ANALYSIS OF COMPLEX SCENARIOS IN THE NOISE MITIGATION OF MAIN INFRASTRUCTURES IN ITALY IN LIFE SILENT PROJECT

Mauro Cerchiai [1] **Matteo Bolognese** [1] **Andrea Panci** [1]

ABSTRACT

Transportation infrastructures are responsible for most noise exposure in Europe. The Europe Environmental Noise Directive prescribes a cycle of noise mapping, citizen involvement, and action plans to reduce annoyance and sleep disturbance. In Italy, national regulation shares with END the aim to reduce noise, but is more focused on the definition, and respect, of noise limits rather than considering noise effects on citizens. In the case of multiple noise sources acting in the same area (complex acoustics scenario), Italian regulation asks transportation infrastructure managers to cooperate and share the mitigation costs. In these cases, without an integrated mitigation plan, acting on one source can lead to higher costs or, at worst, an increase in exposure. However, the regulation does not provide practical guidelines on how to manage this process, thus very little progress has been made in mitigating noise in those complex scenarios. The Life SILENT project aims to address this problem by developing a methodology for highlighting conflicts in complex scenarios and solving them, reducing total citizen exposure while minimizing costs and considering EU requests at the same time. The present work will describe a preliminary study conducted with this intent.

1. INTRODUCTION

Environmental noise is a significant health concern in Europe, identified as the second most critical environmental stressor in six European countries, according to the WHO's 2018 "Environmental Noise Guidelines for the European Region" [1]. Approximately 20% of the European population resides in areas where noise levels pose health risks, leading to substantial economic costs due to non-productive workdays, healthcare system burdens, and decreased property values [1].

The Environmental Noise Directive (END) provides essential tools, such as Action Plans, to develop effective noise reduction measures by integrating local and regional actions as per Member States' regulations [2].

Despite the establishment of national noise limits, challenges persist in implementing these Action Plans effectively considering also national legal framework. Fragmented responsibilities and a decentralized approach often delay noise mapping and Action Plan execution. Additionally, the absence of common guidelines for prioritizing interventions hampers the development of uniform methods, leaving decisions to local authorities based on health impact assessments and public consultations [2].

While there is a growing body of research on health impact indicators for prioritizing interventions, the mitigation of multiple noise sources in complex scenarios, particularly outside urban areas, remains underexplored. There is a notable lack of interventions and pilot projects that provide practical, verified examples for infrastructure managers.

In Italy, the Ministerial Decree 29/11/2000 (DM 2000) establishes that in case of limits exceeding due to concurrent infrastructures, the operators must proceed to a joint execution of the noise remediation actions. This scenario is likely to be spotted in the case of parallel infrastructures e.g. a highway that runs parallel to a railway

line, very common along the Italian costal lines. However, this approach was never applied to real cases, also considering END requirements, due to a lack in the definition of accountability and the procedure to be followed.
The SILENT Project (Sustainable Innovations for Long-life Environmental Noise Technologies) [3] aims to address these issues by developing mitigation proposals for population exposure to noise in complex scenarios involving road and rail sources. This project will explore the current state of Remediation Plans, identify critical issues, and propose regulatory measures to establish measurable and replicable intervention procedures in complex acoustics scenarios.
The first step towards this goal is to experiment with a simple case study to understand the critical points to be solved.
In the present paper, the case study of Italy, Fano (PU) will be presented.

2. METHODS

The test site of Fano covers a total area of 0,9 km^2 with a total resident population of 621 inhabitants. The site was selected due to exceeding noise limits caused by the combined effect of road and railway sources. The two infrastructures run parallel for all the length of the test site as shown in Fig. 1.

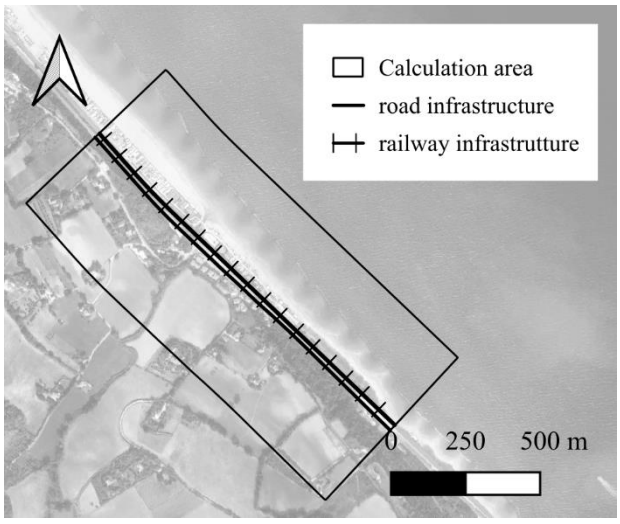

Figure 1. The test site of Fano.

According to the Italian law, when a regulatory limit exceedance is attributable to multiple sources, the relative responsibilities will be assigned by the calculation of the priority index (P_i) defined by DM 2000. The calculation starts by partitioning the total area of interest into several smaller areas in which the noise limits are uniform, the noise level does not change more than 3 dB (A), and the population distribution is the same. To obtain those A_i, the intersection between isophone areas (Figure 1), Census areas (Figure 2), and noise limits (Figure 3) must be done. In this way the priority index can be calculated as follows:

$$P_i = \sum R_i \, (L_i - L_i^*) \qquad (1)$$

Where R_i indicates the number of resident inhabitants in the area A_i. The A_i are the areas in which the values L_i and the limit L^*_i are constant. For each A_i, the value R_i is obtained by multiplying the surface by the population density provided by the corresponding census area.
In order evaluate relative responsibility in the case of concurrent infrastructures it is of pivotal importance to have homogenous noise exposure data.
GIS approach is mandatory in order to obtain the priority index Pi.
The first step is to obtain the required geospatial and traffic input data:

- Terrain model [4],
- Buildings layer (with heights),
- Census areas [5] (Fig. 2),
- Infrastructures' map,
- Traffic data.

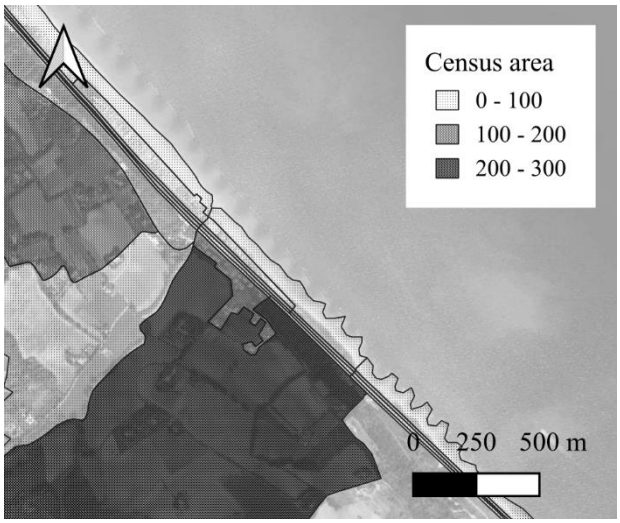

Figure 2. Number of residents per census areas in the test site of Fano.

Usually, all geospatial input information is provided by national or local authorities by open-data services. The unavailability of shared data can represent a significant issue in the process of identifying priority indices and subsequently undertaking shared acoustic mitigation paths.
The test site in Fano represents a case study in order to define a possible approach to overcome such problems.
The **building profiles**, lacking in public open data database, were extracted from OSM [6] and the height was extrapolated comparing the DTM and the Digital surface Model (DSM) provided by [4]. **Infrastructures' maps** and **traffic data** were provided by operators of the two infrastructures. This source of data is preferred to the OSM or other web service providers because it is more accurate in terms of number and exact location of the road lanes and railway lines.
ISTAT, the Italian National Institute of Statistics, provides **census areas** in shapefile (*.shp)* file format for all the municipalities with the number of people for different areas. From such information local population density can be computed. Finally, to calculate the required value R_i noise levels must be computed and compared with noise limits (Fig. 3).

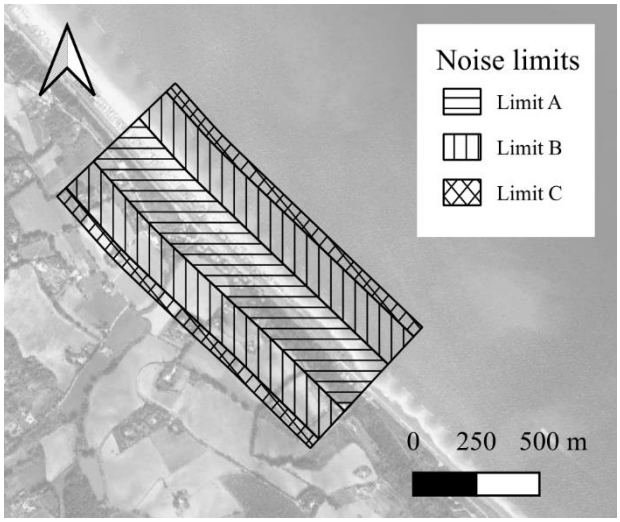

Figure 3. Noise limits for the test site of Fano.

With this aim, geographical and traffic data were used as input for commercial acoustic simulation software. The software allows us to calculate a noise map in accordance with the CNOSSOS-EU framework.

3. RESULTS

The present section will report the results for the test site of Fano. Noise simulation software produced a noise map for each infrastructure. In Fig. 4 the noise levels for the road infrastructure are reported as an example. The maximum calculated L_i overall is 79 dB (A), and the maximum for road and railways is 73 dB (A) and 79 dB (A) respectively.

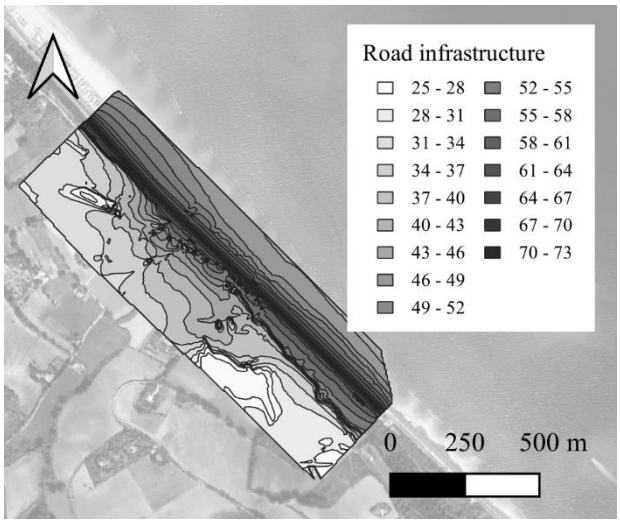

Figure 4. Noise isophones in dB (A) in the test site of Fano for the road infrastructure.

Those maps were then used to obtain the final A_i reported in Fig. 5 with the corresponding P_i value for the railway infrastructure. The results in terms of P_i for the test site of Fano are presented in Tab. 1.

Table 1. P_i calculated for the day (06-22) and night periods (22-06).

Source	P_i Day	P_i Night
Road	153	395
Railway	739	8564

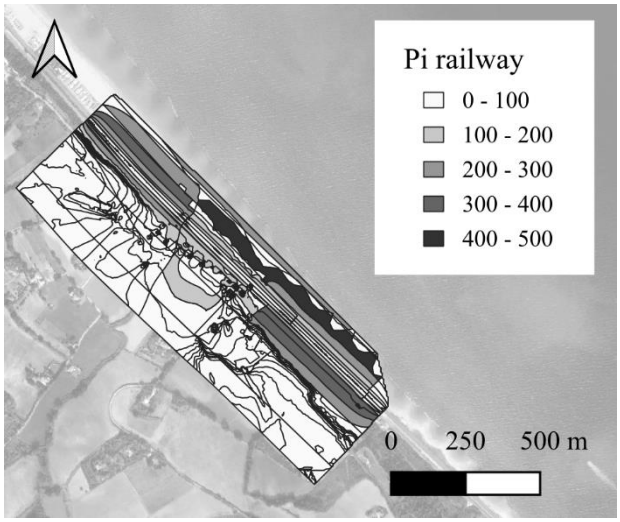

Figure 5. Priority values for the test site of Fano for railway infrastructure.

4. DISCUSSION

The results presented in Tab. 1 show that railway noise has higher priority both in the day and night period. The difference is more important during the night compared to the day, with a P_i for the railway almost 22 times bigger than the road one. This behavior can be ascribed to two independent causes: at night road traffic decreases consistently but railway traffic remains unchanged. At the same time noise limits L^*_i decrease by 10 dB (A) in the night period.

For the Italian regulation, both infrastructures would be remediated but they will be scheduled in different cycles of remediation plans due to the great difference in the priority levels. This causes an inefficient resolution of the concurrency, non-optimized spending and, in the worst case, an increase in population exposure. This could be the case of a noise barrier installed between the infrastructures to remediate the railway. The barrier, while remediating railway noise, will lead to an increase of almost 3 dB (A) of road noise due to unwanted reflection.

5. CONCLUSION

As we showed in this paper, Italian Regulation, especially the noise indices proposed, are not sufficient to resolve a (simple scenario with concurrent infrastructures like the case study of Fano (PU), where the two infrastructure runs parallel with no buildings in between and very few buildings in the calculation area, meaning little population affected by the traffic noise. The results underline the need for a different approach towards the resolution of complex scenarios. The Life SILENT Project will develop and test new indicators to better evaluate the concurrency and support the future remediation plan with more accurate and relevant information.

USING MICROPHONES IN OUTDOOR PASS-BY NOISE TESTING FOR VEHICLE SPEED MEASUREMENT

Fabio Lo Castro1* **Maria Luisa Ariza Alvarez[1]** **Massimiliano De Luca1**

ABSTRACT

In environmental noise pollution assessments, the Statistical Pass-By method (SPB, ISO 11819-1) is employed to evaluate different road surfaces based on their influence on traffic noise. It requires measuring the speed of heavy and light vehicles, with an error of less than 2.5 %, as they pass in front of and perpendicular to a Class I microphone, positioned 7.5 meters from the center of the road lane, along with the speedometer readings and the corresponding sound pressure levels (SPL). In this paper, we focus on evaluating the feasibility of using one or more microphones, instead of a speedometer and a video camera, to enhance performance in speed measurement, vehicle classification, vehicle counting, and sound pressure level (SPL) detection. The soundtracks used were recorded during the SPB measurements conducted along Highway A91 in Rome, Italy.

Keywords: *traffic noise, vehicle speed, road monitoring, sound measurement, microphone detection.*

1. INTRODUCTION

The accurate estimation of vehicle speed is a fundamental component of traffic management, urban monitoring, and road safety technologies. Traditionally, speed measurement has relied on radar, laser sensors, and video-based systems. However, these technologies often involve high costs [1]. In this context, passive acoustic sensing using microphones has emerged as a cost-effective and scalable alternative for vehicle speed estimation.

According to the Statistical Pass-By (SPB) method, which requires the use of microphones to measure sound pressure levels, a relevant question arises: can these microphones also be used to estimate vehicle speed through acoustic signal analysis? Specifically, two methodological approaches are investigated: a frequency-domain analysis, which exploits variations in the spectral components of recorded signals, and a time-domain analysis, which relies on signal amplitude and the time delay of signal arrival at multiple microphones to infer speed. The accuracy and error margins of both methods are evaluated and compared

Recent studies have demonstrated the potential of acoustic signal processing for vehicle speed estimation. For instance, a Doppler-based method employing spectrogram seam tracking was proposed to estimate vehicle speed from engine harmonics, achieving an average error between 0 and 10 km/h, with reduced accuracy at lower speeds (10–30 km/h) due to weaker Doppler shifts [2]. Similarly, multi-microphone arrays were utilized to enhance accuracy in dense traffic conditions [3].

Other studies, explored variations in noise levels as an indirect speed indicator, reporting errors of up to 17% at 50 km/h, improving to 8% at 120 km/h; however, it was concluded that the method does not meet the precision requirements of ISO 11819-1 [4].

In parallel, Doppler-shift techniques and various correlation-based methods within microphone arrays were reviewed to estimate traffic parameters [Borkar and Malik], while a high-resolution spectral method (AR-z spectrum) was proposed to detect harmonic signals in noisy environments, enhancing the identification of vehicular acoustic features [5].

The primary objective of this study is to determine which of the two proposed methodologies, frequency-based or time-domain analysis, yields the lowest error rate in speed estimation. To validate the accuracy of the proposed approach, simultaneous speed measurements were obtained using a laser-based sensor, providing a reliable reference for direct comparison with the results derived from acoustic signal analysis.

2. MATERIALS AND METHODS

2.1 Sound source description and models

The object of investigation is the speed of a vehicle as it passes in front of one or more microphones, as illustrated in Figure 1. The vehicle is assumed to have multiple acoustic sources. In the case of an internal combustion engine (ICE) vehicle, the primary sources of noise include the engine, typically located at the front of the vehicle, the exhaust system at the rear, tire and wheel noise from four or more contact points, and aerodynamic noise

The ICE vehicles dominate at lower speeds, but as speed increases beyond 40 km/h [6], road and tire noise (caused by rolling resistance, road surface texture, and tread pattern) becomes more prominent. Aerodynamic noise is considered significant when speeds exceed 100 km/h [7-8].
The spectrum of the ICE noise exhibits a fundamental frequency, f_0 (Eqn. 1) in the frequency range of 50 to 150 Hz [9], which is proportional to the number of cylinders, N, the firing frequency and its harmonics. These components are influenced by the engine's revolutions per minute (RPM) and the transmission gear ratios.

$$f_0 = \frac{N}{2}\left(\frac{RPM}{60}\right) \quad (1)$$

The Exhaust System Noise, due to the turbulent exhaust gas flow and muffler design, has a frequency range of 50 Hz to 3 kHz. The road/tire/wheel noise generates broadband noise starting from 125 Hz to 4 kHz, but is predominant at frequencies ranging from 500 to 2 kHz [10]. In electric vehicles, the electric motor noise is in the range of 1 kHz to 10 kHz [11]. It is quieter than an IC engine, but at speeds higher than 50 km/h the whole noise is comparable, if they mount the same tire size and model, due mainly to road/tire noise. Wind and Aerodynamic Noise Sources due to the Airflow around the vehicle, mirrors, and body gaps are in the frequency range of 500 Hz to 5 kHz. [12].
The model used to simulate the vehicle noise source is, as a first approximation, a moving monopole source with broadband noise attributed to tire–road interaction. This modeling choice is justified by the fact that not all recorded vehicle sounds in this study originate from ICE vehicles. Moreover, in some ICE vehicles, engine noise is significantly reduced due to improved acoustic insulation and vibration-damping engine mounts [13].

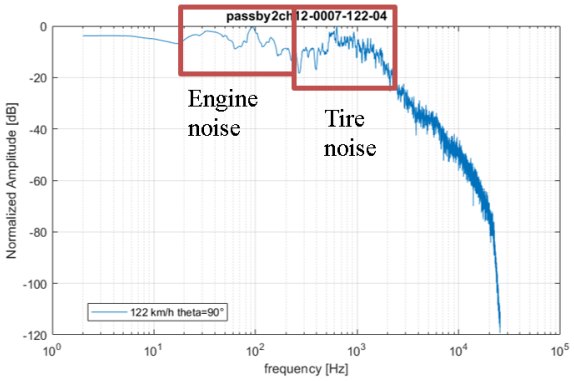

Figure 1. Example of a pass-by passenger vehicle normalized noise spectrum versus time.

2.2 Measurement set-up

Acoustic and speed measurements were conducted on the A91 highway in Rome, Italy, following the ISO 11819-1:2023 standard requirements. The highway consists of two lanes in each direction. For this study, two additional microphones were used for multisensor, located as illustrated in Figure 2.
Microphone M3 was placed 7.5 m from the centerline of the slow lane at a height of 3.0 m, while M1 and M2 were positioned 6.45 m from the centerline, also at 3.0 m in height. The distance between M3 and M1 (d_{13}) was 2.2 m, and the distance between M1 and M2 (d_1) was 1.9 m.
The microphones used were ½" Class I omnidirectional condenser microphones. Data acquisition was performed with a Sinus Apollo system, featuring four simultaneous acquisition channels, set to a sampling rate of 51,200 ksps.

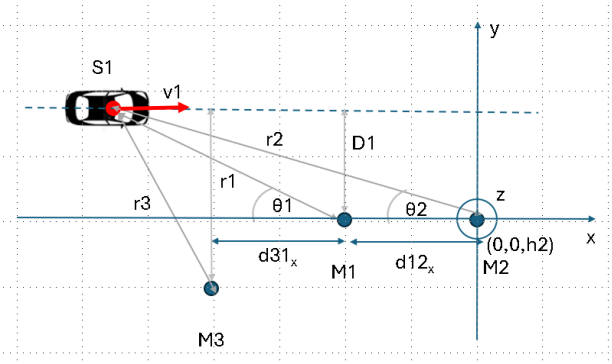

Figure 2. Measurement site and microphone positions; geometry of the problem, top view.

Vehicle speed was recorded using a SODI Scientifica KV Laser Statistic Analyzer, which provides an accuracy of ±1 km/h. This ensured precise speed measurements, allowing a reliable synchronization between noise levels and vehicle velocity, as required by the Statistical Pass-By (SPB) method.

The measurement site, located near the Smart Pole of the ANAS Smart Road project (PON-IR 2014-2020), was selected based on an inspection that ensured compliance with ISO 11819-1:2023 requirements. Particular attention was given to minimizing interferences from obstacles such as guardrails and road barriers, as their presence can alter sound measurements.

Tests were conducted at night when traffic density was lower, reducing the overlap of multiple sound sources and allowing a single vehicle pass-by. This also helped in ensuring that vehicles passed at a constant speed, preventing unwanted variations in noise levels and frequencies.

2.3 **Analysis methods**

In this study, both frequency-domain and time-domain analyses are employed for vehicle speed estimation. A single microphone (M3) is used for time- and frequency-domain analysis, leveraging sound pressure level (SPL) and the Doppler effect to estimate vehicle speed. Additionally, two microphones (M1 and M2) are utilized for time difference of arrival (TDOA) analysis to determine speed based on acoustic wave propagation delay. The inclusion of a third microphone (M3) enhances accuracy by precisely calculating the vehicle's distance from the microphones rather than relying on assumptions.

2.2.1 *Frequency-based analysis*

This approach utilizes variations in the spectral components of the acquired acoustic signal to infer vehicle speed, employing signal processing techniques.

Doppler shift and harmonic extraction

When a vehicle is moving relative to a fixed microphone position, the sound captured by the microphone presents changes in frequency content due to a Doppler effect. As the vehicle approaches, the sound is compressed, increasing its frequency; conversely, as it moves away, the frequency decreases. The frequency shift, $\Delta f = f(t) - f_0$, is measured in the spectrogram, generated by Short-Time Fourier Transform (STFT) or by the instantaneous phase (IF), obtained as the time derivative of the phase of the complex spectrum of the signal [14-15]. The source speed is estimated, as shown in Eqn. 2, based on the difference between the maximum and minimum detected harmonic's frequency.

$$|v_v| \cos(\theta) = \left(\frac{f_a - f_d}{f_a + f_d}\right) \qquad (2)$$

Where: f_a and f_d are the frequencies during vehicle's approaching and departure the CPA; θ is the vehicle's approach angle; v_v is the vehicle's constant speed.

The frequency variation respect to f_o usually is less the 11% at the maximum highway speed.

.

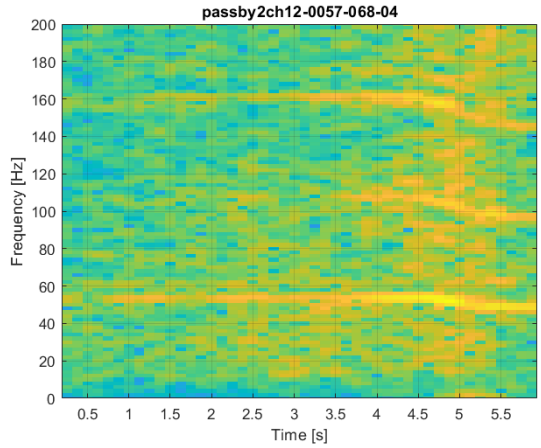

Figure 3. Example of a vehicle sonogram calculated using the STFT. The frequency variation of the engine harmonics due to the Doppler effect is observed.

To improve accuracy, engine harmonics are tracked, and spectral interpolation techniques are applied to refine signal variations [2].

2.2.2 *Time-Domain analysis*

In the time-domain analysis, two approaches were employed for vehicle speed estimation: one based on the measurement of sound pressure level over time, and the other on the time delay between signal arrivals at multiple microphones. In the first approach, the narrowing of the sound pressure level curve correlated with vehicle speed is used to estimate the speed. In the second method, correlation techniques combined with maximum likelihood estimation are applied to determine the time delay, which is then used to calculate the speed.

One microphone narrow envelope technique

This method relies on the observation that the sound pressure envelope of a passing vehicle exhibits a narrowing effect as vehicle speed increases [16]. This approach, which uses a single microphone, offers a low-cost and easy-to-deploy solution for traffic speed monitoring using minimal equipment, without requiring inter-sensor synchronization.

During the pass-by, the recorded acoustic signal shows a bell-shaped envelope centered around the vehicle's closest point of approach (CPA) (Figure 4). As the vehicle moves faster, the duration of this envelope shortens, resulting in a steeper and narrower profile.

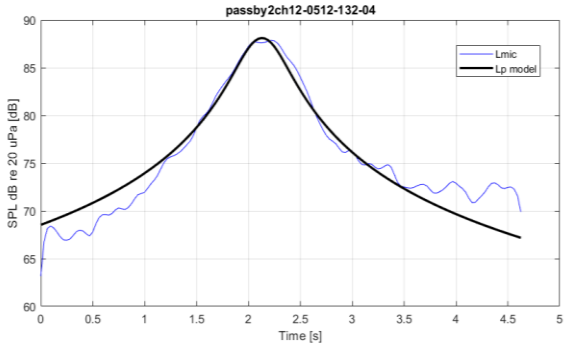

Figure 4. Sound pressure level recorded, Lmic, recorded at the microphone and curve modelled.

The sound pressure level, L_p, at the microphone can be written as:

$$L_p(t, v_0) = L_w - 8 - 20log_{10}(r(t, v_0)) + ID - A + n \quad (3)$$

Where: L_w is the sound power level of the vehicle; *r(t)* is the distance between the vehicle and the microphone changing in time; *ID* is the directivity index; *A* is the attenuation along the path; and *n* is the unwanted noise.

The distance between the microphone and the vehicle, which depends on time t and the vehicle's speed, v0, assumed constant during the measurement, can be expressed as:

$$r(t; v_0) = \sqrt{D^2 + \left(v_0(t - t_{CPA})\right)^2} \quad (4)$$

Where D is the perpendicular distance from the microphone when the vehicle is at the CPA at the time, t_{CPA}.

To mitigate the impact of variations in the distance between the vehicle and the microphone, amplitude normalization techniques and band-pass filtering are employed to eliminate low and high-frequency noise.

The signal has been analyzed in three frequency bands: (50–200) Hz, (500–3000) Hz, and (3000–8000) Hz, each corresponding to different sound sources as described in Paragraph 2.1. For each band, one or two sources were considered, located either at the center or at the front and rear of the vehicle, with corresponding modifications applied to Equation 4.

To determine the speed, v0, the vehicle speed v that minimizes the mean square error between the processed

recorded sound pressure level, $y(t)$, and the model $L_p(t,v)$ is calculated as follows:

$$\underset{v}{\text{Arg min}}\left(\frac{1}{T}\sum_{t=0}^{T}\left(y(t)-L_p(t,v)\right)^2\right) \quad (5)$$

The results obtained for each band have been averaged.

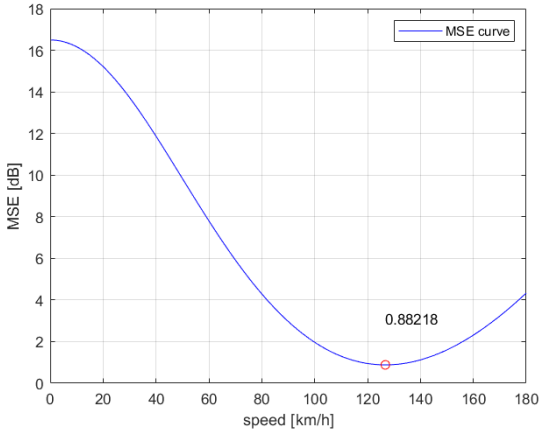

Figure 5. Curve of the mean square error of the Time Difference of Arrival (TDOA) estimation

Two-microphone technique and the Time Difference of Arrival (TDOA) estimation

In this method, at least two microphones are required to measure the TDOA, $\Delta\tau$, of the acoustic wave generated by the vehicle, positioned at a known distance, d. It is given by:

$$\Delta\tau(t) = \frac{r_2(t) - r_1(t)}{c} \quad (6)$$

Where r_1 and r_2 are the unknown vehicle distances from each of the two microphones, and c is the speed of sound. $\Delta\tau$ also represents the time delay between the acoustic signals received at each microphone. The received signals, $y_1(t)$ and $y_2(t)$, can be modelled as:

$$y_1(t) = h_1(t) * s(t) + n_1(t) \quad (7)$$
$$y_2(t) = h_2(t) * s(t-\tau) + n_2(t)$$

Were $s(t)$ is the source acoustic signal; $h_1(t)$ and $h_2(t)$ are the impulse responses from the instantaneous position of the moving vehicle and each microphone; $n_1(t)$ and $n_2(t)$ represent the unwanted signals, which also contain uncorrelated noise; τ is the delay of the second signal relative to the first signal, which is assumed to be the reference and not delayed. If the positions of the microphones are not sufficiently close to each other, the impulse responses cannot be simplified to an amplitude difference between the received signals.

Signal processing techniques are employed to identify similarities between signals captured by microphones, detecting the temporal offset between them. The maximum likelihood technique is applied, constructing a correlation matrix between microphone signals to identify the delay that maximizes correlation.

Due to the motion of the vehicle, the sound source is non-stationary, and thus the signal is also non-stationary. In this condition, the Least Mean Square (LMS) algorithm can be used to find the delay. However, if the process is considered quasi-stationary over a short time interval, this allows for the application of the Fourier transform, thereby enabling the use of the cross-correlation function, $R(t)$, defined as the product of the transformed signals [17], to estimate the delay

$$\underset{t}{\arg\max}\ (R_{ss}(t-\tau)) \quad (8)$$

By substituting Eqn. 4 into Eqn. 6 for each distance, r_1 and r_2, the vehicle speed can be determined. [3]. As the vehicle approaches the CPA, the values of τ change rapidly, and the FFT-based correlation may fail. In this condition, it is useful to apply a fitting function. We use the logistic tanh function (Figure 6) to model the delay behavior:

$$\tau(t) = a\tanh\left(b(t-c)\right) \quad (9)$$

Where a represents the delay when the vehicle is far from the microphone, c is the time corresponding to the CPA, and b is the slope of the curve, which is proportional to the vehicle speed.

$$v = b * D \quad \left[\frac{m}{s}\right] \quad (10)$$

Where, D is the perpendicular distance from the vehicle to the microphones at the CPA.

This method has proven particularly useful in dense traffic environments, where tracking individual vehicles may be unfeasible. Passive sound detection using a microphone array has been shown to capture the overall acoustic pattern of traffic across multiple reference points [18].

By applying cross-correlation algorithms to the collected signal, the average vehicle speed within specific lanes can be estimated. Unlike Doppler-based methods, passive detection does not rely on a single vehicle's emitted signal but rather on the overall acoustic pattern of traffic, increasing its applicability in complex urban conditions.

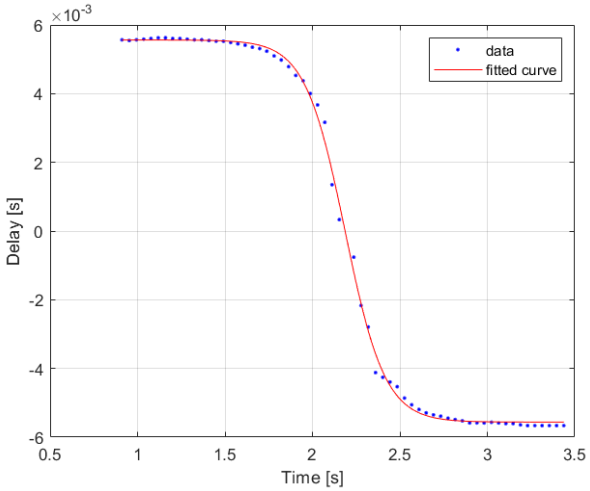

Figure 6. Signal time difference of wave arrival (blue dotted), and the fitting function.

3. RESULTS AND DISCUSSION

For speed calculation and accuracy evaluation, over 400 valid events were recorded, and the measured speeds were associated with these events. The distribution of the vehicle speed is shown in Figure 7. In each pass-by, only one vehicle was present, no vehicles in the other 3 lanes, and the difference between the maximum level during pass-by and the minimum before another pass-by was greater than 6 dB.

The classification was based only on vehicle type (passenger or heavy vehicles), without distinguishing between EVs and ICE vehicles.

Applying the different signal processing techniques, explained in the previous paragraph, to the recorded audio signals to estimate the vehicle speed, the results are summarized in Table 1 and Table 2.

Considering the increasing number of microphones from one to three, there is little improvement in the spread of the measured values from 10.0 km/h to 8.6 km/h. If it is considered the same number of two microphones, the method based on TDOA exhibits a better standard deviation from 8.9 km/h to 8 km/h.

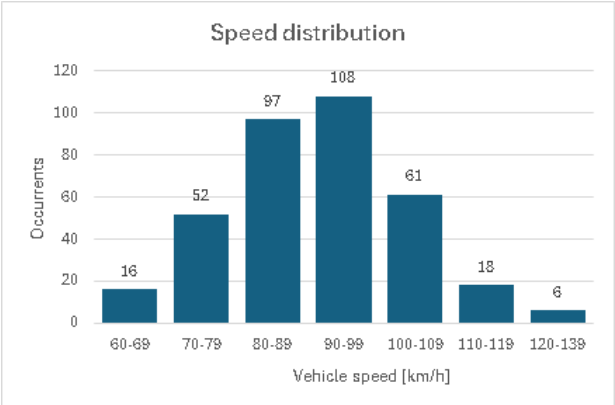

Figure 7. Vehicle speed distribution, measured with laser instrumentation.

The values at the extremes of the tables are not considered reliable due to the limited number of measured velocity cases in those ranges.

130-139	-3.7	n.d.	-4.9	4.9
Global	0.5	7.7	4.1	8.0

The high standard deviation observed in the speed evaluation is primarily attributed to limitations in the automatic processing. In the case of the SPL envelope-based methods, the model often fails to align accurately with the measured signal when the envelope's peak is flat rather than sharply defined, as assumed by the model. For the TDOA method, the error arises near the point of inversion of the time difference of arrival, where the fitting procedure may fail due to a limited number of data points or inaccuracies in their evaluation.

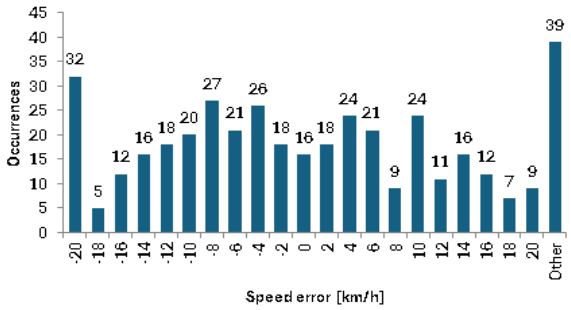

Figure 8. 1-Mic SPL envelope-based speed estimation method distribution error.

The distributions of the speed estimation error for the 1-mic SPL envelope-based and 2-mic TDOA are shown in Figure 8 and Figure 9. Although the standard deviation is higher for the first method, the failure rate, labeled as 'Other' in the figures, is lower than that of the second method, suggesting greater robustness.

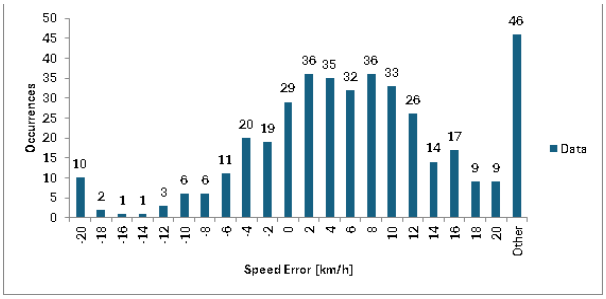

Figure 9. 2-Mic TDOA speed estimation method distribution error.

The other 2-mic method shows the same robustness, while the 3-mic method is the least robust method, with 61/401 fails.

4. CONCLUSIONS

In this study, a database of acoustic events, recorded during measurement sessions conducted in accordance with the ISO 11819-1 standard, was first established. Each event, corresponding to a single vehicle pass-by, was classified by vehicle type, either as a passenger vehicle or a heavy truck. This database was subsequently used to evaluate five elementary methods for estimating vehicle speed based on the pass-by sound generated by the vehicle itself. Four of these methods operate in the time domain, while one is based on frequency-domain analysis.

The uncertainty associated with the estimated values remains relatively high compared to other methods reported in the literature. This is primarily due to occasional failures in automatic processing, where the model fitting does not adequately match the measured data. Further studies are currently underway to address these issues and enhance the performance of the proposed algorithms

ABSTRACT

As part of the LIFE SILENT project[1] (focused on developing innovative and eco-friendly solutions for noise mitigation in road and railway contexts - innovative materials and advanced technologies are being explored to design Low-Height Noise Barriers (LHNB) with enhanced acoustic properties and a significantly reduced environmental impact. For this scope a comparative Life Cycle Assessment (LCA) was conducted to evaluate the environmental impacts of different typologies of LHNBs.
The LCA focused on the production phase ("from cradle to gate") of three LHNB solutions, analysing their material composition and overall environmental performance. Solution 1, the STRAILastic barrier, incorporates recycled rubber, which significantly reduces its Global Warming Potential (GWP) compared to barriers made mainly of virgin materials. Solution 2, composed primarily of reinforced concrete and recycled rubber, and Solution 3, including steel, aluminium, and PET foam which both exhibit higher environmental impacts due to the predominant use of high-emission materials such as concrete and aluminium.
The study highlights the crucial role of integrating recycled materials in reducing environmental impacts and underscores the need to optimize designs to minimize the use of high-impact components. This standardized LCA approach provides a comprehensive framework for assessing and fostering sustainable practices in noise mitigation infrastructure.

Keywords: *Life Cycle Assessment, Low-Height Noise Barriers, Environmental Impacts, Recycled materials, Acustic performance*

1. INTRODUCTION

The aim of this study is to design an innovative Low Height Noise Barrier (LHNB) made from recycled materials, with improved acoustic properties thanks to the implementation of metamaterial technology. Furthermore, the last step of this work package is to test a new LHNB prototype in a controlled test environment (laboratory or similar) and characterise its acoustic performance.
As the metamaterial technology is applicable to any material, it is essential to start with a material capable of guaranteeing the best environmental sustainability. In turn, this can be demonstrated by evaluating the most important Key Performance Indicators (KPIs) of the environmental impact of any material. This evaluation must be done in a systematic way, following a standardized method in order to ensure an objective and accurate understanding, based on objective data. Several methods of this kind exist, but the most widely accepted are reducible to the Life Cycle Assessment method (LCA) codified in some international standards [[1],[2],[3],[4]]. LCA is a quantitative approach that follows a systematic method to study and compare the impacts of products and systems throughout their life cycle.

In the current study the GWP (Global Warming Potential) category is quantitatively evaluated, also considering the EU "net zero" objectives, aimed at urgently reducing greenhouse gas emissions.
Therefore, the objective of this study is to demonstrate, through a comparative Life Cycle Analysis (LCA) focused on the production phase (A1-A2-A3) and based on sustainability criteria, that the selected low-height noise barrier (Strailastic msw360), thanks to the use of recyclable materials, is capable to minimize the GWP environmental impact compared to the other low-height noise barriers available on the market. Moreover, this highlights important sustainability considerations in the design and implementation of the analysed products.
Through the application of the Life Cycle Assessment (LCA) methodology in the "*from cradle to gate*" phase, we were able to assess the impact of the different components of the barriers, identifying the solutions that most effectively minimize environmental impacts.
From the preliminary sustainability assessment conducted on the Strail LHNB, compared to two other types of LHNB, it emerges that the LHNB supplied by Strail represents the solution that most effectively minimizes environmental impacts.
The presence of recycled rubber in the composition of the Strail barrier has contributed significantly to reducing the overall environmental impact compared to the exclusive use of virgin materials. This highlights the positive potential of recycling and reusing materials to mitigate environmental impact, while also providing a sustainable solution for waste management.

2. OBJECTIVES AND SUCCESS CRITERIA

The LCA methodology allows the quantification of the impacts of a product or process, and in this study, it will be used to evaluate, analyse and compare the impacts of the Strail low-height noise barrier with two other low-height noise barriers currently available on the market [5].
LCA is a quantitative approach that follows a systematic method, regulated by international ISO standards [[1],[2],[3],[4]], to study and compare the impacts of products and systems throughout their life cycle. It is essential to have a quantitative sustainability assessment tool in order to ensure an objective and accurate understanding, based on objective data.
According to the current ISO reference standard regulations, an LCA study consists of the following phases, which will be further detailed in the following sections.

1. Goal and scope definition: preliminary phase where the study's objectives, declared unit, boundaries of the system studied and assumptions are defined;
2. Inventory analysis: quantification of input and output flows for all analysed processes;
3. Impact assessment: aggregation of inventory results, with scientific models, into a number of potential environmental impacts;
4. Interpretation: analysis of the results obtained in order to draw conclusions.

The four steps of a life cycle analysis are interrelated, making the whole process iterative (**Errore. L'origine riferimento non è stata trovata.**). Each phase is based on the results obtained in the previous phase, thereby promoting the completeness and coherence of the study. If there is a need to integrate further information in a previous step or to revise the initial settings, any changes are also carried over to the subsequent levels of the analysis.

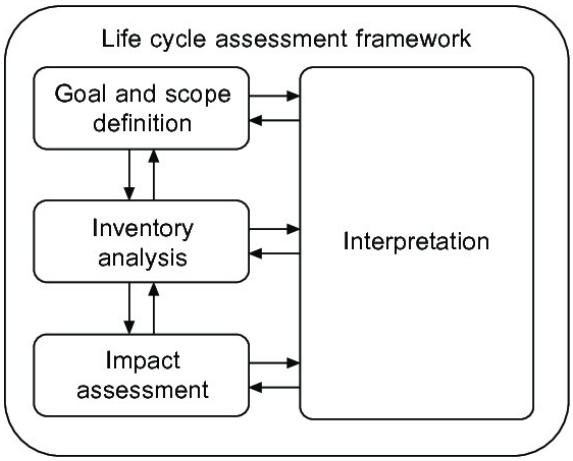

Figure 1. LCA phases according to ISO 14040/14044

Life cycle analysis approaches provide various perspectives for assessing the environmental impact of a product or system over time. These include the assessment of the entire life cycle, from production to disposal (Cradle to Grave), adopting circular practices that allow for the complete reuse of materials (Cradle to Cradle), and focusing on the initial stages of the life cycle until the product is ready for use (Cradle to Gate). These approaches offer complementary perspectives for understanding and addressing the challenges related to the sustainability of products and industrial processes.

The success of this study is demonstrated by the successful completion of the LCA analysis of the Strail low-height noise barrier and two main competitors.

3. GOAL AND SCOPE DEFINITION

The LCA analysis in question focuses on assessing the environmental impacts of the Strail low-height noise barrier, compared to two competing products currently available on the market. In this study, the life cycle analysis was conducted 'from cradle to gate', considering all stages of the product life cycle from the production of raw materials to the manufacture of the noise barriers. This approach allowed us to comprehensively evaluate the environmental impact of different types of noise barriers until they are ready for installation.
In the comparative study of the three LHNBs, it is important to note that the analysis focused exclusively on the materials constituting the sound-insulating part of the barriers themselves. Support and anchoring structures of the barriers, which may include elements such as steel and reinforced concrete, as well as packaging and packing processes, were deliberately excluded from the assessment.

Declared unity
The unit declared examined, against which all the quantitative input and output data collected in the study are calculated, is the production of 1 linear meter of noise barrier.

System boundaries
The modules for which the environmental impact of barriers is quantified in this study are the following:

- A1: Procurement of raw materials for barriers production;
- A2: Transportation of raw materials for barriers making;
- A3: Processing of raw materials to obtain the barriers.

Data quality and Impact Assessment Methodology
The study uses generic secondary data from the Environmental Footprint 3.1 databases [6], which is part of the broader Ecoinvent 3.10 database [7]. The data, representing the period 2020-2023, reflect both European and global contexts. Impact assessments are conducted using OpenLCA 2.0.0, applying the "Environmental Footprint (Mid-point indicator)" method to evaluate Global Warming Potential (GWP) as a key performance indicator (KPI).

4. INVENTORY ANALYSIS

Inventory analysis is the most crucial phase of an LCA study. It involves collecting data to quantify the inflows and outflows from the system during its life cycle in relation to the declared unit. Inputs include the use of natural resources, materials, and energy while Outputs include emissions to air, water and soil associated with the system and the generated waste.
Once the processing is complete, the sum of inputs and outputs for each unit process yields the "inventory," which is a catalogue of all mass and energy flows entering and leaving the system.
The environmental impacts of the secondary data used in the analysis are automatically counted by selecting the material to be modelled from the databases used, which already contain all the information from its supply chain, from raw materials extraction to production.
Below are all the technical specifications considered in the inventory analysis of the barriers considered.
The Strail Barrier will be identified as “Solution 1”, while the other two barriers will be referred to as “Solution 2” and “Solution 3”.

4.1 Solution 1: STRALastic_mSW 360

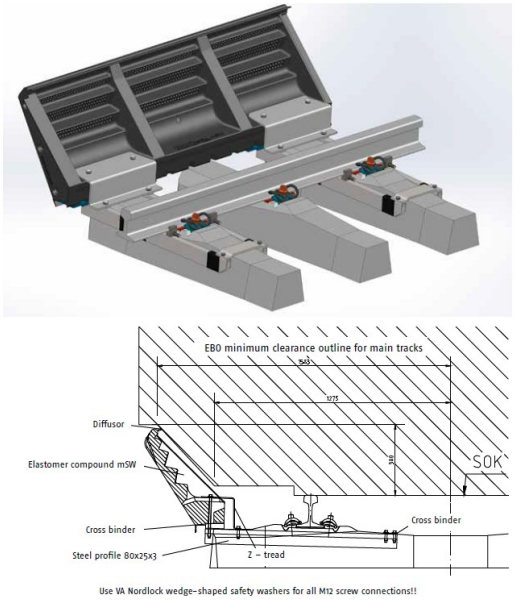

Figure 2. STRAILastic_Msw 360

Barrier Module: length 1.8 m, height 0.53 m and thickness 0.30 m.

Weight of recycled material 61,564 kg per 1,8m of length (data provided by Strail), which is approximately 34,202 kg/m.
Weight of virgin material 58,605 kg per 1,8m of length (data provided by Strail), which is approximately 32,558 kg/m [8].
The processes used are summarized in the following Table.

Table 1. Processes Used in STRAILastic_mSW 360 Low Height Noise Barrier Definition

	Database	Process	Amount [kg/m]
Recycled Material	Strail Self Calculation	Buffering meal retreading (Waste tire industries)	3,801
	Strail Self Calculation	Rework STRAIL shredded & broken (old used panels)	4,881
	Strail Self Calculation	Roughing Rubber meal (waste tire industry)	4,881
	Strail Self Calculation	Rubber granules (waste tire industry)	20,641
Virgin Material	Ecoinvent 3.10	Grinding sulphur Sodium silicate production, spray powder, 80%	1,318
	Ecoinvent 3.10	Stearic acid Chloropropionic acid	0,133
	Ecoinvent 3.10	MBTS 2-methyl-2-butanol production	0,079
	Ecoinvent 3.10	ZBEC market for dithiocarbamatePro-compound	0,052
	Ecoinvent 3.10	Plasticizer oil Softener rubber production	1,929
	Ecoinvent 3.10	Latex latex production	0,502
	Ecoinvent 3.10	New rubber layer (DP 1350x2,5) market for seal, natural rubber based	11,772
	Ecoinvent 3.10	New rubber layer (DP high light protection 3,0x960D300DPU) market for synthetic rubber	16,772

4.2 Solution 2

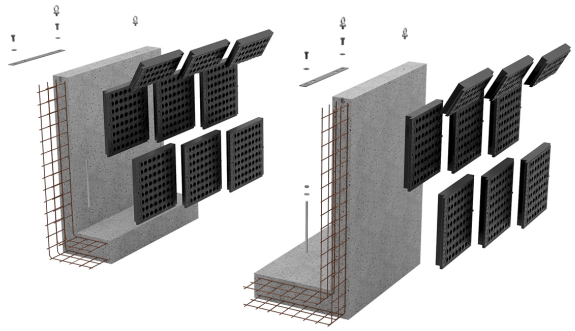

Figure 3. Representative image of Solution 2

Barrier Module: length 1,0 m, height 0,67 m and thickness 0,20 m.
Assuming that the thickness of this barrier is made up of 0,15 m of reinforced concrete and 0,05 m of recycled rubber, we have:
Volume of reinforced concrete = 1,0 m × 0,67 m × 0,15 m = 0,1005 m^3
Weight of reinforced concrete = Density of concrete (average 1400 kg/m^3) × Volume ≈ 140,07 kg (assuming a weight of 14 kg for steel and 6 kg for construction timber)
Volume of recycled rubber per meter = 1,0 m × 0,67 m × 0,05 m = 0,0335 m^3
Weight of recycled rubber per meter = Density of recycled rubber (average 800 kg/m^3) × Volume ≈ 26,8 kg
The processes used are summarized in the following Table.

Table 2. Processes Used in the definition of solution 2

Database	Process	Amount [kg/m]
Ecoinvent 3.10	Recycled Rubber - market for waste rubber, unspecified	26,8
Environmental Footprint 3.1	Concrete C20/25 (Ready-mix concrete), production mix, at plant, technology mix, C20/25	140,07
Environmental Footprint 3.1	Reinforced steel (wire), production mix, at plant, EAF route, wire	14,0
Environmental Footprint 3.1	Solid construction timber (softwood) (EN15804 A1-A3), production mix, at plant, technology mix, 529 kg/m3 at 15% moisture	6,0

4.3 Solution 3

Figure 4. Representative image of Solution 3

Barrier Module: length 2,04 m, height 1,04 m and thickness 0,24 m.
Total module weight 150 kg.
Therefore, the weight per meter of barrier is about 75 kg/m.
It is assumed:
Steel weight ≈ 40,0 kg
Aluminium weight ≈ 25,0 kg

PET foam weight ≈ 10,0 kgnot modify headers, footers or page numbers in your submission. These will be added electronically at a later stage, when the publications are assembled.
The processes used are summarized in the following Table.

Table 3. Processes Used in the definition of solution 3

Database	Process	Amount [kg/m]
Environmental Footprint 3.1	Reinforced steel (wire), production mix, at plant, EAF route, wire	40,0
Environmental Footprint 3.1	Aluminium foil , single route, at plant, primary production, 2.7 g/cm3 - EU-28+EFTA	25,0
Environmental Footprint 3.1	Polyurethane rigid foam, production mix, at plant, from methylene diisocyanate (MDI) and polyols, 18- 53 kg/m3 - EU-28+EFTA	10,0

5. IMPACT ASSESSMENT

Impact assessment is the phase where the inputs and outputs, reported in the inventory, are translated into potential environmental impacts. The environment is a complex system of physical, chemical and biological factors, living and non-living elements, and relationships in which all the organisms that inhabit the planet are immersed, where any variation of one of these components affects the whole system. Therefore, to study such a complex reality, the LCA methodology involves the compartmentalization of the entire environmental system into a limited number of impact categories.
Each impact category is determined by a different reference unit that allows quantifying the impact following classification and characterization operations.

Classification
The classification is a qualitative step in which emissions from modelled elementary flows, collected in the inventory, are associated with the impact categories according to the potential environmental effects. It answers the question "what does this emission contribute to"?

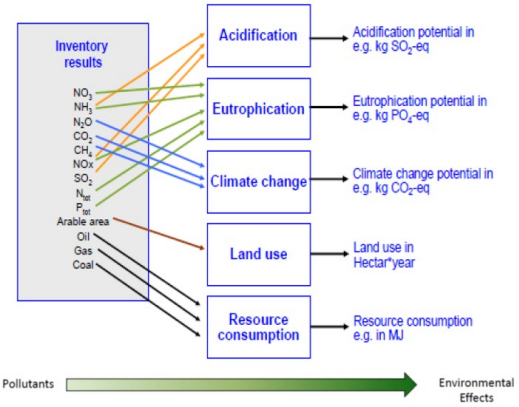

Figure 5. Example of classification of some substances (JRC Scientific and Technical Reports) [9]

Characterization
Characterization allows quantifying the contribution of different elementary flows within an impact category. It answers the question "how much does this emission contribute to the impact compared to the others?". The environmental impacts assessment was carried out through the *"Environmental Footprint (Mid-point indicator)"* impact assessment method. In the current study, we will consider only the GWP (Global Warming Potential, reference unit kg CO_2 eq.) category, also considering the EU "net zero" objectives, aimed at urgently reducing greenhouse gas emissions.

We will examine the results of the LCA analysis conducted on different types of noise barriers. Through a critical and in-depth analysis of these results, we will provide a clear and informative view of the environmental impact of the available options and the contribution of specific materials that compose them.
At the end of our research, we aim to conduct an in-depth comparative analysis of the different solutions examined to identify the most sustainable and least impactful from an environmental point of view. Through this process, we aim to provide a comprehensive and objective assessment of the options available, allowing for an informed and conscious choice in line with sustainability principles.

5.1 Results of the STRAILastic_mSW 360 Analysis (Solution 1)

The results obtained from the LCA analysis for the Strail barrier are represented through the following bar chart that shows the LCA modelling process of the barrier with the respective contributions of the materials that compose it.

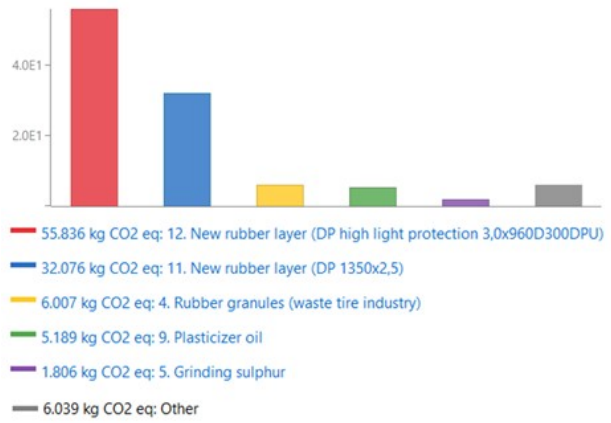

Figure 6. GWP Contribution of the materials composing the "Solution 1: Strail" (OpenLCA)

Based on the results of the LCA analysis conducted on the Solution 1 Strail barrier, composed of a combination of recycled rubber and virgin rubber, it is evident that the significantly more impactful components in terms of Global Warming Potential (GWP) are those related to the production of virgin rubber. These results unequivocally underline the importance of recycling and reusing materials in the design and production of infrastructure such as noise barriers.

5.2 Results of the SOLUTION 2 analysis

The results obtained from the LCA analysis for the Solution 2 are represented through the following bar chart that shows the LCA modelling process of the barrier with the respective contributions of the materials that compose it.

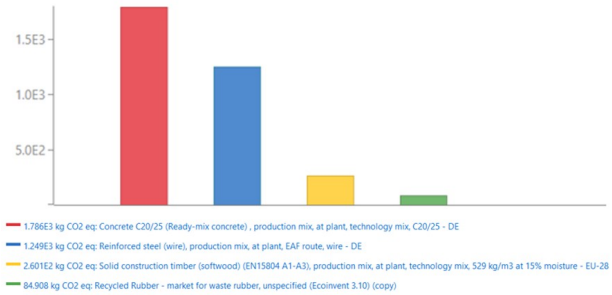

Figure 7. GWP Contribution of the materials composing the "Solution 2" (OpenLCA)

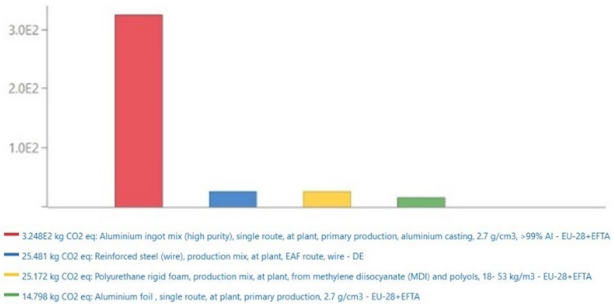
Based on the results of the LCA analysis conducted on the "Solution 2", composed mainly of reinforced concrete with a reduced percentage of recycled rubber, it is clear that the most impactful component in terms of Global Warming Potential (GWP) is the reinforced concrete. It is important to note that despite the use of recycled material, the substantial presence of reinforced concrete has a significant impact on the overall environmental impact of the barrier.

5.3 Results of the SOLUTION 3 analysis

The results obtained from the LCA analysis for the Strail barrier are represented through the following bar chart that shows the LCA modelling process of the barrier with the respective contributions of the materials that compose it.



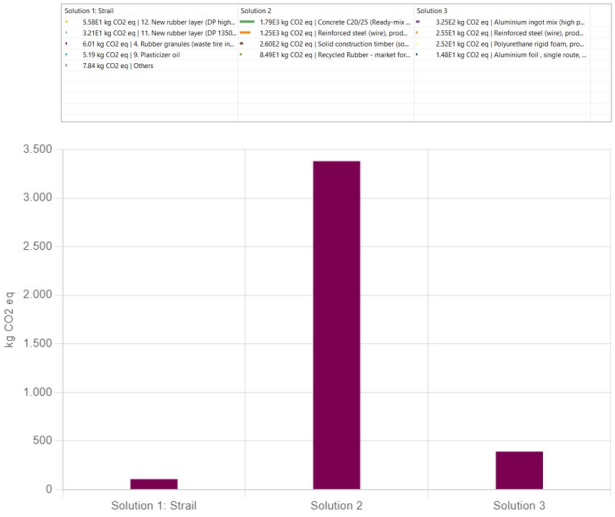


Figure 8. GWP Contribution of the materials composing the "Solution 3" (OpenLCA)

Based on the results of the LCA analysis conducted on the "Solution 3", composed of steel, aluminum and PET foam, it reveals that aluminum has the most significant impact in terms of Global Warming Potential (GWP), while steel and PET foam have very similar CO2 equivalent quantities.

5.4 Results of Comparative Analysis

After examining the impacts associated with the Global Warming Potential (GWP) component of the three low-height noise barriers, the results of our comparative analysis are presented in Figure 14 to identify the solution that best fits the environmental sustainability criteria defined by this indicator.

6. CONCLUSIONS AND RECOMMENDATIONS

In conclusion, this study provided an in-depth analysis of the environmental impact of different types of noise barriers, highlighting important sustainability considerations in their design and implementation.

Through the application of the Life Cycle Assessment (LCA) methodology in the "*from cradle to gate*" phase, we were able to assess the impact of the different components of the barriers, identifying the solutions that most effectively minimize environmental impacts.

From the preliminary sustainability assessment conducted on the three solutions of noise barriers, the LHNB supplied by Strail represents the solution that most effectively minimizes environmental impacts.

The presence of recycled rubber in the composition of the Solution 1 Strail barrier has contributed significantly to reducing the overall environmental impact compared to the exclusive use of virgin materials. This highlights the positive potential of recycling and reusing materials to mitigate environmental impact, while also providing a sustainable solution for waste management.

Although the use of recycled materials is essential, it is necessary to consider the overall contribution of predominant high-emission materials (such as reinforced concrete in the Solution 2 and aluminium in the Solution 3) that can contribute significantly to the overall environmental impact. This highlights the importance of considering not only the presence of recycled materials, but also the overall composition and relative amount of each material within the final product when assessing environmental impact. The high impact of these materials underscores the importance of carefully examining alternatives during the design process to reduce the overall environmental impact of these barriers. This may include identifying substitute materials or optimizing the design to reduce the use of high-emission materials.

This study represents a significant step towards a deeper understanding of the environmental implications associated with LHNBs, providing a solid basis for future development in the design of more sustainable barriers. We are confident that the results and conclusions drawn can influence and guide informed and responsible decisions in the context of environmental sustainability, thus contributing to promoting positive progress towards a future characterized by greater environmental respect and fairness for future generations.

ABSTRACT

This paper shows LIFE SILENT project – WP5, a European Community co-financed project which aims to find sustainable and eco-compatible solutions to reduce noise in complex urban situations, where different noise sources are present (especially roads and railways) in densely inhabited areas. The described activities are related to the project phase of developed solutions and to the following implementation in the test site which has been identified between the city of Rome and its international airport: a major highway and a primary railway are located very close to each other, and a hospital is just between them. The solutions which are been chosen are "at source" mitigation: a noise-reducing asphalt for the highway and a Low Height Noise Barrier (LHNB) for the railway. They will be further adapted to the specifics of the test site.
Nowadays, a noise measurement campaign has been completed, in order to identify the current sound levels at various receivers.

Keywords: *noise, railway, roads, mitigation.*

1. INTRODUCTION

According to the World Health Organization, 20% of the European population is exposed to noise levels above 65 dB(A) during the day [1]. Reducing noise levels is particularly complex in urban environments, where various noise sources coexist. In such contexts, noise mitigation generally excludes the use of solutions that could interfere with the urban context, such as traditional noise barriers, for many reasons, such as the proximity of receptors to the noise source, visual impact, etc.
To achieve these goals, the LIFE SILENT project [2][3] involves the development of innovative and sustainable noise-reducing pavements for road infrastructure and low-height noise barriers (LHNB) for railway infrastructure and testing in a test site, in order to provide transport infrastructure managers with information to support the dissemination of these technological solutions.

2. INNOVATIVE SOLUTIONS

Regarding noise-reducing pavements, during the LIFE SILENT project, the solution developed in the IASNAF [4] project will be optimized. It consists of a sustainable low-noise mixture enriched with functionalized cellulose fibers of plant origin, by replacing them with waste materials (packaging and textiles) to make the process more sustainable.
As for the low-height noise barrier (Fig. 1), it will be made with recycled materials appropriately shaped based on recent results in the field of metamaterials to achieve better sound-absorbing performance and greater durability. The proposed solution, thanks to its reduced height, will provide significant landscape integration, thus reducing the visual impact usually attributed to traditional noise barriers while maintaining acoustic effectiveness to be quantified based on boundary conditions.

Figure 1. Example of a low-height noise barrier (LHNB).

3. TEST SITE

The solutions developed and tested in the laboratory will be implemented in a test site located in a densely populated area (Muratella, Rome, Italy), which includes both roads and railways at close distance (see Fig. 2).

Figure 2. LIFE SILENT project test site.

Specifically, the identified area, which has about 150,000 inhabitants, is crossed by the Roma-Fiumicino airport railway line managed by RFI and the A91 highway managed by ANAS. The railway line is characterized by passenger traffic of over 70,000 trains/year with a maximum speed of 110 km/h, while the A91 highway is characterized by traffic flow of about 72,000 vehicles/day.
The pilot area mainly consists of residential buildings with 3-4 floors above ground at a short distance from the railway and highway. Additionally, there is the San Giovanni Battista hospital (see Fig. 3), located between the A91 highway and railway line.

Figure 3. San Giovanni Battista Hospital (aerial view).

According to the European Environmental Noise Directive 2002/49/EC (END), both infrastructures in the area must be acoustically mapped every five years and an Action Plan must be drawn up to define strategies and solutions to mitigate noise levels at receptors. The RFI Noise Remediation Plan (updated 2018), which also incorporates Action Plans, currently provides for two noise barriers in the investigation area measuring 385 and 704 meters long and 4 and 5 meters high along the railway line.
The mitigation measures provided by ANAS's Action Plan include noise-reducing pavement for an extension of 1.9 km and direct interventions at receptors. Additionally, there is already a 3-meter high noise barrier along the highway on the north side.

4. IMPLEMENTATION OF DEVELOPED SOLUTIONS

Prior to implementing developed solutions in the identified pilot site, some ex-ante evaluations will be carried out to set reference values against which to evaluate overall performance of new pavement and noise attenuation introduced by LHNB.
Specifically:

- Acoustic measurements of road pavements using Statistical Pass-by (SPB) [5] and Close Proximity (CPX) [6] techniques based on ISO 11819 standard to evaluate influence of existing pavement on traffic noise and calibrate source model. This evaluation will be carried out using Urban Pass-By Method developed within LIFE NEREiDE [7] project;
- Noise level measurements at receptors according to DM 16/03/1998 to calibrate propagation model;
- Texture and mechanical impedance measurements of road surface according to UNI CEN 13036-1 [8] and UNI EN ISO 7626-5 [9];
- Annoyance measurements of exposed population according to guidelines developed within LIFE NEREiDE project through psychoacoustic and social surveys. Zwicker descriptors defined by ISO 532-1 [10] and DIN 45692 [11] will be evaluated to determine psychological and physiological response of exposed population in terms of annoyance.

Based on inputs from measurement campaign, acoustic model will be calibrated and various scenarios simulated to map overall noise level and contributions from individual noise sources.
To facilitate monitoring of road section and make results robust and reliable over long term, pilot area has been equipped with DYNAMAP system [12], an automatic system capable of continuously measuring noise levels

and providing real-time acoustic maps developed within LIFE Dynamap project.
The sensor has been installed on a vertical road sign pole close to the A91 motorway and in proximity to the San Giovanni Battista Hospital (see Fig. 4).

Figure 4. Dynamap sensor installation.

Then follows a design phase supervised by road and railway infrastructure managers to ensure appropriate safety standards during which developed solutions will be adapted to specific test site requirements. A co-design approach will also be promoted to ensure citizen participation in development of these solutions for easier acceptance.

Finally, noise-reducing pavement will be laid along a highway section measuring 1.9 km and low-height noise barrier (LHNB) will be installed along a railway section measuring 200 m.

5. CONCLUSIONS

Preliminary activities are currently underway for developing identified innovative solutions and planning field activities for LIFE SILENT project.

5.1 Measurements of road pavements

Measurements using the Statistical Pass-By Method were carried out in January and February 2025, in a site close to the San Giovanni Battista Hospital near a Smart Pole of the Anas Smart Road project (see Fig. 5).
Measurements of the acoustic emission due to tyre/pavement interaction by means of Close-ProXimity (CPX) method, instead, were organized on 2-3 July 2024. The CPX measurements were carried out in the slow and fast lanes of both carriageways, eastbound towards Rome centre and westbound towards Fiumicino.

Figure 5. Statistical Pass-By set-up measurement.

For each road section investigated, at least three acquisition runs were carried out at the reference speed of 80 km/h.
On the road sections investigated there were different porous pavements, called in this report Ante Operam 1 (AO1), Ante Operam 2 (AO2) and Ante Operam 3 (AO3). Fig. 6 shows the instrumented vehicle used in the measurements.

Figure 6. CPX instrumented vehicle

In Table 1 the results obtained for the road sections investigated are shown. The reported LCPX values

represent the spatial average value over the section considered. For each of the investigated pavements, both the average LCPX level value for each run and the final average over all acquired runs are reported.

Table 1. Results obtained for the investigated pavements at the reference speed of 80 km/h.

Pavement	Lane	speed [km/h]	Run	East Direction		West direction	
				L_{CPX} for run [dB(A]	L_{CPX} (Average) [dB(A]	L_{CPX} for run [dB(A]	L_{CPX} (Average) [dB(A]
AO1	Slow	80	1	99.4	99.4 ± 1.0	99.6	99.8 ± 1.0
			2	99.1		99.8	
			3	99.8		100.0	
			4	99.4		96.0	
AO2	Slow	80	1	96.4	96.2 ± 1.2	96.1	96.0 ± 1.0
			2	95.5		96.0	
			3	96.3		101.5	
			4	96.5		101.6	
AO3	Slow	80	1	100.7	100.5 ± 1.1	101.4	101.5 ± 1.0
			2	100.6		97.8	
			3	100.7		98.1	
			4	99.9		98.1	
AO1	Fast	80	1	98.2	98.2 ± 1.0	95.7	98.0 ± 1.0
			2	98.2		95.6	
			3	98.2		95.7	
AO2	Fast	80	1	95.1	95.2 ± 1.0	102.3	95.7 ± 1.0
			2	95.3		102.1	
			3	95.1		102.2	
AO3	Fast	80	1	100.5	100.3 ± 1.0	99.6	102.2 ± 1.0
			2	100.1		99.8	
			3	100.3		100.0	

During data processing, the LCPX level was corrected for the reference air temperature and for the rubber hardness of the reference tyre as specified by the technical standards.
In addiction, at the same time, measurements of the road texture using a triangulation point profile sensor complaint with the requirements of ISO 13473 standards were carried out.
The texture measurements instead concerned only the slow lanes of both carriageways. Table 2 shows the results in terms of the MPD (Mean Profile Depth) indicator in the slow lane for the two directions analysed.

Table 2. Results obtained in terms of indicator MPD (Mean Profile Depth) for the investigated pavements.

Pavement	Direction	Lane	MPD
AO1	East	Slow	2.05 ± 0.32 mm
AO2	East	Slow	0.59 ± 0.10 mm
AO3	East	Slow	1.89 ± 0.17 mm
AO1	West	Slow	2.03 ± 0.22 mm
AO2	West	Slow	0.56 ± 0.09 mm
AO3	West	Slow	0.59 ± 0.12 mm

In a second stage, also texture and mechanical impedance measurements of road surface will be carried out to exploit the construction site built for the new pavement implementation.

5.2 Noise level measurements at receivers

Beside noise measurement at receptors to calibrate propagation model, a monitoring campaign has been organized in order to detect railway and road noise contribution.
The noise measurements were made according to the Decree of the Ministry of the Environment dated March 16, 1998, "Techniques for the detection and measurement of noise pollution."
"PR" measurement locations (Reference Points) for the characterization of source noise were positioned, in free-field conditions, close to the railway and road line. "PS" measurement locations (Significant Points) were placed at the receivers, in particular at the most exposed façade to railway noise, at the middle position between the two sources railway and highway and at a receiver affected only by road noise.
In Fig. 7 a map extract with the indication of the measurement locations is shown.

Figure 7. Measurement locations

Some pictures of the measurement campaign are shown in Fig. 8.
the results of the measurements are reported In Table 3.

Table 3. Noise measurements at reiceves results

Measurement Location	Leq,A [dBA] Day	Leq,A [dBA] Night
PR-1	63.2	55.4
PR-2	61.5	53.8
PR-3	61.4	57.3
PS-1	62.9	57.4
PS-2	58.9	55.0

PS-3	-	-
PS-4	65.2	61.8

at measurement location PS-3, individual train pass-bys could not be distinguished because of building ventilation and extraction system with predominant noise. Similarly, results at the measurement point PS-4 are affected by the presence of Via della Magliana close to the A91 motorway.

Figure 8. Measurements at receivers.

5.3 Annoyance measurements of exposed population

A questionnaire will be distributed and submitted to people present at a meeting with the president of the Municipality. Furthermore, on the same day it will be also distributed to families thanks to teachers of the school "I.C. Santa Beatrice - Plesso Santa Beatrice".

ABSTRACT

Noise pollution is a significant environmental and public health challenge, particularly near urban infrastructure such as highways and airports. Traditional mitigation methods, such as vertical barriers, often disrupt landscapes and ecosystems. Ground shaping, an innovative approach that modifies terrain to reduce noise propagation, remains largely unexplored despite its promising potential. Building on prior research that simulated its effectiveness, this study empirically evaluates the noise reduction performance of specific ground shapes. Using a 1:500 scale model in a controlled acoustic environment, a robotic arm was used to create precise three-dimensional ground forms. These forms were positioned between a noise source emitting broadband noise (100–16,000 Hz) at 65 dB SPL and a miniature microphone at a scaled distance equivalent to 425 meters. Results demonstrate that ground shapes reduce noise to varying degrees, with specific geometries achieving an average reduction of over 2.5 dB and a maximum exceeding 7.5 dB. These findings highlight the potential of ground shaping as a sustainable alternative to traditional noise mitigation, offering empirical support for its integration into urban and environmental planning while enhancing public health and minimizing ecological disruption.

Keywords: *urban noise, ground forming, noise mitigation, robotic earthmoving, acoustics*

1. INTRODUCTION

Ground shaping, though potentially effective for noise reduction, has yet to be experimentally validated. Schiphol Airport in the Netherlands implemented a landscape design plan to combat noise through ground shaping, but its effectiveness remains largely unquantified due to the lack of specific experimental research [1]. Additionally, noise monitoring studies have highlighted the significant impact of aircraft noise on nearby communities [2].

Environmental acoustics software—such as SoundPLAN, CadnaA, TNM, Predictor-LimA, and IMMI—use standardized models (e.g., ISO 9613, CNOSSOS-EU, TNM) to predict noise levels and assess mitigation strategies like vertical barriers [3, 4]. While widely used in urban planning, these tools are not well-suited to simulate non-standard interventions like ground shaping, and often rely on idealized input data. As such, empirical measurements remain essential to capture site-specific effects and validate model assumptions.

This research aims to fill that gap by using robotic earthmoving and scale models to experimentally evaluate the noise reduction effectiveness of different ground forms in high-noise environments. Rather than relying solely on simulations, we focus on direct measurement to explore the acoustic potential of terrain shaping under controlled but realistic conditions.

1.1 Rationale

Ground forming involves reshaping terrain to influence environmental factors. This study aims to empirically evaluate its effectiveness in reducing urban noise levels near airports. It addresses a significant gap in current noise mitigation strategies by systematically exploring the relationship between ground shapes and noise reduction. The goal is to generate insights into terrain acoustics and contribute to the broader field of environmental acoustics, architecture, landscape design, and robotic earthmoving.

1.2 Novelty

Unlike traditional vertical noise barriers, ground forming offers a sustainable, landscape-friendly alternative that can simultaneously reduce noise and enhance urban spaces. This research employs robotic earthmoving to create specific ground shapes in a lab environment, allowing for precise experimental control and repeatability. By bridging simulation and reality, the study aims to enhance the reliability of noise reduction models and contribute valuable insights to environmental noise management.

2. STATE OF THE ART

This section reviews the current knowledge of environmental noise, urban noise mitigation methods, and the role of robotic earthmoving in noise reduction. The subsections focus on the challenges posed by noise pollution, existing mitigation strategies, and innovations using terrain shaping.

2.1 Environmental and Urban Noise

Environmental noise is a significant public health issue, contributing to a range of adverse health effects, including cardiovascular diseases, cognitive impairment, and sleep disturbance [5]. Long-term exposure to environmental noise is associated with increased risks of ischemic heart disease, hypertension, and mental health issues [6]. The World Health Organization (WHO) guidelines recommend road traffic noise levels not exceeding 53 dB Lden (day-evening-night average) to avoid adverse health effects, or 45 dB Lnight to prevent sleep disturbance [7].

Recent studies highlight the increasing issue of urban noise pollution and its impact on public health. Studies show that exposure to noise levels exceeding the WHO guidelines for road traffic noise has significant adverse effects. Despite the recognition of these risks, few studies explore outdoor noise reduction techniques beyond traditional barriers, especially in environments near airports and highways.

2.2 Urban Noise Mitigation Methods

Traditional mitigation techniques have predominantly focused on reducing indoor noise levels, with some outdoor solutions, like the use of vertical barriers, being common. These barriers are generally effective in reducing noise from road traffic, but they often disrupt the landscape, negatively impacting local ecosystems and human activities [7–9]. In urban settings, the deployment of vertical barriers often presents challenges, such as limiting land use and not integrating seamlessly into the landscape [10].

However, these approaches have been shown to reduce noise, with mixed effectiveness depending on design and context. Additionally, low-frequency noise from aircraft remains a major challenge for standard noise barriers [11]. A key problem with vertical barriers is that they limit land use and do not integrate well into the surrounding environment. Urban planners are now seeking alternatives that reduce noise while maintaining the aesthetic and environmental value of urban landscapes.

2.3 Robotic Earthmoving and Terrain Modification

Advancements in robotic earthmoving technology have significantly improved our ability to create precise and repeatable terrain modifications [12]. These robots have been employed in various soil manipulation tasks, including leveling, shifting, and piling [13]. The development of autonomous systems and mobile robotic platforms for earthworks has opened up new possibilities for large-scale, highly accurate terrain reshaping [14].

