order to cover all relevant aspects of auditory hazard. In addition, the differences between DRC as well as their individual qualities and restrictions are not yet entirely understood. The topic is therefore still subject to extensive civilian and military research worldwide. Various studies have compared existing DRC against each other, with respect to the predicted hazard or the resulting Maximum Permissible Exposures (MPE) per day (and per weapon/HPD combination).

For example, van der Eerden et al. [1] compared the A-weighted Sound Exposure Level (ASEL) to the risk predicted by the AHAAH. They concluded that there is no simple correlation between the two, especially due to the AHAAH's non-monotonic behavior. In particular, with growing impulse strength in terms of increasing Weber radius of synthesized Friedlander waves, ASEL grows monotonically, while the hazard predicted by the AHAAH decreases again, after having reached its maximum at an ASEL of around 140 dBA. In addition, the authors found that the AHAAH was disproportionately sensitive to additive continuous noise in comparison to ASEL. This can also be interpreted as low robustness against SNR [2].

The Pfander criterion ignores any sound below −10 dB with respect to the peak [3]. A major difference between Pfander and AHAAH thus concerns the inclusion of room reflections. Furthermore, their relationship shows the same non-monotonic behavior as between ASEL and AHAAH [3]. Pfander and ASEL were assumed to be too different to be converted into one another [4].

As ASEL also covers continuous noise, it is widely used in any context. For complex noise that exhibits both impulsive and continuous components, however, an adjustment in terms of "impulsiveness" (quantified by statistical kurtosis) correlated better with medical data than ASEL alone [5]. Likewise, the US military standard 1474E [6] includes an adjustment by the duration of the impulse in order to correct ASEL's assumed overestimation of large-caliber weapon noises.

As most of the mentioned studies were based on synthesized sounds, they provide valuable insights into the direct relationship between DRC and certain controlled parameters. However, these results cannot be easily transferred to actual weapon usage under realistic training conditions. We therefore compared hazard predictions by several DRC based on real recordings of shooting noise with different weapon configurations and under different ecologically valid environmental conditions (indoor and outdoor). The dataset is briefly described in Sec. 2, while the evaluated DRC are summarized in Sec. 3.

We further tried to predict the differences between DRC by selected acoustical descriptors that are supposed to cover sound qualities which might cause the respective differences. These descriptors are summarized in Sec. 4. In Sec. 5, correlations between DRC are analyzed and discussed in terms of their prediction by acoustical descriptors using multiple linear regression. Finally, general conclusions are drawn in Sec. 6.

2. DATASET & PREPROCESSING

The evaluation is based on the same dataset as described in [2]. It comprises impulsive noise events that were recorded within the multinational measurement campaign NATO RTG SET-286 carried out in 2023. These included 10 single shots with 9 weapon configurations reaching from pistol to anti-material rifle (some with silencer) using live ammunition in 8 environmental conditions (4 outdoor, 4 indoor) as well as 4 explosive configurations (stun grenade and 3 different door breaching charges) with 4 repetitions. Cleaned from defective items, the dataset includes 731 impulses. The stimuli are assumed to cover a majority of infantry soldiers' noise exposure. Recordings were made in 1 m distance at 90° left to the muzzle, with respect to shooting direction, at 1.6 m height or approximate ear level (for explosive, distances were only approximate between 1 m and 3 m).

For the calibrated recordings, the phase was occasionally flipped to always positive peak, DC offset was removed, and noise events were cut to 1 s duration, with the onset (where the amplitude first reaches −3 dB resp. peak) aligned to 5 ms. Signals were low-pass filtered by an 8th-order Bessel filter at 22 kHz cutoff frequency, as recommended by [7].

3. DAMAGE RISK CRITERIA

For each noise event of the above-described dataset, the auditory hazard was predicted by 6 different DRC: Pfander, Leq, LAeq, LIAeq, LAeq-Kurtosis, and AHAAH. Irrespective of the applicable limit, each of these DRC includes a hazard prediction function that we express in the form of hazard level L_H in dB for allowing meaningful comparisons. As the exact definitions used in this work may differ from other publications or national standards, we briefly summarize them below.

The Pfander criterion expresses auditory hazard by the Pfander level $L_\mathrm{H}^\mathrm{Pfander}$, see Eqn. (1), which depends on the unweighted (or Z-weighted) peak Sound Pressure Level (SPL) $\hat{L}_\mathrm{p}$ and C-duration T_C which is the sum of all time periods during which the waveform exceeds −10 dB below $\hat{L}_\mathrm{p}$ [8].

$$L_\mathrm{H}^\mathrm{Pfander} = \hat{L}_\mathrm{p} + 10\log_{10}(T_\mathrm{C}) \tag{1}$$

Leq predicts hazard based on sound energy. Sound exposure within a certain period of time is $E = \int p(t)^2 \mathrm{d}t$. The unweighted Sound Exposure Level (SEL) or L_E with respect to $E_0 = 400\,\mu\mathrm{Pa}^2\mathrm{s}$ is then interpreted as hazard level $L_\mathrm{H}^\mathrm{SEL}$:

$$L_\mathrm{H}^\mathrm{Leq} = \mathrm{SEL} = L_\mathrm{E} = 10\log_{10}(E/E_0) \tag{2}$$

LAeq extends Leq by incorporating the A-weighted sound exposure E_A:

$$L_\mathrm{H}^\mathrm{LAeq} = \mathrm{ASEL} = L_\mathrm{A,E} = 10\log_{10}(E_\mathrm{A}/E_0) \tag{3}$$

LIAeq is an extension to LAeq that adjusts ASEL through the A-duration T_A, i.e., the duration between the last zero crossing before and the first zero crossing after the peak, as given in Eqn. (4). In the actual standard, T_A is restricted between 0.2 ms and 2.5 ms [6]; however, as no other DRC includes such hard parameter clipping, we

leave T_A unrestricted for the current evaluation. Note that we use the alternative version for 1 s window length [6].

$$L_\mathrm{H}^\mathrm{LIAeq} = L_\mathrm{A,E} - 1.5 \cdot 10 \log_{10} \left(T_\mathrm{A}/0.2\,\mathrm{ms}\right) \quad (4)$$

LAeq-Kurtosis, originally developed for complex factory noise [9], adjusts ASEL by the statistical measure of kurtosis β, as given in Eqn. (5). A $\beta > 3$ (larger than kurtosis of Gaussian noise) means stronger tails of the probability distribution, i.e., more extreme values due to impulses. The amount of adjustment is set to $\lambda = 4.02$ [9]. Kurtosis is computed for the entire 1 s analysis window.

$$L_\mathrm{H}^\mathrm{LAeq\text{-}K} = L_\mathrm{A,E} + \lambda \log_{10} \left(\beta/3\right) \quad (5)$$

The AHAAH implements a physical model of the hearing system. It interprets the maximum basilar membrane displacement due to noise exposure as potential hazard H^AHA, expressed in Auditory Risk Units (ARU) and hazard level after (6). Note that we consider only the unwarned mode, meaning that the acoustic reflex is initially deactivated and gets triggered by the impulse [10, 3]. The acoustic reflex ramps in with a time constant of $\tau = 11.7$ ms, starting at 9 ms after the 134 dB threshold is exceeded for the first time. For consistent results with lower levels, we use an adaptive threshold at -3 dB below the peak. Due to the sharp rising edge of weapon noises, in theory following a Friedlander wave, the resulting error in trigger time is considered negligible.

$$L_\mathrm{H}^\mathrm{AHA} = 10 \log_{10} \left(H^\mathrm{AHA}/10^{-10}\,\mathrm{ARU}\right) \quad (6)$$

4. ACOUSTICAL DESCRIPTORS

In order to better understand the differences between DRC, we tried to predict their results by different combinations of acoustical descriptors. These are briefly summarized below.

4.1 Peak, action times, and energy

Most of the examined DRC themselves are already constructed from a couple of descriptors which we include into the analysis: peak SPL $\hat{L}_\mathrm{p}$, C-duration T_C, A-duration T_A, SEL L_E, ASEL $L_\mathrm{A,E}$, kurtosis k. In addition to these, we add common variants using A- and C-weighting that are not yet contained: $\hat{L}_\mathrm{A,p}$, $\hat{L}_\mathrm{C,p}$, and CSEL ($L_\mathrm{C,E}$) To account for spectral differences, we use the Spectral Centroid (SC) that is the frequency-weighted sum of spectral bins normalized by their unweighted sum.

4.2 Diffuseness

An important sound characteristic that is not yet covered by the above descriptors is diffuseness, i.e., the amount of reflections or reverberation that is defined by the environment in which the noise is perceived. A simple statistical descriptor for diffuseness is the Direct-to-Reverberant energy Ratio (DRR), i.e., the ratio between direct and reverberant sound energy. In practice, a Room Impulse Response (RIR) is split at an arbitrary time, typically 2.5 ms after the onset, into the direct and the reverberant part. For impulse noise, the recordings can already be interpreted as impulse responses, which allows us to directly obtain DRR according to Eqn. (7):

$$\mathrm{DRR} = 10 \log_{10} \left(\frac{\int_{t=0}^{2.5\,\mathrm{ms}} p(t)^2 \mathrm{d}t}{\int_{t=2.5\,\mathrm{ms}}^{\infty} p(t)^2 \mathrm{d}t} \right) \quad (7)$$

4.3 Psychoacoustical descriptors

If the frequency weighting curves that are so commonly used in noise assessment actually reflect anything, then that is sound perception.

Using A- and C-weighting curves for predicting auditory hazard implies the assumption that there is a relationship between auditory perception and the risk of hearing injury. We might therefore assume that psychoacoustical sound quality metrics correlate with that risk as well. Using the Sound Quality Analysis Toolbox (SQAT) [11], we computed Perceptual Loudness (PL) in sone [12], Perceptual Sharpness (PS) in acum [13], and Perceptual Roughness (PR) in asper [14]. Note that we used the time-variant (non-stationary) definition in free field and skipped the first 4 ms of the analysis window, i.e., starting 1 ms before the onset. As we seek single predictor values instead of block- or band-wise results, we used averages as well the maximum values as descriptors: $\mathrm{PL}_\mathrm{mean}$, PL_max, $\mathrm{PS}_\mathrm{mean}$, PS_max, $\mathrm{PR}_\mathrm{mean}$, PR_max.

4.4 Acoustic reflex and banded energy

The AHAAH incorporates several non-linear effects that are surely not covered by the acoustical descriptors that have been introduced in this section so far. Two of these are the acoustic reflex and the maximum basilar membrane displacement. Below, we derive very simplified signal processing models for both aspects, in order to obtain acoustical descriptors that may express similar information.

4.4.1 *Acoustic reflex*

As the activation of the acoustic reflex is a binary decision (triggered when the instantaneous sound pressure passes a threshold of 134 dB) its activation function equals a step function $u_\mathrm{A}(t)$ that is 0 before the onset, and 1 afterwards. In the AHAAH model, activation is smoothed by a 1st-order low-pass RC filter with time constant $\tau = 11.7$ ms, which we implement as leaky integrator whose output $s_\mathrm{A}(t)$ is the smoothed activation function:

$$s_\mathrm{A}[n] = (1-\alpha)u_\mathrm{A}[n] + \alpha u_\mathrm{A}[n-1] \quad (8)$$

$$\text{where} \quad \alpha = e^{-1/(\tau F_\mathrm{s})} \quad (9)$$

Once the acoustic reflex is fully activated, its effect can be regarded as a shelving filter that attenuates frequencies below 3 kHz by up to -21 dB (gain $g_\mathrm{S,min} = 0.089$) [15, 21]. Assuming that the filter attenuation is directly controlled by $s_\mathrm{A}(t)$, the dynamic filter gain becomes:

$$g_\mathrm{S}(t) = 1 - (1 - g_\mathrm{S,min})\, s_\mathrm{A}(t) \quad (10)$$

The applied filter uses a constant cutoff frequency at 3 kHz and a slope of 1, combined with the dynamic gain $g_\mathrm{S}(t)$. The application of this simple filter model of the acoustic reflex on a noise measurement is now defined as "unwarned"- or uw-weighting. For the already-included sound energy predictors SEL, ASEL, and CSEL, we add their respective variants $L_\mathrm{E,uw}$, $L_\mathrm{A,E,uw}$, and $L_\mathrm{C,E,uw}$ to the analysis.

4.4.2 *Maximum banded sound exposure*

Within the AHAAH, the displacement of the basilar membrane is analyzed at 23 discrete locations of equal spacing across its length from the oval window to the round window [16, 15]. These locations are attributed to equally-spaced frequencies on a logarithmic scale, from 11.76 kHz down to 0.38 kHz. A rough approximation of this excitation pattern can be achieved by a gammatone filterbank (GTFB), a widely used model for the auditory filters [17]. For modeling auditory perception, their center frequencies are typically tuned to equal spacing on the ERB-rate scale, with constant bandwidth in parts of the Equivalent Rectangular Bandwidth. In order to match the AHAAH model, we tune them to the same 23 center frequencies, with bandwidths set accordingly so that neighboring bands overlap at their -4 dB cutoff frequency (e.g., as done in [18]). The exposure within the 23 frequency bands b is computed with Z-, A-, and C-weighting, in order to obtain banded exposure levels L^b_E, $L^\mathrm{b}_\mathrm{A,E}$, and $L^\mathrm{b}_\mathrm{C,E}$, respectively. As the AHAAH evaluates the maximum across locations, we likewise compute the maximum across bands, $L^\mathrm{max}_\mathrm{E}$, $L^\mathrm{max}_\mathrm{A,E}$, and $L^\mathrm{max}_\mathrm{C,E}$, respectively, as acoustical predictors of auditory hazard. In addition, we also consider their uw-weighed variants: $L^\mathrm{max}_\mathrm{E,uw}$, $L^\mathrm{max}_\mathrm{A,E,uw}$, and $L^\mathrm{max}_\mathrm{C,E,uw}$.

5. CORRELATIONS BETWEEN DRC AND ACOUSTICAL DESCRIPTORS

Based on the acoustical descriptors that were derived above, we aimed at explaining differences between DRC and at predicting the respective hazard level by other means. We investigated all possible and meaningful combinations of 1-, 2-, and 3-way linear prediction models (without and with interactions) made from the above descriptors, for predicting the hazard levels of the evaluated DRC. Combinations are considered as meaningful if the predictors are either more robust with regard to technical parameters of the measurement (as of [2]) or more computationally efficient in view of an implementation on embedded platforms. Best fitting models are selected with respect to the Akaike Information Criterion (AIC) in order to avoid overfitting.

5.1 Pfander and Leq

The Pfander level is known for being a good predictor of signal energy, yet avoiding actual integration. The correlation between L_E and $L^\mathrm{Pfander}_\mathrm{H}$ is shown in Fig. 1 for outdoor and indoor recordings, respectively. Outdoors, we observe almost perfect correlation ($L^\mathrm{Pfander}_\mathrm{H} \approx L_\mathrm{E} + 3$ dB, $R^2 = 0.989$). If analyzing the difference between target ($L^\mathrm{Pfander}_\mathrm{H}$) and the linear model based on SEL, the resulting Probability Density Function (PDF) is a superposition of two almost normal distributions (Fig. 2, $R^2 = 0.955$). In Fig. 2 and all following figures, marker colors correspond to weapon categories (Pistols P, Assault Rifles AR, Battle Rifles BR, Sniper Rifles SR, and Explosive E), while marker shapes depict specific models/configurations; filled/unfilled markers represent outdoor/indoor settings, respectively. As the difference between Pfander and Leq primarily concerns diffuseness, the best performing two-way model uses SEL in combination with the DRR ($R^2 = 0.973$), resulting in a PDF more close to normal (Fig.3). Individual weapon configurations now spread along straight lines, which suggests that the majority of the remaining variance is within weapon conditions. The remaining variance could not be explained without the Pfander descriptors $\hat{L}_\mathrm{p}$ or T_A themselves.

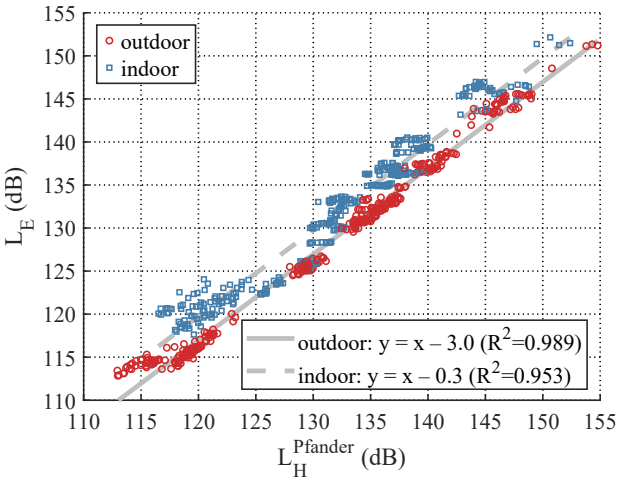

Figure 1. L_E as a function of $L_\mathrm{H}^\mathrm{Pfander}$.

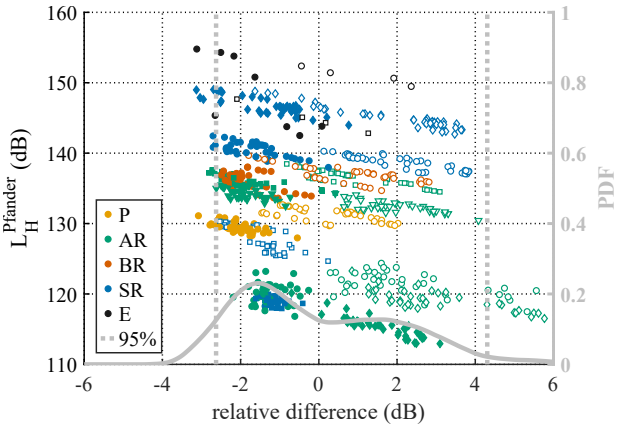

Figure 2. $L_\mathrm{H}^\mathrm{Pfander}$ predicted L_E ($R^2 = 0.955$). Marker coding: color = weapon category, shape = weapon model, filled/unfilled = outdoor/indoor.

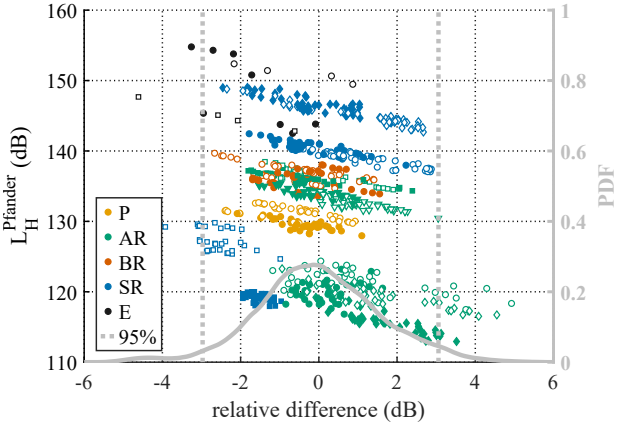

Figure 3. $L_\mathrm{H}^\mathrm{Pfander}$ predicted by L_E and DRR ($R^2 = 0.973$).

5.2 LAeq

The difference between LAeq and Leq is shown in Fig. 4. It follows a characteristic curved shape due to the interplay between A-weighting and noise level. As all tested noises originate from explosions (firearms or explosive charges), the resulting sounds are band-limited, in theory exhibiting a Weber spectrum. Its center frequency decreases with increasing Weber radius, i.e., increasing intensity. Maximum sound energy is thus passed for ASEL ≈ 130 dBA, when A-weighting and Weber spectrum maximally overlap, i.e., when their center frequencies match. The center frequency can be expressed by SC. An interaction between SEL and SC is thus supposed to account for the difference between ASEL and SEL. The best-performing two-way linear model with interactions, however, combined SEL directly with the A-weighted peak, as shown in Fig. 5 ($R^2 = 0.997$). It must be noted that the interaction model of $\hat{L}_\mathrm{C,p}$ and k_A was almost as good ($R^2 = 0.996$).

5.3 LIAeq

As LIAeq depends on A-duration, it is extremely sensitive to the exact measurement specifications and signal preprocessing, which makes it almost impossible to obtain consistent results [2]. Figure 6 shows the difference between LIAeq and LAeq, thus the effect of A-duration. Note the sniper rifle with silencer (blue squares) for which the A-duration is not meaningful and thus leads to extreme variance. Although a more robust equivalent to T_A might be interesting, no useful predictor could be found within the tested acoustical descriptors including their combination. The best-performing descriptor was $\hat{L}_\mathrm{p}$ with only moderate correlation ($R^2 = 0.420$).

5.4 LAeq-Kurtosis

The difference between LAeq-Kurtosis and LAeq (i.e., the contribution of kurtosis adjustment) is shown in Fig. 7. Similar as for the difference between Pfander and Leq, the difference is mainly due to diffuseness. While ASEL alone increases with higher diffuseness due to the added energy of reflections, the resulting difference between indoor and outdoor that is visible in Fig. 7 is effectively minimized through kurtosis adjustment, leading to similar $L_\mathrm{H}^\mathrm{LAeq\text{-}K}$ indoor and outdoor. $L_\mathrm{H}^\mathrm{LAeq\text{-}K}$ could be well predicted by

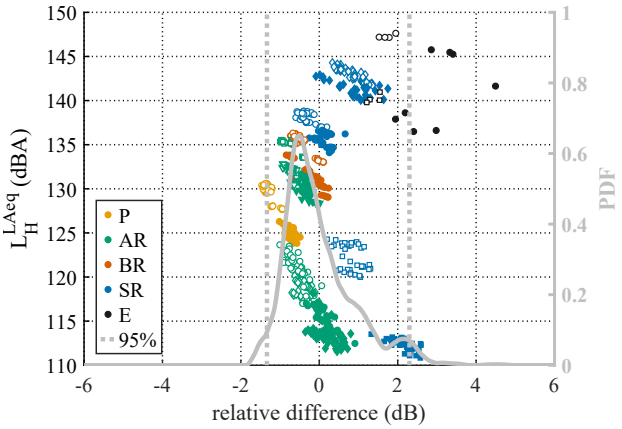

Figure 4. $L_{A,E}$ predicted by L_E ($R^2 = 0.991$).

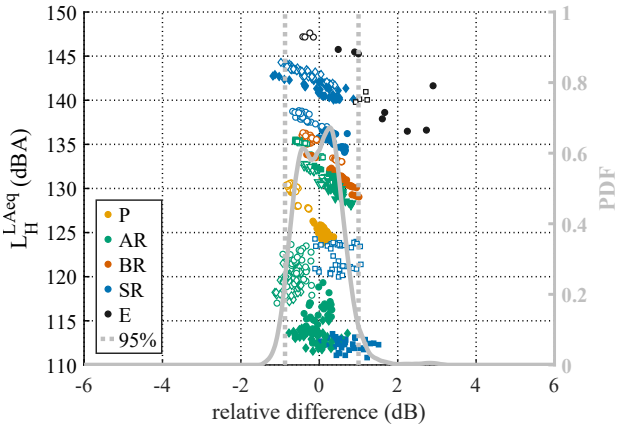

Figure 5. $L_{A,E}$ predicted by L_E and $\hat{L}_p$ (with interaction, $R^2 = 0.997$).

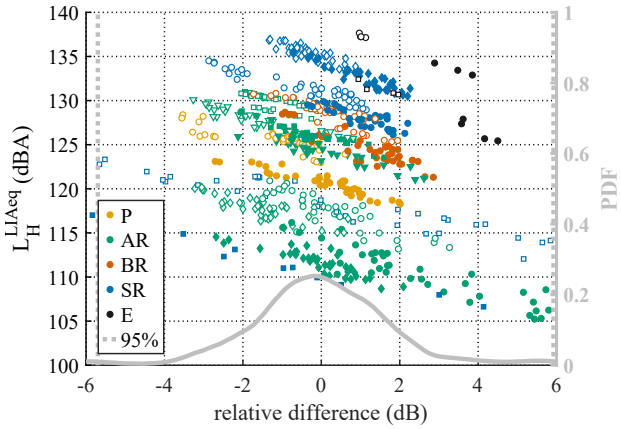

Figure 6. L_H^{LIAeq} predicted by $L_{A,E}$ ($R^2 = 0.897$).

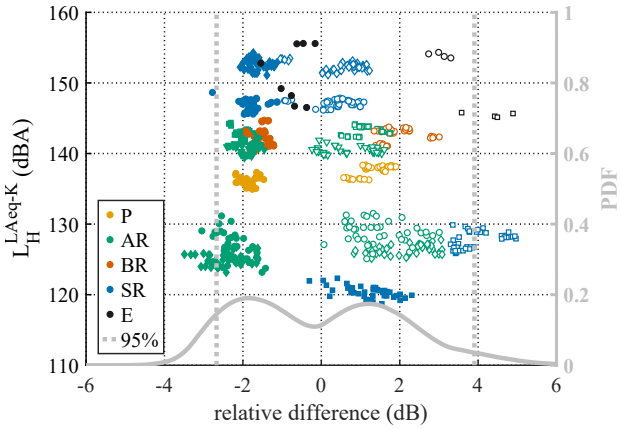

Figure 7. L_H^{LAeq-K} predicted by $L_{A,E}$ ($R^2 = 0.960$).

$\hat{L}_{C,p}$ alone ($R^2 = 0.986$), as shown in Fig. 8, even better by an interaction model of $\hat{L}_{C,p}$ and CSEL ($R^2 = 0.998$) or best (in terms of lowest AIC) by DRR_A, $\hat{L}_{A,p}$ and $L_{A,E}$ ($R^2 = 0.999$, see Fig. 9). The best single predictor for kurtosis alone was DRR_A ($R^2 = 0.822$).

5.5 AHAAH

The best-performing single linear predictor of L_H^{AHA} was the maximum banded ASEL, $L_{A,E}^{max}$ (Fig. 10); however, the AHAAH is too complex for being predicted by such a simple signal model and thus only moderate correlation was achieved ($R^2 = 0.640$), on par with ASEL ($R^2 = 0.624$). The unwarned version of banded ASEL with simplified acoustic reflex was no improvement, as the reflections are anyway underrated due to other mechanisms within the AHAAH. The best-fitting two-way model is therefore a linear combination of $L_{A,E}^{max}$ in conjunction with DRR, as shown in Fig. 11 ($R^2 = 0.904$).

6. CONCLUSIONS AND OUTLOOK

We compared 6 DRC for impulse noise in terms of their respective prediction of auditory hazard. Comparisons were based on a dataset that covers a majority of the impulsive noise exposure of infantry soldiers.

In order to explain the differences between hazard predictions, we tested different kinds of acoustical descriptors based on the unweighted, A-weighted, and C-weighted sound recording. Classical descriptors included action times, SEL, and peak SPL. Statistical descriptors included kurtosis and DRR. Psychoacoustical descriptors included perceptual loudness, sharpness, and roughness. Additional

descriptors were derived in order to account for specific characteristics of the AHAAH model. These include a simple filter model of the acoustic reflex as well as a rough approximation of the maximum basilar membrane displacement across fixed positions by taking the maximum exposure across auditory filters.

Most variance between the examined DRC could be explained by linear models of one or multiple descriptors. The difference between Pfander and Leq is mainly due to reflections and thus well expressed by the DRR. The difference between LAeq and Leq, i.e., the effect of A-weighting, could be explained by the interaction between SEL and either peak or SC. LAeq-Kurtosis could be almost perfectly predicted by a combination of C-weighted peak and CSEL. Finally, the auditory hazard predicted by the AHAAH model was best modeled by the maximum of banded ASEL in combination with DRR. The difference between LIAeq and LAeq, i.e., the A-duration, however, could not be sufficiently modeled by any of the tested descriptors. Loudness, sharpness, and roughness did not perform well in predicting the examined DRC. However, this does not exclude a possible correlation with the actual risk of hearing injury, as the examined DRC themselves are insufficiently validated in this concern. We can further conclude that a major aspect of the AHAAH model can be replicated by banded energy. We suppose that similar results could even be obtained from ASEL in $1/3$-octave bands. The simple acoustic reflex model was not useful in this concern, presumably because its effect is concealed by an even stronger effect of diffuseness that is better

covered by the DRR. For specific applications such as mobile noise dosimetry, it might be beneficial to use such an alternative computation that is either more robust or less computationally expensive.

The DRR generally proved to be a good predictor of differences between DRC that emerge from diffuseness. As the Pfander criterion exhibits low robustness against measurement specifications due to dependency on peak and zero crossings [2], it might be tempting to replace its computation by a more robust prediction model using SEL and DRR. However, the DRR was found to be equally sensitive as C-duration and is therefore no useful substitute. Other measures of diffuseness should therefore be evaluated in the future. A major shortcoming of this evaluation is the restriction to impulse noise, although some of the DRC were designed for complex noise that includes continuous sound by vehicles or machinery. As the data included only a subset of soldiers' noise exposure, future studies should also include complex noise and heavier weapons in order to draw more general conclusions.

SPEECH INTELLIGIBILITY IN NOISE OF SINGLE-SIDED DEAF COCHLEAR IMPLANT USERS FOR NEAR AND DISTANT TALKERS

Thomas Wesarg[1*]
[1] Department of Otorhinolaryngology, Medical Center – University of Freiburg, Germany

ABSTRACT

People with single-sided deafness (SSD) encounter hearing problems particularly related to speech perception in noise. Among the different treatment options, only the cochlear implant (CI) allows for a (re)habilitation of binaural hearing. Various studies with SSD CI users have shown binaural benefits of CI in speech intelligibility in noise (SIN) for near target talkers including the summation effect, and benefits of the application of remote microphone technology in SIN for distant talkers both on group level.
The aim of this paper is to evaluate the relations between the speech intelligibility in quiet (SIQ) with the CI only and the benefit of a CI in SIN for near talkers on the one hand, and the benefit of remote microphone technology in SIN for distant talkers on the other hand, in adult SSD CI users. The analysis revealed that the SIQ with the CI only was positively correlated with the benefit of remote microphone technology in SIN for distant talkers, while it was not correlated with the benefit of a CI in SIN for near talkers.

Keywords: *cochlear implant, remote microphone, speech intelligibility, summation effect*

1. INTRODUCTION

People with single-sided deafness (SSD) have difficulty understanding speech in challenging listening situations, particularly in noisy environments [1,2]. According to [3], SSD is defined as having a four-frequency (0.5, 1.0, 2.0, and 4.0 kHz) pure-tone threshold average (4PTA) of at least 70 dB HL, i.e. a severe to profound hearing loss in the poorer ear, a 4PTA of at most 30 dB HL, i.e. normal or nearly-normal hearing (NH) in the better ear, and an interaural threshold gap of at least 40 dB HL. Treatment options for SSD include conventional contralateral routing of signal hearing aid, bone conduction device, and cochlear implant (CI). However, (re)habilitation of hearing in the poorer ear and restoration of binaural hearing can only be achieved with a CI.
Several studies have shown CI treatment of people with SSD to enable significant improvements of speech intelligibility in noise (SIN) when binaurally listening with the NH ear and the CI compared to monaural listening with the NH ear only. These studies investigated SIN for near target talkers, i.e. talker-to-listener distances of at most 1.5 meters, and revealed various binaural effects with CI, particularly head shadow and summation [4-7]. For bilateral CI users, the summation effect, which is assessed for frontal presentation of target speech in quiet or collocated noise, has been shown to relate negatively to the interaural asymmetry in SIN, i.e. the difference in monaural SIN between the better and poorer CI [8,9]. In SSD CI users, the summation effect may also be negatively related to the interaural asymmetry in monaural speech intelligibility (SI), i.e. the difference in SI between the NH ear and the CI, and positively related to the SI with the CI only. The first aim of this paper is to evaluate the relation between the binaural summation effect for speech in noise and the monaural speech performance in quiet with the CI in SSD CI users.
SI for distant talkers in multi-source noise environments with medium and higher noise levels such as frontal teaching in a noisy classroom is poor in unilateral, bimodal and bilateral CI users, and is significantly improved by the application of remote microphones (RMs) [10,11]. RMs pick-up the target speech with a high signal to noise ratio (SNR) and transmit it wirelessly to a receiver connected to or built in a hearing device, e.g. CI sound processor or hearing aid (HA). RMs have also been shown to improve

SIN for distant talkers in multi-source classroom noise in SSD CI users, when used with the CI, NH ear or bilaterally [12]. In SSD CI users, the benefit of RMs, when used with the CI, in SIN may be positively related to the SIQ or SIN with the CI only, respectively. The second aim of this paper is to investigate this relation with regard to the monaural speech performance in quiet with the CI.

2. BENEFIT OF A COCHLEAR IMPLANT

2.1 Methods

To assess the relation between the summation effect with a CI for speech in noise and the monaural speech performance in quiet with the CI, the SIN data of the twelve adult subjects with SSD who participated in a prospective hearing device comparison study at our department and received a cochlear implant during this study [7] were analyzed. In this study, the summation effect was calculated as the difference in speech reception threshold (SRT) between listening in unaided condition preoperatively and binaural listening with the NH ear and CI at six months post activation, and this summation effect is referred to in the present paper. The SRTs were measured for presentation of sentences of the Oldenburg sentence test (OLSA, German matrix test) in collocated speech-shaped noise at 65 dB SPL from a frontal speaker one meter apart from the participants. The Freiburg monosyllabic word recognition score (WRS) in quiet obtained with the CI only at six months post activation within clinical routine was used to describe the monaural SIQ with the CI. To analyze the relation between the summation effect and the monaural SIQ with the CI, the Spearman's rank correlation coefficient is calculated.

2.2 Results

The twelve SSD CI participants showed median SRTs in speech-shaped noise of -4.7 dB SNR (-6.2 dB SNR – 3.1 dB SNR) preoperatively unaided and -5.8 dB SNR (-8.2 dB SNR – -4.7 dB SNR) binaural at six months post activation resulting in a significant median summation effect of 1.4 dB (0.2 dB – 2.8 dB; p = 0.013) [7]. At six months with CI, their median monaural WRSs were 100% (90% – 100%) with the NH ear and 25% (0% – 40%) with the CI resulting in a median interaural difference in monaural WRS of 72.5% (60% – 90%). Figure 1 presents a scatterplot of the individual summation effects versus the individual monaural WRSs with the CI. Between these measures, there was no significant correlation (p = 0.615).

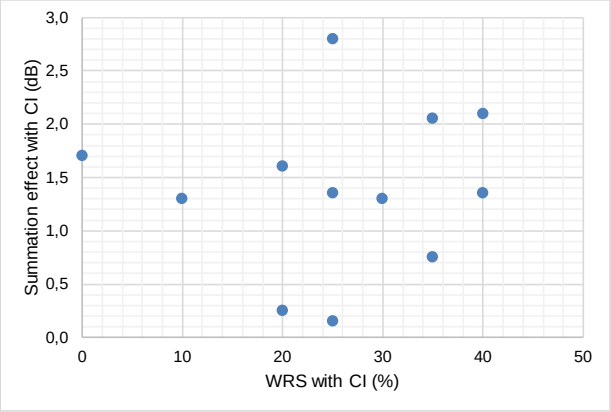

Figure 1. Scatterplot of summation effect versus monaural word recognition score (WRS) with CI.

2.3 Discussion

Contrary to our expectation, there was no significant correlation between the binaural summation effect with the CI for speech in noise and the monaural SIQ with the CI in the twelve SSD CI participants. The missing correlation might be due to the application of a speech in quiet instead of a speech in noise measure to assess the monaural speech performance with the CI, and/or the small sample size and thus low statistical analysis power. Therefore, future studies should include more SSD CI users and use speech in noise measures for both the summation effect and the monaural speech performance to investigate the relation between these measures.

3. BENEFIT OF A REMOTE MICROPHONE

3.1 Methods

The relation between the benefit of a RM in speech performance in noise and speech performance in quiet with the CI is assessed using the SIQ and SIN data of the eleven adult SSD CI users who participated in a prospective remote microphone technology study at our department [12]. In this study, the participants had a CI experience of ten to 122 months at the time of testing. For monaural listening with the NH ear as well as binaural listening with the NH ear and the CI (condition NH+CI), and, amongst other RM conditions, for binaural listening with the NH ear and the CI with a RM (transmitter Roger Pen, receiver Roger X; Phonak AG, Stäfa, Switzerland) connected with the CI (NH+CI/RM), the speech recognition score (SRS) for presentation of OLSA sentences from a loudspeaker 5.5 meters in front of the participants in a multi-source

classroom noise established by Schafer and Thibodeau [13] was measured. At the position of the participants, the speech level was 60.3 dB(A) and the noise level was 65 dB(A) yielding an SNR of -4.7 dB.
For each participant, the benefit of the RM used with the CI, is calculated as the difference in speech recognition score (SRS) between the NH+CI/RM and NH+CI listening conditions. The present paper refers to this RM benefit and to the Freiburg monosyllabic WRS with the CI only obtained at the time of testing in this study, and the Spearman's rank correlation coefficient is calculated to analyze the relation between these measures.

3.2 Results

In multi-source classroom noise, the eleven SSD CI participants yielded median SRSs of 16.0% (0.7% – 39.3%) with the NH ear, 18.0% (4.0% – 36.7%) in the NH+CI condition, and 87.3% (27.3% – 95.3%) in the NH+CI/RM condition. Compared to binaural listening with the NH ear and CI, binaural listening and using a RM with the CI enabled a significant median improvement in SRS, i.e. a significant median benefit of the RM of 57.3% (16.0% – 91.3%). At the time of testing, the participants' median monaural WRS with the CI was 55% (50% – 95%). A scatterplot of the individual benefits of the RM used with the CI versus the individual monaural WRSs with the CI is illustrated in Figure 2. The rank correlation analysis revealed a significant positive correlation between these measures (*rho* = 0.5456, *p* = 0.082).

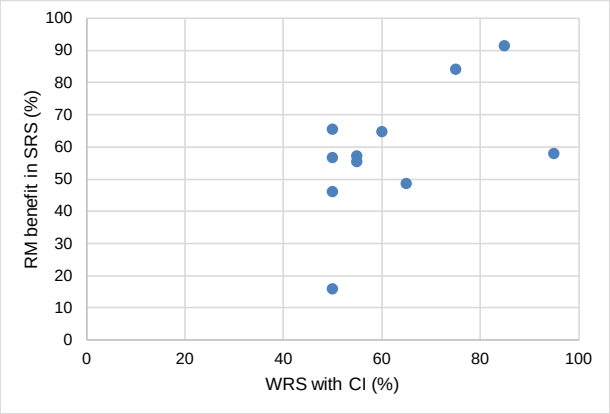

Figure 2. Scatterplot of benefit of a remote microphone (RM) used with CI in speech recognition score (SRS) versus monaural word recognition score (WRS) with CI.

3.3 Discussion

According to our expectation, there was a significant positive correlation between the benefit of the remote microphone (transmitter Roger Pen, receiver Roger X) used with the CI in SIN for a frontal talker in a multi-source noise classroom environment and the SIQ with the CI only in the eleven SSD CI participants. This result suggests that SSD CI users showing a good monaural SIQ with the CI should use RMs with the receiver attached to their CI, while SSD CI users with poor SIQ with the CI only should use RMs with the receiver Roger Focus attached to their NH ear, to obtain a considerable improvement in speech performance for distant talkers in multisource-noise environments. The benefit of the RM in SIN assessed in the eleven SSD CI users in the remote microphone technology study [12] is due to the improvement of the SNR of the target speech at the listener's position, which is based on both overcoming the spatial decay of target speech-level over the distance between the talker and the listener and the application of an adaptive beamformer in the RM transmitter. However, the contributions of both effects were not investigated separately in this study, and thus cannot be disentangled.