Recent research has demonstrated the use of robotic technologies for autonomous terrain manipulation. These technologies enable precise shaping of the landscape in a repeatable manner, allowing for highly controlled experimental testing [15]. Robotics in earthmoving allows researchers to produce ground shapes that can be tested for noise mitigation capabilities, ensuring accuracy and precision in experiments.

2.4 Recent Innovations in Noise Mitigation Using Ground Shaping

In addition to traditional vertical barriers, recent innovations have explored terrain modifications as a means to mitigate noise in outdoor environments. Previous studies

have shown that certain terrain shapes, like concave and convex forms, can significantly alter the propagation of sound waves, creating acoustic shadows that reduce noise exposure [16, 17]. These studies found that mounds with varying heights could reduce noise by up to 28 dB under ideal conditions, with larger terrain shapes achieving better results.

These studies demonstrated that altering the ground shape could help reduce the reflection of sound waves, with notable reductions in noise levels. Despite promising simulation results, there is a lack of empirical data validating these simulations in real-world settings.

2.5 Research Gaps

While simulation studies have made significant progress in predicting the potential benefits of terrain shaping for noise reduction, there is a lack of empirical validation in actual field environments. Key gaps in the research include: (1) a lack of direct comparisons between different ground shapes and their effectiveness in noise reduction across a range of frequencies; (2) insufficient exploration of how robotic technologies can be employed to create accurate ground forms for testing; and (3) limited understanding of how terrain modification can be effectively integrated into urban planning and landscape design. This research aims to fill these gaps by conducting scale model experiments with controlled acoustic conditions and robotic earthmoving technology, providing empirical data to validate the effectiveness of ground shaping for noise reduction.

3. OBJECTIVES AND SIGNIFICANCE

This study aims to empirically evaluate the effectiveness of ground shapes in reducing noise levels using scale model experiments that simulate real-world urban noise conditions. The key objectives include: (1) identifying the most effective ground forms for reducing noise in scale models; (2) analyzing the potential for applying these findings to full-scale outdoor scenarios; and (3) exploring how scale models and robotic technologies can advance our understanding of terrain-acoustic interactions.

The expected significance of this work lies in the development of more sustainable and integrated noise reduction strategies. By providing empirical validation for terrain shaping, the research offers a potential alternative to conventional vertical barriers—one that can be better integrated into urban planning and landscape design, with implications for future environmental policy.

4. METHODOLOGY

This section describes the experimental approach used to assess the effectiveness of different ground shapes in reducing noise. It covers the scale model setup, the robotic earthmoving process, and how noise attenuation is measured.

4.1 Experimental Setup

The experimental setup (seen in Fig. 1) uses a 1:500 scale model to replicate urban noise conditions, allowing controlled experimentation while maintaining key real-world acoustic interactions [18]. Ground shapes, including convex, concave, tri-convex, and random, were created using robotic earthmoving technology (see Fig. 2). Noise is generated using a speaker, and its attenuation along the shaped ground is measured using a high-precision microphone. This setup allows for controlled, repeatable experiments to assess the impact of different ground shapes on noise propagation.

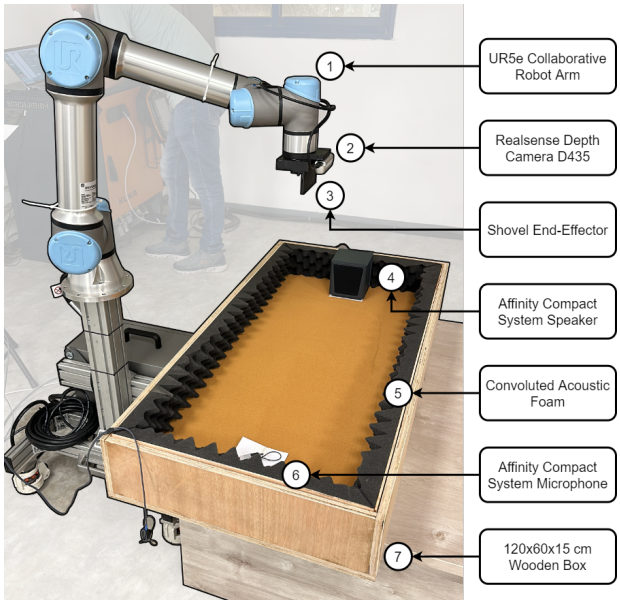

Figure 1: The experimental setup: (1) UR5e robot, (2) Intel RealSense D435 depth camera for 3D scans, (3) a custom 10×5 cm shovel for robotic earthmoving, (4) Interacoustics Affinity speaker (noise source), (5) convoluted acoustic foam , (6) Interacoustics Affinity microphone for noise measurement, and (7) a 120×60×15 cm box for the terrain model.

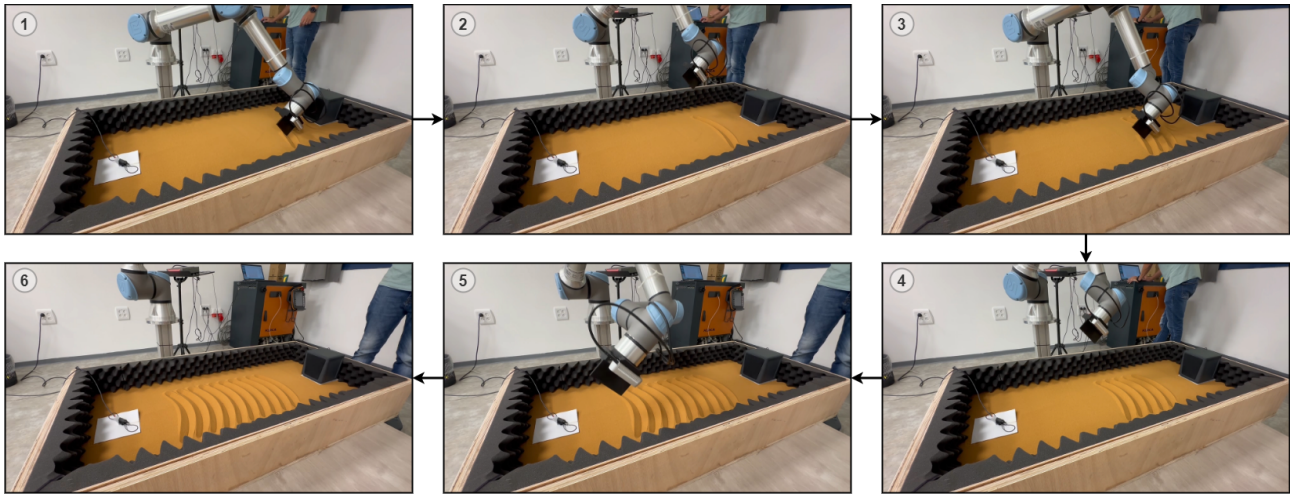

Figure 2: The robotic earthmoving process displayed on the Convex toolpath.

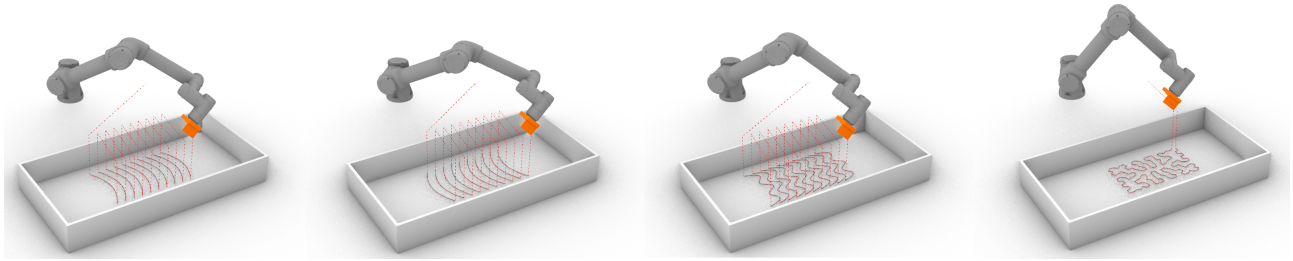

Figure 3: The robotic toolpaths designed for shaping ground forms (left to right): (a) Convex, (b) Concave, (c) Tri-Convex, (d) Random.

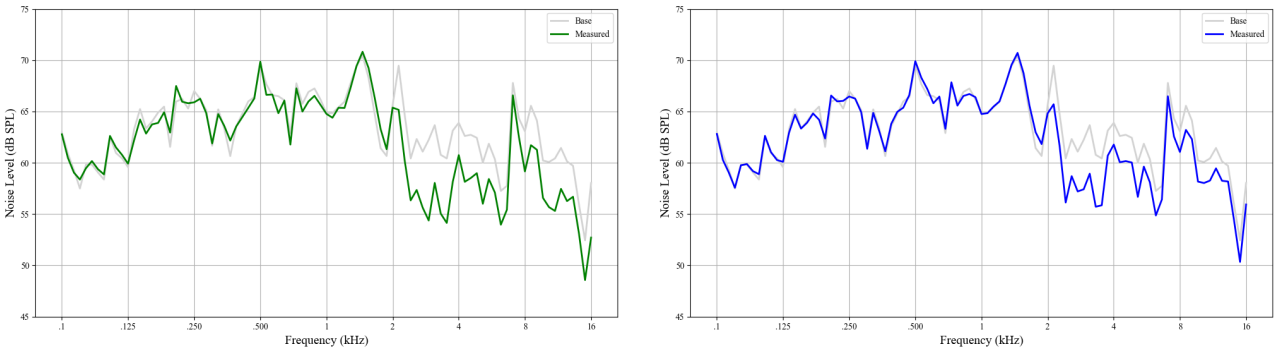
Figure 4: The resulting ground shapes (left to right): (a) Convex, (b) Concave, (c) Tri-Convex, (d) Random.

4.2 Robotic Earthmoving



The robot was pre-programmed to produce each of the four geometries, following toolpaths corresponding to each shape (see Figs. 3–4). The terrain, consisting of sifted dry sand, was leveled using a custom tool before creating the next shape. To eliminate any other noise, all non-essential electronic equipment in the lab was turned off during measurements.

4.3 Noise Measurements

Each terrain geometry underwent five consecutive noise measurements to minimize variability and ensure robust data. The microphone was manually positioned at one end of the box, maintaining a fixed 85 cm distance from the speaker. An initial noise measurement, referred to as 'Base' in the graph, was performed on a leveled ground surface to provide a controlled baseline for comparison.

(a) Convex

(b) Concave

(c) Tri-Convex

(d) Random

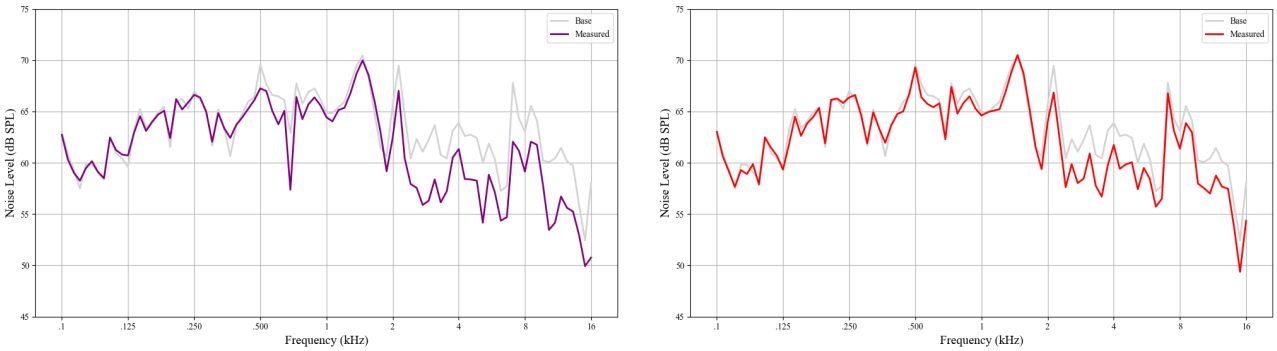


Figure 5: Noise attenuation for each tested ground shape compared to the 'Base' measurement (gray). Each plot illustrates the frequency-dependent noise reduction achieved by the specific terrain configuration.

5. RESULTS

All tested ground shapes showed a measurable reduction in noise level compared to the base especially for frequencies higher than 2kHz, with some proving more effective than others (see Table 1 and Figs. 5 and 6). Among the tested geometries, the concave shape achieved the greatest maximum reduction, with a 7.86 dB decrease in noise levels. The tri-convex shape followed closely with a maximum reduction of 7.27 dB, while convex and random shapes exhibited lower peak reductions of 5.06 dB and 3.77 dB, respectively.

The average attenuation values were calculated within the measurable frequency range of the setup (400–16,000 Hz). On average, the tri-convex shape reduced noise by 2.61 dB, followed by concave (2.37 dB), convex (1.55 dB), and random (1.55 dB). These results suggest that terrain shaping influences noise propagation, with the tri-convex shape providing the most consistent noise reduction, while the concave shape exhibited peak attenuation.

Table 1: Noise reduction summary for the tested ground shapes, showing the attenuation (Δ dB) relative to the base measurement.

Shape	Avg Δ (dB)	Max Δ (dB)
Convex	1.55	5.06
Concave	2.37	**7.86**
Tri-Convex	**2.61**	7.27
Random	1.55	3.77

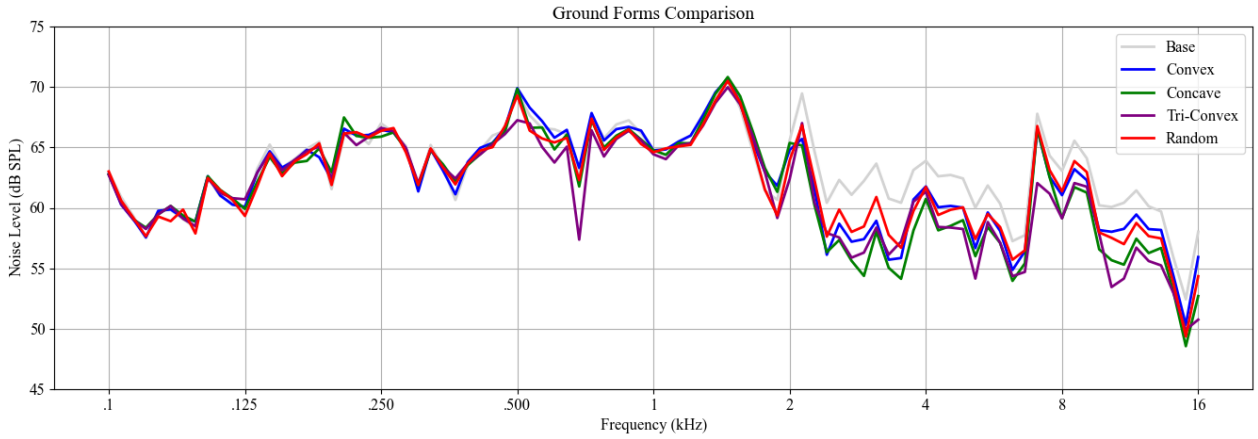

Figure 6: Comparison of noise attenuation across all tested ground shapes. The graph presents the frequency-dependent reductions in noise level relative to the 'Base' measurement, highlighting variations in attenuation effectiveness among the different geometries.

6. CONCLUSIONS

This study addresses a crucial gap in understanding how terrain modifications can mitigate urban noise. By using advanced robotic technologies to shape ground forms and validate their effectiveness through scale model experiments, the research offers a new approach to noise reduction.

While the findings provide valuable insights, three limitations should be noted: (1) the speaker–microphone distance constrains the measurement of frequencies below 400 Hz, as the corresponding wavelengths do not complete a full cycle within the setup; (2) the Sound-Level-Meter captures frequencies only up to 16,000 Hz, excluding higher frequencies that may be relevant in real-world conditions; and (3) although the tested ground shapes demonstrated measurable noise reduction, further exploration of alternative geometries—including variations in height and spacing—could enhance attenuation.

Future work will address these limitations by broadening the frequency range of analysis, scaling up experiments, and testing a wider range of geometric configurations. Nevertheless, the presented findings already demonstrate the potential of robotic earthmoving to precisely manipulate terrain for noise control. These insights may influence urban planning practices and environmental policies, offering a sustainable, landscape-integrated alternative to traditional noise barriers.

SELF-SHIELDING WINDOWS : SCALE MODEL MEASUREMENTS AND NUMERICAL SIMULATIONS

Timothy Van Renterghem* **Pieter Thomas**
Ghent University, Department of Information Technology, WAVES research group, Technologiepark 126, Gent-Zwijnaarde B 9052, Belgium

ABSTRACT

The concept of self-shielding windows is introduced as an innovative approach to mitigate sound exposure in urban environments at the most exposed façade. Unlike conventional windows aligned parallel to the building façade, this study examines the sound pressure level exposure at windows oriented obliquely toward the sky. This configuration forces sound from street-level sources to diffract around convex elements before reaching the windows, resulting in reduced sound exposure. Additionally, these façade geometries promote a diffuse sound field within the street canyon, diminishing the influence of specular reflections from opposing façades. However, reflections and scattering from nearby elements may offset these benefits by increasing exposure levels. To elucidate the significance of these physical phenomena, scale model experiments were conducted with simplified triangular façade elements at varying angles and story heights. Especially at the higher stories, significant noise reduction was measured. The experimental findings were further validated by 3D full-wave numerical simulations, reinforcing confidence in both the accuracy of the scale model measurements and the reliability of the numerical predictions for optimizing façade elements.

Keywords: *urban sound propagation, street acoustics, environmental noise, building envelope design, scale model.*

1. INTRODUCTION

Street acoustics play a central role in urban sound propagation studies. Three main strategies can help limit noise exposure during propagation in streets: introducing absorption, implementing screening, or promoting diffusivity.
Since building materials are typically rigid or nearly so, achieving significant absorption with common materials is challenging. However, building envelope greening, such as non-ground-based green walls [1], is worth considering. The use of low-height screens has been shown effective [2][3], though they generally shield only a limited area. To maximize their noise-mitigating potential, incorporating some degree of absorption is recommended [3].
Promoting diffuse reflection is another effective approach. Studies have demonstrated its benefits for both longitudinal and cross-sectional sound propagation in streets [4][5]. Balconies along façades contribute to this effect [6][7]. With well-designed parapets, balconies can also provide direct shielding of the façade, though this differs from common practice, which often leaves gaps between the vertical and horizontal surfaces. Additionally, balconies enhance diffuse reflection. Due to their typical dimensions, they interact with lower-frequency sounds, which are more dominant in surface transport noise spectra.

2. SELF-SHIELDING WINDOWS

The concept of self-shielding windows is introduced here as an innovative approach to reduce noise exposure. Unlike conventional windows, which are aligned parallel to the building façade, these windows are oriented obliquely toward the sky. This configuration forces street-level sound to diffract around convex façade elements before reaching the windows, effectively reducing noise exposure. Additionally, these façade geometries enhance the diffusion

of sound within the street canyon, thereby minimizing the impact of specular reflections from opposing façades.
This concept was first introduced in Ref. [8] based on full-wave sound propagation simulations using a 2D approach, but validated with real-life sound measurements in street canyons [9]. It emerged from an exploration of both conventional and more inventive façade and street profiles to reduce road traffic noise exposure.
However, further studies on this specific building envelope geometry are needed to better understand the underlying physical mechanisms. Similar to the effects observed near balconies, reflections and scattering from higher-positioned elements could potentially offset the noise reduction benefits by increasing exposure levels. Therefore, further optimizations may be necessary to assess its feasibility for practical implementation

3. SCALE MODEL STUDY

3.1 Street geometry

A simple scale model of a street (length of 2450 mm) consisting of smooth plywood panels, with façade height of 910 mm and the distance between opposing façades of either 977 mm (no façade elements, perfectly rectangular cross-section) or 990 mm (with façade elements). Note that there is a slightly different street width in the reference situation for practical reasons. Foam blocks are used to terminate the street avoiding diffraction at its edges (see Fig. 1).

3.2 Sound source

The sound source (tweeter) is located in a strongly acoustically insulated box, hung below the bottom of the panel representing the street surface (see Fig. 1). The connection between the loudspeaker box and the street is by a cylindrical opening with diameter 10 mm. This setup should prevent all flanking transmissions. White noise sequences (of 30 seconds) were emitted by the tweeter with repetitions.

3.3 Microphones

Five type-1 ½ inch microphones were used for simultaneous measurements, one at the first floor at the left façade (only in the flat façade case, see Fig. 1), and 4 on top of each other along the right façade, all flush mounted. Given the execution of the measurements in a semi-anechoic room and having full control over the loudspeaker and its amplitude, high signal-to-noise ratios are obtained in this experiment.

3.4 Scale factor

Assuming a scale factor of 15, and taking into account the flat frequency range of a ½ inch microphone, the maximum sound frequency to be reached at full scale is 1330 Hz. Note that the scale model measurements are mainly intended for validation purposes, at least in this low frequency range. Nevertheless, the peak of road traffic rolling noise at moderate urban vehicle speeds is believed to be captured.

Figure 1. Scale model setup showing the surface sound source at street level, and the street canyon in absence of façade elements. In this work, focus is on the 4 flush mounted microphones along the right facade.

3.5 Façade elements

Isosceles triangular facade elements with external angles of 60°, 45° and 30° were used. In Fig. 2, the 60° outer angle configuration is shown, with triangles at both facades, and 4 microphones flush mounted at the elements' faces directed towards the sky, along the right façade.

Figure 2. Scale model showing a single configuration of 24 self-shielding façade elements (with 60° outer angles). Four microphones are visible along the right façade centrally positioned in the upwardly directed faces.

4. NUMERICAL SIMULATIONS

4.1 The 3D FDTD method

The explicit pressure-velocity finite-difference time-domain (FDTD) method is used, with staggered-in-place and staggered-in-time update schemes, modelling linear sound propagation in absence of air absorption. Acoustic pressures are located in the center of each computational cell, the particle velocities on the faces that border the cell. A lowest-order spatial and temporal discretization is used here. Perfectly matched layers (PML) are used to simulate an unbounded atmosphere where needed. All other surfaces are considered rigid. The interested reader is referred to Ref. [10] for a justification of these model choices.

For simplicity, the sound source is modelled as a point source in the centre of the first grid cell above the street surface. The receivers are similarly positioned in the centres of the first cells next to the flat façade or directly near the oblique face of the triangular elements. Although this involves reflections not present in the experimental scale model given the flush mounted microphones and the construction of a surface source, when comparing configurations in a relative way, as will be done here, such effects are expected to largely level out.

Grid spacing was equal to 5 mm, with a time step of 8.49 µs, leading to a Courant number equal to 1, ensuring numerical stability while minimizing computational cost and phase errors [10]. Optimized PMLs of 40 cells thick ensure near perfect reflection free boundaries. When imposing a limit of 10 computational cells per wavelength, the 1/3 octave band frequency of 6.3 kHz can be attained (scale model frequencies). Along the street length, a stretch of 2 m is modelled. Although there is a fine discretization in the model relative to the wave length, staircase effects cannot be excluded in case of oblique surfaces [11] which are prominent in this work.

4.2 Mirror source method

The FDTD simulations are accompanied with the mirror source method (see e.g. Ref. [4]), at least for the flat façade geometry. With this method, including higher frequencies comes naturally. Relevant parameters such as the number of mirror sources are increased until sound pressure level differences (see further) converged.

This technique is mainly used to assess the effect of small deviations from the exact positioning (but manually measured) of sources and receivers in the scale model.

5. RESULTS

5.1 Validation case 1 : Level differences between stories along flat façade

Figure 3 shows the differences in 1/3 octave band levels between the 4th floor and first floor microphone, in case of fully flat facades, along the right facade. The bunch of thin colored lines show mirror source simulations using a large number of combinations using small deviations on geometrical parameters such as street width and heights of the microphones.

The microphone capsule surface covers multiple FDTD grid cells, leading to significant variations in the actual exposure. To stabilize results, averaging over a receiver zones of 1.5 times the microphone diameter was performed. To some extent, this procedure also accounts for small deviations in exact positioning.

Starting from 400 Hz on, the scale model measurements, FDTD simulations and the mirror source approach are in good agreement. At high frequencies, small variations in exact positioning lead to strong level differences.

The peak at 315 Hz is almost perfectly predicted by the FDTD model. This peak is much more moderate with the mirror source model, potentially pointing at being related to diffraction of sound which is not modelled with the latter.

Note that the strong level difference peak at the 160 Hz 1/3 octave band only appears in the measurements, and might indicate a deficiency of the measurement setup (of unknown nature). When scaling up to real sound frequencies (so near 10 Hz at full scale), however, its relevance if very minor in environmental noise sources.

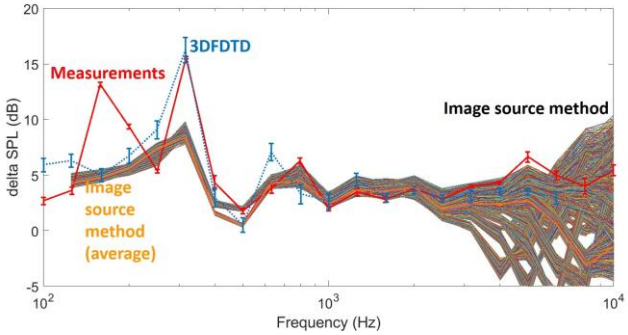

Figure 3. Measurements and simulations of the sound pressure level difference between the 4th and first floor microphone, for the flat façade case.

5.2 Validation case 2 : Self-shielding window insertion losses

In Fig. 4, measured and predicted insertion loss spectra are presented. The 3D full wave simulations are in adequate agreement with the measurements and give confidence on both the measurements performed and the numerical simulations.

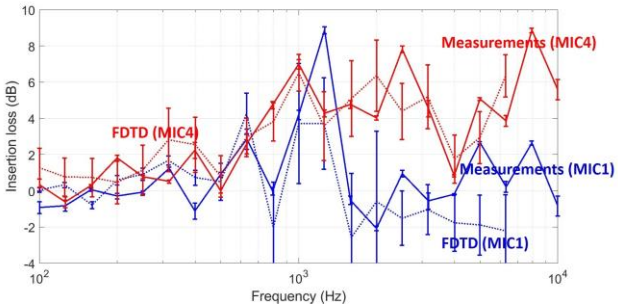

Figure 4. Measurements (full lines) and FDTD simulations (dashed lines) of the insertion losses at the 4th (MIC4) and first (MIC1) floor due to inclusion of 24 triangular elements (with 45° outer angles). The total length of the errorbars equals two times the standard deviation.

Note that simulating the insertion losses involves shifts in interference patterns, making it hard to correctly model the amplitude of these peaks. Further note that the microphones were placed in the middle of the oblique face pointing upwards, so microphone height relative to the street surface is not exactly the same as in the flat façade configuration. Another difference is that the street width in the flat façade situation is slightly lower than in the configuration including triangular façade elements. The large errorbars on the simulations further show that small shifts in receiver position can lead to large differences in insertion loss.

5.3 Element shape

In Fig. 5, insertion loss spectra with different outer angles are shown at the 4th floor, where effects are largest. A 60° outer angle involves smaller façade elements, and consequently, the position of the window pane stays closer to the flat façade configuration. At scale model sound frequencies between 10 kHz and 20 kHz (660 Hz and 1330 Hz at full scale), level reductions exceeding 8 dB (30°), between 6 dB and 8 dB (45°) and between 2 dB and 4 dB (60°) are measured.

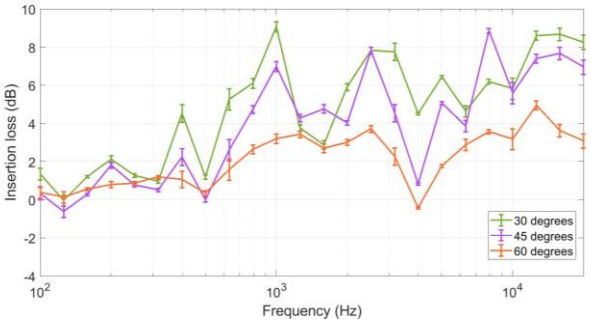

Figure 5. Measurements of the insertion losses at the 4th floor due to inclusion of 24 triangular elements with different outer angles.

5.4 Number of elements

Compared to the influence of the outer angles of the façade elements as discussed in Section 5.3, the effect of the number of elements is limited as becomes clear in Fig. 6. The neighboring columns of elements at the right façade (12 elements relative to 4 elements) hardly influence the insertion loss along the central column where the microphones were placed. This means that for the current setup scattering by these side elements do not influence the exposure levels.

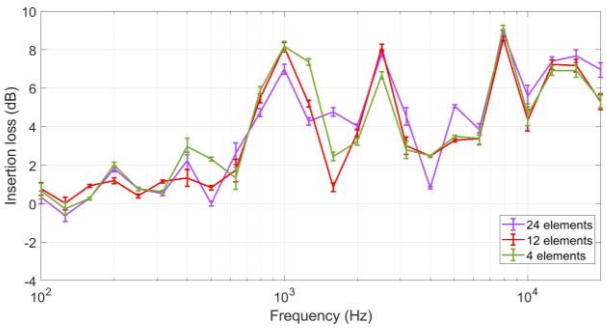

Figure 6. Measurements of the insertion losses at the 4th floor due to inclusion of an increasing number of triangular elements (45°). The case with 24 elements is the one shown in Fig. 2, “12 elements” only has elements along the right façade (with the left façade fully flat), and “4 elements” means a single column of elements on the right facade (with the left façade fully flat).

In the higher sound frequency range (above 10 kHz, at scale), the presence of elements along the left façade leads to a small increase in insertion loss, likely by limiting specular sound paths reaching the upper microphone.

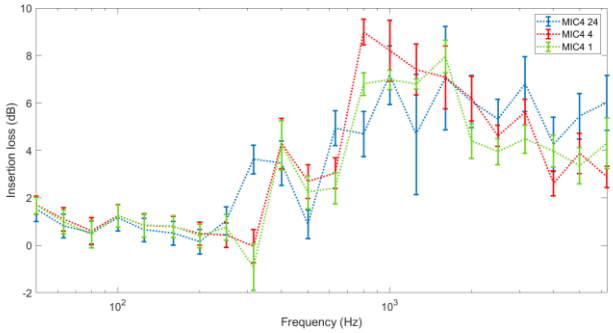

Figure 7. Simulated insertion losses with FDTD at the 4th floor due to inclusion of an increasing number of triangular elements (30°). The case with 24 elements is the one shown in Fig. 2, "4 elements" means a single column of elements at the right façade only (left façade fully flat), and "1 element" means a single element at the right façade (where the microphone is located) with the left façade fully flat.

Analysis of Figs. 7 and 8 indicate different behavior at the 4th floor (top floor) and second floor microphone with relation to the number of façade elements. At the top floor microphone, no elements are present above. Above 2 kHz (130 Hz at full scale) 24 elements lead to the highest insertion losses overall. Preventing specular reflections from the left façade leads to a significant reduction in exposure levels as can be concluded when comparing 24 elements to 4 elements.

Using 4 elements gives a slightly higher insertion loss than when only using a single element, although given the peaky behavior, this does not hold for any frequency. This might point at a second order effect where also specular reflections from the right façade are prevented. Overall, given that many reflections contribute to the sound pressure level at the higher stories, a large number of façade elements seems beneficial.

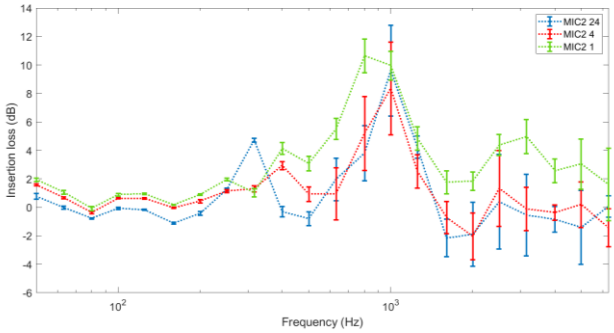

Figure 8. See caption of Fig. 7, but now for the microphone at the second floor.

At the lower stories (here second floor), a single element is clearly the optimum, only allowing for direct shielding. Note that the effect is quite pronounced since an outer angle of 30° leads to rather large façade elements. When having 2 elements on top and one below (so 4 elements in a single column along the right facade), multiple scattering and reflections tend to limit the insertion loss. Adding elements to the left façade (24 elements) does not impact the insertion losses relative to 4 elements.

6. CONCLUSIONS AND OUTLOOK

The concept of self-shielding windows presents a promising noise mitigation solution for the most exposed façades in urban streets. This approach is particularly effective at higher floors, where it can achieve substantial noise reduction compared to fully flat façades. Notably, the greatest improvements occur in key frequency ranges associated with common transport noise sources.

The design of individual elements plays a crucial role in achieving significant noise reduction, as demonstrated by studying triangular elements with varying angles in the current work. At higher stories, interactions with other elements help reduce the intensity of specular sound paths, enhancing overall effectiveness. At lower stories, these interactions mitigate insertion losses due to scattering and reflections from higher positioned elements

Scale model measurements, combined with full-wave 3D numerical simulations, confirm that the simulations accurately capture the underlying physics. Moreover, they validate the precision of the measurements, which is an equally challenging task. Predicting insertion losses in such environments is particularly complex, as pronounced interference shifts create a highly variable spectral response, making it very difficult to fully model their magnitudes.

The numerical model enables further optimizations without the need for labor-intensive scale model measurements. Continued research is required to enhance the architectural quality of the simplified triangular façade elements used in this study while considering cost-effectiveness and the potential integration of thermal performance.

7. ACKNOWLEDGMENTS

The authors are grateful to master thesis students Jules Bastiaensen and Joren Goeteyn for initiating the practical work on the scale model.

ABSTRACT

The outdoor propagation of infrasound can be impacted by atmospheric conditions, such as temperature inversions and winds, that channel sound into acoustic waveguides allowing for efficient long-range propagation. For near ground acoustic waveguides, ground impedance can also play an important role. In this study, the Semi-Analytic Finite Element (SAFE) method is used to predict the acoustic field generated by a point source emitting into a stratified, range independent atmosphere with a logarithmic wind profile. We study the influence of ground impedance by setting two cases with different ground boundary conditions: a fully reflective ground condition, mimicking sea propagation; and an impedance ground boundary condition, mimicking a sandy landscape. We found a significant contrast in the two test cases for the near-ground acoustic waveguides, especially for a particular near-ground acoustic mode. Thus, ground impedance should be included in predictions

1. INTRODUCTION

The outdoor propagation of infrasound can be impacted by atmospheric conditions, such as temperature inversions and winds. By refracting sound downwards, acoustic energy gets channeled into acoustic waveguides, reducing geometric spreading. Lower frequencies, notably infrasound, which experience decreased atmospheric damping, can travel efficiently inside these ducts, leading to increased sound pressure levels down-range of an emitter. For highly refracting conditions, near-ground waveguides can be dominant features in the acoustic field and, due to their interaction with the ground, be influenced by the acoustic behavior of this surface.

Large energy converters such as wind turbines and biogas power plants are possible emitters in the lower frequency spectrum and, when installed next to populated areas, raise concerns regarding exposure levels and annoyance. Accurate prediction of the noise levels at these locations is important and depends on a good understanding of the influence of the ground surface on the acoustic field.
Numerical predictions for the outdoor propagation of sound tend to either be heavy, due to large domain size, or rely on approximations, to reduce computational costs. The semi analytical finite-element (SAFE) method has been introduced by Kirby as an alternative to PEs to model outdoor sound propagation for range-independent domains [1], [2]. The procedure translates the acoustic field into a set of vertical atmospheric acoustic modes, propagating in the down-range direction. The method was originally introduced by Waxler [3] with numerical solutions for modes based on

an approximate wave equation. Using the SAFE method enables the solution of the exact governing equations with arbitrary atmospheric profiles while being able to accommodate a range-independent Ingard-Myers impedance boundary condition at the ground level [2]. The SAFE method has been tested against analytic solutions [1] and validated against test cases computed with the direct numerical computations of the Linearized Euler Equations [4]. It has also been shown to be particularly efficient for highly refracting atmospheres, requiring a limited number of modes for accurate near-ground far-field predictions [5].

In this study, the Semi-Analytic Finite-Element (SAFE) method is used to predict the acoustic field generated by a point source emitting into a stratified, range-independent atmosphere with a logarithmic wind profile. We study the influence of ground impedance by setting two cases with different ground boundary conditions: a fully reflective ground condition, mimicking sea propagation; and an impedance ground boundary condition, mimicking a sandy landscape. In the downwind direction, we found a significant contrast for the near-ground acoustic waveguides while the acoustic field at higher altitudes is significantly less affected. We conclude that ground impedance should be included in near-ground predictions as it plays an important part in both amplitude and distribution of sound pressure levels.

2. SAFE METHOD

The SAFE method is derived and discussed with more extent in [1], [2]. A short description is given here.

The method starts with an accurate pressure equation for acoustic waves propagating in stratified, range-independent atmospheres for frequencies above the Brunt-Väisälä limit, nominally 0.05 Hz (from [6], Eq. 2.58).

$$\left[\frac{1}{c^2}D_t^3 - D_t\left(\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial z^2}+2\tilde{g}\,\frac{\partial}{\partial z}+\tilde{g}^2-\frac{2\tilde{g}}{c}\frac{\partial c}{\partial z}\right)+ 2\frac{\partial u_0}{\partial z}\frac{\partial}{\partial x}\left(\tilde{g}+\frac{\partial}{\partial z}\right)+\left(2\tilde{g}+\frac{1}{\rho}\frac{\partial \rho_0}{\partial z}\right)D_t\left(\tilde{g}+\frac{\partial}{\partial z}\right)\right]p' = \rho D_t^2 Q, \quad (1)$$

where p' is the acoustic pressure, ρ' is the acoustic density, u_0 is the background velocity in the range direction (x), $\tilde{g}$ is the acceleration of gravity divided by the speed of sound squared ($\tilde{g} = \frac{g}{c^2}$), Q is a mass source, $D_t = (\frac{\partial}{\partial t} + u_0\frac{\partial}{\partial t})$, x denotes the range coordinate, z the height coordinate and t denotes time. This two-dimensional equation results from assuming a stratified atmosphere in a linearized two-dimensional Euler equation

$$\begin{cases} \frac{d\rho'}{dt} + (V'\cdot\nabla)\rho_0 + \rho_0\nabla\cdot V' + \rho'\nabla\cdot V_0 = \rho_0 Q \\ \frac{dV'}{dt} + (V'\cdot\nabla)V_0 + \frac{1}{\rho_0}\nabla p' - \frac{\rho'\nabla p_0}{\rho} = F \\ \frac{ds'}{dt} + (V'\cdot\nabla)s_0 = 0 \end{cases}, \quad (2)$$

with F being a force source, (ρ_0, p_0, V_0) being quantities related to the background field, namely, density, pressure and velocity, and (ρ', p', V') the same quantities for the acoustic field.

The pressure field may be expressed as a sum of range propagating vertical modes, following the Ansatz

$$p'(x,z,t) = \sum_{n=1}^{\infty} A_n p_n(z) e^{iwt - ik_0\gamma_n x}, \quad (3)$$

where A is the complex mode amplitude, p_n are the mode shapes, k_0 is the reference wave number and γ_n are the eigenvalues associated with the mode shapes. Equation 1 then turns into an eigenvalue problem in the height coordinate

$$+k^2[1-\gamma M]^3 p' + [1+\gamma M]\left\{\left(\tilde{g}^2 - \frac{2\tilde{g}}{c}\frac{\partial c}{\partial z}\right) + 2\tilde{g}\frac{\partial}{\partial z} + \frac{\partial^2}{\partial z^2} - k_0^2\gamma^2\right\}p' + 2\gamma\frac{\partial M}{\partial z}\left(\tilde{g}+\frac{\partial}{\partial z}\right)p' - \left[2\tilde{g} + \frac{1}{\rho}\frac{\rho}{\partial z}\right][1-\gamma M]\left(\tilde{g}+\frac{\partial}{\partial z}\right)p' = 0, \quad (4)$$

with M being the Mach number [4,5].
Equation 4 can be solved using the finite-element method and an eigen solver. The ground impedance ($\tilde{Z}$) is set on the finite-element approximation by following the steps in [2] and using the Ingard-Myers boundary condition expressed as a function of purely acoustic pressure.

$$\frac{\partial p'(0)}{\partial z} = \left[\frac{ik_0}{\tilde{Z}}(1-\gamma M_0)^2 + \tilde{g}_0\right]p'(0), \quad (4)$$

For the test cases shown here, we use an in-house FE solver, based on quadratic elements and the *eig* function from the scientific Python package *numpy*. More details about the method and the weak formulation of the eigenvalue problem are available in Refs [1], [2].

The modes' amplitudes are computed by employing a vertical mode matching scheme that was derived to mimic

a harmonic point source. Details about the mode matching can again be found in Refs [1], [2].

3. RESULTS

We computed two cases with the same atmospheric conditions: $u_0 = 2.33 \cdot \ln(1 + 2.3z), v_0 = 0,$ $t_0 = 293.15\,K,$ $\rho_0 = 1.23\,Kg/m^3,$ and $p_0 = 1\,atm;$ and different ground impedances, namely: a fully reflective ground surface ($\tilde{Z} = \infty$), mimicking sea propagation; and an impedance ground boundary condition ($\tilde{Z} = 38.79 - 38.41i$), mimicking a sandy landscape. For both test cases, the acoustic field was excited via a 10 Hz point source placed at the origin of the range coordinate and at height of 100m.

Figures 1.a) and 1.b) show a normalized pressure contour plot for both scenarios. The acoustic pressure has been normalized with the maximum recorded acoustic pressure for each. Downwind from the source, the plots show significant differences close to the ground, whereby the lower-altitude acoustic waveguide visible in Figure 1.a) is not evident in Figure 1.b). Below 250m, the remaining acoustic features related to atmospheric ducting are visible in both plots, having more contrast in Figure 1.a). For higher altitudes, both plots are qualitatively very similar. In the upwind direction, the acoustic field seems to not have been significantly affected by the difference in ground impedance.

The acoustic transmission, at the heights of, respectively, 1.8m and 500m, is plotted in Figures 1.c) and 1.d), along a range extending from -5km to 20km. At each height, the results for the two ground impedances are presented with the maximum recorded acoustic pressure being used as a reference. In Figure 1.c), the transmission recorded at 1.8m is evidently affected by the addiction of a ground-impedance, with a clear alteration in the downwind near-ground ducted pattern, being starker for the fully reflective ground surface. The acoustic field appears as more dampened for the sandy landscape scenario. Figure 1.d) indicates a quantitively similar transmission between both scenarios at an altitude of 500 m. At both heights, results in the upwind direction are similar.

Having noted a more prevalent effect on the near-ground acoustic field of the ground impedance change, five modes have been selected. These are modes that are important to the far-field (low dampening) and concentrate at least 15 per cent of their energy (signal energy) below 250 m. Figures 1.c) and 1.d) show that while these modes are not sufficient for an accurate prediction, at 500m, they provide good results for the near-ground far field, where the field is more affected by the change in impedance.

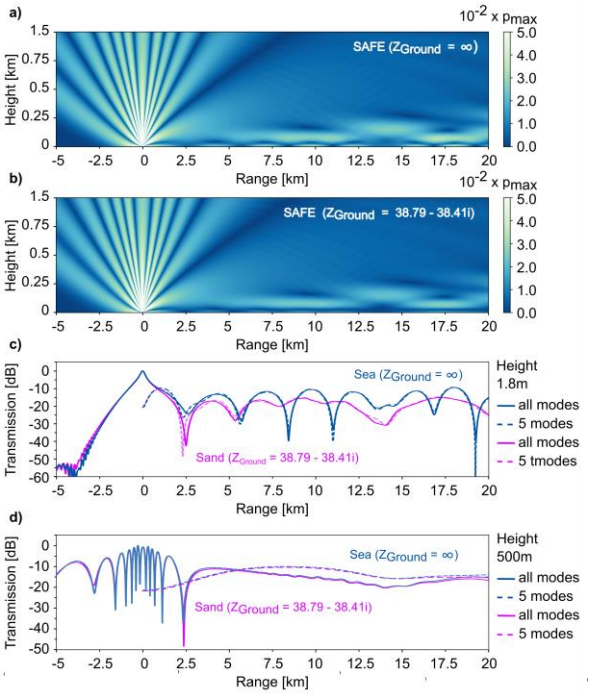

Figure 1. Normalized pressure contours of a point source radiating sound at 10 Hz in a atmosphere with a logarithmic wind profile and constant temperature and pressure for a) a fully reflective sea surface and b) a sandy landscape ($\tilde{Z} = 38.79 - 38.41i$). Transmission Loss along a horizontal line at a height of c) 1.8 m, d) 500m.

With the near-ground far-field prediction reduced to five propagating modes, a mode decay plot for each of the two cases is shown, respectively, in Figures 2.a) and 2.b). The modes have been paired up by how close their real parts are and given a numbering. Comparing the two figures, mode 5 seems to have been, by far, the most affected by the change in ground impedance. By looking at Figure 1.c), where the real and imaginary parts have been plotted for each case, one can check that the energy of the mode is highly concentrated near the ground and that the overall modal shape has not been severely altered. The respective eigenvalues of 0.972860-0.000996j (sand) and 0.971968-

1.205441e-06j (sea) also show that the phase-speed of the mode (real part), has almost been retained, with the attenuation of the mode (imaginary part) having been significantly increased.

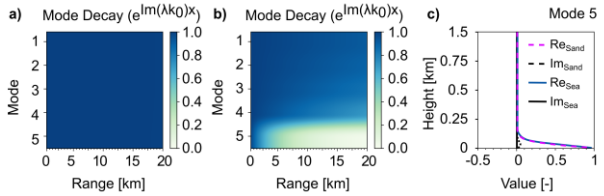

Figure 2. Modal decay plot for a) sea and b) sandy surface and a logarithmic wind profile. c) The real and imaginary parts for the 5th mode in the sea and sand surface test cases.

4. FINAL COMMENTS AND CONCLUSIONS

The purpose of this paper was to dwell into the influence of ground acoustic impedance for acoustic propagation in a highly refracting atmosphere. We did this by comparing the results of the SAFE method in two different test scenarios, each with the same atmosphere with a logarithmic wind profile and a different ground impedance: the 1st variation mimicking propagation along a fully reflective sea surface and the 2nd along a sandy landscape. Downwind from the source, the computations showed a significant change in the near-ground acoustic field, indicating a strong dampening of acoustic modes closer to the ground. Apart from the near-ground field, the acoustic field below 250m seems less sensitive to the change, with the same patterns in the contour plots being visible. Upwind from the source, we speculate that the upward refracting effect of the atmosphere contributed to a clear insensitivity to the change in ground impedance. The results for the higher altitudes in both directions presented themselves as almost unchanged. By reducing the modal base down to five modes, we deciphered that one mode was particularly affected by the change in ground impedance. We conclude that, in the context of highly refracting atmospheres, ground impedance plays a bigger role in near-ground predictions and that a limited number of modes, with most of its energy near the ground, experience noticeable changes. This result appears to indicate that there might be a reduction in complexity for predicting acoustic in highly-refracting atmospheres with ground impedances jumps by focusing the analysis on the more affected modes.

IMPROVEMENTS IN MEASURING ACOUSTIC IMPEDANCE OF OUTDOOR GROUND SURFACES

Andreas Fuchs **Manfred Haider**
AIT Austrian Institute of Technology GmbH, Transportation Infrastructure Technologies.

ABSTRACT

The acoustic impedance of a ground surface has an influence on sound propagation over long distances and therefore needs to be known to predict the sound imissions for residents suffering from transport noise. In the Commission Directive (EU) 2015/996 (CNOSSOS-EU) as well as in more detailed methods (e.g. NORD2000), a classification of flow resistivity is given for various ground surfaces. In Nordtest NT ACOU 104:1999 a suitable measurement method for measuring ground surface absorption is described. In this work, the setup of NT ACOU 104 is combined with modern approaches to signal processing and analysis. Quarterly measurements were carried out at eight locations in which the impulse responses between the loudspeaker and microphones were measured. In analyzing the measurements, the ground surface's effective flow resisitivty was calculated using least-squares optimization, and various impedance models were investigated for appropriability. The performance of the different impedance models was evaluated by predicting the sound pressure of a third additionally measured microphone position.

Keywords: *acoustic impedance, ground surface, measurement*

1. INTRODUCTION

The study of the interaction between airborne sound and a surface has many applications, e.g. noise abatement in machines or room acoustics. Especially for understanding outdoor sound propagation the interaction with the ground surface must be well understood.

In the Commission Directive (EU) 2015/996 (CNOSSOS-EU) the ground surface is categorized in eight categories, where the acoustic absorption properties of the ground are mainly linked to its porosity [1]. The eight categories of CNOSSOS-EU extend the seven *impedance classes* of the HARMONOISE model [2], which is considered overall to be more elaborate and in complex and more realistic situations superior to the NMPB 2008 model [3], which is the basis for CNOSSOS-EU. Table 1 lists the eight categories of ground surfaces. In CNOSSOS-EU a factor G is used, which controls the amount of absorption of the surface. In the sound propagation model HARMONOISE as well as in the similar NORD2000 [4], the ground impedance class is expressed by a effective flow resistivity σ_e, which is used as an input factor for calculating the surface impedance with the empirical Delany-Bazley model. HARMONOISE and NORD2000 only use seven classes and make no distinction between the classes G and H. [1]

For the determination of the effective flow resistivity NORD2000 refers to the Nordtest method NT ACOU 104 [5], which devides the acoustic impedance of ground surfaces into twelve flow resistivity classes using the Delany-Bazley impedance model. For many research questions, a precise prediction of outdoor sound propagation is mandatory, if a reliable determination of the acoustic ground surface for the NORD2000 or HARMONOISE models is necessary. As the latest version of NT ACOU 104 dates back to 1999, more modern approaches to signal processing and analysis are examined in this paper.

[1] For a hard surface HARMONOISE suggests a flow resistivity of 200 000 kPa s m^{-2} whereas NORD2000 suggests a flow resistivity of 20 000 kPa s m^{-2}.

Table 1: Ground impedance classes with factor G (CNOSSOS-EU) and effective flow resistivity σ_e (HARMONOISE).

	Description	G	σ_e (kPa s m^{-2})
A	Very soft (snow or moss-like)	1	12.5
B	Soft forest floor (short, dense heather-like or thick moss)	1	31.5
C	Uncompacted, loose ground (forest floors, pasture field)	1	80
D	Normal uncompacted ground (forest floors, pasture field)	1	200
E	Compacted field and gravel	0.7	500
F	Compacted dense ground (gravel road, parking lot)	0.3	2000
G	Hard surfaces (mostly normal asphalt, concrete)	0	20 000
H	Very hard and dense surfaces (dense asphalt, concrete, water)	0	200 000

2. MEASUREMENT OF GROUND SURFACE IMPEDANCE

This section gives a short summary of the NT ACOU 104 test method. Afterwards, the studied alterations are presented.

2.1 NT ACOU 104

The nordtest method NT ACOU 104 measures the level difference in third-octave bands between two microphones above a ground surface [5]. The set-up of the microphones and loudspeaker is shown in Fig. 1. The test signal shall consist of a broadband random or pseudo random noise and the time-averaged sound pressure level over at least 15 seconds is recorded for each third-octave band j in the frequency range from 200 Hz to 2500 Hz. The measured level difference

$$\Delta L_{i,j}^{\mathrm{M}} = L_{\mathrm{eq},i,j,\mathrm{top}} - L_{\mathrm{eq},i,j,\mathrm{bottom}} \qquad (1)$$

is recorded and averaged over four independent measurements i of an adjacent piece of identical ground to calculate ΔL_j^{M}.

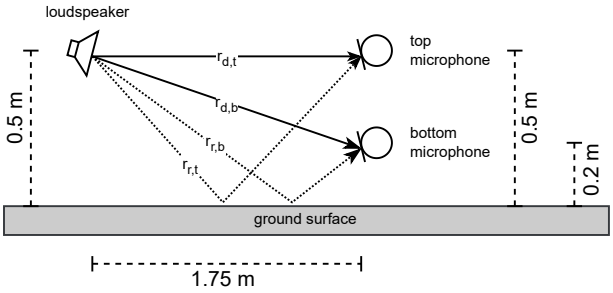

Figure 1: Measurement set-up according to NT ACOU 104.

This measured and averaged level difference ΔL_j^{M} is compared to precalculated level differences $\Delta L_j^{\mathrm{C}}(x)$ for distinct classes of flow resistivity, where the class with the smallest linear error is selected as flow resistivity. For a general parameter x, which might be multi-dimensional, this minimization can be written as:

$$\min_x E(x), \quad E(x) = \sum_j \left|\Delta L_j^{\mathrm{M}} - \Delta L_j^{\mathrm{C}}(x)\right| \qquad (2)$$

In NT ACOU 104, values are given in tables for $\Delta L_j^{\mathrm{C}}(x)$ for twelve different flow resistivity classes for a single-layer Delany-Bazley impedance model, as well as for a porous layer above a rigid surface with 0.05 m, 0.1 m and 0.15 m thickness for high and low temperatures. For measurements to be valid, the standard deviation between the repeated measurements for each third-octave band $s_{\mathrm{D},j}$ shall not exceed 4 dB. Also, the error E should be less than 15 dB. In an informative annex in NT ACOU 104 the use of a different impedance model is described.

2.2 Proposed adaptions to NT ACOU 104

The following adaptions to NT ACOU 104 are proposed and presented in this section:

- record impulse responses with time windowing,
- always solve the minimization problem for continuous values,
- examine different impedance models
- validate best fit with third microphone position.

2.2.1 Record impulse responses and use time-windowing

Recording broadband noise is sensitive to disturbing noise sources, wind noise and the surrounding area. For the in-situ measurement of the intrinsic characteristics of sound

reflection of noise barriers under direct sound field conditions (as described in EN 1793-5 [6]), impulse responses are used to measure the reflection index of noise barriers and the measurements can be performed along a highway under normal operation. If a Maximum-Length-Sequence (MLS) is used as test signal for NT ACOU 104 to calculate the impulse responses, this technically still classifies as a pseudo random test signal. This adds robustness against disturbing noise sources for the measurements. However, another advantage of impulse responses is the possibility to perform time filtering to suppress unwanted reflections. Beside the calculation of an impulse response, we propose the use of the Adrienne time-window from EN 1793-5 [6] with a length of the flat top (main part) of 10 ms and total window length of 14.8 ms. Therefore, a third-octave band level can be calculated for a impulse response $h(t)$, a time window $w_\mathrm{A}(t)$ and the Fourier transform $\mathcal{F}$ with

$$L_j = 10\log\left(\int_{\Delta f_j} |\mathcal{F}[h(t)w_\mathrm{A}(t)]|^2\right) \tag{3}$$

for the third-octave frequency bands j with a width of Δf_j. Figure 2 shows the measured impulse response for the top microphone over grass (green line) as well as the proposed Adrienne time window (orange line). At around 5.1 ms the first peak of the direct path is visible, whereas at 6 ms the first peak of the reflected component can be distinguished. The time window is long enough to include the whole impulse response of the loudspeaker for both components.

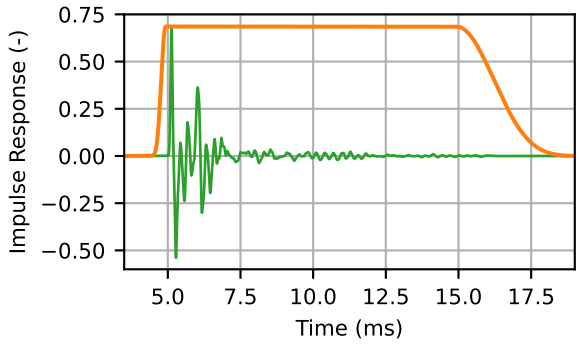

Figure 2: Impulse response (green) and Adrienne time window (orange).

2.2.2 *Solving the minimization problem for continuous values*

Instead of a table look-up from NT ACOU 104 we suggest solving the minimization problem for continuous values of the required impedance parameter(s). This can be achieved with the underlying Weyl-Van der Pol equation, which is able to predict the sound pressure p from a point source above a locally reacting ground as a superposition of the sound pressure from the direct path p_d and the reflected path (p_r), which is multiplied with the *spherical reflection coefficient* Q [7]:

$$p = p_\mathrm{d} + Qp_\mathrm{r} = \frac{\mathrm{e}^{\mathrm{i}kr_d}}{4\pi r_d} + Q\frac{\mathrm{e}^{\mathrm{i}kr_r}}{4\pi r_r}, \tag{4a}$$

$$Q = R_\mathrm{p} + (1-R_\mathrm{p})(1+\mathrm{i}\sqrt{\pi}w\mathrm{e}^{-w^2}\,\mathrm{erf}(-\mathrm{i}w)), \tag{4b}$$

$$w = \frac{1+\mathrm{i}}{2}\sqrt{kr_r}(\cos(\theta)+Z^{-1}), \tag{4c}$$

$$R_\mathrm{p} = \frac{\cos(\theta)-Z^{-1}}{\cos(\theta)+Z^{-1}} \tag{4d}$$

and R_p as the plane wave reflection coefficient of the locally reacting ground surface, r_d and r_r as the distance between source and receiver position for the direct and reflected path respectively, the wave number k, the incident angle θ and the normalized impedance of the ground Z. If the Delany-Bazley impedance model is used, then the impedance is calculated with [5]

$$Z = 1 + 9.08\left(\frac{f}{\sigma_\mathrm{e}}\right)^{-0.75} + i11.9\left(\frac{f}{\sigma_\mathrm{e}}\right)^{-0.73}. \tag{5}$$

The predicted sound pressure levels must be calculated in third-octave bands for both microphone positions for comparison with the measurement data. Afterwards, the minimization in Eqn. (2) can be solved for continuous values of the required impedance parameter.

2.2.3 *Examination of different impedance models*

Including the Annex D, NT ACOU 104 suggests the use of three different impedance models: Delany-Bazley, Delany-Bazley with an additional porous layer above a rigid surface and the variable porosity model. Among the commonly used impedance models models [8], [9], we studied the following ones by using the respective model in the plane wave reflection coefficient in Eqn. (4d):

Delany-Bazley The semi-empirical Delany-Bazley [8] model given in Eqn. (5) with the parameter effective flow resistivity σ_e.

Variable Porosity The variable porosity model considers an increasing porosity with increasing depth as approximation with two parameters (effective flow resistivity σ_e and effective rate of change of porosity α_e) and uses the heat capacity ratio γ [7]:

$$Z = \frac{1+\mathrm{i}}{\sqrt{\pi\gamma\rho_0}}\sqrt{\frac{\sigma_\mathrm{e}}{f}} + \frac{\mathrm{i}c_0\alpha_\mathrm{e}}{8\pi\gamma f}. \tag{6}$$

Zwikker-Kosten The phenomenological model from Zwikker-Kosten uses the three parameters flow resistivity σ, porosity Ω and structure factor K [7]:

$$Z = \frac{\sqrt{K}}{\Omega}\left(1 + \frac{\mathrm{i}\Omega\sigma}{2\pi f\rho_0 K}\right). \tag{7}$$

Taraldsen Taraldsen transformed the phenomenological model from Zwicker-Kosten to a one-parameter model (effective flow resistivity σ_e) [7]:

$$Z = \left[\sqrt{\gamma}\frac{\Omega}{\sqrt{T}}\left(1 + \frac{f*}{f}\right)\right]^{-1} \tag{8a}$$

$$f* = \frac{1}{2\pi\rho_0}\frac{\Omega}{\sqrt{T}}\sigma_\mathrm{e} \tag{8b}$$

$$\frac{\Omega}{\sqrt{T}} = 100\left(10^{X/10}\right) \tag{8c}$$

$$X = \frac{1}{19.76}\Big[-10\log(\sigma_\mathrm{e}) + 404.55 + \sqrt{546.166 + [9.35 - 10\log(\sigma_\mathrm{e})]^2}\Big]. \tag{8d}$$

Slit-pore The slit-pore model is based on the simulation of the internal structure of the absorber with interconnected slits and pores. For the impedance of the ground, the assumption of identically wound slit-like pores is used with the three parameters flow resistivity σ, porosity Ω and tortuosity T [8] and uses the Prandtl number Pr:

$$Z = \frac{1}{\rho_0 c_0}\sqrt{\frac{T}{\Omega^2}\frac{\rho(\lambda)}{C(\lambda)}} \tag{9a}$$

$$\rho(\lambda) = \frac{\rho_0}{G_S(\lambda)} \tag{9b}$$

$$C(\lambda) = \frac{1}{\gamma P_0}\left[\gamma - (\gamma-1)G_S(\lambda\sqrt{Pr})\right] \tag{9c}$$

$$G_S(\lambda) = 1 - \frac{\tanh(\lambda\sqrt{-\mathrm{i}})}{\lambda\sqrt{-\mathrm{i}}} \tag{9d}$$

$$\lambda = \sqrt{\frac{6\rho_0\pi f T}{\Omega\sigma}} \tag{9e}$$

For the Delany-Bazley, the Zwikker-Kosten as well as for the slit-pore model also the respective layered model is considered, where the impedance is calculated with

$$Z = Z_\mathrm{n}\coth(-ikd) \tag{10}$$

with the layer thickness d of the porous material over a rigid surface. Z_n is the impedance of the according impedance model (Eqn. (5), (7) or (9a) respectively).

2.2.4 *Validate best fit with third microphone position*

For validation purposes, we propose to measure a third microphone position between the top and bottom microphone in the set-up of NT ACOU 104 (see Fig. 1), which is 35 cm above the ground. The *validation* level difference $\Delta L^\mathrm{M}_{\mathrm{v},j}$ is calculated from the difference from the validation to the bottom microphone via Eqn. (4a) and Eqn. (1). This gives the advantage of new independent measurement data on an identical test specimen with minimal extra effort. The *validation error* E_v is then similar to Eqn. (2)

$$E_\mathrm{v} = \sum_j \left|\Delta L^\mathrm{M}_{\mathrm{v},j} - \Delta L^\mathrm{C}_{\mathrm{v},j}(x)\right|. \tag{11}$$

Figure 3 shows the level difference ΔL_j for the standard set-up from NT ACOU 104 (top to bottom microphone) as well as as the level difference from the additional proposed validation microphone to the bottom microphone $\Delta L_{\mathrm{v},j}$. The computed level difference values are calculated for a flow resistivity class of 400 kPa s m^{-2},

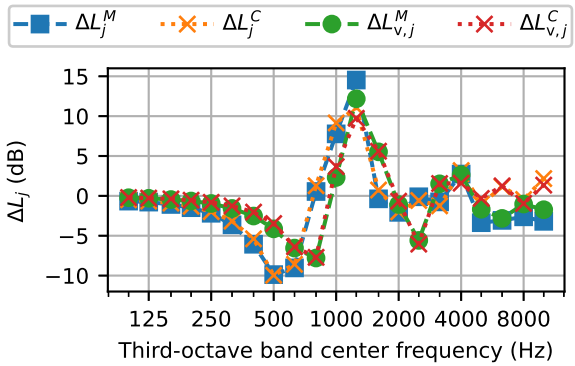

Figure 3: Measured ($^\mathrm{M}$) and computed ($^\mathrm{C}$) level difference between the top and bottom microphone (ΔL_j) and additional validation microphone and bottom ($\Delta L_{\mathrm{v},j}$).

which was calculated for a minimum error of E (Eqn. (2)). For the additional validation microphone the third-octave band values of the level difference $\Delta L_{\mathrm{v},j}$ are different to ΔL_j due to the changed geometry. Nevertheless, the computed values are quite close to the measured values for a frequency range from 100 Hz to 4000 Hz. This gives the ability to validate the obtained value of $\sigma_\mathrm{e} = 400\,\mathrm{kPa\,s\,m^{-2}}$ for a microphone and geometry, which was not included in the calculation of the value.

3. MEASUREMENTS

The analysis presented in this paper is based on measurements which were performed to study the ground surface absorption of earth berms for calculating sound propagation alongside highways. Therefore, measurements were performed on flat and inclined surfaces, although NT ACOU 104 suggests only to perform measurements on a flat surface. For the measurements on the slope, the set-up according to NT ACOU 104 is rotated with respect to the inclination. Measurements were performed on two sites, with multiple measurement positions for each site:

Site A: 2 measurement positions on level ground and 4 measurement positions on tilted surfaces with angles ±16° and ±35°. [2]

Site B: 2 measurement positions on tilted surfaces with angles 35° and 38°.

The measurements were performed repeatedly on the same spots on a quarter year basis from Q4 2023 until Q3 2024. Although, all measurements sites can be considered covered with grass, the ground was much more compacted in Q4 2023. In Q1 2024 and Q3 2024 very similar conditions could be found with low length grass, where in Q2 2024 the measurements were performed on a hot day with high grass. The measurement sites are less than 30 km apart from each other. Figure 4 to Fig. 7 show pictures of the measurement sites. As this study did not focus on performing measurements, the variation of the measurement sites is limited. Nevertheless, the data set spans over four of the seven impedance classes of HARMONOISE (classes B - E from Tab. 1).

For the measurements a MLS signal was used as test signal with a length of two seconds, which was repeated

[2] For a positive angle the loudspeaker is below the microphone and emits sound upwards the slope, whereas for a negative angle the loudspeaker is placed above the microphones.

Figure 4: Picture of measurement site A Q4 2023.

Figure 5: Picture of measurement site A Q2 2024.

Figure 6: Picture of measurement site B Q4 2023.

Figure 7: Picture of measurement site B Q2 2024.

30 times. Therefore, it is possible to calculate a two second long impulse response for each microphone, which was averaged 30 times.

4. RESULTS AND DISCUSSION

In this section the proposed adaptions to NT ACOU 104 from section 2.2 are evaluated.

4.1 Solving the minimization problem

The minimization problem in Eqn. (2) is solved using a curve-fitting algorithm. This gives the ability to calculate continuous values for the impedance model parameters, especially a continuous value for the effective flow resisitivty for the Delany-Bazley model instead of the 12 classes according to NT ACOU 104. Figure 8 shows a box plot of the error E from Eqn. (2) and validation error E_v from Eqn. (11) for all obtained measurements, if the effective flow resisitivty, which minimizes E, is determined with a table lookup as in NT ACOU 104 or if a continuous value is calculated. This value is then used to calculate the validation error E_v by using it to predict the level difference. Afterwards, the predicted level difference is compared to the measured level difference between the validation and bottom microphone and the validation error E_v calculated. As expected, the errors are smaller for the fitting approach compared to the table lookup method. However, the improvement can be seen even better for the validation error E_v, where the mean error is decreased by about 2 dB.

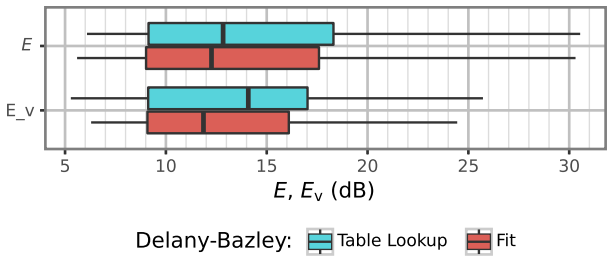

Figure 8: Comparison of the error between the measured and computed level difference for the standard set-up (E) and the validation set-up (E_v) for all obtained measurements (Delany-Bazley model).

4.2 Impulse Responses

For all performed measurements the effective flow resistivity σ_e was determined according to the Delany-Bazley model by running a curve fitting algorithm on the error function $E(x)$ (Eqn. (2)) for two specific test cases:

Noise The $L_{\mathrm{eq},j}$ values are calculated with time filters on the recorded signal and averaged over 60 s.

Impulse Response Instead of the $L_{\mathrm{eq},j}$, the L_j from Eqn. (3) are used as third-octave band levels and are calculated by deconvoluting the recorded signal to obtain the impulse response.

Figure 9 compares the effective flow resistivity σ_e for the two test cases, where no significant deviations are visible. For one measurement the deviation is 6 %, for all other measurements the deviation is less than 5 %, Also, for more than half of the 27 data points the deviation is less than 1 kPa s m^{-2}.

In the standard deviations between the four measurements for each measurement position no significant difference can be found, as the mean difference between the standard deviation for the *noise* and *impulse response* test case for each measurement position for all third-octave bands is smaller than 0.1 dB. As the measurements were performed without external noise sources, the main benefit of the impulse response calculation can not be shown. Nevertheless, the results are similar and there is no apparent downside to using impulse responses.

4.3 Impedance Models

The error E as well as the validation error E_v can also be used to compare different impedance models. Figure 10

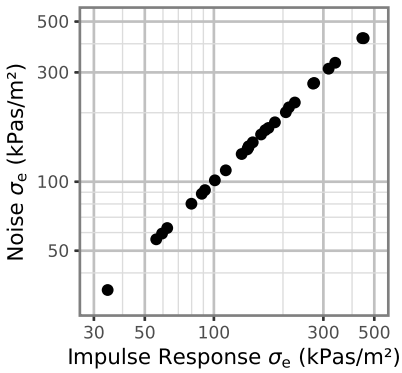

Figure 9: Estimated effective flow resistivity σ_e with the Delany-Bazley impedance model by directly processing the noise signal or calculating impulse responses.

shows box plots, where the range of the occurring errors for all obtained measurements is visible with respect to the impedance model. Again, the validation error E_v is calculated by using the obtained impedance model parameters, which result from minimizing the error E for the top to bottom microphone set-up, for predicting and comparing the level difference of the validation to bottom microphone set-up. The impedance models are ordered by increasing number of parameters from top to bottom. For the one-parameter Taraldsen model it was not possible to find a good fit. All the other newly considered models performed similar or better than the Delany-Bazley model. Especially, the variable porosity model (except for a few outliers) and also the phenomenological model from Zwikker-Kosten show promising results pushing the mean of the errors in the dataset closer to 10 dB than the Delany-Bazley model. However, the Delany-Bazley model shows a quite reasonable performance considering its simplicity. The respective layer variants of the models show small improvements, but might not be applicable for the performed measurements. The validation error E_v is in the same range as E except for the Taraldsen impedance model, which supports the assumption that the fit of the these models can be generalized and can be used for sound propagation calculations.

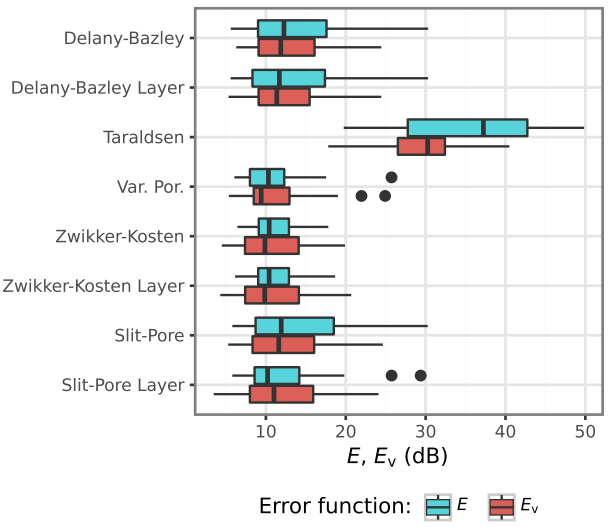

Figure 10: Comparison of error E and validation error E_v of the impedance models for all obtained measurements.

4.4 Influence of Angle

In contrast to NT ACOU 104, measurements were also performed on tilted surfaces. No significant influence of the angle of the surface on the error and the validation error could be found, which means the fit to the standard set-up and the validation set-up works for tilted surfaces as well as for flat ground. Nevertheless, the obtained values for the flow resistivity are quite different for the different angles. Figure 11 shows the estimated effective flow resis-

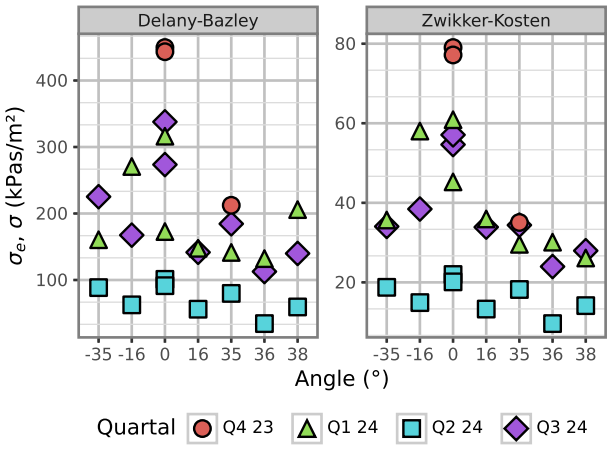

Figure 11: Estimated (effective) flow resistivity for the Delany-Bazley (σ_e) and the Zwikker-Kosten (σ) model for all obtained measurements.

tivity σ_e for the Delany-Bazley impedance model as well as the flow resistivity σ for the Zwikker-Kosten model for all measurements for the different surface angles for the repeated measurements. It can be seen, that the flow resistivity is significantly lower in Q2 2024, which may be attributed to a drier ground. This can also be attributed to the porosity Ω in the Zwikker-Kosten model, which is significantly higher in Q2 2024 than for the other quarters. For Q4 2023 not all measurements were performed. Nevertheless, the respective highest values for the flow resistivity were measured in this quarter, which get close to class E according to the HARMONOISE classification (compacted field). For the measurements, which were not performed in Q2 2024, it can be seen that for the non flat measurements the estimated flow resistivity is lower. This may be attributed to a less compacted ground on the earth berm. It should be noted, that the measurements at 36° and 38° inclination were performed at a different site, which might have different sound absorbing characteristics.

5. SUMMARY AND OUTLOOK

In this paper, adaptions to the standard NT ACOU 104 for measuring ground surface absorption were presented. The measurements were obtained on grass covered earth berms. The use of a third microphone for validation provides valuable insight into how well the estimated parameters can actually describe the acoustic properties of the ground surface. Because the extra effort seems reasonable compared to the information gain, we recommend the use of an extra microphone position. Also, no significant difference in the analysis with impulse responses to the previous method could be found. As the measurement with impulse responses is generally seen as more robust, we encourage their use instead of evaluating noise signals.

Depending on the application, the use of a fitting algorithm to determine a continuous parameter as well as other impedance models, might improve sound propagation over long distances. Nevertheless, this must be supported by the underlying sound propagation calculation method and must be evaluated in further research. Also, the measurement on inclined surfaces showed promising results over short distances due to the low validation error. However, further research is encouraged to evaluate if for larger propagation paths it is more beneficial to use values obtained from the inclined plane than from the flat surface.

ASSESSING FOREST ACOUSTICS: A COMPARISON OF IN-SITU AND SCALE MODEL ACOUSTIC IMPULSE RESPONSES

Sinuo Feng[1*] **Francis Stevens**[1] **Andrew Chadwick**[1]

[1] AudioLab, School of Physics, Engineering and Technology, University of York, UK

ABSTRACT

Acoustic impulse responses (IRs) can be used for the analysis of a space's acoustic properties and for convolution based auralisation (which has many applications, including in music production and sound design). However, the vast majority of impulse responses are recorded indoors, typically in musical performance spaces. As a result there are relatively few IRs available recorded in outdoor conditions. This paper presents an analysis of IRs recorded in a forest environment, comparing in-situ results with those recorded using a scale model. The in-situ recordings were measured in mono and B-format, and are analysed in terms of reverberation parameters and spatial characteristics. A 1:10 scale model of the forest environment was then constructed and measured. This work aims to contribute to the understanding of sound propagation in a forest environment (particularly in terms of the acoustic effect of tree trunks of different diameters at different positions relative to the listener, which previous studies have determined to be of particular importance) and to assess the suitability of scale modelling in this context. The resultant impulse responses are available online.

Keywords: *forest acoustics, acoustic impulse response measurement, scale model*

1. INTRODUCTION

An understanding of the acoustic properties of forest environments is of great importance to many fields, including noise propagation, soundscape evaluation, and sound design [1, 2]. There is existing literature focussing on different aspects of forest acoustics, but work remains to be done in developing a full understanding of how the different physical characteristics of a forest (the layout, number of trees, tree trunk diameters, bark material) combine and result in a particular acoustic. This work investigates the acoustics of a forest environment, by assessing in-situ impulse responses and scale model measurements, and aims to answer the following questions:

1. What are the acoustic properties of tree trunks in a forest environment?
2. Is a scale model a good approach to studying forest acoustics?

The structure of this paper is as follows: Section 2 presents a review of relevant prior research; Section 3 presents the method of impulse response recording used in the forest and the scale model; Section 4 presents the analysis and comparison of the impulse responses from both environments; and Section 5 concludes the paper, considering the above questions.

2. BACKGROUND

This section presents a brief review of the relevant existing literature, include material on the study, analysis, and modelling of forest acoustics, and acoustic scale modelling.

2.1 Forest acoustics

Sound attenuation by vegetation has been investigated since at least 1946, when Eyring investigated the acoustic properties of a Panamanian jungle [3]. It has been proposed that trees can be used as noise barriers near sources such as highways and railroad tracks [4,5]. The form and layout of a forest have been indicated as important properties in determining sound attenuation [6, 7]. This is related to the interaction of various acoustic phenomena in a forest environment. Noise attenuation can occur due to sound energy absorption and scattering effects by branches, foliage, and shrubbery [5, 8]. The effect of sound propagation in a forest environment has been shown to be highly frequency dependent [9]. A relatively small sound attenuation in a frequency range between 1 and 2 kHz was observed by Fricke, and a similar reduction in attenuation was found by Kragh, typically between 500 Hz and 2 kHz [7, 10].

Previous IR measurement work has been conducted in a forest environment, where Shelley et al. conducted a study at Koli

National Park in Finland using a B-format microphone and a single speaker [11]. This method followed ISO 3382 IR measurement procedure (designed for indoor measurement) [12]. The analysis of acoustic parameters, including reverberation time (T30) and clarity (C50) was conducted, and a reverberation time of between 1.3s and 1.7s was found in the 1 kHz octave band. Previous studies have indicated that tree trunks are a key factor in sound scattering above 1 kHz in a forest environment [9, 13–15]. Chobeau determined that the scattering caused by tree trunks is dependent on the apparent diameter of the trunk and the relationship between the diameter and the frequencies present in the incident sound [16]. Generally, tree trunks scatter sound frequencies with wavelengths equal to or smaller than their diameters [9].

Previous studies in modelling forest acoustics have considered tree trunks as the key factor in sound propagation. *Treeverb*, a digital reverberator, simulates acoustic reverberation in a forest environment, modelling the scattering of acoustic waves among trees in a simplified forest model [17]. Fig. 1 shows a simple example of a forest modelled in this way, where T1, T2, and T3 are the interconnected tree-nodes, S is the source and R is the receiver. In this work an image-source model, along with Morse's solution to the acoustic scattering from a cylinder [18], was used to generate IRs. In [19] a similar approach was used to model forest acoustics, using a set of waveguides to connect the tree nodes (extending the scattering delay network approach in [20]).

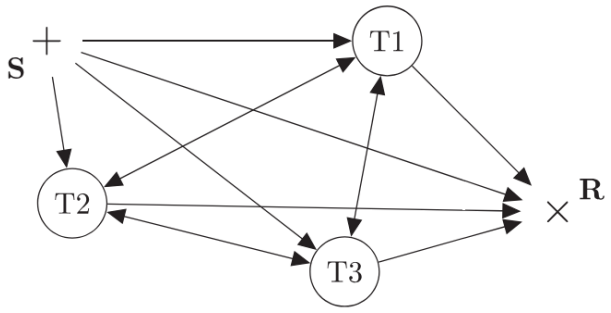

Figure 1. An example of a simplified model of a forest, consisting of three tree-nodes, T1, T2, T3, a source, S, and a receiver, R. From [19].

2.2 Scale modelling

Acoustic scale modelling was first used in the design of concert halls and opera theatres in the 1930s [21]. This method allows for the prediction of the acoustic properties of a full-scale space as it captures complex wave effects such as diffusion, diffraction, and ground interference [22, 23]. The model scale factor (k) determines the relationship between the scale frequency (f_{scale}) and the corresponding full scale frequency (f_{real}) [24]:

$$f_{\text{scale}} = k \times f_{\text{real}} \tag{1}$$

When determining the scale factor there is a trade-off between the capability of the available recording equipment [25], the space available, and the increased air absorption at higher frequencies [26]. When constructing a scale model, the materials used should closely approximate sound absorption coefficients (SACs) at the scaled frequencies [27].

Scale modelling has previously been used to study sound propagation in outdoor spaces. Cox et al. studied the acoustic properties of Stonehenge using an acoustic scale model [23]. This research used a scale factor of 12, and IR measurement and analysis were conducted in accordance with ISO 3382 [12]. The Exponential Sine Sweep (ESS) method was used with frequencies ranging from 800 Hz to 96 kHz. Four compact tweeters, arranged in a square configuration, and an ultrasonic microphone were used to approximate an omnidirectional source and receiver. The model stones were designed and constructed to minimise sound absorption (given the typically low SAC of stone), and unvarnished Medium Density Fibreboard (MDF) was used to model the ground, to match the SACs of grassland in a true scale frequency range of 125 Hz to 1 kHz. The scale modelling work presented in this paper draws on Cox et al.'s approach.

3. METHODOLOGY

This section covers the methods of IR measurement used in the real forest (Section 3.1), the design and construction of the scale model (Section 3.2), and the scale model IR measurement (Section 3.3).

3.1 Forest IR Measurement

The chosen measurement site was in Wheldrake Woods, c. 8 miles south-east of York [28]. Fig. 2 shows the chosen environment. The trees are all the same species (*Abies Grandis*), and consist primarily of tall, straight, trunks with no large branches. The ground surface is relatively flat with no additional low vegetation.

Two source and two receiver positions were selected for measurement. Source *S1* was placed with clear sight lines to Receivers *R1* and *R2*. *S2* was placed with a tree obstructing its view of both receivers. Each position was at least 1m away from the nearest tree. The positions and diameters of the trees within an area of 20m $\times$ 20m around the sources and receivers were measured, the layout of which is shown in Fig. 3. The size of the surveyed area was determined by the maximum scale model size, as discussed in Sections 3.2 and 3.3.

The IRs were measured with the ESS method, using a Genelec 8130A loudspeaker to reproduce a sine sweep of 15s duration with a frequency range of 60 Hz - 20 kHz ($f_s = 48\,\text{kHz}$). Recordings were made using two microphones: an Earthworks M30 omnidirectional measurement microphone (mono), and a

Figure 2. The forest environment considered in this study. The measurement setup can be seen: an Earthworks M30 omnidirectional measurement microphone and a Genelec 8130A loudspeaker.

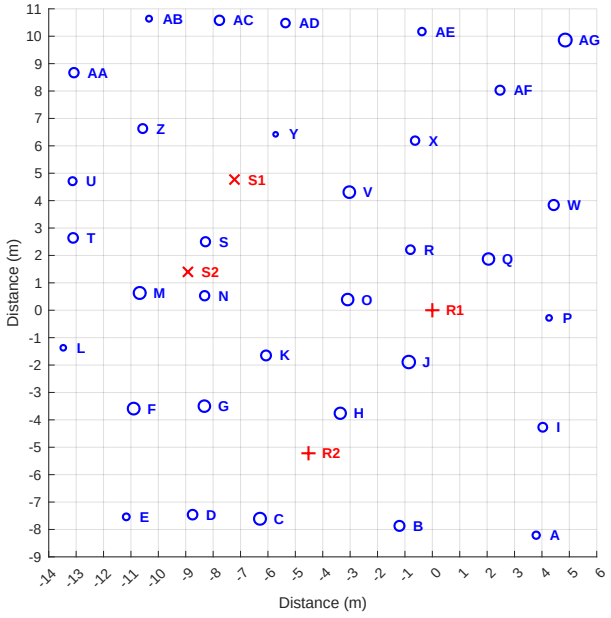

Figure 3. Diagram of the layout of the forest environment, showing source, receiver, and tree positions. Within the measurement area there were 33 trees with diameters ranging between 0.17m to 0.47m.

Soundfield ST450 MkII (B-Format). The speaker and microphones were placed at a height of 1.5m. For each source position, four measurements were made: first recording a sweep with the speaker facing *R1*, then three further recordings with the speaker rotated clockwise 90° each time. These four orientations were then averaged to approximate an omnidirectional source [11].

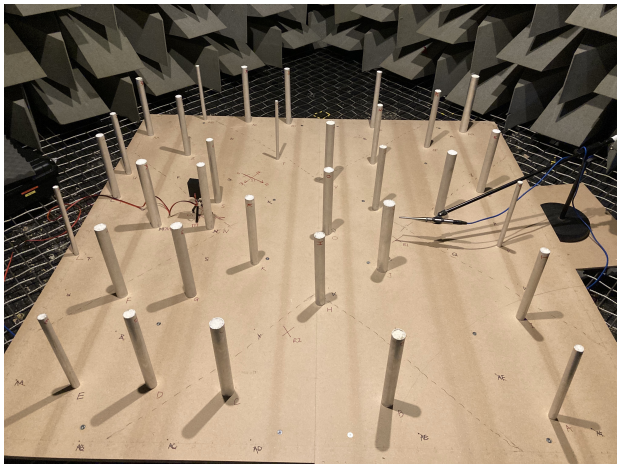

Figure 4. A picture of the forest scale model setup in the anechoic chamber, formed by 33 aluminium tubes (filled with plaster) and an MDF board. Here source and receiver are at position S2R1.

3.2 Design of the scale model

The scale model was constructed with a scale factor of 10. This was determined by the maximum usable area of the anechoic chamber in which the recording took place, and the microphone in use (an Earthworks M30) having a flat response up to 30 kHz. This allowed for useful measurement up to $f_{real} = 3\,\text{kHz}$, and the use of available materials with SACs appropriate to this scale.

Aluminium tubes were used to model the trees, due to their smooth surface which is reflective at high frequencies. To avoid capturing the resonant frequencies of the tubes, each was filled with plaster. The tubes were chosen from available diameters, resulting in some minor error (maximum 6.85%).

In this experiment, the height of each tube was 40cm. This was chosen as it is more than twice height of the source/receiver in the scale model (15cm). Unvarnished MDF was used to model the ground, as in [23].

To construct the scale model, a square MDF board (with side length of 2.1m) was mounted to the floor of the anechoic chamber. Dowels were then used to attach the model trees in their correct positions. The final forest scale model setup is shown in Fig. 4.

3.3 Scale Model IR Measurement

A Peerless OC20SC14-04 tweeter with a diameter of 33.2mm, and a frequency response from 750 Hz to 38 kHz was used as the source in the scale model measurements, with the Earthworks M30 used to record the signals produced. A 15s duration ESS ($f_s = 96\,\text{kHz}$) was used with a frequency range from 1 kHz to 30 kHz, allowing for IR analysis of octave bands from 125 Hz to 2 kHz at full scale. For each source/receiver pair, 16 recordings were made: four speaker orientations (as in the in-situ measurement), each recorded four times (in an attempt to improve the signal-to-noise ratio [23]). These 16 takes were then averaged and equalised for the speaker's response using an inverse filter based on a free-field measurement of the speaker.

4. EVALUATION

This section presents analysis of the IRs measured in-situ and using the scale model. This includes ISO 3382 analysis and spatial analysis of the B-format recordings. The full sets of recorded IRs are available online [29, 30].

4.1 Forest IR Analysis

Fig. 5 shows the reverberation time (T30) results for the four forest IRs. They each show a similar trend, with a pronounced peak across the 500 Hz, 1 kHz, and 2 kHz octave bands, where the values are above 1.5s. These results are partly due to the measured tree trunk diameters (ranging between 0.17m and 0.47m), which correspond to wavelengths from 735.6 Hz to 2072.5 Hz, this is an expected result given the importance of tree trunk reflections identified in the literature [9, 13–16].

Ground interference is likely to have an impact below 500 Hz [13,31], resulting in constructive and destructive interference in the 125 Hz, 250 Hz, and 500 Hz octave bands [32]. Low-frequency wind noise in the recordings may result in overestimation of reverberation time, particularly for the 125 Hz octave band. The significant drop in reverberation time for the 4 kHz and 8 kHz octave bands is due to the open nature of the forest and absorption by tree bark [19, 33].

Fig. 6 shows a comparison of Definition (D50) results for the four forest IRs. D50 values are generally above 80%, suggesting significant sound attenuation at high frequencies and good speech intelligibility. A reduction in D50 is observed for the 1 kHz and 2 kHz octave bands of each IR, due to the increased reverberant energy. At position S2R1, the source is occluded by *Tree O*, and at position S2R2, the source is occluded by *Tree N*. Without a clear line of sight between source and receiver there is no true direct sound present in the IR, resulting in a decrease in D50 [34]. This is particularly evident in the results for S2R1.

Fig. 7 shows a waveform plot of the S1R2 IR. Alongside the IR, red lines indicate the timings of reflections from the tree trunks in the environment (calculated using the forest layout data). It can be seen that a number of strong early reflections in the IR line up with these predicted timings, confirming the impact that tree trunks have on a forest's acoustic properties.

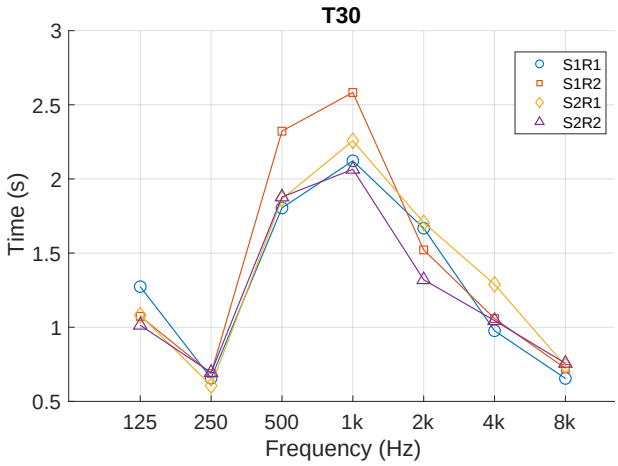

Figure 5. Reverberation time (T30) results for the four forest IRs.

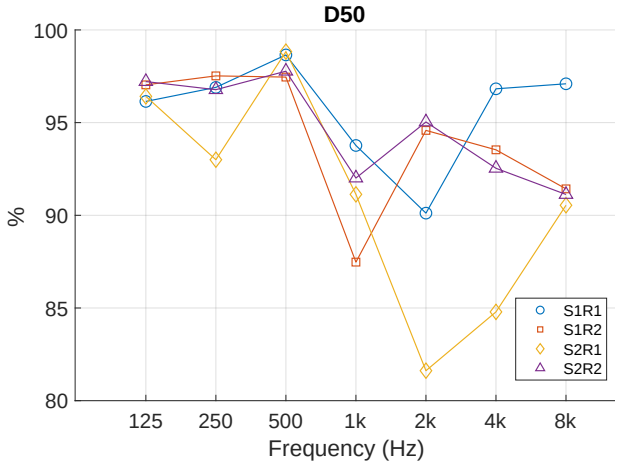

Figure 6. Definition (D50) results for the four forest IRs.

The spatial information captured in the B-format IRs can be evaluated by spatial impulse response rendering (SIRR) analysis. Here the signals are divided into discrete time frames, and then a short-time Fourier transform (STFT) is performed on each channel. A instantaneous intensity vector **I** vector can then be estimated according to:

$$\mathbf{I}(\omega) = \frac{\sqrt{2}}{Z_0}\Re\{W^*(\omega)U(\omega)\} \tag{2}$$

where U(ω) is vector [X(ω), Y(ω), Z(ω)], Z_0 is the char-

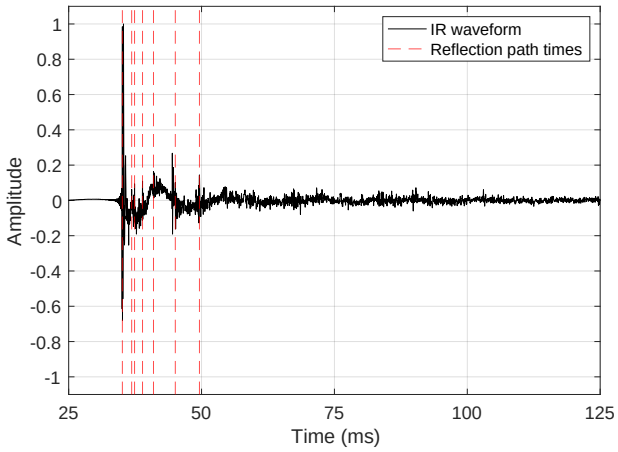

Figure 7. Waveform plot of the S1R2 IR recorded in the forest. The red lines indicate the timing of first-order reflections from nearby trees.

acteristic acoustic impedance of air, and $*$ denotes the complex conjugate [35].

Fig. 8 shows a SIRR plot for the IR at position S1R2. Only the horizontal plane is considered in this SIRR analysis, due to the open nature of the forest environment precluding significant directional information in the vertical plane [36]. The arrows indicate the direction of arrival of sound in each frequency bin for each frame. An arrow pointing to the right corresponds to a sound arriving straight-on to the microphone (0°); an arrow pointing down corresponds to a sound coming from the right to the microphone (90°). These arrows are overlaid on a spectrogram of W-channel of the IR, allowing for concurrent analysis of the magnitude and direction of arriving acoustic energy.

The SIRR plot shows a strong direct sound followed by a set of early reflections coming from different directions. At certain points in time, clusters of arrows can be found pointing in the same direction. These indicate reflections from particular tree trunks, and a summary of the first-order reflections (with suggestions of the particular trees contributing to them) is given in Table 1. This analysis could be continued to include further reflection paths; previous work has shown the importance of reflections of up to third-order in outdoor environments [36].

4.2 Scale Model IR Analysis

The scale model IRs were interpolated to be 10 times longer, in order to conduct analysis at true scale. Fig. 9 shows the waveform plot of the IR recorded at position S1R2 in the scale model. As before, red lines indicate the estimated reflection path times calculated using the forest layout data. The results show that the reflections indicated in the waveform align well with the potential reflections indicated in the actual layout, and the error range

Table 1. Details of the first-order reflections identified in the SIRR analysis in Fig. 8.

Timing	Direction of arrival	Frequency	Relevant Tree(s)
12-16ms	0°	0-5 kHz	*K*, *S*, *H*, *N*, *O*
20-22ms	315°	1-5 kHz	*M*
22-26ms	45°	1-4 kHz	*V*, *Y*
28-30ms	225°	2-5 kHz	*C*

is small. The waveform shows a strong direct sound followed by clusters of early reflections, which is similar to the IR recorded in the real forest (as shown Fig. 7).

Fig. 11 shows the early decay time (EDT) results for the four scale model IRs, which can be compared with Fig. 10 (which shows the EDT results for the in-situ forest IRs). EDT was chosen for comparison here as it has previously been shown to be useful when comparing scale model and real-world IRs [23]. EDT results in the scale model show generally low values due to the limited number of model trees and the anechoic environment. Although a similar trend can be found in both results: higher EDT values in the 250 Hz octave band than at 500 Hz, then a general increase for higher bands.

Spectral plots of the IRs are shown in Fig. 12 (in-situ) and Fig. 13 (scale model). Results were calculated by filtering the IRs into one-third octave bands and then calculating the dBFS values (decibels relative to full scale) for each band. There are similarities in the spectra, with a decrease in magnitude centred around the 250 Hz band, and an increase above this range.

The spectrum of the forest shows another small decrease in response of 2 to 4 dB around 800 Hz, and the results from the scale model show a similar reduction at positions S1R2 and S2R1. In the case where the source and receiver are obstructed by a tree, the frequencies are greatly pronounced below 800 Hz in the real forest. For these receiver positions in the scale model, the magnitudes are higher at the tree-obstructed (*S2*) position below this frequency. Above 250 Hz, the scale model magnitudes are generally higher than in the real forest.

5. CONCLUSION

This paper has presented the measurement and analysis of IRs recorded in a forest environment, comparing in-situ IRs with those recorded using a scale model. The questions posed in Section 1 will now be considered:

1. What are the acoustic properties of tree trunks in a forest environment?
2. Is a scale model a good approach to studying forest acoustics?

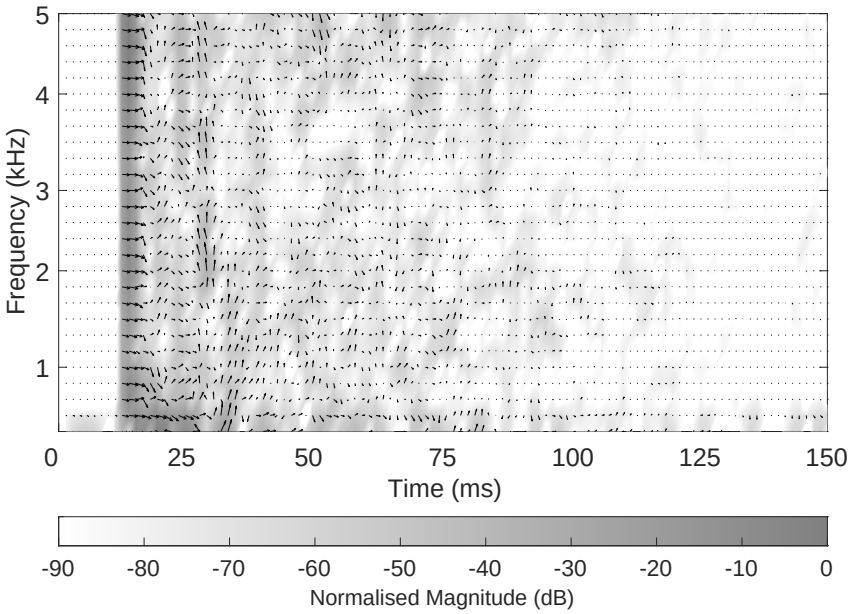

Figure 8. SIRR analysis plot of the B-format IR reorded at position S1R2 in the forest, where a spectrogram of the IR's W-channel is overlaid with arrows representing the direction of sound arrival (in the horizontal plane) in different frequency bins for each time frame.

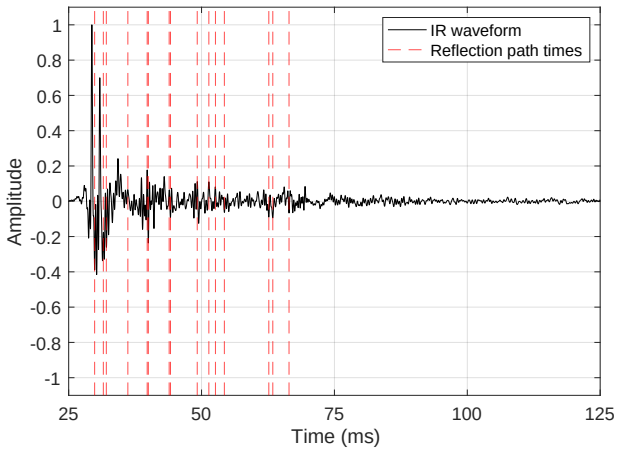

Figure 9. Waveform plot of impulse response recorded at position S1R2 in the scale model. The red lines indicate the estimated timing of early reflections.

The presented IR analysis has demonstrated the impact that tree trunks have on the acoustic of a forest environment. The presence of tree trunks results in strong early reflections (as shown by the SIRR analysis results), and can occlude sound paths reducing the acoustical clarity (as shown by the D50 results), and can increase reverberation time in 1 kHz and 2 kHz octave bands (as shown by the T30 results). The results presented here are limited by the small number of source and receiver positions, and the area of the forest environment surveyed and measured.

The results from the scale modelling work indicate that this may be a useful approach to the study of forest acoustics, as there are similarities between the scale model and in-situ results presented in the evaluation. That said, there are still a number of unanswered questions that bear consideration. There is further work to be done in assessing the appropriateness of the materials used in the scale model, and whether they correctly represent the full scale acoustic behaviour. The scale model used here is also limited to 33 trees in a 20m $\times$ 20m area (as determined by the chosen scale factor and model size limitations). Further work investigating the effect of the scale factor on the results, and the impact of the number of modelled trees, should be conducted.

ABSTRACT

ISO 9613-2:2024 standard, titled "Acoustics — Attenuation of sound during propagation outdoors — Part 2: Engineering method for the prediction of sound pressure levels outdoors", which is a governing standard for outdoor sound propagation calculations, was recently revised with significant enhancements to improve the accuracy, consistency, and applicability of noise prediction models. The revision refines key parameters, such as meteorological corrections, ground effects, and source characterization, along with improved formulas for attenuation due to atmospheric absorption, updated guidance for terrain and obstacle modeling, and expanded methodologies for complex source configurations.

The new features were evaluated in this paper by presenting examples from a commercial noise mapping software that has already adapted the new revision, assessing their impact on noise modeling practice compared to the previous version, ISO 9613-2:1996. The paper also highlights how the updates align with advancements in measurement technologies and software tools. By summarizing these amendments, it offers valuable insights for acousticians, engineers, and regulatory authorities integrating the revised standard.

1. INTRODUCTION

Modeling of outdoor sound propagation poses a critical aspect to urban and rural tranquility, environmental noise assessment, regulatory compliance, and civil planning, as urban acoustics are defined by different noise sources, environmental factors affecting noise propagation and a complex geometry with a high number of surfaces and materials [1].

ISO 9613-2:2024 standard, titled "Acoustics — Attenuation of sound during propagation outdoors — Part 2: Engineering method for the prediction of sound pressure levels outdoors", offers an engineering method for predicting sound attenuation in open environments to estimate noise levels from noise sources ranging from industrial facilities to transportation networks and urban development [2-3]. Since its release in 1996, ISO 9613-2 has been in wide use by acousticians. However, due to the latest advancements in computational noise modeling, environmental acoustics, and noise prediction methods, it went through a revision and was updated in 2024. ISO 9613-2:2024 introduced new correction factors, and refined existing formulas to provide more accuracy in noise modeling of various environmental conditions.

In the 1996 version of ISO 9613-2, sound attenuation was taken into account mainly for ground effect, atmospheric absorption, geometrical divergence, reflections, and diffraction [2]. However, research in outdoor sound propagation revealed some limitations in the use of these calculations, especially with respect to ground effect modeling, multi-edge diffraction, and reflections from curved surfaces [4-5]. One of the newly added features in the 2024 revision addresses these gaps by introducing a ground effect correction factor (K_{geo}), improved screening calculations, and refined directivity correction (D_c) for

chimney stacks. Furthermore, the revision includes a comprehensive approach to calculate the foliage attenuation as an alternative to the simplified empirical method of ISO 9613-2:1996.

This study compares ISO 9613-2:1996 and ISO 9613-2:2024 by highlighting the influence of these changes on environmental noise mapping. The methodology section summarizes the main computational changes implemented in the 2024 version and the corresponding scientific literature. Finally, the results section presents the effect of these updates utilizing a commercial noise mapping software which implemented ISO 9613-2:2024, in the form of noise maps. By linking the theory behind the updates in the standard with relevant practical examples, this study describes how ISO 9613-2:2024 improves the accuracy of outdoor noise predictions, and make it a more effective tool for acousticians, urban planners, and policymakers.

2. MATERIALS AND METHODS

As mentioned earlier, the purpose of this study is to compare ISO 9613-2:1996 and ISO 9613-2:2024 standards as they pertain to advancements in outdoor noise propagation modeling.

The comparison is made following an organized approach beginning with a review of ISO 9613-2 revised methodology, which is primarily based on octave band calculations to predict outdoor sound levels taking into account the influence of ground effect, atmospheric absorption geometrical divergence, reflections, and screening by obstacles [2-3]. ISO 9613-2:2024 implements some clarifications adopted from ISO 17534-3 standard, titled “Acoustics — Software for the calculation of sound outdoors — Part 3: Recommendations for quality assured implementation of ISO 9613-2 in software according to ISO 17534-1”, which includes improved screening calculations [6]. The mathematical refinements studied in this paper are; K_{geo}, a geometric correction factor that eliminates ground effect attenuation (A_{gr}) under certain height conditions, A_{bar}, barrier attenuation, A_{curv}, which considers additional attenuation from curved surfaces and is part of the attenuation due to miscellaneous other effects (A_{misc}), foliage attenuation, A_{fol}, and chimney stacks directivity factor, D_c.

2.1 Ground Effect Correction Factor

K_{geo} factor in the 2024 revision directly addresses the need for ground interactions with the sound waves, which depends on the ground surface and source-receiver geometry, given by the following formula:

$$K_{geo} = \frac{d_p^2 + (h_S - h_R)^2}{d_p^2 + (h_S + h_R)^2} \quad (1)$$

where,

d_p: the source to receiver distance projected on the horizontal plane, expressed in meters;

h_S: the height of the source above ground, expressed in meters;

h_R: the height of the receiver above ground, expressed in meters.

This new factor led to the need of revising the existing formula to calculate A_{gr} in dB as follows:

$$A_{gr} = 10 \log[1 + (10^{\frac{-A'_{gr}}{10}} + 1) \times K_{geo}] \quad (2)$$

$$A'_{gr} = A_S + A_R + A_m \quad (3)$$

where,

A_S: the source region, stretching over a distance from the source towards the receiver of $30\,h_S$, with a maximum distance of d_p;

A_R: the receiver region, stretching over a distance from the receiver back towards the source of $30\,h_R$, with a maximum distance of d_p;

A_m: a middle region, stretching over the distance between the source and receiver regions. If $d_p < (30\,h_S + 30\,h_R)$, the source and receiver regions will overlap, and there is no middle region.

In summary, K_{geo} eliminates the ground effect if the source and receiver heights are much larger compared to the distance between them, which was confirmed by research that highlighted the need of this factor to increase the modeling accuracy due to the inconsistencies of ground reflection in previous methods [7].

2.2 Improved Screening Calculations

As mentioned earlier, the updated version of the standard expands the screening effect extensively. This effect varies depending on the height of the noise measurement and the distances between the sound source and the screen or barrier [8], this has been done by improving the calculation of the barrier attenuation (A_{bar}) which is determined by (Z_{min}) the minimum difference between the paths of the direct sound as if there were no barrier and diffracted path above the barriers. This is particularly helpful in multi-edge diffraction settings like urban environments.

Furthermore, ISO 9613-2:2024 implements the reflection condition recommended in ISO 17534-3. The barrier

attenuation (A_{bar}) in dB, which represents the sound attenuation due to a barrier is considered be equal to the diffraction attenuation of the barrier for each octave band (D_z) if the ground effect (A_{gr}) attenuation is larger than zero.

$$A_{bar} = D_z \; if \; A_{gr} > 0 \tag{4}$$

2.3 Reflection of Cylindrical Surfaces

ISO 9613-2:2024 now sheds light on two major parts; the first focusing on planar reflections, while the second deals with curved structures as in chimney stacks, storage tanks or silos. A reflection model for cylindrical surfaces was introduced to calculate additional attenuation based on the radius and the angle of incidence.

Curved surfaces in sound wave interactions emphasize the imperfection of the existing models in urban scenarios. For example, curved architectural elements can lead to unplanned sound concentration [9], requiring design interventions to achieve noise free distribution.

New refinements in diffraction and screening calculations have also been introduced. The complex barriers or multi-screen situations [10] lead to underestimation of noise reduction when using a single diffraction edge model as screening attenuation in ISO 9613-2:1996. It further improves this by introducing side screening factors that include diffraction across multiple edges, resulting in more accurate attenuation estimation. Figure 1 illustrates how sound rays are expected to reflect from a cylinder considering all dimensions in projection are parallel to the axis [4].

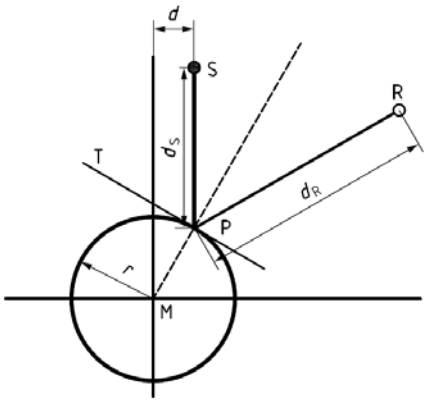

Figure 1. Reflection of sound ray at a cylinder.

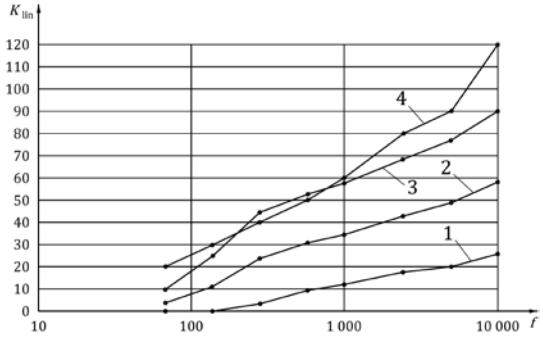
The introduction of an additional attenuation term (A_{curv}) also includes reflections from cylindrical surfaces in dB, where A_{curv} can be defined as:



$$A_{curv} = 10\log[1+\frac{2d_s d_R}{r(d_s+d_R)}(1-k^2)^{\frac{-1}{2}}] \tag{5}$$

$$k = \frac{d}{r} \tag{6}$$

where,
M: center-point;
S: point source;
R: receiver;
R: radius, expressed in meters;
P: point of reflection;
T: tangent in point of reflection;
d_S: source-receiver distance, expressed in meters;
d_R point of reflection-receiver distance, expressed in meters;
d: distance of the straight line defined by the incident ray from the center-point, expressed in meterts.

2.4 Attenuation of Foliage

The 2024 revision provides a more comprehensive foliage attenuation (A_{fol}) method, whereas the 1996 edition included only a simple empirical correction for tree belts or vegetation. The new method includes five forestry parameters, namely stem diameter (D), basal area (G), standing stock (V), horizontal structuring (S), and low height foliage (Z). Vegetation density, thickness and structural parameters were found to have a significant impact on sound attenuation in urban and suburban areas [11], which makes this update consistent with these findings. In addition, the frequency dependent attenuation factor (K_{lin}) is introduced in the new method to improve prediction under different environmental conditions. Figure 2 below highlights the typical ranges of K_{lin} as specified in ISO 9613-2:2024 [3].

Key

K_{lin}	attenuation factor, expressed in decibels per kilometre
f	frequency, expressed in hertz
1	light forest
2	normal forest
3	dense forest
4	attenuation with simplified method A.2.2 for 20 m ≤ d_f ≤ 200 m

Figure 2. Typical K_{lin} factors for different forestall parameters.

2.5 Directivity of Chimney Stack

Finally, the directivity correction of chimney stacks (D_c) is introduced. In ISO 9613-2:1996, chimney stacks were modeled as point sources, with the assumption of an omnidirectional radiation pattern. Nevertheless, the update indicates that industrial stacks have strong directional characteristics and hence a correction factor is required to account for the receiver level calculations. This correction is now embedded in the 2024 update and defined as D_c, which is a function of the opening geometry and radiation characteristics which depends on the frequency. Chimney stack directivity correction (D_c) is now included in the calculation of the receiver level for the equivalent continuous downwind octave band source sound pressure level at a receiver location.

This study evaluates the methodological improvements in outdoor noise prediction using practical simulations of a commercial noise mapping software, i.e. SoundPLAN. The impact of these updates is illustrated with figures and examples through the next section.

3. RESULTS

The present section summarizes the findings of noise modeling utilizing both ISO 9613-2:2024 and ISO 9613-2:2024. The results are presented in the form of noise maps.

3.1 Ground Effect Correction Factor

To evaluate the effect of K_{geo} on environmental noise propagation, two cases were assessed assuming a fully reflective ground (G=0), and noise maps highlighting the difference between 1996 and 2024 versions results were generated. In Figure 3, a point source was placed at a height of 50 m above ground level and a vertical cross-sectional grid noise map was generated to reflect the difference in noise levels between both versions. In a close distance at the same height of the source, a 3 dB difference was observed, which can be related to the fact that K_{geo} removes ground effect if the source and receiver heights are much larger compared to the distance between them. However, in Figure 4, the source was positioned at 2 m above ground level and therefore the difference between both versions is negligible.

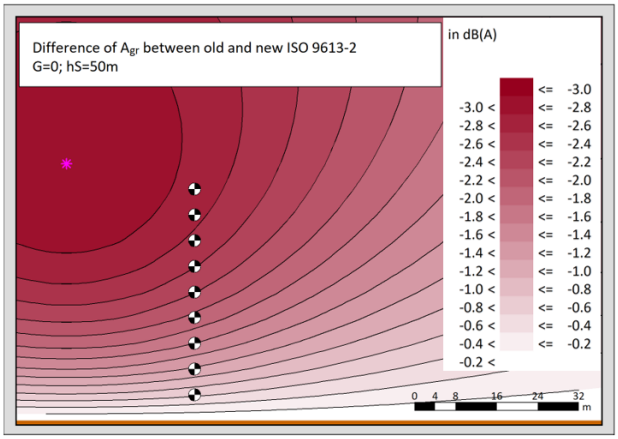


Figure 3. Difference of A_{gr} between 1996 and 2024 ISO 9613-2. Source height 50 m above ground level.

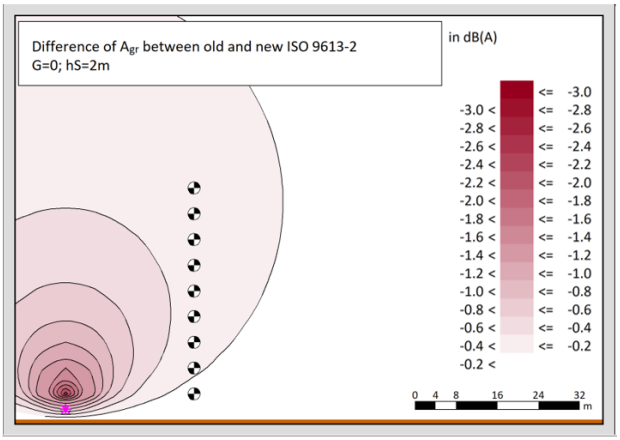

Figure 4. Difference of A_{gr} between 1996 and 2024 ISO 9613-2. Source height 2 m above ground level.

3.2 Reflection of Cylindrical Surfaces

Figure 5 and Figure 6 below show the difference in sound ray reflections at polygons and cylinders for 1/1 octave bands from 63 Hz to 8000 Hz.

In ISO 9613-2:1996, A_{curv} was not defined. Therefore, cylindrical surfaces were modelled as polygons. However, after defining A_{curv} in ISO 9613-2:2024, cylinder objects are now introduced in the mapping software, to account for more reflection points of sound rays. It can be noticed that cylinders have continuous reflections for all frequencies, while polygon objects have minimal reflections on examined frequencies until 500 Hz and straight line reflections due to the multi-edge polygon from 1000 Hz reaching 8000 Hz.

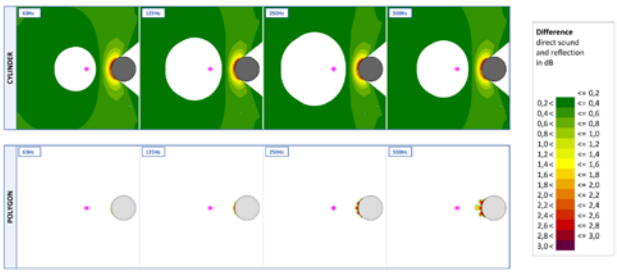

Figure 5. Difference between direct sound and reflection for 1/1 octave bands from 63 Hz to 500 Hz at polygon and cylinder objects.

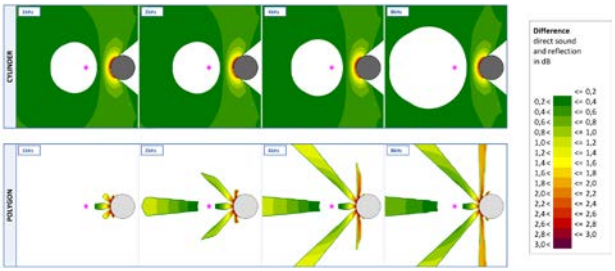

Figure 6. Difference between direct sound and reflection for 1/1 octave bands from 1 kHz to 8 kHz at polygon and cylinder objects.

3.3 Directivity of Chimney Stack

Chimney stacks and other vertical upward-facing open objects' sound is modelled as a point source in the center of the opening assuming omnidirectional radiation. However, ISO 9613-2:2024 indicates that a frequency-dependent directivity correction factor (D_c) shall be considered in noise modeling based on tables resulted from measurements conducted on large industrial chimneys [3].

Figure 7 illustrates how sound waves propagate at 125 Hz and 4000 Hz after implementing the chimney stack directivity correction D_c. This implementation is expected to increase precision and accuracy of noise modeling when compared in-situ sound propagation of chimney stacks.

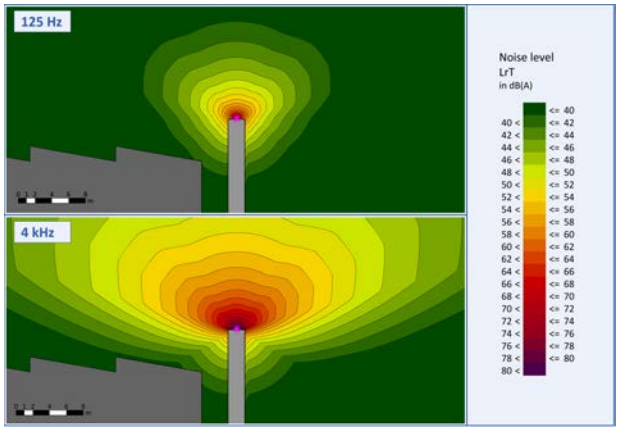

Figure 7. Sound propagation for a chimney stack (radius 1m) implementing directivity correction at 125 Hz and 4 kHz.

In summary, ISO 9613-2:2024 significantly enhances the accuracy of outdoor noise modeling by introducing key refinements that are directly applicable to environmental noise assessments. In practical tools like SoundPLAN, visualizations of parameters such as A_{curv} and K_{geo} illustrate

how curved surfaces influence noise propagation and how source and receiver heights affect ground attenuation. These advancements are expected to improve noise mapping overall and enhance the precision of environmental noise evaluations in particular.

4. CONCLUSION

The differences between ISO 9613-2:1996 and ISO 9613-2:2024 are substantial in terms of the modeling of sound propagation. The standard's predictive accuracy is improved through introduction of K_{geo} for ground effects, A_{curv} for cylindrical reflections, refined screening calculations and expanded foliage attenuation model. These changes are shown to be practical for the implementation in noise mapping software, which show that they result in more accurate noise assessments and better mitigation strategies. This revision ensures that ISO 9613-2 continues to be a reliable outdoor noise prediction standard for urban planners, environmental engineers, and regulatory agencies alike.

NOISE POLLUTION IN SPAIN: TOWARDS A COMPREHENSIVE ASSESSMENT

Ignacio Soto-Molina[1,2*] **Miguel Ángel González García**[1]
Carlos Soriano Pastor[1] **Rosa María Arce Ruiz**[2]

ABSTRACT

This research addresses the lack of a comprehensive view of noise pollution in Spain, which affects both citizens' quality of life and the preservation of terrestrial habitats. Strategic Noise Maps (SNMs), developed under the Environmental Noise Directive (END), currently cover only agglomerations with more than 100,000 inhabitants and major infrastructure (roads, railways, and airports). Consequently, large areas of the territory, smaller municipalities, and other significant sources, such as industry, ports, leisure activities, and events, are ignored, resulting in information gaps. This work highlights the need for an integrated diagnosis of noise produced by all sources, regardless of whether or not they are within the scope of the END, and shows progress in the development of a methodology for an integrated diagnosis of road noise, covering all sources of road traffic noise in Spain. Furthermore, it proposes analyzing the effects of noise pollution on human health and the loss of terrestrial habitat quality, with the goal of generating concise information for society. Through this assessment, the aim is to establish a solid foundation for the implementation of policies and measures to reduce noise levels, thus ensuring effective protection against noise pollution in Spain.

1. INTRODUCTION

In Spain, there is no comprehensive understanding of the existing noise pollution issues affecting both the quality of life for citizens and the habitats for terrestrial wildlife [1, 2]. Strategic Noise Maps, prepared by various Competent Authorities, offer insights into the noise situation in urban agglomerations with over 100,000 inhabitants and near major sources (significant noise emitters) as defined by the Environmental Noise Directive (END). This includes roads with more than 3,000,000 vehicles per year, railways with more than 30,000 traffic per year, and airports with more than 50,000 operations per year. However, areas likely impacted by sources that do not meet these thresholds, as well as other types of noise sources, are often not adequately studied [3, 4]. These data may not, therefore, be included in the National Information System on Noise Pollution (SICA) [1] . According to the information available on SICA, Spain only reports to the European Commission strategic noise mapping data for 64 agglomerations with more than 100,000 inhabitants, 21,000 km of major roads, 1,800 km of major railways, and 13 major airports.

This means, studies for 87 cities with populations between 50,000 and 100,000; 613 cities with populations between 10,000 and 50,000; 2,381 cities with populations between 1,000 and 10,000; and 4,986 towns with fewer than 1,000 inhabitants [2] have not been included in the strategic noise mapping.

Furthermore, derived from the consultation of the

[1] https://sicaweb.cedex.es/
[2] https://www.ine.es

transport network cartography of the National Geographic Information Center of Spain [3], excluded from the END scope are 154,000 km of roads, 21,770 km of railways, and 1,136 air facilities, including aerodromes, heliports, and hydro-aerodromes.

Regarding industrial sources, a significant number of 9,067 industrial facilities registered in the Spanish State Registry of Emissions and Polluting Sources (PRTR) [4], and 1,345 wind farms deploying over 22,000 wind turbines are not included in the SICA. Also, according to the Spanish public body Puertos del Estado [5], 49 major state port facilities are also out of the scope of END.

Lastly, local disturbances from sources such as leisure noise, neighborhood activities, urban service noise, recreational events, and construction noise are also overlooked in the SICA, and have an important effect on health [5].

From what has been discussed so far, it can be deduced that the Environmental Noise Directive suffers from "original sin." By determining the study areas based on noise sources, rather than sensitive receptors, it leaves a large part of the human population and sensitive receptors in the natural environment outside its scope.

This lack of a comprehensive perspective on noise pollution has led organizations such as the European Environment Agency (EEA) to attempt to assess noise problems globally [6], using gap-filling statistical methods [7]. However, these estimates can be significantly biased due to the lack of comprehensive data, and they do not address the problem, as they still fail to identify areas affected by noise that require corrective action.

For these reasons, the Spanish Ministry for Ecological Transition and the Demographic Challenge (MITECO) asserts the need for a comprehensive assessment of noise pollution problems. This assessment is crucial for establishing an initial understanding of noise-related issues, analyzing the potential human health impacts of noise pollution, and how it correlates with the degradation of natural terrestrial habitats. Providing synthesized information on noise pollution in Spain could be made publicly accessible through synoptic documents that would support monitoring and evaluating the effectiveness of policies aimed at mitigating noise pollution.

The aforementioned diagnosis is currently in the development phase, with the MITECO team working on global noise models for roads, aeronautical noise, and railways, and advancing evaluation methodologies for the remaining sources (industry, leisure activities, works and other). In this communication, we focus on the global road noise model. It is considered one of the most important because, globally, road traffic has the greatest impact on the acoustic quality of the environment [8].

2. OBJETIVES

Thus, the objectives of the global analysis of road noise in Spain are as follows:

General Objective: To comprehensively assess road traffic noise pollution across Spain, including areas not covered by the Strategic Noise Maps established under the Environmental Noise Directive (END), in order to provide a complete understanding of the issue, enhance the knowledge base on the health and environmental impacts of noise, and support policy-making through accessible and nationally consistent tools.

Specific Objectives

- To identify and quantify the acoustic impact of road traffic in areas not included in the END, such as municipalities with fewer than 100,000 inhabitants, rural environments, and low-traffic interurban roads.
- To fill the existing data gaps in the National Information System on Noise Pollution (SICA), by incorporating information on road segments, environmental conditions, and population exposure.
- To estimate the number of people potentially exposed to harmful noise levels in areas not currently addressed by strategic noise mapping.
- To evaluate the impact of road traffic noise on the acoustic quality of terrestrial habitats, particularly in protected areas such as the Natura 2000 protected areas network.
- To develop a transparent and reproducible nationwide modeling methodology, integrating open data and open-source technologies.
- To provide a solid technical foundation for the design and implementation of public policies such as the National Noise Strategy, ensuring effective, equitable, and consistent noise protection throughout the Spanish territory.

3. MAIN REFERENCE WORKS

Few studies address noise impact assessment using national-scale models. Countries implementing systemic environmental noise management models typically incorporate advanced statistical methodologies and large-scale data approaches to effectively quantify the impacts of noise pollution [7].

However, several relevant reference works, platforms, and tools have contributed to the development of comprehensive noise assessments at the national and international levels. These resources provide methodological guidance, technical capabilities, and strategic perspectives applicable to the Spanish context.

Notable progress has been made in the Fourth Round of the END implementation in France, where a national database, PlaMADE, was adopted [9]. This database compiles essential data for the development of large-scale noise maps through automated processes using open-source modeling tools [10]. This method not only improves the efficiency of data processing but also provides a more comprehensive national overview of noise pollution, helping competent authorities develop informed noise reduction strategies.

The U.S. National Transportation Noise Map [6], developed by the Volpe National Transportation Systems Center, provides a large-scale visualization of noise exposure from transportation sources across the United States. It serves as a reference for national modeling using open datasets, integrating road, rail, and airborne noise data with demographic information. Similarly, the U.S. National Park Service Noise Map provides large-scale maps of existing acoustic conditions across the country, as well as a map of natural conditions, calculated from long term measurements of sound in national parks as well as urban and rural areas across the country [7].

As for open and collaborative tools, the *Noise Map Tool* [8] is an interactive dashboard that visualizes global noise pollution generated by aircraft and other modes of transportation. It compiles real-time aircraft positions and performs noise simulations to estimate hourly noise exposure near airports. Developed and maintained by Nawar Halabi, it exemplifies the potential of data-driven, web-based noise assessment platforms.

From a computational perspective, some works have highlighted the importance super-computing for noise assessments. For example, the work of Ming Cai et al. [11] presents methodologies for modeling urban traffic noise in complex 3D building environments using high-performance computing, which has implications for model refinement in dense urban areas. Also, the noise maps of major infrastructures in France from the Fourth Phase, previously mentioned, have been produced using supercomputing systems [10].

Together, these references, among others, lay the foundation for the national assessment of road noise pollution in Spain. They highlight the integration of standardized assessment frameworks (CNOSSOS-EU), the use of massive data, environmental considerations, and advanced computing as pillars of modern noise assessments.

4. METODOLOGY

The methodology outlined in the following sections focuses on the development, calculation, and calibration of a large-scale road traffic noise model in Spain. Much work remains to be done in the evaluation of results for the exposed population and impacts on the natural environment, aspects not addressed in this paper.

4.1 Geographical Scope of Study

The study area is the entire national territory. The calculation area is the entire territory located within 1,500 meters of any road axis (streets, roads, highways, and motorways) mapped in the National Geographic Institute's transport network database and considered capable of supporting road traffic.

Regarding distance calculation, in Stylianos Kephalopoulos et al. (2014) [3], a calculation distance of less than 800 meters is recommended. However, since that publication, the CNOSSOS-EU method has been corrected [12]. The propagation method is based on the ISO 9613-2 standard [13, 14], which does not establish a distance limit. The CEDEX CNOSSOS-EU technical application guide [15] establishes calculation distances greater than 2,000 meters for average daily traffic intensities greater than 300,000 vehicles. Since the propagation method is based on spherical divergence and attenuation and corrections due to atmospheric and environmental conditions, a 1,500 meters source-receiver distance is considered adequate for the purpose of this study.

[7] https://www.nps.gov/subjects/sound/soundmap.htm
[8] https://noise-map.com

4.2 Software and Hardware Tools

NoiseModelling software [16] (NM) is used. *NoiseModelling* is a free and open-source tool designed to calculate noise maps in urban areas, as well as road, railway, and industrial source maps. As stated on its GitHub repository [9], it can be freely used for research, education, or by experts for professional use. NM has been used in various academic and institutional settings [10]. Of note is the creation of the French Government's strategic road noise maps, corresponding to the Fourth Round of END, through the creation of a national database, which feeds the NM software and allows for periodic updates of these maps [10]. The version of *NoiseModelling* used in this study was 4.0.5. According to the developers, this software reasonably complies with the ISO 17534-4:2020 standard checks for the application of the CNOSSOS-EU method.

The noise simulations were carried out using a high-performance workstation equipped with an Intel® Xeon® w9-3475X processor running at 2.21 GHz and 512 GB of installed RAM (fully usable). This equipment was provided to MITECO by the Center for Studies and Experimentation of Public Works (CEDEX) [11], Spain.

4.3 Data Sources for Acoustic Environment Modelling

The following data sources were used to design the acoustic environment, all from the official cartography of the Spanish National Geographic Information Center (CNIG) [12]:

Road transport network mapping, which includes all types of roads with traffic, from residential streets to major thoroughfares.

National Topographic Database (BTN), from which information on buildings, both residential and other types, is extracted.

Digital Terrain Model (DTM), at a scale of 1:25,000, used to obtain the topography.

Digital Building Surface Model (MDSnE2.5 2nd Coverage), used for automatic building height assignment.

4.4 Traffic Data and Emission Power Assignment

In CNOSSOS-EU method, the emission power of roads is obtained from their traffic intensity, pavement conditions and vehicle type distribution. The traffic intensity of main roads was obtained from the massive data provided by the Ministry of Transport and Sustainable Mobility [13]. This source offers traffic information for the main national roads and many sections of regional and provincial roads [14].

For the remaining roads for which traffic data are unavailable, the assignment was carried out according to the recommendations of the *Good Practice Guide for Strategic Noise Mapping and the Production of Associated Data on Noise Exposure* [17]. All roads have been assigned the CNOSSOS-EU reference pavement.

4.5 Calculation Process

The simulation process involved dividing the calculation area into 1,058 subdomains, each corresponding to one of the 25,000-scale sheets of the national topographic database. For each subdomain, specific layers were generated, including roads, buildings, a digital terrain model (DTM), and receptors. The calculations were launched by piloting the *NoiseModelling* software using scripts, as indicated in the official documentation [15]. However, it was also necessary to develop additional Python scripts to automatically generate and execute the corresponding software commands for batch processing.

Due to computational capacity constraints, the density of receptors was limited by applying a triangulation with a maximum mesh size of 2,500 m^2, which corresponds to a maximum spacing of 50 m between receptors. This triangulation was performed using the Delaunay algorithm implemented in the *NoiseModelling* software, which enables the refinement of receptor density in acoustically sensitive areas (e.g., near buildings), while reducing density in free-field zones. This approach optimizes the computational load without compromising accuracy in critical regions [18]. The evaluation periods, reflection order, meteorological conditions, and probable propagation conditions are those recommended in the CEDEX CNOSSOS-EU guide [15].

[15] https://noisemodelling.readthedocs.io/en/latest/Get_Started_Script.html

After the simulation, the results were transformed into raster format by applying interpolation over the irregular triangular network, enabling spatial visualization and analysis of the acoustic indicators.

4.6 Calibration Procedure

The Strategic Noise Maps (SNM) of the Fourth Round of the Noise Directive (END) of the official agglomerations of A Coruña, Santander, Bilbao, Pamplona, Salamanca, Roquetas de Mar, Madrid, Barcelonès, Vallès Occidental I and II, Sevilla and Valencia were used for the calibration process.

A total of 8,696,039 point pairs were generated, each representing a spatial match between the simulated noise levels and the official SNM data. These point pairs were used to extract and compare values of the calculated noise levels and the reference data. A linear regression model was then applied to fit the simulated results to the official values. This linear transformation was applied to the raster layers of calculated noise levels.

5. RESULTS

5.1 Calculated Noise Map

Table 1 summarizes the descriptive statistics for the initial calculated road traffic noise simulation (LAEQ data), compared to the reference values (LAEQ_Ref) obtained from those points with values above 30 dB, resulting in a total of 8,696,039 valid records.

Table 1: Descriptive statistics of LAEQ and LAEQ_Ref (only values $>$ 30 dB)

Statistic	LAEQ_Ref (dB)	LAEQ (dB)
Mean	56.17	59.75
Median	57.00	58.98
Std. Dev	10.60	11.85
Min	31.00	30.00
Max	101.00	96.80

As observed, the uncalibrated model tends to overestimate sound levels, with LAEQ values on average 3.6 dB higher than the references. Figure 1a shows the histogram of LAEQ distribution, with a peak between 55 and 60 dB, slightly shifted to the right of the LAEQ_Ref distribution.

The correlation between LAEQ and LAEQ_Ref was 0.575, and the linear regression model yielded the following equation:

$$\begin{aligned} L_{AEQ} &= 23.6350 + 0.6429 \cdot L_{AEQ_{\text{Ref}}}, \\ R^2 &= 0.331 \end{aligned} \tag{1}$$

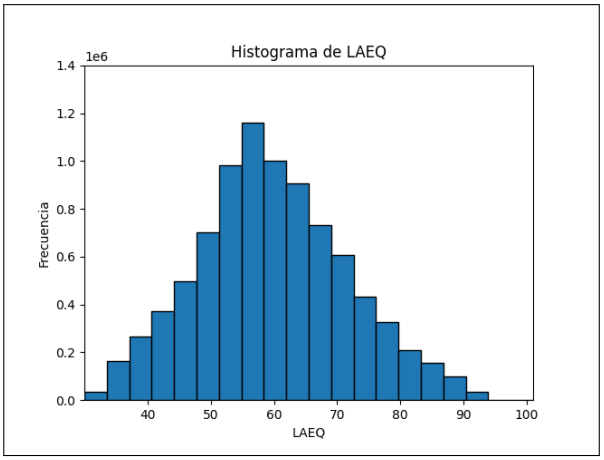
This indicates a moderate association, with only 33.1% of the variance explained by the reference values, and a slope significantly less than 1, suggesting a proportional underresponse of the calculated indicator relative to the reference. The weak association also indicates that there is no real linear correlation between the two variables. Noise data depend on a set of highly heterogeneous variables, and small variations in the input data can significantly alter the model's output [19].

5.2 Calibrated Noise Map

To correct the overestimation observed in the initial model, a calibration process was carried out using a linear regression adjustment. This yielded a calibrated indicator, LAEQ_Cal, which was subsequently used to replace the original values.

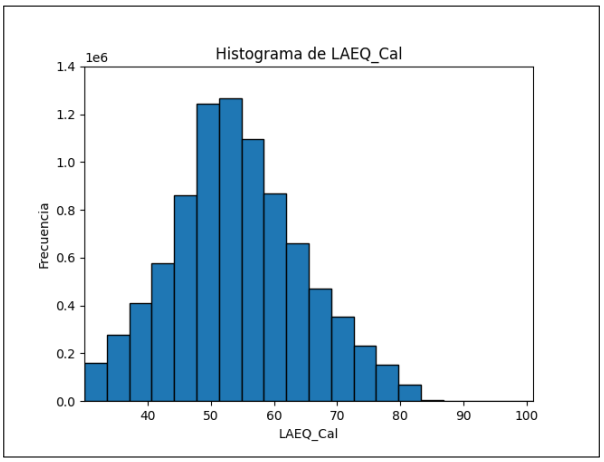
The calibration reduced the average estimated levels, bringing them closer to the reference values, as shown in Table 2.

Table 2: Descriptive statistics of LAEQ_Cal and LAEQ_Ref (only values $>$ 30 dB)



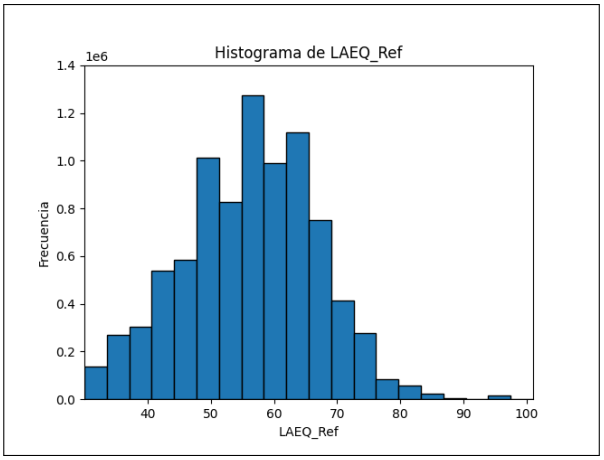
Statistic	LAEQ_Ref (dB)	LAEQ_Cal (dB)
Mean	56.17	54.22
Median	57.00	53.51
Std. Dev	10.60	10.41
Min	31.00	30.00
Max	101.00	86.68

Although LAEQ_Cal tends to slightly underestimate the reference values, the bias has been significantly reduced. The histogram in Figure 1b illustrates a shift of the distribution toward lower values compared to the original LAEQ.



The adjusted regression model is:

$$\begin{aligned} L_{AEQ_{\text{Cal}}} &= 22.0235 + 0.5732 \cdot L_{AEQ_{\text{Ref}}}, \\ R^2 &= 0.340 \end{aligned} \tag{2}$$



With a slightly improved R^2 and points correlation (from 0.575 to 0.583), the calibration enhances the consistency between calculated and reference values.

(a) Histogram of LAEQ (original calculated values).

(b) Histogram of LAEQ_Cal (after calibration).

(c) Histogram of LAEQ_Ref (reference values).

Figure 1: Comparison of LAEQ distributions before and after calibration, and reference values.

6. DISCUSSION

In the creation of a road noise map for Spain, significant differences were observed when compared to official strategic noise maps. Understanding these discrepancies is important for interpreting the data accurately and grasping the wider implications associated with noise pollution assessment and management.

One of the primary factors contributing to the difference between the calculated noise map from this work and the reference maps is the use of lower-precision source cartography, particularly regarding the digital terrain model employed. The DTM used in this study was less precise as a consequence of attempting to cover a larger calculation area within computational limitations. This inaccuracy inevitably leads to an underrepresentation of terrain-induced attenuation effects that are integral to interpreting noise propagation. According to Renterghem et al. [5], inaccuracies in urban noise mapping frequently stem from adjustments made to reflect the topographic characteristics of the area under consideration. The lack of rigorous terrain models can result in an inadequate reflection of real-world conditions, which is essential for properly modeling the effects of topography.

Furthermore, the absence of noise barriers in the calculated map remains another significant area leading to discrepancies. Noise barriers have a significant impact on reducing the levels of road traffic noise in adjacent areas, and their omission results in an overestimation of noise levels in shielded zones. Studies show that effective noise barriers can yield a reduction of up to 10 dB in sound pressure levels, indicating their importance in comprehensive noise assessments, as highlighted by Morley et al. [20]. Without these barriers, the calculated map fails to capture the corrective measures already implemented, leading to an overestimation of noise in some areas.

The varying mesh sizes utilized in the calculations create another layer of complexity affecting the outcomes. The calculated map's larger receiver mesh size leads to interpolation of results derived from the reference maps. When mapping noise on a larger scale, finer resolutions can capture localized variations that a coarser grid may overlook, thus leading to different noise exposure estimations. Differences in mesh size can substantially affect estimations, particularly when significant noise barriers or other mitigating factors spatially coalesce, as discussed by Hauge et al. [21].

Traffic data constitute another relevant difference. The current approach relies on data derived from sources

other than official reference maps and, in some cases, applies generic traffic volume assignments based on road characterization. Reference maps are expected to employ more rigorous methodologies, likely integrating real-world traffic data that reflect precise traffic conditions. Consequently, this variation can lead to misalignment in the noise levels associated with particular roads, as variations in traffic flow and speed contribute significantly to the overall noise profile [19]. Moreover, the software implementing the CNOSSOS-EU standard demonstrates a substantial influence on the results obtained from the noise mapping procedure. Different software tools designed to comply with CNOSSOS-EU may yield variations in results, with discrepancies noted to exceed 5 dB in some studies, as indicated by Khan et al. [22].

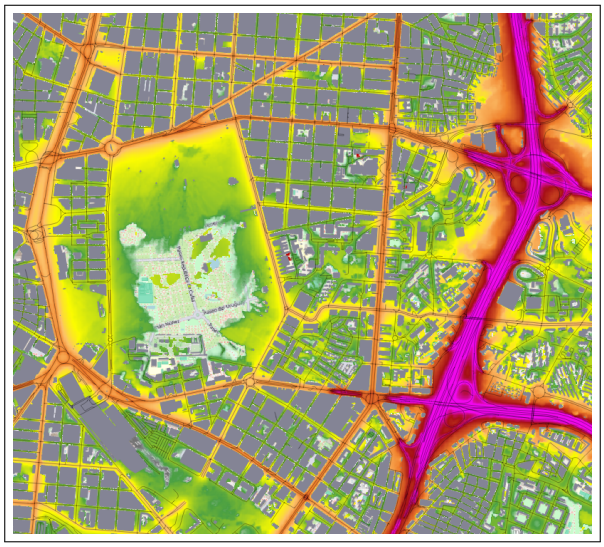


Figure 2: Overview of calculated road noise map for Spain.

The variability found is due to the accuracy of the traffic data, the precision of the design of the propagation environment, the use of different software, the availability of information such as noise barriers, etc. The multiple factors that influence the results of the noise assessment, in this case traffic noise, and the need to standardize methodologies are highlighted.

7. CONCLUSIONS

Despite the observed disparities, it is considered that the main objective of generating a noise map that encompasses all road traffic sources in Spain, regardless of whether they fall within the scope of the END, has been achieved. The objective was to provide a large-scale assessment, and it is generally considered acceptable within the limitations of the approaches adopted. The analysis performed presents significant, but at the same time reasonable and acceptable, discrepancies compared to the reference strategic noise maps.

8. FUTURE STEPS

Looking ahead, much work remains to be done to achieve a comprehensive view of noise pollution in Spain. Some of the most significant work already underway relates to large-scale studies of aeronautical, railway, and industrial noise. In addition, the methodology for studying other sources outside the scope of END and CNOSSOS-EU is currently being designed, such as noise from leisure activities, neighborhood activities, and events, which often cause significant disturbance to the population. The work already underway toward a comprehensive noise assessment in Spain is exciting.

ABSTRACT

Environmental noise is a damaging environmental factor in the cities. Acoustic barriers are commonly used to mitigate highway traffic noise. Nevertheless, they adversely affect the visual aesthetics of the metropolitan environment. We investigated how a certain type of noise barrier application decreased the nearby traffic noise at a designated location. The CNOSSOS-EU calculation method was used to evaluate the road traffic noise. The noise mapping software IMMI facilitated the investigation. The results showed that the noise barrier effectively reduces noise levels at the receptor side where the population exposure was computed. Our findings indicate that, in the absence of a noise barrier, an additional 114 individuals were exposed to noise levels exceeding 50–55 dB(A) during the day (L_{day}), while an additional 175 individuals experienced noise levels exceeding 45–50 dB(A) at night (L_{night}), compared to the scenario where the barrier was in place. This impacts both future population exposure estimates and the execution of urban noise management plans.

Keywords: *noise pollution, road traffic noise, CNOSSOS-EU method.*

1 INTRODUCTION

The term "noise" refers to an unwanted or unpleasant sound [1]. Urban noise constitutes a global issue that has been thoroughly researched internationally [2]. Currently, noise pollution in cities is seen as a public health issue [3]. The World Health Organisation [4] defines environmental noise as noise that is released from all sources and encompasses all types of noise, including that from roads, trains, aeroplanes, factories, public works projects, and even residential areas, except for noise at the industrial workplace. The adverse health effects are usually non-auditory, as the noise levels often do not exceed 85 dB for extended durations. In terms of magnitude, road traffic, air traffic, railway, and industrial noise constitute the four principal causes of environmental noise disturbance in metropolitan settings [5]. Road traffic noise has become the most extensively studied source because of its widespread occurrence and significant level of disruption. In this regard, it is estimated that almost 50% of the European Union's population is subjected to road traffic noise levels that are deemed detrimental to their health and general well-being [6]. The population affected by road traffic noise greatly exceeds that affected by rail, aeroplane, and industrial noise. This is due to the extensive road network, which significantly surpasses all other sources of noise. The existing mitigations seem inadequate in achieving the objectives established by the zero-pollution strategy, and the effectiveness of their implementation is insufficient. Several studies have compared and analysed effective measures, all of which agree that implementing mitigation at the source produces the most favourable outcomes [7]. An effective mitigation should be proven against other potential alternatives and assessed based on cost-benefit analysis. Different approaches can be adopted for dealing with issues regarding road traffic noise, focusing on any of the following phases: source generation, environmental propagation, and reception [8]. At the initial stage, the concept is to interpose physical obstacles, such as acoustic barriers, between the sound source and the receivers. Acoustic barriers are a conventional method employed in noise reduction; by being positioned along the path of sound propagation, they have emerged as a prevalent

approach to address the issue [9]. Research on the effectiveness of various configurations of acoustic barriers provides insight into their ability to reduce sound intensity [10]. An important factor in noise attenuation is the barrier edge's height and shape, which have been thoroughly studied. Indeed, the quantity of barriers and their distance from each other directly impact the performance of the acoustic barrier. For instance, the implementation of parallel barriers is often used to reduce noise in locations close to a road; nonetheless, their efficacy may be inferior when compared to a singular barrier [11]. The opposite acoustic barrier reduces the nearby acoustic barrier's attenuation by reflecting multiple waves [10], [11]. The CNOSSOS-EU calculating technique was approved by the European Commission in 2009 in compliance with Directive 2002/49/EC's article 6.2. The legal foundation for the implementation of future rounds of strategic noise mapping was established in 2015 with the publication of Commission Directive (EU) 2015/996, which mandates that all EU MS switch from their previous nationally based methods to the CNOSSOS-EU standardised method for the 2022 round of strategic noise mapping. Europe is the inaugural region for creating an urban noise mapping and developing the technical underpinnings for such maps [12]. The European Noise Directive advises using computational methods over in-situ measurements for the construction of noise maps whenever feasible [13],[14]. The traffic noise computation models are utilised to compute the noise map [15], which is then conjoined with GIS, and the evaluation of noise pollution relies on L_{den} and L_{night}. This study investigates the impact of road noise barriers on sound levels near a major roadway and identifies the noise levels that reach buildings and the population in the Kismacs district of Debrecen (Hungary). The evaluation focuses on a recently built noise barrier designed to reduce road traffic noise in this district, as a significant increase in traffic is forecasted for this road section due to industrial developments.

2 MATERIALS AND METHODS

2.1 Average Daily Traffic

The source of average daily traffic (ADT) data is Hungarian Public Roads, which is used to estimate the traffic volume for each road section. The road type, the road's county-specific location, the number of the studied section, and the border sections of the examined section are used to assign a specific code number to the cross-sectional traffic data so that the ADT data can be accessed. To create the comprehensive traffic data needed for the noise maps, the raw traffic count data from Hungarian Public Roads was categorised and systematised into acoustic groups. For both road directions, the hourly vehicle traffic data for each lane was added up and then combined for the specified time of day (day and night). The data analysis results were converted into information that the noise mapping software could process.

Table 1. Average hourly distribution statistics by acoustic vehicle category (unit: vehicle/hour) for the section (D: day, N: night)

Time	Cat. 1	Cat. 2	Cat. 3	Cat. 4a	Cat. 4b
2021 D	770.58	12.70	27.27	1.55	1.55
2021 N	148.71	2.73	6.47	0.34	0.34

2.2 IMMI noise mapping program

This program, which originated in Germany, provides numerous opportunities in various domains of noise mapping. The CNOSSOS-EU method was used for the calculations of noise levels within the software, depending on the provided traffic data and other parameters. For each category of acoustic vehicles, IMMI software models noise sources as road sections with a specific average speed and flow rate per hour. The average speed is subsequently computed, and the IMMI software is employed to determine the sound power level for each road section and time interval. In this work, the noise levels were computed for a grid size of 20 m x 20 m in the examined area. Performing individual model runs for every measurement point using “hourly distribution data as input” was shown to be the most appropriate approach for processing the data analysis results. The determination of category-specific average speeds was carried out considering the characteristics of different road sections and traffic lights. A precise calibration of certain parameters is necessary to calculate the transmission of sound from the source to the receivers. The meteorological conditions used in the model closely matched the characteristics observed during the

measurements. The road and building network are sourced from OpenStreetMap, while the road gradient data is collected from the STRM digital elevation model [16]. In the model, the traffic flow for the research area was selected as continuous fluid flow, while the reference surface was chosen as the characteristic of the road surface, the building's height: ground level—3 metres; the roof's height—2 metres.

The base map designates road No. 33 as a line source. The source lines were positioned in the middle of each lane of the road while utilising "CNOSSOS-EU" calculating methods. The buildings near the measurement point were individually modelled based on the Debrecen urban development plan (satellite images allow for the input of additional details, like the height of the buildings).

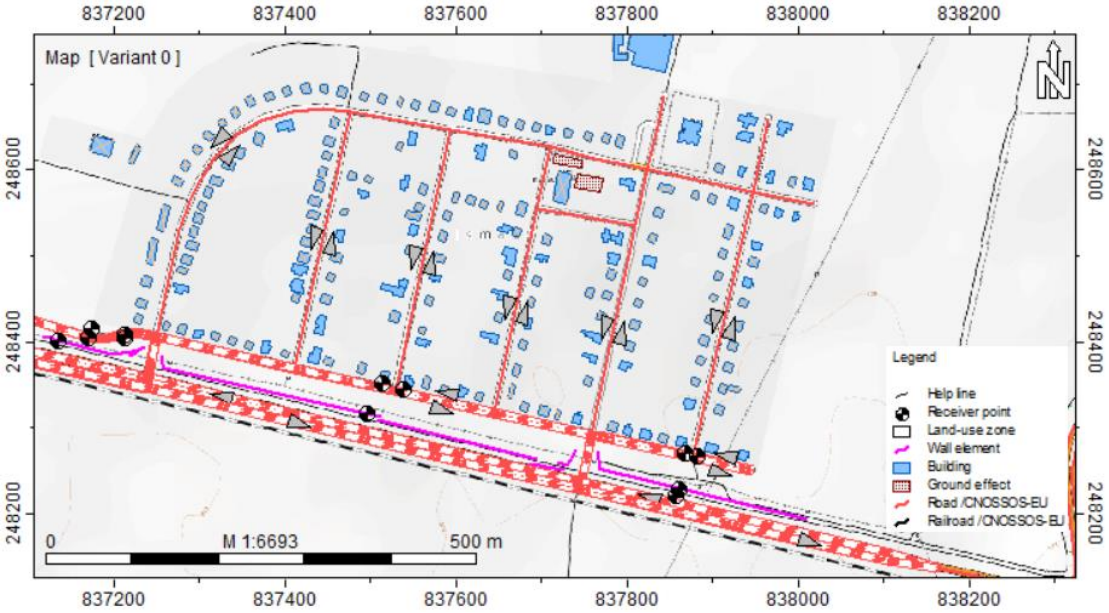

Fig. 1. Base map of the study area under investigation.

3 RESULTS AND DISCUSSION

3.1 Population exposure estimation

During the noise mapping technique, average hourly values for both day and night across the survey period were used as a percentage for each hour of the ADT data. The IMMI noise mapping tool is applicable for several parameters, allowing for the creation of thematic maps. Each of these thematic maps illustrates the population residing in certain residential structures, as ascertained by the IMMI program by examining the parameters of the buildings. This map can be used to analyse how many people are directly impacted by the noise burden that the specified road segment causes. The software can also perform intricate calculations on the involvement topic, allowing it to ascertain the number of people who are impacted by noise exposure ranges at a specific distance from the source. The program analysis determines that the noise pollution from the investigated area affects approximately 427 residents in the modelled area, which is immediately adjacent to the analysed section (Fig. 2).

For the day case (Fig. 3), most residents fall within the 45-to-50 decibel range, with approximately 216 people belonging to this category. The highest load range is 55–60 dB, affecting 14 individuals. For the night case (Fig. 5), most of the residents fall within the 35-to-40 decibel range, with approximately 183 people belonging to this category. The highest load range, which affects two individuals, is between 50 and 55 dB. It is important to observe that more people belong to smaller load categories due to the presence of condominiums that can house more residents at a distance from the roadway compared to those situated near it.

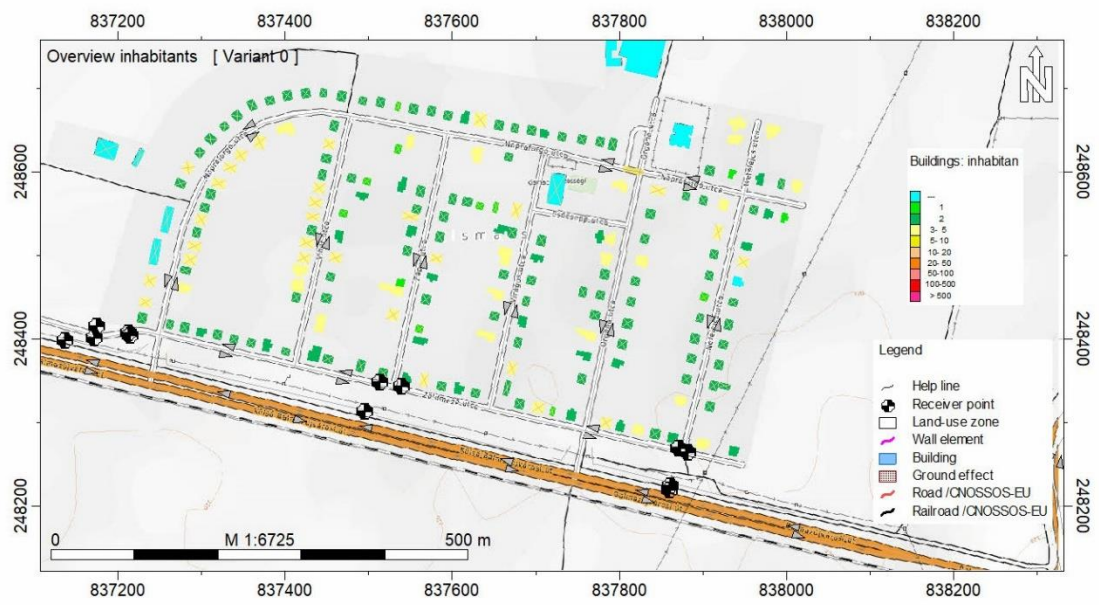

Fig. 2. Number of people living in the near vicinity of the investigated area.