EFFECT OF REDUCING THE STATIC INTERAURAL TIME DIFFERENCE IN BIMODAL LISTENERS

Zirn, S.[1], Roth, S. [1,2], Mueller, F.-U. [1,2], Hemmert, W.[2], Angermeier, J. [1,3]

ABSTRACT

Previous work has shown that the ability to localize sound signals in the horizontal plane can be improved in listeners provided with a cochlear implant (CI) in one ear and a hearing aid (HA) in the contralateral ear (bimodal listeners) when the static interaural time delay between the modalities is technically reduced. The timing mismatch is caused by differences in the processing latencies of CI and HA and by different stimulation sites (CI: auditory nerve; HA: external auditory canal). In 2020 the CI manufacturer MED-EL has made the technical reduction of the timing mismatch available by a programmable across-frequency CI stimulation delay.
To reduce the timing mismatch even further, we now use frequency-dependent delays to minimize the timing mismatch in every frequency band. Results show that the rms and the signed bias of sound localization can be further reduced in most bimodal study participants when using frequency-specific delays compared to an across-frequency delay. However, it is methodically complex to determine appropriate delays for different frequency bands. It is therefore questionable whether frequency-specific delays are useful in clinical practice.

Keywords: *bimodal hearing, sound localization, timing*

1. INTRODUCTION

Bimodal hearing refers to the use of two different types of hearing devices in opposite ears: a cochlear implant in one ear and a hearing aid in the other. This approach leverages the distinct advantages of each device to enhance overall auditory perception, particularly for individuals with asymmetric hearing loss or those who receive limited benefit from hearing aids alone.

A cochlear implant bypasses damaged parts of the inner ear by directly stimulating the auditory nerve with electrical signals, providing access to sound for individuals with severe to profound sensorineural hearing loss [7]. On the other hand, a hearing aid amplifies sound acoustically and is suited for individuals who have some residual hearing capability [3]. When used together in a bimodal configuration, these devices can complement each other, with the cochlear implant providing clear access to speech and the hearing aid enriching sound quality and providing additional auditory cues, such as pitch and timbre, that enhance music perception and spatial awareness [4].

Research and clinical experience show that bimodal hearing can significantly improve speech understanding in noise, localization of sound, and overall quality of life for individuals with hearing loss. This synergistic effect capitalizes on the brain's ability to integrate complex signals from both devices, fostering a more natural and comprehensive listening experience [5, 6]. Despite the synergistic effect and its potential benefits, sound localization is usually significantly worse in bimodal listeners compared to bilateral HA users or even bilateral CI

users [8]. One reason for this are interaural mismatches in bimodal stimulation.

2. INTERAURAL MISMATCHES IN BIMODAL HEARING

Bimodal hearing presents unique challenges, primarily due to potential interaural mismatches in loudness, frequency, and timing. These mismatches can affect the integration of auditory information and the overall hearing experience.

Loudness Mismatches: Loudness perception can differ significantly between the electrically-stimulated ear with a cochlear implant and the acoustically-amplified ear with a hearing aid. The dynamic range of a cochlear implant is typically smaller than that of normal acoustic hearing, requiring careful adjustment to match loudness levels across ears [3]. This discrepancy can lead to difficulty in balancing sound perception, affecting binaural cues necessary for localization and speech understanding in noise [7].

Frequency Mismatches: Frequency mismatches occur because cochlear implants often provide less precise frequency resolution compared to acoustic hearing aids. Cochlear implants convey sound via a limited number of electrodes, each stimulating a broad frequency band, which might not align perfectly with the natural cochlear tonotopy that hearing aids aim to preserve [4]. This can impact the quality of sound perception, especially for complex sounds like music, which rely heavily on fine frequency discrimination [6].

Timing Mismatches: Temporal processing differences between the ears can also pose challenges. Cochlear implants process sound with manufacturer dependent delays due to differences in signal processing and stimulate the auditory nerve directly. However, acoustic hearing aids process sounds in front of the ear and input the amplified sound into the outer ear canal. From there on the natural middle and cochlear delays apply [2]. The resulting timing differences can impair sound localization [1].

Addressing these interaural mismatches involves personalized device programming and fitting strategies to better align the loudness [10], frequency [9], and timing [1] cues offered by each device, thereby enhancing the benefits of bimodal hearing.

3. METHODS

Bimodal hearing test subjects were seated in an audiometric booth equipped with a sound localization setup designed to assess auditory spatial awareness, 11 loudspeakers were positioned in a horizontal arc at ear level in front of the subject, each spaced 15° apart, covering a total span from -75° to +75° relative to the forward-facing position. A central loudspeaker is positioned at 0°, with others extending symmetrically in both directions. Correspondingly, an LED array with 180 LEDs mirrored this setup, each LED representing a loudspeaker position for response indication. The test began with the subject seated, facing the 0° speaker. During the test, pulsed noise with level an spectral roving was randomly played from the loudspeakers. Subjects then indicated perceived sound locations by activating the corresponding LED. These responses are recorded for analysis.
Before the test started loudness between ears/devices was balanced. Subjects were then tested in three different conditions in a randomized order. Condition 1: No compensation of timing nor frequency mismatch. Condition 2: Compensation of timing mismatch by an across-frequency delay applied to CI stimulation. Condition 3: Compensation of the interaural timing mismatch together with the frequency mismatch. In this condition frequency-specific delays were applied to CI stimulation.

4. RESULTS

Figure 1 illustrates the rms error of sound localization of 8 bimodal hearing test subjects.

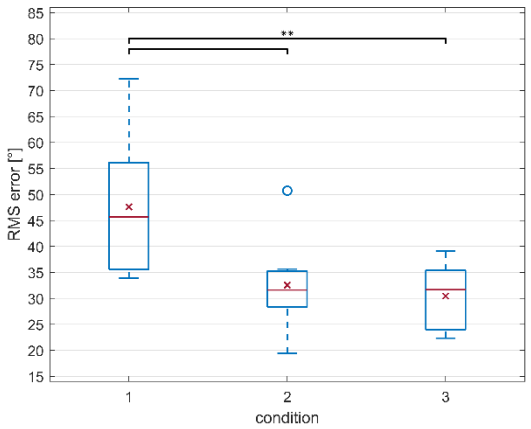

Figure 1. RMS error of sound localization of 8 bimodal listeners in three different listening conditions. Condition 1: Without compensation; condition 2: with timing

compensation; condition 3: with timing & frequency compensation.

Activating the across-frequency delay had no significant effect on the rms error (difference between condition 1 and 2). But we think that including more test subjects will lead to a significant reduction comparable to the results in [1]. Frequency-specific delays (condition 3) further reduced the rms error in some subjects, but in others there was no difference, resulting in a non-significant difference between condition 2 and 3.

5. CONCLUSION

This paper presents results of an ongoing study aiming at reducing the interaural stimulation mismatches in bimodal listening. Results show that the rms of sound localization can be further reduced in some bimodal study participants when using frequency-specific delays compared to an across-frequency delay. However, only a slight further improvement has been achieved in the 8 test subjects tested so far. The approach for combined time and frequency adjustment is methodologically complex, especially the determination of suitable delays for different CI frequency bands. Up to this point, it is questionable whether frequency-specific delays are useful in clinical practice.

6. ACKNOWLEDGMENTS

We thank the test subjects who participated in our study. We would also like to thank MED-EL for their continued support of our research.

A COMPARATIVE STUDY OF FOUR DIRECTIONAL MICROPHONES AND DIRECTIVITY STEERING FOR BIMODAL COCHLEAR IMPLANT USERS

H. Christiaan Stronks[1,2*] **Nienke C. Langerak**[1] **Annemarie J. Schrijver**[1]

[4] Department of Bioelectronics, Delft University of Technology, Delft, the Netherlands

ABSTRACT

Background: Cochlear implant users (CI) experience degraded speech intelligibility (SI) in noise. A contralateral hearing aid (HA) benefits listening in noise, and directional microphones and directivity steering can further enhance SI.
Objectives: Four directional microphones were evaluated for bimodal listeners, including a monaural and binaural broadband front-facing beamformer (BF_M and BF_B) and a novel monaural and binaural narrowband side-beamformer (BF_{MS}, BF_{BS}). Broadband directivity steering (DS) was also evaluated.
Methods: BF_M, BF_B, and DS were tested in diffuse noise with speech administered frontally or to the HA side (S_0N_{dif} and $S_{HA}N_{dif}$). BF_{MS} and BF_{BS} were tested with speech presented on the CI side and noise on the HA side or *vice versa* ($S_{CI}N_{HA}$, $S_{HA}N_{CI}$). SI was assessed by determining speech reception thresholds (SRTs).
Results: In the S_0N_{dif} condition, BF_B significantly improved SI by 2.9 dB SNR and BF_M by 1.3 dB SNR, but not significantly. In the $S_{HA}N_{dif}$ condition, BF_M and BF_B did not benefit SI, but DS improved SI by 3.6 dB. BF_{BS} significantly improved SI by 1.1 dB SNR, but BF_{MS} was ineffective.
Conclusion: Binaural beamformers outperform their monaural counterparts. The novel BF_{BS} is a promising technique for bimodal listeners.

1. INTRODUCTION

Unilaterally implanted cochlear implant (CI) users with contralateral residual hearing may benefit from wearing a hearing aid (HA) in the non-implanted ear, called bimodal hearing. Residual hearing in the other ear offers advantages over electrical hearing alone, including better speech understanding in quiet and noise [1-3]. The bimodal system from Advanced Bionics (Naída Link™) was developed specifically for this population. It features various speech enhancement strategies, including two noise-reduction algorithms based on monaural and binaural directional microphones called 'beamformers' (BF_M and BF_B, respectively). Beamformers are spatial filters that pass on sound from certain angles (usually from the front) while attenuating noise at angles outside of the beam. BF_M (UltraZoom™) is an adaptive beamformer that operates independently on both the CI and the HA and steers its null to the point of the lowest SNR. By contrast, BF_B (StereoZoom™) is a fixed beamformer that combines the input from the CI and HA through wireless voice streaming technology to focus the beam further [4, 5]. Polar patterns for both beamformers are compared to the omnidirectional microphone setting

in Fig. 1. It is also possible to route the signal from the HA to the CI and *vice versa*, referred to as directivity steering (DS, or ZoomControl™). This technique is akin to contralateral routing of signals (CROS), overcoming the head shadow effect by rerouting acoustic input from the HA to the typically better-hearing CI ear [5].

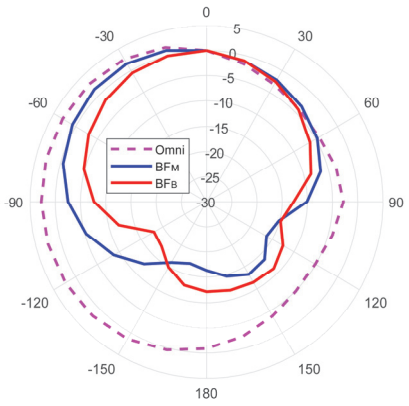

Figure 1. Polar patterns of the front-facing monaural (BF_M) and binaural beamformer (BF_B) and the default omnidirectional microphone setting (Omni) evaluated in experiment 1. The speech processor was mounted on the left ear of a KEMAR manikin. Reference: 0°.

Besides these clinically established broadband applications, a novel side-beamforming approach has been proposed based on artificially increasing interaural level differences (ILDs) at low frequencies [6]. This approach is especially relevant for bimodal listeners where residual acoustic hearing is typically confined to the lower frequencies [7]. ILDs are usually restricted to high frequencies, where the acoustic shadow imposed by the head decreases the sound level of a signal in the contralateral ear [8]. By introducing a narrow-band, side-facing beamformer active only at low frequencies, ILDs can be artificially increased without affecting the physiological ILDs at high frequencies. This technique is especially efficient when speech is present on one ear (e.g., the HA side) and noise on the other (CI side). The introduction of a side-facing beamformer on both ears in this scenario will thus increase the signal-to-noise ratio (SNR) on the HA side, where the speech is presented at the expense of the CI ear, where noise is presented. When the attention is focused on the better side (HA in this example), speech intelligibility (SI) will be enhanced. The advantage of this approach over the classical wide-band CROS or DS application is that it will benefit speech intelligibility in noise, regardless of whether the speaker is present on the CI or the HA side. Benefits can also be expected when speech comes from the front and noise from the sides [6]. As such, these side-beamformers are more versatile and may require less user intervention or rely less on automatic scene analysis than CROS or DS applications. Here, we evaluated two side-facing beamformers. One operated monaurally, i.e., on both ears individually (BF_{MS}), whereas the other operated binaurally (BF_{BS}) by combining the signals from both ears by subtracting the contralateral signal from the ipsilateral side to increase the artificial, low-frequency ILDs further. Polar patterns are shown in Fig. 2.

We performed two experiments. In the first, we evaluated the clinically established broadband, front-facing beamformers (BF_M and BF_B) and DS. In the second, we assessed the effectiveness of the two experimental narrow-band, side-facing beamformers. BF_M, BF_B, and DS were tested in a diffuse field of stationary noise with speech administered frontally (BF_M and BF_B) or to the HA side (DS, BF_M, BF_B). BF_{MS} and BF_{BS} were tested in a less challenging noise setup for a proof-of-principle approach, with speech and noise presented from a single loudspeaker on either side of the head.

2. METHODS

2.1 Participants

Experiment 1 evaluated the broadband beamformers (BF_M, BF_B) and DS in a population of 12 participants unilaterally implanted with an Advanced Bionics HiRes 90K™ device (9 biological females) with a mean age of 64 years (range: 50 – 85). Inclusion criteria were 1) pure-tone audiometric thresholds of at least 80 dB at 125, 250, and 500 Hz in the non-implanted ear; 2) a CI-aided CVC phoneme score in quiet of at least 80%, which are above-average listeners; 3) at least 6 months experience with their CI; 4) age ≥18 years. In experiment 2, the narrowband beamformers (BF_{MS} and BF_{BS}) were evaluated in 18 participants with the same inclusion criteria. However, this population included only people who used a contralateral HA in daily life, whereas the first population also included three participants who were not active HA users and were fitted with an HA for

the study. Pure-tone audiograms of the two populations are shown in Fig. 3. Written informed consent was obtained from each subject. This study was approved by the Institutional Review Board of the Leiden University Medical Center and adhered to the Declaration of Helsinki (Carlson et al., 2004).

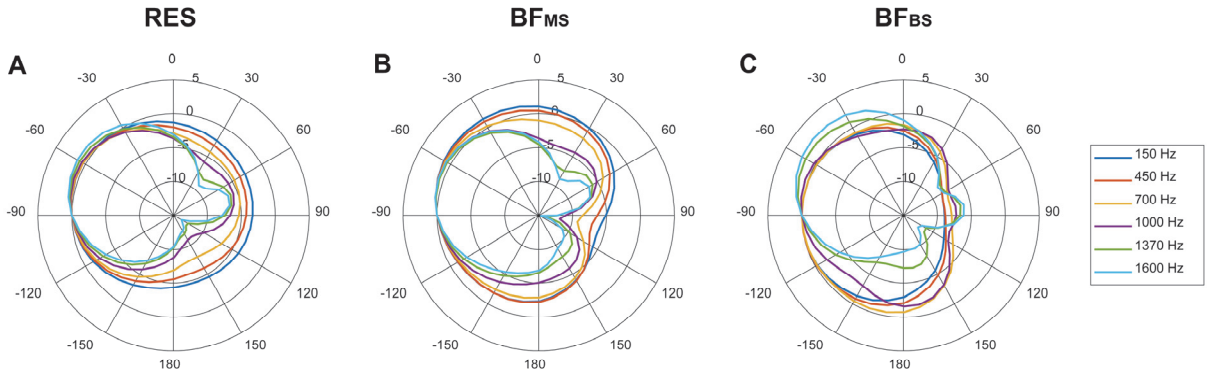

Figure 2. Polar patterns of the microphone settings evaluated in experiment 2. (A) Default microphone setting (Real Ear Sound™, RES). (B) Monaural side-facing beamformer (BF_{BM}). (C) Binaural side-facing beamformer (BF_{BS}). The speech processor was mounted on KEMAR's left ear. Reference: -90º.

2.2 CI and HA fitting

The participants in experiment 1 to evaluate BF_M, BF_B, and DS were fitted with a Q90 CI speech processor (Advanced Bionics LLC, Valencia, CA, USA) and contralaterally with a Naída S IX UP (n = 7) or Naída Link UP (n = 5) HA using PhonakTarget™ fitting software (version 3.3, Phonak, Sonova Holding AG Stäfa, Switzerland). Amplification was based on the clinical audiogram. The voice streaming technology and bimodal fitting rule are designed for the Naída Link and were fitted on the Naída S using customized fitting software (BEPSnet version 3.0.5017.18916, Advanced Bionics). The participants in experiment 1 were subsequently sent home for at least four weeks to accommodate the new fitting.

The participants in experiment 2 to evaluate BF_{MS} and BF_{BS} were fitted with a Harmony™ CI speech processor (Advanced Bionics) and an Audéo M90-312 HA (Phonak) contralaterally using PhonakTarget (version 6.2.5). HA fitting was based on an *in situ* audiogram (Phonak AudiogramDirect™). The experimental BF_{MS} and BF_{BS} algorithms could not yet be implemented on the latest generation of Advanced Bionics CI processors (Q90) available at the time of the study, and front-end processing was performed on an Audéo M90-312 HA that communicated with the Harmony CI speech processor. The pulse-width modulated HA output was converted into an analog signal suitable as auxiliary input for the Harmony CI processor using an audio transformer (Neutrik NTE1, Schaan, Liechtenstein) and a spindle potentiometer (Vishay, Malvern, PA, USA). Calibration was performed with white noise in an ACAM™ audiometry box (Acousticon Inc., Raleigh, NC, USA) using BEPSnet (version 1.14, Advanced Bionics). The HA was worn behind the ear, and the Harmony processor was clipped to the participant's clothing. A custom-made Bluetooth smartphone application (Advanced Bionics) was used to switch between microphone settings.

CI speech processors were fitted with the participant's clinical threshold and maximal comfortable stimulus levels, and HAs were fitted with the Naída bimodal fitting formula [9]. Switching off all noise-reduction algorithms other than those under investigation reduced front-end processing strategies on both devices to a minimum. The adaptive gain control remained operational.

2.3 Speech intelligibility testing in noise

Speech testing was performed in a sound-treated audiology booth. Experiment 1 was used to evaluate BF_M, BF_B, and DS by determining speech reception thresholds (SRTs) using the Leuven intelligibility sentence test (LIST) [10].

Speech was presented in a diffuse field of long-term speech-shaped (LTSS) noise using eight loudspeakers (Control 1, JBL Corp., Los Angeles, CA) as described previously [11].

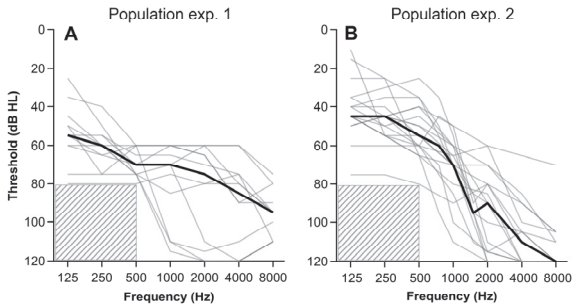

Figure 3. Pure-tone audiograms of the hearing aid ear. (A) Experiment (exp.) 1 evaluated the front-facing broadband beamformers (n = 12). Exp. 2 evaluated the side-facing narrowband beamformers (n = 18). Box: Exclusion criterion (>80 dB HL hearing loss at 125, 250, or 500 Hz). Thick black line: median.

Speech was administered through a MSP5A loudspeaker (Yamaha Corp., Japan) placed ~1 m from the listener at ear level calibrated at 65 dB SPL (Rion NA-28, Rion Co. Ltd., Tokyo, Japan). Speech was administered in front of the listener (S_0N_{dif}) or to the HA side ($S_{HA}N_{dif}$). To determine the SRT, noise levels were adaptively varied according to the LIST protocol [10]. Each listening condition was tested once. Microphone setting and speech angle were tested in a randomized block design, and LIST sentences were randomized across conditions and participants. Care was taken to deploy unique lists for each participant. Some participants found the speech testing challenging. Particularly, the $S_{HA}N_{dif}$ condition resulted in high SRTs in some participants, and we suspect that audibility, rather than noise, was the limiting factor for speech intelligibility. SRTs higher than +5 dB were excluded from the analysis. Linear mixed modeling was used for significance testing, allowing missing data to be included.

BF_{MS} and BF_{BS} were evaluated in experiment 2 by adaptively determining SRTs with the Dutch-Flemish Matrix test [12]. The speech was presented on the CI side and noise on the HA side ($S_{CI}N_{HA}$), or vice versa ($S_{HA}N_{CI}$), using two calibrated loudspeakers (KEF, Ci100QS, GP Acoustics, Kent, United Kingdom). Noise levels were kept constant at 60 dBA while speech was varied adaptively, according to Brand & Kollmeier [13]. The noise was a single male babble based on the ICRA noise [14] and time-reversed to eliminate any intelligible parts. Anecdotal reports from our lab indicate that some CI users can extract meaningful information from the original ICRA babble. Each listening condition was tested and re-tested, except for one participant who participated only in a single session. Performance was better overall than in experiment 1, and no data was excluded. Microphone setting and speech angle were tested in a randomized block design, and Matrix lists were randomized across conditions and participants.

2.4 Statistical analyses

For both experiments, linear mixed models (LMMs) were used in SPSS 29 for Windows (IBM Corp., Armonk, N.Y., USA), where SRTs were entered as the dependent variable. The microphone setting was entered as a repeated fixed variable, and the subject number was included as a random effect with a scaledID variance/covariance matrix. BF_M and BF_B were assessed using the S_0N_{dif} configuration. BF_M, BF_B, and DS were tested in the $S_{HA}N_{dif}$ listening condition. Both listening conditions were analyzed in a separate LMM. BF_{MS} and BF_{BS} were evaluated using $S_{CI}N_{HA}$ and $S_{HA}N_{CI}$ and could be analyzed in a single LMM, including microphone setting, listening condition, and test/retest as repeated fixed factors. The interaction term between the microphone setting and angle was also included.

The variance/covariance matrix for the repeated factors was chosen for each LMM individually by comparing various matrix structures befitting a repeated measures design (including, but not limited to, compound symmetry, diagonal, scaledID, and Toeplitz). Different outcomes of model fit were assessed and weighed when choosing the final variance/covariance matrix, including Akaike's information criterion, distribution of the residuals (Shapiro-Wilk's normality test, histogram), the relation between actual and predicted values, and QQ-plots.

Post hoc multiple comparisons testing was performed on the estimated marginal (EM) means relative to the omnidirectional microphone setting in experiment 1 (BF_M, BF_B, DS) or against 'Real Ear Sound' (RES, Phonak) in experiment 2 (BF_{MS} and BF_{BS}). Šidák's orrection was applied for multiple comparisons testing ($\alpha = 0.05$).

3. RESULTS

3.1 Experiment 1: Evaluation of broadband beamformers and directivity steering in diffuse noise

In the first setup of experiment 1, BF_M and BF_B were tested for their intended use when speech was administered from the front (S_0N_{dif}). The results are shown in Fig. 4A. The LMM revealed a significant main effect of beamforming ($F(2,9) = 6.9$, $p = 0.014$). Compared to omnidirectional microphone settings, BF_B significantly improved SI by 2.9 dB SNR (standard error *SE*: 0.9; 95% confidence interval (*95%CI*): 5.6 to 0.1; degrees of freedom (*df*): 9; $p = 0.042$). The effect of BF_{MS} was more moderate (1.3 dB SNR) and did not reach significance (0.6; -0.4 to 3.0; 10; $p = 0.139$).

When the speech was administered to the HA side ($S_{HA}N_{dif}$, Fig. 4B), the effect of the microphone setting was also significant ($F(3,21) = 10$, $p < 0.001$). Compared to the omnidirectional microphone setting, DS improved SI significantly by 3.6 dB SNR (*SE*: 1.2; *95%CI*: 0.2 to 7.0; *df*: 21; p = 0.032). In this listening condition, BF_M and BF_B deteriorated SI (EM means: -1.8 and -2.6, respectively) but not significantly (1.4; -5.8 to 2.1; 22; $p = 0.723$ and 1.4; -6.7 to 1.5; 21; $p = 0.401$, respectively).

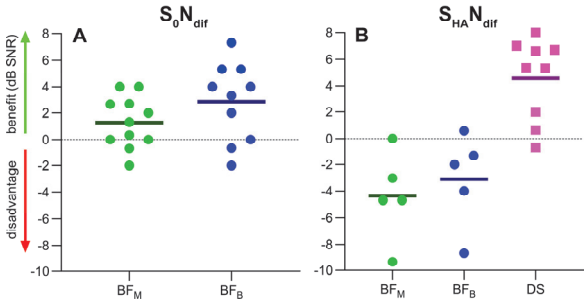

Figure 4. Evaluation of the clinically established broadband, front-facing monaural (BF_M, green symbols) and binaural beamformer (BF_B, blue), and directivity steering (DS, purple) in a diffuse noise field. (A) Effects of BF_M and BF_B when speech was administered to the front (S_0N_{dif}). (B) Effects of BF_M, BF_B, and DS with speech administered to the hearing aid side ($S_{HA}N_{dif}$). Dashed horizontal line: no effect (0 dB SNR difference on the speech recognition threshold). Thick colored lines: mean.

3.2 Experiment 2: Evaluation of side-facing narrowband beamformers

In experiment 2, two listening conditions were tested ($S_{CI}N_{HA}$ and $S_{HA}N_{CI}$), and the results are shown in Fig. 5. Microphone setting and listening condition both had a significant main effect on SRT ($F(2,29) = 5.0$, $p = 0.014$ and ($F(1,35) = 68.0$, $p < 0.001$), respectively). Their interaction was not significant ($F(2,61) = 0.2$, $p = 0.846$). Across both listening conditions, BF_{BS} modestly but significantly improved SI by 1.1 dB SNR (*SE*: 0.4; *95%CI*: 0.0 to 2.1; *df*: 19; $p = 0.046$), but BF_{MS} was ineffective with an EM mean difference of -0.1 dB SNR (0.3; -0.9 to 0.7; 45; $p = 0.985$).

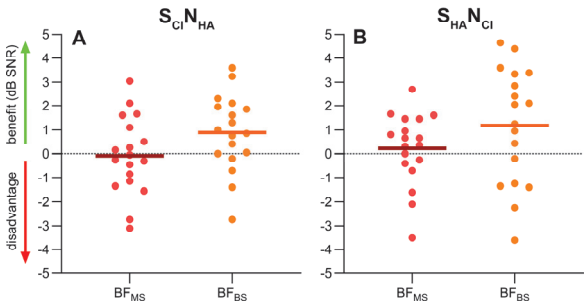

Figure 5. Evaluation of the experimental narrowband, side-facing monaural (BF_{MS}, red symbols), and binaural beamformer (BF_{BS}, orange) in a diffuse noise field. (A) Effects of BF_{MS} and BF_{BS} when speech was administered to the cochlear implant (CI) and noise to the hearing aid (HA) ($S_{CI}N_{HA}$). (B) Effects of beamforming in the $S_{HA}N_{CI}$ condition. Dashed horizontal line: no effect. Thick colored lines: mean.

To investigate the influence of the amount of residual hearing, we performed a correlation analysis by regressing the benefit of BF_{BS} against the average pure-tone threshold across 500, 1000 and 2000 Hz ($PTA_{500\text{-}2000}$) in the HA ear (Fig. 6). For the $S_{HA}N_{CI}$ condition, the correlation was significant ($F(1,16) = 6.1$, $p = 0.0252$, $r^2 = 0.28$), but not for the $S_{CI}N_{HA}$ condition ($F(1,16) = 0.0$, $p = 0.869$, $r^2 = 0.0$). This correlation was not significant for BF_{MS} in both listening conditions ($F(1,16) = 0.4$, $p = 0.550$, $r^2 = 0.0$ and $F(1,16) = 0.6$, $p = 0.451$, $r^2 = 0.0$, respectively).

4. DISCUSSION

Experiment 1 evaluated two directional microphones and directivity steering in bimodal listeners in diffuse stationary noise. The clinically established, front-facing, wideband beamformer BF_B improved SI significantly by 2.9 dB SNR, whereas BF_M resulted in a more modest and statistically insignificant benefit of 1.3 dB SNR. A previous study from

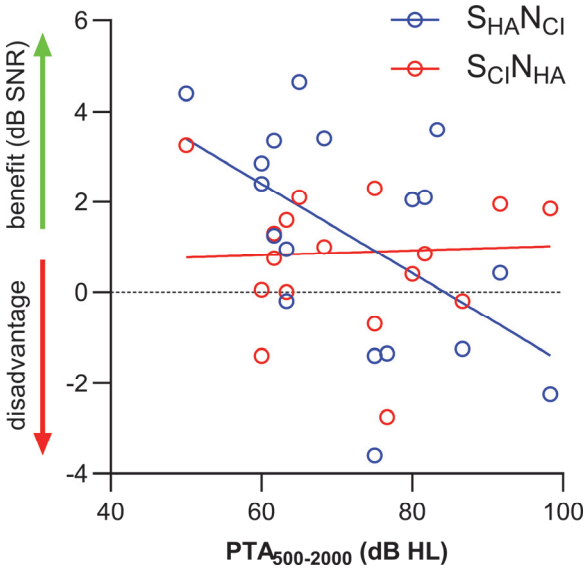

Figure 6. Correlation between the effect of binaural side-beamforming (BF_{BS}) and average pure-tone thresholds at 500, 1000, and 2000 Hz ($PTA_{500\text{-}2000}$) when speech was administered to the cochlear implant (CI) and noise to the hearing aid (HA) ($S_{CI}N_{HA}$, red symbols and line) and *vice versa* ($S_{HA}N_{CI}$, blue). The regression was significant for $S_{HA}N_{CI}$. Dashed horizontal line: no effect.

our lab evaluated the same directional microphones for bimodal users in a diffuse noise field [4]. The authors report an average benefit of BF_B that matches the current data (2.9 dB SNR), although BF_M performed substantially better in that study (2.6 dB SNR). A recent study investigating BF_B for bimodal listeners in an S_0N_{dif} measurement setup found a comparable benefit of 2.3 dB SNR [15]. Another study compared BF_M and BF_B for unilateral CI users with a CROS device in the contralateral ear, again in a diffuse noise field [5]. The reported benefit of BF_B was more modest than in the current study (1.4 dB SNR), whereas the benefit of BF_M was not significant (0.7 dB SNR). The reduced performance in the CROS configuration can be explained by the fact that BF_M and BF_B are implemented as a lighter version in the CROS device to increase battery life [5]. Other studies have investigated these two directional microphones for bimodal listeners and CI users.

As discussed elsewhere [5], the configuration of the noise sources (loudspeaker arrangement) can dramatically affect study outcomes. Front-facing beamformers attenuate noise most effectively when administered to the sides or the back. By contrast, noise sources from the front are passed through unattenuated (Fig. 1). These spatial characteristics make comparing with other studies challenging. Ernst et al. [16] used a diffuse noise setup similar to ours by implementing a ring of loudspeakers and reported benefits of 3.4 (BF_M) and 4.6 dB SNR (BF_M) for bimodal listeners. These relatively large benefits can be explained by the absence of noise from the frontal loudspeaker in their setup, which favors beamforming. By contrast, the authors report substantially reduced benefits of 1.4 (BF_M) and 2.6 dB SNR (BF_B) when a semicircle of loudspeakers was deployed in front of the listeners, again emphasizing the impact of noise administered from the front. Another study that assessed these beamformers for unilateral CI users reports benefits of 5.3 (BF_M) and 7.1 dB SNR (BF_B) [17]. In this study, noise predominantly came from the sides and the back, favoring beamforming effectivity.

Prediction of the benefits of directional microphones as based on polar patterns or manikin (KEMAR) recordings is challenging because of the adaptive behavior of BF_M and the potential overestimation of the SI benefit based on SNR effects alone [5], underscoring the importance of clinical tests for CI users.

When the speech was administered to the HA side, BF_M and BF_B did not significantly affect SI, but DS substantially and significantly improved SRTs by an average of 3.6 dB. This benefit can be attributed to reducing the head shadow effect, assuming that the CI ear was the better hearing side. The theoretical benefit of CROS with speech presented to the ear contralateral to the CI in diffuse noise equals the head shadow effect, i.e., approximately 7 dB [18]. The fact that our reported DS benefit is only about half of this can be explained by residual hearing in the HA ear that mitigates the CROS effect [19]. Further, DS is technically not CROS because attenuation is applied to the HA ear when DS is switched

on, which will somewhat reduce hearing performance in that ear. When noise is administered to the side steered to the better-hearing ear (here, the HA ear), DS will degrade SI. Further, any ILD cues between the devices are lost because of its broadband CROS steering characteristic. Therefore, we advise manual control of this feature and counseling of the end user to explain when to activate DS and when to avoid it. In the future, the automation of DS based on auditory scene analysis can be helpful.

In experiment 2, we assessed two novel, experimental directional microphones that work differently than usual beamformers by increasing low-frequency ILDs while preserving physiological ILDs at frequencies above 1500 Hz. The binaural variant BF_{BS} significantly improved SRTs by 1.1 dB, whereas BF_{MS} did not significantly improve SI. The benefit of BF_{BS} correlated significantly with residual hearing when speech was administered to the HA ear and noise to the other. Modeling studies with an algorithm very similar to $BF_{BS,}$ as used in the current study, showed that the benefit of such an approach could be expected to be up to 16 dB for bimodal listeners when speech is administered frontally, and noise is presented to the CI side, and up to 8 dB when noise is presented to the HA side. With speech also being administered to the side, the effect can be expected to be even higher [18]. One reason for the much smaller benefit found in the present study may be the amount of residual hearing. The previous modeling study simulated hearing loss in a group of typical hearing listeners through a filtering procedure. This resulted in a ski slope audiogram with normal hearing up to 500 Hz and a steeply sloping audiogram at higher frequencies. In our study population, however, the median residual hearing loss was 40 – 50 dB HL between 125-500 Hz.

Another reason for BF_{BS}'s more subtle benefit is that we used the current default microphone setting of Advanced Bionics (RES) as the reference, whereas the simulation study deployed an omnidirectional microphone. RES is also a beamformer that partially mimics, and thus mitigates, the effects of BF_{BS}.

Theoretically, the artificial inflation of low-frequency ILDs is beneficial when speech is administered to the side, regardless of whether it is the CI or the HA ear. However, it will be relevant to verify whether BFBS degrades SI in certain situations and whether it can always be switched on regardless of the auditory scene.

Conclusion

The clinically established binaural beamformer BF_B and the experimental side-facing beamformer BF_{BS} significantly improved SI. Given the insignificant benefits of the monaural counterparts BF_M and BF_{MS}, we recommend using binaural beamforming whenever feasible. DS had a significant advantage when speech was presented to the HA ear; this can also be a helpful technique when speech is administered to the lesser hearing side.

BETTER-EAR-LISTENING VS. COMBINED BILATERAL INFORMATION ACROSS EARS IN ASYMMETRIC HEARING

ABSTRACT

A growing number of cochlear implant (CI) users have asymmetric hearing, where one ear is aided with a CI, and the other ear has different degrees of useable acoustic hearing, ranging from aided with hearing aids (bimodal CI) to normal hearing (CI-Single-Sided Deaf, CI-SSD). Benefits of these combinations include improved quality of life, better speech intelligibility, and better localization abilities. To further understand the varying individual benefit, predictions from two different physiologically inspired computer model versions were compared to data previously collected from eight bimodal and eight CI-SSD users for speech-in-noise tasks (speech-reception-thresholds, SRTs). One model version predicts an SRT for each ear independently, and chooses the better SRT for each task (better-ear-listening). The other model version uses information from both acoustic and electric hearing to predict an SRT (complementary information).
Both model versions showed a satisfactory fit to the measured data (RMS-Error: 2.7 dB). The complementary information model showed a bimodal benefit (3 dB for bimodal CI, 2 dB for CI SSD), surprisingly only for lateral noise incident, but not for frontal sound incident. A better-ear-listening approach explained most of the observed data, only in few cases the complementary information model matched experimental data better.

1. INTRODUCTION

Cochlear implant (CI) listeners with contralateral acoustic hearing (bimodal listeners) or single sided deaf (CI-SSD listeners) show improved speech intelligibility benefits compared to unilateral listeners, particularly in spatially separated speech and noise conditions (e.g. [1]). These benefits of having access to acoustic and electric information in opposite ears are, however, highly variable across individuals. This variability complicates an understanding about how much of the benefits are related to better ear listening, how much are related to complementary usage of information (access to acoustic and electric information), or how much is related to binaural processing. Here we employ a physiologically inspired model to predict group median spatial speech intelligibility of CI SSD and bimodal CI listeners. The model is used either in a “better ear listening” approach or a complementary usage of information approach.

2. METHODS

For comparing model results to actual patient data, patient data was taken from [2]: They measured speech in noise performance in 16 CI listeners, eight of whom were bimodally aided, and eight were CI-SSD. Additionally, eleven normal hearing listeners served as a control group. Matrix-style (e.g. Oldenburg sentence test) sentences were presented in a closed-set format, and speech-shaped noise was added to the sentences. Lists of 20 sentences were used. Spatial rendering of three different sound locations were done by convolving the wave-file with head-related-impulse-responses [3] recorded from microphones located in behind-the-ear hearing aid dummies on an artificial manikin. The three different spatial locations were noise

coming from the left (denoted N-90°), front (denoted N0°), or right (denoted N90°). Speech was always presented from the front (S0°). Target speech reception was 50%, and the SNR changes from first to last presentation of each list adaptively based on the maximum likelihood estimation procedure according to [4].
From the SRTs the following secondary measures were derived: Binaural Summation (sometimes also termed bimodal Benefit, CI-Benefit, or binaural Benefit) was calculated by subtracting the bilateral SRT from the best monaural one. Spatial release from masking (SRM) was calculated by calculating the difference in SRT between lateral noise incident and frontal sound incident.

2.1 Model Details

The model used different features for (impaired) acoustic hearing and electric hearing, which act as inputs for a speech recognition backend (FADE, [6]). The speech recognition backend had a-priori information about the speech token used (Oldenburg Sentence Test, e.g. 50 whole word tokens, with a hidden markov model for transition from silence to word token, and also knows the matrix-like structure of the sentences, thus forming a perfect listener, capable of extracting all available information). Speech and noise tokens (including HRTFs) were exactly the same as in the actual patient data. It outputs a speech reception threshold (SRT) independently for each ear ("better ear listening") or it combines the electric and acoustic feature to one feature set and predicts one SRT from this set (thereby exploiting possible "complementary usage of information").

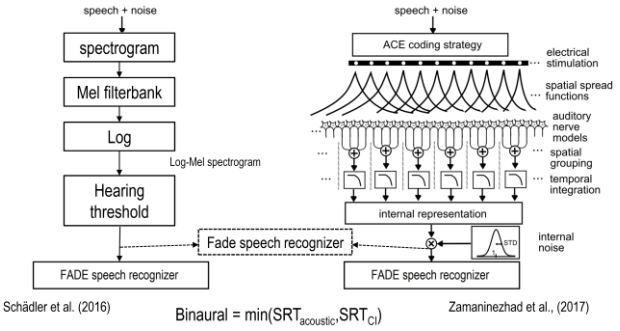

Figure 1. Overview of the model stages. Impaired acoustic model for the left ear, and CI model for the right ear. The FADE speech recognizer backend outputs a SRT using either only the internal representation from one ear as input, or uses the internal representations from both ears concatenated as input. In the case of impaired acoustic hearing, the speech + noise input signal is amplified according to the respective hearing loss.

Hearing loss on the acoustic side was modeled as increased internal noise due to the audiometric thresholds (attenuation), no supra-threshold deficits were taken into account. Aided hearing was simulated by processing the sound stimuli with the research master hearing aid [6] using CAMFIT-gain rule, as in [2]. A mild-to-severe sloping hearing loss was simulated.

CI listening was simulated using a physiologically inspired model of electric hearing [7]. The model simulated ACE coding strategy, an unrolled cochlea with a regular CI insertion, current spread, individual auditory nerve cells (leaky-integrate and fire), taking into account refractoriness, facilitation, and tonotopic organization along the cochlear. More specifically the following model parameters were chosen: Spatial spread of the electric field: 0.3mm, 2200 auditory nerve cells were simulated, and cognitive effects were simulated with a multiplicative Gaussian distributed noise with standard deviation of 0.2 applied to the internal representation. These parameters were empirically chosen such that the median SRT of the CI only data in the actual patient data for frontal sound incident (N0°) matches the corresponding predicted SRT. The acoustic hearing model parameters (default from [5]) matched NH unilateral patient data for frontal sound incident. All the other hearing configurations (bimodal CI, CI-SSD) and noise directions were predicted by the different models.