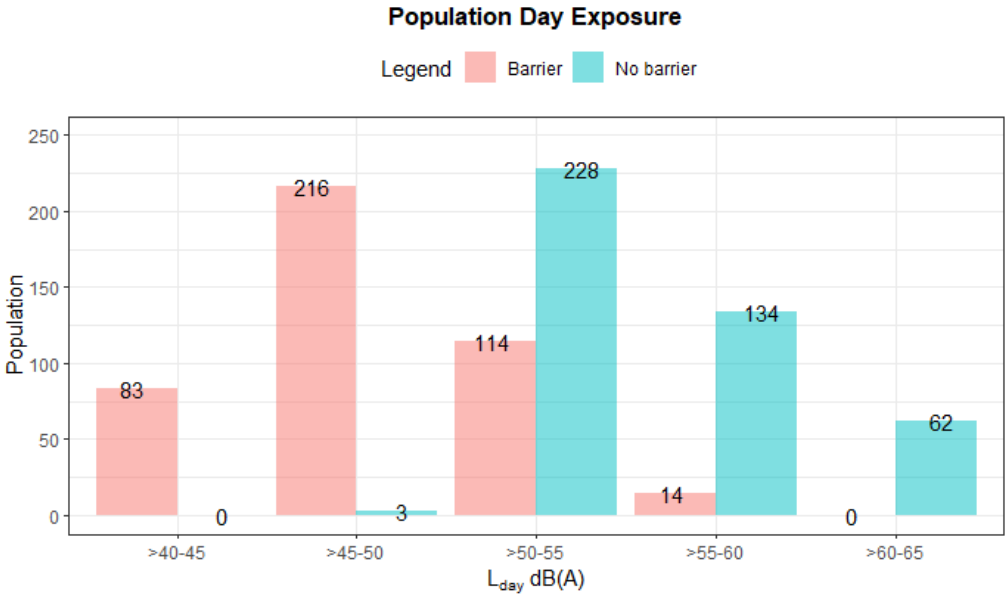
3.2 The efficiency of the acoustic barrier

The efficiency of the existing barrier from the receptor side was evaluated in the investigated area in Kismacs City. The IMMI software was used to calculate the difference that would occur if the current acoustic barrier did not exist. For the noise mapping process, the average hourly distribution results from the ADT (from Hungarian Public Roads) data were used. The comparison was conducted between the simulation results at the receptor side of the barrier, based on the traffic ADT data in scenario one, and the results after the removal of the existing barrier in scenario two. The substantial associations between noise levels and the traffic volume are anticipated, given that road traffic was the primary noise source in the study area.

Fig. 3 details the results of the population exposure assessment for the Kismacs district of Debrecen using L_{day} values and the CNOSSOS-EU model. For the day case, the result indicates that the no-barrier case, as opposed to the barrier case, would expose an additional 114 people to decibel levels of road traffic that are >50-55 dB(A) $L_{day,}$ since most residents fall into this category. For the noise level >60-65, the no-barrier case would expose an additional 62 people to this highest load range level of noise. This conclusion implies that the noise barrier could significantly decrease the population's exposure to noise levels from road traffic in the investigated area. Figure 4 provides a graphic representation of these discrepancies.



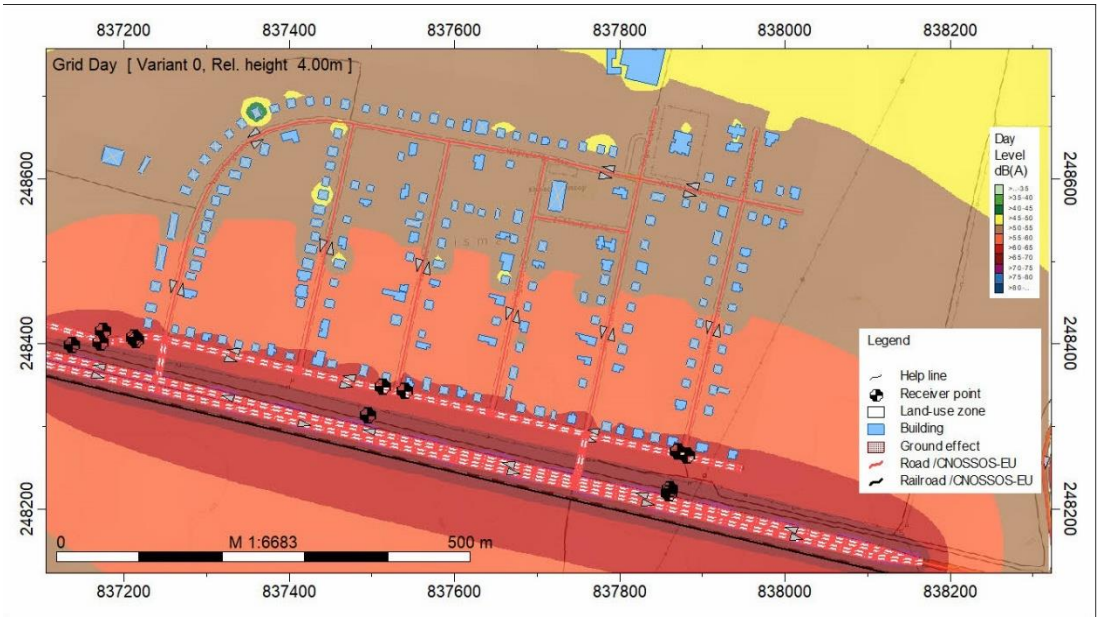


Fig. 3. Population exposure (L_{day}) in the Kismacs district of Debrecen —no barrier/barrier.

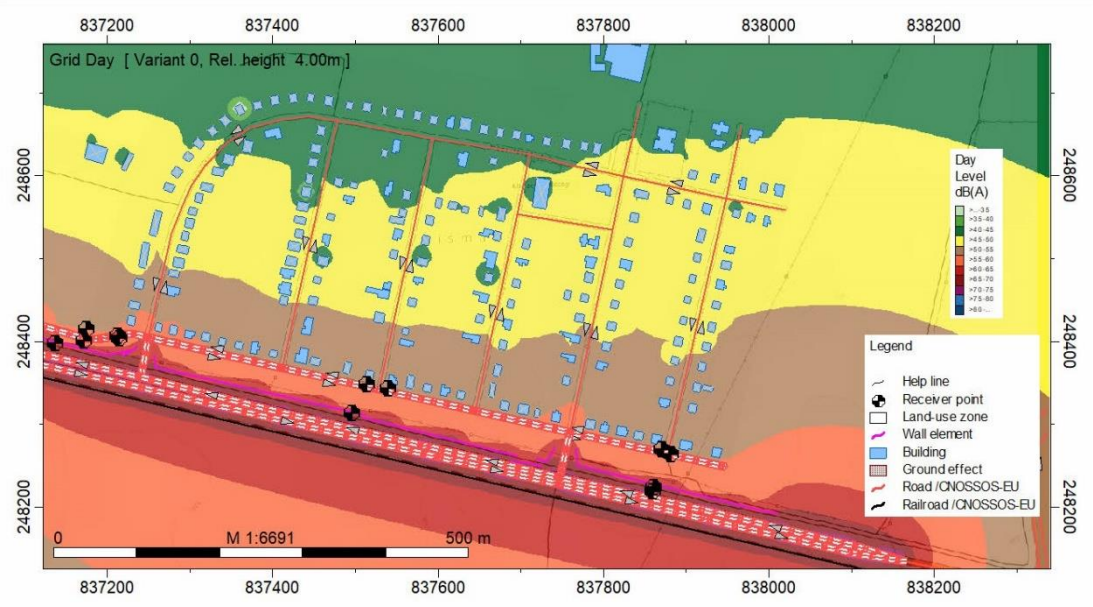

Fig. 4. A graphic representation of the daytime noise variation at the building façade in the Kismacs district of Debrecen —no barrier/barrier.

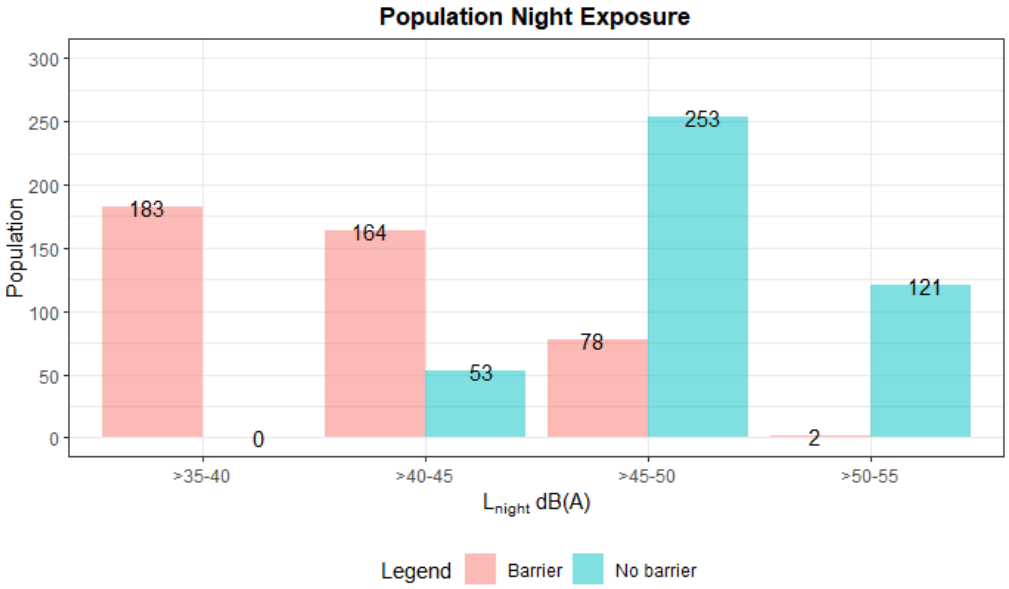
Fig. 5 details the results of the population exposure assessment for the Kismacs district of Debrecen using L_{night} values and the CNOSSOS-EU model. The result indicates that the no-barrier case, as opposed to the barrier case, would expose an additional 175 people to decibel levels of road traffic that are >45-50 dB(A) $L_{night,}$ since most residents fall into this category. For the noise level >50–55, the no-barrier case would expose an additional 119 people to this highest load range level of noise. Like the day (L_{day}) measurement, the barrier modelling case also successfully reduces the road traffic noise levels that the population experiences in the investigated area. Figure 6 provides a graphic representation of these discrepancies.



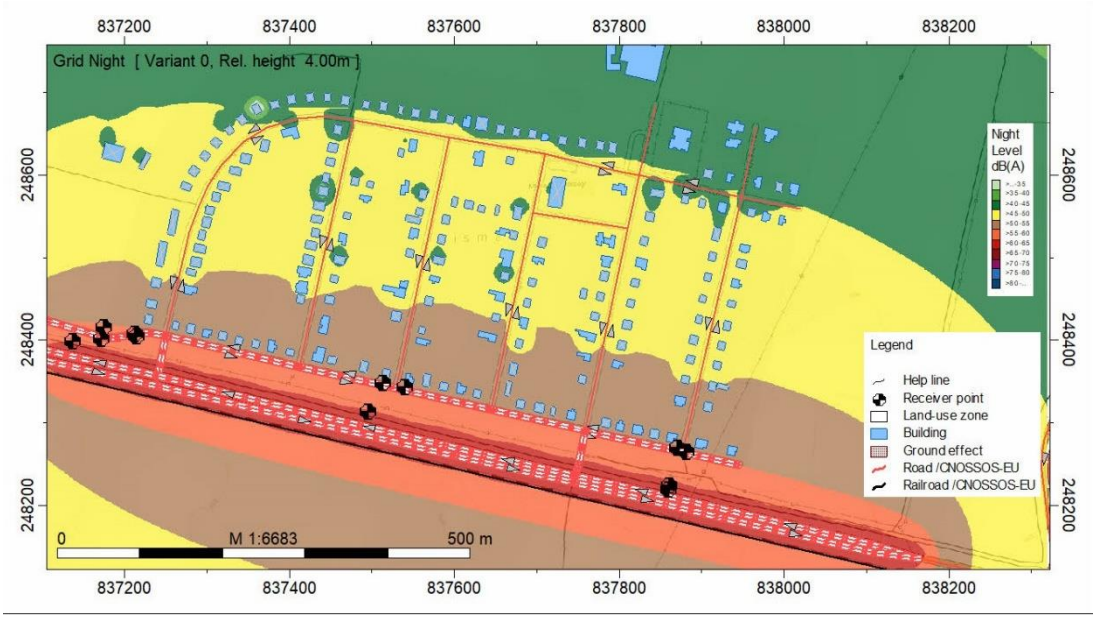


Fig. 5. Population exposure (L_{night}) in the Kismacs district of Debrecen —no barrier/barrier.

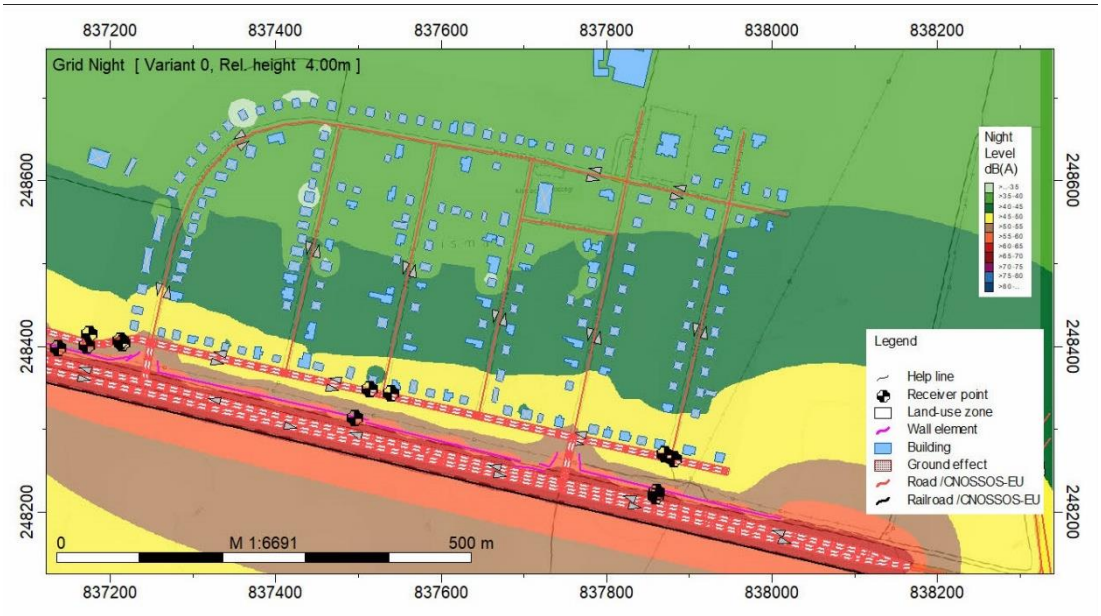

Fig. 6. A graphic representation of the nighttime noise variation at the building façade in the Kismacs district of Debrecen —no barrier/barrier.

4 CONCLUSIONS

The implementation of noise barriers as part of strategies to mitigate environmental noise is a prevalent method of controlling road noise. This study examined the concurrent impact of a particular noise barrier installation on proximal road noise at a designated location. The calculation of population exposure for the investigated area was estimated using the IMMI software tool in accordance with CNOSSOS-EU methodologies. Most populations expected to be exposed to road traffic noise levels exceeding 45-50 dB(A) L_{day} (approximately 216 persons) and 35-40 dB(A) L_{night} (approximately 183 persons) belong to this category. A comparison was performed between the simulation results at the noise barrier's receptor side, derived from the average hourly traffic data in scenario one, and the results after the removal of the existing barrier at each measurement point in scenario two. The software's elimination of the existing barrier revealed that an additional 114 people were exposed to noise levels >50-55 dB(A) $L_{day,}$ and an additional 175 people were exposed to noise levels >45-50 dB(A) L_{night} when no barrier was used, compared to the barrier case that was used. This study revealed that noise barriers can effectively diminish noise levels at the receptor sides of the barriers. With appropriate design, noise barriers can serve as effective tools for reducing noise exposure, as this study has also demonstrated. The conducting modelling could also be suitable for predicting future changes through appropriate traffic forecasting.

FORUM ACUSTICUM EURONOISE 2025

IDENTIFYING NOISE ACTION PLAN PRIORITY LOCATIONS IN IRELAND

Simon Shilton[1*] **Tony Dolan**[2]
[1] Acustica (EU) Ltd, Dublin, Ireland
[2] Environmental Protection Agency, Wexford, Ireland

ABSTRACT

The Environmental Protection Agency (EPA) in Ireland published a guidance note for noise action planning in 2009, to support the Local Authorities designated as Action Planning Authorities (APAs) under the Environmental Noise Regulations (ENR). An update to the guidance note was published in June 2018, in support of the Round 3 noise action plans (NAPs). Ahead of the Round 4 NAPs, the EPA extensively revised the draft guidance note; aligning with the 2018 Regulations, implementing the revisions to the Environmental Noise Directive (END), including Annex II (CNOSSOS-EU as amended) and Annex III (harmful effects). The noise action plans are to be drawn up on the basis of the results of the strategic noise mapping. As there are no statutory noise limit values in Ireland, the EPA developed other relevant criteria for identifying priorities, and the most important areas, exposed to road and railway noise to be addressed within the NAPs. The paper provides an overview of the methodology developed to identify priority important areas (PIA) to be assessed by APAs during implementation of the Round 4 NAPs. The methodology uses a combination of GIS analysis, and localised decision making within the APA to provide a nationally consistent, and locally responsive approach.

1. INTRODUCTION

Environmental noise is the second biggest environmental cause of health problems in the EU, after air pollution (the fine particulate matter in air), according to the World Health Organisation (WHO), and the European Environment Agency (EEA). Prolonged exposure to noise can lead to serious illnesses including: cardiovascular diseases; reduced cognitive performance in children; severe annoyance, which is a form of stress; and sleep disturbance.

The Environmental Noise Directive (END) is the main pan-European regulatory framework established to manage environmental noise, through harmonised procedures to assess levels of noise exposure, assess the impact on human health, and prepare noise action plans. The END is transposed into Irish law through the European Communities (Environmental Noise) Regulations 2018 (amended) (the Regulations) [1].

The Environmental Protection Agency (EPA) is the designated national authority for the purposes of the Regulations and is to exercise general supervision over the functions and actions of noise mapping bodies and action planning authorities, and to provide guidance or advice, where necessary.

The EPA has developed guidance for strategic noise mapping in 2009, 2011 and fully revised for Round 4 using the CNOSSOS-EU assessment methods between 2022 and 2024 [2]. The EPA also developed guidance on noise action planning published in July 2009 [3], with updated sections published for round 3 in June 2018 [4]. The guidance was revised for Round 4 and the draft guidance was issued to the Action Planning Authorities (APA) in December 2024 [5].

As there are no statutory noise limit values in Ireland, the EPA developed other relevant criteria for identifying priorities, and the most important areas, exposed to road and railway noise to be addressed within the noise action plans (NAPs).

The 2009 guidance on noise action planning recommended the use of a noise score matrix to help Action Planning Authorities (APAs) identify priority locations. During the revision of the NAP guidance for Round 4 the matrix approach was reviewed and a revised methodology developed to identify priority important areas (PIAs) to be assessed by APAs during implementation of the Round 4 NAPs.

2. REQUIREMENTS

The Regulations defines an "action plan" as a plan designed for the purpose of managing noise issues and their effects, including noise reduction if necessary. Local Authorities are designated as Action Planning Authorities (APA) under the Regulations, and have a statutory responsibility to make noise action plans, consult with the public, and report to the EPA on all action taken under each action plan in the previous 12 months.

The aims and objectives of the Directive state that the adoption of action plans, based upon noise-mapping results, should be concerned with:

"preventing and reducing environmental noise where necessary and particularly where exposure levels can induce harmful effects on human health and to preserving environmental noise quality where it is good."

Under the Regulations, Action Planning Authorities (APAs) are to determine the measures to be included within the noise action plans, and:

"Each action plan or revision of an action plan shall address priorities which—

(i) may be identified on the basis of exceedances of any relevant noise limit value or other relevant criteria established by the Agency in accordance with subparagraph (3), and

(ii) shall, in the first instance, address the most important area or areas, as the case may be, established by strategic noise mapping."

The noise actions plans are to be drawn up on the basis of the results of the strategic noise mapping of major roads, major railways, major airports and agglomerations as defined in the Regulations, which has previously been completed by the designated Noise Mapping Bodies (NMBs). The strategic noise maps provide graphical and statistical data on the exposure of people, dwellings and areas to noise.

The Regulations require that *"priorities"* and *"the most important area or areas"* are to be addressed.

Additionally, the EPA recommended that noise action plans have regard to Policy Objective 65 from the National Planning Framework 2040, which states:

"Promote the pro-active management of noise where it is likely to have significant adverse impacts on health and quality of life and support the aims of the Environmental Noise Regulations through national planning guidance and Noise Action Plans."

In May 2021 the EU launched the Zero Pollution Action Plan (ZPAP) with a vision for 2050 that air, water and soil pollution is reduced to levels no longer harmful to health and natural ecosystems. The targets set to be achieved by 2030 include *"reducing the share of people chronically disturbed by transport noise by 30%",* compared to 2017.

In support of ZPAP, the EU PHENOMENA project was undertaken to identify cost-effective noise mitigation measures which may help competent authorities to achieve noise reductions across large parts of the exposed population.

The previous version of the EPA guidance notes on noise action planning, from 2009 to 2018, focused noise mitigation measures on locations exposed to high levels of noise, however in the context of the ZPAP it was determined that a different approach would be required to help support APAs actions to reduce the overall health effects of environmental noise. The aim of the revised approach recommends the identification of Priority Important Areas (PIAs). This approach is to support the aspirations of ZPAP by providing for noise reductions to larger numbers of exposed residents.

3. RATIONALE

The objective of the Regulations is to:

"avoid, prevent or reduce on a prioritised basis the harmful effects, including annoyance, due to exposure to environmental noise". Where environmental noise is *"unwanted or harmful outdoor sound created by human activities"*.

The results of the strategic noise mapping provide information on the assessed noise levels at all noise sensitive properties within the assessment area, along with an estimate of the number of inhabitants.

The NMBs *"shall calculate the harmful effects in accordance with the Second Schedule"* of the Regulations. Meanwhile, the APAs *"shall estimate the expected reduction in the harmful effects of noise exposure to the population as a result of the mitigation measures contained in their Noise Action Plans"*. The Second Schedule of the Regulations sets out a mandatory assessment of the harmful

effects of environmental noise using the dose-response relationships set out in Commission Directive (EU) 2020/367 [6] and transposed under S.I. 663/2021 [7], replacing Annex III of the END.

The European Commission, on its Environmental Noise Directive webpage, outlines that the harmful effects assessment methods in *'Annex III of the Environmental Noise Directive describes the methods for calculating the burden of disease caused by exposure to specific noise levels. The methods include dose-effect relations for a set of health endpoints such as cardiovascular disease, annoyance and sleep disturbance. Annex III was revised in 2020 following the latest scientific review of the health effects of noise that is being performed by the WHO.'* Box 2 'Impact of the Guidelines at EU level' in the joint WHO and EEA briefing [9] provides details on the where Annex III originated from and its links to WHO guidelines [10].

The results of the strategic noise mapping, including the harmful effects, may then be used to identify important areas [IAs] where long term noise exposure to noise from transport infrastructure is likely to produce negative health effects on the exposed population. This would be all areas exposed above the outdoor noise levels set out within WHO guidelines [10-12].

The main purpose of the WHO guidelines is to provide recommendations for protecting human health from exposure to environmental noise originating from various sources. They provide public health advice underpinned by evidence, which is essential to drive policy action that will help to protect communities from the adverse effects of noise. The WHO ENG 2018 guidelines reviewed the pertinent literature in order to incorporate significant research undertaken in the area of environmental noise and health since the *Community Noise Guidelines* (1999) [11] and *Night Noise Guidelines for Europe* (2011) [12] were issued. The significant health impacts of noise are most likely to be underestimated, with WHO evidence demonstrating effects from noise levels below the thresholds that countries report against under the Environmental Noise Directive.

The WHO Environmental Noise Guidelines (ENG 2018) formulated recommendations based on the available evidence, and exposure values based on a relevant risk increase of adverse health effects. Thus, the 2018 guideline values define an exposure level at which effects certainly occur. Furthermore, the WHO developed dose-response relationships for the assessment of health effects due to chronic long-term exposure to environmental noise from roads, railways and aircraft. These dose-response relationships have subsequently been adopted by the EU as Annex III of the END as set out in the Second Schedule of the Regulations, which sets out methodologies to be used for the assessment of three harmful effects:

- Ischaemic heart disease due to road traffic noise, and
- High annoyance and high sleep disturbance due to road, railway and aircraft noise.

The WHO definition of health is *"a state of complete mental, physical and social well-being"*. In addition, noise annoyance in this field means a feeling of displeasure, nuisance, disturbance or irritation caused by a specific sound, and in the context of the WHO guidelines and END it refers to long-term (chronic) noise annoyance, rather than just a temporary irritation. The WHO acknowledge that there are uncertainties in the quantification of health impacts from a range of factors, including: in their own recommendations; the modelling of noise exposure; transferability of exposure response functions to locations beyond where they were studied. However, they concluded that the recommended values provide an acceptable estimate of the average response to certain noise levels in Europe.

4. OVERVIEW OF METHODOLOGY

Following consultation with the NMBs and APAs the EPA developed relevant criteria for action plan priorities, recommended as a three-step approach to identify one or more of these priorities due to exposure to noise from roads and railways:

- **Step 1: Important Areas (IA)** – these are locations exposed to environmental noise which may be harmful to human health, such as high annoyance, above the relevant thresholds with reference to the WHO 2018 guidelines on road and railway noise;
- **Step 2: Most Important Areas (MIA)** – these locations are a sub-set of Important Areas where the health effects are highest, typically through a product of noise exposure levels and the number of people exposed to noise;
- **Step 3: Priority Important Areas (PIA)** – where appropriate and relevant to the individual local authority between 5 and 10 MIAs, or groups of similarly affected MIAs, which are identified by the APAs as those which will be addressed during the implementation of the Noise Action Plan (NAP).

5. IDENTIFYING MOST IMPORTANT AREAS (MIAs) – ROADS AND RAILWAYS

The END requires that:
"The measures within the plans are at the discretion of the competent authorities, but should notably ***address priorities*** *which may be identified by the* ***exceeding of any relevant limit value or by other criteria*** *chosen by the Member States and* ***apply in particular to the most important areas*** *as established by strategic noise mapping."*
As there are no statutory noise limit values in Ireland, the EPA has developed other relevant criteria for identifying priorities, and the most important areas, exposed to road and railway noise to be addressed within the noise action plans.
While the below method sounds complex, it can be automated in a few steps within modern GIS (geographical information system) software, resulting in a graphical map which effectively shows the relative number of people highly annoyed due to noise, as shown in Figure 1 below.

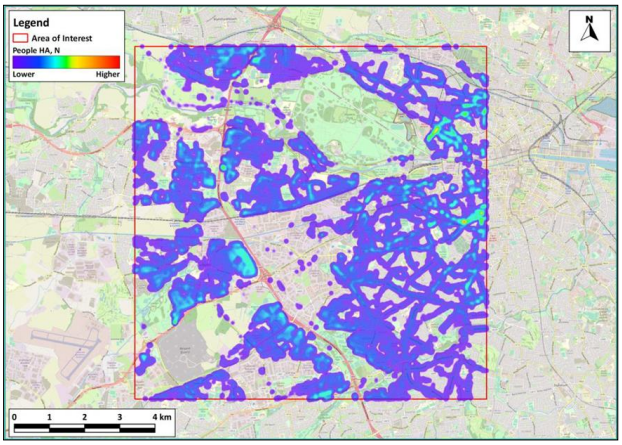

Figure 1. Heat map of density of people highly annoyed due to road traffic noise above 53 dB L_{den}

The results of the strategic noise mapping include noise levels calculated around the facades of noise sensitive buildings, and an estimate of the number of dwellings and people in dwellings within each residential building.
The assignment of population to the calculated noise levels is set out within Annex II of the END (CNOSSOS-EU) and provides building level statistics across the assessment area. Following the method in Annex II of the END, the harmful effects due to noise may also be statistically assessed at the centre point of each building location. For example, the number of people highly annoyed, due to road traffic noise.

It is important to note that this is a statistical approach across the whole population covered by the noise maps and should not be considered to be an accurate assessment of the possible health effects at any specific building. The WHO recommended dose-response curves were derived from meta-analysis of a large number of studies and are considered representative across the overall population within the study.
The point dataset of the number of people highly annoyed is then interpolated to generate a raster heatmap, using a quadratic weighted circular neighbourhood around each point. The heatmap process only includes important areas above the WHO guideline levels, and is generated on a 100 metre radius, which generates 100 m^2 raster cells.
From the heatmap it is then possible to identify the most important areas (MIAs), which are those IAs with the largest concentration of people highly annoyed due to noise. This aims to identify locations where noise mitigation measures may have a positive effect on the quality of life for a large number of people. Using a criterion of 15 or more people highly annoyed per 100 m^2, the MIAs (delineated as polygons) for an example area are shown in Figure 2 below.

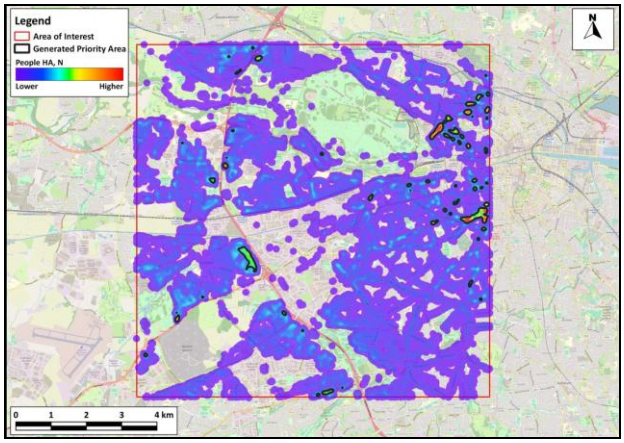

Figure 2. Most Important Areas (MIAs) highlighted (15 people per 100 m^2 criterion)

The criterion of 15 or more people per 100 m^2 has been found to be appropriate in the main urban areas within agglomerations. For edge of urban, or rural, locations it may be found that very few MIAs are identified based on this criterion. In this situation it is recommended that the criterion is reduced to 10, or even 7.5, in order to ideally identify at least 15 to 20 MIAs within the region covered by strategic noise mapping.

The recommended process aims to identify areas with high levels of health impact, due to both noise exposure levels and population density. This is designed to support aims of the EU Zero Pollution Action Plan and provide noise reduction, and associated reductions in health effects, for groups of the population.
It is accepted that this may result in some locations with similar or even higher noise exposure levels and lower levels of population density not being identified as MIAs. It is within the discretion of the APAs to identify specific locations with ongoing noise problems as MIAs, or PIAs, if the automated process does not identify them, but this alternative method of designating PIAs must be backed up with well-grounded evidence in order that comparisons can be made at a Regional/National Level.

6. IDENTIFYING PRIORITY IMPORTANT AREAS (PIAs) – ROADS AND RAILWAYS

The recommended process described in Section 5.2 above is expected to identify a range of most important areas (MIAs), and there are likely to be more identified than it would be possible to address within the current noise action plan lifecycle. It is therefore the task of each Local Authority to select their Priority Important Areas (PIAs), informed by the list of most import areas.
The MIAs are described as areas within the map, and the GIS may be used to develop a series of statistics about each of these MIAs, for example:

- Noise source identifying the Most Important Area, i.e., railways or roads
- Area (m^2)
- Total population
- Number of people highly annoyed (HA)
- Number of people highly sleep disturbed (HSD)
- Population increased risk to ischaemic heart disease (IHD)
- Number of dwellings
- Population noise exposure above END threshold values:
    - road traffic noise exposure in 5 dB bands (L_{den} 55 - >75 dB, L_{night} 50 – >70 dB)
    - railway noise exposure in 5 dB bands (L_{den} 55 - >75 dB, L_{night} 50 – >70 dB).

When considering the selection of PIAs to address under the action plan, it is recommended that the APAs consider the following aspects for each of the MIAs:

- Number of people exposed to noise, and the health effects
- Level of noise exposure
- Potential for grouping adjacent MIAs into a larger PIA
- The main source of transport noise
- Competent body to carry out any proposed mitigation measures
- History of complaints
- Planned road maintenance and resurfacing programme
- Planned speed or traffic calming measures
- Planned nearby developments
- Existing noise reduction measures
- Proposed noise reduction measures
- Options available for noise reduction measures, if available

Based upon all the information available, where necessary, it is recommended that APAs identify at least 5 and up to 10 Priority Important Areas (PIAs) which will be included within the noise action plan, with a plan to undertake an assessment of noise mitigation measures for each PIA within the life cycle of the noise action plan (e.g.: 2024-2028, 2028-33, 2033-38).
The selection of the PIAs from the MIAs is be documented within the NAP, including a rationale for each PIA selected.
The PIAs selected within Limerick Agglomeration are shown in Figure 3, which illustrates how adjacent MIAs exposed to the same source have been clustered into a single PIA.

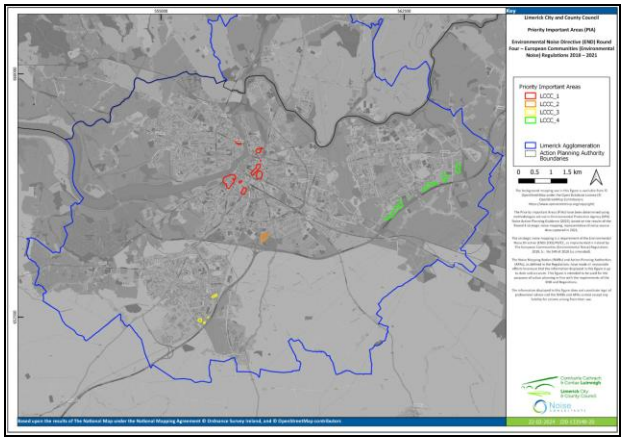

Figure 3. Limerick Agglomeration –Priority Important Areas (PIAs) - LCCC_1: Limerick City; LCCC_2: John Carew Park; LCCC_3: Ballycummin; LCCC_4: Monaleen/Castletroy

7. ASSESSMENT OF NOISE MITIGAITON MEASURES

Following adoption of the NAP, for each of the Priority Important Areas, an assessment of cost-effective noise mitigation measures is undertaken during implementation of the NAP. It is recommended that this assessment includes:

- noise monitoring to confirm exposure levels;
- noise modelling calculations of practical noise mitigation measures, and
- cost-benefit analysis based on estimated costs of implementing and maintaining mitigation works, and monetised benefit to health of noise reduction.

It is recommended that the most cost-effective noise mitigation measures, or combination of measures, are proposed to the relevant departments, organisations and fund holders to be incorporated within their future work plans as robust proposals for cost-effective noise mitigation measures.

8. CONCLUSIONS

The Environmental Protection Agency in Ireland is to exercise general supervision over the functions and actions of noise mapping bodies and action planning authorities, and to provide guidance or advice, where necessary.

The EPA has developed a revised draft guidance note on noise action planning for Round 4 of the END implementation.

As there are no statutory noise limit values in Ireland, the EPA developed other relevant criteria for identifying priorities, and the most important areas, exposed to road and railway noise to be addressed within the noise action plans.

The recommended approach identifies Important Areas (IA) as areas exposed above the relevant thresholds with reference to the WHO 2018 guidelines on road and railway noise.

The recommended approach then identifies Most Important Areas (MIA) on the basis of interpolating a building point dataset of the number of people highly annoyed to generate a raster heatmap, using a quadratic weighted circular neighbourhood around each point.

From the heatmap it is then possible to identify the most important areas (MIAs), which are those IAs with the largest concentration of people highly annoyed due to noise. This aims to identify locations where noise mitigation measures may have a positive effect on the quality of life for a large number of people. Using a criterion of 15 or more people highly annoyed per 100 m^2.

The criterion of 15 or more people per 100 m2 has been found to be appropriate in the main urban areas within agglomerations. For edge of urban, or rural, locations it may be found that very few MIAs are identified based on this criterion. In this situation it is recommended that the criterion is reduced to 10, or even 7.5, in order to ideally identify at least 15 to 20 MIAs within the region covered by strategic noise mapping.

The Action Planning Authorities should then propose 5 to 10 MIAs to be the Priority Important Areas (PIA) to be assessed during the implementation of the noise action. The recommended approach to assessment of each PIA includes noise monitoring, review of noise mitigation measures, and cost-benefit assessment, with the aim to develop robust proposals for cost-effective noise mitigation measures. The recommended process aims to identify areas with high levels of health impact, due to both noise exposure levels and population density. This is designed to support aims of the EU Zero Pollution Action Plan and provide noise reduction, and associated reductions in health effects, for groups of the population.

In late 2024, a number of pilot acoustic design studies were undertaken to look at validating some of the identified PIAs. It is hoped that any lessons learned from these initial pilot studies can be shared with other APAs in 2025.

9. ACKNOWLEDGMENTS

This work has been undertaken with the support of the Environmental Protection Agency, and assistance from Dublin City Council and Noise Consultants Limited.

QUALITY ASSURANCE AND MODELING LIMITATIONS IN NOISE EMISSION CONTROL USING ISO 9613-2 AND ISO 17534

Jochen Schaal * **Dieter Zollitsch**[1]
[1] SoundPLAN GmbH, Etzwiesenberg 15, 71522 Backnang (Germany)

ABSTRACT

The calculation of noise emissions according to ISO 9613-2 is an established method for estimating sound propagation and serves as the foundation for noise emission control. However, the standard offers limited capabilities for modeling complex acoustic scenarios, particularly in accounting for sound transmission through obstacles such as walls and other semi-transparent objects.
Users of simulation software like SoundPLAN often aim for more detailed modeling to accurately represent specific properties of walls or other obstacles. These requirements go beyond the standardized assumptions of ISO 9613-2 and necessitate adaptations to the official calculation methods in the simulation software.
ISO 17534 provides an important framework for software quality assurance by ensuring transparency and comparability of the software products used. However, advanced modeling and calculation approaches, such as those for sound transmission, can compromise the comparability of results if standardized procedures are not established.
This contribution highlights the challenges and opportunities in modeling sound transmission through obstacles, the limitations of ISO 9613-2 in this context, and the role of ISO 17534 in ensuring the quality and validity of simulation results.

1. INTRODUCTION

In the area of noise prediction, software developers are confronted with a conflict between the requirements of quality assurance and the wishes of the users. On the one hand, the quality assurance process, in accordance with standards such as ISO 17534, requires that software solutions comply with standardized test tasks for specific regulations, such as ISO 9613-2, and deliver comparable results within a specified tolerance range. This ensures transparency, comparability, and consistency between different software products in terms of the calculated noise levels.
On the other hand, users are increasingly demanding more detailed and specific modeling that goes beyond the capabilities of existing standards. This includes, for example, the precise consideration of transmission through walls, reflections on slanted surfaces, the simulation of horizontal obstacles such as the roofs of gas stations, or the consideration of tunnel openings. These extensions, however, go beyond the scope of the standards defined in official test tasks and therefore fall outside the scope of standards-based quality assurance.
For software developers, this necessitates a delicate balance: there is the requirement to ensure compliance with standards and the comparability of results. At the same time, the commitment to meeting the practical needs of the users in order to enable realistic and practice-oriented simulations is essential. One approach is to develop optional, well-documented extensions that provide users with additional options without compromising standards-compliant quality assurance.

2. QUALITY ASSURANCE OF SOFTWARE FOR CALCULATING SOUND

The quality assurance of simulation software such as SoundPLAN does not entail the testing or validation of the quality or accuracy of official guidelines, including

ISO 9613-2 and similar standards. As a software developer, it is incumbent upon us to acknowledge the validity of the assumptions inherent in these standards. Any interrogation of these assumptions must therefore be confined to the standardization process. Once published, however, they are binding and are considered the established standard.

Instead, quality assurance focuses on ensuring that different software products with the same input scenarios produce identical results within a defined range of variations. This approach fosters the principles of comparability and consistency among various software solutions. This procedure is specified in ISO/TR 17534 Parts 1 and 2 and provides clear requirements for the verification and validation of calculation results.

For software developers, the existence of official test tasks for the calculation methods to be implemented constitutes a significant advantage. These are typically either provided directly by the creators of the guidelines or developed by specific committees.

Examples are the official test tasks for the German RLS-19, Schall 03 or the Scandinavian NORD2000, which are provided by the respective guideline authorities. Another possibility is test tasks developed by expert committees, as described in ISO/TR 17534 Parts 3 and 4 for ISO 9613-2:1996 and CNOSSOS-EU. In addition, the German Federal Environmental Agency (Umweltbundesamt) provides specific test tasks, e.g. for BUB - the German version of CNOSSOS-EU. Such standardized test tasks make implementation and quality assurance much easier, as they create a uniform basis for validating and comparing software solutions.

However, if no official tests are available, the need to resort to in-house testing arises. This means a lot of extra work, as these test scenarios must be developed and ideally checked by hand to ensure that the implementation is correct. This additional work is not only time-consuming but also carries the risk that the results are less comparable due to the lack of external reference values. In addition, there is always a risk that the same "errors of reasoning" or interpretations that were made when the rules and regulations were translated into software code will be made when the test items are developed internally, especially if this is done by the same person. Therefore, this should always be done by different people, further increasing the effort.

The A-QNS (Association for the Quality Assurance of Noise Propagation Software) was founded to ensure the quality, comparability and transparency of software products for sound immission prediction. The initiative arose from the growing need to establish binding standards and test procedures for the standard-compliant implementation of calculation methods such as ISO 9613-2, CNOSSOS-EU, RLS19 or Schall 03. The main reasons for its establishment were:

1. Ensure standards compliance:
   with the increasing number of sound calculation software products, the challenge has been to ensure that all programs implement the calculation guidelines correctly and consistently. A-QNS ensures that software products use the same input data to produce comparable results.
2. Promotion of transparency:
   in approval procedures, environmental impact assessments and other official processes, it is essential that the calculation results are comprehensible and trustworthy. The A-QNS provides an objective basis for the evaluation of software solutions through tests and certificates.
3. Development of test tasks:
   many standards and guidelines do not contain complete test tasks for software validation. The A-QNS is working on the creation of such tasks in order to be able to test software products independently. Examples include the validation of the acoustic reference model K1 according to RVS 04.02.11-2021 and ÖAL No. 28-2021.
4. Independent quality assurance:
   the establishment of an independent association has created a central body that performs quality assurance impartially and independently of individual software vendors.
5. Cooperation and standardization:
   The association promotes cooperation between software developers, users, authorities and standardization bodies in order to support the further development and standardization of calculation methods and test procedures.

The foundation of the A-QNS was therefore an important step towards creating a reliable basis for the development and testing of software in an increasingly complex technical and regulatory environment. The aim is to increase both user confidence and the acceptance of calculation results in legal and planning contexts.

3. MODELING BEYOND THE LIMITS OF THE STANDARD

Users of simulation software such as SoundPLAN often require more detailed modeling that goes beyond the standardized assumptions of ISO 9613-2:2024. The focus is on specific properties such as the transmission of sound through walls or other obstacles. There is also a desire for more detailed simulation of obstacles, for example to accurately account for reflections from slanted surfaces such as roofs or inclined walls. Another common simulation request concerns horizontal obstacles such as gas station roofs, bridges, or similar structures. This is where the ISO 9613-2:2024 guideline has its limitations, as it only takes into account diffraction above and to the side of objects but does not take into account underside diffraction. Reflections from such horizontal surfaces are also not considered in this standard, although they may play a role in practice.

To meet these partially justified user requirements, it is necessary to adapt the official calculation methods in the simulation software. However, this means that the calculated results are, strictly speaking, outside the calculation standard used and the scope of official quality assurance, since such extensions can be implemented differently by software developers.

4. EXTENSION EXAMPLE - TRANSMISSION THROUGH WALLS

A recurrent request received by software developers involves the extension of the calculation methodology for sound transmission through shielding objects such as walls. This subject is of particular pertinence to mobile noise control solutions in scenarios such as moving construction sites, temporary events, machine enclosures, noise protection cabins, room partitions, and demolition work. These applications necessitate the development of advanced models capable of accurately assessing sound transmission through a diverse range of often temporary obstacles. The existing calculation methods are often found to be insufficient and require further development of the methodology to achieve more realistic and reliable results.

To illustrate this point, this paper demonstrates the integration of this user requirement into the ISO 9613-2:2024 standard. It is important to acknowledge that ISO 9613-2:2024 calculates three paths from the source to the receiver when a screen edge intersects the line of sight between the two objects. These paths include the direct path over the screen edge and the path that goes around both sides of the screen (horizontal extension). The calculated barrier attenuation, D_z, is frequency-dependent and is largely determined by the difference between the direct sound path and the detour via the shielding edge (z).

$$D_z = 10lg\left[1 + \left(2 + \left(\frac{C_2}{\lambda}\right)C_3 z\right)K_{met}\right] dB \quad for\ z > z_{min} \quad (1)$$

For the lateral detours, K_{met} is set to one in the formula. In the subsequent step, the attenuation due to a barrier, including possible corrections (A_{bar}) for the three paths is calculated separately based on D_z. This results in a combined A_{bar} through energetic summation. To take the transmission of a wall into account, D_z of the vertical sound path must be adjusted. The calculation of the lateral paths around the obstacle and the basic procedure remains unchanged. Three different cases must be considered.

a) The line of sight between the source and receiver is not interrupted.
b) The line of sight between the source and receiver is interrupted by several screens.
c) The line of sight between the source and receiver is interrupted by one screen.

In the proposed extension of ISO 9613-2:2024 implemented in SoundPLAN$_{noise}$, all three cases are considered and treated accordingly. This paper focuses on case c), with a screen that intersects the line of sight, which is the most relevant in practice. The following calculation steps are necessary:

1. Determination of a rubber band (connection between source and receiver) across the screen without taking into account the sound transmission. This results geometrically in z>0, d_{ss} and d_{sr} and finally the diffraction reduction, in this case called $D_{z,No,TL}$.
2. Determination of a multipath through the base of the screen, with z_{TL}, $d_{ss,TL}$ and $d_{sr,TL}$. Where z_{TL} takes values less than zero when the base point is below the line of sight. This results in the new diffraction reduction for the base point $D_{z,TL}$.
3. Considering the sound reduction index (R), the two diffraction reductions are then energetically combined to give the final D_z.

$$D_z = -10\log\left(10^{\left(-\frac{D_{z,No,TL}}{10}\right)} + 10^{\left(-\frac{D_{z,TL}-R}{10}\right)}\right) \quad (2)$$

This adjustment reduces D_z and takes into account the additional energy reaching the receiver through the screen. The calculation is performed for each frequency band and only minimally interferes with the basic ISO 9613-2:2024 procedure by adjusting D_z.

5. REAL APPLICATION: BUILDING SERVICES ON THE ROOF WITH ACOUSTIC BLINDS

Noise-intensive building services located on the roofs of buildings often cannot be completely enclosed due to the need for ventilation. In inner-city areas, this often leads to considerable noise pollution for residents and the surrounding area. In such cases, acoustic louvers are often used to reduce the noise sufficiently while ensuring air circulation at the same time. However, their acoustic performance is limited, particularly at low frequencies, where the low mass of the materials reduces their effectiveness. This type of noise control highlights the need for accurate modelling in order to more realistically estimate and optimize the sound insulation effect.

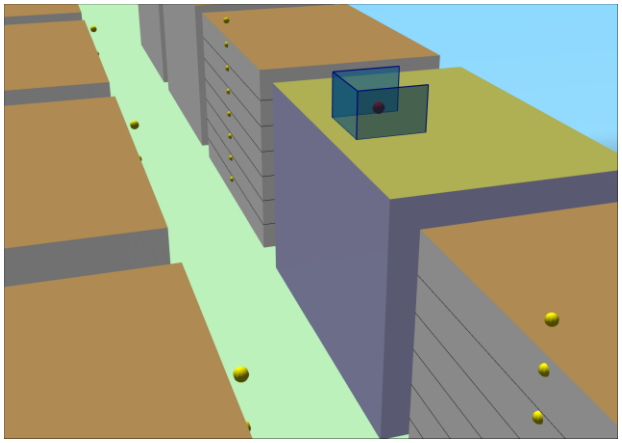

Figure 1. 3D-view of the acoustic model with the acoustic louvers around the noise source.

For the sound source, a spectrum from the literature was used that realistically describes the characteristic emissions for the application under consideration. In our example, a typical product with the following sound transmission loss was used for the acoustic louvers.

Table 1. Spectral sound transmission loss of the considered acoustic louvers.

Frequency [Hz]	125	250	500	1000	2000	4000
STL [dB]	5,0	8,0	9,0	12,0	9,0	7,0

As expected, the 'solid' wall variant with unlimited sound insulation (in accordance with the guidelines) results in significantly lower levels in the surrounding area than the variant with no wall. On the opposite façade, there is a reduction of between 8 and 19 dB, depending on the floor.

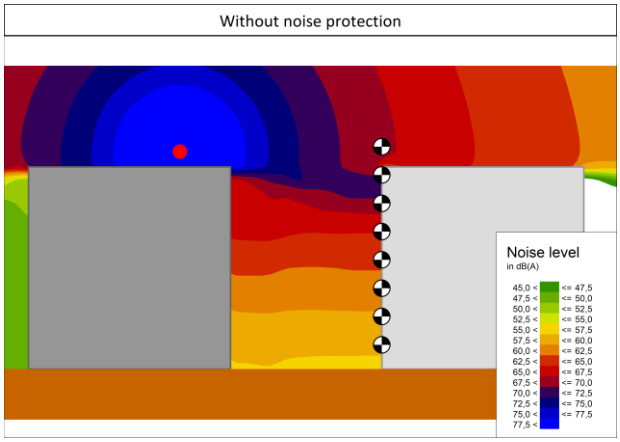

Figure 2. Noise dispersion in the cross-section without acoustic louvers.

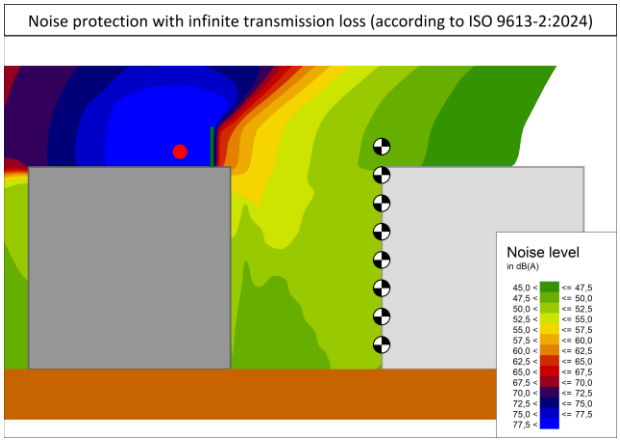

Figure 3. Noise dispersion in the cross-section with acoustic louvers (infinite transmission loss assumed).

The next variant was calculated using a wall with the real sound insulation of the acoustic louvers and the adapted algorithms. The resulting level reduction is only between 5 and 14 dB.

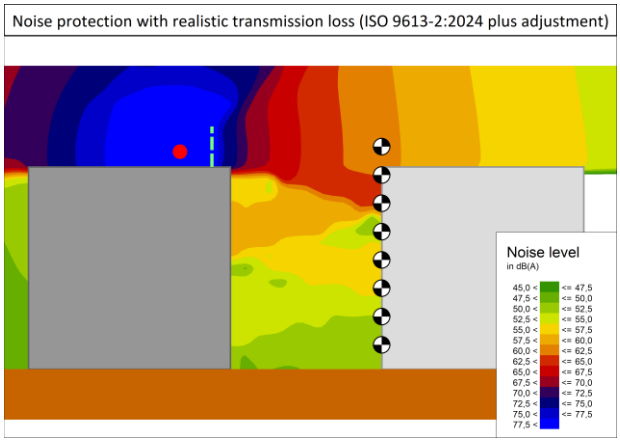

Figure 4. Noise dispersion in the cross-section with acoustic louvers (realistic transmission loss according to Table 1).

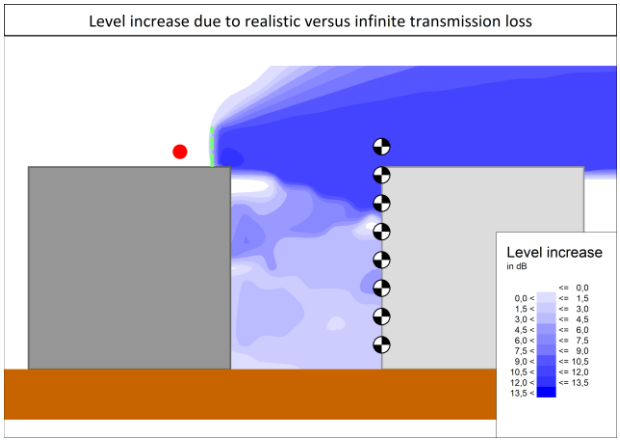

Figure 5. Noise level increase in the cross-section resulting from the realistic transmission loss of the acoustic louvers.

At some points, the passage of sound through the louvers will increase the level by up to 12 dB compared to a wall without a passage, while at other points it will be virtually 0 dB. The effect is highly dependent on height, as reflections play a significant role in this geometric situation. Above the roof, where there are no reflections, the reduction due to the semi-transparent wall is approximately 7 dB, which is roughly equivalent to the average sound reduction of the acoustic blinds.

The implemented extension of ISO 9613-2 in SoundPLANnoise allow for a more accurate modelling of the real acoustic conditions and emphasizes the importance of realistic sound insulation parameters in the simulation of special situations.

6. REAL APPLICATION: TEMPORARY NOISE PROTECTION MEASURES DURING CONSTRUCTION WORK

Construction work in urban areas often causes considerable noise pollution for residents and the surrounding area. Temporary noise barriers or curtains, which can be installed quickly, are an effective way of reducing noise. In the situation studied, work is carried out with a hammer drill on scaffolding attached to an external facade at a height of 11 m. The grey floorboards of the scaffolding are shown in the figure but were not considered in the noise simulation.

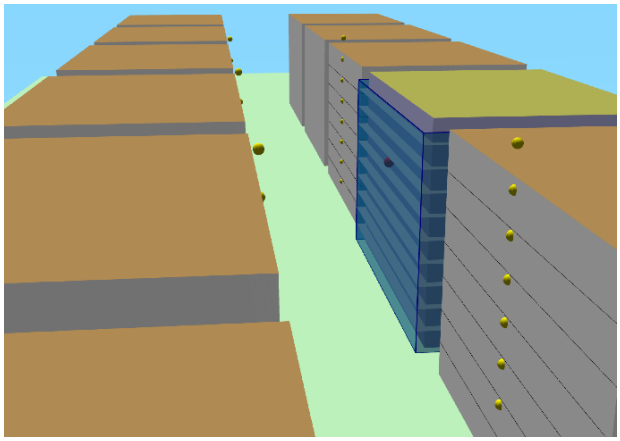

Figure 6. 3D-view of the acoustic model with the noise protection curtain around the scaffoldings.

The product CISILENT Typ L of Calenberg Ingenieure was used as sound insulation curtain. This mobile curtain has excellent acoustic properties, making it particularly suitable for temporary applications such as construction sites and events. Its sound absorbing and insulating properties offer an effective reduction of noise pollution in various application scenarios.

Table 2. Sound transmission loss of the sound insulation curtain.

Frequency [Hz]	125	250	500	1000	2000	4000
STL [dB]	13,2	15,5	17,6	19,0	20,0	24,0

At a computation height of 4 m above ground, there are large reductions of around 20 dB in the relevant area (e.g. road canyon). This result is to be expected, as the algorithm quickly reaches the maximum diffraction limit of 20 dB defined in the guideline due to the large extra path length.

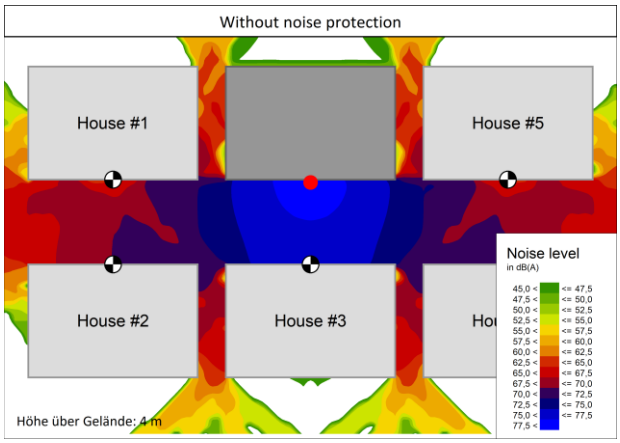

Figure 7. Noise dispersion without sound insulation curtains.

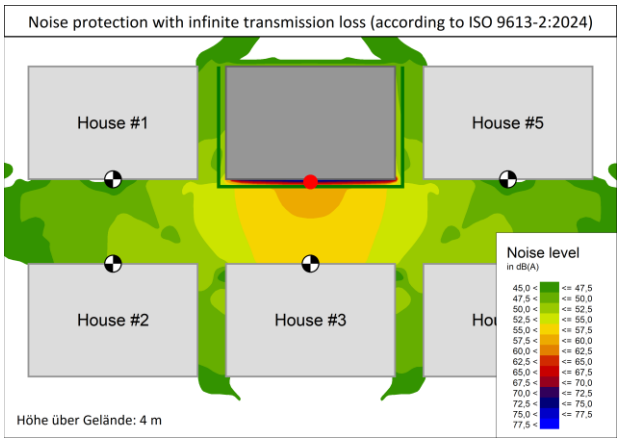

Figure 8. Noise dispersion with sound insulation curtains (infinite transmission loss assumed).

Additionally, there is a slight correction of the levels due to other sound paths, such as reflections and lateral paths. These effects contribute to the level reductions deviating slightly from the theoretical maximum but remain within the limits of the modelled calculation methodology. By adapting the ISO 9613-2:2024 algorithms in SoundPLAN$_{noise}$ to the real sound insulation, the following picture emerges. The level reduction is now about 19 dB. This result correlates very well with the real sound insulation of the noise barrier, considering that additional effects such as reflections and diffracted sound paths can occur.

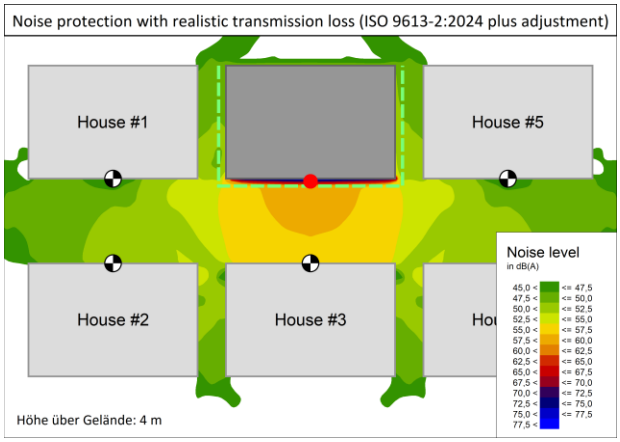

Figure 9. Noise dispersion with sound insulation curtains (realistic transmission loss according to Table 2).

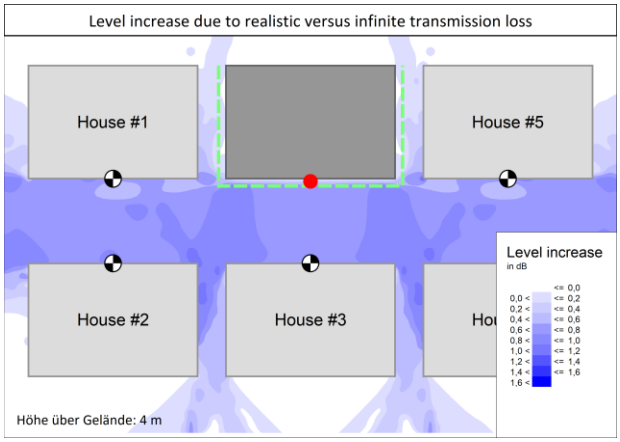

Figure 10. Noise level increase resulting from the realistic transmission loss of the sound insulation curtains.

The proposed adaptation of ISO 9613-2:2024 allows also in this case a more accurate modelling of the real acoustic conditions. In this case, however, the change in predicted results is rather small, around 1 dB, and has very little impact on the results. This is due to the high sound attenuation of the product used, which is close to the maximum diffraction limit of 20 dB.

7. CONCLUSION

The tested extension of ISO 9613-2:2024 by an additional term for the consideration of the sound insulation of walls leads to qualitatively meaningful results. It should only be used by the assessor/acoustician on a case-by-case basis, as the changes in the results are only relevant if the sound insulation is below the maximum diffraction limit of 20 dB. In such cases, a result can be calculated that is a much better estimation of the reality, as otherwise the level reduction would be overestimated by the assessor and complaints could later be made due to excessive noise pollution. Despite the successful extension of ISO 9613-2:2024 in SoundPLAN$_{noise}$ to include an additional term to account for sound insulation, comparability between different software products remains a key challenge. To address this issue from a quality assurance perspective, the following actions are critical:

1. Transparent quality assurance by the software developer:
   the software developer should clearly document which internal and external quality assurance measures are performed. This information should be openly available to users and should include an overview of the test tasks performed.
2. Documentation by assessors:
   assessors should document the software used in their reports, including the version number and quality checks performed. If the calculation settings differ from those recommended by the software developer, it should be noted.
3. Declaration of standard deviations:
   if objects or methods are used in the calculation models that exceed the limits of the standards, this should be clearly indicated and justified in the documentation of the results by both the software developers and the expert.

In addition, software developers should work together to fill gaps in existing standards and to address user requirements in a unified approach. This could be done through committees such as ISO/TC 43/SC 1/WG 56 or the A-QNS group. A revision of the propagation guidelines could also be used to make progress. However, it has been shown that such committees often work slowly and have to deal with conflicting interests, which makes quick innovations difficult. Regardless, it is essential that all interested parties have access to relevant information and documentation to ensure fair competition, transparency and comparability.

COMPARATIVE ANALYSIS OF STRATEGIC NOISE MAPS: USING HEAT MAPS TO FIND WHY TWO CNOSSOS-EU IMPLEMENTATIONS (INOISE AND CADNAA) DIFFER

Andrés L. Peña[1*]

[1] Calpe Institute of Technology, S.L., C/Severo Ochoa, 4, Málaga, Spain

ABSTRACT

Strategic noise maps are the tool to assess the population noise exposure, perform cost-benefit studies of the available measures to be adopted to abate that exposure as part of the noise action plans, and evaluate the effective improvement achieved after its implementation. CNOSSOS-EU is the homogenized calculation method for sound propagation outdoors in Europe, existing several applications implementing it. CNOSSOS-EU includes quality controls every application must fulfil, so no important deviations are expected in the results obtained when using different applications. However, such deviations exist and can be sensitive in some cases. The objective of this study is to present a method to detect where the disparities between both applications are more relevant: a heat map of the deviations obtained at the same grid point results, and an example of application in a real case scenario.

Two of these applications have been chosen, iNoise and CadnaA, to calculate the same strategic noise map of the population area of Santa Rosalía-Maqueda, Málaga. The different approaches in data processing and calculation method implementation of these applications are compared, the detected deviations in the outcomes obtained for both sound propagation and population noise exposure are analyzed, and the causes are inferred.

1. INTRODUCTION

Noise mapping is the presentation of data on an existing or predicted noise situation in terms of a noise indicator, indicating breaches of any relevant limit value in force, the number of people affected in a certain area, or the number of dwellings exposed to certain values of a noise indicator in a certain area [1]. "Strategic" refers to maps designed for the global assessment of noise exposure in a given area due to different noise sources, or for overall predictions for such an area.

CNOSSOS-EU has become the homogenized calculation method for sound propagation outdoors in Europe, being the mandatory calculation method in most European states, starting from December 31, 2018 [2].

This method is paired with strict quality requirements and quality assurance methods defined in the ISO 17534 series, "to ensure, to indicate, and to verify the degree of conformity of a software program with a consistently implementable calculation method/procedure" [3]. Thus, given a certain dataset, any implementation of the CNOSSOS-EU should lead to the same results, this been checked by dozens of tests cases [4]. However, such deviations have been noted [5], and can be of statistical significance, even when assessing the sound power of sources [6].

Two different modelling software suites are compared in this study, DataKustik CadnaA® [7] and DGMR iNoise® [8], in the real case scenario of Santa Rosalía-Maqueda, a town area with a main through road and residential streets,

being roads the only noise source considered. The comparison focuses on propagation differences detected. CadnaA was selected due to having access to a full working educational licence, and iNoise due to having access to a full commercial licence.

2. OBJECTIVES

The objectives are to compare the results obtained by both modelling implementations, minimizing the differences between the models loaded. To achieve this, minimal and unavoidable optimisations were applied to both models.
The author has no commercial or whatsoever interest in any of the two CNOSSOS-EU implementations used in this work, nor recommends the usage of one above the other.
Conclusions are applicable only to this case scenario, as no additional scenarios were checked for correlation.

3. METHODOLOGY

3.1 Data pre-processing

Data was gathered and pre-processed in QGis. Sources used were:

- Terrain digital model → MDT02 layer, 2nd coverage (2015 – up-to-date), with 2m grid spacing, Centro Nacional de Información Geográfica [10]
- Buildings → from Oficina Virtual del Catastro: layer CONSTRU for heights, and INSPIRE layer A.ES.SGDC.BU for layout, current use, construction date, number of dwellings (1 = single dwelling, 2 or more = multiple dwellings) and current status [11]
- Roads → OpenStreetMap project [12]
- Traffic flows and speeds → Plan for traffic flows from Junta de Andalucía, and WG-AEN [13] tool 2.5 where no data was available
- Population → DEGA (Datos Geoespaciales de Andalucía [14], evenly distributed between the buildings located in each data cell, but considering the volume of each building

The information was pre-processed and formatted for each software in QGis and then imported at CadnaA and iNoise.

3.2 Import process

Huge differences between CadnaA and iNoise data import interfaces were noted. While iNoise import/export process is clear, user-friendly and versatile, CadnaA has a completely different approach with a powerful but complex import interface but limiting the model data that can be exported.
As CadnaA allows a model to be calculated with several methods, item types have fields not used by CNOSSOS-EU (i.e., road width). As iNoise models are assigned to a calculation method at creation, the interface is adapted to it, and no unnecessary fields are shown.
Buildings and roads were directly imported and not simplified to minimise the differences between the models of each software. Height lines had to be minimally simplified, as CadnaA was unable to generate a 3D view if this step was avoided, and such a view is required to check for modelling errors. Terrain resolution has been proved to have minimal to no impact in the results [15].
CadnaA's tool to adapt the terrain digital model to avoid burial of roads in several points. While iNoise lacks such tool, these burials were avoided by rising all roads by 0,01m, which is trivial with its mass editing interface.
Road slopes were calculated at QGis, as CadnaA offers no direct option to export its calculated slopes and iNoise has no tool for calculating them.
Sound power levels of roads calculated by both applications were compared with almost no deviations between them, as Table 1 shows. Absence of integrity, duplicities and geometric errors were checked by iNoise for both items and terrain (CadnaA has no equivalent tool).

Table 1. Sound power estimation differences for roads by CadnaA and iNoise (dBA).

	$L_{w,d}$	$L_{w,e}$	$L_{w,n}$
Max, abs	0,450	0,450	0,660
Mean	0,026	0,005	0,101
Median	0,010	0,000	0,050

iNoise building item type has fields for designated use (i.e. residential, educational, industrial…) and dwelling type (no dwellings, single dwelling or multiple dwellings), while population data is managed with the address point item type. Address points are linked to residential buildings.
CadnaA building item type has a "residential" Boolean field and a population field, but there is no way to mark single or multiple dwellings.

3.3 Grid calculation

The calculation grid points were spaced by 2m in both dimensions, a high density, to better asses the differences in propagation obtained by both applications. Both models were not optimised for calculation but to minimise differences, so no conclusions can be made about

performance nor efficiency of both applications, even when they both were run on the same server. Partial views of grid results are shown in Figure 1 (CadnaA) and Figure 2 (iNoise).

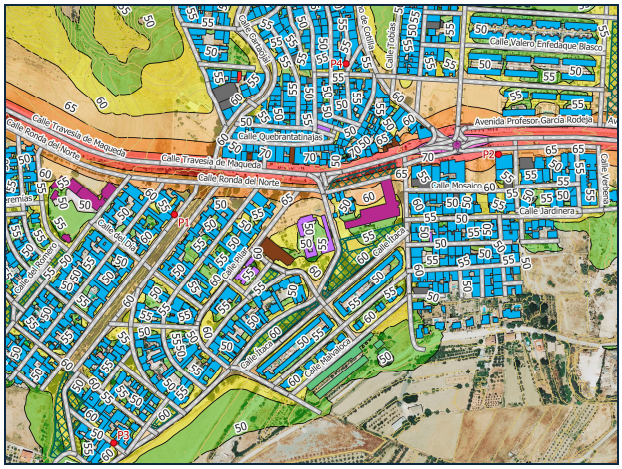

Figure 1. CadnaA grid results (L_{den})

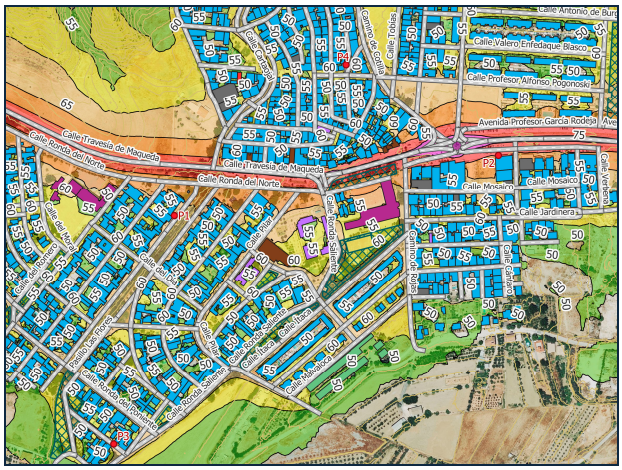

Figure 2. CadnaA grid results (L_{den})

3.4 Population exposure calculation

CNOSSOS-EU include methods 1 (most exposed), 2a (length) and 2b (median value) for population exposure calculation [16].

Unlike iNoise, CadnaA requires grid to be calculated prior to obtain population exposure, and by using the building evaluator item type. The façade exposure calculation method to be used can be chosen, but there is no option to use different methods for both single and multi-dwelling buildings.

iNoise has a tool to automatically mass add receivers at façades, which are calculated independently of the grid. These receivers are linked to the buildings, and the population exposure calculation may consider, if selected, different methods for façades of single and multi-dwelling residential buildings.

These radically different approaches to façade calculation might be behind the deviations detected in population exposure between both applications.

4. RESULTS

4.1 Grid results

As noted before, sound power of roads was estimated with minimal or no differences between both applications. However, sound propagated further according to iNoise compared to CadnaA. Grid point results were compared one by one, excluding those CadnaA and iNoise excluded (i.e., points located inside buildings). A statistical analysis (Table 2) of the deviations was carried out with the 72.388 grid points calculated by both applications. For each point, the iNoise result was subtracted from the CandaA result.

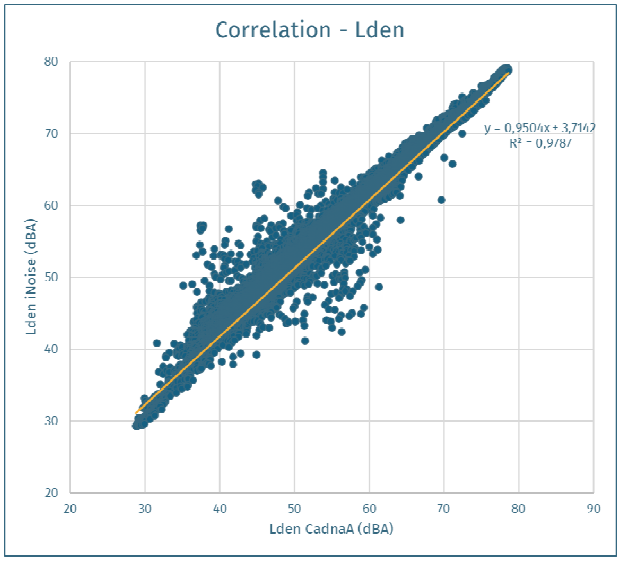

Figure 3. Linear correlation of grid points results

Considering L_{den}, CadnaA deviates >3dBA from iNoise in 105 points (0.15%), while the opposite happens in 3,769 points (5.21%). So, the difference at 68,514 points (94.65%) is in the (-3, 3) interval. A total of 43,530

points (60.13%) are in the (-1, 1) interval. Figure 3 shows linear correlation for L_{den} grid point results, with a Pearson r correlation coefficient higher than 0.97. A histogram for the same data is presented at Figure 4.

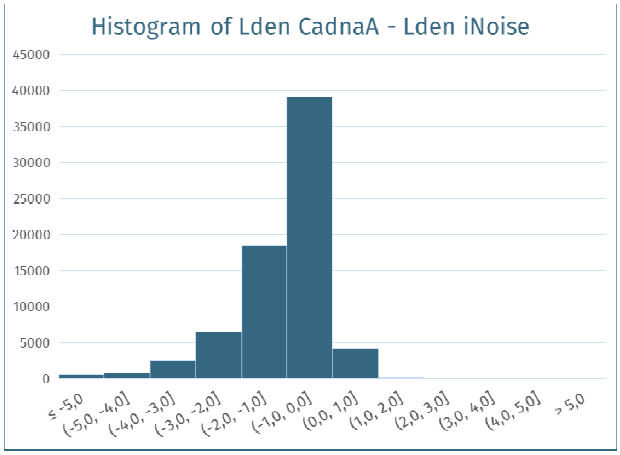

Figure 4. Histogram of L_{den} CadnaA - iNoise

To visualise the areas where the differences were located, the calculated differences were represented as a GIS layer, represented as a heat map as seen in Figure 5. Cold dots mean a higher value was calculated by CadnaA, and the warm areas are those where iNoise is the one estimating a higher result. This map allows examining not only the differences between the results, but how they are located, and may be the reason behind it.

Parameter	L_d	L_e	L_n	L_{den}
Max diff	14.03	14.16	14.04	13.97
Min diff	-19.29	-19.66	-20.08	-19.84
Mean	-0.95	-1.03	-1.04	-1.02
Median	-0.73	-0.78	-0.77	-0.76
Typ.Dev.	1.15	1.13	1.14	1.14
Variance	1.32	1.27	1.31	1.29

Table 2. Statistical analysis (CadnaA - iNoise)

The highest deviations are located 1) close to buildings, and 2) in complex terrain areas. Thus, obstacles as buildings or changes in terrain seem to have a lesser impact in iNoise than in CadnaA, as levels behind or next to obstacles tend to be higher in iNoise. Flat, open areas have almost equivalent results in both applications.