3. RESULTS

Prediction from the two models in comparison to actual patient data can be found in Fig. 2 for absolute SRTs, Fig. 3 for SRM, and Fig. 4 for binaural Summation. Overall the correlation between modelled SRTs and actual SRTs is high (R^2=0,88, $p<0.001$, for both models) with a root-mean-squared error of 2.7 dB, leading to a good match between model and actual human performance. Both models are sensitive to changes in spatial scene. For aided hearing unilaterally condition (red), the hearing thresholds are compensated for in the model, resulting in a close match to NH unilateral listening mode (black, taking the assumption that the hearing loss was completely due to audibility). For SRM, the model values are in general higher than the actual patient data, independent of listening mode (unilaterally, bilaterally, or electric side or acoustic side).

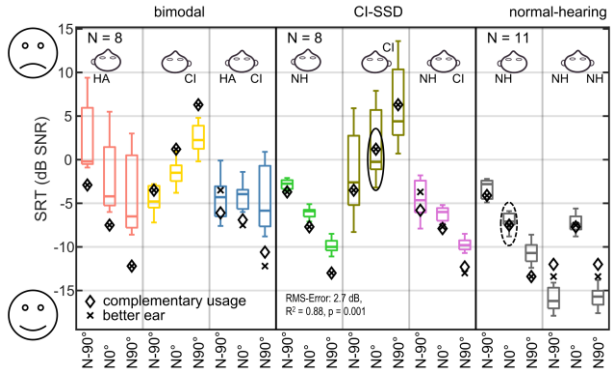

Figure 2. Absolute SRTs for the three different listening groups (bimodal CI, CI-SSD, and NH control group) compared to model predictions (diamonds for complementary use of information model, crosses for better ear listening model). On the x-axis the different noise directions are displayed.

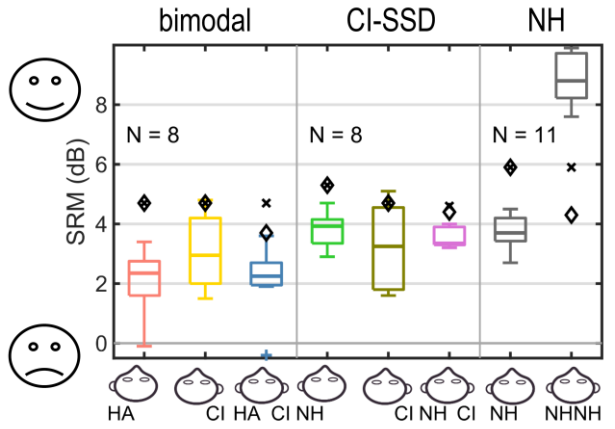

Figure 3. Spatial release from masking for the three different listening groups (bimodal CI, CI-SSD, and NH control group) compared to model predictions (diamonds for complementary use of information model, crosses for better ear listening model). On the x-axis the different hearing configurations are displayed.

For binaural summation, the better ear listening model shows no binaural summation (by design, as there is no interaction between the two ears). The complementary use of information model shows a benefit for N-90 and a decrease for N90. The decrease is of the same order as in the normal hearing control condition. The predicted benefit for N-90 is consistent for both bimodal and CI-SSD groups, and again a bit higher (1-1.5 dB in SRT) than the median of the actual patients.

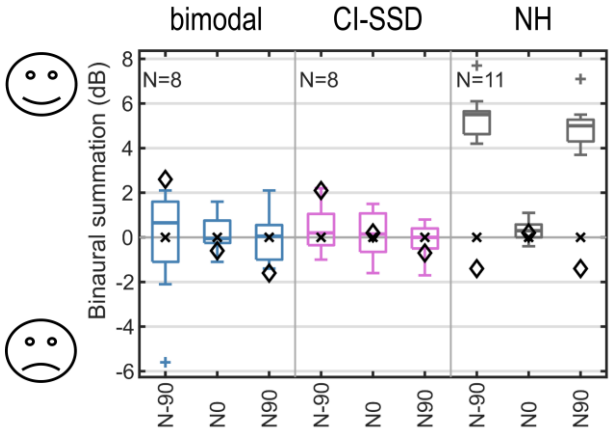

Figure 4. Binaural summation for the three different listening groups (bimodal CI, CI-SSD, and NH control group) compared to model predictions (diamonds for complementary use of information model, crosses for better ear listening model). On the x-axis the different noise directions are displayed.

4. DISCUSSION

There are several small differences between predicted data by the different models and actual patient data:
The model overestimates the SRM independent of feature, due to a "perfect" training of the speech classifier, similar to an experienced patient.
The model for acoustic hearing needs to incorporate subthreshold effects ("Audibility" is restored with MHA). This could be done using tests like tone-detection in noise. Supra-threshold effects were not taken into account here, as no additional measures were conducted during data collection from actual patients. Readily clinically available would be for instance some form of discrimination loss of monosyllabic words.
The combined usage of information model assumes equal contribution of acoustic and electric information, which might not be the best fit [8], and could explain, why there is a benefit for N-90°, and an interference for N90. The combined benefit in actual CI listeners is likely underestimated due to stationary noise masker (less "glimpsing" of acoustic information), anechoic HRTFs, and is noise-direction dependent [2].
This study did not directly investigate the use of binaural processing in bimodal CI and CI SSD. The two models proposed are quite simple, and do not assume any central

interactions or top-down processing (see [9] for a review). However, the comparison to normal hearing control data can serve as guidelines for the achieveable binaural benefit, after acoustic headshadow is accounted for:
Pure binaural processing should yield at least 2 dB SRT benefit in comparable scenarios, see for example the NH binaural summation data reaching 4 dB for lateral sound incident. This is a purely binaural effect, and needs appropiate coding of interaural cues like interaural coherence, time- and level-differences. However, speech in noise might not be the best test to use in clinical practice to show the benefit of having two ears, questionnaires,localisation tasks or binaural masking level difference tests might be more efficient.
Current provision (as of 2025) for bimodal CI for the three major CI manufacturers is in line with the presented outcomes: One manufacturer couples the hearing aid tightly with the CI including synchronizing automatic gain control, and bilateral beamformers. Another aims to minimize the interaural mismatch, and the third mainly focuses on user comfort when streaming audio.

5. CONCLUSION

The models capture the changes in SRT due to different acoustic and electric inputs and due to different spatial scenes. A simple "better ear listening" model explains most of the data in stationary noise for bimodal CI and CI SSD listeners. For noise from the acoustically aided side the complementary usage of information across ears model is more suitable.

6. ACKNOWLEDGMENTS

Simulations were performed on the HPC Cluster CARL funded by the DFG under INST 184/157 1 FUGG.

ABSTRACT

In unilateral deafness or unilateral partial deafness with contralateral normal hearing, the lack of ability to localize sound, decreased speech perception in noise, and increased hearing effort lead to the desire for cochlear implantation. The aim of the present study was to assess hearing abilities in subjects using electric-acoustic stimulation (EAS) with contralateral normal hearing.

16 subjects with EAS in the ipsilateral ear and normal hearing in the contralateral ear were implanted at our department. Speech reception thresholds (SRTs) in noise were assessed in different spatial noise conditions and for different noise characteristics with and without reverberation. Mean error in sound localization was measured with an LED pointer method.

Improved SRTs with EAS stimulation in simultaneous and spatially separated masker conditions were observed. In more diffuse noise conditions and in the presence of reverberation, no benefit on SRTs was found. Mean localization error using EAS was in the range of normal hearing listeners.

Even for patients with contralateral normal hearing, EAS can improve speech perception in noise and restore sound localization in everyday life. While sound localization abilities in the horizontal plane were comparable to normal hearing, SRTs were still worse than in normal hearing participants.

1. INTRODUCTION

Cochlear implant (CI) users often perform well in speech perception under quiet conditions, but their ability to understand speech is notably diminished in the presence of background noise and/or reverberation. In addition, CI users oftentimes have difficulties with sound localization. Individuals with severe to profound high-frequency hearing loss and significant residual low-frequency hearing benefit from soft CI surgery with preserving the residual hearing and using combined electric-acoustic stimulation (EAS).

In the population of EAS subjects, a very rare subpopulation has normal or close to normal hearing in the contralateral ear (EAS-NH) and could, unlike bimodal or bilateral CI recipients, potentially benefit by binaural cues from interaural time differences. Only few studies were published on auditory performance of this population so far [1-3]. In particular, there is a lack of data on speech perception in everyday listening environments, which typically cannot be captured in clinical routine. Furthermore, sound localization performance was not compared with results of other groups of CI users so far.

The aim of this study was to investigate speech perception in noise in different listening conditions and to compare

sound localization abilities with normal hearing subjects and different groups of cochlear implantees.

2. MATERIAL AND METHODS

Experiments were conducted in an anechoic chamber (size: 4.1m x 2.6m x 2.1 m) equipped with a horizontal sound reproduction system with 128 loudspeakers (see [4] for further details on the sound reproduction system).

2.1 Participants

Six EAS-NH subjects (mean age 60±8.5 years) performed study tests. The pure-tone audiograms of the implanted ear measured at study visit are shown in Figure 1.

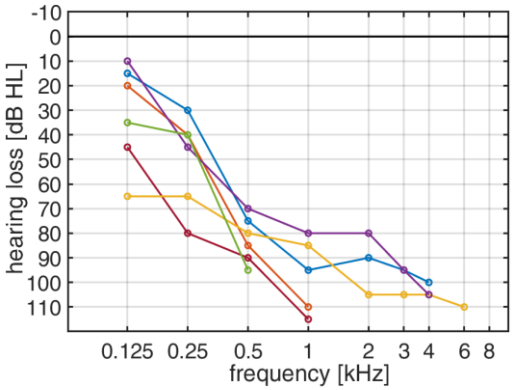

Figure 1. Pure-tone audiograms of the implanted ear measured at study visit (n=6).

2.2 Speech perception test in noise

Speech reception thresholds (SRTs) in noise were measured using the German Matrix Test (Oldenburg Sentence Test) for five different test conditions, which varied in (1) position of speech and noise and (2) in modulation characteristics of the noise:

- S0N30 continuous: speech from 0°, continuous noise at 30° towards the NH ear,
- S0N30 modulated: speech from 0°, modulated noise at 30° towards the NH ear,
- MSNF modulated: speech from 0°, modulated noise presented from 4 virtual noise sources (Multi-Source Noise Field, MSNF according to [5]),
- S-30N30 reverb continuous: speech from 30° towards the EAS ear, continuous noise at 30° towards the NH ear,
- S-30N30 reverb modulated: speech from 30° towards the EAS ear, modulated noise at 30° towards the NH ear.

Details on the technical realization of the room simulation for the conditions "reverb" are described in [6].
For the study, the individual clinical mapping of the EAS sound processors was used. Tests were conducted with EAS fitting ("EAS on" condition) and with deactivated acoustic component while occluding the ear (electric only, "EAS off" condition).
Results were compared to a group consisting of seven normal hearing (NH) subjects (mean age: 26.7±8.0 years)

2.3 Sound Localization

The sound localization test was carried out in the same anechoic chamber using the same sound reproduction system. Sound localization was assessed for seven frontal loudspeaker positions in the horizontal plane between ±60°. The stimuli consisted of five white noise bursts (according to [7]) presented at a level of 65 dB SPL. Test participants used a rotary encoder to indicate the perceived angle of the sound on a LED chain. The mean localization error was determined as the median error over all sound directions.

3. RESULTS

3.1 Speech perception in noise

SRT results for the EAS users with either EAS "on" or "off" compared with NH subjects were shown in Figure 2. SRTs in the EAS-NH group were significantly worse than in the NH group for all five test conditions ($p<0.001$).
SRTs in the EAS-NH group were improved by 0.7 dB (condition S0N30 in modulated noise) to 2.9 dB (condition S0N30 in continuous noise) when the acoustic component of the EAS processor was active.

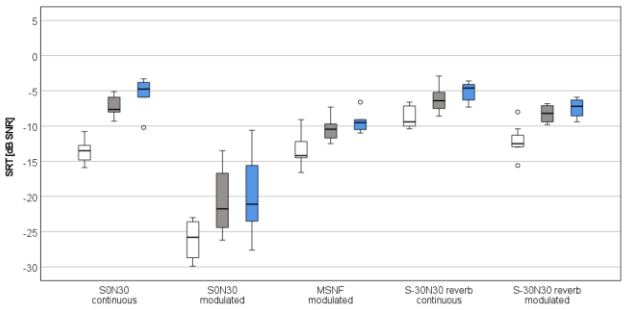

Figure 2. Speech reception thresholds (SRT) in five test conditions with different spatial conditions and

noise modulation characteristics for normal hearing (white boxes), EAS users with EAS on (grey boxes) and EAS off (electric only, blue boxes).

3.2 Sound localization

Mean localization error (MLE) in the EAS-NH group was 8.4°. MLE in the EAS-NH group was 6.1° worse than for subjects with normal hearing (MLE: 2.3°). However, localization performance of the EAS-NH group was 3.5° better than in bilateral CI users and even 10.1° better than in bimodal CI users with a hearing aid in the contralateral ear.

4. DISCUSSION AND CONCLUSION

A beneficial effect of acoustic hearing compared to the electric only condition on speech perception in different complex listening conditions and on sound localization was observed in EAS users with contralateral normal hearing. Sound localization results in the group of EAS-NH were superior compared to all other CI groups.

The results are in line with the results from a study in which greater subjective hearing benefits by using the EAS system compared to other CI groups were reported using a questionnaire [17]. Another study found significant improvements in speech perception in noise and in subjective hearing abilities in EAS-NH users within the first few months of EAS use compared to their preoperative performance [19].

Consequently, it is recommended that CI candidates with residual hearing undergo hearing preservation surgery to enable the use of EAS.

EVALUATING TEST TIME IN SIMULTANEOUSLY RECORDED ABRs

ABSTRACT

Currently, the gold standard procedure for objectively evaluating hearing in infants is the auditory brainstem response (ABR). We have previously explored a novel approach that involves recording multiple ABRs simultaneously in response to narrowband (NB) CE-Chirps centered at 500, 1000, 2000, and 4000 Hz in both ears. In the current study, we investigated the overall testing time when recording ABRs simultaneously compared to consecutively at the clinical discharge levels of 30 and 40 dB estimated hearing level (eHL) to the 4 NB CE-Chirps.

Simultaneous and consecutive ABRs were obtained from 21 young normal-hearing participants within one recording session. Response presence was determined using the recently developed Fmpi, an objective statistical detection method. Testing time was estimated as the total time to reach 95% probability of response present.

The results showed that, for each NB CE-Chirp considered individually, simultaneous ABRs had on average longer testing times compared with consecutive ABRs, a consequence of the overall reduced ABR wave V amplitude evoked by the novel more frequency-specific simultaneous approach. However, the total testing time (8 ABR measurements) was significantly shorter for the simultaneous than that of the consecutive approach.

1. INTRODUCTION

The incidence of hearing loss in newborns is approximately 1 to 3 per 1000 newborns, which makes hearing loss one of the most common birth disorders [1-4]. Newborn hearing screening programs have been employed to identify newborns who require follow-up diagnostic testing, to ensure necessary intervention and treatment facilitating language and cognitive development [5-6]. The Joint Committee on Infant Hearing [4] recommends that the diagnosis of hearing loss is made within the first 3 months of life. The current gold-standard diagnostic evaluation employes the Auditory brainstem response (ABR), where 4 separate audiometric frequencies are evaluated in each ear [7-8]. However, the time required to obtain the 4 frequency-specific thresholds in both ears often exceeds the available test time in the infant population [9]. This limitation often results in the necessity of more ABR sessions to obtain the full hearing assessment. Enhancements in the speed of the ABR test could potentially reduce the test time. A recent study has introduced a novel ABR method, where multiple ABRs can be obtained in both ears in parallel, named pABR [10]. The authors demonstrated the feasibility of recording ABRs in response to five tone bursts at 500, 1000, 2000, 4000, and 8000 Hz simultaneously. In their study, they also evaluated the acquisition time of the pABR and compared it to consecutive presentation [10]. A residual

noise criterion of 20 nV was employed as stopping criterion. Averaging all 10 (5 per ear) tone-burst waveforms down to 20 nV residual noise required a median test time of 30.1 minute, whereas obtaining the 10 tone-burst waveforms using pABR only required 4.6 minutes. Further, when using a Signal-to-Noise Ratio (SNR)-based criterion to evaluate test time, five out of the nine test subjects had faster acquisition time with pABR, with a median pABR speed-up ratio of 1.45 at a high level of 75 dB peSPL (52 to 59 dB nHL), and of 2.99 at 45 dB peSPL (22 to 29 dB nHL).

In a recent study [11-12] we demonstrated that it is possible to obtain multiple frequency specific ABRs to NB CE-Chirp stimuli (mbABR) simultaneously at clinical stimulation levels.

The purpose of this study was to determine and compare the effectiveness—in terms of acquisition time— of the mbABR approach using the data collected in [11-12]. As mbABR and pABR have many similarities, we hypothesized that mbABR would yield an acquisition time advantage over consecutive ABR similar to pABR.

2. METHOD

2.1 Participants

Twenty-four normal-hearing participants (10 males) aged from 20 to 29 years (average age 25), participated in the study. All subjects had pure-tone audiogram thresholds equal to or better than 20 dB HL across the 125 to 8000 Hz range. Otoscopy was conducted to ensure that there was no wax obstruction and that the ear canal was suitable for insert earphone placement. The study was conducted under approval from the Science-Ethics Committee for the Capital Region of Denmark (H-1-2013-138).

2.2 Stimuli and procedure

Four frequency specific NB CE-Chirps LS [13-14] were presented at their corresponding clinical discharge levels of 30 dB estimated hearing level (eHL) and at 10 dB above (40 dB eHL). For adult participants, this corresponded to a 500 Hz NB CE-Chirp presented at 45 and 55 dB nHL, a 1000 Hz NB CE-Chirp presented at 40 and 50 dB nHL, and 2000 Hz and 4000 Hz NB CE-Chirp at 35 and 45 dB nHL, respectively [7, table 7]. The NB CE-Chirps were presented in both consecutive and simultaneous mode at a nominal rate of 40/sec. Jitter was introduced around the nominal rate from a uniform distribution spanning from -67% to +67% of the nominal stimulus interval. NB CE-Chirps had a 200 ms duration and were presented using alternating polarity.

All recordings were obtained in a sound treated and electrically shielded test booth, where the participants were instructed to relax on a bed. First, simultaneous ABRs were acquired at both the discharge and discharge level +10 dB, with a balanced testing order across participants. Then, consecutive ABRs were obtained in a balanced order for the four NB CE-Chirps at both the discharge level and discharge level +10 dB. Lastly, a retesting of simultaneous ABRs was conducted at the discharge level. For the purpose of this study, only the retest data set was used because of a lower residual noise.

At discharge level all ABRs were obtained in both ears on all participants (N = 48 ears). However, only 20 subjects had consecutive and simultaneous ABRs collected at discharge level +10 dB (N = 40 ears).

2.3 Apparatus

ABRs were recorded using a clinical Interacoustics Eclipse system paired with an RME Fireface UC soundcard and custom MATLAB interface [15-16] for control of both stimulus presentation and the collection of ABRs into distinct buffers for each NB CE-Chirp, aligned with the jittered stimulus presentation. EEG activity was captured using disposable surface electrodes at Fz to M1 or M2, with an electrode placed on the cheek serving as ground. For offline analysis, the EEG was band-pass filtered from 83 to 3000 Hz (finite impulse response Kaiser filter, 65 dB stop-band attenuation and 1 Hz transition between pass and stop bands).

RadioEar IP30 insert earphones were used for stimulus presentation. Calibration of NB CE-Chirps was performed using the root-mean-square sound pressure levels defined by [17] for each NB CE-Chirp presented at a rate of 20/sec.

2.4 Data Analysis

21 complete data sets were available for comparison of simultaneous and consecutive ABR at discharge level and 19 data sets at discharge level +10 dB.

The Fmpi-detector was chosen as the objective statistical detector and applied to all data [18]. The Fmpi builds on the clinically well-known Fmp-detector [19] and statistically assesses whether the F-value—a proxy of the SNR—is significantly different from what would be expected from a noise-only recording. If the estimated F-value is high, there is a high probability that a response is present. While Fmp assumes a general (conservative) criterion value for determining significance, the Fmpi estimates the correct criterion value for the individual recording from the noise

properties, leading to faster detections. For this analysis, the stopping criteria was a 95% probability of a response being present. For the consecutive method, per participant total test times were derived by adding the individual test times (i.e., the time to reach a 95% response probability of each individual condition) for each frequency and ear, whereas the maximum test time across all NB CE-Chirps was used for the simultaneous method. Per participant total test times were then used to perform an Analysis of variance (ANOVA) via a Linear mixed effects (LME) model. Here, the total test time (in a log-scale) was set as the dependent variable, the *Condition* (with levels: *Simultaneous* and *Consecutive*) and *Presentation level* (with levels: *Discharge* and *Discharge +10 dB*) as the independent factors, and the *Participant* as the random factor.

3. RESULTS

In Figure 1a, the total test time for each subject is presented for both consecutive (black points) and simultaneous ABR (pink points) at discharge level and discharge level +10 dB. At discharge level the median total test times were 3.25 min for consecutive and 2 min for simultaneous. At discharge level +10 dB the median total test times were 3 and 2.40 min, respectively. On average, simultaneous ABR is 1.55 times faster than consecutive ABR. In the statistical analysis, only the factor *Condition* was significant, confirming a significantly higher performance (lower total test time) for simultaneous than consecutive recordings ($F(1, 55) = 15.49$, $p < 0.001$).

Figure 1b, shows a scatterplot comparing the total test times for simultaneous and consecutive ABRs at both discharge level (orange points) and discharge level +10 dB (magenta points). Points above the identity line correspond to cases where the consecutive total test time was shorter than simultaneous one. However, the vast majority of points fell under the identity line, indicating faster ABR detections for simultaneous testing.

To further examine the test time required for each individual frequency, ear, method, and stimulation level, Figure 2 shows the normalized test time distribution, in which 100% corresponds to the maximum test time across all measurements, for all these variables and for each participant. Here, it can be seen that the lower frequencies (500 and 1000 Hz) took longer for the simultaneous than the consecutive (Interquartile range for consecutive and simultaneous in Figure 2). Despite the simultaneous having this extra measurement time at the low frequencies, which drives the overall test time in the simultaneous recording, the full test is much shorter than in the consecutive mode (Figure 2 top panels).

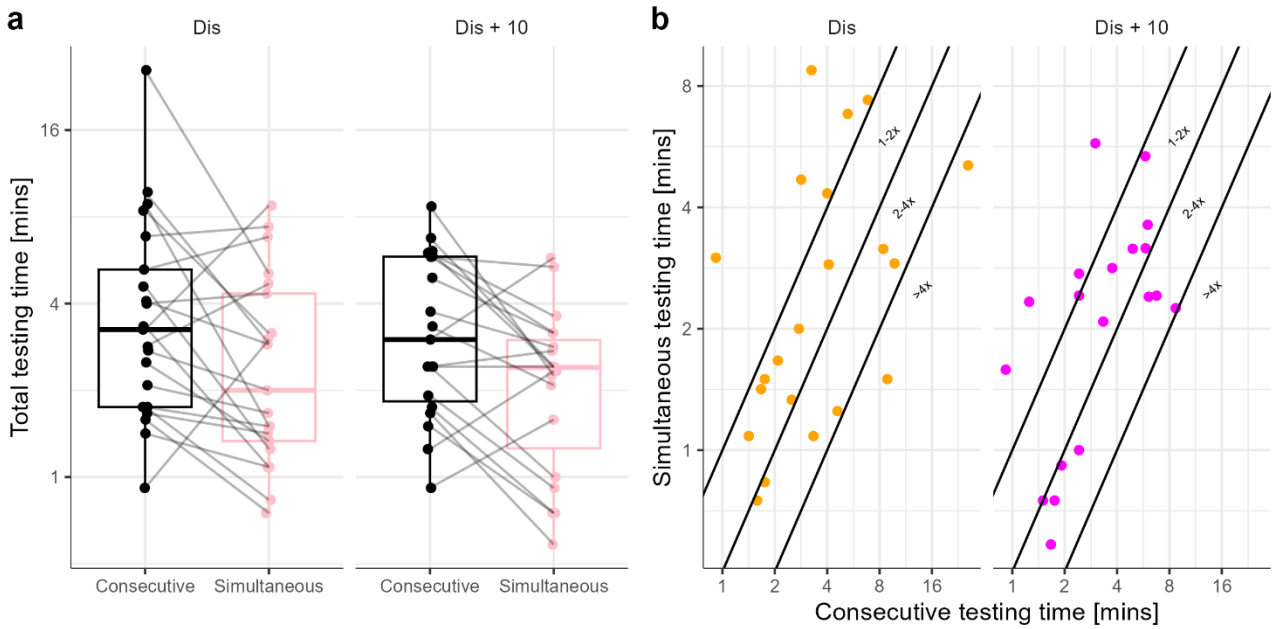

Figure 1 (a): Total test time for consecutive (black points) and simultaneous ABR (pink points) at discharge level and discharge level +10 dB. Boxplots show the median (bold vertical lines), Q1-Q3 interquartile ranges (boxes), and whiskers for 1.5 interquartile range from the hinge. **(b)** Scatterplot of acquisition times for simultaneous and consecutive ABR at both

discharge level (left panel, orange points) and discharge level +10 dB (right panel, magenta points). Points above the identity line correspond to cases where the consecutive total test time was shorter than simultaneous one, while when data points fall below the identity line the total test time was shorter with simultaneous testing. In both panels, each point corresponds to a single-subject measurement.

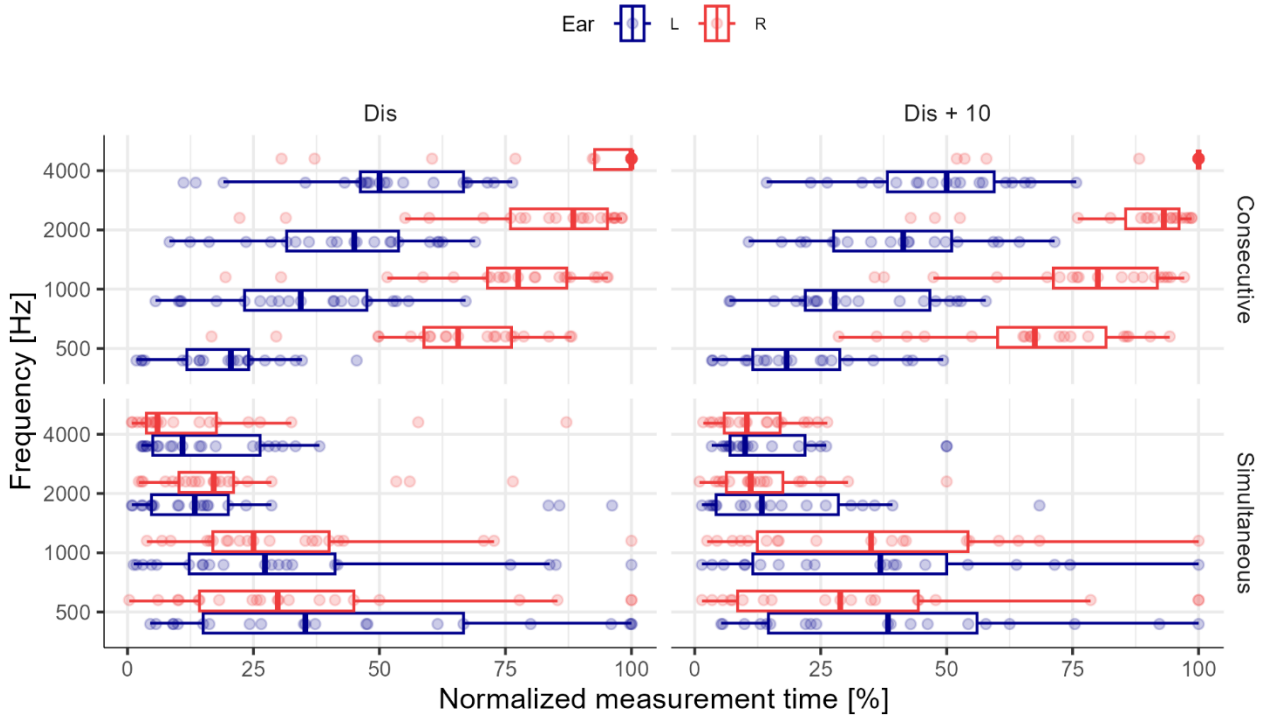

Figure 2: Normalized measurement time (in %) at both discharge level (left panels) and discharge level +10 dB (right panels) for consecutive (top panels) and simultaneous (bottom panels) recordings. The individual center frequencies of the NB CE Chirp are indicated in the vertical axes. A normalized scale was used, such that the longest test time across subjects represents 100%. Red represents the right ear and blue the left ear. Individual points correspond to single-subject data. Boxplots show the median (bold vertical lines), Q1-Q3 interquartile ranges (boxes), and whiskers for 1.5 interquartile range from the hinge. For the purpose of graphical representation, consecutive measurements are shown first for the left ear and then for the right ear, from low to high center frequencies.

4. DISCUSSION

In this study, it was demonstrated that using a simultaneous ABR collection approach in response to NB CE-Chirps results in significantly reduced test time compared to classic consecutive ABR data collection. However, speeding up the test by presenting 8 NB CE-Chirps (4 in each ear) instead of one at a time in each ear, does not speed up the test by a factor of 8. The result from this study shows that on average it takes 1.55 times longer to reach all 8 Fmpi-detection criteria for the consecutive than for the simultaneous ABR. This result is in line with findings from pABR using 0 dB SNR as stopping criterion [10].

In Figure 1a it was observed that the lower level (discharge level) showed a larger difference in median values between simultaneous and consecutive, than at the higher level (discharge level +10 dB). The larger difference at the low level was expected, based on pABR, which showed a larger speed-up ratio at a low level of 45 dB peSPL compared to 75 dB peSPL [10]. In pABR and mbABR, previous experimental and modeling studies have shown that presenting multiple stimuli together has the advantage that they act as maskers for each other [10, 11-12, 20-21]. This changes the ABR waveform morphology especially at the

lowest test frequency, where smaller wave V responses are observed compared to consecutive presentation. As the intensity is increased, the spread of excitation on the basilar membrane broadens towards higher frequencies [23]. This leads to a larger masking effect at higher levels resulting in larger difference in response amplitudes between consecutive and simultaneous stimuli presentation. In turn, this greater masking effect reduces the speed-up benefit from simultaneous presentation, as is seen in the present study as well as those from pABR.

In Figure 2 it was observed that the recording at 500 Hz drives the total test time for simultaneous ABR. This result indicates that further time optimization could be gained in threshold seeking by applying a level-varying approach. In this scenario, data collection at higher frequencies could be continued at other levels, while the 500 Hz is still averaging to a satisfied criterion. However, the interaction among frequency bands, that provides a positive effect in terms of more place-specific response, could be reverted to a negative effect if a change in level of one stimulus, and the concomitant change in spread of excitation, affects the underlying response waveform of another frequency ABR still in progress. This suggests a recommended maximum level difference among stimuli presented simultaneously.

The target population for simultaneous ABR is infants referred for diagnostic evaluation. Infants exhibit distinct waveform morphologies due to the ongoing maturation of the auditory system [24-25]. Therefore, the time advantage of using simultaneous ABR demonstrated here requires validation in the infant population.

5. CONCLUSION

The present study investigated whether there were observable and significant changes in test time when presenting NB CE-Chirps simultaneously compared to consecutively, using clinically relevant repetition rates, presentation levels, and an Fmpi-detector for response evaluation. The results showed a significantly reduced test time when recording the NB CE-Chirps simultaneously.

DIAGNOSING HEARING LOSS USING AIR- AND BONE-CONDUCTED PARALLEL AUDITORY BRAINSTEM RESPONSES

Melissa J. Polonenko[1*] **Ross K. Maddox**[2]

[1] Department of Speech-Language-Hearing Sciences, University of Minnesota, United States

ABSTRACT

The auditory brainstem response (ABR) is an essential tool in screening for and diagnosing infant hearing loss to support optimal language acquisition through early intervention. The parallel ABR (pABR) paradigm measures responses to frequencies from 500–8000 Hz in both ears all at once, rather than the traditional methods of single-frequency measurements in one ear at a time. Our preliminary work in ten adults with maximally varying configurations of sensorineural hearing loss shows that the pABR provides highly accurate thresholds more than twice as fast as serial ABR. Furthermore, our recent work in a group of twenty adults with normal hearing shows that bone conduction pABR measurements are feasible, which is also a necessary part of diagnosing hearing loss by determining the relative contributions of conductive and sensorineural hearing loss. Given these air- and bone-conduction results, the pABR holds promise as a viable clinical tool for objective threshold estimation and diagnosis of hearing loss.

Keywords: *evoked potentials, hearing loss, diagnostics*

1. INTRODUCTION

Early diagnosis of and intervention for hearing loss are critical for facilitating language acquisition. Many countries worldwide use the auditory brainstem response (ABR) to estimate hearing thresholds in infants and other people who cannot complete standard behavioral audiometry. Although the ABR is effective for diagnosing hearing loss [1,2], the auditory-specific responses recorded on the scalp are small compared to the background noise, so the infant must be resting quietly, constraining the exam's duration. Exams often finish with incomplete information, requiring the family to return, further delaying diagnosis and risking attrition. Therefore, faster tests are needed.

The parallel ABR (pABR) was created to address this time constraint by measuring responses to all frequencies in both ears all at once [3]. Compared to traditional methods of single-frequency measurements in one ear at a time, the pABR is a median of 3x faster at a soft level (51 dB peSPL) in adults with normal hearing. Previous studies have also shown better place specificity for the pABR's responses than serial methods [4,5], which may improve estimates of severe hearing losses that require the use of higher levels.

The pABR's accuracy and speed, however, have not yet been tested in people with hearing loss. Neither has the pABR been tested through bone conduction, which is also an essential part of diagnosing the conductive versus sensorineural components of hearing loss. This paper presents preliminary findings for all three: the accuracy and timing of air conduction testing in adults with hearing loss and bone conduction testing in adults with normal hearing.

2. METHODS

2.1 Air conduction testing in adults with hearing loss

Seventy adults with widely varying sensorineural hearing loss configurations were recruited under an approved sIRB protocol between the Universities of Minnesota and Michigan. This paper presents findings from a subset of ten

adults chosen based on maximally different audiometric configurations, who first underwent pABR testing and then returned for testing using traditional serial ABR methods with clinical equipment. Ages ranged from 29 to 69 years.

In the first session, a threshold search was done using the pABR with a real-time custom interface before determining behavioral thresholds with standard audiometry. pABR thresholds were estimated using a leave-one-out regression between the pABR threshold levels in dB nHL and behavioral thresholds in dB HL, a correction step that is routinely done in the clinic. For the second session, the experimenter was blinded to the participant's hearing loss. A threshold search was conducted for each frequency in each ear separately using clinical protocols that were matched as closely as possible to the pABR stimuli. Time to diagnose 10 (pABR, 0.5–8 kHz in both ears) or 8 (clinical, 0.5–4 kHz in both ears) thresholds was compared.

2.2 Bone conduction in adults with normal hearing

Twenty young adults with normal hearing (aged 19 to 31 years) were recruited under the same sIRB protocol. To keep the session under 3 hours, bone conduction was only completed in one ear. Both the ear and order of air- and bone-conduction were counterbalanced across participants.

Air- and bone-conduction behavioral thresholds to the pABR stimuli were measured to determine the correction factors to match levels in dB sensation level (SL) due to the different voltage output for the two transducers. Then ABRs (Fz referenced to A1 and A2, ground at Fpz) were recorded to pABR stimuli (~40 stimuli/second) while participants reclined and rested in a darkened sound booth. An intensity series from 20–70 dB peSPL (~0–50 dB nHL calibrated to an air-conducted 1 kHz tone) was completed using ER2 insert earphones (air) or a B71 bone vibrator (bone) with contralateral masking (400 stimuli/second) through an earphone. Ten minutes of data were collected for each intensity and transducer, totaling 120 minutes. Waveform morphologies for each transducer were compared by their wave V amplitudes and latencies at similar dB SL levels.

3. RESULTS

3.1 The pABR is accurate and faster than serial ABR

Overall, the pABR provided highly accurate thresholds (Fig. 1). There was a 95% confidence interval of 0.78–0.93 for the correlation between behavioral and pABR-estimated thresholds (Fig. 1A). Fig. 1B shows the distribution of threshold differences—most differences (72%) were within one step size (±10 dB), and 90% were within ±15 dB.

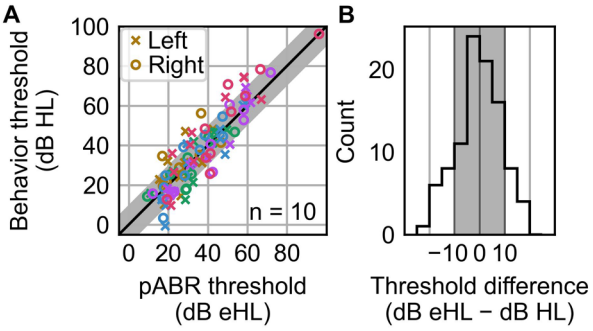

Figure 1. (A) pABR-estimated thresholds are highly correlated with behavioral audiometric thresholds. Jitter applied for visualization (±2.5 dB). Shaded regions represent differences within a step size of ±10 dB. Colors represent frequency: 0.5 kHz (gold), 1 kHz (green), 2 kHz (blue), 4 kHz (purple), 8 kHz (pink). (B) Histogram of pABR-behavioral threshold differences.

Next, the time required to obtain a complete set of thresholds was calculated (Fig. 2). The pABR was faster in all participants, with a mean ± SD testing time of 27.8 ± 8.2 minutes to estimate 10 thresholds versus 69.7 ± 20.9 minutes to estimate 8 serial thresholds, for a significant time reduction of 41.9 ± 20.0 minutes (paired t-test, $t(9) = -6.6$, $p < 0.001$). The median speedup ratio was 2.5x (ranged from 1.4x to 4.2x).

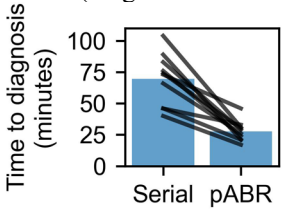

Figure 2. pABR versus serial ABR threshold estimation times. Lines show individuals and bars show the mean.

3.2 pABRs are similar for air- and bone-conduction

Sound played with the same output voltages from the headphone amplifier produced higher behavioral thresholds for bone- vs air-conduction, consistent with the higher force levels required to drive the vibrator. Insufficient force was generated to obtain clear responses above threshold for 8 kHz, which was consequently removed from the analysis. The mean correction factor to convert levels to dB SL was 35 dB for bone- and 25 dB for air-conduction. The levels for bone-conduction were ~5 dB quieter at 0.5 and 4 kHz.

Clear responses were obtained with both transducers at 4 levels (5, 15, 25, 35 dB SL). Wave V peak amplitudes and latencies across all participants and levels are shown in Fig. 3. Wave V metrics correlated between air- and bone-conduction, with a 95% confidence interval of 0.59–0.82 for amplitude and 0.91–0.96 for latency. Overall, compared to air-, the mean ± SE wave V peaks for bone-conduction were smaller by 0.014 ± 0.002 µV ($t(278) = -6.2$, $p < 0.001$) and shorter by 0.198 ± 0.068 ms ($t(278) = -2.9$, $p = 0.004$).