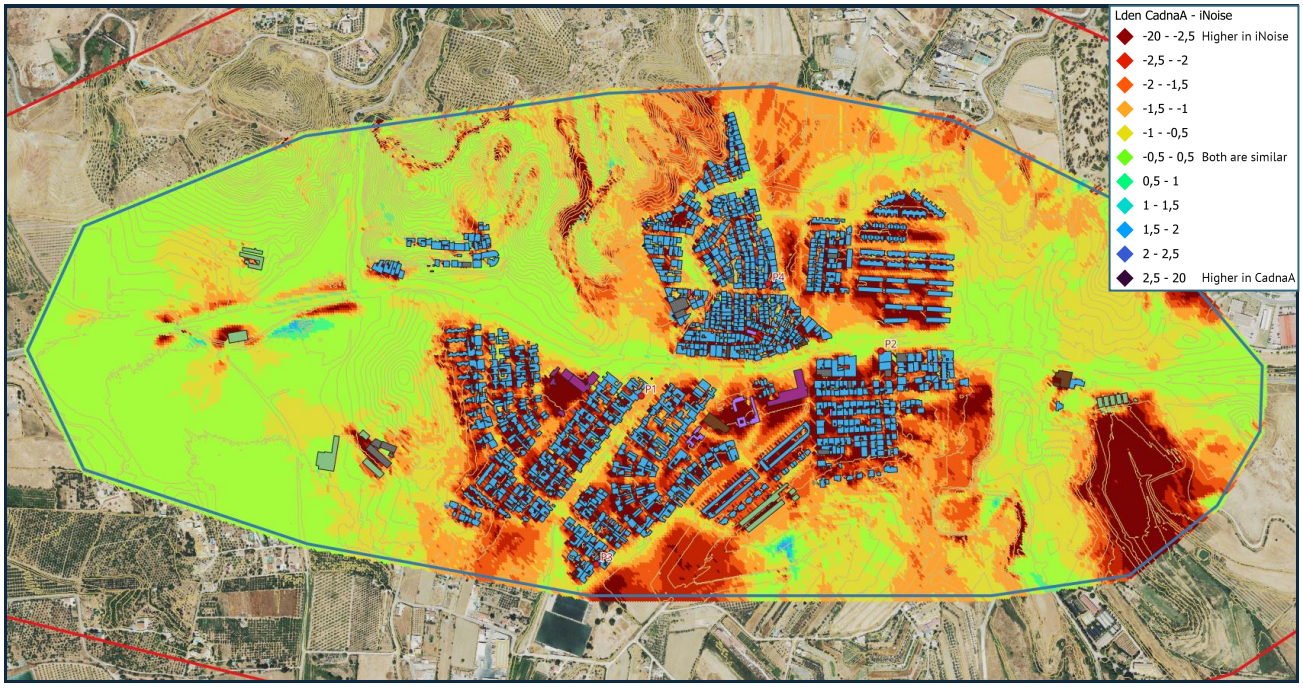

Figure 5. Heat map of L_{den} CadnaA - iNoise

4.2 Population exposure

Noteworthily, deviations in population exposure between both applications were detected to be in the opposite direction: CadnaA obtains higher exposure levels than iNoise, as seen at the Figure 6, with more people considered to be in the higher isophonic ranges.
Day, evening and night exposure levels follow the same trend, so for brevity only L_{den} exposure is shown here.
As stated before, the radically different approaches between both applications to assess population exposure might be the reason of these deviations: independent façade receivers in iNoise vs grid results with building evaluators in CadnaA, and the usage of different calculation methods for single and multi-dwelling façades in iNoise vs a single method for all dwelling types in CadnaA.

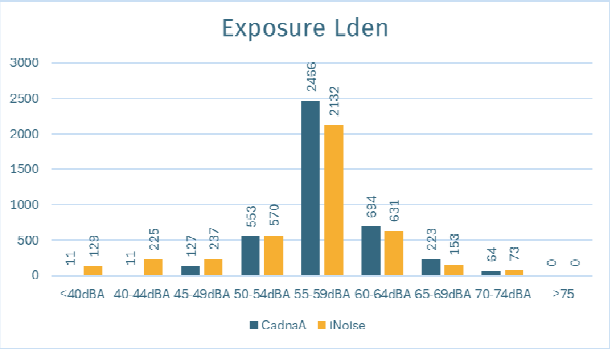

Figure 6. L_{den} exposure levels

5. DISCUSSION

The ISO 17534 is a huge step in harmonising the results obtained by diverse implementations of sound propagation modelling implementations in general, and the CNOSSOS-EU method in particular. These quality tests are a crucial advance in noise modelling across Europe. However, the question on disparities in the results obtained by different applications still remains, as several studies on the matter keep reaching to the same conclusions: fulfilling the test cases considered by the ISO 17534 quality controls is not enough to always achieve consistent results with different CNOSSOS-EU implementations [5][6].
While the ISO 17534 quality control focuses on propagation, reflections, diffractions, abatement, terrain, obstacles, etc., sometimes the divergence in results have other causes: disparities in data importing and management flows, model tools and optimisers, data item implementation, terrain model triangulation algorithms, software licence limitations, grid design and requirements, optional methods or parameters considered, and other hard to homogenise nor reconcile software design decisions taken by the developers of these applications.
No unique and definitive solution can be proposed here, but suggestions and wishes.
Adding implementation directives to the current test cases should improve the homogenisation of CNOSSOS-EU implementation and reliability.
Moving model information between applications should not be this hard. A data exchange file format for acoustic modelling would be of high interest for administrations, the main client for noise maps, and would help to ascertain deviations between implementations with more ease.
While acoustic modelling has had remarkable progression in the last 20 years, and CNOSSOS marked a critical step in the best direction, there is still a fascinating road ahead.

6. CONCLUSIONS

iNoise® and CadnaA® are fully valid implementations of the CNOSSOS-EU method, as they are certified to fulfil all ISO 17534 requirements, as many other solutions available.
While these conclusions are only applicable to this case scenario, deviations in results were found, which was not surprising as this is a recurrent situation every time the results of two or more implementations for the same model are compared.
While statistical analysis provides conclusions on the importance and relevance of deviations in results obtained by several implementations of CNOSSOS-EU, heat maps offer insight on the reasons behind those deviations.
For the case scenario of this study, iNoise calculated a higher propagation of sound than CadnaA, and according to the heat map, the cause of these deviations might be in how each application deal with obstacles and terrain. On the other hand, CadnaA considered population exposure to be higher than iNoise, and in this case the reason behind it might be CadnaA has no option to employ different calculation methods for single and multiple dwellings.

7. ACKNOWLEDGMENTS

The author would like to thank Jordi García and DGMR for their support with iNoise, and Cástor Rodriguez and DataKustik for the same with CadnaA. Alfonso Corz has been crucial and supportive during the whole process. Enrique Nava sparked the idea of representing in a map the differences that should not exist between the results of both

models. Eva García-Escobar, Óliver Peña, Carmen Escobar, Sandra Escobar, Ana Belén Olmo and Elena Olmo helped to gather invaluable field information. Also, a special nod goes to Elena Díaz, who suggested this article should be written.

DEFRA'S NOISE MODELLING SYSTEM: A NEW APPROACH TO NATIONWIDE MODELLING IN SUPPORT OF RESEARCH AND EVIDENCE

James Trow[1*] **Hilary Notley**[2]
[1] Noise Consultants Limited, Warrington, United Kingdom
[2] Department for Environment, Food & Rural Affairs, London, United Kingdom

ABSTRACT

The United Kingdom Department for Environment, Food and Rural Affairs (Defra) commissioned the design and build of an environmental noise modelling system (NMS). The NMS has been developed to support Defra in preparing its environmental noise evidence base by preparing national road and railway noise models. Since its development in 2022, the NMS has successfully delivered national coverage noise models, noise maps and population exposure statistics for all public road and railways sources in England, Wales and Scotland. This paper provides an overview of the design of the NMS, the specific design choices made in its development, and how these design choices feature in models and noise exposure data can be used to support the development of re-search and evidence.

Keywords: *noise mapping, research, Defra noise modelling system (NMS)*

1. BACKGROUND

The UK Department for Environment, Food and Rural Affairs (Defra) commissioned the design and build of an environmental noise modelling system (NMS) in 2021. From inception, Defra has overseen the development of its NMS to ensure that it is capable of transforming the way in which Government can both understand the scale of impact of noise from road and railway sources across England, but also work with stakeholders to integrate their own data sources, provide access to the underlying noise model and results, and ingest and integrate other data sources to support research and develop evidence.

This paper focusses on how design choices in the NMS's development can be used to support the development of research and evidence.

2. NMS DESIGN OBJECTIVES AND REQUIREMENTS

The core functional requirement of the NMS is to deliver Defra's regulatory requirements by producing strategic noise models, maps and exposure datasets for relevant road and railway sources in England, along with preparing analysis to fulfil the requirements of the Environmental Noise (England) Regulations 2006 (as amended) [1], the Defra 25-year Environment Plan [2], and the Public Health Outcomes Framework [3].

These requirements set a design requirement for the NMS to deliver a national noise model and associated noise exposure dataset for England with all public roads and railway including in the noise model. An example noise model within England using the NMS is presented in Figure 1.

Copyright: *©2025 J. Trow et al. This is an open-access article distributed under the terms of the Creative Commons Attribution 3.0 Unported License, which permits unrestricted use, distribution, and reproduction in any medium, provided the original author and source are credited.*

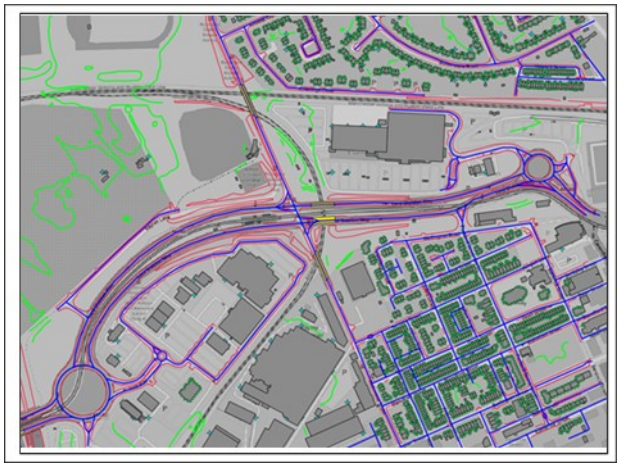

Figure 1. Noise model example highlighting road and railway sources, propagation model and façade receivers

The noise models delivered within the NMS are produced in line with the requirements of the adapted assessment methods based on the Calculation of Road Traffic Noise (CRTN), Calculation of Railway Noise (CRN), and CNOSSOS-EU. A design objective for the NMS is to deliver these requirements through automated processes wherever possible.

The wider design requirement for the NMS is to allow future users across the public sector to access the noise model through the NMS using open data standards.

For Defra, a key requirement of the NMS is to utilise and integrate noise exposure datasets produced from its model to support research and evidence building. It is this requirement which has driven design choices in how data is stored, processed and managed within the NMS, along with how national calculations and the NMS's noise calculation engine have been designed and configured.

3. CONCEPTUAL DESIGN

The NMS is designed as a web accessible cloud computing service hosted in Microsoft Azure. It has been designed to connect a series of components secured behind a web application firewall. The design of the NMS has taken a 'decoupled' approach which utilizes existing commercial products with 'ground up' development in areas such as its database design and Extract Transform Load (ETL) tools.

At the heart of the NMS is a Postgres geospatial database served on Azure CosmosDB. The database has been designed to store noise models and noise exposure datasets alongside each other. In support of Defra's requirements, the NMS has been designed to deliver automated processes whereby selected input datasets are transformed into noise model datasets using Feature Manipulation Engine (FME) software running bespoke ETL tools.

The models are stored in a manner which conforms to its system's open data standards which have been developed in parallel with the NMS. The parallel development of the database alongside the open data standards has highlighted where and how relationships between the datasets held within the NMS can be established and where these relationships can be extended to external data sources.

A core principle in the conceptual design has been to retain internal and external relationships in the noise source, propagation, receiver and noise exposure results datasets. To achieve this the design concept has relied on retaining identifiers through the calculation process which has required developments to the NMS's calculation engine, which utilises LimA calculation cores.

The high-level design of the NMS and its components is presented in Figure 2.

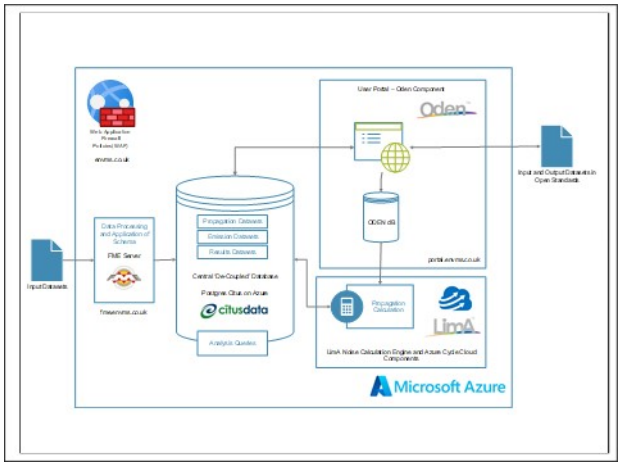

Figure 2. High Level Design of the NMS, its associated components and indicative data flows

4. DESIGN CHOICES AND FEATURES

In developing the NMS, specific design choices were made as part of the data and database architecture to support and facilitate the use of Defra's noise model and exposure

datasets to support research and evidence building. Three key design choices with this end use in mind are discussed.

4.1 Statistical Relational Modelling

A key design choice has been to develop a relational dataset which allows receptor datasets (buildings and noise calculation points) to be joined directly to results datasets stored in the NMS with wider external relational information to facilitate integration with wider Government statistics and data.

Each receptor at a building is provided with its own ID which is linked to each building. Each residential dwelling is pre-computed with population estimates. Each receptor is fed into the NMS's calculation engine with the results provided back to the database with reference to the receptor.

Each building is marked with relevant external identifiers that allows it to be assigned to various statistical geographies as defined by the UK Office for National Statistics. These geographies include Output Areas, Lower Super Output Areas, Ward Code, and Local Authority District Codes. Health Geographics are also assigned [4].

Using the CNOSSOS-EU 2a method for consistency, the database has been designed to allow noise exposure values for a range of metrics to be assigned to each building in 1 dB bands which are stored within the NMS as a dataset.
The retention of relational identifiers with Government statistical geometries within the NMS data model facilitates wider Government statistics to be joined to noise exposure datasets.

To support this, an end user tool referred as the 'Joint Statistics Tool' (JST) has been developed and is hosted within the NMS itself. This tool has been developed so that statistical data can be proportioned to a building level based on population estimates. This approach allows population noise exposure in 1 dB bands as held at building level to be considered based on the likelihood of that population falling into other statistical categories. An example is presented in Figure 3 which indicates how a general health statistic can be joined to noise exposure.

4.2 Source Apportionment

The NMS data model has been developed so that road and railway noise levels at each façade receptor and each grid calculation point can be revealed. This logic can be extended to incorporate noise exposure levels from industry and airport sources allowing the contributions from each noise source at location to be understood.

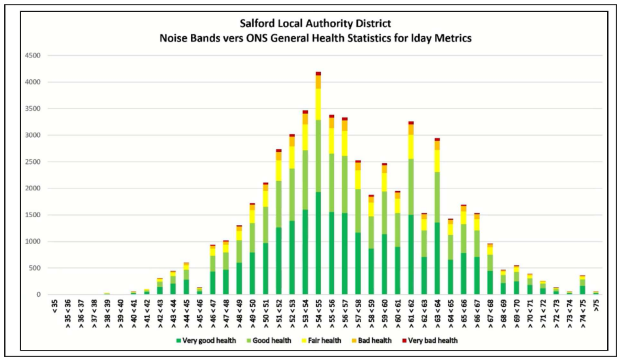

Figure 3. Example of an external statistic joined to noise exposure at building level

For road and railway sources, the concept of source apportionment has been further extended. Developments to the NMS's calculation core allows the contribution from individual road and railway sources to be understood with the contribution from each segment presented in order of its contribution to the overall noise exposure level by noise metric. This logic allows for noise emission parameters within the model to be presented alongside each contribution to provide an end user with an understanding of model inputs alongside their contribution to noise impacts. This is again achieved by retaining and reporting noise level contributions by source identifiers held in the model as stored in the central database by retaining these identifiers through the calculation process.

An example output from the NMS's source apportionment tool is presented in Figure 4.

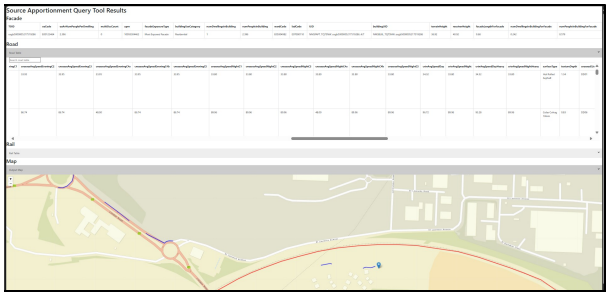

Figure 4. Example output from the NMS's source apportionment tool

4.3 Octave Bands

CNOSSOS-EU requires calculations to be carried out in octave bands. A key design choice has been to retain calculated octave band noise levels for each metric as part of the road and railway noise calculations. The NMS's database design and results tables allow octave band data to be stored for overall levels and as part of the source apportionment logic. Octave band results datasets are stored for façade receivers and noise grids.

Example road traffic noise maps calculated at the 1kHz and 250Hz octave band centre frequencies are presented in Figures 5 and 6 respectively.

Retention of octave band data allows the source and propagation characteristics to be captured over large areas and at discrete receptors opening up the potential to consider exposure relationships based on the character of the noise received.

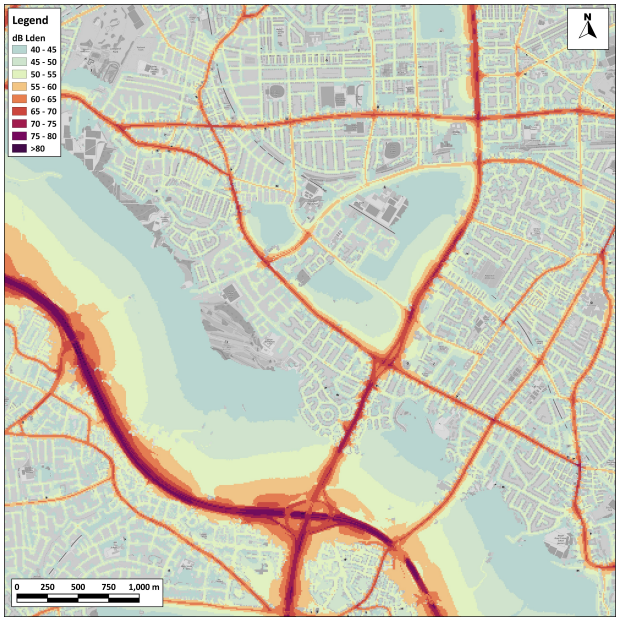

Figure 5. Road traffic noise maps (L_{den}) based on calculated levels at 1kHz

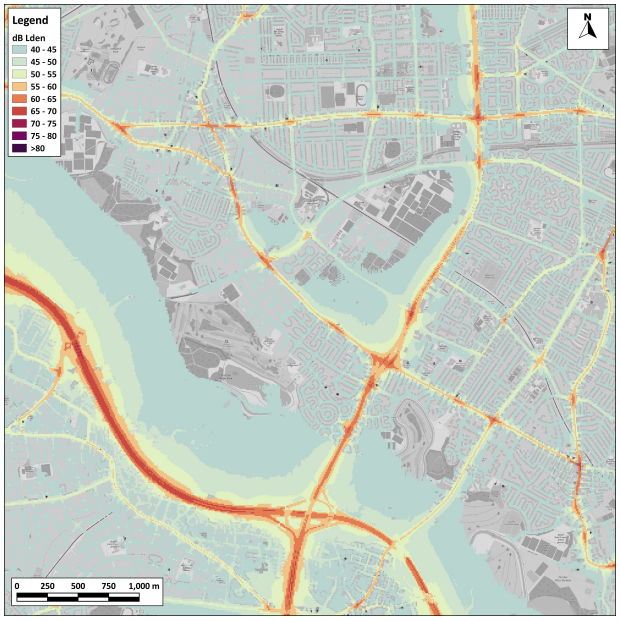

Figure 6. Road traffic noise maps (L_{den}) based on calculated levels at 250 Hz

5. OPPORTUNITIES FOR EVIDENCE AND RESEARCH

Section 4 of this paper highlights three key design choices within the NMS which provide opportunities for evidence building and research.

5.1 Inequalities in noise exposure

The NMS's Joint Statistics Tool provide opportunities for Defra to utilise its national noise exposure dataset to explore inequalities in noise exposure to individual transportation sources and/or combined transportation noise.

Using the JST, external datasets held by UK ONS as prepared using outputs from the 2021 Census [5], can be considered against exposure to environmental noise facilitating research and evidence generation exploring inequalities against a range of socio-economic and socio-demographic factors.

5.1.1 Socio-economic Factors

The National Statistics Socio-economic Classification (NS-SEC) is a standard classification which the UK ONS use to assign information such as occupations, employment status and history in statistical geographics across the UK [6]. ONS datasets also provide information that describe other

information such tenure of household and area-level income deprivation.

This data is held across a range of statistical geographies however through the JST this can be reconciled to building level allowing population and household noise exposure in 1 dB bands to be considered alongside statistical descriptions representing the likelihood that the population at each building falls into a particular socio-economic classification.

When considered and enumerated at regional and/or national level, the JST provides Defra with the opportunity to consider whether inequalities in noise exposure exist with respect to:

- Employment and Unemployment;
- Occupation;
- Household Income;
- Property Values;
- Household Tenure and Type;
- Income Deprivation; and
- Education.

5.1.2 Socio-demographic factors

The same techniques available in the JST provide opportunities to consider noise exposure against socio-demographic factors, namely ethnic group and household composition. The data model therefore provides Defra with the ability to consider whether there are systematic differences in exposure to environmental noise and different groups of people.

5.2 Mixed Source Environments

The NMS provides a national picture of exposure to transportation noise sources. In agglomerations, this is supplemented with exposure to industrial noise. This data is held in a standardised and consistent manner. The main evidence base for the effects of environmental noise still focuses on source-specific impacts and does not incorporate combined exposure to effects of multiple noise sources and/or other pollutants. The NMS and its data model provides opportunities to consider the effects of noise in mixed source environments. The national coverage of the exposure datasets provides further consideration to be given to the combined effects of other pollutants.

Defra carry out regular nationally representative social surveys on attitudes to different aspects of the environment and the work that Defra is responsible for [7]. These surveys include questions on people's response to different noise sources experienced whilst at home. Combining these results with outputs from the NMS provides the opportunity to look at exposure-response relationships at a national level.

5.3 Outcome Mapping

With noise exposure metrics stored alongside population at building level, the data model developed for the NMS provide opportunities to explore how harmful effects due to exposure to environmental noise can be mapped by calculating the number of people highly annoyed, highly sleep disturbed and/or at risk of health outcomes using odds ratios (OR) at building level and enumerating this information into zones, clusters, or within statistical and/or health reporting geographies to geographically map and identify burden through metrics such as Disability Adjusted Life Years (DALY).

The ability to store temporal data allows trends to be tracked over time.

5.4 Impacts on Biodiversity

Ecological research now deals increasingly with the effect of noise pollution on biodiversity [8]. Although habitats are not specific receptors in Defra's model, the national coverage of its noise exposure maps and grids cover biodiversity sites such as:

- Ramsar;
- Special Protection Areas (SPA);
- Sites of Specific Scientific Interest (SSSI); and
- Special Areas of Conservation.

These sites are designated in England as important for wildlife and other factors such as geology. Defra's datasets allow noise exposure to be considered across these areas, with octave band exposure datasets providing the ability for road and railway noise exposure to be considered using different frequency weightings and/or at specific frequencies which may best reflect the hearing characteristics of different species.

5.5 Tranquility Mapping

Outputs from the NMS have already been used by Welsh Government and Natural Resources Wales as part of the development of national tranquility maps [9]. National road and railway noise maps have been combined with other

datasets and rulesets to calculate tranquility indices as presented in Figure 7.

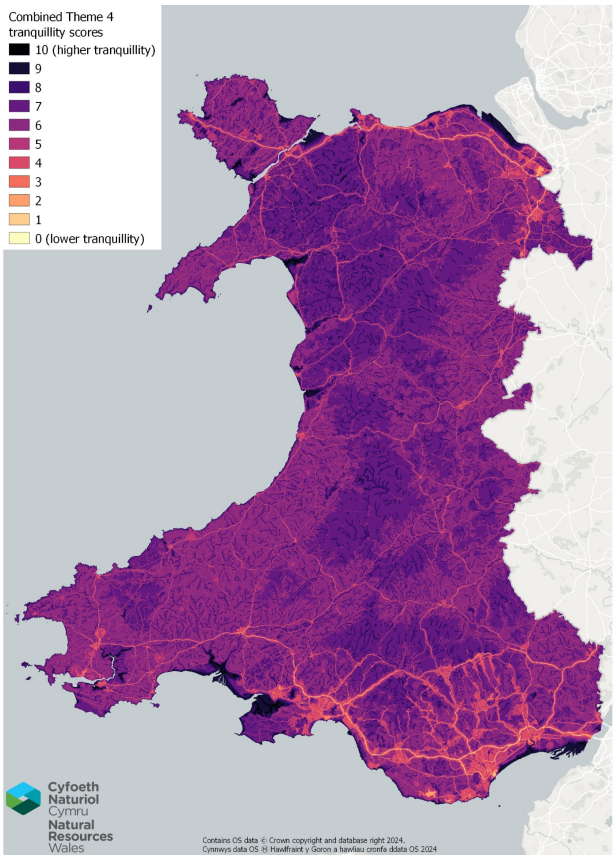

Figure 7. Tranquility map in Wales developed in part using NMS road and railway noise level grid outputs.

6. CONCLUSION

The development of the NMS has met the aims and objectives set out by Defra at the start of the project and even exceeded the expectations of many in the industry, It is the recipient of a number of awards for innovation from professional, government and non-governmental organisations. The NMS provides a solid foundation for building an evidence base over many years, with the flexibility to incorporate future datasets, not only related to noise modelling, but also wider environmental impacts or those associated with the broader built environment.

The above examples all show how the model and its outputs can be used to better understand the impact of environmental noise on the population. The data has also been used to enhance other indicators used widely in UK policy-making. The English Indices of Deprivation measure relative levels of deprivation in neighbourhoods in England [10]. In the next release, for the first time ever, environmental noise exposure to transportation sources will be one of the indices included in this composite measure. This would not have been possible had the NMS not covered all public roads and railway and the whole population of England.

7. ACKNOWLEDGMENTS

The development of the NMS has been a team effort. Defra would like to acknowledge the contributions from Noise Consultants Ltd, Acustica Ltd, Mott MacDonalds, NGIS, Stapelfeldt, M+P and ISVR

CNOSSOS ENVIRONMENTAL NOISE ANALYSIS ASSISTED BY CLOUD-BASED MODEL REFINEMENT AND CALCULATION

Dipl.-Ing. Hartmut Stapelfeldt [1] **Dr. Isabelle Naegelen** [2]

ABSTRACT

The environmental noise modelling system (NMS), DEFRA's approach for Great Britain, already showed the feasibility of cloud-based CNOSSOS noise mapping within Great Britain (GB). Using external resources for Environmental Noise Directive (END) [1] analysis in a "Software as a Service" (SaaS) concept appears to be economically viable. Ideally, noise mapping shall be based on standardized initial data. Over the years a few attempts have been made but with little success (QSI, CityGML etc.) as data providers do not take care of niche interests. In smaller scale projects than NMS, users might prefer to refine their model as part of an automated cloud process rather than manipulating data locally. Luxembourg's road and railway model for END 2022 activities represent an interesting collection of acoustic modelling aspects that require refinement, among others railway usage (XLS) provided by the national rail authority. This paper will present macro applications in context of 2022 END calculations as well as the status of cloud-based model refinement and calculation.

1. INTRODUCTION

Noise mapping and action planning or rather most of environmental noise analysis are common practice over many years. In most of the past the necessary software tools were provided as desktop solutions. With the increase in calculation demands and model size, the remote cluster- or cloud-based calculation, hereinafter called cloud-processing, is getting more relevant.
Calculation software requires model data provision to be canonical (e.g. CityGML QSI, NMS open standard…) or to follow the standard of the respective calculation software. Cloud processing speeds up noise map calculation. The remaining bottleneck is the significant manual interaction for initial model refinement. The authority or the consultant in charge has to compile subject related model data from several suppliers with differing data structures and content rules. Experiences show that the 3 aspects also vary over the time.
The concept promoted in this paper aims at reducing the manual work of model data refinement by making use of cloud-based model processing.

Any manual refinement approach has to consider:

- That the amount of involved data is huge
- Manual work of "Windows style" interactive refinement of graphic features and related attribute information is tedious and prone to human error.

- Expert knowledge remains with the individual engineer who fulfils the task of refinement
- Quality assessment is difficult as extra protocols need to be kept in parallel to the actual work
- Last minute provision of new/extra model data produces stress and the need for instantly available extra workforce

The aspects listed above are the reason why LimA, from Stapelfeldt Ingenieurgesellschaft GmbH SIG, focusses on the use of macros and workflows. This concept has driven SIG's development strategy right from its start in 1992. The concept is also followed in DEFRA's Noise Modelling System [2], where Feature Manipulation Engine (FME) tools are used to undertake refinements that are highly automized. The actual noise calculation in Microsoft's Azure Cloud uses LimA modules.
SIG has already significant experience with remote calculation services based on LimA's calculation cores for a number of years. Based on this we want to take a next step in cloud-processing:
"Why not uploading initial raw data and create a refined model in a Software-as-a-Service (SaaS) concept?"
Long standing experience allows SIG to provide useful macro tools from which a user can select intended model check and refinement steps. Alternatively, he can write his own macros for customized purposes and send them along with the raw data for external processing.
The potential user group may work on medium size model data, still practical to handle via FTP services.

2. REMOTE MODEL REFINEMENT

The final responsibility for model data will always stay with the users. This includes an insight into the original data to identify the required steps of refinement as well as a check of refinement results by the service before any noise calculation is initiated. In the following text LimA's feature types or attribute names are indicated by e.g. "<HIN>".

2.1 Principle steps of the process

Fig. 1. provides an overview of processing steps in remote refinement, which can be described as:

- All initial model data required in the process is available in SHAPE format.
- A CSV-file is filled in that describes the complete task
- Optional substitutes for general background data, such as object definitions or macros by own configurations
- All files are stored in a fixed structure of sub-directories underneath a main project directory
    - FILE_IN Initial model data
    - FILE_OUT Refined model data as result of processing
    - JOB_DEF CSV file with task description
    - PRJ_CONF Files adapted to project needs instead of background defaults
- Main project directory is zipped
- Initiate remote processing by invoking a small dialogue on desktop
- SIG cluster registers and orchestrates the process below:
    - Relevant server is chosen and, if running in the cloud outside SIG cluster is intended, is registered in LimA's remote licensing.
    - Decision on "cluster or cloud" is internal, but with respect to user restriction
    - Data package is sent onto relevant server
- Relevant server
    - Sends acknowledgement to user's FTP
    - Expands data package
    - Interprets CSV and performs workflow
    - Packs results and sends to user's FTP

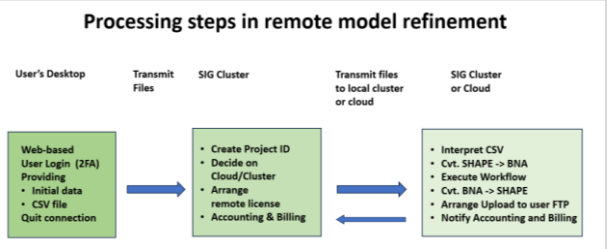

Figure 1. CSV file with task description

A CSV file (Tab. 1.) contains all instructions for model data refinement. It consists of lines covering different steps. Each line starts with a specific keyword or blank in case of identical keywords. Information provided covers:

- FTP for client/service communication
- Project identifier
- Restrictions for use of CPU(s) to limit financial risk in case of human definition during the task
- Restrict use of cloud beyond SIG cluster to be in line with potential restrictions
- Define object definition set, reflecting national and regulatory demands
- Define extra variables for sue in macros
- Repetitive definition for model file treatment
    - File name
    - Conversion rule SHAPE to LimA file

- Repetitive definition of applicable macros with potential list of parameters
- Conversion rule for LimA to SHAPE

3. EXAMPLES OF MODEL REFINEMENT

As contractor of Administration de l'environnement, Luxemburg, SIG took over the task of creating END-conformal noise maps. This included checks and refinements of initially provided model data in cooperation with Kramer Schalltechnik GmbH, Germany.
The task aims at achieving several aspects:

- Ensure valid attribute content by translation tables, syntax checks and default settings
- Simplify model data to reduce memory consumption and speed up calculation
- Fix geometry in case of geometric conflicts or inaccuracies
- Merge traffic data to road or rail networks

Some examples of automated macro processing are now addressed with respect to the Luxembourg model, which may indicate the potential of macro-based data refinement in cloud processing.

3.1 Terrain simplification

Luxemburg has a challenging terrain model. To support its usability by other software tools it was decided to work with a contour line increment of 2.5 m.
Terrain model simplification by smoothing helps to reduce model size. In the project, smoothing with a tolerance of only 1 m already brought down data volume to half. In general, LimA may work with larger tolerances as this is automatically decreased while neighbouring contours come into short distance. Fig. 2 compares project contour lines before and after smoothing.

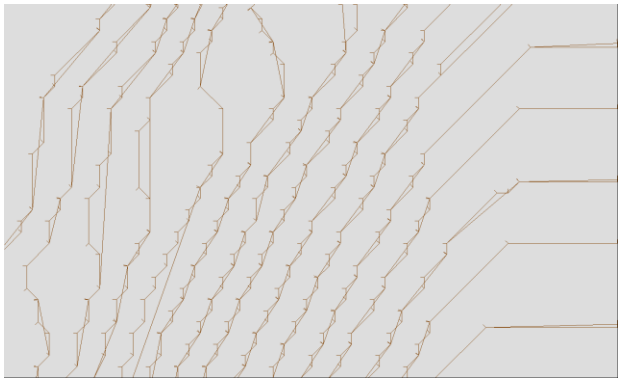

Figure 2. Detailed and smoothed terrain

3.2 Terrain refinement

The terrain model is retrieved from Lidar/radar scan data which takes bridges as terrain level information as seen in Fig. 3.
Therefore, terrain needs to be reshaped by erasing contours within necessary distance to the bridge and then establish a <GBO> break-line on the edge of this region.

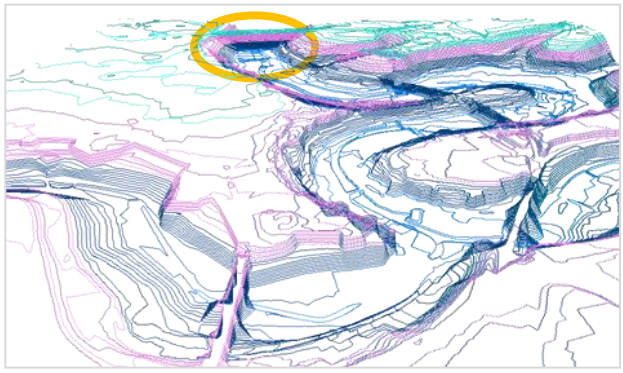

Figure 3. Initial terrain model takes bridges as terrain

Fig. 4 shows the bridge marked in orange in Fig. 3 as green surface and axis in orange. Next to it a <GBO> object with short vertex distances is generated that adjusts itself to the terrain nearby using the remaining contour lines.

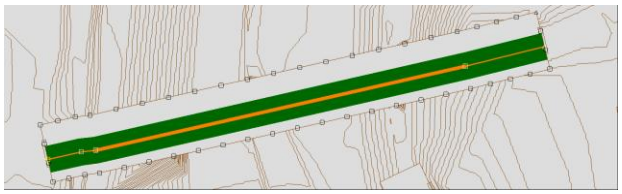

Figure 4. Bridge and clipped terrain

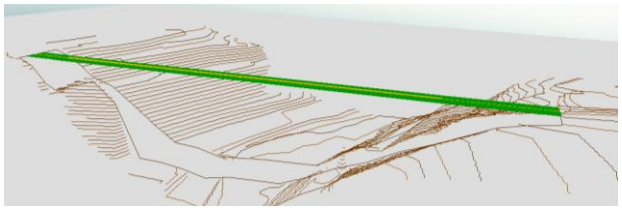

Figure 5. Bridge & clipped and substituted terrain

Original length of bridge axis (fat orange line in Fig. 4.) is extended (slim orange line), following the road centreline until terrain levels represent climb rates reasonable for road traffic. The issue of too short bridge objects seems to have a systematic background as it occurs regularly – maybe the digitized length of road axes are related to the edge of the support constructions at the end of bridges. Fig. 5. shows the resulting 3D model.

3.3 Ground cover

Gound cover polygons (<TOP>) were reduced by two strategies:

- Ignore hard surface areas and make hard ground default
- Simply geometry by smoothing, but keep adjacent polygon vertexes adjacent

3.4 Roads

Traffic data for the road network was provided by Luxemburg "Administration des ponts et chaussées" based on a simulation model which allows estimates for smaller roads in agglomerates. Traffic data is linked to the road network. As mapping also has to cover silent areas, the complete road-net is processed for the two agglomerations of AggloLux and AggloSud. The initial work was undertaken by Kramer Schalltechnik GmbH, and LimA macros are finally used for QA/plausibility checks and for filling up estimated ADT (average daily traffic) for roads that still miss traffic data.
This estimate for residential roads identifies the road-related number of inhabitants. Working upwards from dead-end roads or "half way" split positions up to roads with known traffic, traffic increase is calculated along the shortest connection. Initial values for average daily car movements per inhabitant are adjusted to some further condition.
Fig. 6 shows the result for additionally estimated traffic (slim lines) and the initially provided traffic (fat lines). Colours given per emission in 5 dB steps.

Figure 6. Road net mix of basic and estimated traffic (map: © wmts1.geoportail.lu/opendata)

3.5 Rail

For 2022 END mapping, CFL (Société Nationale des Chemins de Fer Luxembourgeois) provided rail traffic information for an update of the existing rail net model in the form of several XLS files. In order to make data available for macro processing, files were merged into a single CSV file. Content covers:

- Sector index for stretch of relevant railway track
- Client ID, i.e. company running the train service
- Time of service to associate with periods (DEN)
- Locomotive type/Traction
- Number of axles
- Number of trains per year
- Average total weight per train
- Average total length per train

In addition to this, a 2nd file gives a translation table that helps to link CFL train descriptors to CNOSSOS train configurations and assignment to passenger or freight trains. Per track section information is directly integrated into the customized macro:

- Track construction
- Admitted speed

In LimA rail tracks (<CRA>) are objects with all track building information as well as admitted speed and IDs of "train-service"-configurations that are running on the track. Separate "train-services" (<CTN>) are defined as the

combination of vehicle types, technical speed limit and flow per period. Information in the CSV file is used to:

- Create <CTN> train-service objects for each unique train configuration (traction, vehicle types & numbers, daily frequency of service, max. speed)
- Update <CRA> object with respect to train-services running on a specific section of the rail track.
- Calculate track emission per height and per period

3.6 Some hints on other typical project experiences

Further typical tasks within this and other projects include:

- Adjust bridge and noise barrier geometries as these. may be provided by different institutions without proper alignment of geometry (Fig. 7.)
- "Terrain Construction Lines" (<TCL> objects) help to automatically reshape rough or old terrain model next to roads given in 3D (Fig. 8.)
- Organize multipart residential buildings, using attribute <MPRT> to group building parts belonging to the same building and avoid building parts with relative low volume from blocking facades of parts with most inhabitants. When calculating the number of inhabitants per valid façade point this is accounted for (Fig. 10.). Macros also fix geometry conflicts and merge/simplify building parts (Fig. 9.).
- Recognize major roads (ADT 8200 vehicles/day) when roads are represented by separate tracks with individual traffic data
- Recognize anchor points in roundabouts/crossings
- Define average road climb rates along stretches of road

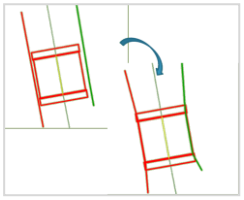

Figure 7. Refinement of bridge and barrier

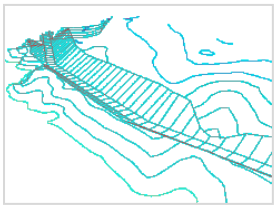

Figure 8. Reconstruction of terrain

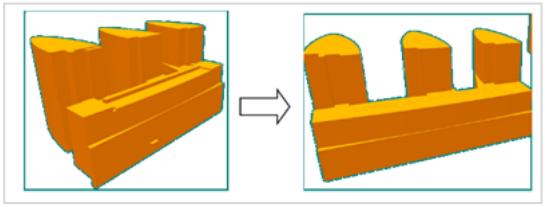

Figure 9. Merging and simplifying of multipart buildings (© GeoBasis-DE / BKG (2018)

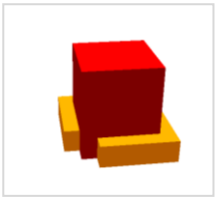

Figure 10. Blocking facades of multipart building

4. CALCULATION AND POST-PROCESSING

For the refined Luxembourg model of ~2600 km², CNOSSOS calculations were performed for road and rail. Road noise calculation took on average 0.65 h/km² of CPU time. As calculation was organized separately per ~100 communities, this includes some overlapping processing.

Figure 11. Luxemburg 2022 END mapping result - L_{den} (map: © wmts1.geoportail.lu/opendata)

5. CURRENT STATUS

In February 2025, SIG released a remote calculation service using LimA calculation cores. The user interface is a combination of freely available QGIS & a plugin interface, LimAQ, that links to LimA. LimAQ communicates with remote servers to undertake LimA noise calculations.
The model data refinement in cloud-processing as described in this paper follows a similar concept but makes use of other LimA modules.
In April 2025 a prototype of such an enhanced remote service has been tested. Support of cloud-processing on SIG's cluster for both services is therefore expected in Q3/Q4 2025.

CONCLUSIONS

- Initial model refinement is regarded as a potential bottle-neck in environmental noise calculations
- Remote noise calculation in external clusters or in the cloud (SaaS) make calculation time much less a concern
- To increase the capability of remote/cloud calculation, model refinement can be transferred into the cloud
- General or user-designed macros help to process the refinements and keep "expert" knowledge available
- The paper demonstrates the advantages in initial model refinement or result post-processing on the practical experience gathered during END work for the Grand Duchy of Luxemburg
- A concept for model data refinement in cloud-processing is introduced, as developed for the LimA software suite for environmental analysis

ABSTRACT

The United Kingdom Department for Environment, Food and Rural Affairs (Defra) commissioned the design and build of an environmental noise modelling system (NMS). The NMS has been developed to support Defra in preparing its environmental noise evidence base by preparing national road and railway noise models. This paper provides an overview of the fourteen research projects undertaken to support the implementation of CNOSSOS-EU in England, and the development of the NMS. This includes sensitivity testing of the road and railway source emission models, developing localised input data for road traffic flows, road surfaces & road junctions; railway and light rail vehicles; ground cover, meteorology and calculation settings for propagation modelling. It highlights the NMS system design, and the open data standards developed to support both internal data process workflows, and interaction with third party systems.

1. INTRODUCTION

The UK Department for Environment, Food and Rural Affairs (Defra) commissioned the design and build of an environmental noise modelling system (NMS). A functional requirement for the NMS is to support Defra in meeting its regulatory requirements to produce strategic noise models and maps for relevant road and railway sources in England, along with preparing analysis to fulfil the requirements of the Environmental Noise (England) Regulations 2006 (as amended) (the 'Regulations') [1], the Defra 25-year Environment Plan (25YEP) [2], and the Public Health Outcomes Framework (PHOF) [3]. These requirements are being delivered by producing a national environmental noise model with associated coverage, beyond the extents required by the Regulations. The noise models are being delivered in line with the requirements of the adapted assessment methods based on the Calculation of Road Traffic Noise (CRTN) [4] and Calculation of Railway Noise (CRN) [5], and CNOSSOS-EU [6].

While Defra had previously undertaken national coverage noise modelling in line with the Regulations during R1, R2 and R3 [7-10], the expansion of the coverage to include all roads and railways in England, and the first large scale implementation of the CNOSSOS-EU methodology in the UK, introduced a number of challenges and opportunities which Defra wished to investigate prior to the NMS system being implemented.

The aim of the research was to support the automated and reproducible modelling and calculations to be undertaken within by the NMS. The main objective developed out of

this aim was to support development of a national coverage noise calculation model, and in turn address queries including:

- What input data is required?
- Where does the model require high quality data?
- Who can supply the input data?
- How can the modelled reflect the UK situation?
- When could the calculations be completed?
- How could such a model be implemented?

2. RESEARCH PROJECTS

To address these queries and support the development of the NMS, and the implementation of CNOSSOS-EU in England, Defra commissioned 14 research studies projects investigating the following topics:

- CNOSSOS-EU Road Source:
  - Unknown traffic flows
  - Junction and roundabout flows
  - Junction and roundabout corrections
  - Road Surfaces
- CNOSSOS-EU Railway Source:
  - Heavy Rail Emissions
  - Light Rail Emissions
- CNOSSOS-EU Propagation:
  - Ground cover modelling
  - Meteo corrections
  - Calculation benchmark testing
- Noise Modelling System:
  - Input Data
  - Data Standards
  - System Design

The final reports for each of these projects are due to be published, and this paper provides a brief overview of the projects and highlights key findings.

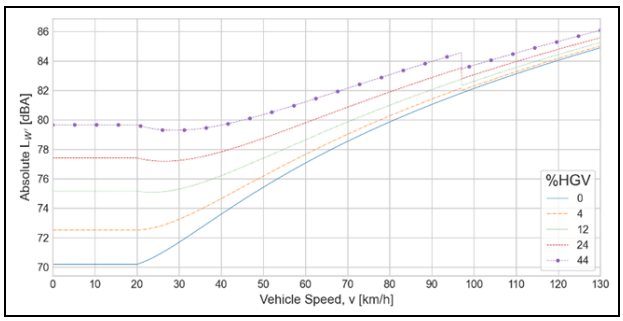

Figure 1. Vehicle speed sensitivity sweeps with composite flows: %HGV, showing discontinuity at 97 km/h.

3. ROAD SOURCE

The investigation of the CNOSSOS-EU road traffic source model aimed to gain an understanding of the effect of input data quality on the uncertainty of the resultant sound power emission levels.

Using an approach first used by the project team when investigating CRTN and NMPB'96 Interim Methods [11,12], a Python implementation of the CNOSSOS-EU road traffic source model was developed to enable parametric sensitivity analysis to be performed for each of the model input parameters. The output results were analysed to quantify accuracy implications & uncertainty, and identify parameters with the greatest influence on road SWL emissions.

The results indicated the input data sensitivity could be characterised as follows:

- **Vehicle speed:** Max uncertainty of ±11 km/h is recommended for traffic volumes typically dominated by cars
- **Surface type:** Deriving surface correction coefficients should be considered for each use case. Uncertainty is lowest where speeds are <30 km/h
- **Surface gradient:** Significant at low speeds for light vehicles (downhill), and at high speeds for medium/heavy emissions
- **Traffic flow:** Changing flow by a factor of 1.6 changes emissions by ±2 dBA. Sensitivity is greatest on lower trafficked roads
- **Flow composition:** Assumptions regarding the %HGVs is more important on lower speed roads
- **Air temperature:** Road traffic noise emissions are relatively insensitive to air temperature

More detail may be found in the 2022 paper [13], and the final report published by Defra.

4. ROAD SOURCE – UNKNOWN TRAFFIC FLOWS

The NMS includes all roads in England; however, traffic count and model data does not include all roads. The project aimed to develop a toolkit to convert 12-hour traffic flow data to annual average day, evening and night data required for strategic noise modelling with CNOSSOS-EU, and to identify approaches to fill gaps in road traffic flow data.

Scale factors were developed for three vehicle categories, and for three road classes, for situations where some road traffic count data was available, Figures 2. Where it was unavailable, and could not be derived based on adjacent

links in the network, a range of default traffic flows by road class were proposed, Figure 3.

	All Vehicle Types	Cars	LGVs	HGVs
Day (0700-1900)	0.806	0.808	0.820	0.740
Evening (1900-2300)	0.116	0.122	0.097	0.082
Night (2300-0700)	0.078	0.070	0.083	0.178

	A Road	B Road	Unclassified Road
Day (0700-1900)	0.834	0.835	0.903
Evening (1900-2300)	0.103	0.086	0.080
Night (2300-0700)	0.064	0.079	0.017

Figure 2. 12-hour Traffic Flow Expansion Factors derived from a sample of traffic counts, and proportion of 24-hour Traffic in other time periods based on a sample of traffic counts.

Category	24hr AADT flow	Source
B Road	3,000	DfT count database
C Road	1,000	DfT count database
Unclassified Road	400	DfT count database
Service Road	400	As Unclassified Road (DfT count database)
Dead end road	200	Breakpoint in DfT traffic estimates and approx. 3dB lower than 400 vehicles option for Service Road roads

Figure 3. Recommended Default values for different road types (24-hour AADT).

5. ROAD SOURCE – JUNCTION & ROUNDABOUT TRAFFIC FLOWS

The NMS includes all roads in England; however, traffic count and model data does not include slip roads and roundabout segments. The project aimed to develop a junction and roundabout traffic flow rulebook suitable for automation within the NMS input data transformation process. Based on a literature review, and analysis of National Highways Webtris data [14], 14 rulebook examples were developed, Figure 4.

6. ROAD SOURCE – JUNCTION & ROUNDABOUT CORRECTIONS

The CNOSSOS-EU road traffic source methodology includes corrections to account for accelerating and

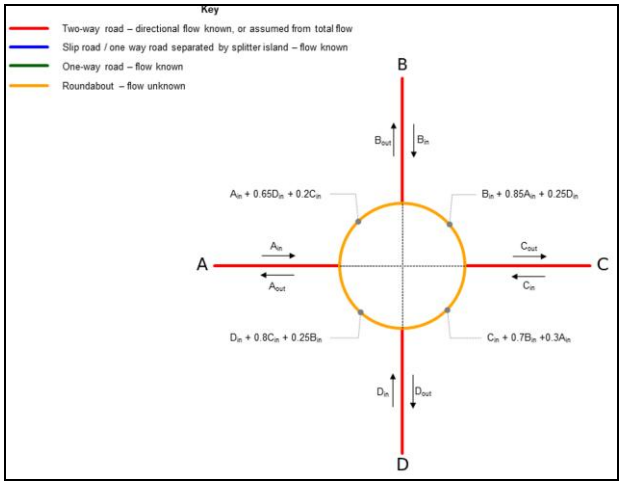

Figure 4. Example of a roundabout rulebook.

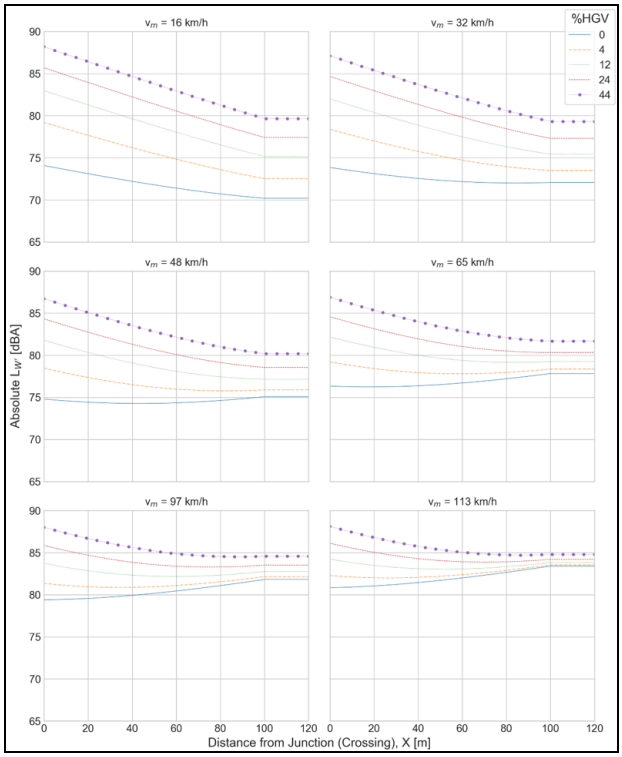

Figure 5. Distance to junction (crossing) with composite traffic flows and range of % HGV.

decelerating traffic within 100m of traffic light-controlled junctions and roundabouts. The project aimed

to quantity the change in calculated road traffic source emission near junctions and roundabouts, and identify how the model could be constructed to implement the corrections.
Parametric analysis was undertaken for each junction type, for each vehicle class, and for a range of composite traffic flows. It was identified that the corrections have larger effects near junctions, at low speeds, for high proportions of HGVs; up to about 7 dBA for composite traffic flows near junctions, and 5 dBA near roundabouts, Figure 5.
The report recommended to include the corrections, with road segments split into 25m lengths (or less) within 100m of the junctions.

7. ROAD SOURCE – ROAD SURFACES

The CNOSSOS-EU methodology includes a table of 17 road surface types in Appendix F Table F-1, these are based on pavement constructions typical within The Netherlands. The project aimed to develop road traffic source emission parameters, and road surface corrections, to represent the English road traffic fleet, and common UK road surfaces.
Based on literature review, existing CPX measurement data, and National Highways pavement management data (HAPMS) [15], source emissions parameters and road surface corrections were developed for UK values for CNOSSOS-EU database.

8. RAILWAY SOURCE

The investigation of the CNOSSOS-EU railway traffic source model aimed to gain an understanding of the effect of input data quality on the uncertainty of the resultant sound power emission levels.
Using an approach previously used by the project team when investigating CRN and RMR 1996 Interim Method [16,17], a Python implementation of the CNOSSOS-EU railway traffic source model was developed to enable parametric sensitivity analysis to be performed for each of the model input parameters. The output results were analysed to quantify accuracy implications & uncertainty, and identify parameters with the greatest influence on road SWL emissions.
More detail may be found in the 2022 paper [18], and the final report published by Defra.

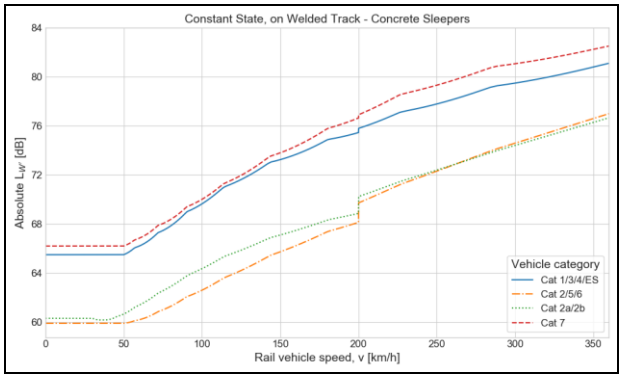

Figure 8. CNOSSOS-UK railway vehicle emission SWL with speed.

The results indicated the most important data collection considerations are to identify:

- Sections of track with impact sources such as joints, and joint density
- The mean speed per vehicle type
- Bridge types which incur a correction and where track is directly fastened to the bridge
- Braking systems
- Curved track, measures against squeal, and curved track known to not squeal, and calculate track curvature
- Rail flow per vehicle
- The number of axles per vehicle
- Wheel diameter for vehicles with cast iron tread brakes

9. RAILWAY SOURCE – HEAVY RAIL

The CNOSSOS-EU rail vehicle database, in Appendix G Table G-5, contains only five example vehicles. The project aimed to develop railway source terms to represent a range of English rail vehicles, on a range of English tracks, in order to improve the quality of the output from the railway source terms model.

Following a literature review, data from previous measurement campaigns and new trackside measurements, extended CNOSSOS-EU railway database tables were developed.

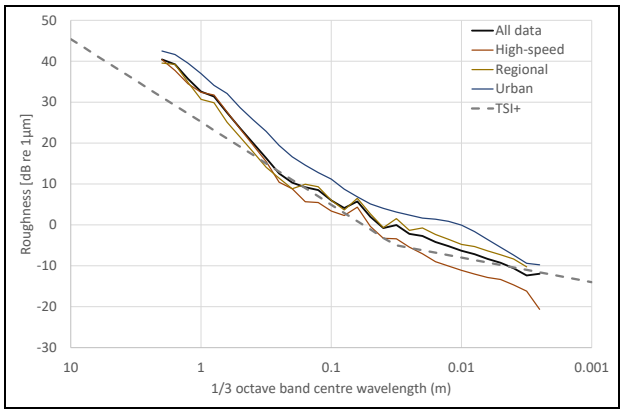

Figure 9. Average (mean) spectra for different track types. Compared to the average spectra across all track forms and the extrapolated TSI limit spectra.

The extended railway database covers:

- 47 CRN rail vehicles to aid model migration, and
- 16 additional CNOSSOS-EU rail vehicle types

The extended database tables also include:

- 4 additional wheel roughness spectra; cast iron tread, composite, disc, and metal sintered brakes
- 3 additional rail roughness spectra; high speed, regional, and urban lines, Figure 9

It was also identified that additional data on rail roughness, and rail fastener stiffness would help further improve the model.

10. RAILWAY SOURCE – LIGHT RAIL

The CNOSSOS-EU rail vehicle database does not contain any specific light rail or tram data. The project aimed to develop light rail source terms to represent a range of English light rail vehicles, on a range of light rail tracks, in order to improve the quality of the output from the railway source terms model.

Following extensive liaison with each of the light rail operators in England and Scotland, literature review and data from previous measurement campaigns, extended CNOSSOS-EU railway database tables were developed.

The extended database covers:

- 12 additional CNOSSOS-EU light rail vehicle types, one per light rail network

Extended database tables also include:

- 1 additional rail roughness spectra, for light rail network
- 1 additional track transfer function, for embedded track

It was also identified that additional data on rail roughness and rail fastener stiffness, and measurement of resilient wheels and traction noise of light rail vehicles, would help further improve the model.

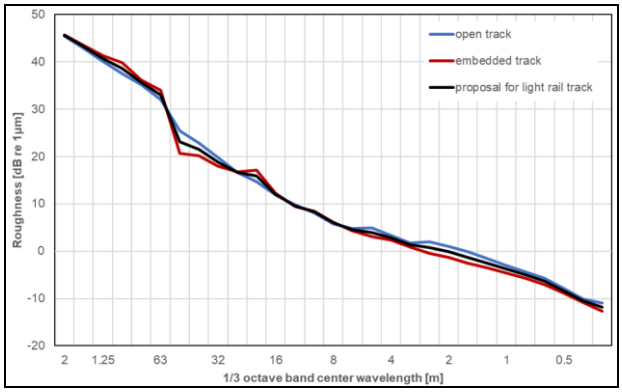

Figure 10. Proposed roughness spectrum for light rail track.

11.PROPAGATION – GROUND COVER MODELLING

The CNOSSOS-EU methodology includes Table 2.5a with G values and flow resistivity for eight different types of ground cover. The project aimed to investigate options available to describe the ground cover in England, and whether the resolution of the ground cover dataset affected the calculated time and the results generated.

Three options, offering broadly low (CLC) [19], medium (CEH LCM) [20], and high (OSMM Topo) [21] resolution description of ground cover areas were identified and tested.

The results of indicated that complexity could double the calculation time, but also appeared to improve the quality of the results. The recommendations were to use CEH LCM 2019 for national mapping, and that it may be preferable to use OSMM Topo data for smaller localised assessments.

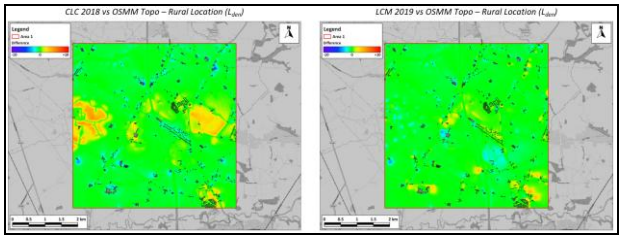

Figure 11. Calculated results difference grids for CLC (left) and LCM (right) compared to OSMM Topo.

12.PROPAGATION – METEO CORRECTIONS

The CNOSSOS-EU calculates propagation twice:

- Straight rays for homogeneous conditions; and
- Curved rays for conditions favourable to propagation from source to receiver

The long-term average sound level is derived using the percentage of favourable propagation (%FP), at the receiver point, based on the source location, for 20-degree increments, for day, evening and night periods, however it is not described how to prepare information of %FP based on long term weather data.

A literature review identified two methods used for NMPB2008 [22] and NORD2000 [23]. The NORD2000 method was fully documented, and all the required input data was available in the UK, namely: average wind speed; wind direction; cloud cover; and air temperature. The %FP was calculated across 131 meteo stations in England, and interpolated to 1 km raster for use within the NMS [24].

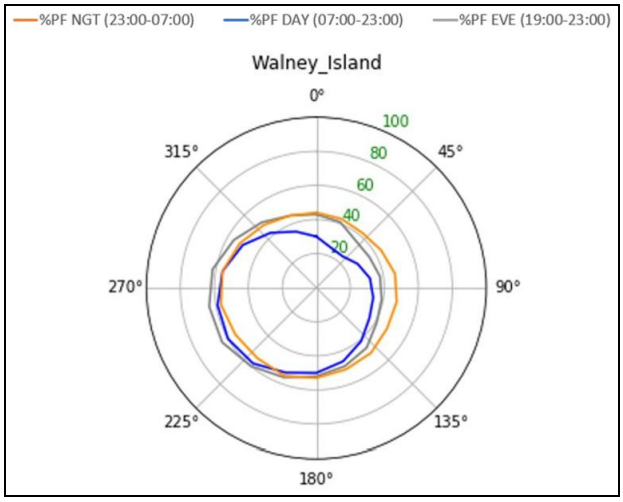

Figure 12. Example of %FP data prepared.

13.CALCULATION BENCHMARKING

The CNOSSOS-EU is a recent methodology, in 2021 when the project commenced there was very little experience in large area noise mapping using the new method.

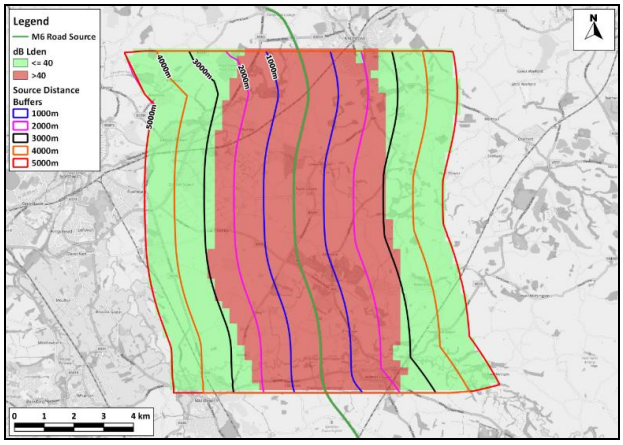

Figure 13. Propagation Distance Test – L_{den} Results.

This project aimed to support decision making on noise calculation parameters, and how this would affect calculation resources, and quality of noise mapping results:

- What source to receiver distance is required for calculated levels of 40 dB L_{den} and 35 dB L_{night} due to road and rail sources?
- What may be considered an optimum set of calculation settings, balancing calculation speed

with results uncertainty, having regard for the CNOSSOS-EU:2020 ±2.0 dB(A) quality criteria?

Using test models covering rural and urban areas, Figure 13, multiple calculation settings were tested one at a time, and in combination. Recommended calculation settings were proposed for delivery of national coverage noise mapping calculations.

14.NMS – INPUT DATA

Strategic noise mapping at national coverage requires a wide range of input datasets, many of which need to be spatially referenced, and come from a range of data suppliers and stakeholders. This project aimed to identify input data requirements, review options for required input data, and identify requirements for input data validation and pre-processing, including QA & QC processes.

Input parameters and results output requirements were identified for CNOSSOS-EU, CRTN, CRN, 25YEP, and PHOF, and reviewed against published literature. Almost 100 datasets were identified and screened, of which 39 underwent detailed review, and 37 were proposed as inputs for the NMS.

Recommended datasets were supplied by OS, EA, CEH, Met Office, NH, DfT, OpenStreetMap, OpenRailMap, RTT, Network Rail, ONS.

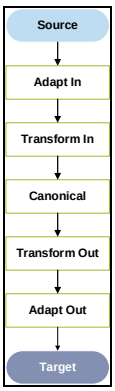

Figure 14. Seven-layer data architecture.

15.NMS – OPEN DATA STANDARDS

There are currently no open data standards for noise models which met all the requirements of the NMS. Open data standards help manage the flow of data through the NMS, and support interoperability with third party GIS and noise mapping software.

Existing spatial data, input data and output data standards, policy & regulatory requirements, government policy on open standards, Defra data principles, and published noise mapping data schemas, were reviewed including:

- INSPIRE, GEMINI, ISO 19100 series, ISO 196500 series, ISO 17534, ISO 15836, COVADIS and EEA Reportnet 3 noise reporting templates
- CadnaA, dBmap.net, eNoise City GML, DIN 45687, IMMI, LimA, MithraSIG, noise3D.net, NoiseMap, NoiseModelling, ODEN, Predictor/iNoise, SoundPlan

Conceptual and logical data models were developed for data flowing in and out of the NMS. The content and format of open data standards were proposed for a range of data layers supporting CNOSSOS-EU, CRTN and CRN, alongside proposals for metadata.

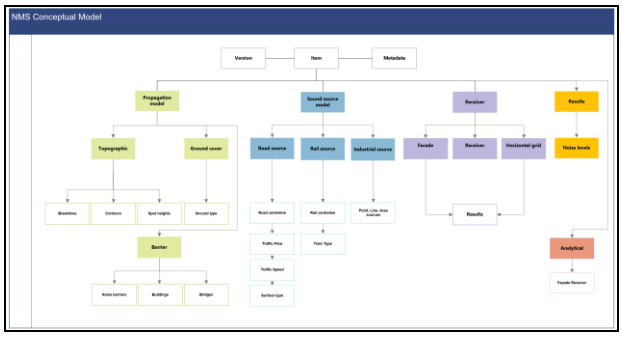

Figure 15. NMS conceptual model.

16.NMS – SYSTEM DESIGN

Off-the-shelf software components within the NMS conceptual design had not previously been combined. This project aimed to develop a mapping prototype of the NMS combining all key components within MS Azure cloud hosting:

- Web application firewall- security
- MS Azure Database for PostgreSQL – Hyperscale (Citus)
- Safe Software FME server – data integration and processing
- Oden – web-based environmental modelling tool
- Azure CycleCloud – HPC orchestrator
- LimA – propagation calculations

The prototype NMS was developed and included a test model area around Manchester [25], and subsequently scaled to full national coverage.

17.CONCLUSIONS

Fourteen research projects were undertaken to support the implementation of CNOSSOS-EU in England, and the development of the NMS. The findings and outputs for the projects were all used during delivery of the strategic noise mapping of roads and railways in England.

18.ACKNOWLEDGMENTS

We gratefully acknowledge Defra for commissioning the research studies in support of the NMS.

ABSTRACT

This paper seeks to offer a thoughtful comparative analysis of different population distribution methods commonly used in the preparation of strategic noise maps, to assess their confidence levels. The examination encompasses three different approaches, including the one suggested by the Spanish Ministry of Transport, Mobility, and Urban Agenda. In the interest of studying which methods appear to be closest to reality, the paper proposes leveraging the "real" data provided by the city councils to serve as a reference ("benchmark") in the analysis. The statistical techniques employed in this study aim to identify statistical differences between the estimates derived from the various methods. Additionally, the study seeks to identify which methods provide estimates that are closest to the "benchmark." The findings from this study will hopefully allow for the formulation of recommendations that could contribute to more efficient territorial planning and better management of environmental noise in urban studies.

1. INTRODUCTION

From the perspective of the effective development of strategic noise maps, the geographic services providing spatial data in Spain have made a qualitative leap since the first round of strategic noise maps to the present. However, there are still data that must be estimated from proxy data and whose level of approximation to reality is questionable. Accurate population allocation on strategic noise maps is crucial for urban planning, as it enables an accurate assessment of environmental impacts and the development of effective mitigation strategies.

Regardless of the method used to assign noise exposure levels to the population residing in multi-occupied residential buildings, where the location of each dwelling within the building is unknown (tool 21.2 of GPG [1]), the population data for that building must be estimated accurately. In most cases, the municipality has the population by census tract, district, neighborhood, etc. (resolved by the tool 19.1: Number of residents of the mapping area or sub-area of GPG). The systematic use of GIS to obtain the residential area of each building within the district, and thus distribute the population by building seems quite reasonable. There are currently several estimation methods available, and the motivation for this study is to analyze the extent to which they deviate from reality. Therefore, this work aims to analyze the application of different population distribution methods in strategic noise mapping as this has an impact on the accuracy of estimates of the noise-exposed population.

2. METHODOLOGY

To this end, three different methods were implemented, since the fourth method corresponds to the actual figures provided by the Puerto Real City Council.

1. Method IMAGINE. The proposal was extracted from the IMAGINE project [2]. This method distributes the population based on the accommodation capacity of buildings. It starts with the number of dwellings per building and multiplies it by an average occupancy rate. The total population is then distributed proportionally across the study area according to accommodation capacity.
2. Method MTMUA. The proposal was extracted from the Ministry of Transport, Mobility, and Urban Agenda for the fourth round of strategic noise maps [3]. In this approach, the total number of dwellings per census tract is calculated, and then the population is assigned proportionally to each building according to its number of dwellings.
3. Method CADASTRE. Population Allocation Methods in Cadastral Parcels [4]. Residential Built-Up Area Method. This method assigns the population proportionally to the built-up area designated for residential use.
4. Benchmark. The Real-Data Method uses detailed census and administrative information to accurately assign the population to buildings and dwellings within a study area (the benchmark).

2.1 Case study and data collection before GIS estimation

Puerto Real (Figure 1) is a municipality in the province of Cádiz with approximately 42,000 inhabitants and an area of 197 km². Located on the Bay of Cádiz, it has important transportation infrastructure, such as the A-4 motorway and the AP-4 highway, which have a significant impact on environmental noise levels.

Figure 1. Aerial view of the municipality of Puerto Real showing the location of the two census tracts.

Census data from the Puerto Real municipality, cadastral records with information on buildings, and geospatial databases detailing urban characteristics and land use were collected. The collected information was integrated into a Geographic Information System (GIS) for subsequent analysis and application. Two census sections were chosen for the case study due to their different urban typologies.

- Census tracts 4-5 (Figure 2) present a high urban density, with mostly residential buildings of up to four stories, combined with small shops and public spaces.

Figure 2. Image of the typical type of configuration of residential building blocks (multi-story buildings) within census tracts 4-5.

- Census tract 3-10A, on the other hand, is characterized by a lower building density (Figure 3), with a predominance of single-family homes and some residential blocks of up to four stories. Its proximity to key road infrastructure exposes it to high noise levels, making it an area of interest for strategic noise mapping.

Figure 3. Image of the typical type of configuration of residential building blocks (semi-detached houses) within census tracts 3-10A.

For this study, 70 residential buildings containing 2,465 inhabitants were selected.

2.2 Statistical tests

To respond to the question that underlies this study, a proposal is hereby made for a comparison of the population data that has been generated by the four methods, on a building-by-building basis. This approach constitutes a relational (paired) analysis, as it involves the use of four quantitative estimates for the same units (buildings) which defines a data vector. Since we have the real data, the analysis consists of analyzing whether there are significant differences with respect to benchmarking using the three alternative estimation methods (named in this study IMAGINE, MTMUA, and CADASTRE). To this end, we will compute the Euclidean and Manhattan distances (also known as City Block) between the predictors with respect to the benchmark. Also, we estimate the Absolute Errors (AE) vector for each method with respect to the benchmark and the Mean Absolute Error (MAE). We will also measure the RMSE (Root Mean Square Errors) and corroborate the results using cluster analysis. Lower MAE & RMSE means a more accurate method, taking into account that RMSE penalizes large errors more than MAE. Take into account that Euclidean distance refers to a measurement metric between the two vectors in Euclidean space and, RMSE is the error function of the square root of the average square distance between the Benchmarking and predicted points of the two vectors. As MAE is the Manhattan distance divided by the sample size, only MAE is shown.

A nonparametric Friedman test is proposed for the absolute errors, wherein the medians are subjected to analysis. The null hypothesis is formulated as follows:

"Ho = there are no significant differences in the calculation and allocation of the population from building to building by the different methods with respect to the benchmark".

After the global omnibus test, in the event that the null hypothesis is rejected, a Bonferroni post-hoc test will be utilized to evaluate the specific differences on a case-by-case basis (for between-subject factors, i.e., method by method).

3. RESULTS AND DISCUSSION

First, the distance between two vectors is calculated to assess their data-to-data similarity (Table 1). Then the RMSE and MAE (Table 2) is used to measure the difference between the predicted and observed data (of the same two vectors).

Table 1. Euclidean distances of the results of the methods with respect to the benchmark.

Distance	IMAGINE	MTMUA	CADASTRE
Euclidean	69.6	93.8	147.7

Table 2. MAE and RMSE.

Error	IMAGINE	MTMUA	CADASTRE
MAE	5.7	7.4	12.9
RMSE	8.3	11.2	17.7

Table 1 and Table 2, indicate that the IMAGINE method is closer to the actual estimate of inhabitants per building.

The diagram for the Absolute Errors (AE) of the three methods in comparison to the benchmark (Figure 4) shows some outliers. IMAGINE method exhibits 3, MTMUA 5, while CADASTRE scores 7. MTMUA shows a Skewed Box Plot.

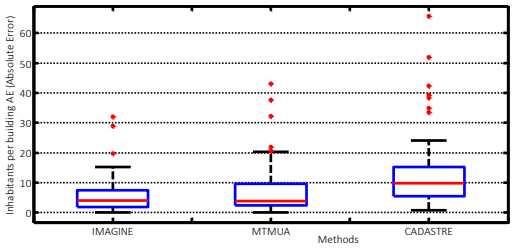

Figure 4. Boxplot of the distributions of population estimates building by building.

Meanwhile, the CADASTRE method points to the buildings with ID 1158548 and ID 600320. These last outliers are explained because the CADASTRE method makes estimates based on the built surface area per plot. If the area being analyzed is not occupied by buildings of a homogeneous type, this leads to large errors in population estimation sooner or later.

Figure 5. Picture of several single-family buildings that constitute a single cadastral reference with the largest area cataloged in the study.

There was an overall statistically significant difference between the mean ranks of the AE of the three methods with respect to the benchmark $\chi 2(2) = 28.9$ $p < 0.001$. As the Friedman test is an omnibus test, a post hoc analysis with Wilcoxon signed-rank tests was conducted with a Bonferroni correction applied, resulting in a significance level set at $p < 0.017$ (as we have 3 tests to perform). There were no significant differences between IMAGINE and MTMUA ($Z = -2.03$, $p = 0.042$). However, there were statistically significant differences with the method CADASTRE in the other two cases with $Z = -4.6$ and -3.7 respectively, and $p < 0.001$ in both cases).

When applying a hierarchical Cluster Method in SPSS using the between-groups of average linkage, with Euclidean distance, the dendrogram corroborates this fact, since both IMAGINE and MTMUA methods perform close results that form part of the same cluster (Figure 6).

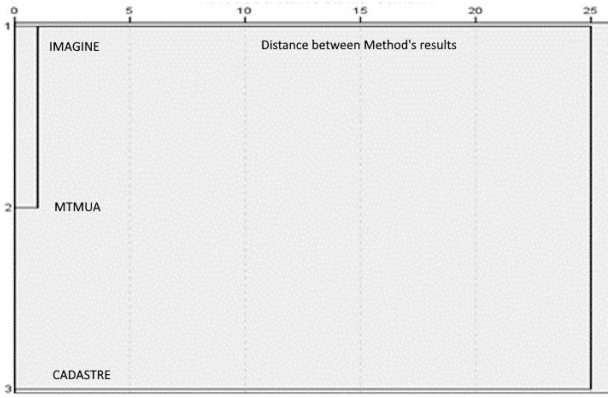

Figure 6. The dendrogram shows that Method 3 (CADASTRE) provides results very far from methods 1 and 2.

4. CONCLUSIONS

The results of this exploratory study indicate that the IMAGINE method is the most promising of the methods analyzed. Furthermore, the introduction of the complexity offered by the procedure proposed by Method 2 (Method MTMUA) appears to be unnecessary. Consequently, the number of dwellings per building does not guarantee a more accurate distribution of the population. A notable limitation of this study is its development in a case study context, indicating a need for further study that allows the generalization of the results. This study aims to advance toward a method that goes beyond those analyzed and that proposes the most interesting explanatory variables that complete the vision of estimating the number of people living in a building.

ABSTRACT

As part of the global noise assessment initiative in Spain, through a National Noise Strategy, which aims to address the lack of a comprehensive understanding of noise pollution, we present progress in the development of an open-source Python tool for modeling and analyzing aircraft noise. Currently, strategic studies are limited to airports with more than 50,000 annual operations, which excludes a significant number of relevant aeronautical infrastructures. This limitation is insufficient to fully understand the global impact of aviation noise, especially in rural or less densely populated areas. Our tool implements the equations of ECAC Document 29, which will allow the calculation of key metrics, SEL and LAmax, on a large scale and on a periodic basis. Furthermore, it will facilitate the use of data from big data platforms such as OpenSky Network. Its modular and scalable design can allow for integration with other open-source software, expanding its functionality and adaptability to different scenarios, or for use on its own. With this initiative, we aim to address the current gaps in the strategic analysis of aircraft noise, promoting the development of more inclusive and accessible mitigation policies for the entire Spanish territory.