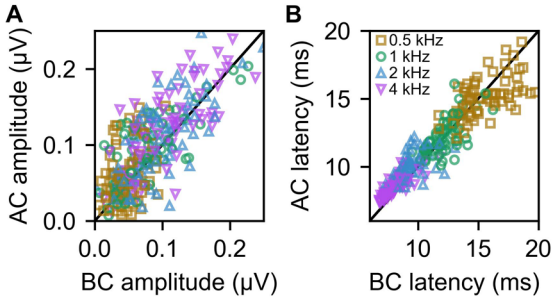

Figure 3. Wave V peak (A) amplitude and (B) latency across participants for stimuli conducted through air (AC) and bone (BC) across 5–35 dB SL levels.

4. DISCUSSION

Preliminary work from the two studies presented in this paper show the feasibility of using air- and bone-conducted pABR stimuli for accurately diagnosing hearing loss.

The pABR provides highly accurate threshold estimates in a subset of adults with widely varying hearing loss (Fig. 1) that are on par with serial ABR [2]. It is also substantially faster in a clinical-like setup than the current serial ABR (Fig. 2), which could facilitate the collection of more complete information during clinical translation of this method. Together with previous work in adults with normal hearing [3], data from all seventy adults in the study will provide further support for the pABR as a viable method for objective threshold estimation across the range of hearing.

Preliminary work in adults with normal hearing shows that bone-conduction pABR measurements are also feasible. Although air- and bone-conduction wave V metrics differed overall (Fig. 3), their responses generally aligned given the 10-dB step sizes. Due to the different voltages required to drive the bone vibrator, the actual dB SL levels were ~5 dB quieter for some frequencies (halfway between step sizes), which could contribute to the smaller responses. Further analyses of the data will reveal the necessary corrections that can be applied to future experimental paradigms to ensure similar output levels are used for both transducers. The larger study provides the necessary behavioral threshold and ABR response information to adjust the frequency-specific stimulus voltage outputs to adequately drive the bone vibrator to produce similarly sized responses. This work represents an important step towards creating a pABR paradigm that includes both air- and bone-conduction so that both the sensorineural and conductive components of hearing loss can be diagnosed.

Given these air- and bone-conduction results in adults, the pABR holds promise as a viable clinical tool for objective threshold estimation and diagnosis of hearing loss while addressing the primary drawback of current methods: speed. This preliminary work represents an important step towards translating the pABR for diagnosing hearing loss and taking the next steps to validating the method for use in infants and other populations that require objective testing.

THE BINAURAL INTERACTION COMPONENT IS ENHANCED WITH CHIRPS RELATIVE TO CLICKS AND PRODUCES BETTER BEHAVIORAL LATERALIZATION

Kerry A. Walker[1*] **Carol A. Sammeth**[1] **Matthew Mavandi**[2]
Nathaniel T. Greene[3] **Daniel J. Tollin**[1,3]

ABSTRACT

The binaural interaction component (BIC) of the auditory brainstem response (ABR) is obtained by subtracting a binaurally-evoked ABR from the sum of monaural left and right ear ABRs. BIC amplitude is modulated by interaural time differences (ITDs) and has been proposed as a biomarker of binaural hearing ability. Traditionally, clicks are used to evoke ABRs; however, chirps are recommended to compensate for the cochlear traveling wave and enhance wave V. Whether chirps improve BIC measurements has not been systematically examined. Here, ABRs and BICs were measured in subjects (n = 6; 21-29 years) for three stimuli; 1) 100-µsec clicks, 2) level-independent CE chirps, and 3) Level-Specific (LS) chirps at four intensities ranging from 65-40 dB nHL. Subjects also completed behavioral testing measuring ITD discrimination thresholds. Compared to clicks, chirps generally elicited larger monaural and binaural wave V and larger BIC amplitudes, particularly at lower intensities. Subjects also exhibited lower ITD thresholds for chirps than clicks, mainly at lower stimulus levels. Chirps may provide an enhancement to ABR wave V and BIC, improving signal-to-noise ratio and reliability. The improved behavioral sensitivity to ITDs with chirps supports the hypothesis that BIC arises from binaural brainstem nuclei that are important for binaural hearing.

Keywords: *auditory brainstem response, binaural interaction component, binaural hearing, interaural time difference*

1. INTRODUCTION

The auditory brainstem response (ABR) is an electrophysiological measure widely used both clinically and in research to investigate the integrity of the auditory system pathway. A binaural interaction component (BIC) can be obtained by subtracting a binaurally evoked ABR from the sum of the monaural right and left ear ABRs [1]. If there were two independent monaural pathways, the resulting difference waveform would be zero (minus any measurement artifact or noise); However, a small negative component appears at approximately the latency of ABR wave V or its roll-off slope in human subjects. This indicates a different amount of synchronous neural activity occurring in the brainstem during binaural stimulation than during monaural. In the literature, this most prominent BIC component has been called “DN1” [2-6].

The ABR BIC has been measured in a number of animal models [2], [7], [8], as well as in normal-hearing human subjects [6], [9-16]. The BIC has been reported to be abnormal in the elderly [17], in persons with multiple sclerosis [18], in specific language disorder [19], and in children diagnosed with CAPD [20], [21]. The ABR BIC is thought to be generated at the level of the lateral superior

olive of the brainstem ([1], [8], [22]), an area that has been associated with neural processing of interaural sound cues.

The BIC has received increasing attention as a non-invasive biomarker of binaural processing. For example, researchers have observed systematic changes in the amplitude and latency of the BIC DN1 component when interaural cues that control perceptual lateralization are varied in normal hearing adults. Specifically, latency of DN1 systematically alters with increasing interaural level difference (ILD) and/or interaural time difference (ITD) cues [3], [6], [12], [23], [24], [25]. In addition, BIC amplitude has been found to correspond with a behaviorally measured ability to lateralize sound as a function of ITD and ILD and its presence is assumed to indicate fusion of binaural stimuli [12], [23], [26]. Recently, Brown et al. [27] and Sammeth et al. [16] reported that BIC amplitude also varies systematically with interaural frequency mismatch and corresponds to ITD sensitivity measured behaviorally.

Unfortunately, however, the ABR BIC has not proven to date to be useful as a potential clinical diagnostic indicator for suprathreshold hearing ability because it is not always obtained reliably in human subjects. While the BIC is readily obtained in sedated animals, it is time consuming and difficult to obtain a clear, replicable response in awake human subjects [6], [28]. This is mostly due to its very small size relative to the size of myogenic (muscle) and other noise artifacts in the waveform, and also because the larger head size in humans than in animal models (such as rodents) results in a surface electrode measurement that is farther away from the neural generators for the BIC [8]. In ongoing efforts to find a means to more reliably obtain the ABR BIC, members of our research lab recently showed that the use of an alternative to a standard ABR click stimulus, namely, a rising frequency "chirp" stimulus, optimizes recordings of the BIC in chinchillas [29]. The current experiment was designed to determine if this stimulus advantage is also seen in human subjects.

The stimuli typically used for measurement of ABRs and BIC is the acoustic click. However, some researchers have suggested that this might not always be the best stimulus choice to obtain a robust auditory electrophysiologic response [30], [31], [32], [33], [34]. This is because the traveling wave on the basilar membrane elicits an auditory system response first from high frequencies, then from progressively lower frequencies [35]. Cochlear tonotopicity reduces temporal response synchrony to a click stimulus, resulting in reduced ABR amplitude. Therefore, chirp stimuli have been developed that compensate for the dispersion of the traveling wave by presenting low frequencies first, then progressively higher frequencies in an upward sweep, and that have been found to produce larger ABR wave V amplitude at least at a moderately/high stimulus level ([24], [31], [33], [34], [36]. As BIC DN1 arises at a similar latency as ABR wave V, we hypothesize that chirps might produce a larger BIC response.

Chirps are now widely used clinically in ABR measurements, but to our knowledge only one publication has directly explored the use of chirps versus clicks to measure BIC DN1 in humans. Reidel and Kollmeier [24] reported that, compared to clicks, chirps designed to enhance monaural ABR wave V also produced larger BIC at low to moderate sound levels, although the enhancement was not as great as seen for wave V.

A chirp stimulus now commonly used in clinical auditory evoked potential measurement equipment that was empirically derived is the "CE-Chirp®" [33], [34]. Because derivation of the standard CE-Chirp is based only on the cochlear traveling wave delay at a moderate/high stimulation level (~60 dB nHL), it is considered a "level-independent" chirp [37]. However, it has been found that the frequency sweep rate of chirps should vary by stimulation level for optimal results [36], [38], [39]. As a consequence, so-called level-dependent chirps, or "Level-Specific (LS) CE-Chirps®", which compensate for this level effect were developed [39], [40].

Of note is that both standard CE-Chirps and LS-Chirps were designed to optimize ABRs measured monaurally, while BIC is derived from binaural versus monaural stimulation. In our study, Owrusky et al. [29] considered that a chirp stimulus specifically derived from BIC DN1 latency for different frequencies of stimulation might be optimal to enhance BIC response amplitude. In their results, however, no additional DN1 amplitude enhancement was found for the DN1 latency-derived chirps compared to LS-Chirps, and therefore in the current study we chose here to only use the standard CE-Chirp and LS-Chirps.

Specifically, the current study compared the ABR BIC measured in normal-hearing young adults across multiple stimulation levels for three stimuli: 1) a standard click, 2) the level-independent CE-Chirp, and 3) the level-dependent LS-Chirps. The purpose was to build on the work of Reidel and Kollmeier [24] and Owrusky et al. [29] to evaluate our hypothesis that LS-Chirps will generate significantly higher response amplitude for the ABR BIC in human subjects across stimulus levels than will either the standard CE-Chirp or a click. In this short paper, our main objectives were to investigate if 1) chirps improve BIC measurement in humans, and if 2) chirps alters ITD sensitivity compared to traditional click stimuli.

2. METHODS

Approval was obtained from the Colorado Multiple Institutional Review Board for human subjects. All subjects had bilateral hearing thresholds < 10 dB HL at frequencies from 250 Hz to 4000 Hz and < 15 dB HL for extended high frequencies of 6000 to 16000 Hz, with symmetrical hearing thresholds between the ears (< 10 dB difference at a given audiometric frequency). None of the subjects had a history of otologic or neurological disorder. Subjects were paid for participation in the study. Subjects were 6 normal hearing adults (4 females) aged 21 to 30 years.

2.1 ABR measurements

ABR measurements were completed across six, 2-hour sessions for each subject, completed on different days. Two sessions were used for each of the three stimulus types. For example, in the first session, measurements were obtained at four stimulus levels, and in the second session, the measurements were replicated.

ABR waveform acquisition was accomplished using the commercially available International Hearing System (IHS) Duet AEP measurement system with research module. EEG was amplified by 100,000 and were bandpass filtered 100-3000 Hz. Artifact rejection threshold was set to ± 20 µV. Three different stimuli were used: 1) 100-µs clicks, 2) CE chirp, and 3) Level Specific (LS) chirp. ABRs and BICs were measured with each stimulus at stimulus levels of 65, 60, 50 and 40 dB HL. For each ABR, 4000 total sweeps were averaged across two runs. The BIC was calculated post-hoc as the binaurally stimulated ABR minus the sum of the right and left ear monaural ABRs. Two complete BIC measurements were completed for each stimulus at each level, to confirm replicability of the DN1.

Stimulus level was calibrated via a 2cc coupler attached to a Larson-Davis sound level meter and Tektronix oscilloscope for determination of peak equivalent SPL of the stimuli compared to a 1000 Hz calibration tone. The stimulus repetition rate was ~11.1 per second and was presented in rarefaction. Stimuli were presented via ER-2 insert earphones. ABRs were recorded from Ambu Neuroline 720 disposable surface electrodes (Ambu Inc., Columbia, MD).

Following skin preparation, electrodes were placed according to the International 10-20 Electrode System [41] using a midline montage: Fz (high forehead) was referenced to the nape of the neck (just above the 7th cervical vertebra), with Fpz (low forehead) as the ground. Electrode impedances were < 5 kΩ (typically 2-3 kΩ) and balanced between electrode pairs within 1 kΩ. Subjects were seated comfortably with a neck pillow in a slightly reclining chair in a darkened room and asked to close their eyes, relax, and sit quietly or sleep during measurements.

2.1.1 Marking of the Waveforms

Marked and labeled peaks (Fig. 1) were initially placed on the waveforms by the first author, who is an experienced audiologist who did all the electrophysiological testing for this study, but were then reviewed by the second author, who is also an audiologist experienced in these

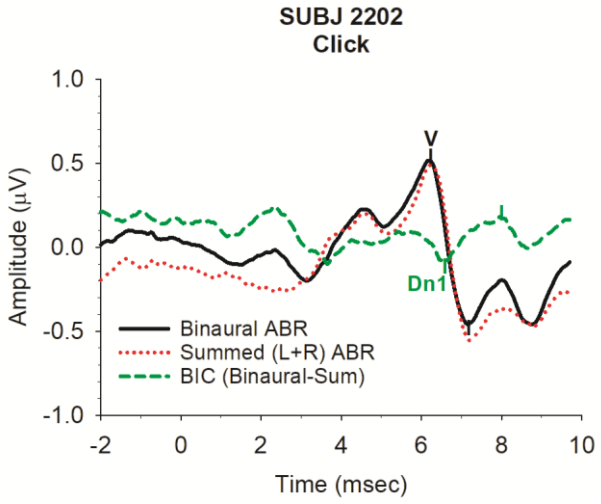

Figure 1. Example Binaural/Summed ABR and calculated BIC using clicks. Wave V was marked from the peak to following trough. BIC DN1 was marked as the most prominent trough and following peak occurring near ABR Wave V.

measures. In all cases, markings were agreed upon by both authors. All identifiable latencies and peak-to-trough amplitudes of waves I through VI of the monaural and binaural ABR waveforms were first marked, to aid in identification of the DN1 component of the BIC in the difference traces. The DN1 component of the BIC was identified as the most prominent negative peak in the temporal region of the difference waveform that corresponded to wave V and its roll-off slope and was only accepted as a valid response if it was replicable across both BIC traces for a given stimulus type and level. DN1 was marked both for latency of the negative trough, and for relative amplitude (negative peak to the

following positive peak) amplitude. When the positive peak following BIC was equivocal (e.g., as sometimes occurred in the presence of multiple fluctuations or a shallow rising slope), it was marked as the most prominent positive point occurring prior to the latency of an identifiable wave VI peak.

2.2 Behavioral ITD discrimination task

Behavioral measurements were completed across multiple sessions. The task measured both ITD discrimination threshold and subjective lateralization of each of the stimuli at four levels, 10, 20, 40 and 60 dB HL. The method was based on that used by Brown and Tollin [42], [43]. This task was implemented in a separate MATLAB program, with stimuli delivered via the playback system and insert earphones described above.

During testing, subjects sat at a desk in a lighted sound booth and responded using a large touch screen monitor (Fig. 2). On the screen was a schematic illustration of a head, with horizontal bars indicating the right and left sides of the head. Each trial consisted of presentations of two sequential sets of tone pips. A train of 5 stimuli (e.g, the CE chirp) at 14/sec was first presented simultaneously to each ear (ITD=0 µs) and this was followed by a train of 5 stimuli with a non-zero ITD. Left-favoring ITDs were imposed by delaying the stimulus to the right ear, and right-favoring ITDs imposed by delaying the stimulus to the left. The subject's task was to discriminate whether the second stimulus (target) fell perceptually to the left or the right of the first stimulus (reference). If the target set was perceived as falling to the right of the reference, the subject was instructed to touch the bar that was on the right side of the screen, and vice versa. Further, subjects were asked to indicate on the bar how far to the right or to the left the target appeared relative to the reference, i.e., a subjective lateralization task. Subjects received immediate feedback regarding the left/right discrimination response, via a green asterisk flashing on the bar if their response was correct, and a red asterisk flashing if their response was incorrect (these colors were readily discriminable by all subjects).

Each run started with the ITD for the second binaural stimulus train at 800 µs. ITD was then changed adaptively depending on the subject's response. A 3-down, 1-up procedure was used, i.e., three consecutive correct responses were required for the ITD to decrease, but one incorrect response resulted in an increase in the ITD, targeting a 79.4% correct threshold (Levitt, 1971). Step size was initially large but then rapidly decreased over a run, so that the task became increasingly difficult. Specifically, a log step size adjustment was used (1/100.2, then 1/10.05); i.e., the adjustment magnitude was a fixed percentage of the ITD magnitude so that step size decreased as subjects approached threshold. Within a run, two separate 3-down 1-up tracks were initialized and run simultaneously. Testing continued until 8 reversals were observed. The first 4 reversals were discarded, and the geometric mean of the last 6 reversals averaged to determine the ITD discrimination threshold for that condition.

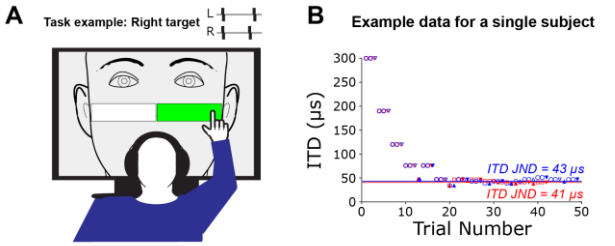

Figure 2. A) Subjects responded using a touch screen monitor and received feedback regarding the left/right response. B) A 3-down, 1-up procedure was used. Testing continued until 10 reversals were observed and the last 6 averaged to determine the ITD discrimination threshold (i.e,. ITD JND).

Practice runs were completed to familiarize and train subjects on the task. Subsequently, three runs were completed for each of the four stimulus levels, randomly ordered, and the average of the ITD discrimination thresholds for the three runs per frequency condition and stimulus level was used for final analysis.

3. RESULTS

3.1 ABR measurements

ABR measurements, and subsequent BIC, were obtained in 5 subjects in response to 1) click, 2) CE Chirp, and 3) LS Chirp stimuli presented at 65, 60, 50, 40 dB nHL. Replicable BIC detection rates ranged from 100% (50 dB CE Chirp) to 20% (65 dB LS Chirp) (Fig. 3).

As ABR BIC is derived from ABR wave V, peak-to-peak amplitudes of binaural and summed ABRs were examined to characterize enhancements to wave V, and subsequent DN1, due to differing stimuli (Fig. 4). Statistical analyses using paired t-tests revealed significantly larger binaural and summed wave V amplitudes to CE Chirp stimuli at 40 dB nHL compared to LS Chirp and Click stimuli ($p<0.05$). For summed monaural waveforms, wave V amplitude to CE Chirp stimuli at 50 dB nHL was also significantly larger than wave V evoked from LS Chirp

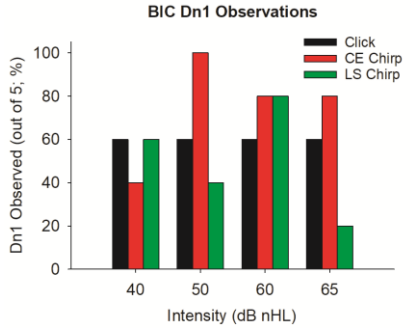

Figure 3. Percentage of replicable BIC DN1 observed from 5 subjects for each test condition.

stimuli ($p<0.05$). All other conditions did not reveal significant wave V amplitude differences between stimulus type. DN1 amplitudes also were not statistically different across all stimulus types ($p>0.05$ for all).

3.2 Behavioral ITD discrimination task

Behavioral testing was completed by 6 subjects using the same stimulus type as ABR with additional high-pass filtered stimuli at 2 kHz and a reverse chirp stimulus (Fig. 5). The high-pass condition was completed to remove the dominance of low frequency fine structure ITD cues [44]. Intensity levels included 60, 40, 20, and 10 dB nHL. Paired t-tests revealed enhanced ITD discrimination to unfiltered LS Chirp stimuli compared to Click at 10 dB nHL ($p<0.0001$) and CE Chirp ($p<0.05$). ITD discrimination was similar across stimulus types at higher intensities. With regards to filtered stimuli, high-pass at 2 kHz to remove low-frequency fine structure cues, similar statistical differences were observed as ITD discrimination was significantly better to LS Chirp at 20 dB nHL compared to click at 20 dB nHL ($p<0.0001$) and CE Chirp compared to click at 10 dB nHL ($p<0.001$).

4. CONCLUSIONS

Overall, a replicable BIC was observed in all participants for at least one stimulus type, however, the use of chirp had variable effects on BIC producibility. As expected, use of chirps generally enhanced ABR wave V, specifically at lower intensities, however, this difference was not observed for both chirp types. With regards to behavioral data, clicks yielded poorest performance compared to chirps at lower intensities. As high pass filtering eliminated an ITD

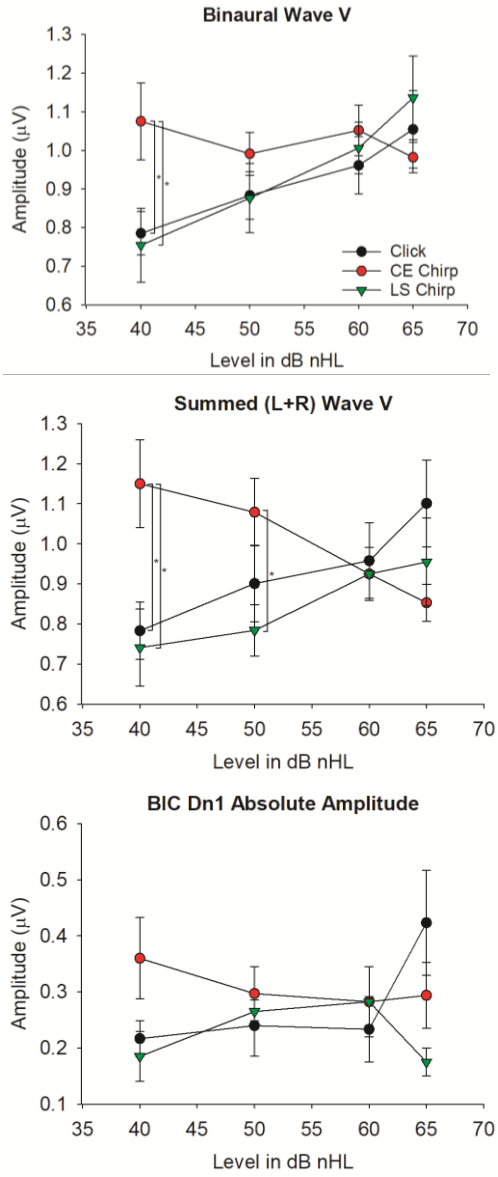

Figure 4. Average Wave V (Top, Middle) and DN1 (bottom) peak-to-peak Amplitude +/- 1 SE as a function of intensity for each stimulus. Statistics: t-tests:*$p<0.05$. Top)

dominant region (around 750 Hz;), we see significant differences between chirp and click extend to both 10 and 20 dB nHL conditions. However, no difference was observed between chirp types for filtered conditions. Across both electrophysiological and behavioral experiments, a chirp advantage over traditional click stimuli occurs at

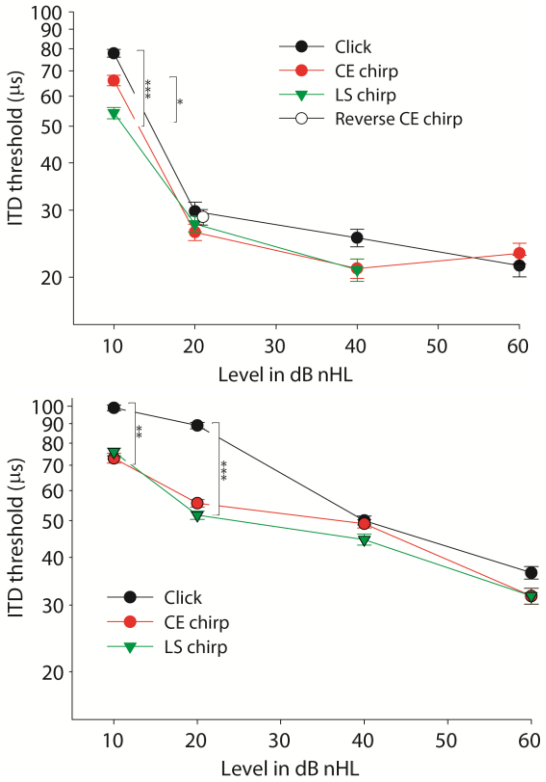

Figure 5. ITD thresholds as a function of intensity for each stimulus. Top) unfiltered stimuli. Bottom) 2 kHz High pass filtered stimuli. Paired t-tests: * $p < 0.05$; ** $p < 0.001$ and *** $p < 0.0001$

lower intensities improving perceptual lateralization and wave V characteristics. These finding support the use of chirp stimuli particularly at lower, near-threshold intensities for binaural hearing assays. To date, 5 subjects have completed both electrophysiological and behavioral measurements and future research will examine relationships between measured outcomes to investigate the utility of BIC as a marker of binaural hearing.

5. ACKNOWLEDGMENTS

This work is supported by NIH-NIDCD R01DC017924 awarded to co-author Daniel Tollin and Achim Klug. Portions of this work were completed as part of Graduate Experiences for Multicultural Students (GEMS) program, R25HL103286-07.

A PILOT STUDY ON ASSESSING AUDITORY MASKING USING AUDITORY STEADY-STATE RESPONSES

Anna Sergeeva* **Preben Kidmose**
Department of Electrical and Computer Engineering, Aarhus University, Denmark

ABSTRACT

Auditory masking is important in the characterization of human hearing and hearing impairment. Traditionally, masking is assessed through behavioral methods, witch requires active participant engagement. This study investigates the potential of using Auditory Steady-State Response (ASSR) to assess auditory masking, enabling masking assessment without requiring active participation.

ASSRs were measured in response to a 40-Hz amplitude-modulated probe signal with and without the presence of a masker. The probe signals were 1/3-octave bandwidth Gaussian noise centered at 891 and 1414 Hz (center frequency, CF) and presented at 10, 20, 30, and 40 dB above individual behavioral masking thresholds (MT). The masker was lowpass Gaussian noise (cut-off 707 Hz) presented at 65 and 85 dB SPL (masker level, ML).

The ASSR amplitude increased with presentation level (PL) and decreased in the presence of a masker, confirming a masking effect on ASSR. At 65 dB ML, ASSRs did not differ between center frequencies when probe signals were presented relative to MT, suggesting a simple relationship between MT and ASSR. At 85 dB ML, an effect of CF was observed, suggesting that the relationship between MT and ASSR is more complex than initially anticipated, and involving all the experimental parameters (CF, PL, and ML).

1. INTRODUCTION

Auditory masking is a fundamental concept in audiology, describing the phenomenon where the perception of one sound (the probe-signal) is influenced by the presence of another sound (the masker). It is typically assessed through behavioral tests, where individuals are tasked with detecting the probe signal. The behavioral masking threshold refers to the minimum level of a probe signal allowing behavioral detection of the probe in the presence of a masker. Behavioral masking thresholds are commonly studied in psychoacoustic experiments and serve as the basis for models widely employed in hearing aid fitting [1]. Psychoacoustic models of masking have described frequency-specific masking effects and the critical band theory, which explains masking in terms of auditory filters and their bandwidths [2]. However, behavioral measurements are inherently subjective and depend on the participant's attention, motivation, and cognitive state. Furthermore, significant variability in masking thresholds exists among individuals, particularly those with hearing loss [3]. This variability creates challenges for accurately predicting and compensating for masking effects in hearing aid algorithms.

Auditory Steady-State Response (ASSR) is widely used in clinical practice for hearing assessment, particularly in estimating frequency-specific hearing thresholds in individuals unable to perform behavioral tasks. ASSR reflects the neural system's entrainment to the stimulus, and is typically measured in response to an amplitude modulated stimulus [4, 5]. This neural entrainment can be influenced by external factors, such as the presence of a masking sound. Masking affects the signal-to-noise ratio (SNR) of the auditory stimulus, and increased masking reduces SNR, resulting in decreased ASSR amplitude.

Evidence of the effects of masking on ASSR and other electrophysiological measurements has been reported in various contexts. Several studies have shown that masking

noise applied contralaterally can suppress ASSR amplitudes [6–8]. Furthermore, contralateral noise, even at levels that do not cause significant behavioral threshold elevation, has been shown to significantly elevate the thresholds of the 40-Hz ASSR [9]. Similar effects of masking have been observed in other auditory measures, such as the Auditory Brainstem Response (ABR). For instance, the latency of wave V in the ABR increases with rising levels of broadband white noise masker, while the amplitudes of both wave I and wave V decrease [10].

Masking effects on the ASSR can be considered as an undesirable factor that negatively impacts its estimation. However, the masking effects can also be utilized to study the masking phenomenon itself. Unlike behavioral methods, this approach enables an objective assessment of masking effects without requiring active participation from the subject. To our knowledge, ASSR-based estimation of masking thresholds has not been previously explored.

This study examines the masking effect on the ASSR and its relationship to the behavioral masking threshold. The masker is a low-pass noise signal presented at two intensity levels. There were two probe signals, each a one-third octave amplitude-modulated noise, centered at different frequencies above the masker's cutoff. Each probe was presented at four levels relative to the behavioral masking threshold. This experimental design allows us to quantify the masking effect on the ASSR as a function of presentation level and spectral distance from the masker.

In designing this study, we hypothesized that ASSR amplitude would increase monotonically with probe intensity, enabling masking threshold estimation using a methodology similar to ASSR-based hearing threshold estimation. Additionally, we expected the masking effect on the ASSR to be independent of the probe signal's center frequency, provided the probe levels were set relative to the behavioral masking threshold.

By exploring the relationship between behavioral masking threshold and ASSR, this study aims to enhance our understanding of physiological masking mechanisms and assess the potential of ASSR as an objective tool for estimating masking thresholds.

2. METHOD

2.1 Subjects

Six participants (4 women, mean age: 33.2 years) with normal hearing thresholds (<20 dB HL for octave frequencies between 500 and 4000 Hz) and no history of hearing disorders were included in the study. Behavioral hearing thresholds for each ear were measured using the ascending method as outlined in ISO 8253-1:2010 [11].

This study was conducted as a preliminary pilot investigation to refine experimental procedures and assess feasibility. Participants were staff or students from our department who voluntarily agreed to participate based on informed consent.

2.2 Measurement setup

EEG was recorded concurrently from four scalp electrodes and 16 ear electrodes. The scalp electrodes were placed at left (M1) and right (M2) mastoids, Fpz and AFz according to the 10-20 EEG electrode system [12], and attached to the skin using custom designed electrode holders made of silicone with double adhesive pads. Prep pads were used to clean the skin prior to the attachment of the scalp electrodes. A small amount of gel (Electro-Gel, Electro-Cap International, Inc., USA) was applied on the scalp electrodes. The data recorded from ear-electrodes were not used in this study.

The EEG recordings were acquired with a sampling rate of 1000 Hz by a 32 channel portable MOBITA EEG amplifier (TMSi B.V., The Netherlands). The recording electrodes were Ag/AgCl electrodes with a diameter of 4 mm [13]. The ground electrode was placed on the neck using a disposable wet gel electrode (Ambu WS, Ambu A/S, Denmark). The auditory stimuli were presented to the test subjects using insert earphones (3M E-A-RTONE for ABR, 50 Ohm, 3M, USA) via an RME soundcard (Fireface UC, RME, Germany) with a sampling frequency of 48 kHz.

Synchronization of the auditory stimuli and EEG recordings was achieved using a trigger signal generated by the soundcard. The trigger signal, periodic at 0.1 Hz, was sent to the EEG amplifier's trigger input via a g.TRIGbox (g.tec medical engineering GmbH, Austria).

2.3 ASSR stimuli and recordings

The probe signal consisted of 40-Hz amplitude-modulated (AM) 1/3-octave Gaussian noise (GN) signals with center frequencies of 891 Hz and 1414 Hz. The masker was low-pass GN with a cut-off frequency of 707 Hz. Both the probes and the masker were filtered in the frequency domain. Initially, the GN signals in its entirely length were transformed to the frequency domain using a Discrete Fourier Transform (DFT). A window function was then applied to set frequencies outside the band of interest

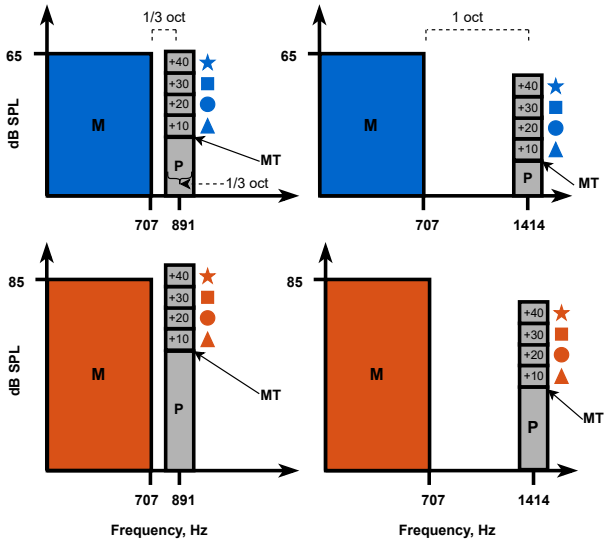

Figure 1. Schematic representation of the paradigm. The masker (M) was presented at levels 65 dB SPL (blue) and 85 dB SPL (orange). The probes (P) were presented at levels10 dB (triangles), 20 dB (circles), 30 dB (squares) and 40 dB (stars) above the behavioral masking threshold (MT), which were determined for each center frequency and masker level.

to zero. Finally, the complex spectrum was transformed back into the time domain using the Inverse DFT. This filtering method ensures a filter characteristic with steeper slopes than the auditory-filter bank. The masker was presented at levels of 65 and 85 dB SPL, while the stimuli levels were set at 10, 20, 30, and 40 dB above individual behavioral masking thresholds (MT). Stimuli were presented diotically. A schematic representation of the paradigm is shown in Figure 1.

Behavioral masking thresholds were determined for each masker level and center frequency (500-ms 1/3-octave GN centered at 891 and 1414 Hz served as probe-signals) using a three-alternative forced-choice paradigm with a 1-up, 3-down adaptive procedure. The initial step size was 5 dB. After four reversals, the step size was reduced to 2 dB and the test proceeded until 12 reversals were reached. The threshold was calculated as the average of the last 8 reversals. A computer monitor displayed a response box with three buttons representing the stimulus intervals in each trial. During stimulus presentation, the buttons were highlighted successively in sync with the corresponding intervals. The subjects were instructed to press the button corresponding to the interval containing the probe and received immediate feedback indicating whether the response was correct or incorrect.

ASSR measurements were conducted for each combination of masker level, probe level and center frequency. In the presence of a masker, EEG was recorded for 20, 20, 10, and 10 minutes for stimuli presented at 10, 20, 30, and 40 dB above MT, respectively. Similarly, for reference without masker, EEG was recorded for 10, 10, 5, and 5 minutes at 10, 20, 30, and 40 dB above MT, respectively. Longer recording times were used at lower stimulus levels to account for the lower ASSR amplitudes, ensuring sufficient data to achieve a significant response.

The total recording time was 6 hours, distributed over three days. On the first day, recordings were conducted at a center frequency of 891 Hz with two masker levels and four probe levels, totaling eight recordings (2 hours). The same procedure was followed on the second day for a center frequency of 1414 Hz, also resulting in eight recordings (2 hours). On the third day, recordings were performed without the masker (16 trials, 2 hours). Within each recording day, stimuli were presented in randomized order.

Both behavioral tests and EEG recordings took place in a double-walled sound-attenuating room. During EEG recordings, participants were seated in a comfortable chair and instructed to relax but remain awake and to have open eyes. They were offered the option to watch a silent, subtitled movie of their choice to avoid becoming drowsy during the experiment.

2.4 Data analysis of EEG

Analysis of the EEG data was performed offline after the recordings were completed. ASSRs were estimated from the average of the mastoids with reference to Fpz. The data was band-pass-filtered using an 8th order, zero-phase filter with passband between 10 and 100 Hz and Butterworth characteristic. A notch filter was applied to remove 50 Hz line noise. The trigger signal was used to split the dataset into epochs of 10 seconds length and the epochs were averaged using weighted averaging [14].

The averaged epoch was transformed into the frequency domain by means of a DFT. The ASSR was determined as the amplitude at the modulation frequency bin, and the background noise was calculated as the root-mean-square in the frequency band ±6 Hz relative to the modulation frequency (excluding the modulation frequency) [4].

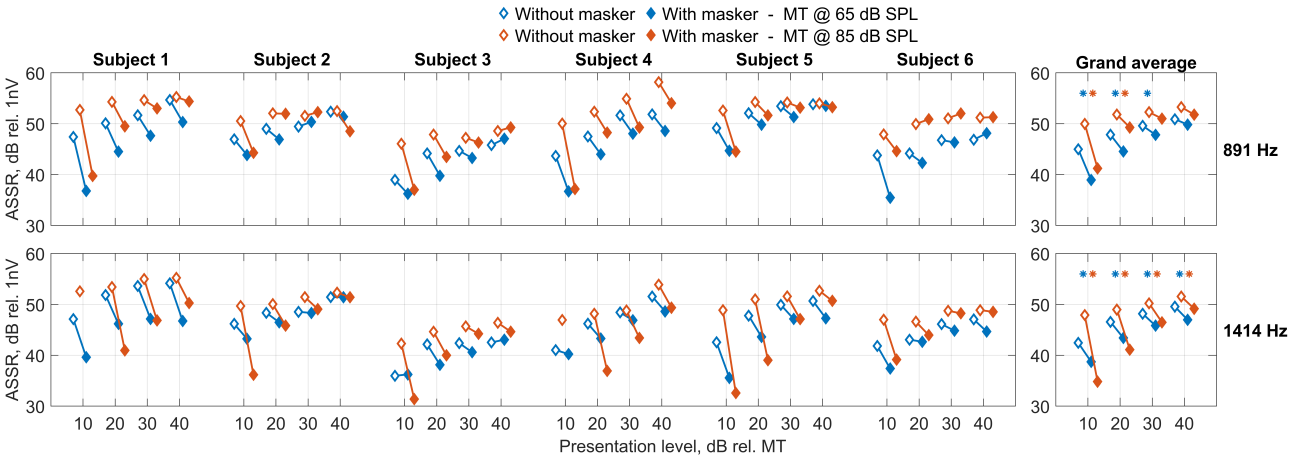

Figure 2. ASSR as a function of the presentation level for each CF (891 Hz – upper subplots, 1414 Hz – lower subplots) and masker level (blue for 65 dB SPL, orange for 85 dB SPL). Data is shown with (filled rhombs) and without (empty rhombs) the masker. Left: individual subject data; right: grand average across subjects. Asterisks indicate significant difference between ASSR with and without the masker (blue for 65 dB SPL, orange for 85 dB SPL).

Statistical significance of the ASSR amplitude was determined based on an F-test [15]. The F-ratio was calculated as the ratio between the power at the modulation frequency and the average power in the frequency band ±6 Hz relative to the modulation frequency (excluding the modulation frequency). An F-ratio with a p-value ≤ 0.05 was regarded as statistically significant. Only statistically significant ASSRs were included in the subsequent statistical analysis.

2.5 Statistical analysis of the recorded ASSR

Differences between ASSRs in the presence and absence of the masker were evaluated using a paired permutation test [16] with 1000 permutations. For the statistical analysis of ASSRs in the presence of the masker, mixed-effects models were employed in R (lme4, version 1.1.35.5, Rstudio R-4.4.2) [17]. The model included *Center Frequency* (*CF*: 891 and 1414 Hz), *Masker Level* (*ML*: 65 and 85 dB SPL), *Presentation Level* (*PL*: 10, 20, 30 and 40 dB MT) and all their interactions as fixed effects. *Subject* (*S*) was included as a random effect to account for inter-subject variability. Statistical significance of the fixed effects was assessed through model reduction based on likelihood ratio test using the `anova` function in R. Post hoc analyses were conducted using estimated marginal means (EMMs) computed with the emmeans R package [18], with Bonferroni correction applied to adjust p-values for multiple comparisons.

3. RESULTS

Table 1 presents the mean and standard deviation of behavioral masking thresholds (MT) in dB SPL (relative to 20 μPa) across six subjects for each masker level (ML) and carrier frequency (CF). For comparison, it also includes the mean and standard deviation of behavioral thresholds measured without a masker using the same procedure.

For each subject, ASSR was recorded in 32 different conditions (2 CF $\times$ 4 PL $\times$ 2 ML $\times$ with/without masker). Six subjects were included in the study, yielding a total of 192 ASSR recordings, of which 2 recordings were not

Table 1. Mean (standard deviation) of the behavioral masking thresholds in dB SPL across the subjects for each masker level and without the masker.

Center Frequency	Masker Level		
	65 dB SPL	85 dB SPL	Without
891 Hz	29.8 (4.7)	55.7 (2.3)	7.6 (4.1)
1414 Hz	18.8 (2.9)	39.5 (3.5)	9.6 (2.2)

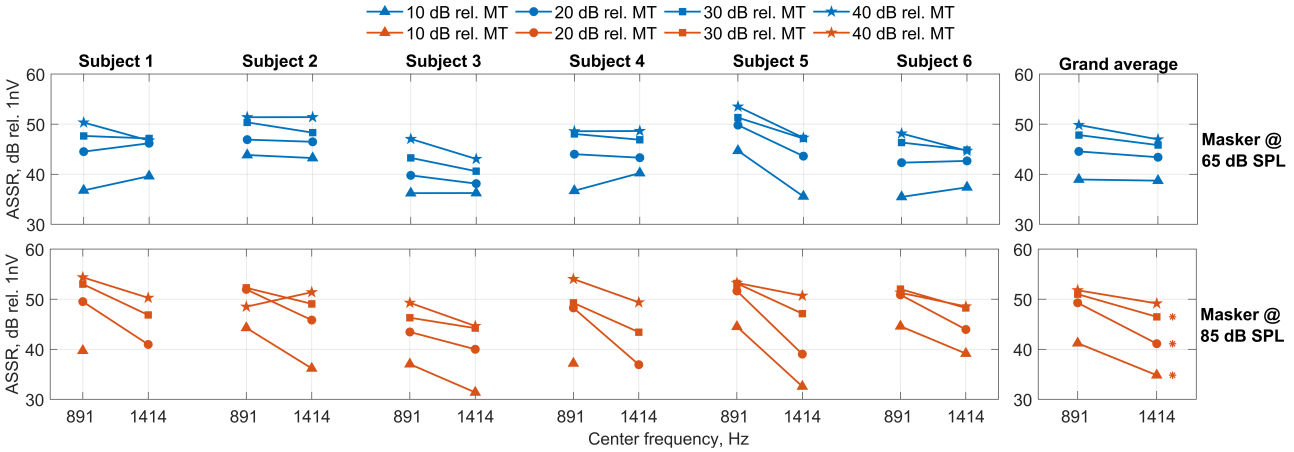

Figure 3. ASSR as a function of the CF for stimuli presented 10 dB (triangles), 20 dB (circles), 30 dB (squares) and 40 dB (stars) relative to masking threshold. Data is shown for masker levels of 65 dB SPL (blue, upper subplots) and 85 dB SPL (orange, lower subplots). Left: individual subject data; right: grand average across subjects. Asterisks indicate significant difference in ASSR amplitude between 891 Hz and 1414 Hz.

significant. Thus 190/192, corresponding to 99 % of all recordings, were significant.

Figure 2 illustrates the relationship between ASSRs to different stimuli in the experimental design, both with and without the masker. The data is shown for each individual subject followed by the grand average (only significant data points are shown). The figure reveals a reduction in ASSR amplitude in the presence of the masker, particularly at lower presentation levels. This difference diminishes as the presentation level increases.

Table 2 provides p-values from permutation tests comparing ASSRs with and without the masker. Significant differences are marked with asterisks in the grand average plots shown in Figure 2.

Figure 3 illustrates the relationship between ASSR and center frequency (891 and 1414 Hz) for stimuli presented with masker at two levels (65 and 85 dB SPL) across various presentation levels relative to the masking threshold. The data points represent the same ASSR measurements with masker shown in Figure 2, but they are visualized in a different way. Data is shown both for individual subjects and as the grand average across all subjects. The figure demonstrates that when the probe signal is presented relative to the masking threshold, ASSR amplitudes remain relatively stable across center frequencies when the masker level is 65 dB SPL. In contrast, for masker level of 85 dB SPL, a noticeable reduction in ASSR amplitude is observed at 1414 Hz compared to 891 Hz.

A full mixed-effects model was fitted to the ASSRs with the masker: $ASSR \sim CF + ML + PL + CF{:}ML + CF{:}PL + ML{:}PL + CF{:}ML{:}PL + (1|S)$

Residuals met model assumptions for normality (Shapiro-Wilk test: w = 0.989, p = 0.678) and homogeneity of variance (Bartlett's test: $\chi^2(15) = 22.996$, p = 0.084). Likelihood ratio tests during model reduction revealed a significant three-way interaction (*CF:ML:PL*, $\chi^2(3) = 12.1$, p = 0.007), indicating that the model could not be simplified.

Table 3 presents the post hoc analysis of estimated marginal means comparing ASSRs at center frequencies 891 Hz and 1414 Hz. Significant reductions at 1414 Hz are marked by red asterisks in Figure 3.

4. DISCUSSION

The behavioral masking thresholds presented in Table 1 align with previous empirical findings and established auditory system theories [1]. Initially, we observe a a clear increase in the threshold when a 65 dB masker is present compared to the without-masker condition. This confirms that the masker has an effect and that the measured threshold is a masking threshold rather than a hearing threshold. At both center frequencies (891 Hz and 1414 Hz), thresholds were higher at a masker level of 85 dB SPL than at 65 dB SPL, confirming that masking thresholds increase with masker level. Notably, consistent

Table 2. p-values from paired permutation tests, comparing ASSR with and without the masker for each masker level, center frequency and presentation level.

		Presentation Level			
Center Frequency	**Masker Level**	10 dB MT	20 dB MT	30 dB MT	40 dB MT
891 Hz	65 dB SPL	0.001	0.001	0.049	0.303
891 Hz	85 dB SPL	0.001	0.049	0.227	0.110
1414 Hz	65 dB SPL	0.013	0.001	0.001	0.045
1414 Hz	85 dB SPL	0.001	0.001	0.001	0.001

Table 3. Post hoc analysis of estimated marginal means comparing ASSR at different center frequencies for each masker level and presentation level, SE - standard error of mean.

Masker Level	**Presentation Level**	**$ASSR_{891Hz} - ASSR_{1414Hz}$**	**SE**	**t.ratio**	**p-value**
65 dB SPL	10 dB MT	0.234	1.25	0.188	1.000
65 dB SPL	20 dB MT	1.159	1.25	0.930	1.000
65 dB SPL	30 dB MT	2.008	1.25	1.611	0.881
65 dB SPL	40 dB MT	2.871	1.25	2.304	0.186
85 dB SPL	10 dB MT	6.458	1.40	4.604	<.001
85 dB SPL	20 dB MT	8.167	1.25	6.553	<.001
85 dB SPL	30 dB MT	4.522	1.25	3.628	0.003
85 dB SPL	40 dB MT	2.635	1.25	2.114	0.147

with established masking theories, a 20 dB increase in masker level resulted in a more than 20 dB increase in masking threshold. Additionally, in this study, where the masker was low-pass filtered noise with a 707 Hz cutoff frequency, the masking threshold was higher at 891 Hz than at 1414 Hz. This finding supports the auditory filter bank theory, which suggests that masker penetration decreases as the detection band is further away from the masker bands [1, 2].

Figure 2 illustrates the ASSR amplitudes as a function of presentation level for each center frequency (CF) and masker level (ML), with data shown both with and without the masker. The results indicate that ASSR amplitudes are generally lower in the presence of a masker compared to when a masker is absent, which is consistent with findings previously observed in the literature [6, 7]. This masking effect is particularly prominent at lower presentation levels, where the difference between ASSR with and without the masker is most pronounced. As the presentation level increases, the masking effect diminishes, and ASSR amplitudes with the masker approach those observed without it.

These findings are statistically supported by the paired permutation test results presented in Table 2. At 1414 Hz, significant differences were observed at all presentation levels for both masker levels. At 891 Hz, the effect was significant at 10, 20, and 30 dB MT for the 65 dB SPL masker, and at 10 and 20 dB MT for the 85 dB SPL masker, with no significant difference at higher presentation levels. This pattern further confirms that the masking effect is stronger at low probe levels and becomes less pronounced as the probe level increases. We hypothesize that, when the probe is near the masking threshold, the probe signal - and consequently, its modulation - is masked by the masker signal to a high degree. However, as the probe level increases, an increasingly larger part of its modulation surpasses the masking threshold, resulting in a stronger neural representation of the modulation.

Additionally, Figure 2 demonstrates a clear monotonic increase in ASSR amplitude with increasing presentation level, both in the presence and absence of a masker. This trend is consistent across subjects and frequencies. The observed increase in ASSR amplitude aligns with previous studies showing that higher presentation levels recruit a greater neural population, leading to stronger responses [19–21]. Although the presence of a masker reduces the ASSR amplitude, the relationship between ASSR and presentation level continues to exhibit a monotonic increasing pattern as a function of presentation level. This suggests that ASSR can serve as an objective measure for predicting behavioral thresholds. Specifically, in the absence of a masker, the threshold

corresponds to the hearing threshold, whereas in the presence of a masker, it corresponds to the masking threshold.

Figure 3 illustrates ASSR amplitudes as a function of center frequency (891 Hz vs. 1414 Hz) for different presentation levels relative to masking threshold (MT) and masker levels (65 dB SPL and 85 dB SPL). The figure shows that with a 65 dB SPL masker, ASSR amplitudes remain relatively stable across frequencies at all presentation levels. In contrast, with an 85 dB SPL masker, ASSR amplitudes at 1414 Hz are notably lower than at 891 Hz, with this effect being most pronounced at lower presentation levels. This pattern suggests a complex interplay between masker level, center frequency, and presentation level, indicating that physiological masking is not simply a linear function of these parameters.

A mixed-model reduction procedure confirmed this complexity by revealing a significant interaction between masker level, presentation level, and center frequency. To further examine this interaction, post hoc analyses were conducted. At 65 dB SPL, no significant differences were found between 891 Hz and 1414 Hz across all presentation levels, suggesting that there is the same relationship between ASSR and behavioral masking threshold across probe frequencies.

However, at 85 dB SPL ASSR amplitudes at 1414 Hz were significantly lower than at 891 Hz for presentation levels of 10, 20, and 30 dB MT, indicating a stronger physiological masking effect at the higher masker level. Interestingly, no significant difference was observed at 40 dB MT. One possible explanation is that at this high presentation level, ASSR amplitudes at 891 Hz may have reached a saturation point, reducing the observable difference between the two frequencies. Previous studies have reported that ASSR amplitudes tend to saturate at levels above 80 dB SPL [22–24].

5. CONCLUSION

This study was based on the hypothesis that the ASSR amplitude depends on the probe's presentation level relative to the behavioral masking threshold. While the empirical findings strongly support such relationship, they also reveal a more complex interaction involving the masker level and the probe signal's center frequency relative to the masker's cut-of frequency. Future studies will further explore these interactions.

HOW FREQUENCY-BASED PROCESSING MAY HELP CLINICIANS IMPROVE SOUND QUALITY PERCEPTION IN COCHLEAR IMPLANT USERS?

Louis Villejoubert[1*] **Lorenzo Picinali**[2]

ABSTRACT

Sound quality in cochlear implants (CIs) remains a critical challenge despite advancements in speech understanding. While CI technology's impact on sound quality degradation is well-documented, less is known about specific "frequency-to-place factors" such as frequency-to-place mismatch (FTPM) and issues with the electrode-neuron interface (ENI). This study explores innovative methods to assess the relationship between sound quality and these factors. The first experiment examines vowel perception through combinations of the first and second formant frequencies varied across a spectral continuum. Participants selected vowels from a close-set list (/a/, /i/, /ɔ/, /u/, /ɜ/) and then rated their confidence of their selection. Individual vowel maps were calculated to assess shifts in internal vowel representation potentially linked to FTPM (although not accounting for other ENI aspects). The second experiment evaluates sound quality transmission across electrodes using paired chord comparisons. Participants rated sound quality between chords and their inversions, isolating electrode-specific degradation. Ten post-lingually deafened adult CI users with over 12 months of experience participated. Preliminary findings reveal good test-retest reliability. Vowel experiments showed some preference for shifted configurations, while chord tests highlighted significant variability across electrodes. These methods may serve as clinical tools to optimize CI setup, improving sound quality for users.

1. INTRODUCTION

A cochlear implant (CI) is a neuroprosthetic device designed for people with severe hearing loss. Once implanted, users must adapt to new stimulation patterns imposed by both the CI technology and individual factors. Some of these individual factors are referred to as "frequency-to-place factors" because they alter the distribution of frequency information delivered to the auditory system.

The primary individual factor of interest here is frequency-to-place mismatch (FTPM). FTPM refers to the discrepancy between the frequency information delivered by an electrode and the frequency typically processed at the location stimulated by this electrode. This phenomenon occurs mainly because electrode arrays rarely allow stimulation along the entire length of the cochlea. Specifically, electrode arrays seldom reach the apex of the cochlea, where low frequencies are usually processed. To maintain effective transmission of the frequency spectrum, fitting strategies often involve a trade-off: a wide range of frequency information is transmitted, although not always to the ideal location. For example, frequencies ranging roughly from 100 Hz to 8000 Hz are transmitted, even though the most apical electrode typically corresponds to a location associated with a characteristic frequency (CF) of approximately 290 Hz [1]

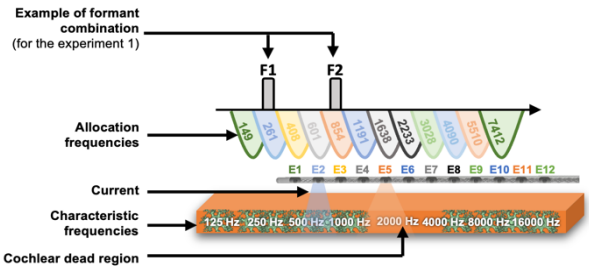

Figure 1. Simplified representation of cochlear implant processing illustrating the concepts of FTPM, poor ENI quality, and the functionality examined in Experiment 1. For FTPM, the illustration depicts a discrepancy between the allocated frequencies—the frequency information that is filtered and transmitted—and the characteristic frequencies—the cochlear regions typically responsible for processing those frequencies. Poor ENI quality is represented by missing neurons (i.e., a cochlear dead region). Its potential impact on transmission is illustrated by the wide current spread around electrode 5 (E5).

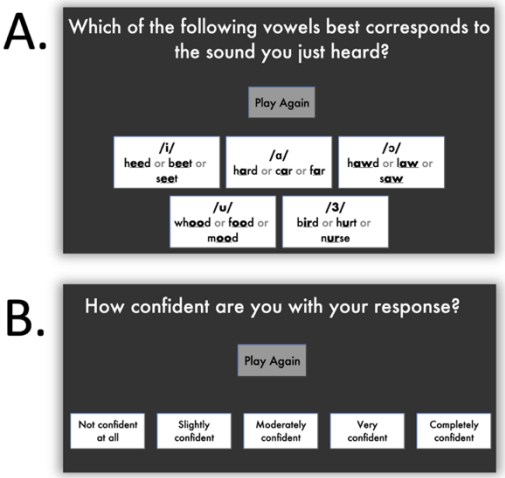

Figure 2. Illustration of the two consecutive questions presented during each trial in Experiment 1. Part A represents the identification task, while Part B assesses participants' confidence in their identification judgments.

(Figure 1). The term CF refers to the estimated frequency typically processed at a specific location within the cochlea. CF is determined through imaging methods such as computed tomography. Once estimated, the CF at the place stimulated by each electrode is compared to the allocated frequencies (AL) of each electrode—i.e., the frequencies around which information is extracted during CI processing—resulting in the FTPM value (Equation 1).

While most CI users experience some degree of FTPM, much remains unclear regarding its effects on perception and the adaptation process. This knowledge gap likely arises because the perceptual impact of FTPM varies significantly depending on the type of auditory signal. In speech understanding tasks, whether conducted in quiet or in noise, the long-term impact appears minimal [2]. However, FTPM has a more noticeable negative effect on sound quality, as indicated by one study [3]. The detrimental effects of FTPM are even more pronounced in music-related tasks such as pitch scaling, pitch discrimination, or melody recognition [4].

1.1 Experiment 1

The first experiment aims to explain how post-lingually deafened CI users with extensive implant experience process vowels in relation to the frequency distribution pattern imposed by FTPM. The experiment consisted of presenting combinations of first and second formants associated with a constant fundamental frequency (at 100 Hz). "The first formant ranged from approximately 230 Hz to 1720 Hz, and the second formant ranged from 415 Hz to 4000 Hz. Sounds were synthesized using the Parselmouth library, which enables the use of Praat directly within a Python environment.

For each combination, participants selected the perceived vowel from a closed-set list (/a/, /i/, /ɔ/, /u/, /ɜ/) and rated their confidence in their choice using a Likert scale. Using these two responses, individual perception heatmaps for each vowel were computed separately for each CI user. The same paradigm was performed with 10 normal-hearing (NH) listeners to create vowel reference heatmaps, which were then compared to CI users' individual heatmaps. The calculated shifts were then related to FTPM values to estimate the degree of adaptation to FTPM (see Equation 2).

1.2 Experiment 2

Experiment 2 builds on the findings from previous FTPM re-mapping studies that there are individual differences in the efficacy of the approach. One hypothesis is that adaptation depends not only on FTPM but also on the quality of the electrode-neuron interface (ENI).

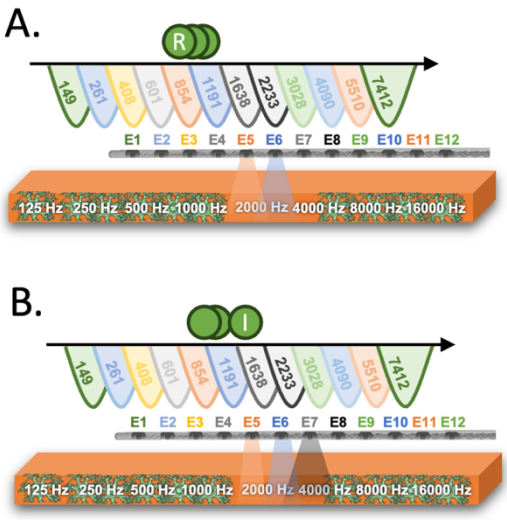

Figure 3. Illustration of an example chord pair used in Approach 2. Part A depicts the root chord, where the root note primarily stimulates electrode 5 (E5). Part B shows the inverted version of the chord, specifically stimulating electrode 7 (E7).

ENI quality describes how effectively the signal is transmitted between a specific electrode and targeted neurons. It encompasses factors such as the distance between the electrode and neurons, fibrosis around the electrode, current spread, and the number and health of stimulated neurons. Negative consequences of poor neural health have been documented for speech understanding [5].

To estimate the ENI quality of each electrode, we employed a method involving paired comparisons of chords. For each paired comparison, the root and inverted versions of a chord were presented to participants. Chords are musical units defined as combinations of notes that, when played together, are perceived as pleasant. In Western music, the most basic chord is a triad (consisting of three notes): a root note, a third interval, and a fifth interval. An inverted chord maintains the third and fifth interval notes, while the root is moved one octave higher. Theoretically, the root and its inversion differ slightly but should sound similarly pleasant. However, within paired comparisons and CI testing, differences in ENI quality at stimulation sites might influence participants' preferences between the root and inverted chords (see Figure 2). This hypothesis underlies the second approach described here: each pair of root/inverted chords was tailored to each

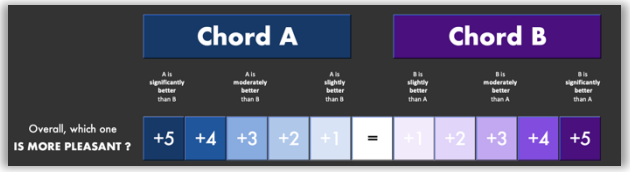

Figure 4. Illustration of the testing interface used in Experiment 2. After listening to each pair of chords—one root and one inverted—participants were asked to indicate which chord sounded more pleasant using this 10-option rating scale. Collected data were then analyzed using a Bayesian statistical model to estimate the pleasantness associated with each electrode.

CI user's mapping strategy, stimulating two different electrodes differently.

To validate this approach for estimating ENI quality, results from Experiment 2 were compared with the Panoramic ECAP (PECAP) method. The PECAP method uses forward-masked electrically evoked compound action potentials (ECAPs) to estimate neural activation patterns during CI stimulation. Specifically, PECAP provides estimations of current spread and neural health for each electrode along the cochlea.

$$FTPM = abs\left[\frac{log_{10}\left(\frac{CF}{AL}\right)}{log_{10}(2)}\right] \quad (1)$$

$$Shift = (Adaptation\ Completed) - FTPM \quad (2)$$

These experiments provide new tools for investigating how sound quality perception differs between NH and CI users. Initial results suggest that vowel perception in CI users may be shifted relative to NH listeners, potentially reflecting the influence of FTPM. The chord comparison task revealed variability across electrodes that could relate to differences in ENI quality and current spread. Further results, including detailed comparisons and relationships with neural health measures, will be presented at the conference.

ABSTRACT

Hyperacusis describes the condition in which individuals perceive mid-level sounds as uncomfortably loud, despite exhibiting normal hearing thresholds. Audiological assessments of hyperacusis commonly include the typical audiometric test battery, including uncomfortable loudness levels (ULLs), and a hyperacusis questionnaire (HQ). An estimate of the loudness growth function is often not included. This study investigated the correspondence between HQ scores, loudness functions, and key audiological measures. All twenty-two listeners had normal hearing ($<$ 20 dB HL within the range 0.25-8 kHz) and no tinnitus. Extended high-frequency thresholds (10–16 kHz) were also measured. Listeners completed a HQ and Categorical Loudness Scaling (CLS) test. ULLs were also measured using pure-tone stimuli and the audiometric standard procedure (ULL-SP) and an adaptive procedure using speech-shaped noise stimuli adapted from the CLS task (ULL-CLS). The results indicated that elevated thresholds in the 12–16 kHz range were associated with a straightening of the entire loudness function. Additionally, significant correlations were observed between HQ scores and ULL-SP at 0.5, 2, and 4 kHz. Listeners with higher HQ scores exhibited steeper lower segment of the loudness function, indicating a more rapid growth in perceived loudness for low- to mid-level stimuli.

Keywords: *Hyperacusis, High-Frequency Audiogram, Loudness, Categorical Loudness Scaling.*

1. INTRODUCTION

A three-round Delphi survey involving hearing healthcare professionals has proposed a consensus-based (90% agreement level) definition of hyperacusis as: “A reduced tolerance to sound(s) that are perceived as normal to the majority of the population or were perceived as normal to the person before their onset of hyperacusis, where “normal” refers to sounds that are generally well tolerated.” [1]. The reported prevalence of hyperacusis can vary depending on the definitions and assessments used [2] but is typically cited as ranging between 8-15% [3, 4]; with a higher prevalence associated with certain syndromes and autism spectrum disorders [5]. Hyperacusis can be associated with fear of certain acoustic and social environments, avoidance behaviours, and reduced quality of life [6]. Hyperacusis is known to often share some comorbidity with tinnitus [7], and both conditions are considered to emerge as a consequence of the brain’s attempt to compensate for cochlear trauma resulting from acoustic over-exposure. Hyperacusis may arise as a result of damage to synapses between inner hair cells and auditory nerve fibres, known as cochlear synaptopathy [8], which may manifest as a degradation in the neural coding of speech [9].

Clinical assessments of hearing are based on an assessment of hearing thresholds for sounds presented at the standard audiometric frequencies (SAF) of 0.25-8 kHz. Hyperacusis and early stages of cochlear synaptopathy may not be evident as elevated SAF thresholds [10]. Low uncomfortable loudness levels (ULLs) measured using

pure-tone signals, as part of a standard audiological hearing test battery, may also be associated with hyperacusis. However, pure-tone ULLs may be variable amongst a population that reports hyperacusis [11], so ULLs on their own may be insufficient as a psychophysical indicator of hyperacusis. For that reason, combined assessment criteria may provide an improved indicator of hyperacusis [5], for instance, combining ULLs with scores from the Hyperacusis Questionnaire (HQ) [12]. Aazh and Moore suggested a minimum average ULL of 77 dB HL (averaged across test pure-tones of 0.25, 0.5, 1, 2, 4, and 8 kHz) and a score of at least 22 at the HQ as best indicators of hyperacusis [13]. Audiological assessments commonly include measures of ULLs and/or measures of the stapedius reflex as well as the HQ, but an estimate of the loudness growth function is often not conducted. Individual loudness perception can be assessed using the Categorical Loudness Scaling (CLS) test, in which the loudness perception for stimuli of different levels is assessed [14].

There is growing evidence supporting the assessment of hearing thresholds at an extended range of audiometric frequencies (EAF), such as 9 to 20 kHz, for providing an early indication of vulnerability to risk factors such as ageing, disease, ototoxic drugs, and noise exposure [15]. Although cochlear synaptopathy may contribute to difficulties in perceiving and understanding speech in adverse listening conditions, it may not necessarily manifest as elevated hearing thresholds in a SAF audiogram [16, 17]. It has been suggested that EAF audiometry might be useful as a biomarker of cochlear synaptopathy [10, 17], but it is still unclear how, and by which mechanisms, cochlear synaptopathy and EHF hearing loss are associated with hyperacusis, despite normal thresholds in the SAF range [18].

The current study investigated the correspondence between HQ scores, loudness growth functions, ULLs, and SAF and EAF audiograms.

2. METHOD AND PROCEDURE

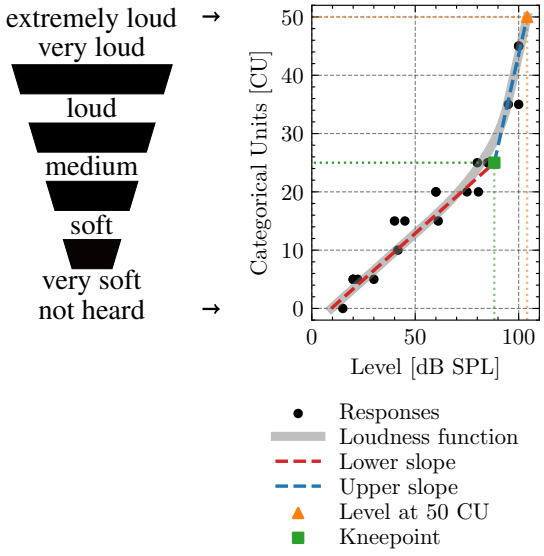
2.1 Participants

Twenty-two listeners participated in the measurements (14 women, 8 men; mean age 26.9 years). All provided signed consent for the study, which had been approved by the UCL Ethics Board. The test session took 1.5 hours.

2.2 Facilities and Apparatus

The measurements took place in a double-walled sound-attenuated room. Audiometric thresholds, standard audiometric ULLs, and the CLS test were measured using a calibrated clinical audiometer, Auritec Audiometer with Ear3.0 software, Earbox3.0 soundcard and Sennheiser HDA300 headphones.

2.3 Audiometry



Audiometry was performed separately for listeners' right and left ears using pure-tone sound signals of 0.25, 0.5, 1, 2, 4, 6 and 8 kHz, following the British Society of Audiology (BSA) recommended procedure to obtain a SAF audiogram. All listeners had normal hearing as assessed by a SAF audiogram (i.e., hearing thresholds $<$20 dB HL) and no reported tinnitus. Listeners were also assessed with an EAF audiogram using pure-tone sound signals of 10, 12, 14 and 16 kHz.

ULLs were measured using pure-tone stimuli and following the audiometric standard procedure (ULL-SP). Aazh and Moore suggested a slight amendment to the BSA protocol when measuring ULLs using pure-tone signals for individuals with hyperacusis [19]. We followed such a protocol, which only slightly extended the overall audiological testing time. This approach allows for a more gradual exploration of the loudness space when measuring ULL-SP values in a population with hyperacusis.

The ULL-SP values were obtained separately for the right and left ears for 0.5, 2, and 4 kHz pure-tone signals, and then averaged across both ears. For comparison, ULLs were also measured using speech-shaped noise and an adaptive procedure based on the one used in the CLS test (ULL-CLS). A MatLab script was specifically created to run this adaptive CLS procedure to obtain the ULL-CLS thresholds. The ULL-CLS measurements were conducted for the right and left ears individually (monaural) and then averaged across both ears. Additionally, measurements were taken with both ears simultaneously (binaural diotic).

2.4 Categorical Loudness Scaling Test

The CLS test provides measures of loudness categorisation across an individual's dynamic range of hearing. In the CLS procedure, listeners categorised the subjectively-perceived loudness of a test signal using a pre-defined 11-point categorical scale (see Fig. 1a). Each of the categories is assigned a numerical value, referred to as a Cat-

(a) (b)

Figure 1: a) Representation of the 11-level categorical scale presented to listeners during the CLS test. Categories are mapped to categorical units (CUs) from 0 to 50. b) Example of loudness functions fitted to a participant's CLS test responses. The levels corresponding to the kneepoint at 25 CU and inferred at 50 CU, derived from the fitted functions, are indicated by the green and orange dotted lines, respectively.

egorical Unit (CU), from 0 to 50 CU. The stimuli consisted of speech-shaped noise of 1-s duration, including on- and off-ramps of 50 ms. The CLS adaptive procedure described in [14] was used to automatically adjust the stimuli presentation levels based on listeners' responses. Each listener first undertook a practice run with the CLS test followed by three recorded runs of the test.

Loudness functions were obtained by minimizing the least-square error between two linear segments intersecting at a fixed loudness level of 25 CU and the participants' responses to the CLS test. The upper and lower linear segments were smoothed between 15 and 35 CU using a quadratic Bezier curve. The fitting procedure 'BTUX' used in this study is described in [14]. Four parameters could then be derived from the loudness functions: slope values of the lower and upper linear regression segments, sound level at the point of intersection (kneepoint), and inferred level at 50 CU. The kneepoint describes the point at which the growth rate changes between the lower and upper portions of the function. For each listener, the four parameters were averaged over 3 repeated runs. Figure 1b depicts the process of defining the lower and upper function slopes, the kneepoint, and the level at 50 CU from the fitted CLS data of a single run.

2.5 Hyperacusis Questionnaire

Each listener completed the Hyperacusis Questionnaire (HQ) to quantify and evaluate potential hyperacusis symptoms. The HQ is a standardized questionnaire designed based on the literature on this pathology and consists of 14 items [12]. It was shown to be sensitive enough to discriminate between individuals based on their hyperacusis symptoms. The overall score ranges from 0 to 42, and a score greater than 28 could indicate strong auditory hypersensitivity according to [12]. Studies [13] and [20] suggested cut-off scores of 26 and 22 respectively.

3. RESULTS AND DISCUSSION

The current study investigated the correspondence between HQ scores, CLS results, and audiogram (SAF and EAF).

Figure 2 illustrates the relationship between upper and lower slopes of the loudness function and averaged audiometric thresholds, averaged across listeners' right and left ears, within each of three frequency ranges: 0.25–4 kHz, which is the main speech frequency range of the SAF; 6–10 kHz, where early indications of noise damage may be evident at the higher-frequency end of the SAF; and 12–16 kHz, an extended audiometric frequency range (EAF). This resulted in three mean thresholds per listener.

The lower slope of the loudness function shows minimal correlation with the averaged audiometric thresholds of 0.25-4 kHz and 6-10 kHz. In contrast, the lower slope of the loudness function is positively correlated (although not significantly) with the averaged audiometric thresholds at 12-16 kHz.

As listeners' thresholds increased in the 12-16 kHz EAF range, the lower slope of the loudness function became steeper. For all these listeners, thresholds were within normal limits for the SAF, indicating that for these listeners loudness perception at medium sound levels is increased compared to listeners that do not show elevated thresholds in the EAF range. The upper slope is negatively correlated (although not significantly) with the averaged audiometry thresholds at 12-16 kHz. Thus, as listen-

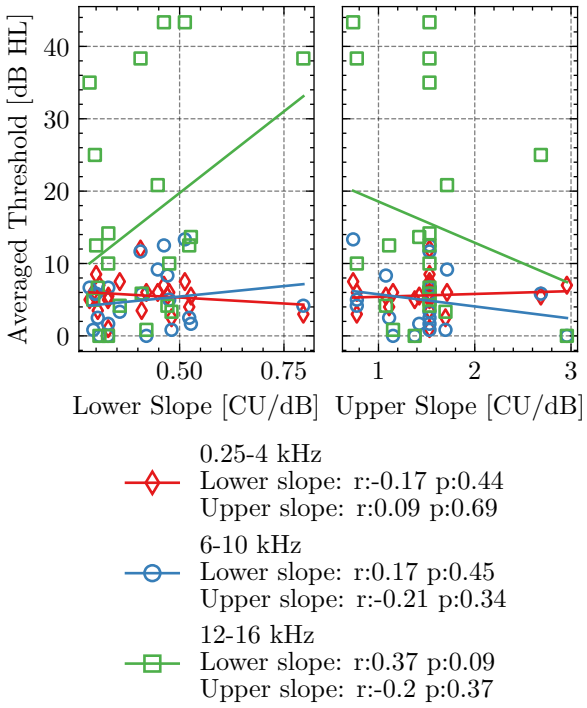


Figure 2: Data from all listeners. Averaged audiometric thresholds (across ears and within frequency ranges) as a function of CLS loudness function fit parameters, lower slope (left) and upper slope (right); and linear regressions for each frequency range.

ers' thresholds increase in the 12-16 kHz range, the upper slope of the loudness function becomes shallower. Note that a similar trend, although smaller in size, is found for the averaged thresholds in the 6-10 kHz range but is not found for the averaged thresholds of 0.25-4 kHz. This indicates the importance of the EAF audiogram in characterising early indication of a change in loudness perception. These trends suggest that for individuals with elevated audiometric thresholds in the 12-16 kHz range, the slopes of the lower and upper segments of the loudness function become more aligned.

For those individuals with audiometric thresholds within normal limits (<20 dB HL) as measured for sound frequencies of the SAF but elevated thresholds as measured for sound frequencies of the EAF, loudness perception grows more quickly with physical sound level for low- to mid-level sounds (a linearisation across both parts of the loudness function).

Some previous studies have indicated minimal or no relationship between audiometric thresholds and hyperacusis scores [7]. This may be the case for thresholds measured between 0.5 and 8 kHz, frequencies that are often tested within clinics (SAF). However, evaluation at higher signal test frequencies may be useful in monitoring and understanding the progression of altered loudness coding and its association with hyperacusis [13].

There is physiological and psychophysical evidence that assessment of hearing integrity at signal test frequencies above 8 kHz may provide a useful indicator of hearing health and an early indicator of hearing dysfunction [21]. The cochlear regions associated with the response to higher-frequency sounds are known to be especially sensitive to the effects of ageing [22], and to the use of ototoxic drugs [23]. Studies report mixed findings with respect to the relationship between high-frequency threshold elevation and noise exposure [24, 25]. Overall, elevated high-frequency thresholds may be indicative of early hearing damage prior to a noticeable perceptual change in hearing, and may be useful for early diagnosis and monitoring of hearing health [15].

Figure 3 shows the hyperacusis score per listener plotted against their ULL-SP scores (ULLs obtained using the standard audiometric procedure with pure-tone stimuli) and ULL-CLS scores (ULLs obtained using the adaptive procedure as in the CLS test with the speech-shaped noise of the CLS test). The dB HL values for ULL-SP were converted to dB SPL for comparison with the ULL-CLS values.

ULL-SP at 0.5, 2, and 4 kHz present a strong significant correlation with the HQ score (all $p<0.05$); a higher HQ score is associated with a lower ULL-SP value. One of the definitions of hyperacusis that reaching a 78.8% agreement in a three-round Delphi survey of hearing healthcare professionals suggested that hyperacusis may also be characterised by the following statement: "Hyperacusis can *sometimes* be described as a reduction in the uncomfortable loudness levels (ULL) in pure tone audiometry (PTA)" [1].

Whilst both monaural and binaural ULL-CLS are also correlated with the HQ score in the same direction, and with a correlation strength approaching that seen between the HQ score and ULL-SP, the results for ULL-CLS are not significant. The ULL-CLS binaural thresholds are observed to be lower than monaural ULL-CLS thresholds as expected due to binaural summation [26]. Overall, the binaural and monaural ULL-CLS thresholds are lower than all the ULL-SP thresholds. This is also expected for

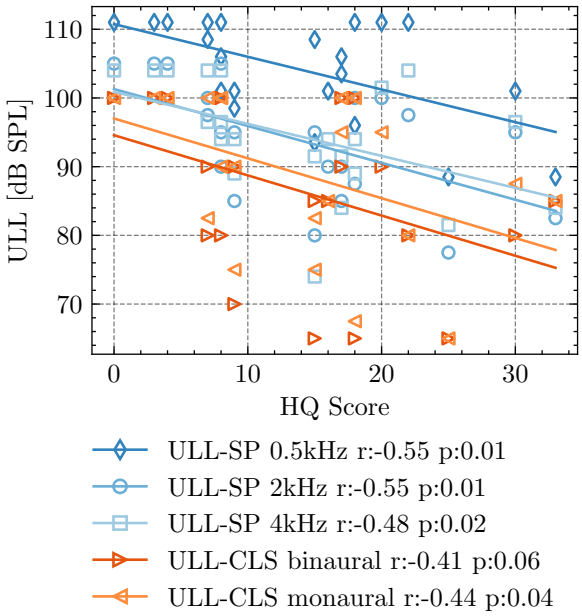

Figure 3: Data from all listeners. i) ULL-SP estimates obtained using pure tones and the BSA procedure and ii) ULL-CLS estimates obtained using the method based on the CLS adaptive procedure and CLS speech-shaped noise stimuli, with monaural (averaged across both ears) and binaural presentations. The ULLs are plotted as a function of the Hyperacusis Questionnaire (HQ) scores.

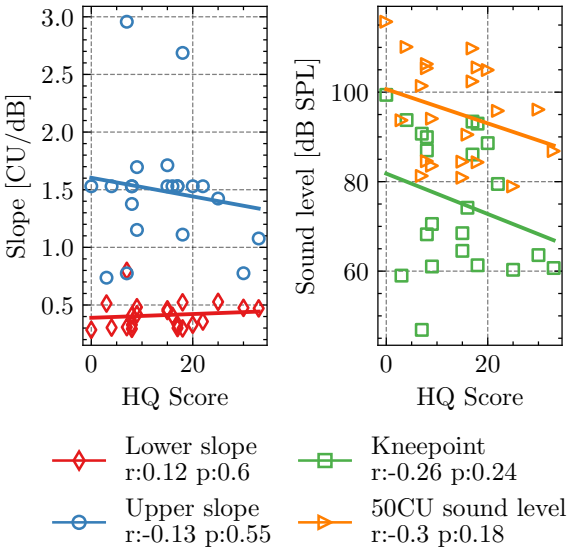

Figure 4: Data from all listeners. Loudness function parameters: lower and upper slopes (left) and kneepoint and level estimates at 50 CU (right) as a function of the Hyperacusis Questionnaire (HQ) scores.

complex sound stimuli, such as the speech-shaped noise used in this case, which inherently include modulations, compared to pure tone signals [27, 28].

Figure 4 illustrates the relationship between the CLS loudness function parameters and the HQ score. As HQ scores increase, the value of the lower slope remains essentially the same, while the upper slope tends to decrease. The values for the kneepoints and the sound levels inferred at 50 CU tend to decrease with increasing HQ scores. Note that these trends are similar to those observed for the comparison between CLS and audiometric thresholds (EAF). Individuals who scored higher on the HQ tended to demonstrate a categorical loudness function that had a steeper lower portion of the function, representing a more rapid increase in loudness with increasing sound level, and a shallower upper portion of the function. Individuals that scored higher on the HQ also displayed a lowered kneepoint of the function fit to the CLS data.