Keywords: *aircraft noise, open-source modeling, ECAC Doc 29, noise assessment, strategic noise mapping*

1. INTRODUCTION

The challenges posed by aircraft noise have become a major public concern, recognized for their impact on both population health and environmental quality [1]. Long-term exposure to aircraft noise has been linked to various adverse effects, such as increased stress levels, and sleep disturbances [2, 3]. These impacts extend beyond simple annoyance, as demonstrated by systematic reviews emphasizing the correlation between noise exposure and psychological disorders such as anxiety or depression [2, 4].

Despite growing evidence of the negative implications of aircraft noise, current strategic assessments conducted in Spain, in accordance with the Environmental Noise Directive, appear to be insufficient. They focus primarily on large airports handling more than 50,000 operations per year, leaving a considerable number of smaller aviation infrastructures unaccounted for in the assessments [5]. Consequently, this omission limits comprehensive noise assessment efforts, resulting in a fragmented understanding of the broader implications of aircraft noise in different environments [3, 6]. A more comprehensive and inclusive assessment is needed to implement effective management and mitigation strategies, such as a National Noise Strategy, supported by reliable and accessible tools for environmental noise assessment.

The increasing availability of innovative technologies and open-source tools can significantly improve noise modeling initiatives [7]. An effective assessment tool not only provides accurate data on noise levels but also acts as a platform for public engagement, helping to bridge the gap between affected communities and regulators [2, 8].

2. OBJETIVES

The main objective of this study is to develop an open-source software tool for general-scale aircraft noise calculation, applicable at a national level, using flight trajectory data from various sources. To achieve this, two specific tools are being developed:

- **Flight Path Tool:** This tool extracts the required parameters from real flight data based on ECAC Doc 29 (ECAC29), Volume 2, Chapter 3: *Description of the Flight Path*.
- **Noise Calculation Tool:** This tool implements:
  - Chapter 4: *Noise Calculation for a Single Event*.
  - Chapter 5: *Calculation of Cumulative Levels*.
  - Chapter 6: *Calculation of Noise Contours*.

Once these modules are developed, the ultimate goal is to enable large-scale noise calculations by processing raw flight data, ensuring efficient and scalable analysis of aircraft noise impacts in a periodically updatable assessment.

3. MAIN REFERENCE WORKS

We highlight some of the works we consider most relevant related to the implementation of the ECAC29 [9] calculation model or other aeronautical noise calculation models in software, highlighting their contributions to understanding and mitigating aircraft noise. It is worth noting that the first [10] and second [11] works are related to a Matlab development of the ECAC calculation model. The first one code is available in the GitHub repository [1] .

The study by Casado, J., et al. (2023) [10] investigates missed approach maneuvers as a method to reduce noise and pollution associated with aircraft operations. By analyzing the implications of aircraft refueling strategies, the authors offer insights into practical approaches to minimizing the environmental impact of aviation activities, providing valuable data for regulatory measures and future modeling initiatives. The calculation tool is software developed by the authors.

The study by Zepeda Núñez, P.P.J. (2021) [11] focuses on the definition of a simplified aircraft noise model to study the impact of noise directivity patterns on a trajectory optimization tool called NOICE. This study underlines the importance of incorporating noise directivity into modeling to achieve more accurate assessments and effective noise mitigation strategies.

Meister, J., et al. (2021) [12] conducts a systematic comparison of different aircraft noise calculation software, providing critical assessments based on real-flight data. By highlighting discrepancies in noise predictions, it lays the groundwork for improving modeling accuracy and regulatory compliance.

Pretto, M. et al. (2020) [13] uses web data to predict noise emissions based on the ECAC Doc.29 model, demonstrating an innovative methodology that combines real-time data collection and predictive analytics to better inform noise management practices at airports.

Zellmann, A. et al. (2018) [14] presents an aircraft noise emission model that integrates detailed aircraft flight parameters into the noise calculation process. It serves to improve the predictive capability of noise emissions, representing a significant advancement in the modeling landscape.

Arntzen, K., et al. (2012) [15] explores the effects of varying weather conditions on noise contour predictions using the ECAC Doc. 29 model, highlighting important aspects of environmental influences on noise dispersion in urban environments.

These references, among many others, highlight the ongoing efforts to refine and expand noise modeling practices in the aviation sector, with particular attention to how various methodologies assess the environmental impact of aviation noise. They also emphasize the importance of applying crowdsourced data to modeling and its potential for studying aircraft noise.

4. METODOLOGY

The methodology applied in this work can be summarized in the selection of the programming language, the adaptation of the ECAC 29 prescriptions in the tools, and in the validation systems that are being applied.

4.1 Selected Programming Language

Although it is common for other projects to use MATLAB as the programming language for scientific tools [10], in this case, Python has been selected. Python is widely used in the scientific field due to its simplicity, readability, and extensive ecosystem of libraries that facilitate robust tool development [16]. Its clear syntax allows for easy code maintenance and debugging, which is crucial for scientific projects requiring verification and reproducibility [17]. Additionally, Python's large community provides

[1] https://github.com/GRCDEV/ANCM

access to numerous specialized libraries for data processing, mathematical computations, and geospatial analysis [18]. Its ability to seamlessly integrate various modules and file formats, such as CSV and JSON, makes it highly efficient for handling diverse datasets [19]. Moreover, its widespread adoption in research fosters collaboration and validation of methodologies [18].

Several key libraries, used in our code, enhance Python's capabilities in scientific applications. The **csv** library is used for tabular data processing, while the **os** library enables interaction with the operating system [20]. The **math** library provides essential mathematical functions, and **pandas** supports structured data analysis. For handling geospatial data, the **json** library is used for configuration files, and **shapely** enables geometric operations [21].

4.2 Flight Path Tool Implementation

Since the aim is to implement a segmentation tool that transforms massive flight data into segments compatible with the ECAC Doc. 29 model, no attempt has been made to emulate segmentation from the tables provided in ECAC29 Volume 3. Instead, work has been done on a tool that, by applying Chapter 3 of Volume 2 of ECAC Doc. 29, allows segmentation to be obtained from such massive data, for example, the OpenSky [2] Network [22].

Two modules have been depeloped at the moment. The first module prepares trajectory data from flight data sources, identifying distinct flight paths, ensuring chronological consistency, and computing distances between consecutive aircraft positions. Distance calculation between two geographical points (latitude and longitude) employs the Haversine Formula [23].

The second module segments the previously prepared trajectories strictly according to the guidance in ECAC Doc.29 (Section 3.6). It divides each flight trajectory into contiguous straight segments, performing linear interpolation of critical parameters such as height, velocity, and acoustic power, as explicitly indicated by the ECAC Equation 3.2a (Eqn. 1):

$$X(f) = X_{start} + f \cdot (X_{end} - X_{start}) \tag{1}$$

where $X(f)$ represents interpolated parameters (such as altitude, velocity, or power setting), and f is the fraction along the segment (0 at the beginning and 1 at the end).

Moreover, the segmentation procedure complies with ECAC guidelines for subdividing trajectory segments based on significant velocity changes. If the velocity difference between two consecutive points exceeds 10 m/s, the segment is subdivided according to the ECAC29 Equation 3.5 (Eqn. 2):

$$n_{seg} = \min\left(\left\lfloor 1 + \frac{\Delta V}{10} \right\rfloor, 5\right) \tag{2}$$

where ΔV is the absolute velocity difference between consecutive points (m/s), and n_{seg} is the resulting number of subsegments (up to a maximum of 5).

Additionally, vertical adjustments related to terrain elevation are applied in line with the ECAC methodology (section 3.3.4). The adjusted aircraft height relative to terrain or observer elevation is given by Equation 3:

$$z' = z - z_o \tag{3}$$

where z is the aircraft altitude, and z_o is the terrain (or observer) elevation.

Through this implementation, the Python code converts raw flight data into properly segmented flight paths in accordance with the ECAC Doc.29 Volume 2 (Section 3), ensuring accurate inputs for subsequent acoustic modeling procedures.

4.3 Noise Calculation Tool Implementation

The noise calculation tool implementation follows the methodology outlined in ECAC Doc 29 Volume 2 , Chapter 4, specifically focusing on the calculation of the segment-level noise metrics $L_{max,seg}$ and LE_{seg} (Sound Exposure Level).

The code structure is organized into distinct modules, each containing several scripts that, in summary, perform the following operations:

- **Input Data Module**: Responsible for loading aircraft performance and noise data from the ANP database, runway, and receptor information.
- **Geometric Calculations Module**: Calculates geometric parameters essential for determining distances, angles, and projection points.
- **Noise Calculation Module**: Computes the event noise levels per flight segment, implementing the equations described by ECAC.

The core of the noise calculation is based on the methodology described in ECAC Doc 29, particularly focusing on Equations (4-8a) and (4-8b):

[2] https://opensky-network.org/datasets/states/.

ECAC29 Equation (4-8a) defines the maximum level of noise for a single flight segment ($L_{max,seg}$) as:

$$L_{max,seg} = L_{max}(P,d) + \Delta I(\phi) - \Lambda(\beta,\ell) \quad (4)$$

Equation (4-8b) describes the sound exposure level for a segment ($L_{E,seg}$):

$$L_{E,seg} = L_E^{\infty}(P,d) + \Delta V + \Delta I(\phi) - \Lambda(\beta,\ell) + \Delta F \quad (5)$$

In the Python implementation, these equations are computed through several intermediate steps, structured as follows:

4.3.1 Baseline Noise Levels from NPD Data

First, the baseline event noise levels, $L_{max}(P,d)$ and $L_E^{\infty}(P,d)$, are interpolated from Noise-Power-Distance (NPD) tables, based on the corrected net thrust (power setting) and the slant distance (d) between the receptor and the flight segment midpoint.

4.3.2 Corrections

Duration Correction (ΔV): Implemented exclusively for sound exposure levels (SEL). This correction adjusts exposure based on the difference between actual segment duration and reference duration as provided by the NPD data:

$$\Delta V = 10 \log_{10}\left(\frac{V_{ref}}{V_{seg}}\right) \quad (6)$$

Engine Installation Correction:The engine installation correction ($\Delta I(\phi)$), which accounts for lateral directivity effects, is computed based on the depression angle (ϕ). This angle is calculated geometrically as the difference between elevation angle (β) and bank angle (ϵ).

Depending on the engine installation type defined for each aircraft (*'Fuselage'*, *'Wing'*, or *'Prop'*), specific empirical coefficients (as recommended by ECAC guidelines) are applied:

- For *'Fuselage'* installation:
  - $a = 0.1225$, $b = 0.329$, $c = 1$
- For *'Wing'* installation:
  - $a = 0.0039$, $b = 0.062$, $c = 0.8766$
- For *'Prop'* installation, no correction is applied:
  - $\Delta I(\phi) = 0$

Thus, the correction term $\Delta I(\phi)$ is calculated following the Equation 7 implemented in the Python code:

$$\Delta I(\phi) = 10 \cdot \log_{10}\left(\frac{\left(a \cdot \cos^2(\phi) + \sin^2(\phi)\right)^b}{c}\right) \quad (7)$$

Lateral Attenuation Calculation: The lateral attenuation, $\Lambda(\beta,\ell)$, is calculated following ECAC procedures, considering the elevation angle (β) and lateral distance (ℓ), applying empirical relationships provided in Section 4.5.4 and Equation 4-18 of ECAC and ECAC29 (Equation 8):

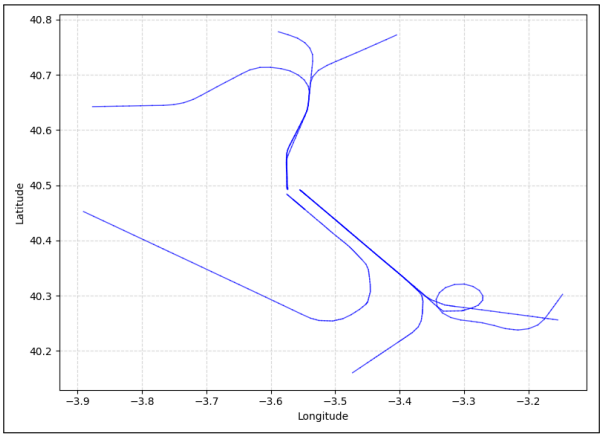
$$\Lambda(\beta,\ell) = \Gamma(\ell) \cdot \Lambda(\beta) \quad (8)$$

where $\Gamma(\ell)$ is a distance factor and $\Lambda(\beta)$ is long-range air-to-ground lateral attenuation calculated according to ECAC29 Equations 4-19 (a-d).

Finite Segment Correction (ΔF): The noise calculation for a single flight segment requires determining the fraction of sound energy contributed by each segment. In the implemented Python code, this fraction is computed for both SEL and L_{Amax} following ECAC Doc 29, using Appendix E equations, as well as the special cases defined by equations 4-20 and 4-21(a-b) for specific observer-segment positions.

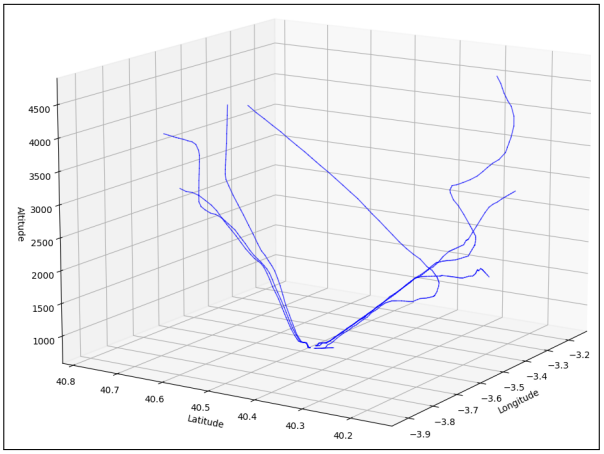
In our the Python module, these calculations are performed sequentially. The structure of the Python code directly mirrors the ECAC methodology:

1. Calculate geometric parameters (β, ϕ, distances, etc.).
2. Extract NPD values and apply interpolations for baseline noise levels $L_{max}(P,d)$ and $L_E^{\infty}(P,d)$.
3. Apply corrections sequentially (engine installation, lateral attenuation, duration, and finite segment correction).



Thus, the Python implementation aims to closely adhere to the ECAC guidelines, to ensure that the calculations for $L_{max,seg}$ and $L_{E,seg}$ accurately reflect the intended methodology.

5. RESULT AND DISCUSSION



Below are the results obtained up to the time of writing this paper, highlighting that we are still in the process of developing and fine-tuning the tools described.

5.1 Flight Path Tool Implementation Status

The current development of this tool is considered satisfactory. It allows for the extraction of plausible flight paths from massive data, their representation, export to GIS, and height adjustment, if terrain is required (Figure 1).

(a) 2D trajectories.

(b) 3D trajectories.

Figure 1: 2D (a) and 3D (b) trajectories of Madrid-Barajas Airport, on June 27, 2022. Data source: OSN

However, the accuracy of noise calculations using ECAC Doc 29 is still unknown and requires further study. Since the ECAC Doc 29 developer volume does not include such comparison cases, it must be verified using available reference cases, such as the strategic noise maps prepared by the Kingdom of Spain for major airports [3] .

5.2 Noise Calculation Tool Implementation Status

This section presents, on one hand, the analysis of the global results (calculated vs. reference) of SEL in the receiver grid (Grid SEL) and, on the other hand, the detailed evaluation of various parameters influencing Segment SEL (dB) (individual trajectories, acoustic corrections, elevation angles and directivity, etc.). The ECAC Doc29 criterion is employed, which recommends monitoring δ_{RMS} (root mean square of the differences) to assess the agreement between the model and the reference data.

5.2.1 Grid SEL Analysis

Looking at Table 1, we see that globally, an RMS Difference (δ_{RMS}) of approximately 1.19 dB (Figure 2) is presented for the entire set of cases, with a correlation of 0.9738 and a mean difference of 0.16 dB. This indicates that, although the overall dispersion may exceed 1 dB, the spatial trend of SEL is reproduced quite consistently.

Table 1: Comparison of Grid SEL Analysis.

Case ID	r	Mean dB Diff.	δ_{RMS}
Global results	0.9738	0.1591	1.1897
JETFAC	0.9945	-0.1153	0.5211
JETFAS	0.9934	-0.1406	0.5774
JETFDC	0.9576	0.3253	1.6169
JETFDS	0.9579	0.3191	1.6150
JETWAC	0.9940	-0.0387	0.5292
JETWAS	0.9939	-0.0408	0.5305
JETWDC	0.9581	0.3975	1.6350
JETWDS	0.9583	0.3766	1.6332
PROPAC	0.9982	-0.0013	0.2805
PROPAS	0.9982	-0.0040	0.2805
PROPDC	0.9688	0.3343	1.4129
PROPDS	0.9686	0.2947	1.4131

Examining each specific case, a differentiated behavior is observed between straight (S) and curved (C) trajectories. In straight paths (AS, DS) or approaches/takeoffs without turns, δ_{RMS} usually remains very low (0.28–0.58

[3] https://www.transportes.gob.es/aviacion-civil/medioambiente/mapas-estrategicos-ruido

dB in some cases), with mean differences < 0.15 dB. However, when the trajectory includes a curved segment (AC, DC), the RMS increases significantly (1.4–1.6 dB). This suggests that, although the model satisfactorily handles straight operations, turning maneuvers require further adjustments, particularly regarding thrust, bank angle, and lateral directivity.

Cases with propeller aircraft (PROP) show very low RMS in straight operations ($\leq$0.28 dB), indicating a high level of refinement for that aircraft type and flight profile. However, in curved operations, RMS increases to around 1.4 dB, consistent with jet trends. Nevertheless, the global correlations in all cases typically exceed 0.95, supporting the robustness of the model in terms of spatial noise pattern.

In summary, the values in the Grid SEL (dB) confirm that the general approach is valid, with the largest differences concentrated in trajectories with pronounced curves, where δ_{RMS} exceeds 1 dB and reaches 1.6 dB.

5.2.2 *Segment Parameters and Acoustic Factors*

To understand the potential sources of discrepancy in the calculated noise levels, we performed a detailed analysis of the parameters that determine the Segment SEL(dB), as shown in Table 2 (Geometric Analysis), Table 3 (Acoustic Corrections) and Table 4 (Segment SEL Analysis).

Table 2: Geometric Analysis: Calculated vs. Reference Data

Variable	r	Mean Diff.
λ (ft)	1.000	0.000
d_{p} (ft)	1.000	0.063
d_1 (ft)	1.000	0.343
d_2 (ft)	1.000	0.349
q (ft)	1.000	-0.171
Lat_{displ} (ft)	1.000	0.058
d_{NPD} (ft)	1.000	0.065
$Thrust_{\text{P}}$ (lb/e)	0.993	-42.960
β (°)	0.573	-15.576
γ (°)	1.000	0.000
ϕ (°)	0.619	-12.705
θ_{bank} (°)	1.000	0.000

On one hand, the geometric distances (e.g., slant_distance, d_1, d_2, segment length λ, etc.) exhibit extremely high correlations (close to 1.0) and minimal mean differences.

Table 3: Acoustic Corrections: Calculated vs. Reference Data

Variable	r	Mean Diff.
SEL_{base} (dB)	0.997	0.245
$\Delta I(\phi)$ (dB)	0.739	-0.203
$\Lambda(\beta, \ell)$ (dB)	0.912	0.897
ΔV (dB)	0.976	0.740
ΔF (dB)	0.985	-0.979
ΔSOR (dB)	-	0.255
ΔImp (dB)	-	-0.070

This indicates that the positions of both the segment and the receiver are being represented with very high accuracy. However, the angles (i.e., β and ϕ) show lower correlations (about 0.57–0.62) along with average differences of around 10°–15° and standard deviations of 26°–29°. Because corrections such as lateral attenuation $\Lambda(\beta, \ell)$ and noise fraction ΔF depend strongly on these angles, even modest angular discrepancies tend to become amplified in the resulting acoustic calculations.

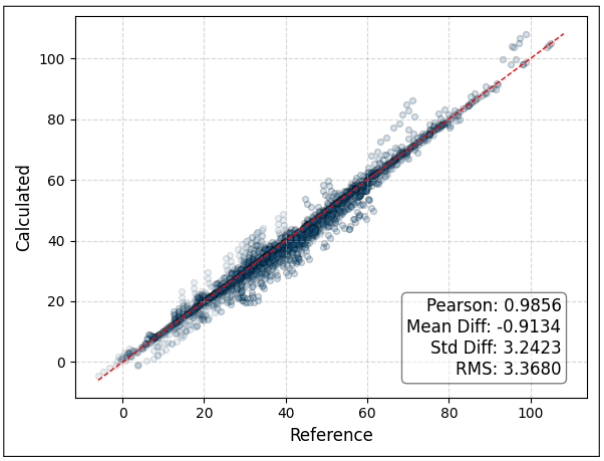


Table 4: Segment SEL Analysis: Calculated vs. Reference Data

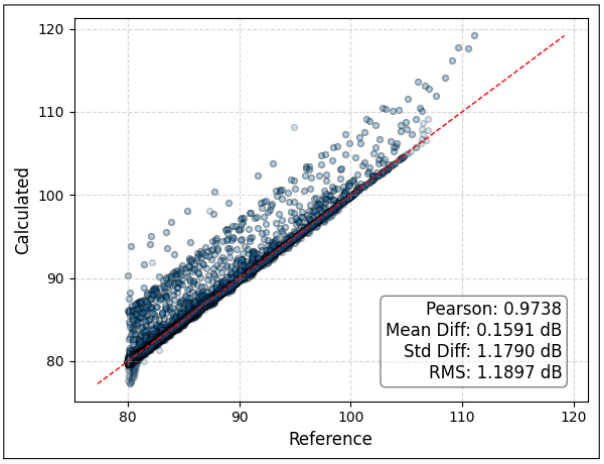
Variable	r	Mean Diff.
δ_{RMS} (dB)	0.986	3.368
Mean Diff. (dB)	-	-0.913
Std Dev. (dB)	-	3.242



Regarding the acoustic corrections, the baseline SEL (the tabulated NPD reference) achieves excellent correlation ($\sim$0.997) but still exhibits a mean difference of about 0.24 dB, meaning that the overall NPD data are sound, but some residual inaccuracy remains when the final corrections are applied.

In addition, lateral attenuation and noise fraction show notably higher dispersion (with mean differences of $\sim$0.90 dB and $\sim$0.98 dB, respectively), consistent with the aforementioned angular issues. The engine installation correction $\Delta I(\phi)$ also introduces some scatter (correlation 0.739, mean difference ~ -0.20 dB) if the angles ϕ and β are not accurately captured. Finally, while the Segment SEL(dB) itself displays a very high correlation

(0.986), its δ_{RMS} of 3.37 dB indicates that some segments still deviate by a few decibels from their reference values (Figure 2a).

(a) Correlation Segment SEL(dB).

(b) Correlation Grid SEL(dB).

Figure 2: Correlation of Segment SEL(a) and Grid SEL(b) between reference and calculated results.

6. CONCLUSIONS

This work represents significant progress in the development of an open-source tool for large-scale aircraft noise assessment, in accordance with the guidelines of ECAC Doc. 29. The integration of two of its modules—the Flight Path Tool for data segmentation and the Noise Calculation Tool for calculating event noise levels—will allow for robust noise estimates.

This development currently presents reasonably good fits, especially for straight trajectories. In these cases, the model achieves very low RMS differences (often less than 0.6 dB) and high correlation coefficients, indicating the robustness of the basic methodology.

However, some challenges remain. On curved trajectories, δ_{RMS} differences tend to increase (reaching approximately 1.4−1.6 dB in grid analyses and even higher in segment-level assessments), primarily due to uncertainties in the estimation of angular parameters (elevation and directivity angles, β and ϕ). These angles are required for subsequent acoustic corrections (such as lateral attenuation and noise fraction), and even slight discrepancies in their values can be amplified, resulting in larger deviations in the final SEL calculations. Further refinement of the calculation of these angles is necessary to reduce these deviations and improve overall accuracy.

Looking ahead, tuning and calibration work is planned to improve the accuracy of the geometric and acoustic corrections, particularly in determining cases based on the relative position of the trajectory segment and the receiver, and corrections affected by angular parameters. Furthermore, the integration of noise segmentation and calculation modules into a unified framework is necessary to enable the agile use of big data.

Once finalized, the full code is intended to be made publicly available. This open-source tool is expected to not only advance the scientific assessment of aircraft noise at a general level, but also serve as a key resource to support the upcoming National Noise Strategy, thus contributing to more comprehensive and effective environmental noise management.

7. ACKNOWLEDGMENTS

The authors thank Miguel Ausejo Prieto (Eurocontrol SA) and Antonio Donoso López (SENASA) for their contributions and recommendations in this work.

ABSTRACT

The urban acoustic environment is often affected by road traffic noise, which has a negative impact on health and mental well-being by causing annoyance and discomfort to residents and visitors. Nevertheless, urban areas also have sounds that are pleasant to people. In this study, a mixed methodology was designed and applied in neighbourhoods in southern Chile. Urban road traffic noise and annoyance were quantified using noise maps estimated with open-source software and validated with measurements. In addition, walking interviews were conducted to assess self-reported mental well-being of residents. In parallel, the soundscape perceived by visitors was evaluated through guided soundwalks and surveys. Preliminary results suggest that in places where the population was highly annoyed, there was a lack of mental well-being. However, where the soundscape was dominated by natural sounds, mental well-being improved despite high estimated percentage of road traffic noise annoyance. Future studies aim to generalise our results and to investigate the observed positive influence of specific groups of sound sources on mental well-being in urban areas with high levels of road traffic noise.

1. INTRODUCTION

Road traffic noise damages physical and mental health [1]. Annoyance is one of the psychological adverse effects most studied, which has led to the definition of dose-effect relationships, allowing the estimation of the percentage of highly annoyed population (HA%) at specific levels of road traffic noise (Lden) [2]. Recently, it has been hypothesised that annoyance could be a mediator between noise and well-being. Relationships have been investigated linking noise exposure levels outside dwellings, neighbourhood urban characteristics and questionnaires associated with diagnoses of mental disorders such as anxiety and depression, both of which decrease well-being [3]. Nevertheless, clear connections are not yet established, especially considering that in public spaces many other elements of the built environment influence directly and indirectly mental well-being [4], which interact with the urban acoustic environment [5], affecting the short-term perceptions of visitors and residents. The aim of this study is to examine if annoyance (HA%) estimated based on a long-term health effects-related noise indicator (Lden) can be useful to describe and identify locations in public spaces of urban neighbourhoods where the acoustic environment affects mental well-being of residents and visitors.

2. METHODOLOGY

2.1 Study area: neighbourhoods

The study was carried out in two neighbourhoods in Valdivia, a city from southern Chile. Neighbourhood population differs according to their total area, as well as the availability of public space and green areas.

Figure 1 shows the difference between the scales of the studied neighbourhoods.

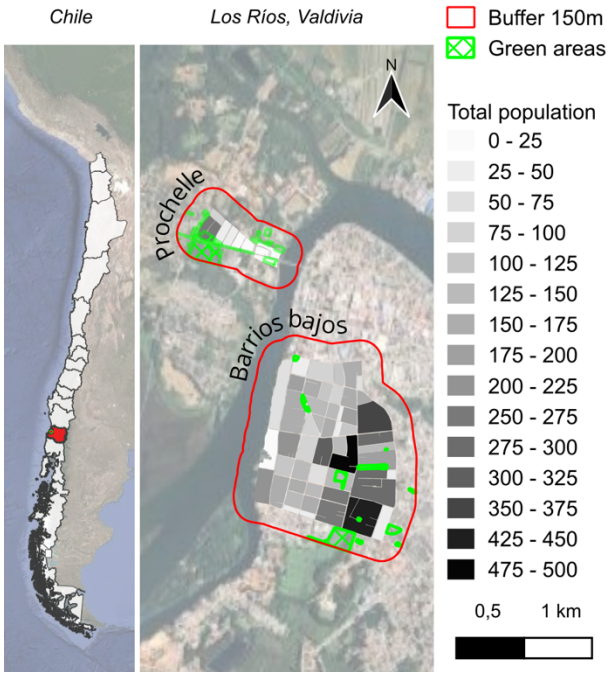

Figure 1. Barrios Bajos and Prochelle, Valdivia [6].

2.2 Noise measurements for noise mapping validation

Road traffic noise measurements were conducted on different streets in each neighbourhood to calibrate the noise maps. First, a street categorisation method was used to distinguish noise levels according to their functionality in an urban environment [7]. A simplified version was applied which requires data on transport infrastructure, road length, median width, sidewalk width, number of traffic lights at intersections and public transport bus routes [8]. Figure 2 identifies the three street groups and the measurement points. Category C1 groups the main streets of each neighbourhood, category C2 are the streets that connect C1 to residential streets C3.

All measurements lasted 15 min., under the supervision of an expert, and were carried out during the daytime, between 07.00–19.00 hrs on weekdays, avoiding periods of traffic congestion. A type 1 sound level meter was placed at 1.2 m from the roadside, following ISO 1996-2 standard for equipment location and favourable meteorological conditions, and checking the calibration of the instrument before and after each measurement campaign.

Additionally, speed and traffic flow were measured for the day, evening (19.00–23.00 hrs) and night (23.00–07.00 hrs), considering CNOSSOS categories [9], and segregating light and heavy public transport.

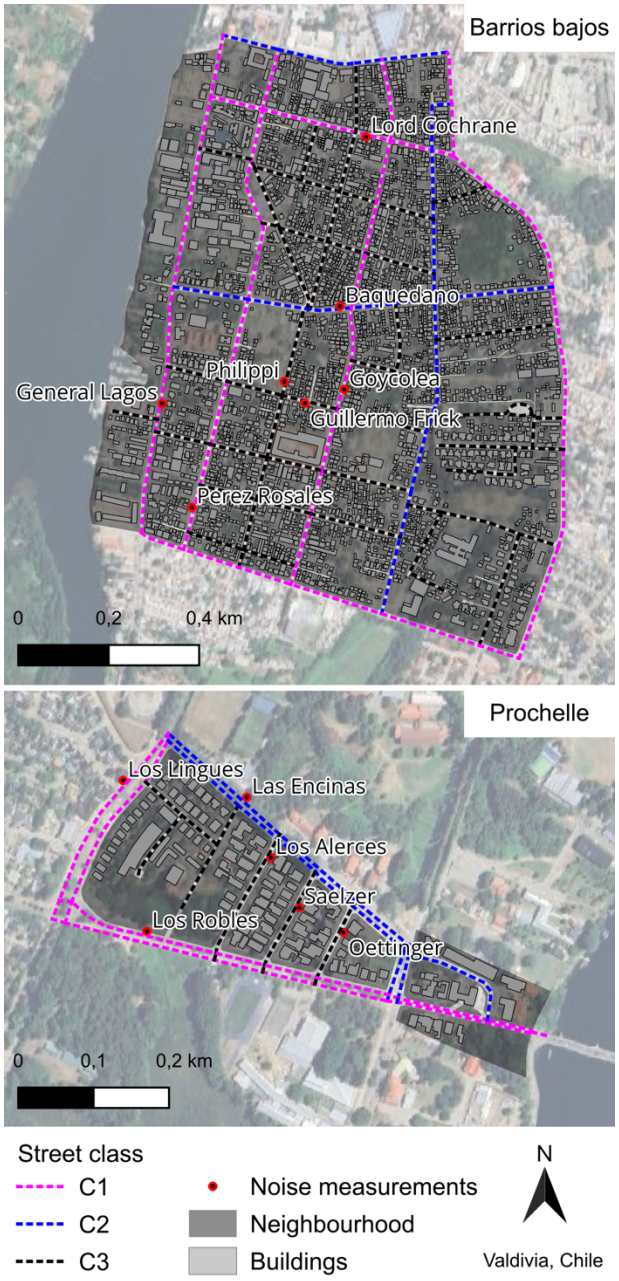

Figure 2. Street categorisation and noise measurement points in the studied neighbourhoods.

2.3 Road traffic noise annoyance maps

Noise maps and exposure were calculated using NoiseModelling [10]. Given the lack of reliable public databases in Chile, the buildings of each neighbourhood were mapped in-situ, their height was estimated through the number of floors of each site, assuming each floor height of 3 metres. The elevation of the terrain was generated from contour lines provided by the Municipality of Valdivia. The ground type and the acoustic absorption of the neighbourhood was obtained with the methodology described in other studies [11]. Weather conditions, traffic light intersections and street pavement type were determined in situ for each neighbourhood during the noise measurements.

Subsequently, the estimation of people highly annoyed by road traffic noise in public space was estimated using the equation described by *Guski et al. (2017)* [2], using isolines at a height of 1.5 metres from the ground. This represents the locations in the neighbourhood where a certain percentage of residents and visitors will potentially experience annoyance from road traffic noise.

2.4 Walking interviews to assess self-reported mental well-being of residents

For the assessment of mental well-being of neighbourhood residents, 76 volunteers from Barrios Bajos, and 56 from Prochelle participated. All of them recruited with the support of local associations.

A qualitative Walking Interview method was used with each resident, using the Natural Go–Along technique [12], to obtain recordings of residents' self-reported perceptions of their built environment. The interviews were conducted on weekdays between January 2023 and January 2024. The dialogue was 1:1 between the researcher and residents, capturing the usual hidden or unnoticed relationships with the places, highlighting environmental perception, spatial practices and social context, among other aspects. Each resident was asked to freely narrate their walking experience, and to stop at those places capable of evoking emotions or behaviours associated with greater affective impact.

General and then increasingly specific questions were asked to the residents, such as: *How do you feel while walking in this place?. What noises and sounds in this street provoke emotional reactions in you?*. The route of each interview was chosen voluntarily by the residents and recorded with the Strava app. Each conversation audio was recorded, coded and analysed by using Atlas.ti software. Photographs of aspects highlighted by the interviewers were also collected.

2.5 Guided soundwalks and surveys to assess soundscape perceived by visitors

The soundscape assessment involved 21 visitors in Barrios Bajos, and 16 in Prochelle. All volunteers had previously visited each neighbourhood, but no one was resident.

Their soundscape perception was assessed through Google form questionnaires using Method A of Part 2 of ISO/TS 12913 in Spanish [13, 14]. Complementarily, the taxonomy of sound sources was extended from traffic noise (e.g. cars, buses, trains, airplanes), other noise (e.g. sirens, construction, industry, loading of goods), sounds from human beings (e.g. conversation, laughter, children at play, footsteps), and natural sounds (e.g. birds call, flowing water, wind in vegetation), to a disaggregated version which includes sounds present in Latin American soundscapes (see Table 1). Also, at the start of each soundwalk, visitors were introduced to breathing and deep listening techniques, discussed in previous publications by the authors [15].

The soundwalks were organised in groups of no more than five volunteers, on different days of the week and at different times, between June 2023 and March 2024. Was required to not produce sounds that could interfere with the acoustic environment. Winter clothes like waterproof jackets and umbrellas sounds was not supposed to influence the responses of the participants. Eating and drinking were not allowed during the walks.

Every soundwalk route was designed by the researchers based on an ethnographic sound analysis of each neighbourhood, defining stop nodes that would represent each section of the route. The first questionnaire was applied at each node and was divided into three parts: identification of sound sources, soundscape quality and general evaluation. In this study, results are analysed with respect to the predominance of sound sources identified on each section between the stop nodes. Future publications by the authors will analyse all the findings.

Table 1. Sound taxonomy, adapted from [15].

Technophony
Transport
N1. Road traffic noise: car, bus, motorcycle, etc.
N2. Other transport noise: aircraft, vessels, etc.
N3. Non-motor traffic: bicycle, carriage, etc.
Urban noises
N4. Urban management: build-in, gardening, etc.
N5. Other noises: rumbles, gun shots, fans.
Music
AM. Amplified music: through loudspeakers.
NM. Non-amplified music: musical instruments.
Anthropophony
H. Human movement: footsteps, rubbing, etc.
S. Speech: conversations, whisper, voices, etc.
V. Vocal expressions: cry, laugh, cough, etc.
CT. Cultural or traditional: bell, siren, preach, etc.
Biophony
DA. Domestic animals: dog bark, cat meow.
FA. Farm animals: crow, bellow, neigh.
EA. Exotic animals: birds, amphibians, insects.
WA. Wild animals: hoot, roar, growl, howl, buzz.
Geophony
PN. Wind: Zum.
W. Water: rain, river, ocean waves, waterfall.

3. RESULTS

3.1 Noise mapping validation

Measurement points for noise, speed and traffic flow were included as receivers in each neighbourhood noise model to calculate differences between the measurements (see Table 2). Several iterations were performed by modifying the parameters of CNOSSOS model [9] to adapt them to the particularity of each neighbourhood in southern Chile.

Air temperature and relative humidity were set to 15°C and 70%. The most significant modification was the type of pavement in old streets. SMA surface with 8 mm stones (NL05) was assigned to consider the sound absorption due to the lack of maintenance of concrete pavements (NL06). An overall target accuracy of ±2 dB uncertainty in the emission level of the source is considered. For one point (see Table 2 (*)) the defined accuracy was not achieved, as the 15 min. measurement did not stabilise, because the flow was too low, and CNOSSOS overestimated in such situations. However, for most of the points the target was reached, therefore, every setting applied in the noise model was replicated in all other streets of the same road category for each neighbourhood.

Table 2. Differences between noise modelling and measurements at the neighbourhoods.

	Street		LAeq (dB)		
	Class	Name	Mea.	Mod.	Diff.
Barrios bajos	C1	P. Rosales	68,2	70,03	-1,8

		Oettinger	56,4	58,8	-1,6
*15 min measurements non-stabilized due to low traffic flow.					

3.2 Noise annoyance maps and source sources affecting mental well-being

Locations where people were annoyed by noise and places where sounds generated positive emotions are identified on maps. During the walking interviews, the acoustic environment was mentioned 65 times in Barrios Bajos, and 28 in Prochelle, playing an important role in the perception of well-being.

3.2.1 Barrios Bajos

Road traffic noise (N1) is predominant for visitors on the path between the start and nodes A and B. As well as between nodes E and F (see Figure 3). On the other hand, on the path between nodes B, C and D, visitors can distinguish an important presence of the sounds of domestic animals (DA) and exotic animals (EA). The proximity of the river at node E makes visitors perceive the sound of water. Along the whole route urban noises and music were present.

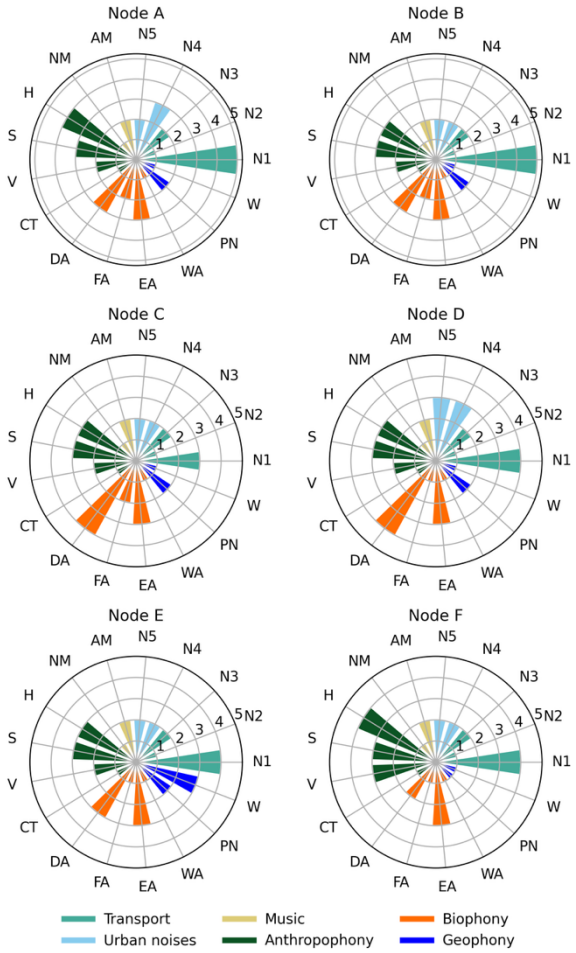

Figure 3. Sound source dominance at Barrios Bajos. 1) Not al all; 2) A little; 3) Moderately; 4) A lot; 5) Dominates completely.

Complementarily, Figure 4 shows the map of road traffic noise annoyance estimated for Barrios Bajos. Likewise, nodes A, B, C, D, E and F of the soundwalks were overlapped, together with the identification of public spaces where residents mentioned technophonic and anthropophonic noise sources that generated negative emotions, and biophonic and geophonic noise sources that generated positive feelings.

Two places were defined as quiet and positively valued. Quietness was a concept incorporated by the residents which was not defined in the taxonomy.

Among interviewed residents, high volume of traffic and vehicles parked on streets with multiple points of interest are associated with emotions of discomfort, insecurity, fear and stress. Likewise, heavy public transport operating at high speeds generates anger, rage, fear and insecurity. Moreover, streets with limited traffic led to emotions of insecurity and fear (women), especially when they walk late in the evening and at night.

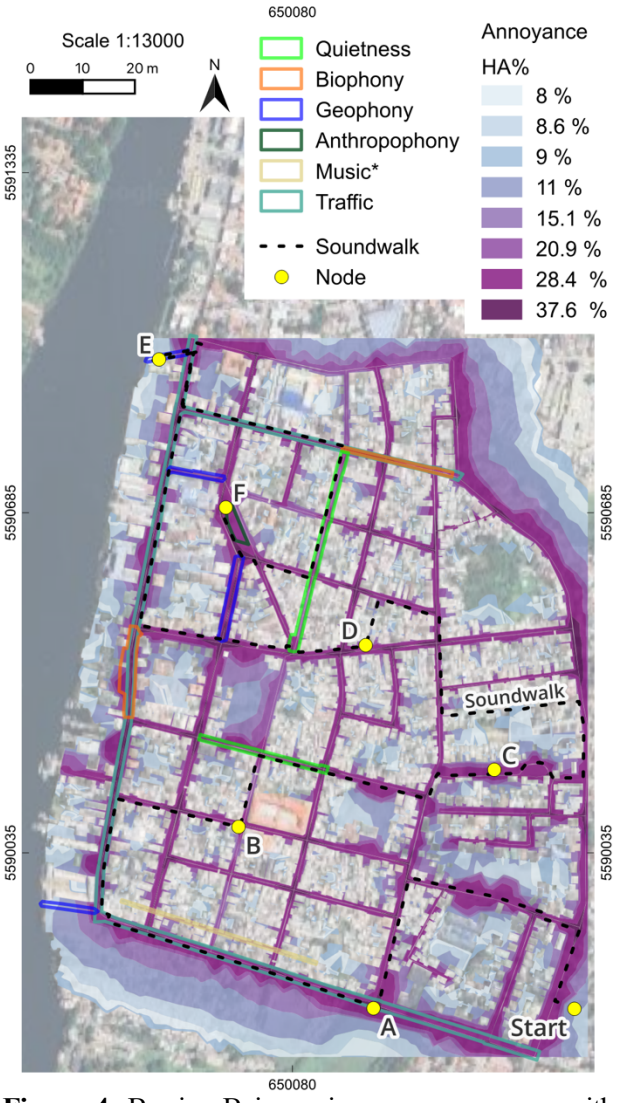

Figure 4. Barrios Bajos noise annoyance map with sound sources impacting mental well-being.

A negative externality of traffic is noise. Residents indicated that road traffic noise triggers annoyance and unpleasantness, especially the noise from heavy public transport in congested streets. Further sources of noise identified in the acoustic environment of the neighbourhood were the dogs' barking which created displeasure and

insecurity. As well as noise from neighbours and music in the street, which annoy residents and make them uncomfortable at night.

However, several sound sources generate positive emotions in residents. Children's voices in squares and playing in open spaces generate pleasure and joy. The sound of the wind produces tranquillity and calm in public spaces near or by the river. Similarly, when the wind interacts with trees, residents feel pleasure and joy. In addition, when birds are in the trees, the sound of their calls brings enjoyment and happiness, while in riverside locations it produces tranquillity, relaxation and joy. The absence of noise associated with urban life in wide and narrow streets are interpreted as quiet areas which give a sense of tranquillity among residents.

3.2.2 Prochelle

In this neighbourhood, road traffic noise (N1) and the sound of wind (PN) were predominant for visitors throughout the entire soundwalk. However, on the path between A and B, people perceived also exotic animals (EA) (see Figure 5).

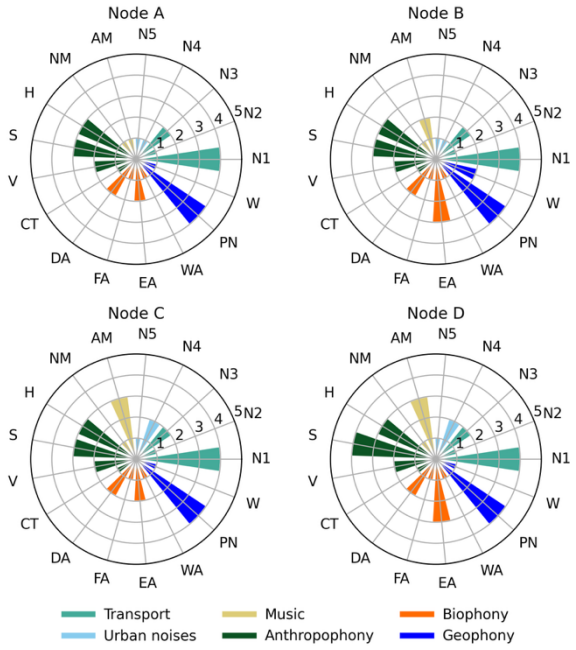

Figure 5. Sound source dominance at Prochelle.
1) Not al all; 2) A little; 3) Moderately; 4) A lot; 5) Dominates completely.

In addition, Figure 6 shows the road traffic noise annoyance map estimated for Prochelle, overlaying the soundwalk nodes, together with the identification of public spaces where residents recognised technophonic noise sources which generated negative emotions, and biophonic and geophonic sound sources which generated positive emotions.

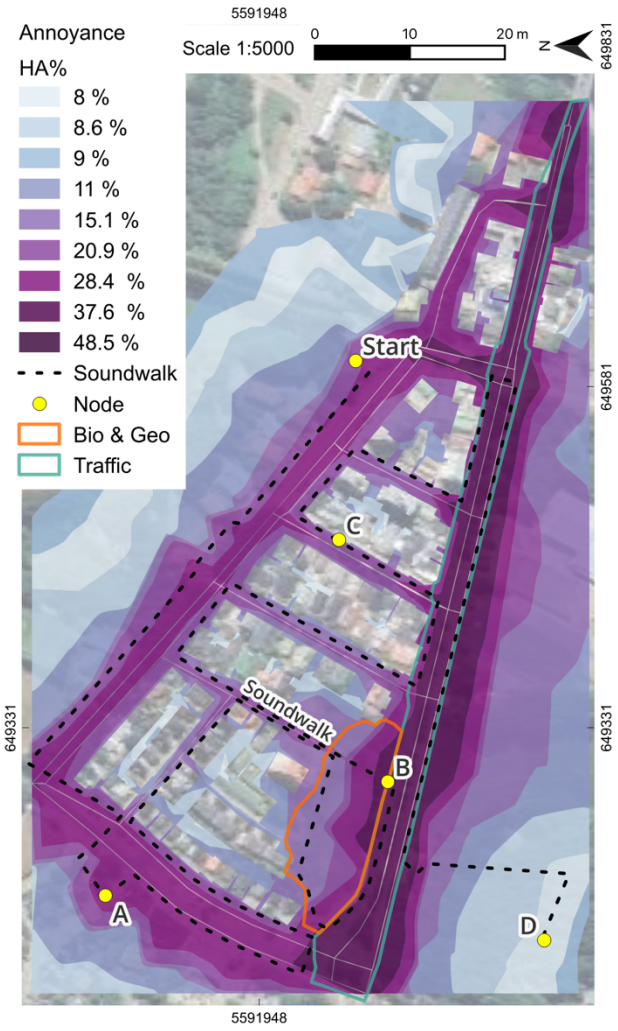

Figure 6. Prochelle noise annoyance map with sound sources impacting mental well-being.

Significant volumes of traffic flow at high speeds were associated with emotions of fear, stress, annoyance, discomfort, displeasure, and frustration among interviewees. Conversely, on narrow streets where vehicles drive at slow speeds, residents experienced peace, calm, security and tranquillity.

This result was directly related to places where sources of noise were explicitly identified (see Figure 6). Road traffic noise became associated with emotions of anger, anxiety, insecurity, unpleasantness and annoyance among respondents. In addition, at congested periods, the noise of horns generates mainly anxiety.

Meanwhile, the natural sounds of the acoustic environment were associated with emotions of pleasure, tranquillity, calm and enjoyment among residents. The sound of the wind interacting with the trees was associated with pleasure, enjoyment, calm, peace and satisfaction. Likewise, in some interviews it was mentioned that at a specific time of the year at Los Patos Lagoon (marked as Bio & Geo in Figure 6) the sound of frogs croaking was associated with feelings of calm, awe and satisfaction among residents. In the same area, several residents indicated that not hearing the typical noises associated with the city makes them feel quiet, calm, peaceful and safe.

4. DISCUSSION

Overall, when neither residents or visitors recognised a significant presence of sound sources different from traffic, annoyance maps were useful to locate places where road traffic noise negatively affects mental well-being. However, in Barrios Bajos, where HA% was between 20.9–28.4%, i.e. levels around 65–70 dBA, geophony (water flowering mostly produced by wind) enhanced well-being even though in the same area (path D–E) traffic noise was predominant. Likewise, in areas without heavy public transport routes but significant dominance of human movements sounds (path E–F), people perceived quietness. Furthermore, our findings suggest that even if there were high HA% levels (e.g. in the street parallel to the river) the sounds of exotic animals across the neighbourhood produce emotions associated with positive mental well-being. Similar patterns are observed in Prochelle, where despite HA% between 20.9–37.6% (levels around 65–75 dBA) with dominance of traffic noise (path A-B), in areas with wind sounds combined with trees and wild animals, people feel emotions that improve their mental well-being and make them perceive tranquillity regardless of the high noise levels. Consequently, noise annoyance maps can only describe a lack of mental well-being when there are no other biophonic and geophonic sound sources that potentially psychologically mask road traffic noise [5]. Such sounds are closely linked to other elements of the urban context which synergistically influence mental well-being [4].

5. CONCLUSIONS

- According to residents and visitors, road traffic noise was the most dominant source of noise in all the studied neighbourhoods, negatively affecting their mental well-being by generating emotions of annoyance and discomfort.
- In locations with elevated noise levels, annoyance due to road traffic noise, calculated through long-term indicators, identified areas that induce a lack of mental well-being.
- In places where geophonies and biophonies were present in combination with traffic, participants reported better mental well-being, as these sound sources induced positive emotional states such as quietness, calm, pleasantness, tranquillity, happiness, enjoyment and relaxation.
- It is not sufficient to generalise and use annoyance as an indicator of a lack of mental well-being, as in some urban environments there are also soundscapes that contribute to enhance the urban experience. These relationships need to be explored by considering all dimensions of the soundscape in future studies. As well as mapping other noise indicators which might be more related to short-term effects.
- Studying the acoustic environment from its noise and soundscape dimension is a good practice which helps to understand how people experience, listen and feel public spaces of the built environment.

ABSTRACT

This study designs a comparison of the estimation of road traffic noise from different urban traffic representations between their corresponding modelling chains. Based on a microscopic traffic dataset in Stockholm, three kinds of urban traffic representations (Microscopic traffic representations, Aggregated traffic representations, and Hybrid traffic representations) and their corresponding traffic noise estimation models are introduced from distinct perspectives. The distribution result of $L_{\mathrm{Aeq},1h}$ highlights that all models follow similar distribution patterns in noise exposure despite different traffic representations, while still slight differences in peak noise intervals remain. Two proposed hybrid traffic representation methods expand acoustic indicator sights from aggregated traffic representations by introducing dynamics and stochasticity, which can yield comparable noise estimates at high percentile indicators. The noise maps highlight that a general but uneven underestimation exists in all other modes compared to microscopic traffic representations. Desired improvements of hybrid traffic representation methods are discussed, aiming to bring acoustic evaluation enrichment in urban traffic environments.

1. INTRODUCTION

Accurate noise estimation is critical for understanding the environmental impact of traffic systems. In recent years, various traffic output data from traffic simulation models have been widely utilized in estimating traffic noise. Stressed in different urban conditions and spatial scales, corresponding model chains provide unique analytical perspectives in traffic noise estimation [1–3]. Macroscopic traffic models provide aggregated link-based traffic speed and flow rate [4], while micro-simulation traffic models provide granular outputs (such as float point trajectories) as a basis for noise modelling. In addition, hybrid representations allow the gap between trajectories and aggregated representations to be bridged [5, 6]. This article aims to describe the state of the art of the various couplings and implementations currently available, and to propose a comparative analysis of their advantages and limitations, including implementation specificities, and resulting acoustic level accuracy.

These different traffic representation datasets are derived from the same micro-simulation scenario in an urban area in Stockholm. Noise levels are estimated for each dataset using established acoustic models in the latest version of CNOSSOS-EU [7, 8], and compared to the reference micro-simulation based estimation. This research provides insights into the influence of different traffic representation outputs from a microscopic traffic representation scenario on noise estimation, which could be referred to by practitioners in selecting traffic outputs for urban noise assessments.

2. METHODS

2.1 Traffic representations

The study is based on microscopic traffic data, typically representative of higher density traffic on the island of Södermalm in Stockholm, Sweden. In order to assess the impact of different traffic representations on noise estimations, three kinds of traffic representations are introduced from distinct perspectives in this part.

2.1.1 Microscopic traffic representations

SUMO Mode
The original traffic simulation is based on SUMO (Simulation of Urban Mobility) [9], which is an open-source, highly flexible microscopic traffic simulator widely used for modelling urban traffic dynamics. SUMO provides detailed vehicle-level movement data, including individual vehicle trajectories, acceleration, deceleration, lane-changing behavior, and interactions with traffic control mechanisms such as traffic lights and stop signs.

In this case study, the simulation is configured to simulate typically high traffic volumes and frequent stop-and-go movements.

2.1.2 Aggregated traffic representations

Computational efficiency and usability of microscopic traffic data in large-scale studies are usually limited. Aggregated traffic representations represent the classic approach commonly used in noise mapping [10], as it relies on available urban traffic counting loops or similar detection methods. Based on SUMO Mode, three distinct aggregated scenarios are analyzed: Flow Sensor Mode, Time Mean Speed Mode, and Space Mean Speed Mode. Each mode provides a unique perspective on link attributes including traffic flow rate and mean speed.

Flow Sensor Mode
In this mode, traffic speed is estimated using randomly placed flow sensors along each link. The methodology follows these steps:

- A single sensor point is randomly assigned to each road link.
- The sensor has a detection range of 10 meters, to avoid duplicate records, recording vehicle positions and passing time on the nearest link to the vehicles.
- As recorded vehicles pass through the sensor's detection area, their speeds are calculated.
- The link mean speed is then computed as the average speed of all vehicles detected by the sensor.

This approach mimics real-world traffic monitoring via stationary sensors but is limited by the fact that only a small portion of each road segment is observed, potentially leading to biases in speed estimation.

Time Mean Speed (TMS) Mode
The Time Mean Speed (TMS) [11] mode refines speed measurement from Flow Sensor Mode by considering all the appearances of vehicles on the same link. The process involves:

- Identifying vehicles that appear on the same nearest link at least twice within a given time window, capturing travel distance and time between vehicle positions.
- Calculating the speed of each detected vehicle along the nearest link.
- Computing the average speed of all identified vehicles on the link.

Space Mean Speed (SMS) Mode
The Space Mean Speed (SMS) [11] mode focuses on speed accuracy by incorporating the total travel time and travel distances regardless of the identification of single vehicles. This method follows a similar counting mechanism to the TMS mode but differs in speed computation:

- Vehicles are counted if they appear on the same nearest link at least twice.
- The total travel time and travel distance of all the vehicles along the link are recorded.
- The space mean speed is then computed as the ratio of the total travel distance to the total travel time for all vehicles on the link.

2.1.3 Hybrid traffic representations

In addition to the three traffic aggregation methods discussed earlier, this study explores two hybrid traffic representation methods. These methods aim to reconstruct individual vehicle movements along road links using link-aggregated traffic data, specifically traffic flow rates and average traffic speeds. By leveraging these hybrid techniques, we can generate a more detailed microscopic representation of traffic while preserving the macroscopic traffic characteristics derived from aggregated datasets, such as the traffic output from

macroscopic and agent-based simulation models.

Two proposed methods introduce stochastic variations to generate more dynamic vehicle trajectories: Density-Based Vehicle Movement Reconstruction [12] and Poisson-Based Vehicle Trajectory Reconstruction [13]. Each method uses different statistical modelling techniques to introduce variability in vehicle movements while maintaining consistency with the underlying link-aggregated data, giving an output similar to a microscopic traffic simulation with individual vehicle position and speed on 1-second time resolution. Time Mean Speed (TMS) Mode was selected as the base dataset. This choice ensures that vehicle movements are reconstructed based on a more refined speed estimation approach.

Density-Based Vehicle Movement Reconstruction Mode
This approach reconstructs individual vehicle movements at each predefined position based on the estimated road traffic density along each link. Traffic density is a key parameter in traffic flow theory, representing the number of vehicles per unit length of a roadway. The computed density determines the probability of vehicle occurrence at different positions along each road. Individual vehicle movements are then reconstructed through iterative probabilistic processes.

Poisson-Based Vehicle Trajectory Reconstruction Mode
The second method reconstructs vehicle trajectories using a Poisson process, which is commonly used to model the random arrival of vehicles in traffic flow theory. Unlike the density-based method, this approach does not rely on estimating the occurrence probabilities of all the possible positions along each road, but on distributing vehicles' trajectories under a Poisson random arrival model.

2.2 Modelling chains

All the noise simulation modelling chains in this article consist of two parts: the traffic model output representations and the noise calculation model. For aggregated scenarios, the noise levels emitted by road traffic are estimated based on the average flow rates and speeds of vehicle flows per road section. Alternatively, the noise source levels are estimated from the trajectory points along the roads for dynamic traffic scenarios including SUMO Mode, Density-Based Mode, and Poisson-Based Mode.

2.3 NoiseModelling

NoiseModelling [14] serves as the core computational framework for the noise calculation model, which is an open-source library capable of producing noise maps. This research employs the CNOSSOS-EU standard methodology to estimate noise emissions and propagation effects, utilizing its emission model, path-finding algorithm, and attenuation model to simulate noise transmission from traffic sources to receiver points. However, for the acceleration correction component, the IMAGINE method is applied over CNOSSOS-EU here. While CNOSSOS-EU includes a distance-based acceleration correction in relation to intersections, the choice made to use the IMAGINE method [15] offers a more precise approach to capture acceleration-induced noise variations by directly considering the actual accelerations.

2.4 Case Study and Parameters

This study is based on the traffic conditions in the Södermalm district, a central island in Stockholm, covering approximately 10 km² of urban traffic activity. Södermalm is a densely populated area with a well-developed road network, making it an ideal location for evaluating different traffic representation methods. (See Figure 1)

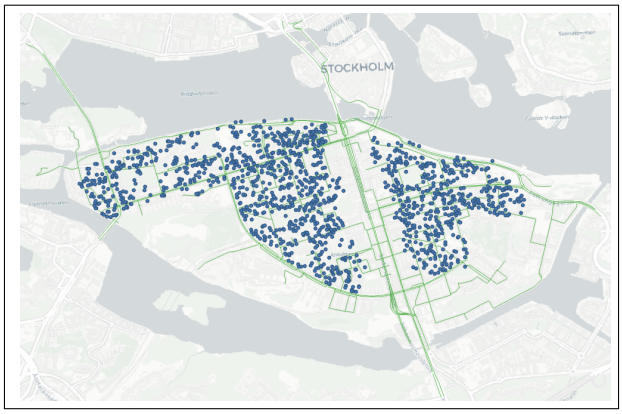

Figure 1. Network and position of noise receivers.

Most of the major roads within the study area are included in the simulation, with microscopic traffic data

suitable to capture a representative snapshot of urban mobility and one of the most significant noise sources throughout the day.

Since this research primarily investigates traffic representation methods, vehicle composition is intentionally simplified. To reduce complexity and maintain consistency in the analysis, only light vehicles are simulated, while heavy vehicles, buses, and motorized two-wheelers are excluded. These vehicle types introduce additional variability in both traffic dynamics and acoustic noise emissions, which may lead to increased uncertainty in hybrid traffic representation methods.

To assess the impact of traffic on noise levels, a total of 1,389 receiver points are strategically placed around buildings and along traffic corridors. The following noise level indicators are considered in the analysis: $L_{\text{Aeq},1h}$ (A-weighted equivalent continuous sound level per hour per point) is computed for all traffic scenarios. $L_{A10,1h}$, and $L_{A1,1h}$ are evaluated specifically for dynamic traffic representation scenarios (SUMO Mode, Density-Based Mode, and Poisson-Based Mode), where more detailed vehicle movement patterns are simulated.

Table 1 provides a summary of the key parameters used in the acoustic calculations for this study.

Table 1. Parameter values for sound propagation

Parameters	Configuration
Maximal order of reflection	1
Maximal order of diffraction	1
Maximal distance source-receiver	250m
Maximum source-reflection distance	50m
Receivers height	1.5m
Ground absorption coefficient	G=0
Spatial resolution	D=20m

3. RESULTS

3.1 Statistical results

Figure 2, 3, and 4 present the Kernel Density Estimation (KDE) curves of the road traffic noise indicators chosen $L_{\text{Aeq},1h}$, $L_{A10,1h}$, and $L_{A1,1h}$ across various modelling chains. These figures allow for a direct comparison of noise level distributions under the different traffic simulation approaches introduced in 2.1, including the initial SUMO microscopic mode, the density-based mode, and the Poisson-based mode.

As shown in Figure 2, the KDE curves of $L_{\text{Aeq},1h}$ illustrate the overall equivalent noise levels across different scenarios. Despite minor variations, all modes exhibit a similar bimodal distribution, indicating that the general noise exposure trends remain consistent regardless of the underlying traffic modelling approach. However, the SUMO mode (blue curve) shows slightly higher noise levels in the first and the second peaks, and gains more density in the highest noise interval (60 - 70 dB), which may be explained by a more detailed representation of vehicle flow dynamics.

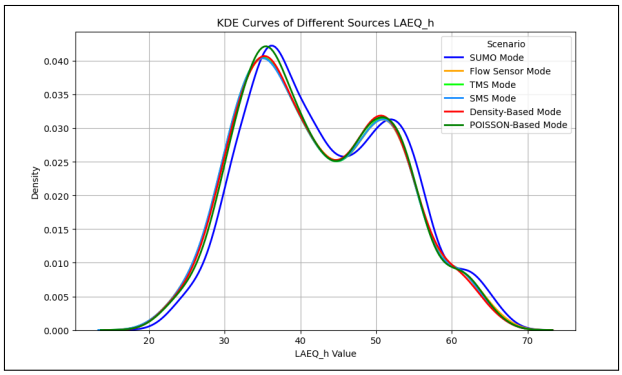

Figure 2. KDE Curves of Different $L_{\text{Aeq},1h}$.

Figure 3 presents the KDE curves for $L_{A10,1h}$. Unlike $L_{\text{Aeq},1h}$, which can be estimated from any aggregated traffic scenario, $L_{A10,1h}$ requires dynamic approaches to capture variations in noise over time. Therefore, only the SUMO microscopic mode, the Density-based mode, and the Poisson-based mode are represented in this figure. The Density-Based mode (red curve) and the Poisson-Based mode (green curve) align closely with the SUMO mode, particularly at lower noise levels. However, minor deviations appear in the tail of the distribution, indicating that high-intensity noise events may be influenced by traffic flow representation differences.

Figure 4 focuses on $L_{A1,1h}$, capturing the highest noise levels experienced during the simulation. Similarly to $L_{A10,1h}$, $L_{A1,1h}$ can only be derived from dynamic

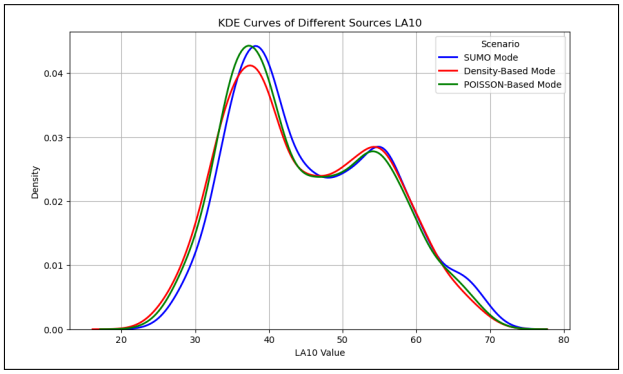

Figure 3. KDE Curves of Different $L_{A10,1h}$.

traffic models. The results indicate that the SUMO microscopic mode captures more pronounced peaks, reinforcing the idea that detailed vehicle-level modelling better represents transient events such as acceleration and braking. The Density-Based and Poisson-Based modes follow similar trends but exhibit smoother distributions, likely due to their simplified vehicle representation.

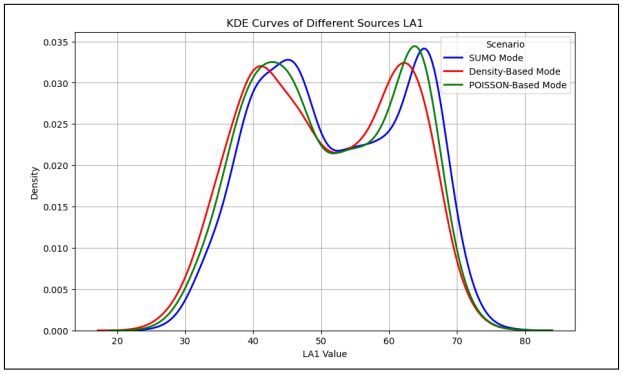

Figure 4. KDE Curves of Different $L_{A1,1h}$.

3.2 Noise mapping

Figures 5, 6, 7, 8, and 9 display the estimated $L_{\text{Aeq},1h}$ difference values of various scenarios compared with the reference SUMO mode. These figures contribute to explaining the deviations from the SUMO mode (blue curve), as most of the estimated $L_{\text{Aeq},1h}$ levels are underestimated while only a few of the receivers exhibit higher $L_{\text{Aeq},1h}$ levels in aggregated link-based scenarios.

Noteworthy is the fact that among these figures, the portion of receivers at which levels are greatly underestimated (deep blue color dots) is much reduced for Density-Based and Poisson-Based modes when compared to the other three aggregated traffic representation scenarios. This result suggests that hybrid traffic representations have the potential to alleviate the underestimation induced by the loss of details in the description of vehicle dynamics associated with aggregated traffic representations.

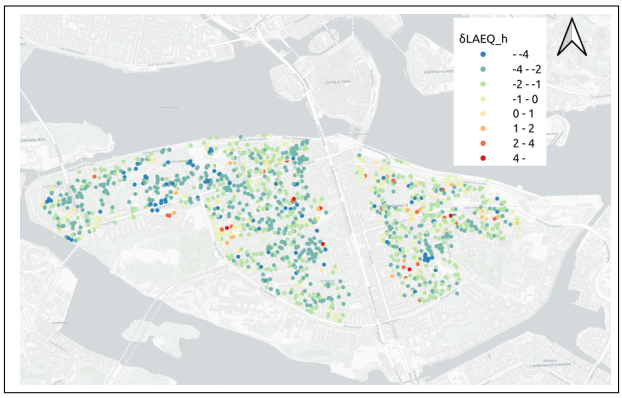

Figure 5. Sensor Mode acoustic indicators compared to SUMO Mode.

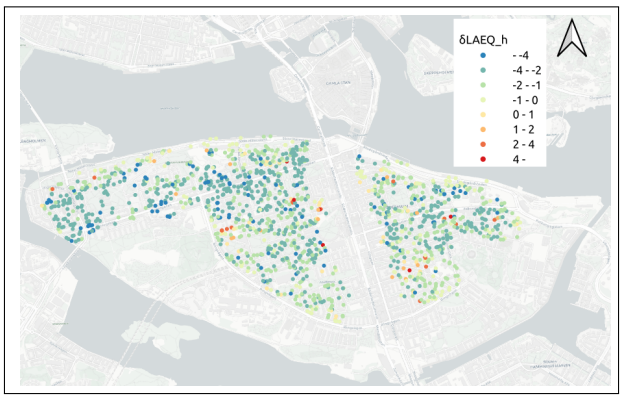

Figure 6. TMS Mode acoustic indicators compared to SUMO Mode.

4. CONCLUSIONS

This study offers a comparison of different modelling chains for estimating road traffic noise, focusing on

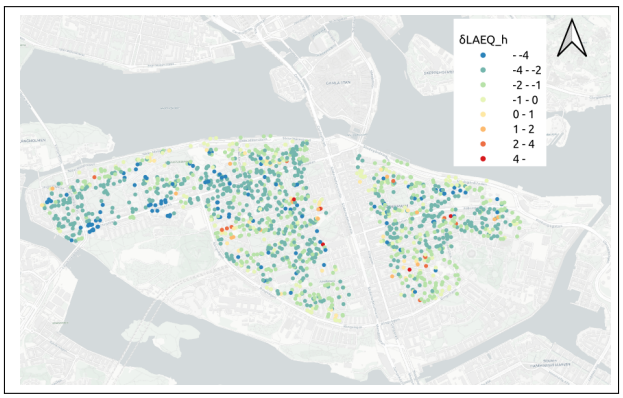

Figure 7. SMS Mode acoustic indicators compared to SUMO Mode.

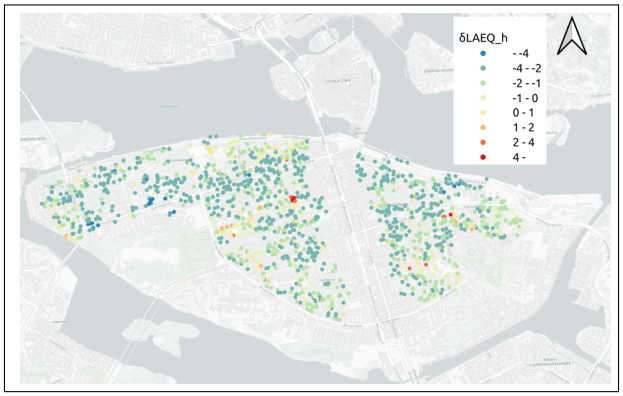

Figure 8. Density Mode acoustic indicators compared to SUMO Mode.

variations in noise distributions under distinct traffic representation approaches. By analyzing the Kernel Density Estimation curves of various noise indicators and noise indicator maps, several key observations are made.

First, despite differences in traffic representation, all models exhibit similar distribution patterns. This suggests that hybrid traffic modelling approaches, including Density-based and Poisson-based methods, can yield comparable noise estimates, especially at high percentile indicators. These indicators are limited in aggregated link-based scenarios, making hybrid methods a practical alternative when detailed microscopic data is unavailable.

However, the differences observed in the KDE curves and the distribution of noise maps indicate that while

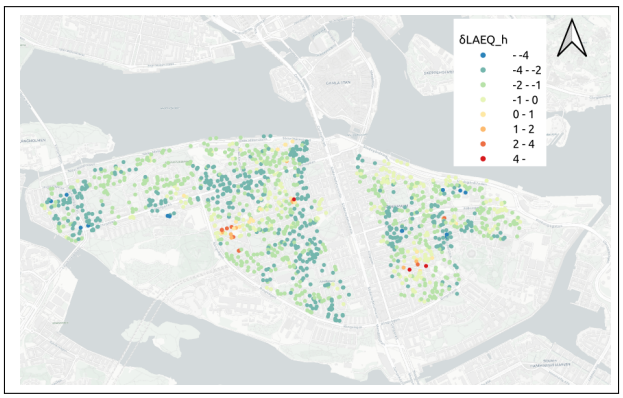

Figure 9. Poisson Mode acoustic indicators compared to SUMO Mode.

these methods effectively capture general trends, they may not fully account for noise from transient vehicle behaviors and uneven vehicle movement distributions. These factors can contribute to variations in high-noise conditions, generally leading to slightly lower noise level estimation when ignored.

Overall, this comparative analysis highlights the influence of different traffic representations on noise estimations with a range of noise indicators. While detailed microscopic simulations offer high-fidelity vehicle dynamics, Density-based and Poisson-based methods provide alternatives, particularly suited for scenarios with limited data availability. Compared to detailed microscopic simulations and static aggregated link-based scenarios, these approaches maintain a balance between broad accuracy insights and practicality. Future research could further refine these models by integrating detailed vehicle behaviors and improving their adaptability to complex urban traffic environments.

ABSTRACT

The United Kingdom Department for Environment, Food and Rural Affairs (Defra) commissioned the design and build of an environmental noise modelling system (NMS). The NMS has been developed to support Defra in preparing its environmental noise evidence base by preparing national road and railway noise models. This paper discusses the challenges and solutions as part of Defra's NMS project to enable CNOSSOS-EU calculations to be delivered on 10 metres grids and at the facades of all residential buildings in England, Scotland and Wales.

Keywords: *noise mapping, cloud calculation, Defra noise modelling system (NMS)*

1. INTRODUCTION

The UK Department for Environment, Food and Rural Affairs (Defra) commissioned the design and build of an environmental noise modelling system (NMS) in 2021. The NMS has been developed to support Defra in preparing its environmental noise evidence base by preparing national road and railway noise models. Defra's model has been produced to fulfil the requirements of the Environmental Noise (England) Regulations 2006 (as amended) (the 'Regulations') [1], the Defra 25-year Environment Plan (25YEP) [2], and the Public Health Outcomes Framework (PHOF) [3]. This has required the model to incorporate all public road and railway noise sources and provide national coverage with respect to calculated noise maps and exposure statistics. The noise models have been delivered in line with the requirements of the adapted assessment methods based on the Calculation of Road Traffic Noise (CRTN) [4] and Calculation of Railway Noise (CRN) [5], and CNOSSOS-EU [6].

The NMS has been designed to connect a series of components secured behind a web application firewall. The design of the NMS has taken a 'decoupled' approach which utilizes existing commercial products with 'ground up' development in areas such as its database design and Extract Transform Load (ETL) tools [7].

At the heart of the NMS is a Postgres geospatial database served on Azure CosmosDB. The database has been designed to store noise model and noise exposure datasets alongside each other. In support of Defra's requirements, the NMS has been designed to deliver automated processes whereby selected input datasets are transformed into noise model datasets using Feature Manipulation Engine (FME) software.

The models are stored in a manner which conforms to its system's open data standards which have been developed in parallel to the NMS.

***Copyright**: ©2025 H. Stapelfeldt et al. This is an open-access article distributed under the terms of the Creative Commons Attribution 3.0 Unported License, which permits unrestricted use, distribution, and reproduction in any medium, provided the original author and source are credited.*

Noise calculations are delivered using a calculation engine which utilizes LimA [8] software modules including noise calculation cores. The calculation engine utilizes a range of components including Azure Cycle Cloud which provides flexibility by allowing calculations to scale up and down by deploying additional virtual machines to the calculation task.

The NMS and the calculation of Defra's model using CNOSSOS-EU has introduced unprecedented computation challenges with a need to balance scale with efficiency and accuracy demands. This paper discusses the key challenges and solutions to delivering CNOSSOS-EU calculations within the NMS at a national level.

2. KEY REQUIREMENTS

Defra set several requirements for its NMS and its noise model which have a direct impact on the approach and requirements for noise calculation. These are summarised as follows:

1) The NMS must be cloud based and scalable
2) Defra's noise model must be developed through automated processes, where practically possible, using authoritative datasets and stored centrally within geospatial database
3) The spatial quality of the noise model must be suitable for localised, detail applications as well as strategic use for national mapping exercises – this means that model simplification is not an option while setting up the geospatial database
4) The noise model must be stored in open standards independent of any noise modelling or calculation solution removing the ability to optimise the noise model itself for a particular calculation solution
5) The noise model must comprise of all public road and railway noise sources and not just those defined under the relevant Regulations
6) The NMS must be capable of delivering noise calculations down to 40 dB L_{den} and 35 dB L_{night} introducing the need for much larger calculation radius and introducing new efficiency techniques applicable to low noise level environments
7) Calculations must be capable of being run for England in 35 days
8) Any techniques adopted to increase computational efficiency should not result in a calculated uncertainty of more than ± 2dB for 90% of receiver point levels.