4. CONCLUSION

There is a straightening of the entire loudness function for low- to mid-level sounds for individuals with elevated thresholds for sound frequencies of 12-16 kHz. These individuals had audiometric thresholds within normal limits (<20 dB HL) for sound frequencies of 0.5-8 kHz, and no tinnitus. High frequency thresholds (>12 kHz) are informative regarding the perceptual effects of increased loudness growth which may be associated with hyperacusis. There was a strong significant correlation between the HQ score and ULL-SPs obtained at 0.5, 2, and 4 kHz (all $p<0.05$). Individuals who scored higher on the HQ tended to exhibit a categorical loudness function with a steeper lower portion, indicating a more rapid increase in perceived loudness, and a shallower upper portion of the function. Individuals who scored higher on the HQ also displayed a lower kneepoint in the function fitted to the CLS data, defined as the intersection between the lower and upper portions of the fitted curve.

ABSTRACT

The measurement of cortical responses to frequency cues relevant for speech understanding can potentially lead to earlier and more effective clinical diagnosis and intervention in hard-to-test populations. To assess cortical responses to changes in frequency, it is important to minimize the presence of other simultaneous cues, such as loudness, which might also evoke cortical responses, potentially biasing the interpretation of the response data. To minimize this effect, we propose a new method that uses amplitude roving—commonly used in behavioral testing to ensure the cue of interest is focused on—to reduce loudness-related cortical responses. Neurophysiologically, the effect of intensity roving might translate to a form of neural adaptation to signal variance, which results in a reduced sensitivity to intensity changes.

In this study, we investigate the effects of amplitude roving on EEG responses to spectral changes in pure tones. We investigate the extent to which intensity roving can reduce cortical responses driven by intensity changes. The results show that intensity roving can significantly reduce the cortical response to amplitude changes, while responses to spectral changes remain salient.

Keywords: *acoustic change complex, amplitude roving, loudness, speech discrimination*

1. INTRODUCTION

The use of cortical auditory evoked potentials (CAEPs) as objective biomarkers of hearing in clinical practice has promising potential for guiding diagnostics in hard-to-test populations [1–3]. Cortical measures of suprathreshold discrimination can potentially supplement existing methods, particularly within the context of spectral discrimination as a proxy of perceptual vowel discrimination abilities. One such measure is the acoustic change complex (ACC), a cortical response driven by suprathreshold acoustic cue transitions. ACC responses have, for example, been demonstrated with frequency and amplitude transitions [4–8]. While the ACC is sensitive to changes in frequency, inherent simultaneous changes in loudness may also evoke neural responses [9, 10]. Cortical responses to loudness must therefore be disentangled from the compound response, and potential methods for minimizing this confound must be investigated.

In psychophysical studies, amplitude roving across trials is commonly used to reduce the perceptual weight

of loudness cues [11]. Roving involves the randomization of task-irrelevant acoustic features—here, the stimulus intensity—to render them unreliable for the listener. In the neurophysiological domain, amplitude roving can be applied via random fluctuations in stimulus level across stimulus presentations and, as such, increases the stimulus level variance, which might reduce neural sensitivity to intensity changes. Animal studies indicate that neuronal adaptation to level variance occurs in the auditory cortex [12–14]. An increase in intensity variance through amplitude roving might therefore lead to reduced EEG-measured cortical sensitivity to intensity fluctuations as populations of neurons adapt their firing rate.

In this study, the concept of cortical neural adaptation is exploited through amplitude roving in a suprathreshold frequency discrimination paradigm employing pure tones. Specifically, we investigated ACC responses to periodic changes in intensity (as a proxy measure of loudness changes) as well as changes in frequency. ACCs were obtained either with or without amplitude roving in the form of random low-frequency amplitude modulations applied across the signal intervals.

2. METHODS

This paper presents a subset of the data that was obtained from a study of 26 young ($\leq$ 33 years) normal hearing participants, in which their electroencephography (EEG) responses were recorded. Recordings were carried out at the Technical University of Denmark (Kongens Lyngby, Denmark). All the experiments were approved by the Science-Ethics Committee for the Capital Region of Denmark (H-1-2013-138). All participants provided their written consent prior to taking the test.

Stimuli consisted of amplitude modulated (AM'ed; 41 Hz) loudness-balanced tones. ACC responses to the following stimulus changes were examined: (1) *intensity change*, where two 848 Hz AM'ed tones are presented with a level increment of +5 dB and (2) *frequency change*, where a 848 Hz AM'ed tone is followed by a loudness-balanced AM'ed tone of 970 Hz—i.e., with loudness cues minimized. These conditions were then presented again, but with the intensity levels roved by applying a low-frequency randomized envelope to the stimulus (envelope frequency components from 0.5 Hz to 4 Hz, fully modulated). In all conditions, the baseline intensity was set to a sound pressure level (SPL) of 65 dB. An overview of these conditions is presented in Table 1.

Cortical responses were recorded using a BIOSEMI^{TM} ActiveTwo system using a 64 + 2 external channel layout, following the 10-20 system, and responses were referenced to the Cz-electrode. Recordings lasted around 5 minutes, divided into epochs of 2 seconds (150 epochs), corresponding to the time intervals of the acoustic change in the stimuli.

EEG from the mastoid electrodes were analyzed using a statistical detection method termed the Fmpi [15]. The Fmpi measures the probability that a given F-value—the ratio between the variance of the averaged recording within a time window where the cortical response is expected (50 to 550 ms after change onset) and the variance of the post-average residual noise—is obtained by chance.

EEG processing included band-pass filtering (2-30 Hz) and weighted averaging according to [16]. To investigate how the response strength increases as more epochs are averaged together, we performed the analyses in incrementing number of epochs (step = 20 epochs).

The response detection threshold was set at an alpha level of 0.05. The total number of significant detections was then converted to a percentage of the total number of recordings per condition, denoted as detection rate.

Statistical analyses were performed via analyses of variance using a Generalized Linear Mixed Model (GLMM) with a Gamma distribution.

#	Δf [Hz]	ΔSPL [dB]	Roving
1	0	+5	No
2	122	0	No
3	0	+5	Yes
4	122	0	Yes

Table 1. Overview of experimental conditions (labeled by number). **Δf** and **ΔSPL** refer to frequency- and intensity changes respectively. The last column indicates whether roving was applied (yes/no).

3. RESULTS

Figures 1A&B show an overview of the ACC waveforms averaged across all participants and epochs. Responses to intensity changes only (Fig. 1A) are visibly smaller than ACCs to changes in frequency (Fig. 1B). Similarly, responses when the amplitude level of the stimuli was not roved (fig. 1A&B, top panels) are larger than for the roved conditions (fig. 1A&B, bottom panels). This is especially apparent in the intensity change conditions (Fig.

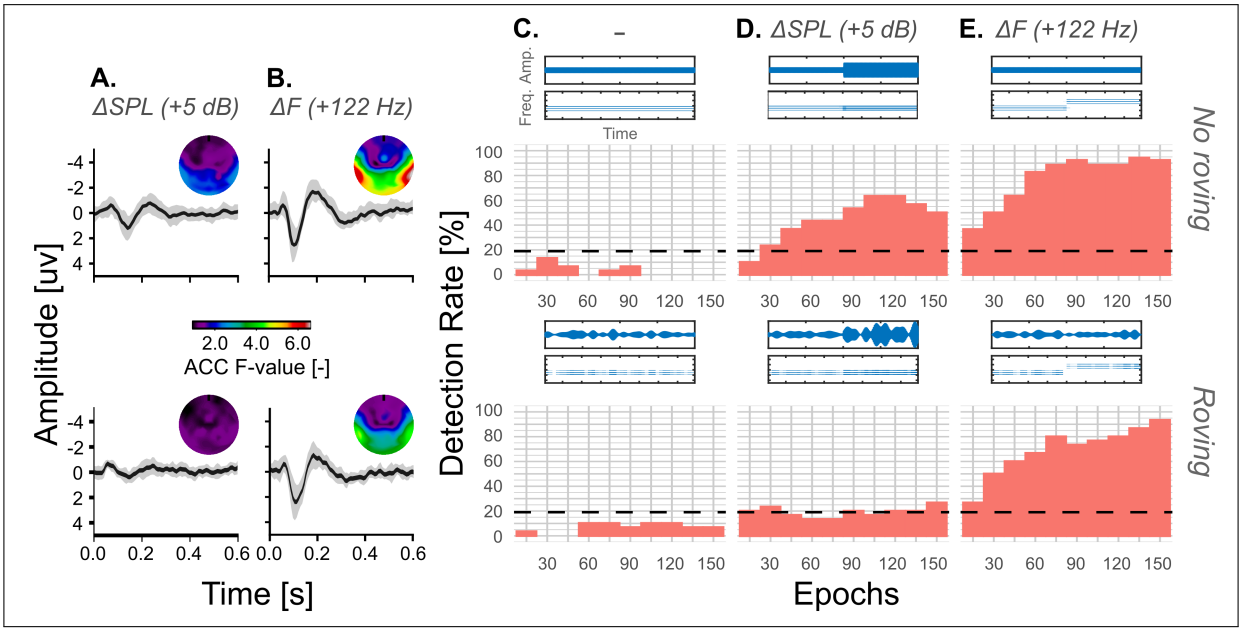

Figure 1. **A-B**: Waveforms and topographic maps of average ACCs across all participants and two mastoid channels for intensity (**A**) and frequency (**B**) conditions. Non-roved conditions are at the top, roved conditions on the bottom. Waveforms are plotted in time window 0 to 0.6 s and expressed as voltage in µV. Mean (solid) waveforms with standard deviation (shaded) are given. Additionally, topographic maps show ACC F-values from the Fmpi-detector (full recording length, number of epochs = 150) across all 64 (excluding mastoid) recorded channels along the scalp. All results are referenced to Cz. **C-E**: Results from an Fmpi-detector across varying number of epochs (time window: 50 ms to 550 ms) across all participants. Results are categorized by condition; Panel **D** shows the intensity change condition, panel **E** shows the frequency change condition. Non-roved conditions are at the top and roved conditions are on the bottom. Panel **C** shows results for the no change reference. The x-axis shows the varying number of epochs used in the detector, with the detection rate (percentage of significant responses that were obtained) on the y-axis. Dashed lines show the Bernoulli confidence interval (95%) for chance detection. The explanatory diagrams above the detection plots show the stimulus of the respective condition both in the time- and frequency domain.

1A), while this difference is less distinguishable in the frequency change condition (Fig. 1B). Topographic maps of the ACC F-value across the scalp (Fig. 1A) suggest that responses are reduced when roved in both conditions.

Detection rates across all participants (see Section 2) are shown in Figures 1C-E. By assessing detection rates in baseline recordings (i.e., a non-change reference) (Fig. 1C), the detection rates fall within the Bernoulli confidence interval (95%) for chance detection (dashed lines). For the intensity change (Fig. 1D) and frequency change (Fig. 1E), the patterns differed depending on whether roving was employed or not. In the intensity change condition without roving (Fig. 1D, top panel) the number of detections increased steadily throughout the recording. However, in the intensity change condition with roving (Fig. 1D, bottom panel), responses fluctuated roughly around chance level. In the frequency change conditions, both with and without roving, the number of detections increased steadily throughout the recording.

To provide statistical evidence on the effects of frequency, intensity and roving on the ACC we performed an analysis of variance (ANOVA) using a GLMM to predict the F-value using the following independent factors: the *acoustic cue* (frequency or intensity), *amplitude rov-*

ing (applied or not applied), and their interactions. The participant was included as a random factor. The results revealed that *acoustic cue*, ($\chi^2(1)$ = 40.60, p $<$ 0.001), *amplitude roving* ($\chi^2(1)$ = 17.91, p $<$ 0.001) and their interaction ($\chi^2(1)$ = 9.78, p = 0.0018) were significant factors.

Post-hoc analyses (Bonferroni corrected) on the model's estimated marginal means revealed a significant difference between intensity (roving vs. no roving; ΔF-value = 0.72, p $<$ 0.001), and no significant difference for the frequency condition (roving. vs. no roving; ΔF-value = 0.74, p = 0.13). Further inspections revealed that responses to the frequency change with roving were still significantly larger than responses to the loudness change without roving (ΔF-value = 1.00, p = 0.006).

4. DISCUSSION

Our results indicate that ACC responses to intensity changes decreased significantly when employing amplitude roving, whereas ACCs to frequency changes did not significantly differ when roving was applied. Moreover, the responses to frequency changes were larger compared to those in response to intensity changes. Overall, this suggests that amplitude roving effectively reduces the contributions of intensity cues in the cortical response, without compromising the response to frequency changes.

Through roving, the stimulus statistics were manipulated to increase the variance. Previously, animal studies have shown that, when subjected to a high amplitude variance context, intensity-rate decoding functions of individual cortical neurons are more adapted to the increased intensity range over which they operate, in comparison to a low amplitude variance context [12, 13]. In the present study, increasing the variance reduced the compound response to intensity changes, suggesting that like in animals, human cortical responses to changes in intensity becomes less distinct when these changes are contextualized by an increased level of variance. Since intensity changes were introduced as a proxy measure for perceptual changes in loudness, our results suggest—based on the strong reduction in responses—that cortical responses arising from changes in loudness are similarly reduced by applying amplitude roving.

5. CONCLUSIONS

Amplitude roving reduced cortical responses to loudness changes, but minimally affected responses to frequency changes. This finding can be particularly useful in the development of clinical objective methodologies of suprathreshold auditory processing. In cases where loudness cues cannot be strictly controlled for, e.g. when evaluating cortical responses to spectral changes between vowels, roving can be applied to minimize the potentially confounding loudness cue. Additionally, this method could be useful in populations where loudness perception is changed, e.g. due to hearing impairment. However, additional research is needed to confirm a reduction in loudness-driven responses via amplitude roving in these populations.

ABSTRACT

This review outlines the current status and proposes future directions for using auditory brainstem responses (ABRs) to continuous speech as a tool in hearing aid assessment. In current clinical practice, ABRs measured via electroencephalography (EEG) in response to short stimuli, averaged across repetitions, are a cornerstone of objective hearing screening and evaluation. Recent advancements have demonstrated that ABRs can be estimated from EEG recorded during continuous speech listening by using linear models which map the auditory speech features, extracted using auditory models, to continuous EEG activity. This approach enables the simultaneous investigation of multiple auditory pathway stages using complex, ecologically valid sounds; advancing potential future hearing assessments that can be seamlessly integrated into daily life. Current findings indicate that responses similar to click-ABRs, with a salient wave V peak, can be estimated from natural continuous speech. These responses are sensitive to speech level, can be captured using insert earphones or in a sound-field environment, and can be obtained from aided older listeners with hearing impairment. While these advancements bring us closer to ecologically valid objective hearing device and fitting assessments, there are remaining hurdles to overcome, such as assessing ABRs to continuous natural speech during standard hearing device use.

1. INTRODUCTION

Estimating brainstem responses to natural speech could potentially provide essential information on how a given hearing device processing scheme fits individual peripheral hearing abilities, offering the potential to improve hearing aid algorithms and fitting. Such assessments would require a method that can quantify *early* responses to *continuous natural speech* in a *reliable* way, is *sensitive* to changes in the incoming speech stimulus, and can be applied in *hearing aid users* while they are *using standard hearing devices*.

Current objective assessments of early sound processing do not fulfill all these requirements. The auditory brainstem response (ABR) is often employed for capturing early neural responses to sounds. Traditionally, methods to estimate ABRs measure the electroencephalogram (EEG) while the listener is exposed to many repetitions of the same sound. The EEG responses to each sound are averaged across a reasonably high number of sound repetitions (typically thousands) to estimate a transient neural response. This limits the stimuli to short duration sounds such as clicks [e.g. 1], chirps [e.g. 2–4], tones [e.g. 5, 6],

or syllables [e.g. 7, 8]. The transient stimuli are poorly suited for assessing the speech-specific hearing device signal processing algorithms [9], and the isolated speech units fail to capture the complexity of natural continuous speech [10]. However, in the past decade, approaches to estimate brainstem responses to continuous natural speech have been developed, refined, and extended [11–17].

These methodological advances enable the estimation of ABRs to continuous natural sounds, capturing the response of the brainstem to natural speech (NS-ABR). Beyond its potential in hearing aid assessment, NS-ABR also holds promising applications in research and clinical diagnostics. NS-ABR offers the potential for simultaneous estimation of speech processing in higher stages of the auditory pathway, as well as pairing with behavioral measures of speech comprehension. Initial results show intriguing patterns of brainstem and cortical processing in the presence of hearing loss and amplification [13] that could deepen our understanding of speech processing along the auditory pathway. In clinical diagnostics, NS-ABRs could add ecological relevance by providing an objective measure of peripheral auditory encoding of *speech* rather than *click* or *chirp* stimuli, supporting the identification of potential barriers to speech perception. Furthermore, presenting familiar sounds may increase measurement comfort for listeners, potentially lowering agitation which could lead to reduced movement and muscle tension artifacts and thus improve data quality [12, 13].

Here, we focus on perspectives for using NS-ABR in hearing aid assessment, where it could help evaluate the effects of device software on brainstem speech processing under different real-life conditions, offering essential feedback on algorithms and personalized fits in varied listening environments. We review current knowledge about the NS-ABR in terms of optimized response computation, understanding the response, its reliability, sensitivity to sound changes, and investigate hurdles still to overcome towards its application in hearing aid assessment.

2. COMPUTING THE ABR TO CONTINOUS SPEECH: TRFS MEET AUDITORY MODELS

NS-ABRs are typically estimated using forward linear models that map broadband speech features onto the time-lagged EEG response, estimating a temporal response function (TRF), in analogy to previous cortical analyses of continuous speech responses [e.g. 18–20]. This TRF can be interpreted as the evoked response to a unit change in the speech feature, often yielding a prominent peak at latencies similar to wave V of the click-ABR [11, 12, 16]. As linear models are unable to capture nonlinearities in the auditory periphery, this approach has recently been refined by non-linearly transforming the speech waveform into a signal simulating neural activity at the brainstem level using auditory nerve models (ANMs) [14–16]. Employing ANMs before neural response estimation via the TRF has considerably improved model performance and response signal-to-noise ratio (SNR) [15]. These improvements have led to shorter acquisition times [15] and allow for response estimation not only to continuous speech presented via insert earphones, but also to music [14], or speech presented in the sound-field [16]. While adding an ANM increases response SNR, other optimizations of the computation method, or improvements in EEG acquisition SNR for these specific signals could further reduce measurement time.

Although continuous speech and music are often encountered in daily life, a considerable share of real-life sound environments also include mixed and overlapping signals, and pauses. In conversations for example, speech often overlaps, and longer silent pauses occur [21]. In addition, sounds with very different spectrotemporal characteristics than speech or music, such as for example traffic noise, contribute to shaping real-life soundscapes. Further research could shed light on whether the current NS-ABR approach needs extension for application throughout those different and complex sound environments.

3. RESPONSE ORIGIN, SENSITIVITY, AND RELIABILITY OF THE ABR TO CONTINUOUS SPEECH

As a foundation for NS-ABR applications, it is crucial to understand the origin, sensitivity, and reliability of the response. Response analogies can facilitate interpretation and knowledge transfer from the extensive body of research on traditional brainstem measures. The estimated TRF mapping continuous broadband speech features to neural signals has been interpreted as an ABR [11, 12]. Its prominent response peak has a latency similar to ABR wave V measured to clicks [11, 12]. This short latency of less than 15 ms suggest a brainstem origin [22], as transmitting the neural signal to higher stages along the auditory pathway requires more time. The prominent peak of the NS-ABR is also positively correlated with the click-ABR wave V in both amplitude and latency [11, 12, 16], with the inferior colliculi and auditory midbrain areas thought to be the main sources of click-ABR wave V

[23–25].

When computed using a suitable auditory model, NS-ABR showed sound level sensitivity similar to click-ABRs [17]. Both showed larger amplitudes and shorter latencies at higher sound levels, and these level-dependent latency changes were consistent across the speech and click measures on an individual level [17]. This further underlines the analogies between NS-ABR and click-ABR, and suggests level sensitivity of the NS-ABR crucial for potential applications. In analogy to effects previously observed for click-ABRs [26], first results with processed 'peaky' speech stimuli show effects of energetic masking [27]. The target speech stream was presented in an increasing number of competing speech streams, leading to decreased SNR with increasing competing streams. In tact with decreasing SNR, ABR peaks to continuous 'peaky' speech occurred at longer latencies and lower amplitudes [27] - potentially indicating a similar sensitivity to masking for NS-ABR.

Another important consideration for applications is the test-retest reliability. In older aided participants with hearing-impairment, initial results indicate high test-retest reliability for identical speech stimuli, but differences for different speech material produced by the same speaker, potentially suggesting a high dependency of the response on the frequency content of the used speech signals [12]. While more work is needed for a comprehensive overview of NS-ABR test-retest reliability and its sensitivity to different abilities and sound environments, first findings on both are promising.

4. TOWARDS APPLICATION IN HEARING AID ASSESSMENT

Beyond understanding the response origin, its sensitivity, and reliability, further research is needed to lay the groundwork for use of NS-ABR as a tool in hearing aid assessment. Crucially, there is a need to understand the NS-ABR in the target group for hearing aids: people with hearing impairment - including those using their devices at the time of measurement. As the prevalence of hearing impairment shows a steep increase with age, particularly above the age of 50 [28, 29], older adults are the primary target population that could benefit from this tool. Initial findings in older adults with hearing impairment indicate that clear NS-ABRs could not be identified when presenting speech at 65 dB without any amplification [13]. Given that ABRs to clicks presented at low sensation levels relative to individual's hearing impairment are drastically reduced in amplitude [30], this suggests that the chosen 65 dB speech presentation level was too low for the participants' hearing loss and the sensitivity of the applied simpler NS-ABR method, which did not yet incorporate an auditory model [13].

The next step towards applying NS-ABR in hearing aid assessment is investigating the response in hearing impaired listeners *with amplification*. The same work that presented unamplified speech discussed above [13] also presented amplified speech to the older listeners with hearing loss, applying a linear amplification algorithm to the speech and directly presenting it via insert earphones. Findings for NS-ABR are consistent with those for click-ABR wave V, showing longer latencies and reduced amplitudes in older individuals with hearing impairment receiving amplification compared to younger normal-hearing listeners [12, 13]. More research on the NS-ABR in listeners with hearing impairment across all age groups is needed for a comprehensive understanding of the response in this diverse population.

Although these first findings are promising, evaluating hearing aid performance in real-life soundscapes requires estimating NS-ABR in listeners with hearing impairment *while providing amplification through an actual hearing aid*. This necessitates *sound-field speech presentation*. As a first step, we demonstrated that measuring NS-ABR in the sound-field was feasible in normal-hearing adults [16]. Slightly longer EEG recording time was required due to room acoustics, but this effect was migitated by pairing the TRF approach with a powerful auditory model, improving response SNR and resulting in clear NS-ABRs in all participants [16]. The next step is to integrate these elements by quantifying NS-ABRs in older individuals with hearing impairment while providing amplification through a standard hearing aid receiving sound in the sound-field.

5. OUTLOOK

ABRs measured to continuous natural speech (NS-ABR) instead of clicks and chirps is an emerging method with promise for applications. Initial research indicates that NS-ABR is reliable [13], sensitive to both speech level [17] and likely masking [27], can be quantified in older listeners with hearing impairment when presenting amplified speech [13], and when presenting speech via headphones [11–14, 17] as well as in the sound-field [16]. These findings suggest its potential for hearing aid assessment.

However, further research is needed to assess the feasibility of NS-ABR in individuals with hearing impairment while using standard hearing aids. By providing objective feedback from neural brainstem auditory processing of natural speech, the NS-ABR could help assess hearing aid software, such as noise suppression algorithms, and their adaptation to the individual listening needs in auditory scenes close to real life. This could contribute to improved hearing aid designs and better outcomes for hearing aid users.

ABSTRACT

The Auditory Change Complex (ACC) is a transient cortical auditory-evoked potential, recorded via electroencephalography (EEG), and elicited by changes in an ongoing auditory stimulus. It provides insight into auditory discrimination, making it a relevant tool for evaluating cochlear implant (CI) performance. Previous studies have demonstrated that the ACC can be recorded in CI recipients, and many have reported a strong correlation with behavioural outcomes. However, these studies typically used equipment and analytical techniques not widely available in clinical settings.

As a first step toward developing a clinically feasible method for ACC recording, we adapted our EEG research protocol for amplitude-modulated (AM) rate discrimination for use with normal hearing listeners using the Eclipse system (Interacoustics). Our findings show that the ACC can be reliably recorded using this system, with good test-retest reliability. As expected, larger AM rate changes and lower carrier frequencies (CFs) elicited greater ACC amplitudes. Furthermore, increasing the presentation rate by reducing the inter-stimulus interval diminished the ACC response, and changing presentation level had minimal and inconsistent effects across participants. We are now exploring optimal AM rate changes and recording parameters for CI users, and will discuss preliminary results regarding the potential for routine clinical use in CI fittings.

1. INTRODUCTION

Cochlear implants (CIs) are electronic hearing devices used to restore hearing in individuals with severe-to-profound deafness. They work by decomposing incoming sounds through a bank of bandpass filters, extracting the slowly-varying envelope cues within each filter band and using them to amplitude modulate fixed-rate electrical pulse trains presented to each electrode [1-2].

Envelope cues are crucial for speech understanding as they convey linguistic information across a range of modulation frequencies. Typical speech envelope modulations occur

within the 2-50 Hz range, with lower modulation rates (~2-5 Hz) providing syllabic and prosodic information and higher rates (~5-50 Hz) providing manner of articulation and voicing cues [3]. Modulation rates above 50 Hz provide pitch cues and the ability to discriminate periodic from aperiodic sounds. These modulation frequencies are associated with oscillatory activity in the auditory cortex. Delta (1-4 Hz), theta (4-8 Hz), and low gamma (25-50 Hz) oscillations are known to play crucial roles in processing the multi-timescale, rhythmic properties inherent in speech, facilitating the tracking of its dynamic nature [4]. These oscillatory patterns serve as foundational elements in speech and language processing, aiding in the segmentation of incoming information into units of appropriate temporal scales [4]. Slower oscillations, such as delta and theta, are implicated in phrasal and syllabic processing, while faster oscillations in the low gamma range are associated with phoneme-level processing.

Despite the success of cochlear implants, there remains significant variability in speech-perception outcomes among CI users [5-10]. One factor that contributes to this variability is the ability to accurately encode and process the temporal and spectral features of sound, which are essential for speech understanding, particularly in complex listening environments [11-13].

Although subjective speech-perception tests remain the standard method of assessing CI benefit, they are limited in scope. These behavioural measures are influenced by non-auditory factors such as attention, motivation, and cognitive ability, and are not suitable for individuals—such as young children or some adults—who cannot reliably complete listening tasks. This makes it challenging to determine whether a CI has been optimally programmed to provide access to the full range of relevant speech cues. Currently, however, there are no standardised, objective approaches to verify CI fitting. Tools such as electrically evoked compound action potentials (eCAPs) can assist in setting initial stimulation levels, but they provide only a rough indication of neural responsiveness and do not confirm functional access to speech information.

There is growing interest in using objective, neurophysiological measures to inform and verify fitting based on auditory detection and discrimination abilities in CI users. One such measure with the potential to support this goal is the Auditory Change Complex (ACC), a cortical auditory-evoked potential elicited in response to a change in an ongoing auditory stimulus [14-15]. The ACC typically exhibits the standard obligatory cortical P1–N1–P2 morphology, similar to responses evoked by sound onset, but time-locked to the point of stimulus change. This makes it a valuable tool for assessing auditory discrimination in a way that is both objective and functionally meaningful.

Previous studies have demonstrated that the ACC can be reliably recorded in CI users in response to changes in place of stimulation [16-19], indicating electrode discrimination abilities; rate of amplitude modulation—typically for rates below 50 Hz [19-22], which relates to the ability of the listener to use envelope cues—and stimulation level [23], as well as speech tokens [24-26]. Several studies have also reported correlations between ACC responses and behavioural speech perception measures [27, 28] and the development of these responses over time following device activation [29]. However, these studies have often utilised recording equipment and analytical techniques that are not typically available in clinical settings.

The primary aim of this study was to evaluate the feasibility of recording the ACC to changes in the AM rate using a clinical evoked-potential system (Eclipse, Interacoustics). We performed an initial study with normal-hearing listeners to validate our protocol and ensure that responses could be obtained for stimuli that have previously been used with the Biosemi EEG system [4]. We wanted to investigate the effects of various stimulus parameters on the ACC response amplitude, similar to the approach taken by Calcus et al [15], but using the Eclipse system. Both the N1-P2 and Root Mean Square (RMS) amplitude were evaluated. The parameters investigated were the magnitude of the AM rate change, carrier frequency (CF; equivalent to a centre frequency of a CI channel), presentation rate (adjusted by increasing the inter-stimulus interval), presentation level and direction of AM change (low to high versus high to low). We also evaluated test-retest reliability across two test sessions.

In a second phase of testing we are exploring the optimal AM rate change to use and are evaluating whether the Eclipse can be used to measure ACC responses in CI users.

2. METHODS

Two experiments were conducted using a two-channel clinical evoked potential system (Eclipse, Interacoustics). Experiment 1 investigated the effects of CF, stimulus level, AM rate change, presentation rate (adjusted by changing inter-stimulus-interval) and direction of AM rate change

(low to high or high to low) on the ACC amplitude. Test-retest reliability across sessions was also examined. Experiment 2 explores the interaction between CF and AM rate on the ACC amplitude, and testing is still ongoing.

2.1 Experiment 1

2.1.1 Participants

Twelve participants (9 females, 3 males) aged 26 to 44 years (mean age = 34.8 years) were recruited. All had normal hearing thresholds. The full experiment took two sessions to complete. The first session took two to three hours, and the follow-up session took approximately 30 minutes.

2.1.2 Stimuli and paradigm

Stimuli were 900-ms sinusoidally amplitude-modulated (AM) pure tones, created using custom MATLAB scripts. Stimulus presentation was controlled using the Eclipse EP software (Interacoustics) connected to an SP90A active loudspeaker (RadioEar). All stimuli were calibrated at 65 dB SPL prior to testing.

A total of four CFs were tested, including 626, 1438, 3313, and 5688 Hz, which correspond to the centre frequencies of electrodes 19, 13, 7 and 3 in the Cochlear Ltd device (assuming all electrodes are active). Halfway through the stimulus (at 450 ms), the AM rate was changed from 12 to 114 Hz (or vice versa). The modulation depth was 100%, and the presentation rate was set to 0.5 Hz (i.e., 1100-ms inter-stimulus interval, the quiet period between consecutive stimulus presentations). At the CF that elicited the largest ACC amplitude (usually 626 Hz), the effects of the magnitude of the AM rate change (12-40, 12-80, 12-114 Hz), presentation level (55, 65, 75 dB SPL), direction of the change (12-114 (up; low-to-high), 114-12 (down; high-to-low), and presentation rate (0.5 & 0.8 Hz with an inter-stimulus interval of 1100 ms and 350 ms respectively) were also assessed. Test-retest reliability of the ACC was evaluated by repeating the recording at the best CF and at a 12-114Hz AM rate change on Session 2. Finally, we included a 12-Hz AM no-change condition at the best CF. An example stimulus with an AM rate change is shown in Figure 1.

All conditions were presented in three blocks until 100 sweeps were accepted for each block (total of 300 sweeps per condition). Participants sat in a comfortable chair and watched a subtitled video for the duration of the experiment.

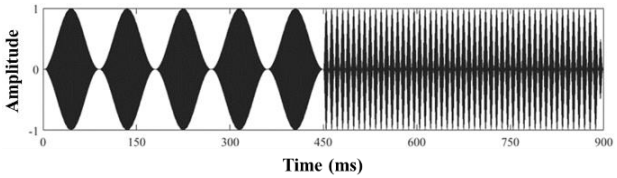

Figure 1. Example stimulus with an AM rate change. The CF for this stimulus is 1438 Hz, and the AM rate change is 12 to 114 Hz (change halfway at 450 ms).

2.1.3 EEG recording, EEG analysis, and statistical analysis

All EEG recordings were obtained using the Eclipse EP system (Interacoustics) at a sampling rate of 500 Hz. Pre-gelled disposable electrodes were placed on FPz (active), the low forehead (ground), and both mastoids (linked reference) in accordance with the standard clinical protocol. Impedances were checked prior to testing and were kept below 3 kΩ. The artefact rejection threshold was set to 40 or 80 µV depending on the participant, and the recording automatically stopped after 100 accepted sweeps. Each sweep (-90 to 810 ms post-stimulus onset) was saved for offline analysis with a 0.5-Hz high-pass hardware filter.

Individual sweeps were low-pass filtered at 30 Hz and baseline-corrected using the pre-stimulus quiet baseline period (-90 to 0 ms post-stimulus onset). For each participant and condition, all 300 sweeps were then averaged into one waveform. The amplitude of the ACC was quantified by determining the peak-to-peak amplitude for N1 and P2, which were defined as the lowest and highest amplitude values between 500-600 and 575-750 ms, respectively. The N1-P2 amplitude was chosen as the primary measure as it is the clinical standard. However, we also measured the root mean squared (RMS) amplitude within the 500-750-ms window post-stimulus onset for comparison. RMS amplitude provides an index of overall response magnitude that is less sensitive to individual differences in waveform morphology and avoids the subjectivity involved in identifying component peaks. This might make it a more suitable option for automated analysis.

Data were analysed with Repeated-Measures Analysis of Variance (RM-ANOVA) and Paired-Samples T-Tests, using jamovi (version 2.6) statistical software. Separate analyses were run to assess the effects of CF (626, 1438, 3313, 5688 Hz), magnitude of AM rate change (12-40, 12-80, 12-114 Hz), stimulus level (55, 65, 75 dB SPL), presentation rate (0.5, 0.8 Hz) and AM direction (12-114 (up), 114-12 (down)). Post-hoc pairwise comparisons were

corrected for multiple comparisons using a Bonferroni correction. Test-retest reliability (Session 1, Session 2) was assessed using a two-way random-effects intraclass correlation coefficient (ICC(2,k)) and Spearman's rank correlation.

2.2 Experiment 2

2.2.1 Participants

Four participants (2 females) aged 35 to 43 years (mean age = 39.75 years) were recruited to this pilot study. All had normal hearing thresholds. Two of the four participants had previously been tested in experiment 1.

2.2.2 Stimuli and paradigm

The stimuli were created, controlled and calibrated in the same way as in Experiment 1. Three CFs were tested (626, 1438 and 3313 Hz) at three AM rate changes (12-40, 12-80, 12-114 Hz) and a no-change condition at each CF.

2.2.3 EEG recording, EEG analysis, and statistical analysis

As per Experiment 1 (see 2.1.3).

3. RESULTS

3.1 Experiment 1

The coloured lines in Figure 2 show the group-grand-average waveforms (the average waveform computed across all participants, after first averaging each individual's responses across trials) for the largest AM rate change (i.e., 12-114 Hz) measured at four different CFs, as well as the group-grand-average waveform for the no-change condition in black. The waveforms show an initial typical onset response and an ACC after the AM change within the expected time windows.

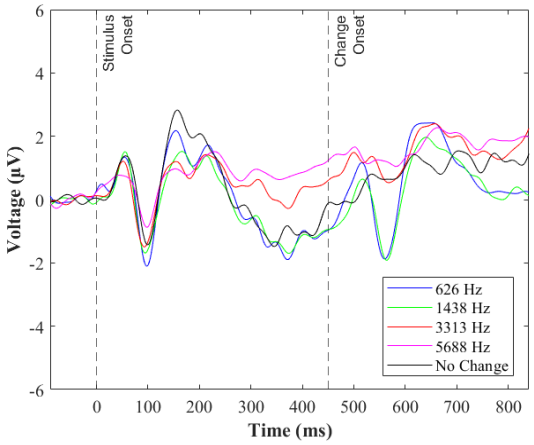

Figure 2. Group-grand-average waveforms for the change (coloured) and no-change conditions (black lines). Different colours represent different CFs. The 'change onset' at 450 ms indicates a change from 12- to 114-Hz AM rate. The group grand average refers to the average waveform computed across all participants, after first averaging each individual's responses across trials.

Figure 3 shows the mean ACC N1-P2 amplitude and standard deviation for all conditions tested in this study. Grey circles show single-participant data. Coloured bars show change conditions, and the no-change condition is shown in black. Change conditions generally evoked larger ACCs compared to the no-change condition.

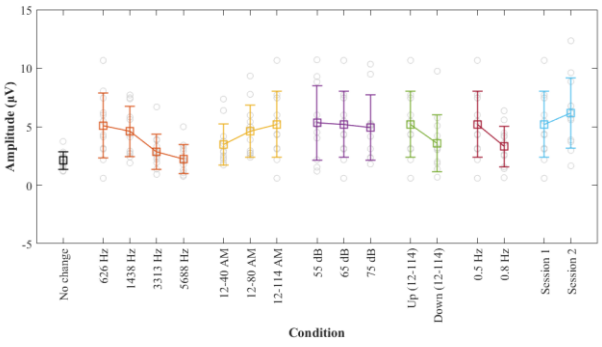

Figure 3. Mean ACC N1-P2 amplitude and standard deviations (± 1) for all conditions tested in this study. Coloured bars show change conditions grouped by their manipulation, and the no-change condition is

shown in black. Grey circles show single-participant data.

3.1.1 N1-P2 amplitude

RM-ANOVA showed a significant main effect of CF ($F(3,33) = 16.7$, $p < .001$) and AM rate change ($F(2,22) = 13.9$, $p < .001$) but no significant main effect of stimulus level ($F(2,20) = 0.512$, $p = 0.607$) on N1-P2 amplitude.

Post-hoc comparisons revealed significantly greater N1–P2 amplitudes at lower CFs: 626 Hz elicited larger responses than 3313 Hz ($p = .018$) and 5688 Hz ($p = .002$); and responses at 1438 Hz were significantly larger than those at 3313 Hz ($p = .015$) and 5688 Hz ($p = .002$). For AM rate change, amplitudes were significantly smaller at 12–40 Hz compared to both 12–80 Hz ($p = .045$) and 12–114 Hz ($p = .012$). Presentation rate also significantly affected amplitude, with larger responses at 0.5 Hz ($M = 5.20$; $SD = 2.82$) versus those at 0.8 Hz ($M = 3.30$; $SD = 1.70$), $t(11) = 2.76$, $p = .019$, Cohen's $d = 0.80$. There was no statistically significant difference in N1-P2 amplitude between upward (12-114 Hz) ($M = 5.20$; $SD = 2.82$) and downward (114-12 Hz) ($M = 3.60$; $SD = 2.43$); $t(11) = 1.95$, $p = 0.077$. direction of AM rate change. There was good test-retest reliability of N1-P2 amplitude (ICC = 0.889) and a significant positive correlation (Spearman's $\rho = 0.874$, $p < 0.001$) between sessions 1 and 2.

3.1.2 RMS amplitude

There was a significant main effect of CF ($F(3,33) = 19.5$, $p < .001$), stimulus level ($F(2,20) = 5.50$, $p < .012$) and AM rate change ($F(2,22) = 13.9$, $p < .001$) on RMS amplitude.

Post-hoc comparisons indicated significant differences in RMS amplitude between CFs 626 Hz and 3313 Hz ($p = 0.016$), 626 Hz and 5688 Hz ($p = < .001$) and 1438 Hz and 5688 Hz ($p = < .001$), AM rate changes 12-40 Hz and 12-114 Hz ($p = < .001$) and 12-80 Hz and 12-114 Hz ($p = 0.037$), and stimulus levels 55 dB SPL and 75 dB SPL ($p = 0.035$). There was also a significant effect of presentation rate 0.5 Hz ($M = 3.39$; $SD = 4.00$) and 0.8 Hz ($M = -0.36$; $SD = 3.77$); $t(11) = 2.79$, $p = 0.018$, and direction of AM change from upward (12-114 Hz) ($M = 3.39$; $SD = 4.00$) to downward (114-12 Hz) ($M = 0.038$; $SD = 4.80$); $t(11) = 2.77$, $p = 0.018$. There was good test-retest reliability of RMS amplitude (ICC = 0.877) and a significant positive correlation (Spearman's $\rho = 0.797$, $p = .0019$) between sessions 1 and 2.

3.2 Experiment 2

As testing is still ongoing (currently N = 4), statistical analyses were not performed. However, as shown in Figure 4, the general trend indicates the ACC N1-P2 amplitude diminishes as CF increases and AM rate change decreases. The ACC appears to be recordable using the clinical system at all AM rate changes tested at CF 626 Hz and 1438 Hz, although responses to the 12-40 Hz AM rate change are weak. At CF 3313 Hz it does not look possible to record the ACC for smaller AM rate change differences, despite each participant reporting that they could clearly hear the change.

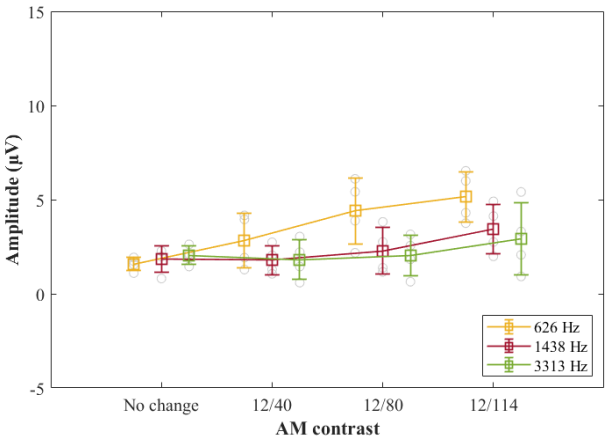

Figure 4. Mean N1–P2 amplitude (μV) as a function of AM rate change at three carrier frequencies (626 Hz, 1438 Hz, 3313 Hz). Error bars show ±1 SEM.

4. DISCUSSION

The primary aim of this study was to evaluate whether the ACC to AM rate changes can be reliably recorded using a clinical evoked-potential system (Eclipse, Interacoustics), as a step toward developing an objective measure for verifying CI fitting and informing mapping. In addition, we aimed to investigate how various stimulus parameters—including CF, AM rate change, presentation level, presentation rate, and direction of change—affect the amplitude (N1-P2 and rms) of the ACC response. In normal-hearing listeners, we found that the ACC could be robustly recorded using this system, with good test-retest reliability. These findings support the feasibility of adapting ACC protocols for clinical use, using equipment that is already available in many audiology departments.

The results of Experiment 1 suggest that several stimulus parameters significantly influenced ACC amplitude. ACCs were largest at lower CFs, with the strongest responses typically observed at 626 Hz. This is consistent with previous findings suggesting greater cortical sensitivity to lower-frequency modulation cues [20, 30, 31]. As expected, larger AM rate changes also evoked greater ACC amplitudes (N1-P2 and RMS), reflecting the increased neural response to more salient acoustic changes. This pattern aligns with prior work using research-grade EEG recording systems [15, 30]

The direction and speed of stimulus presentation also impacted response amplitude. Upward changes in AM rate (12–114 Hz) elicited stronger ACCs than downward changes (114–12 Hz), potentially reflecting perceptual asymmetries or differences in adaptation across modulation frequencies [31-33]. Faster presentation rates reduced ACC amplitude, likely due to reduced neural recovery time or attentional effects [14, 24, 34].

Notably, presentation level had only a modest and inconsistent influence on the ACC, which may be advantageous in clinical contexts where stimulus level cannot always be precisely controlled.

Importantly, ACCs were recordable across most test conditions, and test-retest reliability was high, indicating that the response is stable over time. This is a key requirement for clinical implementation, where repeatable and interpretable results are essential for guiding decisions. The ability to record robust ACCs with the Eclipse system using stimuli modelled after previous research protocols demonstrates the potential for clinical translation without the need for complex analysis pipelines or specialised hardware.

The preliminary data from Experiment 2 suggest that ACC responses are weaker at higher CFs, especially when paired with smaller AM rate changes. This trend is notable, as it may limit the clinical utility of the ACC in assessing the perception of fine-grained modulation changes in higher-frequency channels. However, responses at 626 Hz and 1438 Hz were reliably present even at smaller AM rate changes, suggesting that lower-frequency channels may provide a more consistent window into temporal processing abilities. Further work is needed to determine whether these trends hold in CI users and how best to adapt parameters for individual implant configurations.

Together, these findings suggest that the ACC has promise as a clinically feasible, objective measure to support CI programming. Unlike eCAPs, which provide only an estimate of neural excitability, the ACC reflects discrimination at the cortical level via the detection of a change in an acoustic stimulus, and it may offer more direct insight into a CI user's ability to access critical AM cues that are so important for perceiving distinctive speech features. This is especially relevant in cases where behavioural testing is not possible, such as in young children or adults with additional needs. While ACCs have been widely studied in research contexts, our study contributes to the growing evidence that they can be measured using accessible clinical systems and under test conditions that align with practical constraints.

There are several limitations to this study. First, the experiments were conducted in normal-hearing listeners, and while this allowed for controlled testing of stimulus parameters, recordings in CI users are needed to fully assess clinical applicability. Second, data collection for Experiment 2 is ongoing and currently does not allow for statistical analysis, though observed trends provide useful guidance for ongoing work. Finally, although the ACC is promising as an objective measure of auditory discrimination, further research is required to understand how it relates to real-world speech perception and functional benefit in CI users.

In the next phase of this work, we are recording ACCs in CI listeners using the Eclipse system, focusing on optimising AM rate changes and exploring the extent to which these responses may support objective verification of CI fitting. So far, we have collected data from a single CI user under two conditions, both using a 1438-Hz carrier that was amplitude-modulated at 25 Hz before switching to 80 Hz at 550 ms. First, we used the participant's clinical MAP, but with all audibility and noise reduction features disabled to ensure the processor did not alter the stimulus. Second, we set the parameters below the participant's hearing thresholds (confirmed as inaudible), enabling us to observe the CI-related artefact in the EEG without a neural response. The recording protocol extended to 900 ms, providing a 350-ms window after the modulation change (25 Hz to 80 Hz) to capture ACC. We leveraged the second (inaudible) condition to locate and characterise the CI-related artefact in the EEG. The data were first low-pass filtered below 25 Hz, then we applied a frequency-domain algorithm that detects and suppresses narrowband peaks (e.g., residual CI noise) by replacing them with the surrounding baseline in the frequency domain (calculated

via FFT). This procedure preserves the low-frequency cortical responses while minimising contamination from artefact.

If validated in this population, the ACC may offer a valuable addition to current programming tools, providing clinicians with a neurophysiological measure of auditory discrimination that is both practical and clinically meaningful.

ALTERATIONS IN STEADY-STATE SYNCHRONISATION BETWEEN ACUTE AND CHRONIC TINNITUS SUGGESTS REDUCTION IN THE NEURAL CORRELATES OF TINNITUS OVER TIME

ABSTRACT

The mechanism of tinnitus remains unclear as the generation and persistence of tinnitus is not widely understood. The acute tinnitus population serves as an ideal subject for investigating the mechanisms behind the origin and persistence of tinnitus, from its initial onset to its subsequent chronification. One of the neural markers for measuring tinnitus are central gain and alterations in neural synchrony or central gain, linked to tinnitus can be measured using the Auditory Steady State Response (ASSR). The experiment was carried out on 39 participants with acute tinnitus (18 followed back six months post baseline), 30 with chronic tinnitus, and 27 controls. The results revealed cross sectionally, there were no significant differences in both absolute amplitudes of ASSR across intensities and the slope of ASSR growth function between the groups. However, longitudinally, there was a near significant increase in ASSR amplitude at low and medium intensity levels over time. Our findings indicate that the near significant differences in ASSR amplitude is attributable to changes in neural synchronisation, attentional modulation, tinnitus-related distress, and diminished GABAergic inhibition coinciding with the onset of tinnitus, which typically decreases over time. The alterations occurring at the onset may facilitate the persistence of tinnitus.

1. INTRODUCTION

Tinnitus has been found to originate most commonly because of hearing damage, which can be either an audiometrically detectable hearing loss or an undetectable kind of 'hidden' hearing loss such as cochlear synaptopathy [1]. In principle, for optimal functioning of the auditory system, each hierarchical level should have an input/output function that maintains a stable and optimum range of output values despite potentially large changes in the range of inputs. But, due to peripheral auditory insults, input to the central auditory system is reduced, thus altering the equilibrium of the input/output function. In order to maintain the input/output function, the brain typically changes the slope function by increasing the rate of excitatory to inhibitory firing to achieve homeostasis [2,3]. This alteration of slope in the input/output function is gain and helps achieve homeostatic plasticity [3].

One of the objective markers of gain is the use of Auditory Steady State Response (ASSR) [5]. Amplitude Modulation (AM) results in neurons exhibiting a *mixed coding* response at the level of primary auditory cortex, which encompasses both phase locking to the modulation frequency, and an elevated firing rate in response to the unmodulated tone [6]. The 40 Hz ASSR has been used in tinnitus studies as a potential measure of neuronal sensitivity in tinnitus [6]. The slope typically dictates the degree of excess input/output function, which cannot be fully deduced from a single data point (intensity) measurement and requires at least 2 data points (intensities). Therefore, it is necessary to do an intensity dependence analysis (across different intensities) of the steady-state response, which will provide the slope function to facilitate the determination of central gain related to the ASSR.

The generation and persistence of tinnitus has been unclear and although there have been studies that talk

about possible mechanisms of tinnitus generation and persistence, they are either from first principles, chronic tinnitus studies, or animal studies. There needs further research on acute tinnitus individuals as they are the ideal population to study how tinnitus generates and how does it transit from acute to chronic stages of tinnitus. According to the sensory precision model [3], tinnitus arises from changes in the brain's estimation of sensory precision following hearing loss. In the acute phase, reduced auditory input leads to a down-weighting of peripheral signals and an up-weighting of internal predictions, resulting in the emergence of tinnitus as a compensatory percept. Over time, if the altered sensory precision persists, the brain may recalibrate to treat the internally generated tinnitus signal as behaviorally relevant, leading to chronic tinnitus. This model suggests that persistent tinnitus reflects a maladaptive stabilization of heightened precision attributed to non-auditory predictive signals. Keeping this literature in mind, we hypothesize that central gain diminishes as a regression towards the mean from the Acute to the Chronic stage, leading us to predict a decline in ASSR slope and amplitude over time.

2. METHODS

2.1. Participants

We studied 39 participants with Acute Tinnitus (which we defined as duration 3 days to 6 weeks, with one outlier having a duration of 12 weeks), 30 participants with Chronic Tinnitus (defined as duration more than 6 months), and 27 hearing-matched (to the acute tinnitus group) non-tinnitus controls. Participants were recruited through community advertising on Google Ads, and internally within Newcastle University's research volunteer pool. The 39 Acute Tinnitus participants were invited for reassessment after a minimum of 6 months from tinnitus onset (which we took to indicate their chronic stage), and 18 of them volunteered for and completed this further testing. We refer to this as the 'Post Acute' group, to distinguish it from the group recruited during the chronic stage of tinnitus.

Control participants were matched to the acute tinnitus group for age, sex, hearing, and stimulus frequency and presentation ear.

2.2. Audiological assessment

The experimenter interviewed the subjects before the experiment, verifying a medical history consistent with subjective tinnitus and the absence of atypical symptoms or concerns regarding an undetermined underlying cause. Participants underwent a Pure Tone Audiometry (PTA) test to establish hearing thresholds at octave frequencies ranging between 250 Hz up to 8 KHz. Thresholds were estimated based on the initial presented level at either 40 dBHL or above depending on the participant's residual hearing [7]. The frequency and loudness of tinnitus were assessed using a *tinnitometry* (i.e. psychoacoustic measurement of tinnitus characteristics) approach for patients with acute or chronic tinnitus. In instances of unilateral Tinnitus, matching stimuli were delivered contralaterally, whereas in bilateral tinnitus, they were administered bilaterally. Participants initially matched the loudness of their tinnitus, followed by matching its frequency, commencing at a reference frequency of 6 kHz.

2.3. ASSR stimuli

The ASSR stimuli comprised 15 stimuli per frequency (5 stimuli for each of three intensities per frequency) within a total experiment duration of 15 minutes. These stimuli were Amplitude Modulated sounds with a modulation frequency of 40Hz and a modulation depth of 100% at 1 kHz and the participant's matched tinnitus frequency (or, for controls, the matched tinnitus participant's frequency), each lasting 30 seconds, with an interstimulus interval of 2 seconds.

For every frequency, three different intensities were presented. Stimuli were presented in one block, with intensities and frequencies fully randomized within that block. To account for hearing loss, loudness recruitment and hyperacusis, whilst keeping the stimuli clearly audible yet comfortable, stimulus intensities were presented in accordance with each participant's dynamic range, i.e. the range between their hearing threshold and uncomfortable loudness level, which were established for the specific experimental stimuli at both 1 kHz and the tinnitus frequency. Figure 1 depicts the intensity levels presented.

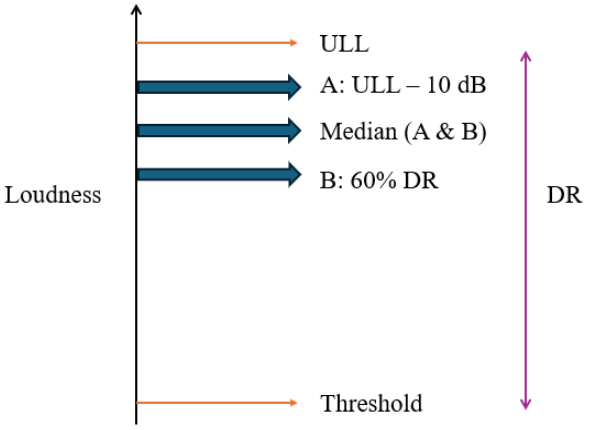

Figure 1: Stimulus presentation levels across 3 intensities based on tailored dynamic range for each subject
ULL: Uncomfortable Loudness level, DR: Dynamic Range.

2.4. EEG and Data analysis

Data were processed in MATLAB, version R2019a, using the EEGlab toolbox [8] and customized code. Data were re-referenced to the P9/P10 (Linked mastoids) montage. The data were further segmented into 30 seconds epoch around each trigger which was followed by a baseline correction. Following the segmentation of the EEG data into 50% overlapping 1s Hanning-windowed sub-epochs, a frequency analysis was conducted utilizing a Fast Fourier Transform (FFT) to transfer the time-domain data into the frequency domain, facilitating the identification and extraction of spectrum peaks, notably at 40Hz.

After pre-processing, we used customized code to perform automatic peak detection at 40Hz and signal to noise ratio calculation to determine the ASSR amplitude and signal to noise ratio. We did this using data from FCz to measure the peak amplitude for ASSR at 40Hz for both 1Khz and tinnitus frequency. Similar analysis was done for noise floor estimation, where the FFT amplitudes were averaged across the neighboring frequencies between 38 and 39, and between 41 and 43, Hz of Amplitude Modulation. The presence of a meaningful ASSR was ascertained via visual evaluation of the response at 40Hz and objectively through F-statistics [9], which analyzed the variance of peak amplitude and noise floor values; a meaningful response was judged to be present only if the ASSR response was significantly larger than the noise floor values based on a value of $p < 0.05$. Each subject had amplitude and noise floor calculated for 3 intensities across 2 frequencies of 1 kHz and tinnitus frequency. From these, the ASSR slope function at each frequency was calculated as the quotient of the Amplitude Dynamic Range (ADR: relative difference of the high and low ASSR amplitude) and Stimulus Dynamic Range (SDR: relative difference of the high and low stimulus intensity). Statistical analysis was carried out for both, across groups between acute, chronic, and controls along with a within group statistical analysis between acute and post-acute tinnitus.

3. RESULTS

3.1. ASSR Amplitude

The ASSR mean amplitude was individually evaluated among the Acute, Chronic, and Control groups for both 1 kHz and tinnitus frequencies. Before comparing amplitudes at low, medium, and high levels, we assessed the absolute stimulus presentation levels (dBSL) to establish whether possible differences in measured amplitude could be explained by stimulus presentation level. A MANOVA was carried out to establish the effect of groups (Acute, Chronic, and Controls) on the stimulus presentation levels (low, medium, and high).

3.1.1. 1 kHz

To determine the effect of group and intensities on the ASSR amplitude, we conducted a two-way Analysis of Covariance (ANCOVA) with two factors: groups (Acute, Chronic, and Controls) and intensities (low, medium, and high), with two covariates: stimulus presentation levels (low, medium, and high), and hearing thresholds at 1 kHZ. Results revealed no statistical significant main effect of intensities ($F(2,277) = 2.348$, $p = 0.097$, partial $\eta^2 = 0.017$) and statistically significant main effect of groups ($F(2,277) = 3.066$, $p = 0.048$, partial $\eta^2 = 0.022$) with near-significant difference between Chronic Tinnitus and Controls ($p = 0.055$) and no significant difference between Acute Tinnitus and Chronic Tinnitus ($p = 1$) and between Acute Tinnitus and Controls ($p = 0.142$). Controls had higher overall amplitude ($M = 1678.7$, $SE = 84.93$) when compared to Chronic Tinnitus ($M = 1388.95$, $SE = 79.62$). There was no statistically significant interaction between the groups and intensities on the amplitude ($F(4,277) = 0.279$, $p = 0.891$, partial $\eta^2 = 0.004$). With respect to the longitudinal comparison, a repeated measures 2-way ANOVA was performed to compare the effect of groups and intensities on the amplitude. Results revealed a main

effect of intensity ($F(2,16) = 23.814$, $p < 0.001$, Wilk's $A = 0.251$), no main effect for group ($F(2,16) = 2.667$, $p = 0.135$, Wilk's $A = 0.873$), and no interaction effect between groups and intensities ($F(2,16) = 0.957$, $p = 0.405$, Wilk's $A = 0.893$). We however carried out a simple main effect analysis using paired t test to determine the impact of group on amplitude for individual intensities, and the results indicated presence of near-significant difference between Acute and Post Acute Tinnitus for low intensity ($t(17) = -1.896$, $p = 0.075$) and medium intensity ($t(17) = -2.080$, $p = 0.053$) with Post Acute tinnitus (low intensity: M = 1475.97 SD = 670.05, medium intensity: M = 1674.48, SD = 771.61) having larger amplitude than Acute tinnitus (low intensity: M = 1313.82 SD = 762.2, medium intensity: M = 1456.56, SD = 809.1). No significant difference was found for the high intensity ($t(17) = -0.772$, $p = 0.451$). There was no impact of stimulus presentation levels on the obtained ASSR amplitude with no significant difference between Acute and Post Acute Tinnitus on low, mid, and high stimulus intensity presentation levels.

3.1.2. Tinnitus Frequency

Equivalent analysis was performed at tinnitus frequency and revealed no statistically significant difference for both cross sectional and longitudinal comparisons. Figure 2 depicts the cross-sectional changes in amplitude and figure 3 depicts the longitudinal changes in amplitude

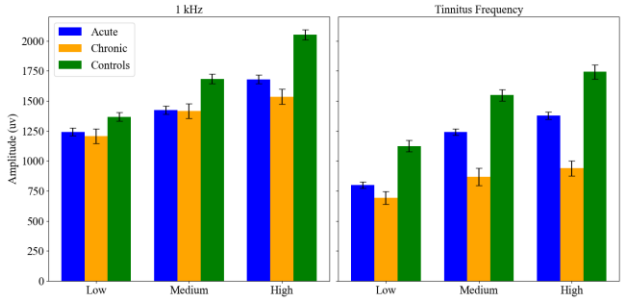

Figure 2*:* Differences in ASSR amplitude at low, medium, and high intensities between Acute, Chronic, and Controls for both 1 kHz and tinnitus frequency.

There is no statistical difference between the groups for any intensities across either frequency. However, controls show a non-significant increased amplitude when compared to both the tinnitus groups.

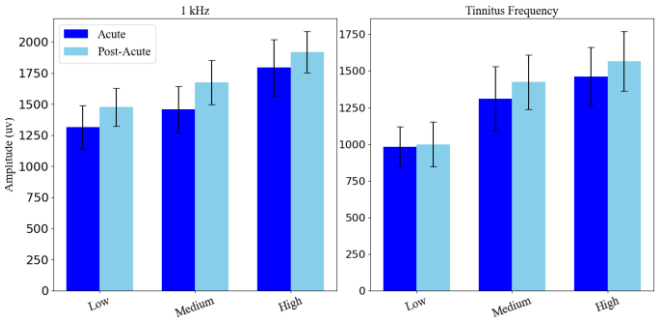

Figure 3: Differences in ASSR amplitude at low, medium, and high intensities between Acute and Post Acute Tinnitus for both 1 kHz and tinnitus frequency**.** *There is a near significant difference (increase in ASSR amplitude) between Acute and Post Acute Tinnitus for low and medium intensity at 1 kHz and none for high intensity. No differences in any loudness categories were noted for Tinnitus frequency.*

3.2. ASSR Slope

In analyzing the variations in slope among the Acute, Chronic, and Control groups, as well as between the Acute and Post Acute Tinnitus groups, we focused on three variables: the Stimulus Dynamic Range (SDR), defined as the difference between high and low stimulus presentation; the Amplitude Dynamic Range (ADR), which represents the difference between high and low ASSR amplitude; and slope, calculated as the ratio of SDR to ADR. Determining whether SDR differed will provide insight into the possible confounding factors that might affect the obtained ADR and slope. Assessing ADR in conjunction with slope will provide a comprehensive understanding of the amplitude growth function for ASSR across different groups

3.2.1. 1 kHz stimuli

A one-way MANOVA was carried out to establish the effect of group on slope, SDR, and ADR; this revealed a significant difference in overall response based on groups ($F(6,184) = 3.964$, $p < 0.001$, Wilk's $A = 0.526$, partial $\eta^2 = 0.114$). An overall main effect was seen for SDR ($F(2,94) = 10.215$, $p < 0.001$, partial $\eta^2 = 0.179$) with difference between Acute Tinnitus and Controls ($p = 0.007$), Chronic Tinnitus and Controls ($p < 0.001$), and no differences between Acute Tinnitus and Chronic Tinnitus ($p = 0.317$). Controls had higher SDR (M = 19.74, SD = 5.94) when compared to Acute (M = 15.42, SD = 5.81) and Chronic Tinnitus groups (M = 13.19, SD = 4.95). There was an overall main effect of group seen for ADR ($F(2,94) = 6.346$, $p = 0.003$, partial $\eta^2 = 0.119$)

with difference between Acute Tinnitus and Controls (p = 0.049), difference between Chronic Tinnitus and Controls (p =0.002), and no difference between Acute Tinnitus and Chronic Tinnitus (p = 0.585). Controls (M = 640.39, SD = 396.70) had higher ADR when compared to Acute Tinnitus (M = 435.73, SD = 344.19) and Chronic Tinnitus (M = 328.49, SD = 263.19). There was, however, no main effect of groups on slope (F (2,94) = 0.961, p = 0.386, partial η^2 = 0.02). There was an effect on SDR of group, which could also be a potential confound. This warranted us to carry out individual one-way ANCOVA to establish the effect of the group on ADR and slope individually, with covariates of SDR and hearing thresholds at 1 kHz. With respect to Slope and ADR, there was no significant effect of group on the values of slope (F(2,92) = 1.279, p = 0.279, partial η^2 = 0.027) and there was no significant effect of group on the values of ADR (F(2,92) = 1.774, p = 0.17, partial η^2 = 0.037) (refer figure 4.5 and 4.6). Longitudinal comparisons between Acute Tinnitus and Post Acute Tinnitus revealed no significant difference in the slope values (t(17) = 0.806, p = 0.431), ADR (t(17) = 0.319, p = 0.754), and the SDR (t(17) = -1.177, p = 0.256) values respectively.

3.2.2. Tinnitus Frequency

Similar analysis was carried out for the tinnitus frequency using nonparametric tests and yielded no statistically significant differences for both cross sectional and longitudinal comparisons. Figure 4 depicts the cross-sectional changes in slope and figure 5 illustrates the longitudinal changes in slope.

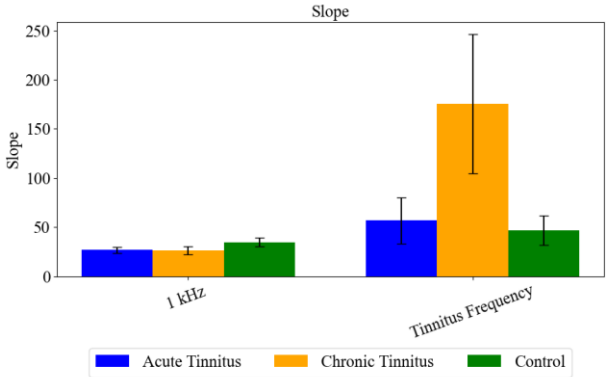

Figure 4: Slope between Acute, Chronic, and Controls at both 1 kHz and tinnitus frequency

Slope values denote Amplitude Dynamic Range/Stimulus Dynamic Range and there were no significant difference in slope across the groups for both frequencies.

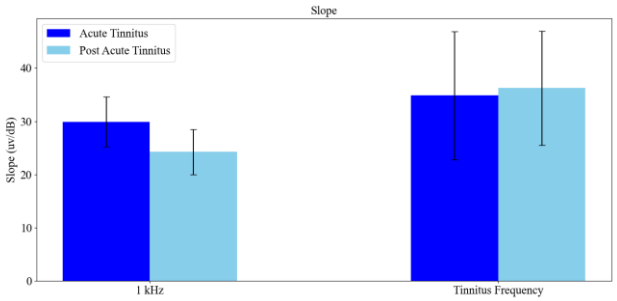

Figure 5: Slope between Acute and Post Acute Tinnitus at both 1 kHz and tinnitus frequency

There was no significant difference in slope between the groups for both frequencies.

4. DISCUSSION

The principal results indicate that there was a near significant increase in the ASSR amplitude at low and mid-level intensities for Post Acute Tinnitus when compared to Acute tinnitus at 1 kHz. Tinnitus frequency did not yield any longitudinal differences. No variations in the slope were seen in either 1 kHz or tinnitus frequency. There were no cross-sectional differences across the groups in either ASSR slope or amplitude. However, there was a non-significant increase in controls for both absolute amplitude and slope, and this finding would help us contextualize the longitudinal changes as we saw increase of amplitude over time which is in the direction toward the Controls.

4.1. No cross-sectional variations across the groups for Acute, Chronic, and Non-Tinnitus Controls

Our first findings indicate that there were no cross-sectional changes among the Acute, Chronic, and Non-Tinnitus Control groups, with respect to either slope and absolute amplitude indicating that the presence of tinnitus isn't associated with the ASSR amplitude. The customised presentation level for the subjects according to their dynamic range may have influenced the outcomes, as the level of hyperacusis has been compensated. In this case, the tailored ASSR presentation level may have curbed the influence of hyperacusis. This was in support of the findings by Paul et al. who investigated the influence of attention on the auditory steady-state response in individuals with and

without tinnitus and their results highlighted that tinnitus patients exhibited diminished attentional modulation of the 5 kHz ASSR, unlike the control group, suggesting that attentional resources may be preferentially allocated to the tinnitus percept, thus limiting further modulation [10]. The findings by Diesch et al. further suggested that the alterations of ASSR in tinnitus individuals when compared to Controls may be partially influenced by attentional processes that imply the complex interplay between tinnitus, attention, and auditory processing. The study further emphasizes the importance of considering attentional factors when interpreting ASSR findings in tinnitus research [11]. Sedley reviewed the role of gain in tinnitus mechanism and highlighted literature that tend to show an increased ASSR amplitudes for tinnitus individuals that is closer to the tinnitus frequency. In our case we did not obtain significant differences at the tinnitus frequency [12]. These studies collectively contribute to our understanding of the neural mechanisms underlying tinnitus and the potential of ASSR as a tool for assessment and treatment.

4.2. Changes between Acute and Post Acute Tinnitus

Concerning the variations seen between Acute and Post Acute, we observed a near significant rise in ASSR amplitude at low and medium intensity levels over time for Post Acute Tinnitus at 1 kHz when compared to Acute Tinnitus. We here consider this finding in the context of our hypothesis that central gain reduces over time, following the onset of tinnitus, as a regression to the mean following a period of hypersensitivity in which tinnitus first occurs. It is to be noted that the finding is in the direction of our hypothesis with reduced ASSR amplitude over time, if ASSR amplitude is interpreted as a positive indicator of central gain. Conversely, we instead interpret increased ASSR amplitude over time as a stabilizing measure as it not only trends towards the pattern of controls but also the absolute amplitude is inversely related to distress. Due to the absence of Acute Tinnitus studies concerning ASSR, we aim to compare the present findings with Chronic Tinnitus studies conducted before and after treatment, as well as the observed alterations in ASSR amplitude. Pantev et al. examined the effects of Tinnitus Retraining Therapy on ASSR and found significant reductions in tinnitus related ASSR following TRT [13]. Sadeghijam et al. utilized binaural beats in stimulating tinnitus patients over a month, measuring the changes in ASSR amplitude between the baseline and post-stimulation. Their results indicated an increase in ASSR amplitude following binaural beat stimulation when compared to baseline, which was attributed to enhanced synchronisation from repeated exposure to binaural beats and an improved temporal map that facilitated a higher stimulation rate [14]. The fact that improved synchronization increased ASSR amplitude is in support with our finding where we attribute that habituation of the tinnitus over time increased ASSR amplitude and in this instance. Further to collaborate the direction of ASSR, we would also lean towards controls as an indicator as there was a non-significant increased amplitude seen in controls.

4.3. Changes in neural synchrony and adaptation

We consider our longitudinal design to be more robust due to which we interpret the current findings based on the longitudinal designs. The generation of ASSR is thought to be a superposition of the Middle Latency Response and Auditory Brainstem Response with a predominant generation at the level of Heschl's gyrus (primary auditory cortex), and possibility of contributions from the auditory belt regions, which are secondary auditory cortical areas [15]. The generation of AM tones throughout the auditory pathway is heavily dependent on mechanisms such as phase locking, temporal envelope coding, rate coding, and population coding (group of neurons firing for different modulation frequencies) [16]. When it comes to tinnitus, it has been posited that consequently to decreased input due to hearing loss, there is aberrant (increased) neural synchrony specifically in the delta band oscillations that manifests as tinnitus [17]. The abnormal increase in neural synchrony of spontaneous activity within the cortical system may have an impact on the incoming acoustic signals, where the neural synchrony is reduced to incoming sounds due to a lack of phase locking, which is essential for the formation of auditory steady-state responses (ASSR). In our case, we attribute that the tinnitus is an ongoing neural response that increases the desynchronization causing reduction of the magnitude of ASSR.

4.4. Gamma Amino-Butyric Acid (GABA) and Tinnitus

Gamma-Aminobutyric acid (GABA) is an inhibitory neurotransmitter in the central nervous system that is an amino acid which is non-proteinogenic in nature [18]. GABAergic neurons releases GABA that plays a significant function of regulating neuronal excitability throughout the nervous system [19]. The amplitude of

ASSR has been associated with changes in GABA. Sugiyama et al. found that boosting GABAergic transmission via lorazepam, a benzodiazepine, increased the 40 Hz ASSR in the early auditory cortex [20]. However, this is an indirect effect mediated through GABA receptors, not a direct effect of GABA itself. Toso et al. further discusses how boosting GABAergic transmission increases the amplitude of the 40 Hz auditory steady-state response in the early auditory cortex [21]. They administered a GABAergic modulator, such lorazepam, and found that this neuromodulator led to a significant increase of the 40 Hz ASSR at both the early transient and later sustained components when compared to the administration of placebo and memantine [21]. This indicates that GABAergic neuronal inhibition contributes significantly to the modulation of the 40 Hz auditory steady-state response in the human auditory cortex. GABA has been linked to tinnitus. A prevailing theory is that the reduced GABAergic inhibition in the auditory pathway may contribute to the onset of tinnitus due to increase in hyperexcitability and this has reflected with the presence of lower levels of GABA at the level of the auditory cortex for tinnitus individuals [22]. However, other research suggests a more nuanced role for GABA, for example, one study found increased GABA-mediated tonic inhibition in the auditory thalami of rats with noise-induced tinnitus which further suggests that GABAergic mechanisms might also play a causative role in tinnitus, potentially by being excess and resulting in thalamocortical dysrhythmia [23]. Our overall interpretation would be that reduced ASSR amplitude during the onset of tinnitus might be attributed to reduction in GABA too which tends to gradually increase over time with increase in ASSR amplitude. However, it is to note that this finding needs more validation, and it is unclear whether GABA would be cause or effect of tinnitus or even whether it plays a role for central gain.

4.3. Summary

The current study indicates that tinnitus-related alterations in ASSR (reduction of 1 kHz amplitude compared to controls) peak at onset and thereafter diminishes, possibly impacted by alterations in neural synchronisation, tinnitus-related distress, GABAergic inhibition and/or attentional modulation. This may or may not suggest a shift in neural activity like central gain, given there were no cross-sectional differences between the groups, particularly between Acute Tinnitus and Controls. The longitudinal variations, particularly at low and medium intensity levels, suggest that the tinnitus activity in isolation diminish over time, that may or may not affect central gain. Figure 6 integrates the above-mentioned arguments and depicts the decline of neural responses linked to tinnitus with time, attributable to enhanced neural synchronisation. This activity represents a continuous stimulation that diminishes phase locking to the incoming signal, while a reduction in tinnitus enhances phase locking to the incoming signal.

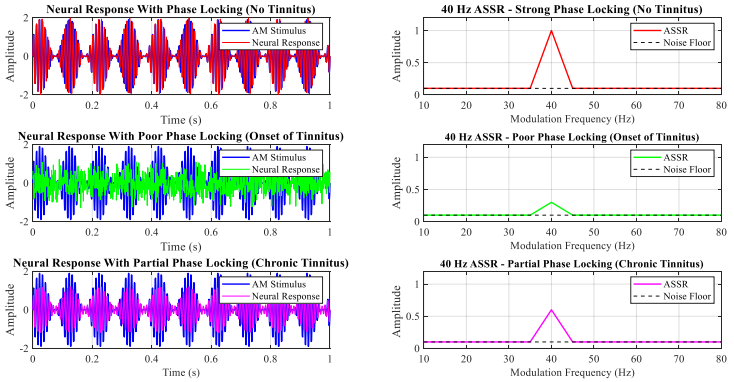

Figure 6: Differences in neural response of AM tones across 3 conditions of No Tinnitus, Acute Tinnitus, and Chronic Tinnitus.

NUMERICAL ANALYSIS OF MINIMUM RESONANCE BANDWIDTHS IN INPUT IMPEDANCES OF HUMAN EAR CANALS

Reinhild Roden[1*] **Matthias Blau**[1,2]

[1] Institut für Hörtechnik und Audiologie, Jade-Hochschule, Oldenburg, Germany.
[2] Cluster of Excellence "Hearing4All".

ABSTRACT

The acoustic input impedance of the human ear canal is a complex function of frequency, reflecting ear canal acoustics and middle and inner ear mechanics. It contains information about the sound pressure at the eardrum and is therefore useful for the individualized equalization of in-ear hearing devices. For clinical applications, it can provide insight into pathological conditions of the ear. To achieve any of the above, it is necessary to determine the ear input impedance with high accuracy. For the validation of impedance measurement system across the entire frequency range up to 16 kHz, for frequency-domain smoothing of measured impedances, as well as for the design of high-frequency couplers, knowledge of the required spectral resolution would be helpful. In this study, minimum relative bandwidths of resonance peaks across the entire frequency range for 41 digitized right ear canal geometries from the IHA database were analyzed, using 3D FEM simulations to determine the input impedance for three different residual ear canal lengths. Results indicate that minimum relative bandwidths decrease from about 0.05 at 5 kHz to around 0.01 at 16 kHz.

1. INTRODUCTION

The input impedance of the ear canal can be used in different applications. A number of studies investigated the viability of employing wideband procedures as a diagnostic tool to ascertain the condition of the middle ear in clinical trials, e.g. [1], [2], [3]. Hence, established medical products integrating these procedures are already available. The main principles of these methods can be found in [4] and [5]. A second class of applications uses the input impedance to estimate the sound pressure at the eardrum, which can potentially be implemented in in-ear hearing systems for individualized equalization aiming at acoustic transparency, e.g. [6]. For the validation of impedance measurement system across the entire frequency range up to 16 kHz, for frequency-domain smoothing of measured impedances, as well as for the design of high-frequency couplers, knowledge of the required spectral resolution would be helpful. This knowledge should be based on the level of spectral detail that would be expected in real ear canal measurements. To this end, the current study analyzes the relative bandwidths of resonances in 3D FEM simulated input impedances of 41 ear canal models from the IHA database [7], [8] for different lengths.

2. METHOD

2.1 Ear canal geometry

The IHA database, containing 3D geometries of torso, head, and complete outer ears with ear canals and eardrums, is being developed. The creation of these geometries was previously described in [7]. For the present contribution, geometry models of the right ear canal of 41 subjects in the database were used. In a first step,

the centerline of each ear canal was determined using the vmtk toolbox [9]. The entrance of the ear canal was then defined as the first plane that is perpendicular to the centerline and intersects the ear canal walls in a way that a closed loop of polygon vertices was created, similar to the method described in [10]. The first and second bends were initially identified through visual inspection and then further refined by locating the nearest local torsion or curvature maximum along the centerline. Of each ear canal, three versions were derived by cuts with planes perpendicular to the centerline, located at the entrance and at the first and second bends, see fig. 1. The eardrum was identified by the following procedure: first, cross-sectional polygons of the medial end of the ear canal were interpolated, and the points with the maximum curvature in the rim region were defined as border points between ear canal wall and the eardrum. Then, the plane with the smallest possible distance to the border points of all cross-sectional polygons was calculated. The tympanic rim was then defined as the intersection of this plane with the 3D geometry. Sometimes, this resulted in unrealistically large eardrums. In these cases, the rotation of the plane was manually adjusted.

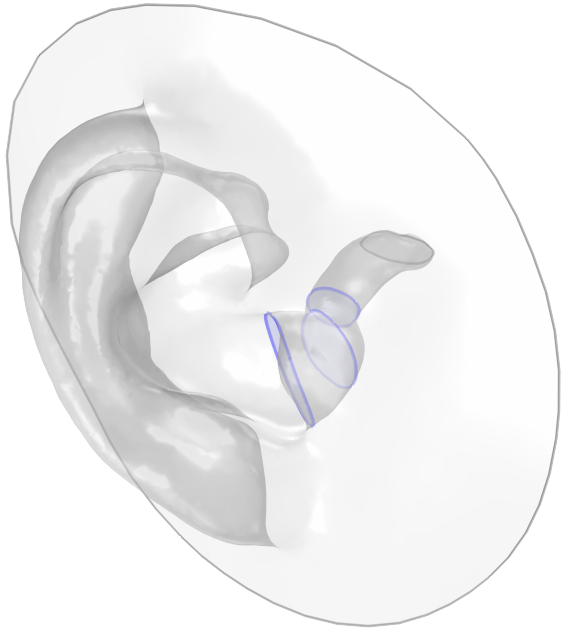

Figure 1. Right outer ear of subject 3 in the IHA database with planes at the entrance, first and second bend (marked blue) and identified eardrum.