In combination, these requirements introduce an unprecedented calculation load with firm requirement with respect to the quality of the calculations.

3. RESPONDING TO REQUIREMENTS

During the development phase, focus on efficient, agile and scalable calculation was considered in three areas:

1) Calculation efficiency – Balancing accuracy and compliance with performance requirements at component level i.e. calculation at a single calculation core
2) Distributive Techniques – how to best distribute calculations within a single multi-core machine and across multiple machines
3) Calculation Management – bringing together calculation efficiency and distributive techniques in a managed way.

All three areas were subject to research and development, and associated testing as part of the NMS project.

4. CALCULATION STRATEGY

4.1 Technical challenges

The NMS project is ambitious with respect to extent of project area, detail of model and accuracy demands in calculation. Maximum calculation effort is required when applying CNOSSOS propagation logic.

4.1.1 CNOSSOS calculation method

Compared to CRTN which was previously adopted by Defra to deliver strategic noise maps, CNOSSOS requires working in octaves instead of main frequency and 8-fold propagation paths analysis for a single source-receiver constellation.

4.1.2 Highly detailed model data

NMS has been designed to provide noise modelling data ready for nationwide as well as localised assessment. The resolution of the model therefore needs to be high, as shown in Figure 1.

Noise emissions of sources are pre-calculated within Defra's model and stored in the central database. This avoids interpretations of emissions calculations by different

software tools which may introduce their own adaptation and same time allows for instant inqueries.
The central database delivers model data in a neutral, open format and enables its use by various software products.

The inclusion of all public road and rail sources results in a significant number of emission sources, beyond what would usually be considered in a conventional noise model. This is evidenced by the residential streets in Figure 1.

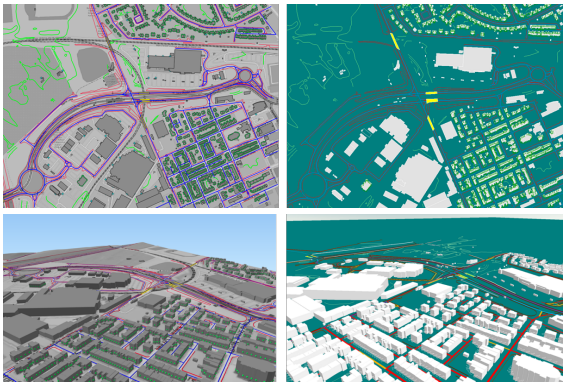

Figure 1. View of Defra's model in open standards (left) and in LimA (right)

4.1.3 Noise Apportionment

The NMS has been designed to support the estimate of noise exposure levels at calculated receiver positions in case of change in emission levels, based on noise apportionment data. For up to 30 most influential sources receptor level contribution per octave as well as the residual noise component need to be stored during the noise calculation. Data is delivered from the LimA calculation cores in a standardised CSV file format which is then ingested back into the central database. This increases calculation overhead by having to write additional information at the end of each calculations. It also requires extensions to LimA's handing of identifier strings to ensure are passed directly from the model into calculation and retained when reporting apportioned noise levels.

4.1.4 Low noise level requirement

To calculate noise at lower levels means that not only major and significant sources of emission are to be considered but rather all roads and rails need to be considered in the calculation. With respect to desired receiver levels in the range of 30 dB, the fetching radius for sources must be set to 3000 m in order to avoid discontinuities in noise grids due to distant high emission sources.

4.2 Calculation parameters and further settings

The immense calculation task does require a careful choice of calculation parameters and extra settings. Though long-standing experience in noise mapping e.g. already showed that small fetching radii for reflector search are reasonable, research was carried out for new parameters and to evidence selected choices in calculation parameters with respect to calculation efficiency (time) and introduce uncertainty (dB).

4.2.1 General calculation parameters

The values chosen for well-established calculation parameters were set to:

3000 m	Fetching radius for road sources
2000 m	Fetching radius for rail sources
25 m	Fetching radius for reflectors
30 dB	Min. relevant receptor levels at night
3 dB	Dynamic error margin (as extreme value)
No	Source segmentation due to ground cover

4.2.2 LimA's established efficiency tools

LimA offers a range of tuning settings to reduce calculation time and 2 key ones are mentioned here as examples. Both of them were introduced into the market by LimA more than 30 years ago.

Most renowned calculation speed tuning feature is the dynamic error margin, whereby a user limits the underestimation of calculated receiver levels, caused by neglection of less relevant sources. It represents a total effect. In many projects this has proven to be a very efficient way to speed up calculation and Figure 2 shows the effect on result and calculation time for a small example with 3 categories of road traffic emission intensity.

However, the need to report noise exposure for all and for major sources hampers the dynamic error concept, as even next to a highway the calculation core might still have to consider minor local roads at distance.

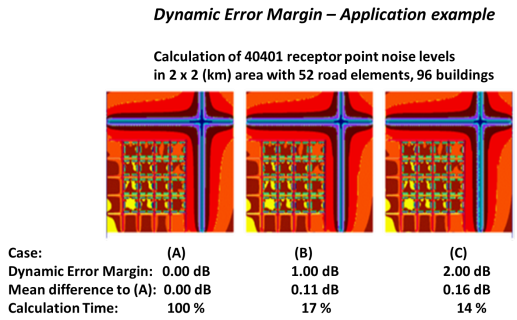

Figure 2. Dynamic Error Margin effects

Another tuning aspect deals with line source segmentation. LimA applies the 'method of projection' where sources are segmented with respect to segmentation of obstacles (e.g. each façade segment of a building) encountered between source and receiver in full 3D geometry analysis. This achieves best continuity for direct and reflected noise contributions.

The 'method of projection' was introduced into the market by LimA and by now is available in most noise mapping products and is described in ISO9613-2024 [8]. However, this only focusses on diffracting barriers.
In distinct model situations the propagation influence of ground cover may become important and an extra segmentation of line sources will be feasible. Therefor LimA does support an optional extra segmentation due to ground cover shapes. With respect to the highly detailed/scattered ground cover data and the fact that CNOSSOS does not deal with this issue, it was decided not to activate this feature.

But with source-receiver distances up to 3 km, and with buildings in urban areas, source segmentation needed further streamlining. Source line segmentation took full details of buildings at a maximum distance of the maximum of 8-fold maximum ground extent or at least 300 m from source or receiver. Source segmentation by further objects at larger distances were only considered with their individual total aperture angle. This technique was found to further rationalise the calculation load.

4.2.3 Efficiency tools developed alongside the project

To further enhance calculation performance it was accepted that under certain circumstances the dynamic error margin logic needed to be subject to 'pre-filtering' of certain sources. This was found to be the case where the calculations were subjected to significant densities of emitter with very similar noise emission levels due to the use of default values. Testing identified that
road and/or rail line sources with an emission level (SPL per m) below 75 dB could be filtered prior to the dynamic error margin when they are at a distance beyond 750 m whilst meeting calculation uncertainty requirement. This logic in effect introduced two calculation radii linked to the importance and influence of different types of sources i.e. high quantity low emission, and low quantity high emission.

Efforts in reflection calculation are reduced by limiting the number of reflecting surfaces next to receivers. Here a minimum aperture angle of 10 degree is used, with adjacent façade segments in same plain especially cared for.

4.2.4 Quality assessment

All strategies are subject to a specific study to ensure calculation accuracy remained within agreed tolerance. Recommended calculation settings result in calculation times of less than 0.4% of benchmark in urban areas, and less than 0.15% in rural areas, with mean difference of about 1.0 dB in urban areas, and 0.5 dB in rural areas, and 95% CI of 2.7 dB in urban areas, and 1.0 dB in rural areas.

4.3 Distribution Techniques

The model is stored in the central database in line with the Ordnance Survey tiling structure. This stores model data in 5 x 5 (km) project areas defined by their OS tile reference. A single CPU takes over a noise calculation task for a 1 x 1 (km) region. With 3 km buffer zone this already results in 49 km² model area to deal with per calculation run.

The NMS was designed to host a central controller node VM which manages a project processing queue and allocates individual projects by their OS tile reference to available VMs, known as the 'worker nodes'. Along with the project details it sends all model data required from central database. All this is organized by PowerShell scripts with the scaling of available worker node VMs managed by Azure Cycle Cloud. This logic is presented in Figure 3.

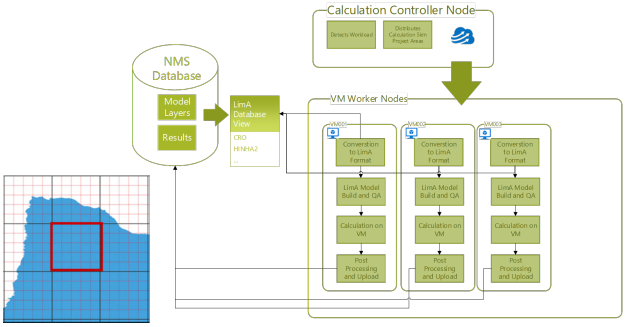

Figure 3. Calculation Distribution Logic

4.4 Calculation Management

Calculation management has to deal with model data transfer, initiating calculation jobs and collecting result files. The demand for apportionment results in massive size result data sets, which can run into several hundred MB per 1 x 1 (km) tile.

4.4.1 Calculation task description

Calculation requirements for project processing are written into Project Management File (*.PRM). This is the only initial user exercise and it is set up in a semi-automated process.

4.4.2 Orchestrate the noise calculation

Once all data has been sent to a worker node, a LimA macro developed for the NMS takes over, defining jobs for LimA modules. The actions comprise:

1) Retrieving model data from the central database and converting the data into LimA format without simplification
2) Creating separate job files per 1 x 1 (km) calculation tile
   For each job the calculation input file is generated with respect to the information in the *.PRM file.
3) Job-files are stored in a central spool directory and are dispatched by LimA's DSERVER.EXE to any available out of 7 parallel processing queues. (One CPU is spared to support OS) with each worker node configured as an 8-core VM
4) When all jobs are finished data is zipped and handed over to separate processes for upload into the database.
5) Finaly the VM either takes over a next project or is powered down.

4.5 Hardware

Chosen hardware in the Azure cloud HPC environment is the result of efficiency tests, i.e. costs vs. calculation speed comparison. This testing demonstrated that the optimum configuration was an 8 core VMs with 32 GB RAM. Potential deployment of tasks on up to 150 VMs was ensured for the actual noise calculation as well as all other processes related to the project. Most of actual costs are linked to active processing and data communication across the network.

5. ACHIEVEMENTS

The NMS has been used to deliver noise calculations at national scale in England, Wales and Scotland. For grid calculations alone, the following number of calculation points have been generated:

- England, 1.329 billion
- Scotland, 803 million
- Wales, 212 million

The typical calculation times have been in the region of 0.2 seconds per calculation point. For England alone, national scale road traffic noise calculations on the NMS have a theoretical calculation time of around 2 days plus data transfer overheads across the NMS's 150 worker node VMs as opposed to 384 days on a single worker node VM. The Azure pricing logic means that the total calculation costs will be equal irrespective of the number of identical VMs involved.

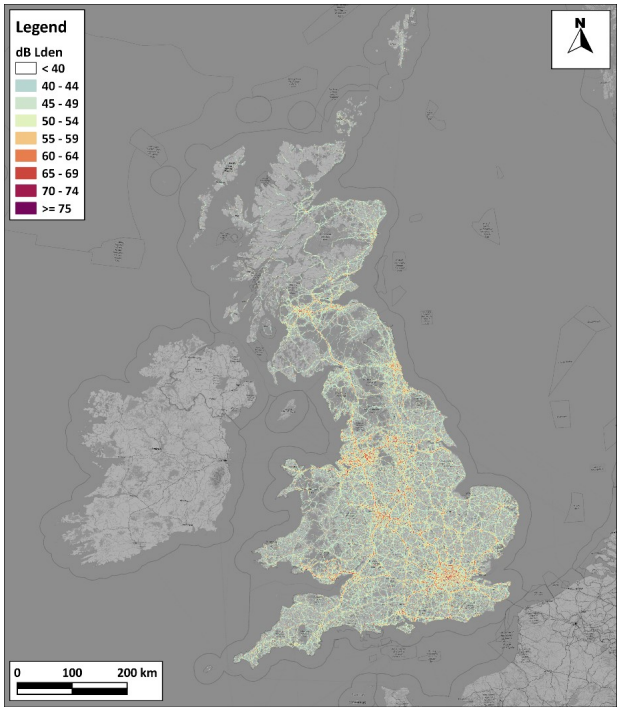

Figure 4. L_{den} road traffic noise map for England, Scotland and Wales

6. CONCLUSIONS

The NMS project demonstrates that detailed large area noise calculations delivered to much lower levels than previously considered are deliverable and achievable through a combination of traditional and optimised efficiency techniques and by utilising modern cloud solutions to create calculation environments.

ABSTRACT

Whether it is NMPB96 or the newer CNOSSOS-EU model, all road traffic noise models require detailed inputs to provide the most reliable estimate of noise exposure.
The present work presents preliminary results of a bilateral project between the Italian National Council of Research (CNR) and Romanian Academy dedicated to the Comparison of different methods for road noise modeling in residential area.
The work presents a comparison of road traffic data acquired in both Italian and Romanian territory with 3 different traffic estimation methods: microwave radar traffic counter, Google API and cameras with recognition by machine learning.

Keywords: *transportation noise, noise mapping, traffic detection, crowd sourced data.*

1. INTRODUCTION

In 2002, the European Commission adopted the Environmental Noise Directive with the aim of preventing exposure, establishing a common methodology and exploring a way to reduce the excessive levels to which the population is exposed. The primary step in noise exposure assessment is acoustic mapping of the main sources (i.e. roads, railways, airports and industries), and this must be performed using a mathematical model. The CNOSSOS-EU method [1] was officially identified in 2015 as the new model to replace the previous NMPB interim method. This revised approach has been formally adopted by the two involved countries and will be mandatory from the 4th mapping round in 2022. The new model offered a great opportunity for European Country and at the same time new challenges in applying a different never tested large scale methodology [2].
Following extensive research, CNOSSOS-EU appears to exhibit certain discrepancies from its predecessor, predicting reduced levels of road traffic noise [3]. The difference can be attributed to several factors, including vehicle categorization and a novel formulation for absorption and diffraction effects. While an offset is expected to have no impact on the noise mitigation phase, it may be particularly relevant for health studies that require accurate noise estimation using validated maps.
In order to achieve this objective, it is imperative to acknowledge the assertion that, within a mathematical model, the quality of an output is contingent upon the quality of the inputs. Consequently, the focus should be directed towards the latter, with the establishment of clear definitions being of paramount importance.
This paper presents the findings from a collaborative study between IPCF, Institute of National Research Council of Italy, and IMSAR, Institute of Romanian Academy. The

objective of the study was to evaluate the availability of the inputs required for the application of CNOSSOS-EU method in Romania, as well as to compare the results obtained from the NMPB and CNOSSOS-EU with respect to input data collection and results. The present paper offers the initial findings of the project, specifically the outcomes of data acquisition employing diverse methodologies, including microwave radar traffic counters, cameras with machine learning recognition, and Google API with Python script elaborations. Thereafter, a comparison will be drawn between the data sets, in order to ascertain potential discrepancies. Finally, these input data sets will be modelled in software to analyze the differences in terms of the derived noise compared to the actual measurements.

2. METHODS

2.1 Data acquisitions methods

A detailed description of the three methods identified for acquiring input data is presented hereafter. The acquisition of traffic data can be achieved through onsite measurements or remote analysis. Onsite measurements are performed with standard microwave radar traffic counters (TC) or with cameras that are optimized for vehicle recognition in the context of CNOSSOS-EU classification (CAM). The third method involves remote analysis, which exploits Google API traffic data (API). The installation of TC and CAM measurement systems is illustrated in Figure 1. The description will then proceed to detail how data are acquired and the flows derived, and the pros & cons of each methodology.

2.1.1 Microwave radar traffic counter (TC)

TC are situated at the roadside to monitor traffic on a maximum of two lanes. They can be installed in a low position (approximately 50 cm from the road surface) or in a high position (more than 2 m from the road surface) to monitor respectively roads with less or more traffic. As there may be occlusion from vehicles, the upper position should give a better view of the road if there are several lanes in the same direction. This system cannot differentiate between two lanes of traffic in the same direction, and passages are stored together. Traffic counting is based on the length of the vehicle as seen by the radar, so the same vehicle passing at different distances from the radar position will have different length values. Different lengths can be set for different vehicle categories in opposite directions, but not for two lanes in the same direction, so the thresholds between them should be set carefully. On the other hand, the system is very easy to install, it does not store any sensitive data and the analysis is done using spreadsheets.

Figure 1. Monitoring with TC and CAM – Bucharest testbed.

2.1.2 Camera with AI recognition (CAM)

AI-powered cameras are based on the YOLO (You Only Look Once) approach to object detection [4,5]. Vehicles are categorized according to a customized approach to CNOSSOS-EU categories identification. The employment of machine learning ensures the expeditious analysis of traffic flows, while a straightforward on-site measurement procedure enables speeds to be calculated. The system

utilized in this study is still required to undergo post-processing analysis in order to obtain flow and speed results, due to hardware constraints. In order to derive speeds, it is necessary to undertake local measurements of the distances between the camera and the road lanes. In order to perform this calibration phase, the road should be temporarily closed. Conversely, cameras have the capacity to detect up to four lanes and divide the flows, rendering them potentially very powerful, even in cases of high traffic volumes.

2.1.3 Google API & Python scripts (API)

Crowd-sourced data can be utilized to estimate traffic volumes. Google API provides travel times through specific calls for selected road stretch (origin-destination). The application of a basic transport equation [6] makes it possible to derive passenger car equivalent flows using Python scripts and then use standard percentages of vehicle categories to derive the flow of each. The API approach has been demonstrated to facilitate the derivation of a substantial database of flows in the absence of on-site measurements. However, it should be noted that API calls do incur a cost (0.01$ for each origin-destination and time). Additionally, transportation functions are incapable of deriving accurate flow in instances of both very high congestion and very low traffic. In both scenarios, the returned travel time, i.e. the speed, is independent of the actual flow, rather dependent upon driver behavior or the overall capacity of the network.

2.2 Testbeds

Two primary testbeds were identified in the project: a mitigated main regional road crossing a small village in Italy (SR 439) and two roads of a residential area in Bucharest (namely a residential road, Strada Secuilor, and the main boulevard, Constantin Brâncoveanu). Table 1 provides a synopsis of the characteristics, while Figure 2 illustrates the locations.

Table 1. Testbeds characteristics

Road, Country	Lanes	Speed limit (km/h)	Distance to houses (m)
Regional, IT	2	50	10-10
Residential, RO	2	30	15-20
Boulevard, RO	4	50	25-25

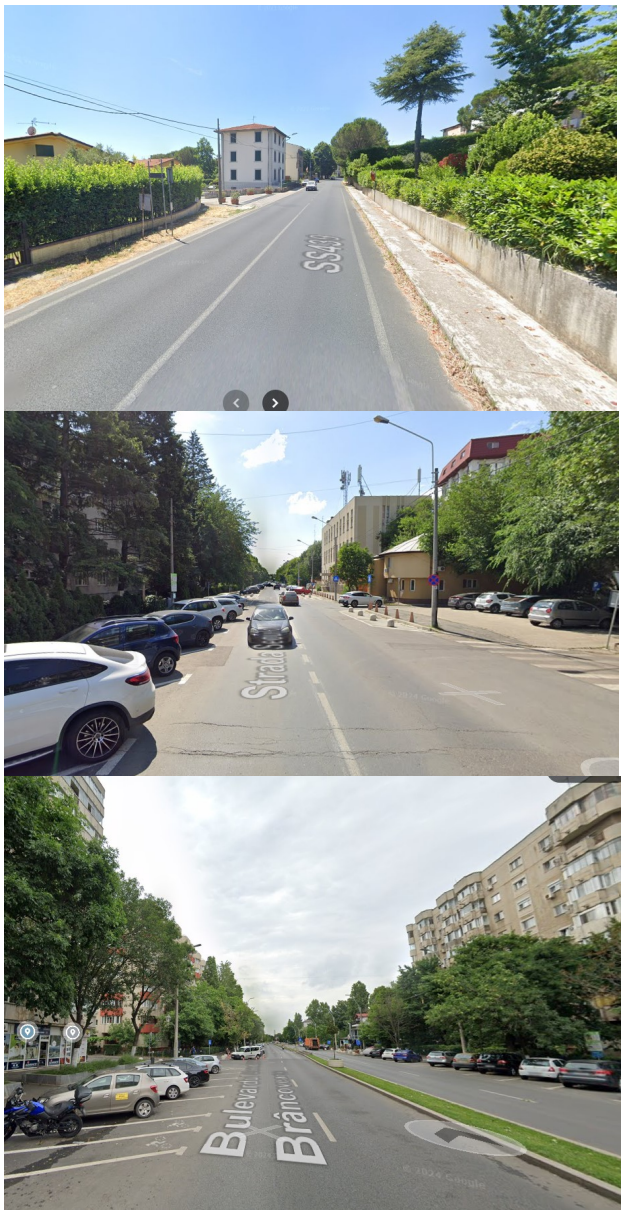

Figure 2. From top to down: SR 439 (IT), Strada Secuilor (RO) and Boulevard Constantin Brâncoveanu (RO).

2.3 Data comparison time base

In the course of the project, a comparison was made of input data gathering methods according to different time bases, depending on the purpose. For the purpose of END noise mapping, it is necessary to compare average day, evening and night-time slices. Furthermore, the 10-minute interval was analyzed in order to verify the suitability of the acquisition methods for advanced dynamic noise mapping, for example to manage congestion and other short-term effects. The focus of this paper is the presentation of results for END noise mapping estimates.

3. RESULTS

3.1 Measurements in testbeds

The first test was carried out in Italy: 24h measurements were taken in Massarosa on the SR439 during April 2024. Second test carried out in Romania: about 24h measurements were performed in Bucharest on the Boulevard Constantin Brâncoveanu and the street Strada Secuilor during September 2024.
All the acquisitions included:

- a roadside AI- camera monitoring all the lanes;
- the call to the API to acquire travel time data every 10 minutes for each direction of traffic;
- a noise level monitoring station.

Furthermore, the standard positioning of traffic counters was subject to variation across different roadways, with the objective of ensuring safety and optimizing traffic flow monitoring. The low position was utilized in Italy, while the high position was employed in Romania. Two traffic counters were installed to monitor the Boulevard; however, technical issues resulted in the failure to capture data from one of the four lanes. Consequently, the data from one of the lanes was doubled to account for the technical issues (modified data are marked with "*" in the following).

3.2 Comparison of average day evening night periods

In order to facilitate a comparison of the accuracy of the modelling process, the derived traffic data are compared in terms of flows and average speed in the three different time slices (day, evening and night) and on the three roads in each direction. The categorization of data is conducted in accordance with the CNOSSOS-EU classification system, which designates categories 1 as light vehicles, category 2 as medium trucks, category 3 as heavy vehicles (excluding urban areas in Romania, where heavy vehicles are not present), and category 4 as two-wheelers.

Acquisitions have demonstrated that the impact of categories other than light vehicles is negligible. Figure 3 illustrates the subdivision of traffic flows according to AI-camera data, for each designated time slice and testbed.

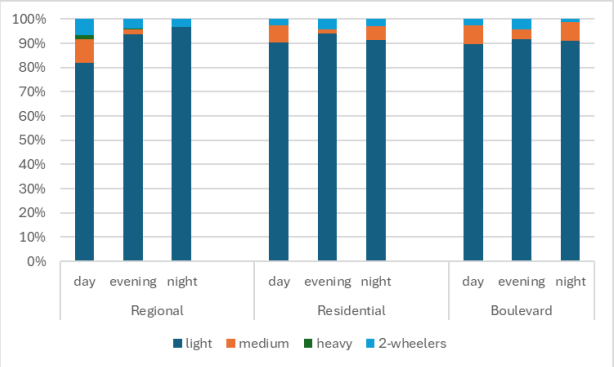

Figure 3. Vehicles categories subdivisions in flows for the three testbeds.

Therefore, the comparison of flows is reported only for light vehicles, as this is sufficient as a proxy for the expected noise differences. Tables 2, 3 and 4 present the estimated flows per hour for the three time slices and for all roads and directions according to the three input gathering approaches.
It is evident that the night-time slice of the Italian testbed reports significantly divergent values for the API method. This discrepancy can be attributed to the different method used to derive the flows: in Italy, the transport parameters were set to the same value in all time slices, whereas in Romania they were varied to reflect the different transport conditions in each time slice.

Table 2. Estimated light vehicles - day

4. CONCLUSIONS

This work has presented the first results of a bilateral project between Italian National Research Council and Romanian Academy. While the whole project aims to analyze the effects of mapping road traffic noise with input gathered with different traffic flow measurements methodologies, the present work shows the results in terms of traffic counts from the testbeds situated in Italy and Romania. Three different methods were simultaneously used, and it results that when the traffic is low, the microwave traffic counter (TC) and camera with artificial intelligence recognition (CAM) methods are similar. CAM generally exhibits higher flows, which should be more realistic than the TC ones. The third approach, Google API approach, necessitates meticulous validation but could serve as a viable method for high traffic roads and average estimates. The transportation parameters that are conducive to deriving API data are the focus of ongoing research in related projects. Regarding noise mapping models, all methods are deemed suitable for deriving comparable noise levels during the day. For other time periods, the use of CAM is recommended, or, alternatively, TC, though only for low-traffic areas. Further analysis will allow for the establishment of variability in noise results due to the input data collection methods and the noise model applied (CNOSSOS-EU or interim NMPB method).

In order to achieve this objective, the remaining of the project will consist of a comparative analysis of the noise emissions of individual vehicles will be conducted. This will facilitate the verification of the similarity between the Italian and Romanian fleets. The measurement approach delineated in [7] will be utilized, and the potential establishment of NMPB or CNOSSOS-EU weighting coefficients for light vehicles will be considered.

EFFECT OF TRAFFIC FLOW ON URBAN NOISE MODELLING

Valentín Gómez Escobar[1*] **Sergio Paloqueme Váquez**[1] **Guillermo Rey-Gozalo**[1]

ABSTRACT

Noise mapping presents multiple challenges to ensure that the simulated values are as close as possible to the actual noise values.
For the optimization and testing of noise maps, it is necessary to measure control points (which must be characterized by a sound level and by a vehicle flow, in the case of road traffic noise maps).
A question arises: how to take into account the effect of traffic on streets near the control point?
This paper presents the preliminary study carried out in the city of Cáceres (Spain), on the effect on the simulated sound level of the variation of the flow of vehicles in the streets adjacent to the one in which a control point has been established. Different assumptions regarding the traffic on these streets have been considered.
The results show that, in streets without heavy traffic, the effect of traffic variation in adjacent streets can be significant.

Keywords: *Noise, noise mapping, traffic noise, uncertainty.*

1. INTRODUCTION

Noise is one of the main pollution factors that affect modern cities. Therefore, noise assessment is an important task in order to evaluate the quality of life of citizens.

Noise assessment can be carried out both from in situ measurement or by simulation software. In any case, both methodologies are complementary since, for instance, simulation results must necessarily be compared with in situ measurements to corroborate the quality of the developed noise model.

According the European Environmental Noise Directive (END), strategic noise maps are the main tool for noise assessment [1].

Noise simulation implies an adequate selection of the noise sources present in the environment. In this work only road traffic noise is considered, both in simulation and in the in situ measurements carried out. This noise source is one of the most important in modern developed cities and is related to different diseases [2,3]. For the strategic noise maps in which road traffic noise is considered, the European Commission established in 2019 a unique method for noise simulation (CNOSSOS-EU) [4].

When simulation an environment, it is necessary to collect different data such as meteorological conditions, road surface, absorption of buildings, vehicle categorization flows, vehicle speed, etc. Due to the large variability of this data, some assumptions are usually made, some of them included in official documents [5,6].

For the validation of noise models it is necessary de comparison of the noise levels obtained with the computational models with in situ measurements. The uncertainty obtained in this comparison can be influenced by different factors [7-8]

For the aforementioned validation, the characteristics of vehicles traffic at the point of evaluation are taken. However, in some streets, mainly in those with low vehicles

flow, the influence of noise coming from nearby streets could be important and data vehicles flow data from these streets are usually not available.

The purpose of this work is to make a first approximation to the possible effect of nearby streets on traffic noise assessment in noise modelling.

2. METHODOLOGY

2.1 Studied city

The simulation and measurements were carried in the city of Cáceres. The city of Cáceres is located in the southwest of the Iberian Peninsula. The population of the city is close to 95,000 inhabitants (although this number increase to more than 110,000 during most of the year due to the influx of more than 10,000 students at the University of Extremadura and, also, numerous tourists). Cáceres is a UNESCO World Heritage site.

2.2 Sampling methodology

For the present study, several sampling points were chosen in different streets of the city. To take into account la variability of traffic flow in the city, the sampling points were distribute among the different types of streets in Cáceres,

Thus, before the selection of sampling points, the streets were classified according to the previously proposed categorization method [9-10]. In Figure 1, a color-coded map of Cáceres is shown for the different categories of streets (only sampled streets are indicated).

Sampling points were randomly selected inside each category and prior to the measurement, each sampling point was analyzed in depth and possible adjacent streets that could influence noise were selected.

During sampling, some photographs of the sonometer location were taken.

At each sampling points, two measurements of 15 minutes of duration were carried out. All measurements were performed in diurnal period (from 7:00 to 19:00). The measurements were carried out on different working days, following the ISO 1996-2 standard [11].

All the measurement were carried out in years 2020 and 2021.

2.3 Noise modelling

The Predictor v.2024 software was used for noise mapping. The following configuration options was used for noise modelling:

- Computational model: CNOSSOS-EU
- Reflection number: 1
- Meteorological conditions: Default values of Toolkit 17 of the WG-AEN [5] were considered.
- Building height: Ground floor—4.5 m; each additional floor—3 m.
- Absorption of buildings and barriers: Reflective
- Vehicles speed: Maximum speed allowed for each street.

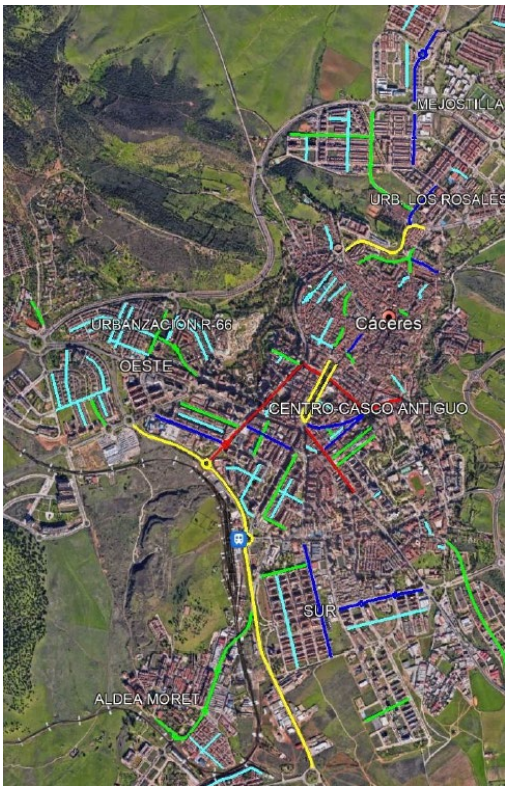

Figure 1. Sampled streets of Cáceres.

The receiver points were located in the noise model at the same position where in situ measurement were taken. In the case of photographs were the exact position of the sampling point could not be precisely determined, the sampling points was discarded.

A total of 100 sound measurements were estimated.

2.4 Street traffic flow

The traffic flow of the street on which the sampling point was placed was determined from the data obtained during sampling.
For the traffic flow of the adjacent streets, two cases were considered:

+ Case 1: No traffic flow
+ Case 2: Average traffic flow of the type of street.

For the present work, three types of street were considered [5]:

- Small main roads. In navy blue and red colors in Figure 1.
- Collecting roads (collecting traffic from service roads and leading it to & from main roads). In green color in Figure 1.
- Service roads: (mainly used by residents living there). In light blue color in Figure 1.

3. RESULTS AND DISCUSSION

As mentioned above, a total of 100 measurements/simulations were considered for the present study. These points were classified according to their location as shown in Table 1:

Table 1. Classification of sampling points considered.

Type	Description	Number
A	Small main roads	34
B	Collecting roads	33
C	Service roads	33

Noise values of the simulations for each sampling point for the two conditions considered (no traffic on adjacent streets and average traffic of the street type on adjacent streets) were compared with the measured level. The differences between the measured and the simulated levels are shown in Figure 2, for no traffic on adjacent streets, and in Figure 3, for average traffic flow.

As can be seen, in both cases, the simulated values are quite similar to the measured values, with very few points where the differences are greater than 3 dBA.

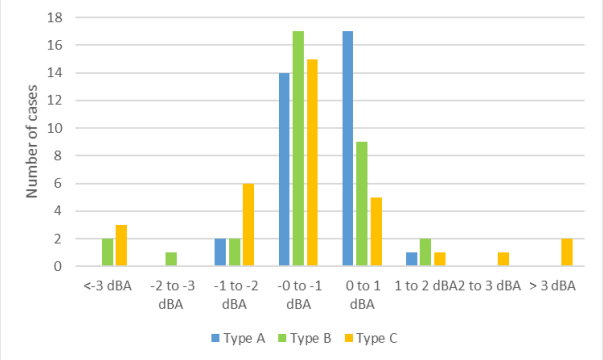

Figure 2. Differences intervals between measured and simulation noise values. Case 1.

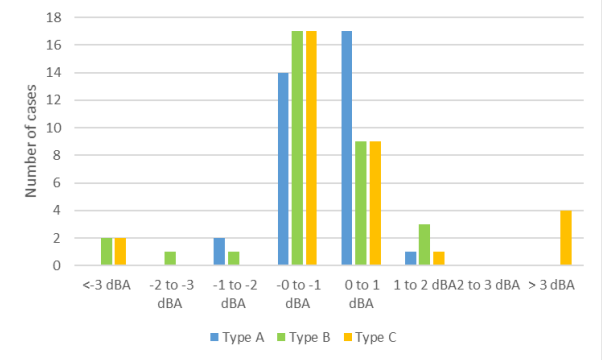

Figure 3. Differences intervals between measured and simulation noise values. Case 2.

In Table 2, comparison between the differences obtained for the two considered cases are shown

Table 2. Comparison between differences of the two considered cases.

	Type A	Type B	Type C
<-1 dBA	0	0	3
-0.5 to -1 dBA	0	0	5
-0 to -0.5 dBA	5	15	22
equal to 0	29	18	3

As can be seen, in the Type A sampling points, the differences between considering the traffic flow in the adjacent streets (case 1) and considering the average traffic flow (case 2) are very small and only in 5 points (15%) small variations (less than 0.5 dBA) are observed in the simulated values. In Type B sampling points, small variations (less than 0.5 dBA) are also observed, but in a larger number of points (45%). Finally, in the Type C streets, service roads, there are greater differences between the two cases considered. Thus, in eight of the considered points (24%) the differences are greater than 0.5 dBA (greater than 3 dBA in 3 points –9%-) and in 22 points the variations are small (less than 0.5 dBA) (67%).

4. CONCLUSIONS

The comparison between the measured and the simulated noise values at 100 measurement points in the city of Cáceres shows that the consideration of traffic on the adjacent streets to the street where measurements are taken can be important, mainly on service roads (those streets used mainly by the residents who live there).

Thus, in these streets, where the noise due to road traffic is not very important since the traffic flows are small, the influence of nearby streets with more traffic should be taken into consideration as, in some cases (about 35% in this study) the differences in the simulated values without consideration of traffic may lead to differences of more than 0.5 dB.

Noise Impact Range Assessment Using UAM Noise Hemisphere

Seung-Min Lee[1] **Chan-Hoon Haan**[1*]
[1] Department of Architectural Engineering, Chungbuk National University, South Korea

ABSTRACT

The present study aims to investigate the noise impact range in urban areas around vertiport using a noise hemisphere model to simulate UAM noise propagation. In order to this three noise hemisphere methods were compared including Integrated, Interpolated, and Background noise compensation. SoundPLAN software was used for noise modeling in a specific area of a vertiport in Seoul. Both horizontal and vertical noise maps were drawn to evaluate the UAM noise effect on the buildings around vertiport. As a result, it was found that the noise impact range varied depending on the noise hemisphere model. In addition, the horizontal propagation range of noise was confirmed to be at least 200 m to 700 m. The vertical propagation range varied significantly depending on the building height, with higher noise levels observed around taller buildings. Based on the results, it is possible to predict the 3D noise impact range by combining horizontal and vertical noise maps when operating UAM in actual urban areas.

1. INTRODUCTION

UAM noise reduction research is being conducted in various fields, including motors and aircraft. Research on noise propagation, which is the focus of this study, is also being conducted in various directions. Several studies have analyzed UAM using the Federal Aviation Administration's (FAA) Aviation Environmental Design Tool (AEDT), which is efficiently used for aircraft noise analysis. One study conducted noise analysis for areas of value for UAM operation by setting fixed-point flight conditions.[1] In addition, a NASA time-marking simulation tool was used to generate noise exposure data for efficient operations to help differentiate differences associated with the integrated noise model implemented in AEDT. Possible changes to assess UAM community noise impact offered more consistently with simulation-based modeling.[2]

However, due to the lack of data, FAA's AEDT and other software do not yet support the operation and analysis of UAM aircraft performance models. Therefore, research on developing an appropriate tool for UAM analysis is also being conducted. For the real-time noise prediction of RPM-controlled multi-rotor configurations, a comprehensive multi-rotor noise assessment (CONA) framework based on a six-degrees-of-freedom flight simulation was developed.[3] Based on this, a study on noise evaluation during multi-rotor landing has been conducted. In addition, a psychoacoustical-based prediction was performed on the noise of the multi-rotor in gusty wind conditions.[4] In addition to references, there is a published study in terms of aircraft development that predicts that the noise characteristics generated by UAM-specific aircraft will be less noisy due to the low propeller load under experimental flight conditions.[5] As such, since UAM's noise analysis method is not standardized, research is continuing to determine the level of noise generated by UAM and the propagation of noise through each noise analysis method.

2. RESEARCH METHODS

Noise data were collected through the flight test of the Optionally Piloted Personal Air Vehicle (OPPAV), an eVTOL UAM aircraft being developed by the Korea Aerospace Research Institute (KARI). The flight test was conducted at the Goheung National Aviation Test Center (NATC) in Goheung, South Korea. Acoustic signals were measured hourly using 80 microphones on the ground runway. The test was conducted at an altitude of 60 m to construct a noise hemisphere. The noise data measured by the OPPAV aircraft using 80 microphones are shown in Fig.

1. Averaging the noise measurements from the 80 microphones yielded an equivalent noise level of 64.0 dB and a maximum noise level of 70.9 dB. The measured noise data were used to generate a noise hemisphere using the SPHPERE-N noise hemisphere generation program.[6] The noise hemisphere with a null value was designated as the 'Integrated noise hemisphere,' and two additional noise hemispheres with corrected null values were added to compare a total of three types of noise hemispheres. Consequently, a 'Compensated noise hemisphere' was created by correcting the null values using background noise data, and an 'Interpolated noise hemisphere' was generated by applying the interpolation method to the null values. [7]

The simulation target areas are two areas in Phase 2-1, corresponding to the K-UAM Grand Challenge. [8] Based on the information presented in the Aeronautical Information Management (AIM), the location of the vertiport in the region and the UAM flight path were set. [9] The simulation was performed using two methods: a single noise source method and a multi-noise source method. The single noise source method aims to investigate the noise level affected by a single noise hemisphere in the region, and the multi-noise source method aims to determine the noise level propagating in the region according to the actual flight path. Both methods were calculated according to ISO 9613-2, and the radius of the noise source was set to 5 m. The color scale of the noise map was set to 5 dB.[10] Fig. 2 shows the location of flight lines and noise sources in the area.

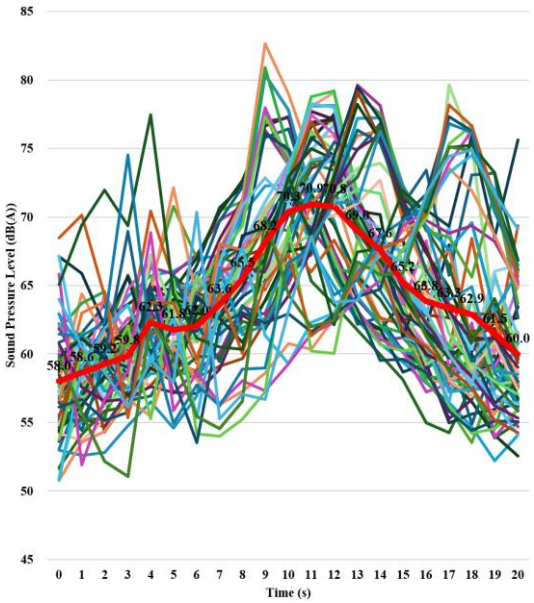

Figure 1. OPPAV noise measurement resluts.

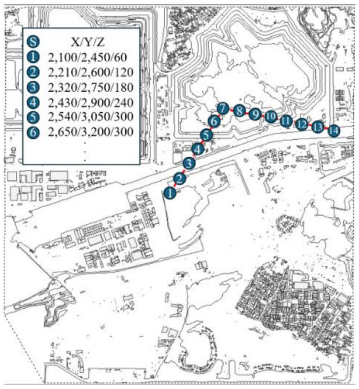

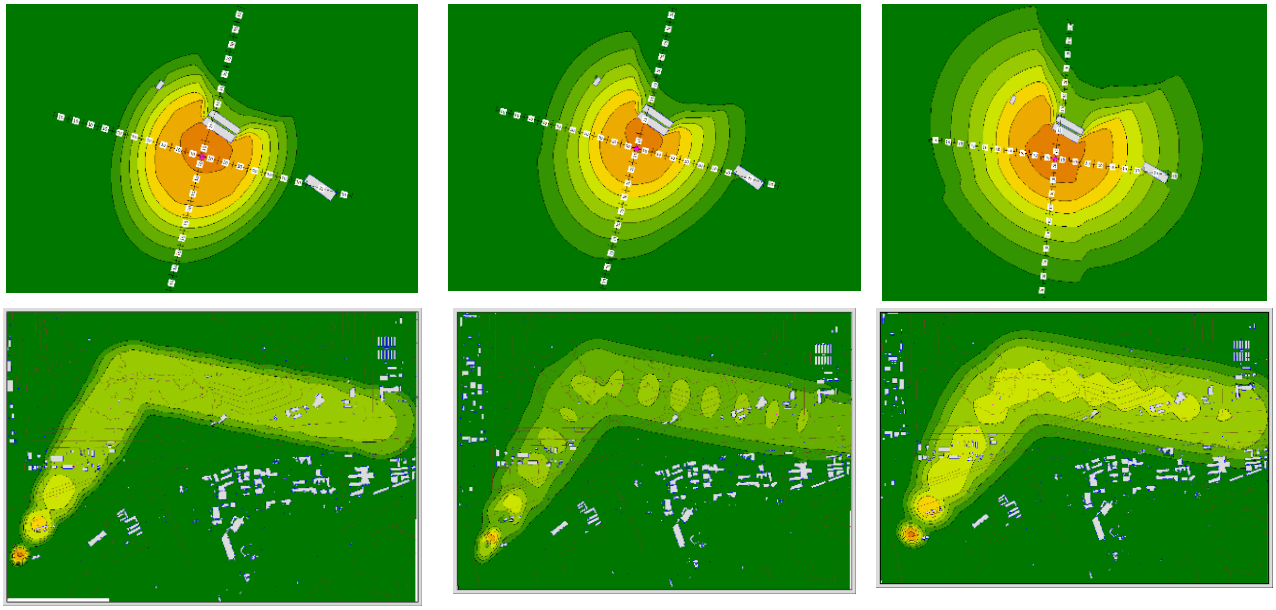

Figure 2. K-UAM Grand Challenge phase 2-1 vertiport and flight path.

3. RESULTS

The planar noise impact range of the Integrated Noise Hemisphere was investigated. The ranges to the left and right were 60 m, respectively, for a total influence of 120 m. In addition, the ranges to the front and rear were 50 m and 75 m, respectively, with the range of influence to the rear confirmed to be longer than that to the side. Investigating the planar noise impact range of the Compensated Noise Hemisphere revealed noise propagation up to 70 m from the left and right, respectively, for a total noise impact range of 140 m. In addition, the ranges to the front and rear were 80 m, respectively, for a total noise impact range of 160 m. Investigating the planar noise impact range of the Interpolated Noise Hemisphere revealed a total noise impact range of 200 m, at 100 m from the left and right. In addition, the total range of influence was 180 m, approximately 90 m from the front and rear. The results of the noise impact assessment using a single and multi-noise source can be seen in Figure 3.

In the Integrated Noise Hemisphere, S1 showed a shape, noise level, and range similar to that of a single noise source. The predicted noise level of S2 is 65 dB to 70 dB, a reduction of 10 dB within the same range, and the total impact range increases by 1.5 times to 200 m. The noise level predicted for S3 is 60 dB to 65 dB, a reduction of 5 dB, and the impact range is 300 m. From S4 onward, all noise sources were expected to be the same, with noise levels of 55 dB to 60 dB, and the impact range being 400 m.

(a) Integrated (b) Compensated (c) Interpolated

Figure 3. Noise impact assessment results

In the Compensated Noise Hemisphere, S1 was found to have a shape in which the noise level is concentrated in the front, unlike a single noise source. The noise impact range is approximately 160 m, and the noise level is predicted to be 70 dB to 75 dB. S2 is predicted to have a noise impact range of 200 m, and the noise level is predicted to be 60 dB to 65 dB, a reduction of 5 dB. S3 is predicted to have a noise impact range of 400 m, and the noise level is predicted to be 55 dB to 60 dB. Subsequently, it was confirmed that the noise sources were similar in noise level and influence range, and that the noise level partially exceeded 50 dB to 55 dB at certain points along the flight path.

In the Interpolated Noise Hemisphere, S1 showed noise levels and influence ranges similar to those of a single noise source. The noise level of S2 is 65 dB to 70 dB, and the noise impact range is predicted to be approximately 400 m. The noise level of S3 is 60 dB to 65 dB, and the noise impact range is predicted to be approximately 500 m. From S4 onward, the noise level was mainly predicted to be 55 dB to 60 dB, but it was also predicted to be 65 dB at some positions along the flight path. The noise impact range was predicted to be approximately 600 m.

4. CONCLUSIONS

Examining the three noise hemisphere influence ranges of UAM, noise propagation from a single noise source was expected to occur within a horizontal radius of approximately 60 m to 100 m, and within a vertical radius of approximately 10 m to 50 m. With multiple noise sources, the propagation range varied depending on the flight altitude. At the maximum altitude of 300 m, noise propagation was expected to occur within a horizontal radius of approximately 400 m to 600 m. Through this, the noise impact range can be predicted for an actual UAM flight path.

The noise measured by OPPAV was higher in the high-frequency band than in the low-frequency band. This is an electric signal generated by an electric motor and can have a strong effect at short distances. Therefore, due to the nature of UAM operations in urban areas, the subjective noise level perceived by occupants of nearby buildings may be higher than the expected noise level. Therefore, appropriate noise evaluation factors should be discussed for UAM noise evaluation.

ABSTRACT

Unmanned Aircraft Systems (UAS) have gained increasing attention, leading to the development of noise measurement protocols, such as the 2023 guidelines from the European Union Aviation Safety Agency (EASA). These guidelines focus on noise measurement procedures for UAS (lighter that 600 kg), outlining measurements and operational requirements. A key requirement is that the difference between the UAS sound pressure level and the background sound level must be at least 15 dBA. This study presents acoustic analysis results from three UAS (weighing under 600 kg) at three different heights, following EASA's guidelines. The study site was chosen with a background noise level of around 48 dBA. Results showed that only the largest UAS (7,3 kg) met the 15 dBA difference at all heights, while the smallest UAS (0,25 kg) did not meet this threshold at any height. Given that low background noise (below 45 dBA) is crucial to fulfilling the guidelines, the study concludes that it is challenging to apply these standards to small UAS. The study discusses whether the EASA guidelines require amendment for small size UAS.

1. INTRODUCTION

The use of Unmanned Aircraft Systems (UAS), has grown exponentially in recent years, expanding to a wide range uses such as mapping, surveillance, package delivery, and infrastructure inspection. However, this rapid expansion raises concerns regarding environmental impact and noise pollution, particularly in urban settings. It is worth noting that awareness of urban environmental quality is increasingly pronounced. A clear example of this is the European Green Deal [1] and the Sustainable Development Goals [2], which currently lead the vision for sustainability in the built environment. According to the European Green Deal [1], one of the main concerns is the negative impact of noise, primarily expressed through the annoyance caused by road traffic noise. Europe, along with other parts of the world, is facing a chronic issue in this regard, with estimates indicating that traffic-related noise (including road, rail, and air traffic) in Western Europe leads to the loss of at least one million healthy life years annually, with road traffic being the dominant source [1].

In order to regulate these aspects, the European Union Aviation Safety Agency (EASA) has established guidelines for drone noise measurement [3], including specific background sound level requirements for its

acoustic testing [3, p. 12]. However, these regulations impose constraints that can be difficult to meet for small UAS. Specifically, the requirement for low background noise levels (differences above 15 dBA) to obtain valid measurements, may hinder the feasibility of testing in real-world environments, where acoustic conditions are rarely ideal.

This paper, based on an experimental study of UAS sound levels, examines the methodology and the plausible limitations of current EASA criteria, raising awareness about the need to revise certain parameters to better align the regulations with the operational reality of certain UAS. By evaluating different models and measurement conditions, this study aims to provide a technical basis for optimizing regulatory procedures and ensuring a more realistic assessment of the acoustic impact of these aircraft.

2. EXPERIMENTAL STUDY'S DESCRIPTION

The main objective of the study is to carry out measurements on different UAS models according to EASA criteria and compare the sound pressure levels of the three UAS. This aimed to analyze noise differences based on UAS weight, proposing certain adjustments.

The experimental study consisted in the measurement of three different UAS, at three different heights. A location and date had to be selected that met specific requirements regarding pavement characteristics, wind speed, temperature, and humidity for the measurements to be carried out, according to regulations. Additionally, the recommendations specify the type of instrumentation to be used for the measurements, how they should be calibrated, and the setup. Finally, the guideline considers two study cases: level flight and overflight. Each of these must meet specific conditions regarding distances and areas of operation.

Specific information about how the experimental study was conducted are specified in sections 2.1, 2.2, 3 and 4

2.1 Flight

The first thing to select was the type of flight that was going to be measured. Due to its relevance and proximity with real situations, the chosen flight was a hover one.

For a hover flight the guidelines has some particular requirements [3, pp. 11-16]. In order to meet them, the three UAS were flown at three heights that were 12, 17 and 25 meters over the measurement point. Selecting these altitudes responds to the fact that 12 m is the minimum height allowed for measurements; 25 m is the reference height required by the regulations; and 17 m, was chosen as a relevant height to study scenarios where UAS fly at relatively low altitudes near people to assess their impact. The rest of the requirements such as the instrumentation and mounting, the operability limits and the measurements' number and duration were also followed precisely.

2.2 Place and date

To meet these requirements, the chosen location was a tennis court in the village of Ruiforco de Torío, in the province of León, Spain. This place was chosen for several reasons, including the fact that it was out of the airspace of Leon's airport. The surface of the tennis court was one of the one suggested in the guidelines [3, p. 10]. Finally, this space is located far from roads and urban areas, which minimizes background noise, however, sounds coming from nature were present (rustling leaves, stream). The days in which this study was conducted were the 29 May 2024 and 11 June 2024, both between 11:00 and 13:30. This dates fulfilled the guidelines recommendations of wind speed, temperature and humidity [3, pp. 8-9].

2.3 UAS

For this experimental study, the UAS used were provided by the Cartography Service from Universidad de León. The characteristics of each UAS is presented here, ordered from the smallest to the biggest:

- **DJI Mavic 4:**
  - Mass: 249 g.
  - Maximum autonomy: 34 minutes.
  - Diagonal size with propellers: ± 213 mm.
  - Maximum horizontal speed: 16 m/s
- **DJI Phantom 4 Pro Plus:**
  - Mass: 1375 g.
  - Maximum autonomy: 30 minutes.
  - Diagonal size with propellers: ± 490 mm.
  - Maximum horizontal speed: 20 m/s

- **DJI Matrice 300 RTK (sensor LIDAR Zenmuse L1):**
  - Mass: 7270 g.
  - Maximum autonomy: 55 minutes.
  - Diagonal size with propellers: ± 1150 mm.
  - Maximum horizontal speed: 23 m/s

3. INSTRUMENTATION AND SOFTWARE

The EASA guidelines also specifies the instrumentation needed to carry out the measurements properly [3, pp. 27-28]. The instruments used in the study were:

- *"Microphone CCLD Free-field 1/2 inch" type 4966-H-041"* by *"Brüel & Kjær"*. It was not necessary to calibrate it as it was brand new. The microphone fulfilled the guidelines. According to the EASA's guidelines, the microphone must be placed face down, over a plaque 7 mm above the ground, and it must be protected by a mesh [3, p. 28].
- Acoustic measurement system *"SQuadriga III"* by *"HEAD Acoustics"*. The only requirement from the EASA guidelines is to have a system that can store data.

For data extraction and analysis, the software *"ArtemiS SUITE"* version 15.7 by *"HEAD Acoustics"* was used. This software fulfills the regulatory requirements for data acquisition and analysis (such as slow analysis, the ability to extract "L_{Aeq}" and "L_{Amax}", A-weighted, etc.).

4. RECORDINGS

4.1 UAS noise recordings

As it is stated in subsection 2.1, the UAS had to fly within certain operability limits and during a certain time. Following the EASA's guidelines [3, p. 12], the UAS must remain within a 8° cone from the vertical above the noise measurement point during 30 seconds of noise recording. A minimum of six runs must be performed and the L_{Aeq} must result from the A-weighted sound level averaged over the 30 seconds.

In order to fulfill these recommendations the first step was to mark the ground with adhesive tape to indicate the action cone radius that the UAS should not exceed at each height. For the three chosen heights 12 m, 17 m, and 25 m, the corresponding action radius are 1.7 m, 2.4 m, and 3.5 m, respectively. The UAS were equipped with a camera system to trace the correct radio action. The dimensions of the action cone are shown in Fig. 1.

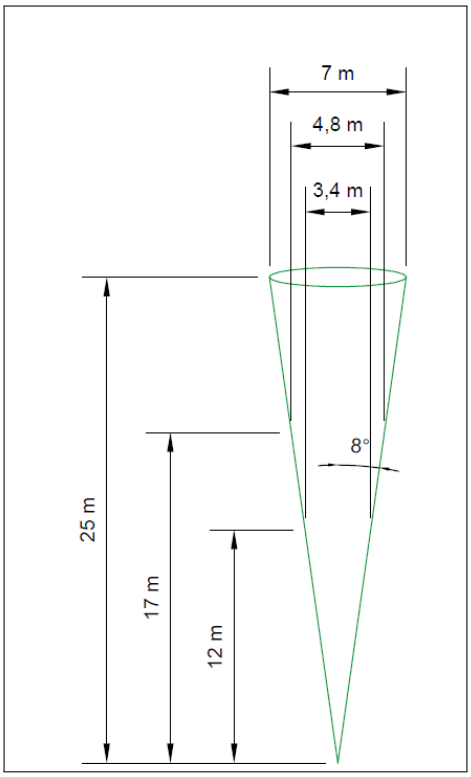

Figure 1. Operability limits for UAS' noise measurement. Adapted from [3, p. 15]

4.2 Background sound levels

To analyze the background noise, measurements were taken in complete silence, without any UAS operating, both before and after recording data for each UAS. The goal is to verify that the background noise remained stable throughout the measurements and, using these values, assess whether the 15 dBA difference between the equivalent background noise level (A-weighted) and the maximum noise level (A-weighetd) produced by the UAS.

The average sound level (L_{Aeq}), the 90th percentile ($L90$) and the maximum sound level (L_{Amax}) are chosen as representative of the background noise level. To compare the UAS' noise values with the background's sound pressure level, the L_{Aeq} of the background noise

must be taken by averaging the values before and after the measurement.

5. RESULTS

The measurements were processed using the *"ArtemiS SUITE"* software, version 15.7 by *"Head Acoustics"*, performing an analysis following the recommendations. According to the EASA's guidelines, for a hovering flight, the following data must be reported [3, p. 40]:

- The date on which the measurement was performed.
- The altitude at which the measurement was conducted.
- The equivalent sound pressure level, "L_{Aeq}".
- The maximum sound pressure level, "L_{Amax}".
- The background noise level, "L_{Aeq}".
- The 90th percentile, "L_{90}". That is, the sound pressure level above which the specified percentage of data is found, in this case, 90

The Tab. 1 contains the sound pressure level of the background noise for each UA test. The average values of L_{Aeq}, L_{Amax}, and L_{90} are shown for each test. The maximum sound pressure level recorded was 50.4 dBA whereas the three L_{Aeq} are around 48 dBA.

Table 1. Comparison of the background noise L_{Aeq}, L_{Amax}, and L_{90} for the three UAS.

	L_{Aeq}	L_{Amax}	L_{90}
DJI Mavic 4	48.2	49.6	47.7
DJI Phantom 4 Pro Plus	47.7	49.2	47.3
DJI Matrice 300 RTK	48.0	50.4	47.4

5.1 UAS' sound level

In the same way as for background noise, sound pressure level data was collected for each UAS at the three heights (12, 17, and 25 m). The following figures Fig. 2, Fig. 3 and Fig. 4 show the results for the three UA at 17 meters, as this height best illustrates which UAS seemed more likely to meet the 15 dBA difference requirement with the background noise. Nevertheless, all collected values are included in the Tab. 2.

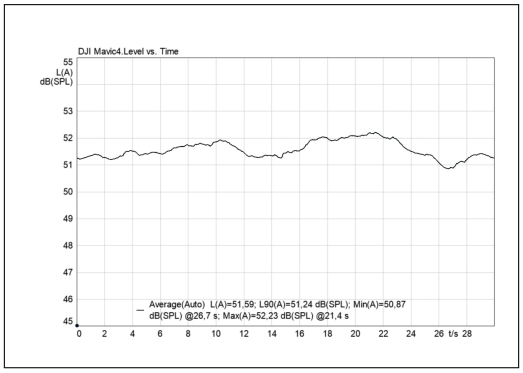

Figure 2. DJI Mavic 4 measurement at 17 m. Level Vs. time.

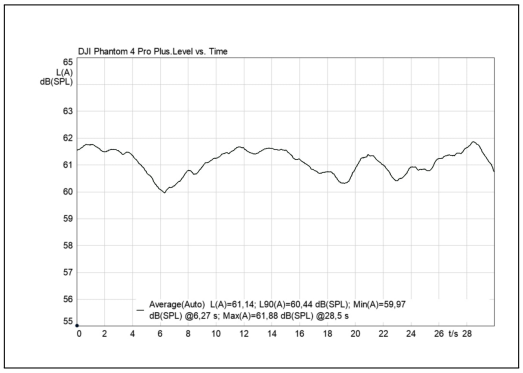

Figure 3. DJI Phantom 4 Pro Plus measurement at 17 m. Level Vs. time.

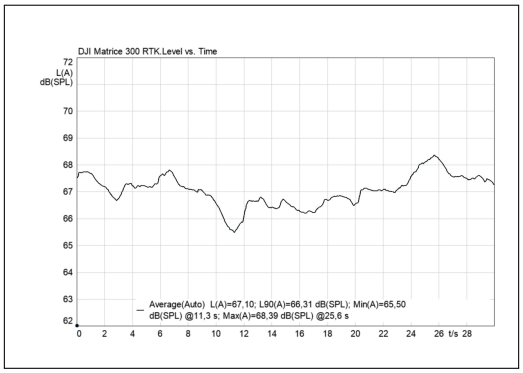

Figure 4. DJI Matrice 300 RTK measurement at 17 m. Level Vs. time.

In order to see the frequency content of the three UAS, the octave band spectrum (A-weighted) measured for the

hover procedure at 12 m (top), 17 m (middle) and 25 m (bottom) height is shown in Fig. 5.

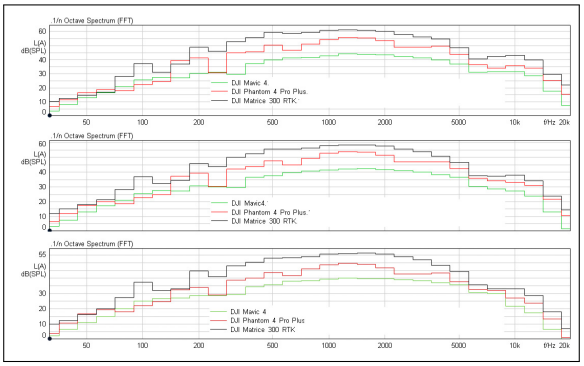

Figure 5. Octave band spectrum (A-weighted) for the three UAS at 12 m (top), 17 m (middle) and 25 m (bottom).

Since the regulations require the L_{Amax}, Tab. 2 shows the L_{Aeq}, L_{Amax} and L_{90} values for each UAS at each of the three different heights, having values between 50.6 and 71.0 dB (L_{Amax}).

Table 2. L_{Aeq}, L_{Amax} y L_{90} values for the three UAS

		12 m	17 m	25 m
DJI Mavic 4	L_{Aeq}	52.5	51.6	49.5
	L_{Amax}	53.7	52.2	50.6
	L_{90}	52.4	51.2	49.0
DJI Phantom 4 Pro Plus	L_{Aeq}	62.9	61.1	56.8
	L_{Amax}	63.8	61.9	57.8
	L_{90}	62.3	60.4	56.3
DJI Matrice 300 RTK	L_{Aeq}	69.9	67.1	64.8
	L_{Amax}	71.0	68.4	65.8
	L_{90}	69.1	66.3	64.1

Comparing Tab. 1 and Tab. 2, it can be observed that the 15 dBA difference with the background noise was not fulfilled in all cases (see Fig. 6). DJI Matrice 300 RTK, the largest of the three UAS, weighing 7270 g, is the only one that meets the 15 dBA difference requirement at all three heights (the differences for each height are: 23 dBA, 20.4 dBA, and 17.8 dBA, respectively). Therefore, this study complies with the recommendations. On the other hand, DJI Phantom 4 Pro Plus, the medium-sized UAS, weighting 1375 g, meets the 15 dBA difference at 12 m, though only marginally (16.1 dBA). At 17 m, it does not meet the requirement, despite being very close (14.2 dBA). However, at 25 m, it falls significantly short of the required difference (10.1 dBA). Finally, for the smallest UAS, the DJI Mavic 4, weighting only 249 g, the 15 dBA difference with the background noise is not met at any of the three heights (5.5 dBA, 4 dBA, and 2.4 dBA, respectively).

In Fig. 6, the difference between maximum noise level from the three UAS and the equivalent background noise for the three heights is shown.

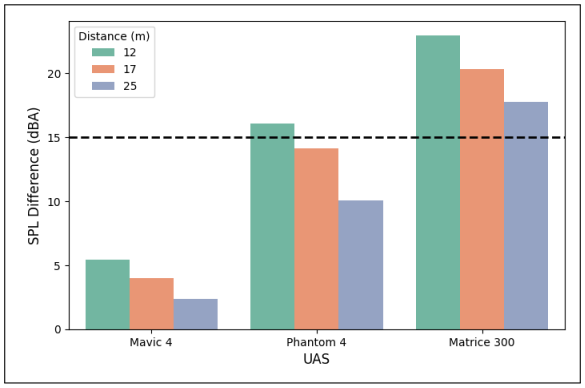

Figure 6. Difference between maximum noise level (L_{Amax}) from UAS and equivalent background noise level (L_{Aeq}). The level difference must be greater than 15 dBA to consider the run as a valid one.

6. DISCUSSION

As it is said in section 5.1 for UAS weighing less than 1.4 kg, it is very difficult to exceed the required 15 dBA difference from the background noise, even when measurements are conducted in a location outside urban areas.

For these reasons, based on this study, it is suggested EASA's recommendations to be revised. The proposed changes include adjusting the difference between maximum level from the UAS and background noise level, for UAS weighting and distance operation. It is suggested EASA's guidelines to study these limitations so it allows UAS below the black line on the Fig. 6 that have not exceed the 15 dBA difference with background noise reduce the threshold. To establish more precise limitations, additional tests should be conducted with UAS of different sizes and across a wider range of altitudes and situations. However, with the collected data,

a multiple linear regression can be established with the independent variables mass (X1) and height (X2), and the dependent variables considered as the difference between background noise level and UA maximum noise level (dBA):

$$y = 13,43747 + 0,001958X1 - 0,364728X2 \quad (1)$$

According to this, when mass increases, the difference in noise level is higher; and when height increases the difference in noise level is lower.

In order to fulfill the 15 dBA difference required, according to the regression with the collected data, a certain mass and height must me accomplished, shown in the Tab. 3:

Table 3. Mass and height requirements to fulfill the 15 dBA difference

Mass (g)	Height (m)
≤3100	12
3650	15
4000	17
5500	25

From this regression, mass below 3100 g requires less noise level difference at different heights. In Tab. 4 an example of plausible values with flights at 12 m height are presented. The same can be done for other height values, however, the intention in the present work is to highlight the variances and plausible adaptations.

Table 4. Minimum difference level for certain UA mass flying at 12 m height

Mass (g)	Difference level (dBA)
250	9
250 - 750	10
750 - 1250	11
1250 - 1750	12
1750 - 2300	13
2300 - 2800	14
2800 - 3100	14,5

Fig. 7 shows the limitations for the UAS Mavic 4 and Phantom 4 Pro Plus according to the values from Tab. 4. UAS Matrice 300 RTK is not included as it weights more than 3100 g.

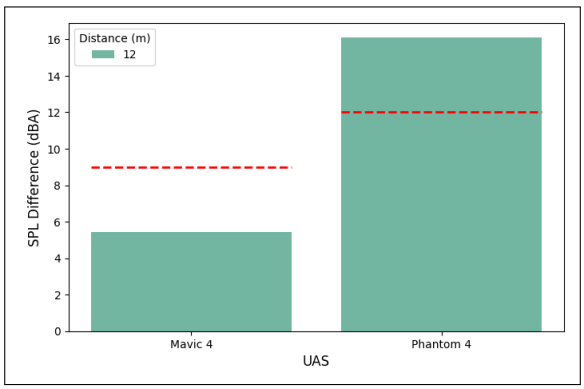

Figure 7. Difference between maximum noise level (L_{Amax}) from UAS and equivalent background noise level (L_{Aeq}) for UAS Mavic 4 and Phantom 4 Pro Plus at 12 m. The red line shows the limitations for each UAS according to Tab. 4

As it is highlighted, to establish more precise limitations, additional tests are needed, however, this work establishes a first relation between UA mass, test height, and required difference level between the background noise level (L_{Aeq}) and the UA maximum noise level (L_{Amax}).

ROTOR NOISE INTERFERENCE MECHANISMS FOR SIDE-BY-SIDE CO-ROTATING CONFIGURATIONS

ABSTRACT

This study investigates the aeroacoustic effects of phase synchronization between co-rotating propellers in side-by-side configurations. Space-time Proper Orthogonal Decomposition (POD) is applied to pressure fluctuations to separate tonal and broadband components, enabling detailed analysis of the acoustic interference phenomena. Experimental results demonstrate that synchronization significantly influences the tonal component, highlighting distinct regimes of constructive and destructive interference at different rotor phase delays. Specifically, the analysis reveals a notable reduction in noise amplitude at certain phase shifts, particularly affecting the second harmonic. An explanation of this scientific outcome is provided and illustrated schematically. Additionally, probability density functions indicate clear changes in the statistical characteristics of pressure fluctuations due to rotor synchronization, reinforcing the effectiveness of the decomposition method. These findings confirm the potential of rotor synchronization as an efficient active noise-control technique capable of achieving substantial noise reduction.

1. INTRODUCTION

U-space fosters drone integration in European airspace, yet noise pollution hinders public acceptance [1]. Studies on isolated rotor noise have intensified [2], but multirotor configurations require a broader aeroacoustic approach [1, 3, 4]. Passive noise control methods, such as serrated propeller edges, negatively affect aerodynamic performance [5], whereas active noise cancellation introduces additional weight and complexity [6]. Rotor phase synchronization emerges as a promising alternative, avoiding aerodynamic trade-offs [6]. This method manipulates rotor phase angles to induce destructive acoustic interference [7], achieving three main outcomes: noise amplitude reduction, modulation, and directivity alteration. Rotor synchronization can achieve significant noise reductions at blade passage frequency [5, 8–11], with co-rotating rotors benefiting more substantially than counter-rotating configurations [12]. Directivity modifications depend on phase differences, resulting in shifts between monopole and dipole radiation patterns [13–15]. Additionally, modulation effects introduce intermittent wave packets into pressure fluctuations [11, 14]. The present study employs space-time Proper Orthogonal Decomposition (POD) to separate the pressure fluctuation field, measured using a linear microphone array, into tonal and broadband components. This decomposition facilitates an in-depth analysis of the tonal component, typically the most annoying, offering detailed insights into the acoustic interference mechanisms between co-rotating rotors arranged in a side-by-side configuration. The paper is organized as follows. The experimental setup, instrumentation, and operating conditions are detailed in §2. Subsequently, the rotor acoustic interference phenomena are described and explained in §3. Finally, conclusions are presented in §4.

2. EXPERIMENTAL SETUP

The experiments were conducted in the Acoustic Wind Tunnel Braunschweig (AWB) optimised for noise measurements above 250 Hz. To simulate hovering conditions, the wind tunnel was deactivated during the tests. A total of 37 microphones were deployed in four non-equidistant linear arrays, with only arrays 1 and 4 used in this study. The acoustic signals were sampled at 102 kHz for 30 s per operating point. The microphone layout is illustrated in Figure 1. The setup comprised three-

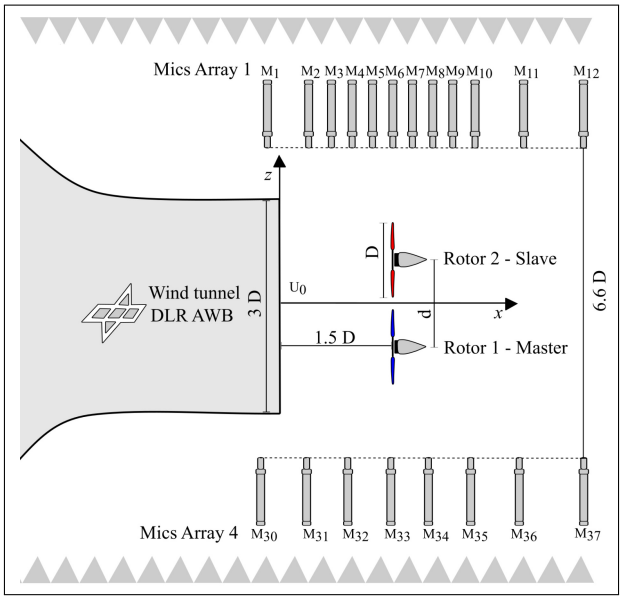

Figure 1. Microphone layout.

bladed KDE-CF155-TP propellers ($15.5'' \times 5.3$) mounted on vertical supports with adjustable spacing (d). The propellers had a diameter of 393.7 mm (D) and a mean aerodynamic chord of 28.5 mm. KDE4012XF-400 motors, controlled by KDEXF-UAS55 electronic speed controllers, powered the propellers. The two microphone arrays were positioned at $3.3D$ from the x-axis, ensuring pressure amplitudes were purely acoustic ($p' \propto 1/r$). A custom synchrophaser controlled the phase delay, $\psi(t)$, between the co-rotating rotors operating at a rotational speed $\omega(t)$. The system employed a Kübler 05.2400 incremental encoder (500 pulses per revolution) and National Instruments hardware, including an NI PXI-1031 chassis, an NI PXI-7350 motion controller, and an NI PXI-6259 multifunction DAQ. A PID controller regulated the phase shift, adjusting the slave rotor relative to the master rotor every 5 ms. The synchrophaser ensured stable rotational speeds and consistent phase differences. Experiments were conducted in hover conditions with phase differences varied in 15° increments. An inter-rotor distance was tested $d/D = 1.20$, with the rotational speed fixed at 5200 RPM. Several test cases were analysed, including an isolated rotor reference case. The blade tip Mach number was $M_{\text{tip}} = 0.31$, and the Reynolds number at 75% span was $Re_{c75} = 1.51 \times 10^5$.

3. RESULTS

The aerodynamic noise of propellers can be decomposed into two main components: tonal (narrow-band) and broadband noise. Tonal noise originates from the periodic blade motion, related directly to blade rotation speed, thickness, and aerodynamic loading. In contrast, broadband noise arises from turbulent structures and their interaction with blade edges, exhibiting random, incoherent characteristics in both space and time. The separation of these noise components is crucial for experimental analysis and validating simulations based on the Ffowcs Williams–Hawkings equation. Recent studies have introduced various separation techniques [16–19]. The space-time POD technique involves organizing collected microphone array data into limited-duration space-time fields structured into a matrix for POD analysis. The resulting modes, eigenvalues, and coefficients allow coherent and stochastic components to be separated through a truncated POD expansion. Key advantages of the space-time POD technique include ease of implementation, low sensitivity to the chosen truncation threshold and time window size, and effective performance even with relatively few microphones, aligning with common aeroacoustic experimental setups. By applying the space-time POD decomposition technique to the raw pressure data, the pressure fields were separated into tonal and broadband components. In Figure 2 the tonal component was notably smoother and perfectly in phase with the raw signal. Figure 3 illustrates the first six space-time modes, which appear pairwise. According to [20], such degeneracy, along with spatial-temporal translational symmetry, confirms the presence of travelling waves. Modes exhibit harmonic structure highlights the POD's effectiveness in isolating coherent periodic structures, aligning with harmonic orthogonal decomposition conditions discussed by [21]. Figure 4 presents the calculated Sound Pressure Spectral Level (SPSL), demonstrating that the coherent component spectrum aligns with the first three harmonics of the raw signal

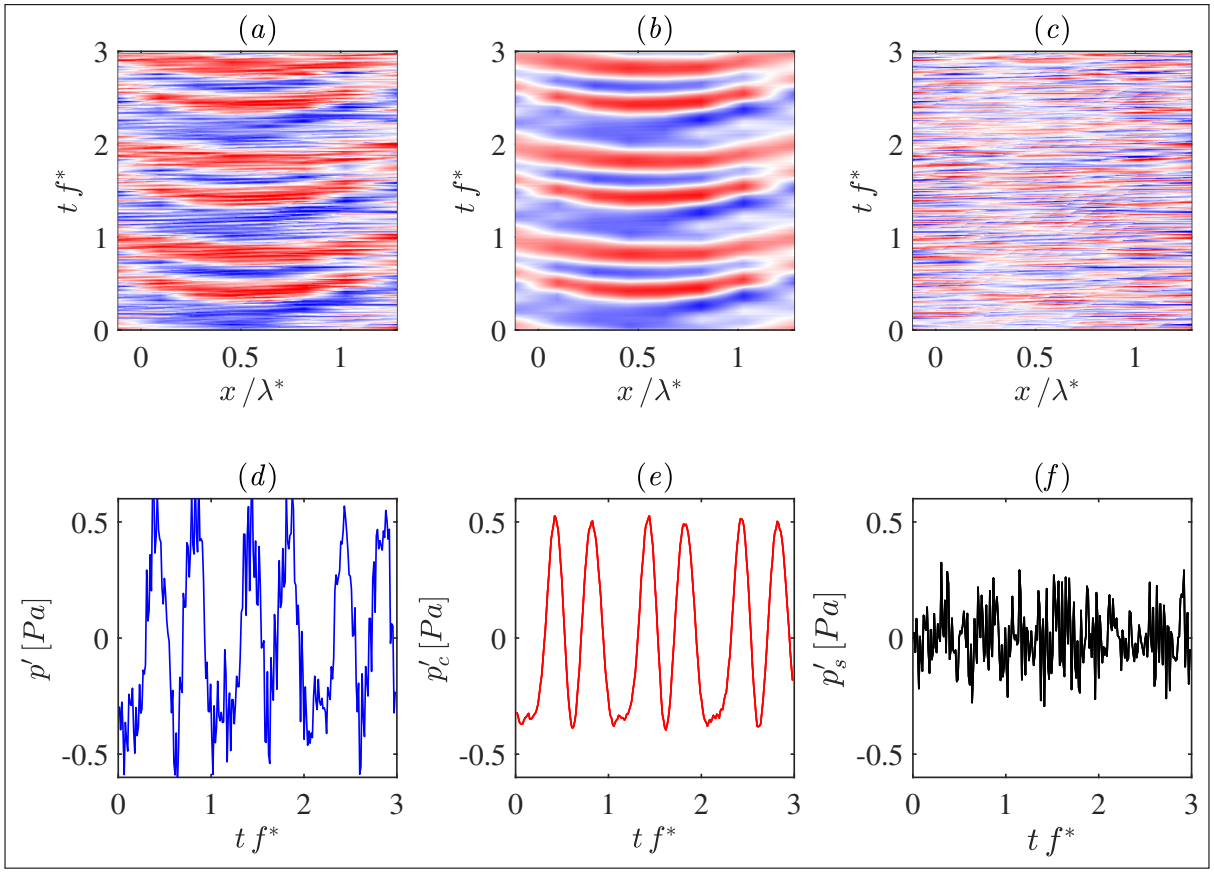

Figure 2. Input-output of the space-time POD decomposition applied to side-by-side rotor for constant phase delay $\psi = 0°$. The first column illustrates the raw data (a, d), the second column shows the tonal component (b, e), and the third column presents the broadband component (c, f). The top row represents space-time fields, while the bottom row shows a single time series at $x/\lambda^* = 0.45$, located in the rotor plane.

and remains nearly flat across the normalized frequency range $f/f^* \in [0.1, 1)$. Additionally, this decomposition technique effectively removes intermediate peaks between harmonics observed in the raw signal, distinguishing it from conventional band-pass filters. Figure 5 shows that the probability density function (PDF) of the incoherent signal closely follows a Gaussian distribution up to 3σ, confirming its stochastic nature. Conversely, the PDF of the coherent component is characterised by a bi-modal distribution, with peaks corresponding to blade passage events. These distinct PDF shapes validate the effectiveness of the decomposition technique in accurately separating tonal and broadband noise components. Figure 6 illustrates the effect of varying phase delay (ψ) between side-by-side rotors. At $\psi = 0°$ (Figure 6a), pairs of red-blue streaks appear for each blade passing period, with the delay between waves determined solely by rotor spacing. Increasing the phase delay to $\psi = 45°$ results in the alignment of compression waves from both rotors, producing constructive interference (Figure 6d). Conversely, at intermediate angles such as $\psi = 15°$ and $75°$, destructive interference occurs due to the overlap between expansion and compression waves, significantly reducing fluctuation amplitude. In Figure 7 is depicted pressure fluctuation time series showing the interference mechanism between side-by-side rotors for different phase delays (ψ). Figure 8 shows the Overall Sound Pressure Level (OASPL) for varying phase delays (ψ) between side-by-side rotors, comparing these results to the noise generated by a single rotor. This figure reveals promising findings, partic-

ularly at angles associated with destructive interference ($\psi = 15°$ and $\psi = 75°$), where the noise produced by two synchronized rotors is notably lower than that of a single rotor. Conversely, constructive interference, observed at $\psi = 45°$, significantly increases the noise level. These findings confirm the potential of rotor synchronisation in effectively reducing aerodynamic noise through controlled interference. In Figure 9, the first harmonic is notably higher under constructive interference than in other cases. Consistent with [22], the second harmonic experiences the most significant mitigation due to destructive interference as reported in Table 1. Figure 7(f) clarifies why the second harmonic is mitigated: synchronisation of compression and expansion waves cancels fluctuations, resulting in a compression-expansion wave with reduced periodicity, as depicted by the grey-coloured fluctuation. The Probability Density Function (PDF) of pressure fluctuations provides valuable insights into how pressure signals change with varying phase delays. In Figure

Table 1. Sound Pressure spectral Level of the first and second harmonics by varying the rotor phase delay.