2.2 3D FEM simulation

For the three variants of the 41 right ear canals, input impedances Z_{ec} were simulated with COMSOL Multiphysics (6.2) using the 3D finite element method. A normal velocity was assigned to the lateral surface of the residual ear canals as an excitation. Furthermore, the eardrum surface was assigned the impedance of the ear drum and the entire inner ear, according to [11] as implemented in COMSOL. The Helmholtz equation was solved, whereby thermo-viscous effects at the ear canal walls were defined as a boundary condition of the Helmholtz equation, as described in [7] on the basis of [12] and [13], and added to the skin impedance. The values for the skin impedance model are provided by COMSOL as an approximation of the experimental data obtained in [14]. For frequencies up to 20 kHz, sufficient spatial resolution of the sound field was ensured (max. element size of 0.5 mm for boundaries, 1 mm for the volume domain, quadratic (Lagrange) element order). The simulations were run at linearly distributed frequencies between 0.1 and 20 kHz with a frequency resolution of 20 Hz. This corresponds to two hundredths of an octave at 4 kHz, which is the frequency region of first resonances for longer ear canals. The input impedance Z_{ec} resulted from the ratio of the average sound pressure p_{ec} to the volume velocity on the input surface q_{ec},

$$Z_{\mathrm{ec}} = \frac{p_{\mathrm{ec}}}{q_{\mathrm{ec}}}. \tag{1}$$

2.3 Relative bandwidth calculation

All computed input impedances were interpolated to a 1 Hz resolution using a cubic spline interpolation. Subsequently, all resonances with a prominence of at least 3 dB were located. For resonances and anti-resonances, the phase response of the input impedance shows a characteristic rise and a fall, respectively, as exemplarily shown in Fig. 2. All peaks with a corresponding phase zero crossing from +25 to -25 ° were examined. In addition to the harmonics of the first resonance, less prominent side resonances without zero crossing appeared occasionally. These were removed from the analysis. The intersection points of the level of Z_{ec} with a constant line at 3 dB below the respective maximum mark the frequencies of the interval $[f_{-3\mathrm{dB,low}}\ f_{-3\mathrm{dB,high}}]$ for the absolute resonance bandwidth. The frequency f_{mid} was then defined

at the arithmetic mean of that interval. The relative resonance bandwidth was finally calculated as

$$\mathrm{BW_{rel}} = \frac{f_{-3\mathrm{dB,high}} - f_{-3\mathrm{dB,low}}}{f_{\mathrm{mid}}}. \quad (2)$$

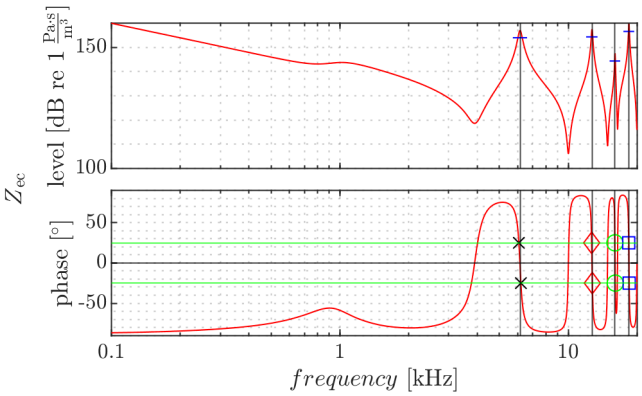

Figure 2. Input impedance for the right ear canal of subject no. 3 cut at the entrance plane.

3. RESULTS

The upper three diagrams in Fig. 3 show the relative resonance bandwidths for ear canals cut at the entrance, the first and the second bend, respectively. Resonances are numbered and sorted by color. For the longest ear canals, up to five resonances were found in the frequency range considered here. The relative resonance bandwidth appears to decay exponentially with logarithmic frequency. The bottom diagram shows all data and a fit using a nonlinear regression model given by

$$\mathrm{BW_{rel}} = 0.26 \cdot \mathrm{e}^{(-0.28\cdot 10^{-3}\cdot \mathrm{f_{mid}/Hz})} + 8.1 \cdot 10^{-3}. \quad (3)$$

This model resulted in an adjusted R^2 of 88.4%.

4. DISCUSSION

Relative resonance bandwidths were calculated for 3D FEM simulations of input impedances on 41 right ear canals of three different lengths. The first resonances occur around 4.5-5 kHz in long ear canals, with relative bandwidths varying between 0.05 and 0.12. Towards higher frequencies, relative bandwidths decay to about 0.01 with decreasing inter-individual variability. A nonlinear model was fitted to this frequency-dependent behavior. The decrease of relative bandwidths with frequency is not surprising, since skin and eardrum are acoustically effective mainly in the mid-frequency range, and their impedances increase at higher frequencies. Keeping in mind that the simulations (a) did not use the higher damping of typical ear canal walls as observed, e.g., in [11] and (b) used an eardrum model that has often been criticized for giving too high impedance values, it appears to be safe to assume a minimum relative bandwidth of 0.01 for the frequency range of human hearing, i.e., up to 16 kHz.

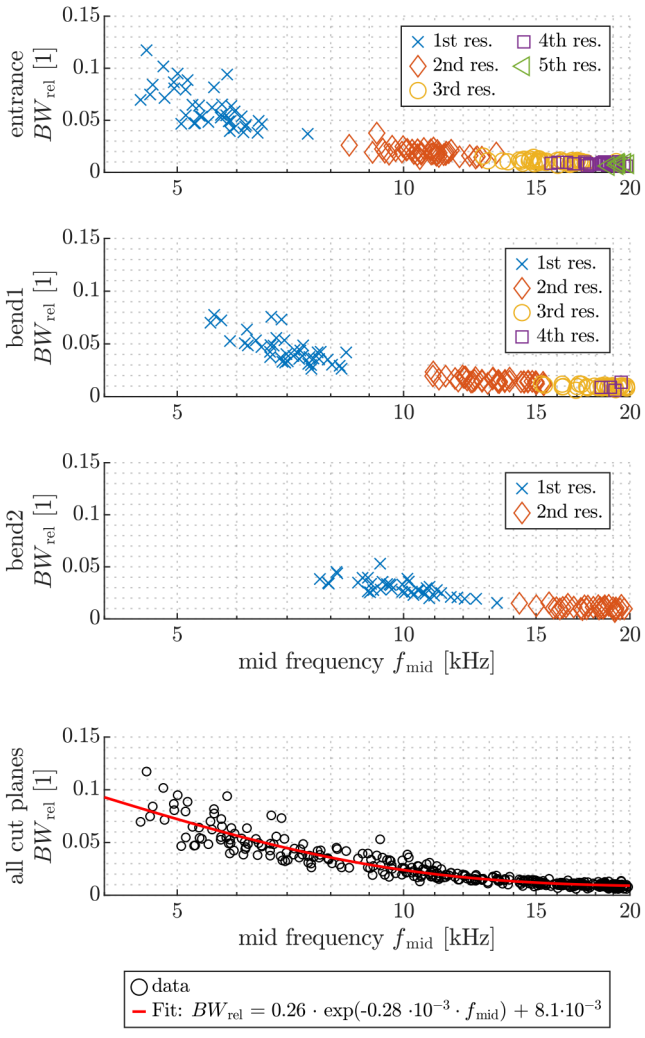

Figure 3. Relative resonance bandwidths of Z_{ec}.

5. CONCLUSION

Relative bandwidths of resonances in the input impedance of human ear canals, computed using 3D FEM simulations with highly conservative assumptions regarding damping effects, are about 0.01 at 16 kHz and larger at lower frequencies. Real ear canals can be expected to exhibit substantially larger relative bandwidths. This result can be used to define the required spectral resolution of impedance measurement systems.

SINGLE-TRIAL ELECTROENCEPHALOGRAPHIC ANALYSIS OF FRONT-BACK CONFUSIONS IN FREE-FIELD AND HEADPHONE-BASED LISTENING CONDITIONS

Nils Marggraf-Turley[1*] **Martha Shiell**[2] **Niels Pontoppidan**[2]
Drew Cappotto[1] **Lorenzo Picinali**[1]

ABSTRACT

Sound source localisation relies on spatial auditory cues, which are described by the head-related transfer function (HRTF). In natural free-field listening, individuals perceive sounds filtered by their own HRTFs. Conversely, binaural (headphones-based) reproduction uses HRTFs to render virtual auditory stimuli. However, in practice, binaural reproduction typically employs non-individual HRTFs, which can impair realism and localisation accuracy, introducing phenomena such as front-back and up-down confusion. Beyond behavioural assessment, perceivable differences under the two rendering conditions can be investigated from a neurophysiological perspective. This study uses electroencephalographic data from an existing localisation study to examine disparities in front-back confusion between free-field and headphone-based (non-individual HRTF) conditions. A multilayer perceptron trained on single-trial event-related potentials classified sound source location pairs symmetric around the interaural axis. Single-trial decoding accuracy correlated with behavioural front-back confusion.

1. INTRODUCTION

The human auditory system localises sounds using spatial auditory cues such as interaural time differences (ITD), interaural level differences (ILD), and monaural spectral cues. These cues, unique to each individual due to anatomical variability, are encapsulated within Head-Related Transfer Functions (HRTFs). Although individual HRTFs enable precise spatial auditory perception, their practical application is limited due to the complexities involved in measurement [1]. Consequently, non-individual HRTFs, often recorded using standardised mannequins such as KEMAR, are widely adopted despite potential inaccuracies, including increased rates of front-back confusion due to inadequate simulation of spectral cues.

Traditional behavioural methods assessing localisation performance with HRTFs rely heavily on subjective reports, which can have low repeatability [2]. Electroencephalography (EEG) provides an objective alternative by recording cortical neural responses associated with auditory spatial perception, potentially bypassing some limitations inherent in subjective feedback.

Previous approaches relating neural response variations to perceptual outcomes show promise [3]. Studies employing event-related potential (ERP)-based decoding have successfully discriminated horizontal and median plane sound locations [4, 5] under free-field listening. More recent work has expanded on these decoding paradigms, indicating lower decoding accuracy for non-individual HRTFs, which was correlated with front-back confusion rates [6]. However, trials were averaged to increase signal-to-noise ratio. Decoding location from a single trial is more advantageous as it paves the way for real-

time applications of EEG-based decoding.

Consequently, this study expands on the decoding approach of [6] by using single-trial decoding with a neural network instead of logistic regression with averaged trials.

2. METHOD

We re-examined EEG data from [6], where twenty-two participants localised auditory stimuli under free-field and headphone-based rendering using the KEMAR HRTF from the SONICOM database [7]. Each participant sat in the centre of a spherical loudspeaker array, stabilised with a chin rest. Stimuli comprised a 1000 ms adapter from 12 azimuthal positions (30° increments), followed by a 100 ms probe from four locations (Az. 30°, 330°, 150°, and 210°). All stimuli were presented at 65 dB SPL.

EEG data underwent band-pass filtering (0.1–40 Hz), epoching (-100 to 600 ms) and downsampling (128 Hz). To mitigate artefacts whilst maximising epochs, our artefact rejection differed from [6]. Amplitude thresholding rejected epochs with maximum amplitude above ±200 µV or below ±1 µV. Single-trial ERPs were classified using a multilayer perceptron (MLP) neural network. Feature vectors were constructed by concatenating electrodes and time points, and scaled using Z-score standardisation. The MLP architecture consisted of an input layer, a hidden layer with 512 units (ReLU activation), a dropout layer (0.4), a second hidden layer with 256 units (tanh activation), another dropout layer (0.4), and an output layer with a sigmoid activation function. Training used the Adam optimiser (learning rate of 0.00001) with binary cross-entropy loss. Model performance was evaluated through 10-fold stratified cross-validation for each subject. Data were balanced across subjects, location pairs, and spatial conditions (N=80). Separate networks were trained per subject, location pair (Az. 30 vs 150, Az. 330 vs 210), and spatial condition (Free-field, KEMAR), each for 35 epochs with a batch size of four.

3. RESULTS

Decoding accuracy data were averaged across location pairs and spatial conditions for correlation with behavioural confusion. Front-back confusion rates from behavioural responses were negatively correlated with decoding accuracy ($r = -0.51, p < 0.05$).

4. CONCLUSION

Our findings demonstrate a significant correlation between location decoding accuracy and behavioural front-back confusion rate from single-trial ERPs. This correlation from single-trial decoding highlights the potential for EEG-based approaches to inform HRTF selection or training paradigms aimed at mitigating confusion in headphone-based spatial audio applications.

EVALUATION OF MICROPHONE NONLINEARITIES IN PROBES FOR MEASUREMENT OF OTOACOUSTIC EMISSIONS

Petr Honzík[1*] **Václav Vencovský**[1]
[1] Department of Radioelectronics, Faculty of Electrical Engineering,
Czech Technical University in Prague, Technická 2, 166 27 Praha, Czech Republic

ABSTRACT

Measurement of Distortion Product Otoacoustic Emissions (DPOAE) relies on evaluating the nonlinear response of the inner ear to two-tone excitation signals, specifically identifying the cubic intermodulation distortion products. However, the accuracy of these measurements can be adversely affected by nonlinear distortions within the electroacoustic measurement chain. This study examines the nonlinear behavior of microphones embedded in probes used for otoacoustic emission measurements. Nonlinearities were characterized using the source harmonic correction method reported in the literature, as there is no perfectly linear source of excitation signal. We focused on the quantification of second- and third-order harmonic distortion, which are key components of the nonlinear response of the microphone. The results are analyzed and compared to similar measurements performed on conventional and MEMS microphones, revealing specific characteristics of the probe microphone's nonlinear response. Strategies for reducing nonlinear distortion in this context, as described in the literature, are also discussed. These findings contribute to the understanding of the limitations and potential improvements in the measurement accuracy of otoacoustic emissions by addressing microphone-induced nonlinearities.

1. INTRODUCTION

Otoacoustic emissions (OAEs) are sound signals generated in the inner ear and transmitted through the middle ear to the external auditory canal [1]. While spontaneous OAEs occur without presenting evoking stimulus into the ear, clinical diagnostics primarily rely on evoked OAEs. Among these, distortion-product otoacoustic emissions (DPOAEs) are widely used [2]. DPOAEs arise from nonlinear interactions in the cochlea when stimulated with two close-frequency tones, f_1 and f_2 ($f_1 < f_2$), with the cubic distortion product at $2f_1 - f_2$ being of primary interest [3]. As a result, any nonlinearity in the measurement chain may compromise the accuracy of the recorded emissions.

The standard OAE measurement probe includes two miniature loudspeakers to separately generate f_1 and f_2, minimizing intermodulation distortion, and a miniature condenser microphone with low self-noise and a flat frequency response. The probe connects to the ear canal via a small tube. This study investigates nonlinearities in the microphone of such probes.

Accurate characterization of microphone nonlinearities is complicated by the absence of a perfectly linear acoustic reference source, making it difficult to isolate the microphone's contribution from that of the source. To overcome this, we apply a harmonic correction method for periodic signals [4], which uses predistortion and a low-distortion reference microphone to suppress source nonlinearities to the noise floor.

The following sections present the theoretical background on microphone nonlinearities, describe the experimental setup, and discuss the measured results along with possibilities for reducing nonlinear distortion.

2. NONLINEAR BEHAVIOR OF CONDENSER MICROPHONES

Nonlinearities in condenser microphones stem from factors such as variable capacitance due to membrane motion, nonlinear damping, and imperfections in mechanical or electronic components [5, 6]. The dominant source is the electrostatic transduction mechanism, which introduces both harmonic and intermodulation distortion [7, 8]. The second harmonic alone accounts for approximately 90% of total harmonic distortion [9], particularly under high sound pressure levels.

Following the model in [10], the analysis focuses on nonlinearities due to electrostatic transduction, assuming other sources are negligible. With negligible charge variation (due to a high polarization resistance), the microphone output voltage is

$$u(t) = -U_0 \frac{\mathrm{d}C(t)}{C}, \tag{1}$$

where U_0 is the polarization voltage, $\mathrm{d}C$ the time-varying change of capacitance, and $C = C_p + C_0$ is the total static capacitance composed of the parasitic capacitance C_p and the static active capacitance $C_0 = \varepsilon_0 S/h_g$ where h_g is the air gap thickness, S the electrode area, and ε_0 the vacuum permittivity.

Assuming the total time-varying capacitance due to the mean membrane displacement $\bar{\xi}(t)$

$$C(t) = C_p + \frac{\varepsilon_0 S}{h_g + \bar{\xi}(t)} = C_p + C_0 \frac{1}{1 + \bar{\xi}(t)/h_g}, \tag{2}$$

can be expressed as $C(t) = C_p + C_0 + \mathrm{d}C(t)$, the time-varying capacitance change can be approximated using Taylor series expansion as

$$\mathrm{d}C(t) = -C_0 \left[\frac{\bar{\xi}(t)}{h_g} - \left(\frac{\bar{\xi}(t)}{h_g} \right)^2 + \left(\frac{\bar{\xi}(t)}{h_g} \right)^3 - \cdots \right]. \tag{3}$$

Substituting (3) into (1), and defining $y(t) = \frac{\bar{\xi}(t)}{h_g}$ and $K_0 = U_0 \frac{C_0}{C_p + C_0}$, the output voltage becomes

$$u(t) = K_0 \left[y(t) - y^2(t) + y^3(t) - \cdots \right], \tag{4}$$

revealing the nonlinear terms. The key model parameter K_0 must be estimated from measurements.

3. MEASUREMENTS ON OAE PROBE MICROPHONE

This section describes the measurement setup and presents results for the frequency-dependent sensitivity and the levels of the first three harmonics measured at various excitation levels.

3.1 Measurement setup

The measurement setup (Fig. 1) includes the Etymotic ER10C probe with two low-noise microphones (total sensitivity 50 mV/Pa), whose signals are summed to improve accuracy, operating linearly up to 120 dB SPL. A B&K 4135 1/4" laboratory microphone serves as the low-distortion reference, and an earplug acts as the acoustic source. All components are mounted in a small plastic cavity to generate high sound pressure levels. To suppress source-induced nonlinearities, we apply a harmonic correction method for periodic signals [4] using predistortion (see "Harmonic correction" block in Fig. 1).

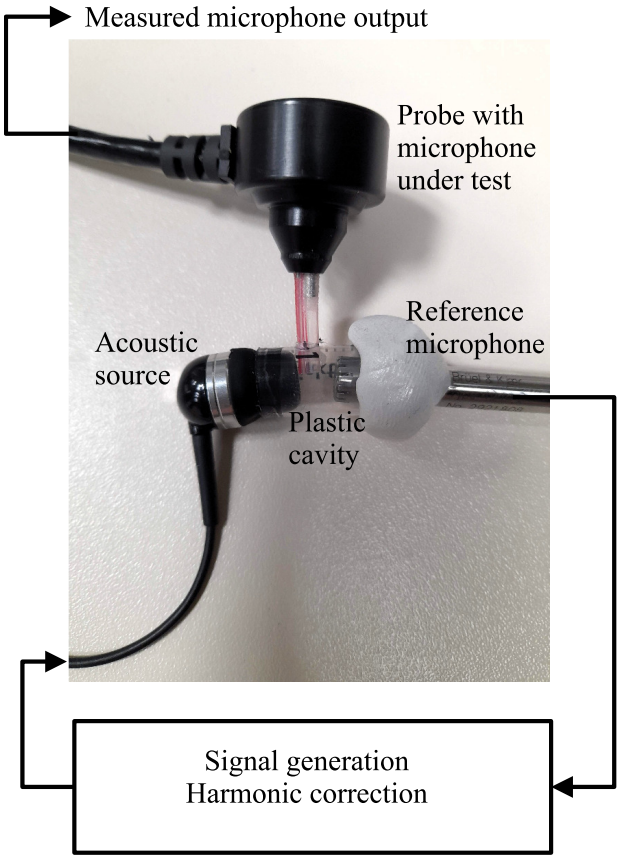

Figure 1. Schematic view of the measuremet setup.

3.2 Sensitivity

The measured frequency-dependent sensitivity is shown in Figure 2 for three different positions of the gain switch on the probe preamplifier. The frequency response is approximately flat between 100 Hz and 10 kHz. In contrast to classical condenser microphones, the phase is not quasi-constant up to the frequency of the first resonance. This is likely caused by unknown, possibly analog, signal processing in the probe preamplifier.

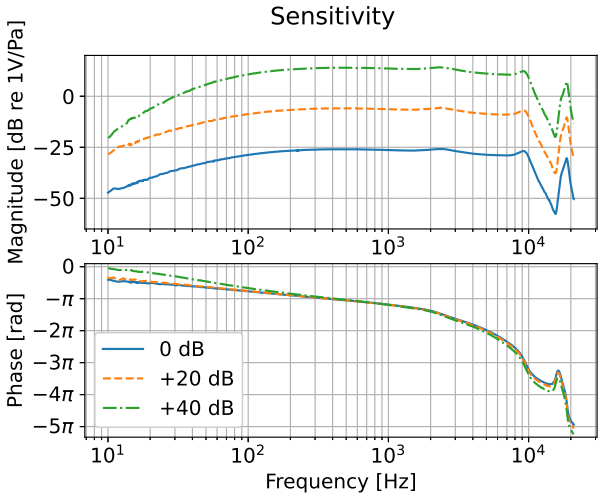

Figure 2. Measured frequency dependence of the magnitude (upper figure) and phase (lower figure) of the microphone sensitivity for the switch position 0 dB (blue solid curve), +20 dB (dashed orange curve) and +40 dB (dash-dotted green curve).

3.3 Nonlinear behavior

In line with previous research [11], the first three harmonics measured at 510 Hz for excitation levels ranging from 70 to 116 dB SPL, recalculated to sound pressure level measured by the microphone under test using its sensitivity, are shown in Figure 3 (points). The dashed lines represent theoretical predictions based on Equation (4) in Section 2, using an estimated value of the parameter $K_0 = 40\ V$. While the measured levels of the first (fundamental) and second harmonics agree well with the theoretical values, the third harmonic is significantly higher than predicted, indicating the presence of additional nonlinear effects not captured by the model. Note that similar results are obtained at higher frequencies [11].

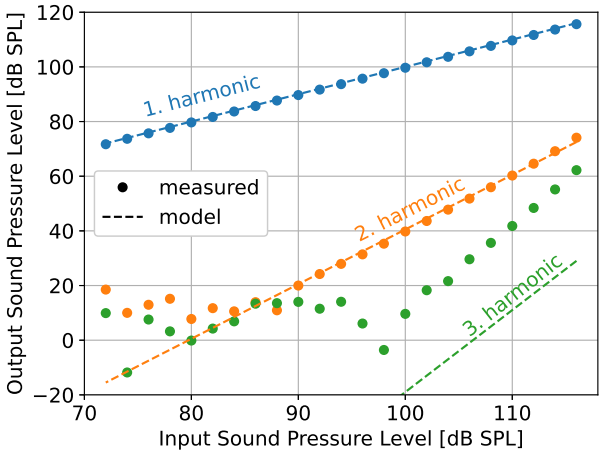

Figure 3. Measured (points) and theoretical (dashed lines) harmonics of the microphone under test at 510 Hz.

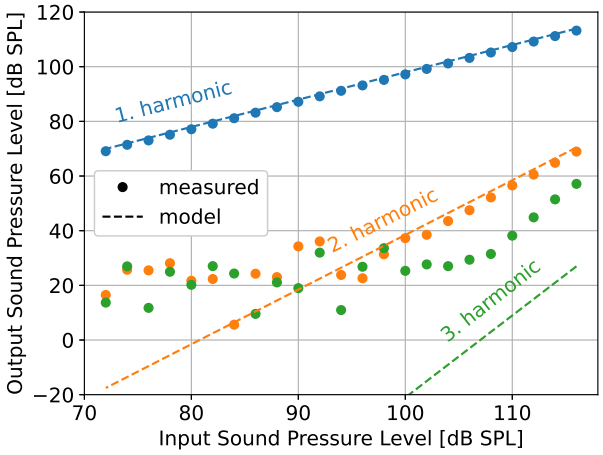

Figure 4. Measured (points) and theoretical (dashed lines) harmonics of the microphone under test at 110 Hz.

Although the frequencies used in DPOAE measurements are usually higher than 510 Hz (typically 1 to 8 kHz), methods have been proposed in the literature [12] that introduce an additional low-frequency component of relatively high amplitude in DPOAE measurements to bias the operating point of the cochlear transducer. It is therefore relevant to examine the nonlinear behavior of the probe at low frequencies. Figure 4 shows the mea-

sured and theoretical levels of the first three harmonics at 110 Hz, calculated using the same value of $K_0 = 40\ V$ and taking into account a slightly lower sensitivity (approximately 38 mV/Pa). The results are consistent with those in the previous figure, although the background noise is higher at this frequency.

4. REDUCTION OF NONLINEAR DISTORTION

Previous research [11] has shown that a low-frequency bias tone at 100 dB SPL, combined with the nonlinear distortion of the probe microphone, can generate higher harmonics of non-negligible amplitude at the microphone output. A recently published study [13] proposes a method for reducing harmonic and intermodulation nonlinear distortion in single-backplate condenser microphones by suppressing the quadratic component. This post-processing technique is based on equation (4) and utilizes the parameter K_0. The approximately linearized output voltage u_{lin} is calculated from the microphone output u as follows [13]

$$u_{lin}(t) \approx u(t) + \frac{1}{K_0} u^2(t). \tag{5}$$

In this work, we apply this simple technique to the output of the OAE probe microphone.

Figure 5 shows the level of the second harmonic component (upper plot) and the Total Harmonic Distortion (THD) parameter (lower plot) after applying the distortion reduction technique for varying values of K_0, at an excitation level of 108 dB SPL and a frequency of 510 Hz. The second harmonic exhibits a sharp minimum near the estimated value $K_0 = 40$ V, decreasing from 56 dB SPL (unprocessed value, blue solid line) to 12 dB SPL, corresponding to a reduction of 44 dB. The THD is reduced from $0.26\,\%$ to $0.026\,\%$, representing a tenfold improvement.

Figure 6 presents the same type of result at 110 Hz. Here, the second harmonic is reduced from 52 dB SPL to 42 dB SPL, resulting in a decrease of only 10 dB. Similarly, the THD parameter is reduced from $0.224\,\%$ to $0.074\,\%$, representing an improvement by approximately a factor of 3. Additionally, the positions of the minima for both the second harmonic and the THD appear to be shifted toward lower values of K_0, even though the original estimate showed good agreement between measurement and theory in Figure 4.

We propose the hypothesis that the significant change in the efficiency of the distortion reduction with frequency

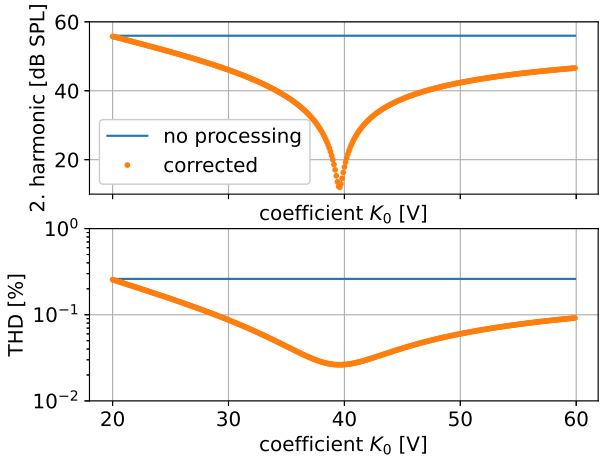

Figure 5. Reduced value of the 2^{nd} harmonic (upper figure) and THD (lower figure) at 510 Hz (orange points) compared with the unprocessed value (blue solid line).

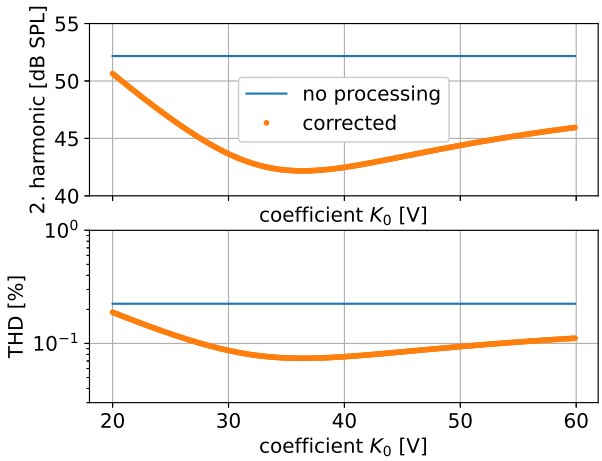

Figure 6. Reduced value of the 2^{nd} harmonic (upper figure) and THD (lower figure) at 110 Hz (orange points) compared with the unprocessed value (blue solid line).

is caused by a phase shift, possibly introduced by post-processing of the microphone output signal in the probe preamplifier. Figure 2 has shown that the phase is not quasi-constant across the entire frequency range. When the phase of the measured signal is extracted from the FFT (not unwrapped) and incorporated into the model, the

phases of the first and second harmonics are predicted correctly at 510 Hz, as shown in Figure 7. Note that the third harmonic is not predicted correctly, either in amplitude or phase, for reasons discussed in Section 3.3.

At 110 Hz, as shown in Figure 8, the phase of the second harmonic shows a discrepancy between the measured data and the model, likely due to an additional frequency-dependent phase shift originating from analog signal processing in the probe preamplifier. We hypothesize that this phase shift affects the efficiency of the distortion reduction technique, which performs better at frequencies where the additional phase shift is negligible.

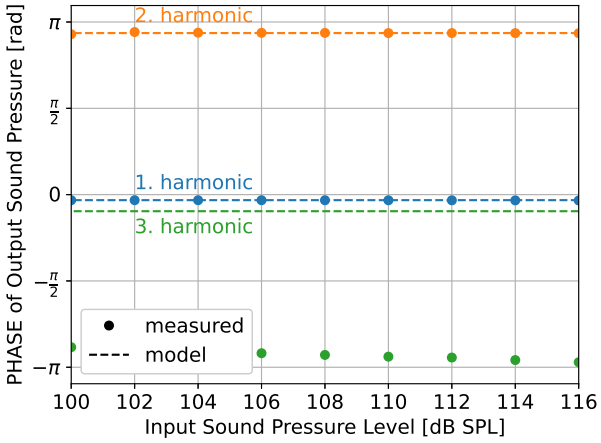

Figure 7. Phase of first three harmonics: measured (points) and theoretical (dashed lines) at 510 Hz.

5. CONCLUSION

This study examined the nonlinear behavior of condenser microphones used in otoacoustic emission (OAE) probes, focusing on its impact on measurement accuracy. A previously published analytical model based on the electrostatic transduction mechanism was applied and shown to predict the measured levels of the first and second harmonics with good accuracy. Furthermore, a distortion reduction technique from the literature, based on this model and parameterized by K_0, was evaluated. When applied as a simple post-processing step, the method significantly reduced the second harmonic component and decreased total harmonic distortion (THD), particularly at 510 Hz.

However, the efficiency of the distortion reduction technique was shown to be frequency-dependent. At 110 Hz, both the suppression of the second harmonic and

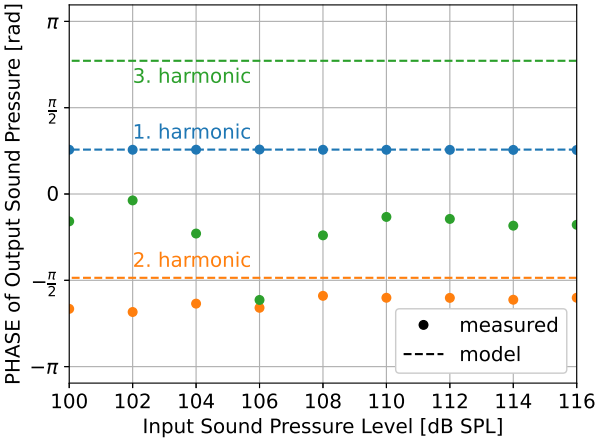

Figure 8. Phase of first three harmonics: measured (points) and theoretical (dashed lines) at 110 Hz.

THD improvement were noticeably lower. This behavior was attributed to an additional phase shift, likely introduced by analog signal processing in the probe preamplifier. Incorporating the measured signal phase into the model improved the agreement for the first and second harmonic phases at higher frequencies, while a clear discrepancy remained at lower frequencies.

These findings highlight the importance of considering frequency-dependent phase characteristics when applying nonlinear distortion reduction techniques to microphone signals. Further investigation of the internal signal processing in probe preamplifiers may help improve modeling accuracy and enable more effective compensation across a broader frequency range.

ABSTRACT

Due to the convergence of Applied Linguistics (in particular, Clinical Linguistics), Acoustic Engineering and the Neonatology Unit of the University Hospital Puerta del Mar in Cadiz, the aim of this study is to conduct a longitudinal neurocognitive study of acoustic-perceptual skills and linguistic function in preterm infants. This will allow to establish the interrelation between both aspects during the 0 to 4 years' stage, to identify possible deficiencies and their manifestation in different stages and, consequently, to achieve better diagnostic and treatment protocols for this population. For this purpose, clinical data, especially neuroimaging data, are contrasted with those derived from the evaluation of the influence of noise exposure in incubators on sensorineural hearing loss and auditory maturation by means of electrophysiological and acoustic techniques.
As for the results, it is expected that the analysis of the data obtained will shed light on the possible auditory and linguistic deficiencies observed, in addition to the design of appropriate specific audiological and speech therapy tools.

1. INTRODUCTION

This study is ascribed to the project "Longitudinal and cross-sectional neurocognitive study of acoustic-perceptual abilities and linguistic function in preterm infants (PretermLA)", funded by the Research Plan of the University of Cadiz (code PR2024-010), within its call for Bridge Projects (2024/2025).
Preterm birth is associated with a spectrum of neurological, cognitive, and linguistic complications [1]. Multiple studies have documented language disorders and deficits in auditory speech processing linked to prematurity and low birth weight [2]. Research indicates that language performance in preterm children shows differences that persist over time, suggesting long-term stability of linguistic vulnerabilities [3,4].
The relationship between prematurity and language development has been extensively investigated, with findings consistently showing that premature birth poses risks for various aspects of linguistic development. These children demonstrate unique trajectories in language acquisition that differ from their full-term counterparts [4]. Neuroimaging studies have revealed altered brain connectivity in premature infants, with extremely preterm children exhibiting increased interhemispheric connectivity for language [5]. Additionally, white matter microstructure has been associated with language abilities in children born very preterm [6].
A critical element often overlooked in this context is the acoustic environment of premature infants. Exposure to incubator noise in Neonatal Intensive Care Units (NICUs) constitutes a risk factor that can lead to stress-related

functional impairments, potentially causing hearing loss [7] and affecting physiological parameters including heart rate, respiratory rate, and oxygen saturation [8]. These early acoustic experiences occur during a crucial period when language acquisition and acoustic-perceptual skills are beginning to develop, with neural encoding of voice pitch and formant structure already present at birth [9].

Despite the substantial evidence linking prematurity to language disorders, there is a significant research gap concerning the longitudinal study of language development in parallel with the perception of speech sounds during early childhood. Previous research has demonstrated through studies of Mismatch Negativity (MMN) that phonological processing at early ages can be an important prognostic factor for predicting future language development in at-risk populations [10]. However, a comprehensive approach combining acoustic assessment, language development, and neurophysiological markers throughout early childhood is still needed.

The present longitudinal study aims to address this research gap by examining the influence of the acoustic environment, particularly incubator noise, on neurocognitive development for language function in premature infants from birth to 4 years of age. By adopting a multidisciplinary approach that combines expertise in acoustic engineering, clinical linguistics, and neuropediatric, this research seeks to provide a deeper understanding of the relationship between early acoustic experiences and linguistic development in premature children.

2. METHODOLOGY

This research employs a longitudinal design with a multidisciplinary approach combining acoustic engineering, clinical linguistics, and neuropediatrics to comprehensively assess the development of language functions in premature infants.

The sample of this research is divided into two groups: an experimental group (EG) and a control group (CG). The experimental group will be composed of between 20 and 50 preterm neonates born at the Hospital Universitario Puerta del Mar during the first year of the project. The inclusion criteria for this group are birth weight less than 1,500 grams or gestational age less than 32 weeks. As for the control group, it will be made up of a similar number of full-term newborns, who will be selected without any pathological condition affecting their linguistic or neurocognitive development.

Sample size calculation was based on previous literature, aiming to detect a minimum effect size of 11.6 points on linguistic tests with 80% power and an alpha risk of 0.05, requiring at least 28 participants per group. Accounting for potential follow-up losses (10%), the target sample size is 31 participants per group.

2.1 Data collection procedures

The methodology of this research is organized in three interconnected blocks. The first, Biomedical Acoustics, focuses on the assessment of auditory thresholds and physiological responses in premature infants, taking into account factors such as stress and exposure to sounds in the incubator. This block utilizes evoked potentials, otoacoustic emissions, and electroencephalograms, employing acoustic stimuli at varying sound pressure levels to achieve this objective. The second block, Clinical Linguistics, focuses on the assessment of language development using standardized tests and the analysis of early vocal production. Speech intelligibility and neurocognitive responses to linguistic stimuli are measured using specialized tools. Early vocal production is analyzed through the recording and processing of manifestations such as crying, gurgles, babbling, and syllabic production, using specialized tools such as PRAAT. The Acoustic-Linguistic Integration block serves to synthesize the data obtained in the two preceding blocks. In this block, statistical analyses are performed to identify significant patterns in the auditory and linguistic development of preterm infants.

3. EXPECTED RESULTS

It is imperative to acknowledge that this research is still in its developmental stage; therefore, the findings obtained thus far should not be considered conclusive.

This research is expected to yield significant findings in several key areas. First, it will provide a comprehensive understanding of acoustic-perceptual and linguistic development in preterm infants, offering detailed data on the acquisition and progression of phonetic-phonological, lexical-semantic, morphosyntactic, and pragmatic skills in this population compared to full-term infants. This will enable the identification of specific developmental trajectories for preterm infants.

Second, the impact of incubator noise on neurodevelopment will be assessed by quantifying the relationship between acoustic conditions and physiological variables such as brain waves, heart rate, oxygen saturation, and sleep patterns. This analysis will be essential in defining safety

thresholds and establishing evidence-based recommendations for NICUs acoustic environments.

Consequently, the present study will concentrate on identifying specific impairments in acoustic and linguistic processing to characterize potential alterations in perceptual mechanisms among preterm infants. This will entail a meticulous examination of auditory thresholds across diverse frequency ranges and their correlation with linguistic development. Furthermore, the neuroanatomical underpinnings of language development will be investigated by integrating acoustic-perceptual and linguistic data with neuroimaging findings, particularly tractography. This comprehensive approach is expected to elucidate the functional neuroanatomical underpinnings of language acquisition in this particular population [6].

This research also aims to develop innovative assessment and intervention protocols. Utilizing the longitudinal data collected, integrated acoustic-perceptual and linguistic assessment protocols will be designed to facilitate the early identification of developmental disturbances in preterm infants, accompanied by personalized therapeutic intervention guidelines.

This research endeavors to enhance the existing body of knowledge concerning auditory maturation in preterm infants. This enhanced understanding is imperative for determining the optimal timing of interventions, such as cochlear implantation in cases of severe hearing loss [11]. Furthermore, the study will establish associations between early environmental factors and various aspects of neurobehavioral and developmental profiles in this population, thereby expanding upon previous research on very low birth weight preterm infants [12].

4. CONCLUSIONS

This longitudinal neurocognitive study addresses a critical research gap in understanding how the acoustic environment, particularly incubator noise, influences neurocognitive development for language function in premature infants. By adopting a multidisciplinary approach that combines acoustic engineering, clinical linguistics, and neuropediatrics, this study aims to provide comprehensive insights into the complex interplay between early acoustic experiences and linguistic development.

The research has significant theoretical and practical implications. From a theoretical perspective, it will contribute to linguistic theory by optimising hypotheses on the nature of the language faculty and developing connections between linguistics and other sciences. This may promote a paradigm shift within Biolinguistics and Clinical Linguistics by developing models of language and its disorders based on the interaction between biological and environmental factors.

From a practical standpoint, the findings will have immediate applications in clinical settings. The data on hearing thresholds and auditory pathway maturation would help improve protocols for early identification and treatment of hearing problems in premature children. The integrated assessment protocols and intervention guidelines developed through this research could be incorporated into routine clinical practice, potentially improving outcomes for premature infants.

The social impact of this research is substantial, as it addresses the needs of a vulnerable population. By improving our understanding of the environmental factors that affect neurodevelopment in premature infants, the investigation contributes to reducing social inequalities and enhancing early diagnosis methods. The results will be valuable not only to healthcare professionals but also to families, educators, and other stakeholders involved in supporting the development of premature children.

5. ACKNOWLEDGMENTS

This work is part of the project "Longitudinal and Cross-Sectional Neurocognitive Study of Acoustic-Perceptual Abilities and Linguistic Function in Preterm Infants (PretermLA)", funded by the Research Plan of the University of Cádiz (Project Code PR2024-010), within its Bridge Projects call (2024/2025).