ψ, deg	$SPSL_1\,[dB]$	$SPSL_2\,[dB]$
0	75,3	74,4
45	82,2	82,4
75	79,6	62,4

10, at $\psi = 0°$, the PDF exhibits a distinct bi-modal distribution, clearly identifying two constant-intensity pressure fluctuations (expansion and compression). At $\psi = 45°$, these peaks shift outward, accompanied by the emergence of two lower-intensity internal peaks, ascribed to installation effects. At $\psi = 75°$, the PDF is dominated by

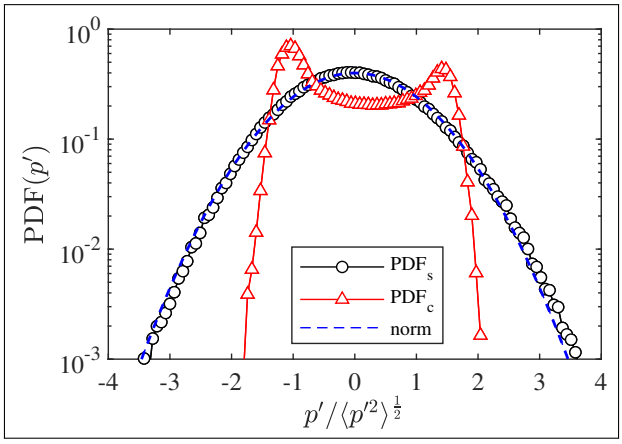

Figure 5. Probability density function of tonal and stochastic components of the pressure fluctuation.

a single expansion peak with an intensity very close to zero. This characteristic represents the acoustic footprint of noise cancellation due to destructive interference. Indeed, as illustrated in Figure 7f, the primary effect of destructive interference is the replacement of the positive-negative oscillation (see red and blue curves) with an extended sequence of values close to zero.

4. CONCLUSION

This investigation demonstrated the effectiveness of rotor phase synchronization as a passive noise reduction technique in co-rotating, side-by-side rotor configurations. Space-time Proper Orthogonal Decomposition (POD) successfully separated measured acoustic fields into tonal and broadband components, enabling precise analysis of acoustic interference mechanisms. Results revealed significant variations in noise levels due to constructive and destructive interference at specific phase angles, with notable reductions observed, particularly at second harmonic. Probability Density Function analyses confirmed clear distinctions in the statistical characteristics of pressure fluctuations, validating the decomposition technique's reliability. Overall, rotor synchronization emerged as a promising aeroacoustic control strategy, offering substantial noise mitigation potential.

INTEGRATED U-SPACE SOCIETAL ACCEPTANCE ASSESSMENT: ENERGY-BASED AND PERCEPTION-BASED ACOUSTIC METRICS

Carlos Ramos-Romero[1*] **Michael J. B. Lotinga**[1] **Antonio J. Torija**[1]

[1] Acoustics Research Centre, University of Salford, UK

ABSTRACT

Innovative Air Mobility (IAM) systems are progressing within the European U-space framework to promote efficient and environmentally friendly air transport. The ImAFUSA project contributes by developing an integrated U-space assessment tool to evaluate environmental, societal, and safety impacts.

This paper focuses on acoustic metrics for assessing environmental noise and annoyance caused by unmanned aerial systems (UAS). It explores both energy-based and perception-based indicators to evaluate UAS noise. These metrics allow the U-space noise assessment accounting for the interaction between UAS and existing soundscapes and number of events.

The IAM noise assessment tool utilises acoustic pressure time-series at listener positions, which can be generated from measurements or auralised signals. In the latter case, the integration of aircraft noise synthesis, flight-control data, and sound propagation along the flight path is potentially feasible as input for the assessment tool. This flexibility highlights the usability of the proposed metrics across diverse input types, laying the groundwork for future extensions that incorporate a broader range of data, including varied operating conditions and advanced predictive models.

Therefore, the calculated metrics would provide insightful estimations for the societal and capacity impact of U-space, potentially contributing to the strategic noise management of the UAM operations.

1. INTRODUCTION

Innovative Air Mobility (IAM) solutions are anticipated to become a transformative element in the skies close to populated areas. In addition to the benefits IAM can offer to commerce, industry, and communication activities, their presence introduces a disruptive element to urban skies, potentially impacting various societal aspects, such as affordability and accessibility of the services and vertiports.

Such developments requires the use of multidisciplinary and innovative tools for precise U-space assessment. In this context, the **ImAFUSA** [1] project, funded by the Horizon Europe Programme, is developing an integrated assessment tool aimed at evaluating the impacts of Urban Air Mobility (UAM) within U-space. The project outputs comprise innovative tools to evaluate environmental, socio-economic, and safety aspects of IAM operations, as well as to analyse their effects on U-space capacity levels.

For the U-space environmental impact assessment, noise, visual and air pollution have been considered within the ImAFUSA framework. However, the focus on noise assessment in this paper reflects the specific scope of the current work, which is dedicated to the integration and application of noise metrics. While other societal and environmental factors are also relevant for IAM integration, noise was reported as a primary concern for EU citizens, as highlighted by the EASA report in 2021 [1]. This integrated Noise assessment tool will enable easy integration in decision-making processes and interdependency studies by taking into account the interaction between the source

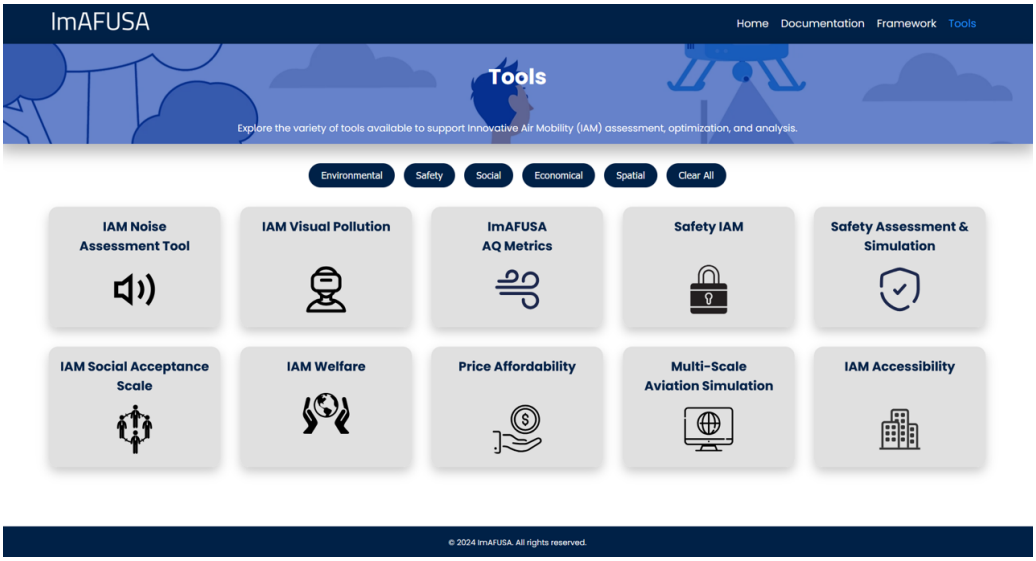

Figure 1. ImAFUSA integrated tools.

(unmanned aircraft), the environment (background noise — soundscape), and the listener (perception).

2. ASSESSMENT FRAMEWORK

ImAFUSA integrates state-of-the-art mathematical formulations and algorithms into an **Im**pact and capacity **A**ssesssment **F**ramework for **U**-space **S**ocietal **A**cceptance.

ImAFUSA focuses on assessing environmental factors such as noise, visual pollution, and air quality; safety considerations; and socioeconomic aspects including affordability, accessibility, economic development, public space utilisation, and connectivity (See. Fig. 1). By quantifying these elements through innovative performance indicators, the tool seeks to aid stakeholders in making informed and sustainable decisions, thereby promoting societal acceptance and positioning Europe as a leader in sustainable aviation.

In particular, the IAM noise assessment tool enables the evaluation of the acoustic impact of U-space use by incorporating both energy-based noise metrics and perception-based (psychoacoustic) metrics.

Expanding the analysis beyond traditional acoustic energy measures to include human perception is expected to enhance the environmental noise assessment of IAM operations. This approach allows for a more comprehensive understanding of community impact, capturing not only the additive effects of sound energy but also how noise is experienced by people in areas targeted for future IAM deployment [2].

These metrics have been extensively applied to single-aircraft and single-event operation scenarios. However, as periodicity or repetitiveness of UAM operations are expected for the potential definition of drone corridors or regular flight paths, a group of metrics should be further generated to quantify the effect of the number of flyover events and the number of people exposed along the flight paths [3]. In addition, high-order interactions between the target noise (aircraft), and masker noise (background noise), previously presented in the literature have also been integrated in the assessment framework [4].

3. NOISE ASSESSMENT METRICS

The set of metrics integrated into the IAM noise assessment tool, currently relies on acoustic pressure time-series data defined at a specific listener position. These signals can originate from various sources, including drone noise recording databases or auralised signals. From recordings, the tool can incorporate data for multiple UAS with varying sizes, take-off masses, numbers of rotors/blades, and operational variables such as altitude and speed (e.g., DroneNoise [5]). In cases where auralised signals are used, the integration of aircraft noise synthesis, operational flight control data, and sound propagation along the

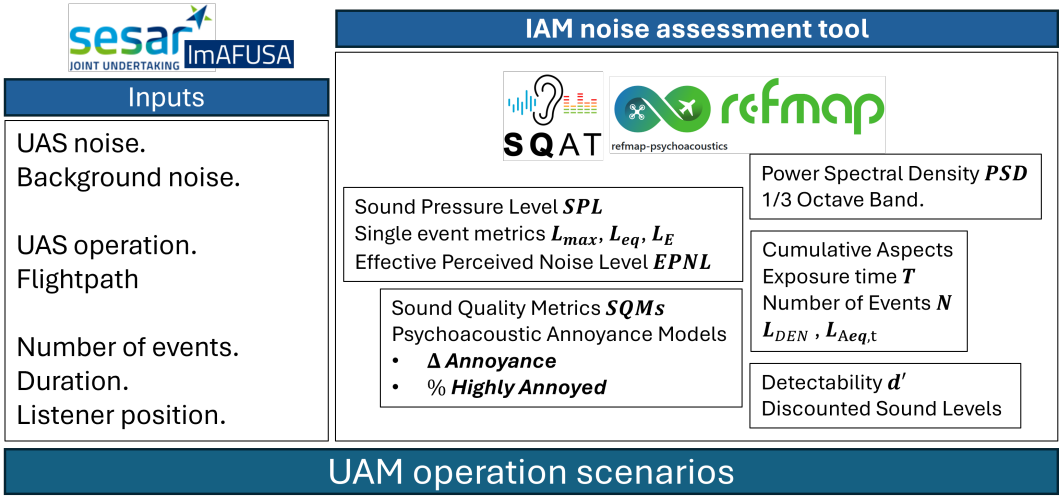

Figure 2. IAM noise assessment tool

flight path is feasible. This flexibility paves the way for future tool extensions that integrate even more comprehensive data sources, enhancing the versatility and applicability of the tool.

In addition to the aircraft noise signals, the tool also provides access to several examples of ambient sounds (e.g., EigenScape [6]). These capabilities enable a better assessment of IAM operation flight scenarios under different simulated operational conditions.

Firstly, energy-based metrics measure the acoustic intensity of the incident noise at a specific receiver point. This group of metrics has been used extensively for conventional aircraft noise assessment [7]. Secondly, the perception-based metrics evaluate the psychoacoustic effects of the sound signal on a human listener. This group of metrics considers the sound quality [8], which becomes important as the operation of IAM solutions is expected to be carried out at lower altitudes, closer to people than conventional aircraft systems [9].

The assessment tool also account for the masking effect of background environmental noise by using a discounting index. This index adjusts the acoustic metrics based on the detectability of the assessed noise source in relation to surrounding sounds. This approach includes in the analysis how much the annoyance response differs due to the non-constant prominence of the noise source in the presence of a masking sound, such as residual background noise along a flight path [4].

This ongoing project also aims to predict virtual scenarios in which more than one vehicle operates in the same urban area, and recurrent operations are expected to be carried out on an established drone path. In this regard, cumulative aspects such as exposure time and number of operations are required. Models incorporating the effects of multiple UAS events are being investigated as part of the ImAFUSA sister project, RefMap [2] [10].

To assess a UAM operation scenario, Fig. 2 illustrates the input parameters required by the IAM noise assessment tool. The inputs are the time-series data of acoustic pressure signals containing the operating source (target or UAS noise) and the soundscape where the source is expected to be operating (masker or background noise). Additional information on overflight operations will assist in the assessment of cumulative effects such as the number of operations and the number of aircraft in the flight corridor.

3.1 Energy-based metrics

3.1.1 Time-series

Sound Pressure Level SPL quantifies the wide variation in acoustic pressure from UAM operations and urban noise on a logarithmic scale in [dB]. SPL is calculated using the root-mean-square (RMS) of the pressure signal relative to a reference pressure (20 μPa). Since hu-

[2] https://www.refmap.eu The ImAFUSA and RefMap projects form the Aviation Twin Transition Cluster.

man hearing sensitivity differs from measurement devices, an A-weighting filter would be applied to better reflect perceived loudness, producing A-weighted SPL in [dBA]. As sound levels vary with source operation, time-window framing is used with exponential weighting to show SPL evolution (e.g., fast weighting: 0.125 s or slow weighting: 1 s).

Power Spectral Density PSD. represents the acoustic power distribution over frequency [11]. Spectral amplitudes are normalised by frequency resolution and expressed in [Pa^2/Hz]. Calculating power over successive time frames creates a 3D spectrogram (frequency vs. time vs. power), while averaging power over time yields a 2D plot spectrum (frequency vs. power), which also be expressed on a logarithmic scale as [dB/Hz]. PSD analysis across the full frequency range can be represented using frequency bands centred at standard frequencies f_c. Each band encompasses energy between a lower and upper cut-off frequency, with the ratio defined as $f_u = 2^n \times f_l$. An octave band corresponds to $n = 1$, where the upper-to-lower frequency ratio is 2. For greater detail, the analysis can use 1/3-octave bands, where $n = 1/3$ [12, 13].

3.1.2 Single-values

For aircraft noise emission, L_{max}, L_{eq}, and L_{E} are used to summarize the SPL evolution over time in a single value. When these metrics consider the sensitivity of the human ear, they are denoted with an A-weighting (e.g., L_{Amax}, L_{Aeq}, L_{AE}).

Maximum Sound Pressure Level L_{Amax} measures the maximum level of acoustic energy at the listener's position due to the operation of the UAM. For a flyover, it is expected to occur at the slant distance where the UAM is closest to the assessed point.

Continuous Equivalent Sound Pressure Level L_{Aeq} characterizes the time-varying acoustic event of duration T as a constant-amplitude sound, representing the averaged sound energy over the same time period.

The Sound Exposure Level L_{AE} allows for the comparison of different time-length signals by uniformly compressing their energy into a reference time T_{ref}. The total sound energy of a UAM operation is typically normalised to $T_{\text{ref}} = 1$ s. For aircraft flyovers, L_{AE} is accurately estimated by including only those sounds that lie within 10 dB of L_{Amax}. The L_{AE} increases by 3 dB if the duration is doubled while keeping the L_{Amax} value, because the energy is doubled [14].

These metrics have been extensively applied to conventional single-aircraft and single-event operation scenarios, and are still valid to evaluate IAM platforms. However, as periodicity or repetitiveness of IAM operations are expected for the potential definition of drone corridors or regular flight paths, a group of metrics should be further generated to quantify the effect of the number of flyover events and the number of people exposed along the flight paths [3].

If a series of non-consecutive overflights n_{eve}, each producing approximately the same SPL at the receiver location, occur over a given period, the cumulative sound pressure level can be estimated by accounting for the combined effect of these events. This scenario is plausible when periodic flights of the same aircraft follow the same path. The cumulative SPL_{eve} is expressed as:

$$\text{SPL}_{\text{eve}} = \text{SPL} + 10\log_{10}(n_{\text{eve}}) \tag{1}$$

This formulation captures the cumulative acoustic impact of repeated events at equal SPLs.

3.2 Perception-based metrics

Effective Perceived Noise Level EPNL was developed for assessing the annoyance characteristic of aircraft noise. It evaluates noise perception resulting from the combination of sounds from different source components, mechanisms, frequency emissions, intensity ranges, and time-series profiles. This metric is an improved version of Perceived Noise Level [14]. EPNL is calculated by measuring a sequence of 1/3-octave band spectra at 0.5-second intervals during the noise event. Each interval spectrum is examined for the presence of tones, and a tone-correction is computed to give the tone-corrected perceived noise level (PNLT). To determine EPNL, the complete set of 0.5-second PNLT values is integrated to calculate the level of the long-term steady sound.

Sound Quality Metrics SQMs are used to assess how sound is perceived by the human hearing system, considering features like tonal components, modulation effects, amplitude, and frequency [8]. These metrics evaluate subjective human sensations of sound, with a linear scale meaning that doubling a SQMs corresponds to doubling the perceived sensation. The following SQMs have been included as predictors of psychoacoustic annoyance models for UAM [15].

Loudness N is a measure of subjective sound strength, evaluated through models that account for non-linear amplitude response and critical bands. It is often considered the strongest indicator of annoyance and is measured in [sone].

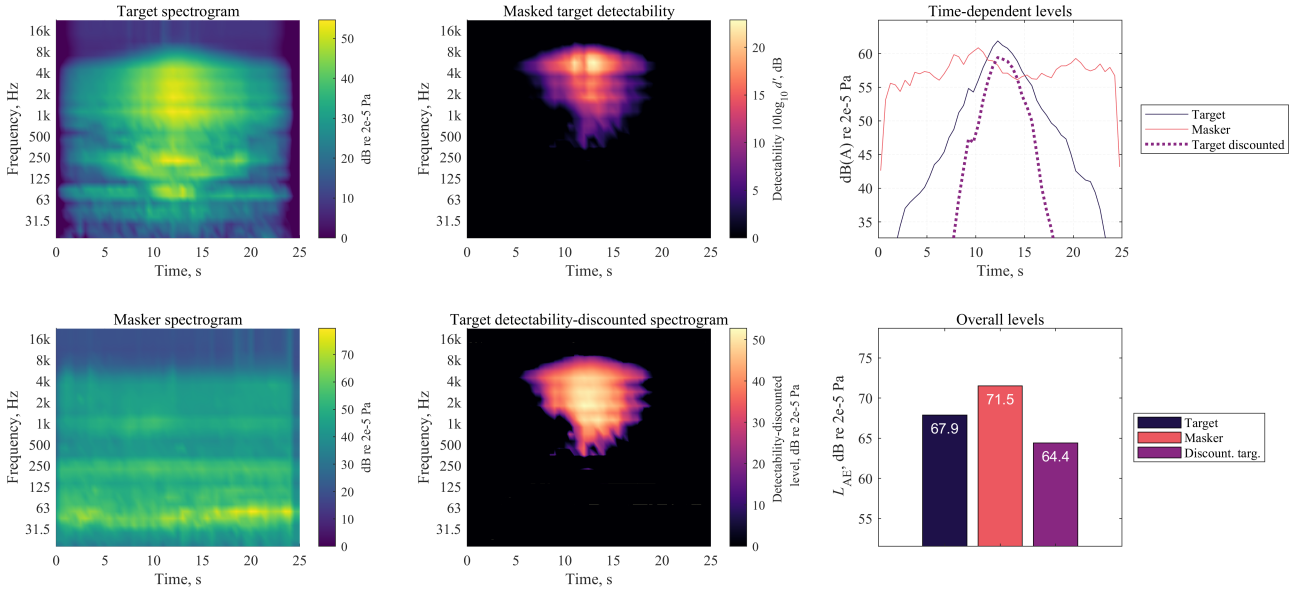

Figure 3. Example of detectability and discounting sound levels for UAS overflight (target) within urban street soundscape (masker).

Sharpness S quantifies the spectral character of a sound based on the balance between high- and low-frequency content. A sound with more high-frequency energy is perceived as sharper. It is measured in [acum].

Fluctuation Strength F assesses the perception of periodic variations in sound, comprising slow modulations (below 20 Hz, with a sensory peak ∼4 Hz) in amplitude or frequency, experienced as beating or pulsating. It is measured in [vacil].

Roughness R is similar to fluctuation strength, but it focuses on faster modulations (15-300 Hz with a sensory peak ∼ 70 Hz), causing the sound to be perceived as having a rough 'texture'. It is measured in [asper].

Tonality T evaluates the presence of pure tones or narrowband components in the sound. It tracks frequencies with salient amplitudes and is measured in tonality units [tu]. To evaluate these SQMs, computational tools have been implemented based on specific standards. The ImAFUSA toolkit integrates noise assessment algorithms developed in SQAT [16, 17] and RefMap [18].

Psychoacoustic Annoyance models use the aforementioned SQMs in non-linear models to assess annoyance. These models have shown good correlation with noise annoyance in jury tests. In one example [15], the 5% exceedance values (95th percentiles) are determined for each SQM. Other models have also been developed for UAS rotor sound [19]. These composite metrics have been found to be effective predictors for psychoacoustic annoyance assessment of UAM noise.

Detectability index d' incorporates ambient sound as a discounting factor for annoyance. Time series of 1/3-octave band power spectra are used to determine the time-dependent masking of the target source (the UAM vehicle) by the environment sound, affecting both audibility, and potentially, annoyance. To simplify the understanding of detectability, two scenarios can be considered. The first one occurs when the UAM signal is prominent over the ambient sound, i.e., it is clearly audible with no significant effect from the ambient sound on annoyance — for example, in a quiet environment. On the other hand, the second scenario involves a situation where the target sound is low compared to the ambient sound, rendering it partially masked, which may lead to a reduction in annoyance compared with the unmasked signal [4] — this scenario could occur environments with high levels of ambient sound.

The d' metric can be estimated from one-third octave band SPL data as a measure of the detectability of a signal. Then, discounted sound level metrics, which are determined from laboratory measurements of annoy-

ance responses, can be derived from the target signal detectability [20]. Fig. 3 presents an example of detectability and discounted sound levels for a UAS overflight which is masked by a urban soundscape: the first column depicts the spectrograms of the target signal (a UAS overflight, upper left panel) and the masker signal (urban street soundscape, bottom left panel); the second column shows the detectability index d' of the UAS (upper centre) in presence of the masking soundscape and the UAS discounted spectrogram (bottom centre); the third column presents the A-weighted SPL time series, with/without detectability-discounting (upper right) and overall A-weighted sound exposure levels, with/without detectability-discounting (bottom right). In the example, the UAS L_{AE} of 68 dB within the ambient sound of 72 dB L_{AE} (in this case, 58 dB L_{Aeq}) is discounted by 3.5 dB.

4. CONCLUSIONS

This document presents the structure and metrics of the IAM noise assessment tool, developed within the framework of the ImAFUSA project. While this work primarily focuses on acoustic impact evaluation, it is designed to be part of a broader set of U-space assessment indicators, including societal acceptance, safety, and environmental impacts. By combining both energy-based and perception-based acoustic metrics, the IAM noise assessment tool aims to support more accurate predictions of community noise impact and contribute to comprehensive capacity assessments for future Urban Air Mobility (UAM) operations within U-space.

ABSTRACT

To effectively integrate drones into densely populated urban infrastructures, it is crucial to assess their impact on the population's quality of life and mitigate any adverse effects. As noise pollution from drone overflights is a top concern, enhancing our numerical capabilities for predicting VTOL aircraft noise in urban environments is essential.
To achieve this goal, we have developed an integrated toolchain comprising three key components: Flight Mechanics, to accurately model aircraft behavior; Noise Emission at the Source: to quantify the noise generated by the drones and finally Urban Environment Noise Propagation using the open-source tool NoiseModelling.
This comprehensive toolchain enables the creation of detailed noise maps for specific drone scenario definitions.
This paper presents an application of our toolchain in a parcel delivery scenario, featuring DJI Matrice 600 drones operating over a 10 km² sector of Madrid in Spain within a day period, incorporating five distribution centers with varying hourly capacities. The results include a range of informative noise indicators, taking into account noise level, number of flyovers and background noise levels.

Keywords: *drone fleet noise, noise source modeling, urban propagation, parcel delivery, indicators*

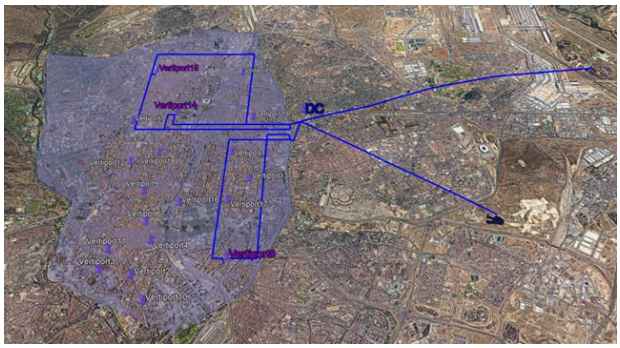
1. INTRODUCTION

Urban Air Mobility (UAM) concepts, particularly those involving Vertical Take-Off and Landing (VTOL) aircraft, are increasingly being explored for applications such as passenger transport, medical logistics, and parcel delivery. As these operations move from theoretical frameworks to real-world implementation, ensuring that they integrate seamlessly into existing urban infrastructures has become a critical research and policy objective. Recent research has proposed a comprehensive U-Space Social and Environmental Performance Framework to assess the broad spectrum of Urban Air Mobility (UAM) impacts on citizens' quality of life, identifying key focus areas such as noise, visual pollution, privacy, equity, emissions, and public safety, and defining corresponding performance indicators for their evaluation [1].
Among the primary concerns associated with drone operations in urban environment and their potential impact on the quality of life of city residents, the focus of this research is on noise pollution. Consequently, the ability to model, predict, and manage noise generated by drones is essential for fostering public acceptance and informing regulation. To address these challenges, we have developed an integrated toolchain that combines three key components: (1) Flight Mechanics, which accurately models aircraft behavior; (2) Noise Emission at the Source, which quantifies noise generated by the drones; and (3) Urban Environment Noise Propagation, using the open-source tool NoiseModelling. This research presents an application of our toolchain in a parcel delivery scenario for the city of Madrid, in Spain, during a single day.
The paper is structured as follows: Chapter 2 describes the noise calculation tool. Chapter 3 defines the parcel delivery scenario. Chapter 4 presents the noise results, while Chapter 5 concludes the paper and outlines future work.

2. NOISE CALCULATION TOOL

The main structure of the noise calculation chain was presented in [2]. Once a drone fleet scenario is defined (by the consortium partner UPC), the ONERA in-house flight mechanics tool DynaPyVTOL [3] calculates all drone and propeller data that are necessary for the aircraft to comply with the target trajectories and velocities. These data (propeller thrust and RMP, vehicle orientation etc.) are used for the noise emission calculation tool CARMEN [4][5][6] that calculates at each time step along the mission trajectory the main noise sources; in this case propeller noise. Each resulting noise sphere is then combined in a traffic pattern by the UGE NoiseModelling urban propagation tool [7], and the main noise indicators are calculated (see [1]).

In the following, a DJI Matrice 600 type is used for calculation. The main noise source on this type of aircraft is propeller noise. For the purposes of this case study, the analysis focuses exclusively on tonal noise contributions. This deliberate scope limitation is driven by two key considerations: computational resource constraints and negligible omission error. Indeed, preliminary estimates indicate that omitting broadband noise components would introduce an error of negligible effect on the overall outcome, thus not significantly impacting the study's conclusions. This applies to our specific case study, but cannot, in any case, be generalized.



3. PARCEL DELIVERY SCENARIO

Mainly two types of drone usages were considered: parcel delivery and emergency delivery. Although emergency scenarios are very interesting for featuring access and equity indicators, they constitute only a minor fraction of future daily drone flights. For noise impact considerations the parcel delivery scenarios are much better suited, given that we are at liberty to set up as many distribution centers as we want, located all over the city and furthermore, deliveries are done to individuals all over the city and are not necessarily limited to fixed destinations such as hospitals.
After analyzing habits of already existing delivery hubs and taking into account results of the SESAR Metropolis 2 project [8], the consortium chose to set up five distribution centers, four located around the city center and one within. These distribution centers are configured to handle identical traffic volumes and rates, with two exceptions: one center is situated near a no-fly zone, and another is located in a sparsely populated area, each with adjusted traffic considerations.
A more detailed description of how these choices were made will be presented in further associated publications.

Two types of concepts of operations (ConOps) are considered: free route and constrained airspace. While the free route scenario links delivery hub and destination in the shortest possible way, the constrained airspace uses a free route when outside of the city center but follows a grid based network when inside the city limits (Fig. 1).

a)

b)

Figure 1. Two types of ConOps: a) free route, b) constrained airspace

One main difference between the two ConOps types has a noticeable impact on noise maps. While the free route drone altitude roughly follows the terrain, the constrained airspace presents four layers of flight altitudes. Those are calculated based on the highest point of the mission, leading to locally very important source – receiver distances (see Fig. 2 for one mission example).

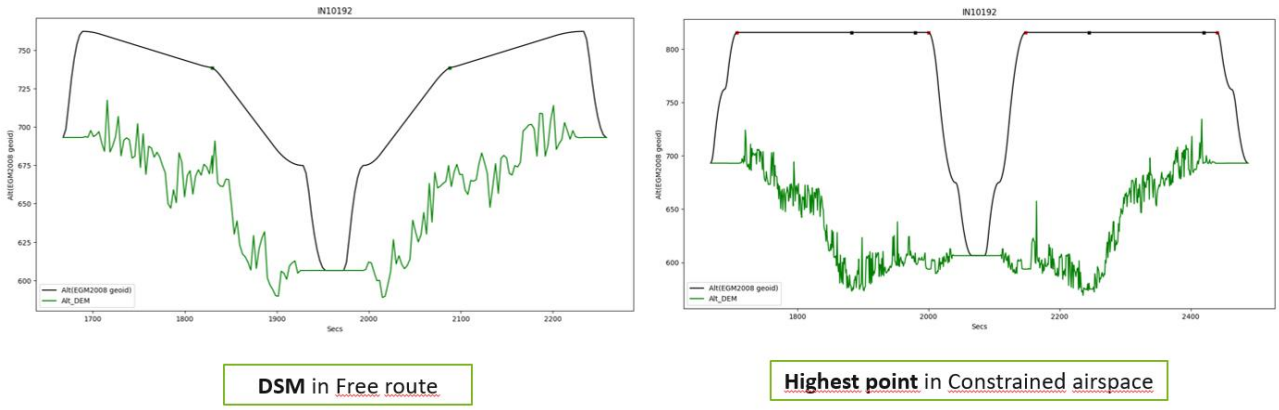


Figure 2. Reference for altitude in two ConOps

Mean height values are around 69 m for free route, and 125 m for constrained airspace, leading to enhanced propagation distances and variable ray paths in the urban environment.
All flight scenarios of the project were calculated by Polytechnic University of Catalonia (UPC) with their tool GEMMA [9].
In the cases presented in this paper, a mean flight frequency of 60 flights per hour (fph) is considered. This number is adapted to time of the day, i.e. one encounters more flights during late afternoon than in the morning for instance (see Fig. 3).

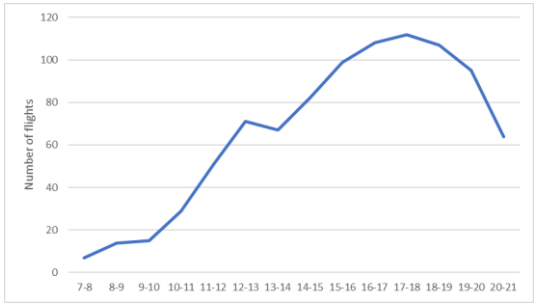

Figure 3. Operations per hour across the day in the area of interest

Lower flight frequencies have been evaluated as well, but are not presented here.
In order to assess the Performance Framework indicators (see [1]), we choose a specific of area of interest, covering a 5.9 km*1.7 km area in Madrid, that includes key elements such as residential areas, recreational zones, restricted locations (e.g., the Royal Palace in purple), and hospitals (see Fig. 4).

Several drone types are considered, which are most suitable for delivery and emergency operations. As explained in chapter 2, only one type is used in the parcel delivery scenarios that serve for noise indicator assessment: a DJI Matrice 600 that has a maximum take-off weight of 15.5 kg and 6 propellers equipped with 2 blades of approximately 0.5 m diameter.

4. NOISE RESULTS

Noise maps were calculated over the whole day for two ConOps (free route and constrained airspace) with varying flight numbers (60/40 fph). For visualization purposes only small time extracts are shown in this paper. Future analyses, scheduled for the upcoming months, will delve deeper into daily patterns and pinpoint locations yielding unforeseen results, providing a more comprehensive understanding.
In the following, two periods of day are considered: 9:00 – 9:15 am and 5:00 - 5:15 pm. These intervals are chosen for their variety in flight numbers (see Fig. 3 and Fig. 4). The only vertiport located inside the area of interest is in the upper part, centered.

Several noise metrics were calculated, including L_{Aeq}, L_{Amax}, ASEL, TA, NA and others.

Figure 5 shows L_{Aeq} noise maps integrated over a 15 minutes period for a morning and an afternoon period for a free route scenario, translating directly into a noise map the trajectory representation of Fig. 4. Noise levels depend on the number of drones, globally leading to a higher impact for the citizen on the afternoon. However, at a finer level of detail the precise flight altitude, urban architecture and the terrain have a non-negligible influence on the noise maps. A

quantification of each parameter's impact on noise levels on the ground needs to be done.

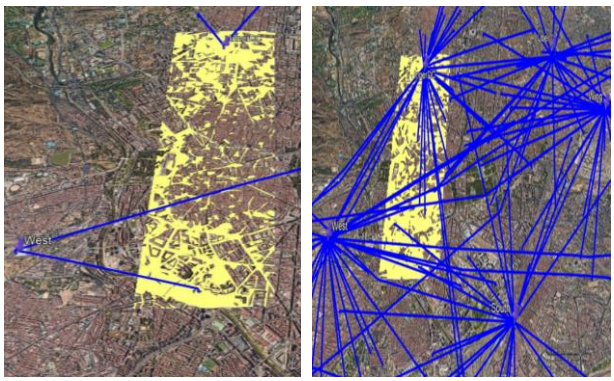

Figure 4. Drone traffic over 15 minutes: morning period (left), afternoon period (right)

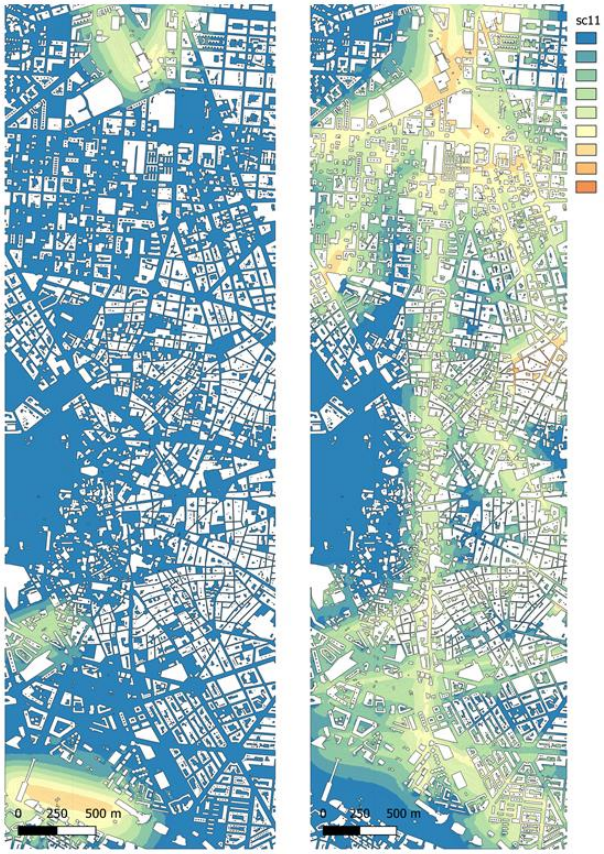

Figure 5. $L_{Aeq,15\ min}$ [dBA], free route : morning period (left), afternoon period (right)

Absolute noise levels are not shown for several reasons. Noise levels depend greatly on drone type and their flight configuration. In this test case the DJI Matrice 600 is equipped with propeller that have only 2 blades and rotate with relatively low rotation frequencies. This leads to extremely low frequency tonal noise content, to which the human ear is not well adapted and hence cannot hear very well. This is well translated by A-weighting filters. This configuration can be considered fortunate for the population since first psychoacoustic studies show that sharpness might be an important contributor to noise annoyance [10][11], and in general low frequencies are better masked by broadband urban background noise.

However for methodology demonstrations, levels are very limited. Other drone types with other propellers would have led to higher noise levels (either due to higher noise emission or higher, and hence less filtered, frequency content).

Another point is that, notably, the 15-minute integration period stands in contrast to commercial aviation norms (being relatively short) and drone flyover durations (being comparatively long), warranting further discussion on its applicability.

This "long" time integration also flattens out a lot L_{Aeq} values when only few drones overfly the receivers during the given time period.

Figure 6 shows a comparison of the two ConOps during the afternoon period. Changing the route type from free route to grid based necessarily implies that different sectors will be overflown. This will have consequences on the number of people exposed, when combining noise and population density. For noise considerations alone, the main impact will come from the difference in flight height as seen in the example of Fig. 2. Since mean flight heights are much higher for the grid based scenario, noise levels could be expected to be lower at receiver positions, since drone-receiver distances increase. However, the area of interest comprises densely built areas; the sound rays therefore encounter many buildings and are partially masked to the receivers. At higher altitudes rays propagate freely, without obstacles, towards the receivers. Contour maps for the grid based scenario are hence often more widespread than for the free route scenario where drones fly lower and are masked by the buildings (see Fig. 6).

In general, more detailed analyses are necessary for assessing what is the exact cause of increased or decreased noise levels: drone number, change in route, presence of buildings, flight height etc.

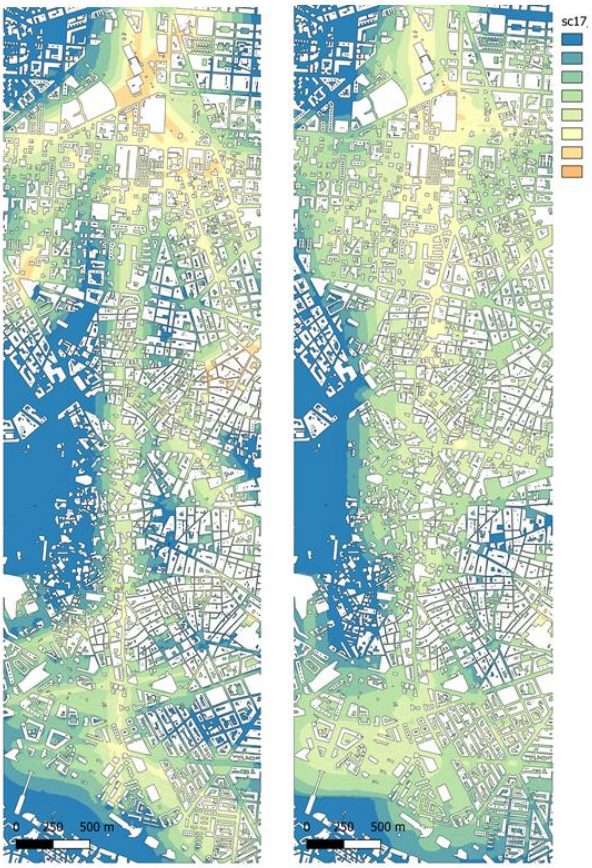

Figure 6. $L_{Aeq,15\ min}$ [dBA], afternoon : free route (left), grid based (right)

5. CONCLUSION

In the MUSE project, we enhanced a noise calculation toolchain to account for drone fleet scenarios, applying it to a parcel delivery case study in a Madrid area, Spain. Scenario types varied in route pattern, flight altitude, flight number etc. In this paper some results are shown for fleets composed of DJI Matrice 600 drones in different configurations, leading to interesting analyses with regard to flight height impact, importance of background noise and choice of drone type.

This work will be developed further in upcoming publications, with more detailed investigations of the impact of flight number per hour (20 / 40 fph) and impact of the considered hour of the day and hence varying number of flights and number of exposed people. Additionally, a more thorough discussion about the employed metrics and indicators will be led. These studies will refine our understanding of drone operations' noise effects, informing strategic decisions in aerospace.

6. ACKNOWLEDGMENTS

The authors acknowledge the MUSE consortium members who contributed to the creation of the scenarios and the discussion about noise indicators, i.e Miguel Baena, Marta Alonso and David Mocholi (NOMMON), Cristina Barrado (UPC), Emir Ganic and Tatjana Krstic (FTTE), Antoine Masse and An Vo Quang (IGN-FI).

THE EFFECTS OF TIME-VARIANT CHARACTERISTICS OF UNMANNED AIRCRAFT SYSTEM NOISE ON REPORTED ANNOYANCE

Zuzanna Podwinska[1*] **Carlos Ramos-Romero**[1] **Marc Green**[1]
Antonio J Torija[1]
[1] Acoustics Research Centre, University of Salford, UK

ABSTRACT

Flight missions of Unmanned Aircraft Systems (UAS) are inherently unsteady due to the complex interactions between the environment (e.g., wind conditions) and the operative flight control system. These interactions result in the unsteadiness of the acoustic footprint, which affects psychoacoustic attributes even during apparently stable operations like hovering. This study investigated how time-varying characteristics of noise produced by hovering multi-rotor UAS affect human annoyance ratings. An in-house framework for synthesis and auralisation was applied to generate a corpus of UAS noise stimuli. The synthesis method allowed the modification of time-variant attributes of both the tonal and broadband components by altering frequency and amplitude modulation parameters. The stimuli were evaluated in a listening experiment in which participants were asked to rate their short-term annoyance in a relative magnitude estimation task. An analysis with mixed-effects linear models revealed that higher modulation depth and lower modulation frequency resulted in sounds rated as more annoying. Additionally, modulation parameters changing over time, particularly aperiodic modulation functions and signals with non-zero slope, produced less annoying sound than constant parameters. Overall, the results emphasise the importance of time-varying characteristics of sound for reported noise annoyance, with potential implications for flight control optimisation of UAS for lower noise annoyance.

1. INTRODUCTION

Since Unmanned Aircraft Systems (UAS) have started gaining interest as a novel resource for transportation systems, their potential contribution to changing the soundscape in populated environments has also emerged as a key topic in environmental acoustics and psychoacoustics. The UAS manoeuvring capabilities allow for rapid changes in flight profile, where integrated control systems (e.g., a proportional–integral–derivative controller) automatically regulate the rotational speeds of electric motors for safety requirements and adapt the operation to sudden changes in environmental conditions (e.g., wind gusts) [1]. These temporal variations in UAS operational conditions are also expected to affect the time-variant characteristics of the emitted noise, which subsequently can affect the response to the noise in affected populations.

This paper studies the potential effect of the time-variant characteristics of UAS noise that might contribute to annoyance ratings during hovering operations. UAS sound synthesis techniques were utilised to generate a corpus of stimuli. This approach allows for inducing time-variant characteristics regarding modulation in both amplitude and frequency over time in a controlled manner [2]. The perceived annoyance of the stimuli was tested in a laboratory listening experiment using relative magnitude estimation, and the relationship between the time-variant features and the reported levels of annoyance was studied.

2. METHODS

2.1 Stimuli

UAS sounds of hovering manoeuvres for two quadcopters were synthesised using additive methods [2]. The vehicles were a DJI Matrice 300 RTK [3] (referred to here as 'M3') which is a medium-size UAS, and a XAG P40 [4]

(referred to here as 'X1') which is a large-size UAS. The sounds consisted of a tonal component and a broadband noise component. The tonal component was expressed as a linear combination of tones tuned to the shaft frequencies, blade-passing frequencies (BPFs), and a corresponding set of harmonics of each rotor. In this study, the first 15 harmonics were considered a representative contribution of the tonal component. The broadband noise component was generated by filtering Gaussian white noise. The applied filter mimics the frequency response of the moving-media filter applied to the noise spectrum of a hovering recording [2]. To manipulate the time-variant characteristics of the generated sound in a controlled manner, modulation parameters for both amplitude and frequency are included in the model.

Amplitude modulation (AM) of the broadband component is controlled by the modulation depth m and an AM function which simulates interaction of two pair of propellers spinning at slightly different RPMs, defined as:

$$AM = (\sin(2\pi BPF_{max}t) + \sin(2\pi BPF_{min}t))/2 \quad (1)$$

where BPF_{max} and BPF_{min} were obtained by peak detection in the BPFs region of the recorded spectrum.

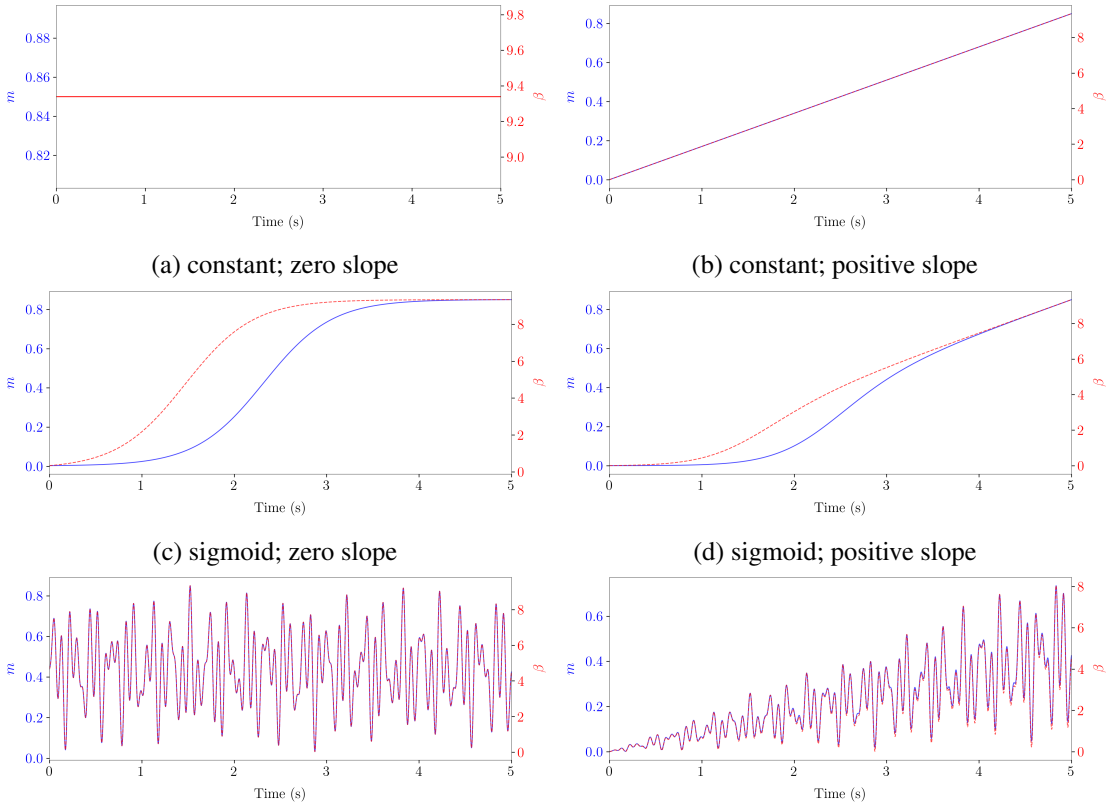
Frequency modulation (fm) of the tones is included in the model to simulate temporal fluctuations of each tone. In this regard, the frequency modulator considers two cases of how fast the tone fluctuates (i.e., high and low modulation frequency). This approach aims to simulate scenarios of instabilities on the motor controller systems as rapid (fm_{high}) or slow (fm_{low}) fluctuations in the RPMs, with resultant variations of tonal frequencies. In this study, the values for the modulator frequency are related with the detected BPFs and number of rotors n_{rotors} as:

$$fm_{low} = (BPF_{max} - BPF_{min})/n_{rotors} \quad (2)$$

$$fm_{high} = (BPF_{max} - BPF_{min}) \times n_{rotors} \quad (3)$$

The final parameter in the modulated tonal component is the frequency modulation index β, which is the ratio between the peak frequency deviation Δf and the frequency of the modulating signal fm. In this paper, the maximum frequency deviation of each tone was settled as constant $\Delta_f = 2.8$ to avoid over modulation.

Because of the differences in BPFs of the two simulated UAS, the high and low frequency modulation values were different for each vehicle. The low fm value was 4.8 Hz for M3 and 2 Hz for X1, while the high fm value was 77 Hz for M3 and 32 Hz for X1.



The modulation parameters described before (m and β) can remain unaltered throughout the signal duration, which is the case for an ideal stable flight hovering operation. However, to add time-variant features to the modulation parameters, two other variables have been included. The first one is the "slope", which indicates a potential increase (positive slope) of m and β over time. The second variable is the time varying profile (TVP) ("constant", "aperiodic", and "sigmoid"). The "constant" TVP means either no change over time (Fig. 1a) or a linear increment of the modulation variable over time (Fig. 1b). The "sigmoid" TVP (Fig. 1c and 1d) describes changes in modulation parameters that exhibit a sigmoid evolution over time, where minimal modulation occurs initially, followed by a rapid increase, culminating in the maximum modulation effect towards the end of the sound. The "aperiodic" TVP (Fig. 1e and 1f) induces changes in modulation variables driven by a function that introduces non-repeating variations in the constant modulation of amplitude and frequency factors Mf_{max} (m or β) (see. Eq. 4). The function comprises a sum of sinusoidal components with non-harmonic frequencies scaled by a modulation rate coefficient Q, which reflects environmental variability such as wind speed.

$$Mf(t; Mf_{max}, Q) = Mf_{max}\big[1 + \sin(2Qt) + \sin(2\pi Qt) + \sin(-2eQt)\big] \quad (4)$$

The resulting test matrix for stimuli generation is shown in Tab. 1, the rows of which correspond to the experimental variables used in the study. Note that for stimuli with a positive slope, their fm and m experimental variable values correspond to the maximum value of the slope.

Table 1: Time-variant characteristics

	M3	X1
FM frequency fm	low (4.8 Hz), high (77.03 Hz)	low (2 Hz), high (32 Hz)
AM depth m	0.4, 0.85	
Time varying profiles	constant, aperiodic, sigmoid	
Slope	none, positive	

(a) constant; zero slope

(b) constant; positive slope

(c) sigmoid; zero slope

(d) sigmoid; positive slope

(e) aperiodic; zero slope

(f) aperiodic; positive slope

Figure 1: Slope-shape variability for m and β.

2.2 Experimental procedure

The listening experiment was carried out in an acoustically-treated room. Participants were seated in the middle of the room and listened to the stimuli being played from a PC running a test interface created in MATLAB and connected to the loudspeaker via a RME MADIface XT USB interface.

A total of 50 5-second synthesised stimuli were used in the experiment. They were all A-weighted RMS normalised and the playback level was set to 65 dB(A). Participants were asked to listen to each stimulus and rate it on perceived annoyance using relative magnitude estimation. A reference sound was given which was a recording of the simulated UAS (either M3 or X1). The participants were asked to arbitrarily rate the test sound, assuming the reference sound was 100 on the annoyance scale. No lower or upper limits of the annoyance scale were given. The responses were provided by writing a number in an input field using a keyboard.

Each participant listened to and rated all of the stimuli, which included all combinations of the experimental variables: vehicle, amplitude modulation depth, modulation frequency, time varying profile and slope.

3. DATA ANALYSIS

Before any further analysis, participant ratings were normalised by subtracting 100 from the rating and then dividing by the difference between each participant's maximum and minimum rating. The limits of the rating scale were not given by experimenters, therefore participants were free to use their own estimate of range for rating the stimuli. The normalisation gives us a scale limited between -1 and 1 and allows us to interpret each rating with relation to each participant's individual scale. It also represents stimuli rated as more annoying than the reference as positive,

and less annoying than the reference as negative.

Then, the effects of the independent variables described in section 2.1 on the ratings were analysed using mixed-effects linear models. Participant ID was set as a random effect and the experimental variables as fixed effects. The interaction between vehicle and other variables was added to test if the choice of UAS model included in the experiment influenced the ratings. Additionally, the interaction between time varying profile and slope was included, as the combination of these two variables resulted in six distinct ways in which the modulation parameters could change (see Fig. 1). All statistical analysis was conducted in R, using packages lme4 [5] for fitting mixed linear models and emmeans [6] for calculating contrasts and marginal means.

To investigate the effect of the experimental variables on psychoacoustic metrics, the stimuli were recorded on a single measurement microphone in the middle of the room where the experiment was carried out, with a sampling rate of 48 kHz. A number of time-varying psychoacoustic metrics were then calculated from the recordings using Head Acoustics ArtemiS SUITE [7,8] and the SQAT Matlab toolbox [9]. Tab. 2 lists all the calculated metrics along with the corresponding window size. For statistical analysis, the first 1 s and last 1.5 s of all time-varying metrics except Fluctuation Strength were removed to avoid artefacts. For Fluctuation Strength, the first 4 seconds had to be removed and only the section of the file 1 second after that was stable enough to be included in the analysis. The 5th percentile values (the values exceeded 95% of the time) were calculated for each metric to represent each stimulus in the statistical analysis. These values were analysed with a Principal Component Analysis (PCA) using the FactoMineR package [10] in R. The data used in the PCA was scaled to unit variance.

Table 2: Psychoacoustic metrics used in the analysis

Metric	Source	Window size (ms)
Fluctuation Strength	ArtemiS	17.4
Impulsiveness	ArtemiS	0.9
Loudness DIN	ArtemiS	2.7
Loudness Hearing Model	ArtemiS	5.3
Loudness ISO 532-3	ArtemiS	1.0
Roughness	ArtemiS	20.0
Sharpness DIN	ArtemiS	2.7
Sharpness DIN/Aures	ArtemiS	2.7
Sharpness ISO 532-3/Aures	ArtemiS	1.0
Tonal Loudness	ArtemiS	5.3
Tonality Hearing Model	ArtemiS	5.3
Tonality Aures	SQAT	80

4. RESULTS

4.1 Annoyance ratings

41 participants took part in the experiment, recruited from University students and staff. The response range before normalisation varied significantly, with some participants using only values close to 100 (e.g. 98-112), and others a much wider range of values (e.g. 58-500). This confirms the need for normalising the data. All analysis results below are based on normalised ratings.

Tab. 3 shows the ANOVA table for the fitted mixed-effects linear model. UAS model as well as both modulation parameters (m and fm) were statistically significant variables. There was also a statistically significant interaction between the variables governing how modulation parameters changed over time: time-varying profile and slope. There was no significant interaction between the vehicle model and any of the other variables.

Table 3: ANOVA table for annoyance ratings

Variable	df	F value	p.value	
vehicle	1, 1996	4.00	0.046	*
m	1, 1996	90.24	<0.001	***
fm	1, 1996	319.25	<0.001	***
TVP	2, 1996	51.18	<0.001	***
slope	1, 1996	215.19	<0.001	***
vehicle × m	1, 1996	3.27	0.071	
vehicle × fm	1, 1996	0.43	0.510	
vehicle × TVP	2, 1996	1.37	0.254	
vehicle × slope	1, 1996	2.54	0.111	
TVP × slope	2, 1996	9.12	<0.001	***

Signif. codes: '***' <0.001, '*' <0.05

Tab. 4 shows a post-hoc contrast analysis for the significant variables and interactions. Annoyance ratings were significantly different between the two tested vehicles, with the X1 rated as slightly more annoying than the M3 ($MD = 0.02, p = 0.046$). Higher annoyance ratings were also found in response to high amplitude modulation depth m compared to low m ($MD = 0.09, p < 0.001$) and low fm versus high fm ($MD = 0.16, p < 0.001$). Overall, a positive slope of change was associated with less annoyance than zero slope (all $p < 0.001$) and this

difference was the largest for the constant time varying profile ($MD = 0.19$). The aperiodic profile was also consistently less annoying than the other profiles (all $p < 0.01$). Fig. 2 illustrates this interaction.

Table 4: Contrast analysis for annoyance ratings

Variable	Contrast	Estimate	p.value
vehicle	X1 − M3	0.02	0.046
m	0.85 − 0.4	0.09	<0.001
fm	low − high	0.16	<0.001
Slope			
TVP: constant	none − positive	0.19	<0.001
TVP: sigmoid	none − positive	0.10	<0.001
TVP: aperiodic	none − positive	0.11	<0.001
TVP			
slope: none	constant − sigmoid	0.10	<0.001
	constant − aperiodic	0.15	<0.001
	sigmoid − aperiodic	0.05	0.005
slope: positive	constant − sigmoid	0.02	0.618
	constant − aperiodic	0.07	<0.001
	sigmoid − aperiodic	0.06	0.001

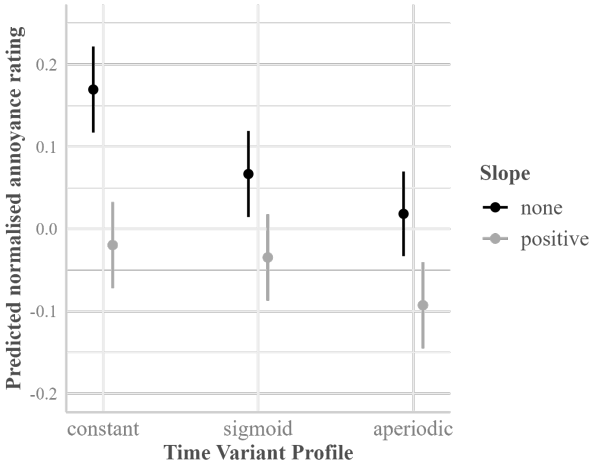


Figure 2: Marginal means calculated from the LMM model for different combinations of the slope × TVP interaction.

4.2 Psychoacoustic metrics

The psychoacoustic metrics were analysed with a PCA. The first 3 components were chosen for further analysis based on eigenvalues being larger than 1. The chosen number of components also corresponds to the most significant decreases in the scree plot gradient (just above the "elbow", see Fig. 3). Together they explain 91% of the variance in the data.

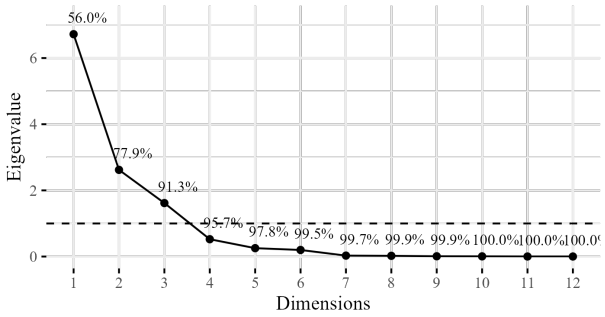

Figure 3: PCA scree plot. Labels show the cumulative variance explained for each additional principal component.

Tab. 5 shows the loadings of all variables on the three principal components. The first component is driven by a number of psychoacoustic metrics. It is positively correlated with Sharpness DIN, Fluctuation Strength and Tonality, and negatively correlated with Loudness ISO, Loudness DIN, and Sharpness ISO. The second component seems to be driven largely by the Loudness HM, but also by Aures Tonality, and to a smaller extent by Roughness, Impulsiveness, and Fluctuation strength. The third component is largely driven by Roughness and Impulsiveness, and to some extent by Aures Tonality. Fig. 4 shows the coordinates of the psychoacoustic metrics in the first two principal components.

Annoyance ratings were added to the PCA analysis as a quantitative supplementary variable. The square cosine metric was calculated between the annoyance ratings and principal components as a measure of their correlation. The correlation was high with PC2 ($cos^2 = 0.71$) and low with PC1 ($cos^2 = 0.006$) and PC3 ($cos^2 = 002$). Fig. 4 shows the projection of annoyance ratings on the 1st and 2nd PCA dimensions. To confirm that annoyance ratings were only related to PC2, a linear regression model was fitted with the annoyance ratings as the outcome variable and the first 3 principal components are predictors. Indeed, only the second component was a statistically significant predictor of annoyance ($\beta = -0.07, SE = 0.006, p < 0.001$).

Table 5: PCA loadings of the variables (psychoacoustic metrics)

Variable	PC1	PC2	PC3
Fluctuation Strength	0.26	−0.32	−0.07
Impulsiveness	−0.17	−0.34	0.55
Loudness DIN	−0.38	0.04	0.01
Loudness HM	−0.12	0.53	0.20
Loudness ISO	−0.38	0.10	−0.01
Roughnes	−0.04	−0.34	0.64
Sharpness DIN	0.37	−0.12	−0.01
Sharpness DIN/Aures	0.33	−0.16	−0.03
Sharpness ISO/Aures	−0.38	0.01	−0.05
Tonal loudness	0.33	0.29	0.13
Tonality HM	0.32	0.29	0.23
Tonality Aures	0.11	0.40	0.40

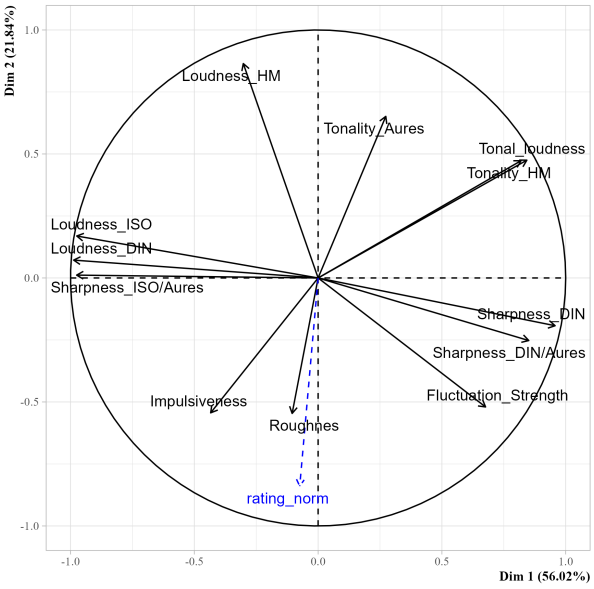

Figure 4: PCA variable plot. Each arrow represents the PC coordinates of one of the variables (psychoacoustic metrics). The dashed blue arrow shows normalised annoyance ratings plotted as a supplementary variable.

To explore the relationship between the psychoacoustic metrics and the experimental variables, the latter were added to the PCA results as qualitative supplementary variables. Tab. 6 illustrates the correlation between these variables and the principal components. The first component has a 99% correlation with vehicle type, indicating it is entirely driven by the difference between vehicles. The second component exhibits significant correlation with all variables except vehicle, while the third component shows significant correlations with fm, m and time varying profile.

Table 6: Square correlation coefficients between the supplementary variables and the principal components. Asterisks indicate statistically significant correlations ($p < 0.05$).

Variable	PC1	PC2	PC3
vehicle	0.982^*	0.000	0.000
fm	0.000	0.143^*	0.173^*
m	0.001	0.080^*	0.311^*
TVP	0.001	0.141^*	0.177^*
slope	0.000	0.273^*	0.006

Fig. 5 shows the individual stimuli divided by experimental variables on the 1st and 2nd principal components.

5. DISCUSSION

The results of the listening tests showed a number of variables that influenced annoyance ratings of simulated UAS noise. The X1 vehicle was rated as more annoying than the M3 vehicle, even with both being normalised to the same L_{Aeq}. The X1 is a larger UAS, with an overall lower pitch sound, which could have contributed to increased perceived annoyance. The difference however was small and the type of UAS did not affect responses to any of the other variables.

The amplitude modulation depth and value of modulation frequency were also significant predictors of annoyance. The higher modulation depth resulted in more pronounced modulation effects, which resulted in higher ratings of annoyance. Similarly, a low value of fm produced a "wobble" which made the modulation more noticeable than in the sound synthesised with high fm. Overall, sounds with more noticeable modulation effects were rated as more annoying.

How the modulation parameters changed over time also had an effect on annoyance. A positive slope in the function driving the change of parameters resulted in a less annoying sound. This could be the result of the modulation being introduced more gradually, making it less no-

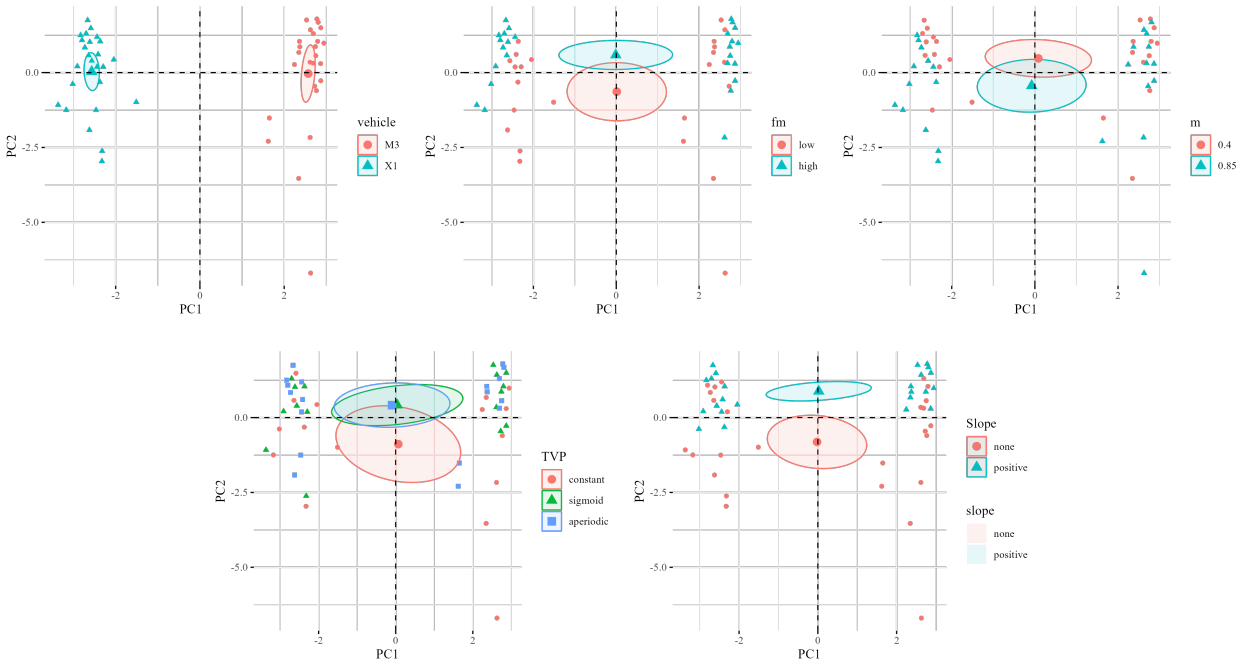

Figure 5: PCA plots of individuals (sound stimuli) with experimental variable means and confidence ellipses around the group means. Each plot shows a different experimental variable.

ticeable. However, the average amount of modulation in the sounds with positive slope was less than in the sounds with zero slope, and it could also be that it was this distinction that drove the ratings. In practical terms, a zero slope scenario would correspond to a static flyover within stable weather conditions, whereas a positive slope could be a result of aircraft movement or adverse evolution of environmental conditions such as an increase in wind speed. Sounds produced using aperiodically-changing modulation parameters were rated as less annoying than those with constant or sigmoidally increasing parameters. This likely is because the randomness of the modulation does not create a clear pattern in the sound and makes the modulation less perceivable. The aperiodic condition is in fact more realistic, whilst the constant condition is a hypothetical extreme.

A PCA analysis of psychoacoustic metrics revealed three principal components of interest. The first component was driven by a number of psychoacoustic metrics and is explained by the difference between the two vehicles. The smaller M3 vehicle was lower in Loudness, but higher in Sharpness, Fluctuation Strength, and Tonality, than the larger X1. The first component of the PCA was not correlated with annoyance ratings, despite the linear model analysis discussed above showing a small statistical difference in ratings between the two vehicles.

The second component of the PCA was strongly correlated with annoyance ratings. Roughness, Fluctuation Strength and Impulsiveness contributed to this component and were all positively correlated with annoyance. This is expected, as Roughness and Fluctuation Strength have been known to affect psychoacoustic annoyance [11], and likewise, the addition of Impulsiveness has been shown to improve predictions of annoyance in response to rotor noise [12]. The second component was also driven by Loudness HM and Aures Tonality, but somewhat surprisingly, these were negatively correlated with annoyance ratings. Loudness Hearing Model is a sophisticated metric which might be picking up a difference in the spectra of the stimuli which was not eliminated by L_{Aeq} normalisation. Regarding tonality, since only parameters related to amplitude and frequency modulation were included as variables in the experiment, and the amplitude of the tonal components remained unchanged, any variation in tonal-

ity values is likely due to an increase in the bandwidth or spread of energy around the tonal frequencies – that is, broader tonal components. This broader spectral content can make the tones less perceptually salient, especially if the energy spreads into adjacent critical bands.

One of the limitations of the current analysis is that the artefacts in calculated psychoacoustic metrics meant that a limited portion of the signals were used to calculate the statistics. This was particularly the case for Fluctuation Strength. In future analysis, metrics other than the 5th percentile might be used to test if we can better capture the changing nature of the modulation parameters. Additionally, a follow up study looks at longer fly-over sounds and methods of rating them in real-time.

6. CONCLUSIONS

This study highlights the significant impact of time-variant characteristics of UAS noise on perceived annoyance during hovering operations. In a laboratory experiment, modulation depth, modulation frequency and the temporal evolution of modulation parameters affected perceived annoyance of synthesised UAS sounds. Overall, low perceptibility of modulation, achieved with low modulation depth, high modulation frequency, as well as unpredictable patterns in the evolution of modulation parameters resulted in lower annoyance. Our analysis also confirmed the influence of Roughness, Fluctuation Strength and Impulsiveness on annoyance, for two different UAS types. Future research will focus on refining psychoacoustic metrics and exploring longer fly-over sounds to better understand the dynamic nature of UAS noise and its impact on human perception.

REVIEW OF THE EFFECTS OF DRONE NOISE ON PEOPLE

Joel Li[1] **Brett R.C. Molesworth**[1] **Marion Burgess**[1*]
[1] School of Aviation, University of New South Wales, Sydney, Australia

ABSTRACT

The current use of drones includes, but is not limited to scientific, commercial, military, and surveillance applications. With the application of drones expanding, and to potentially include air mobility to transport people, they will become part of the transportation mix. The approvals from the government authorities for new uses will of course require evidence of safe operation but will also need to consider the noise impact on the communities. To establish clear guidelines there is a need to have knowledge of the effects of the noise on those in the communities. This paper will present findings from a systematic review on the effects of drone noise on people. The review follows the PRISMA-ScR (Preferred Reporting Items for Systematic reviews and Metanalysis extension for Scoping Reviews) methodology. It involved a search for publications that are available with full text in English from 2000 to 2024. The initial search protocol provided 10,613 unique publications. Of these, 32 studies were found to be relevant for further analysis. This has led to identification of the current gaps in knowledge relating to the effects of drone noise on people.

Keywords: *drone noise, effect of noise, uav noise.*

1. INTRODUCTION

Drones, otherwise known as remotely piloted aircraft (RPA), unmanned aerial vehicles (UAVs), or unmanned aircraft systems (UAS), or colloquially referred to as unmanned aircraft, are either fixed wing or rotating wing aircraft that are operated remotely. They can carry a range of tools including, sensors – thermal, infrared, cameras, data recording tools, transponders, winches and many more depending on the intended use of the aircraft. Future applications may even include the transportation of people.

The use of drones is growing. Drones currently have many uses such as for scientific, commercial, delivery, military, surveillance, and recreational purposes. More use cases for drones are being identified and implemented almost daily. With drones being projected to increase in usage by 20% annually [1], the concern about their noise impact on the community will grow alongside their increasing use.

The effects of noise, which is any unwanted sound, can be measured both subjectively and objectively. Subjective responses can include psychoacoustic effects, which is defined as the branch of psychology concerned with the perception of sound and its physiological effects [2]. Objective responses can include physiological responses to noise from drones.

Current regulations and guidelines used to regulate drone usage struggle to keep up to the rapid changes in development and application of drones. Drone usage and the associated noise impact are often regulated by different bodies. For example, in Australia, the regulations and guidelines from the Civil Aviation Safety Authority (CASA) focus on the safe operation of drones and CASA has stated that "*the issue of aircraft or RPA noise is not part of our role*" [3]. The Department of Infrastructure, Transport, Regional Development, Communications and the Arts in Australia is responsible for the management of drone noise. However the Aircraft Noise Regulations 2018 [4] exempt specific types and operations of drones. The rapid growth and development of drones has outpaced the regulatory framework and in regard to noise, research is needed to investigate the effects of the interaction of drones

and the people within the built environment so that the appropriate guidance and regulations can be created.

The aim of this systematic review is to synthesise and systematically map research that has investigated the effects that noise from drones have on people within the built environment. It is intended to provide the basis for directing future research on this topic by highlighting the gaps in knowledge that need to be addressed for the development appropriate regulations and guidelines on drone usage in Australia.

The following research question was developed to achieve the aims of this systematic review:

- What are the effects of drone noise on people?

2. METHODOLOGY

A systematic review approach was selected as the purpose aligned with the purpose of a systematic review as defined by Page et al[5]. Namely to identify the types of available evidence in a given field; to clarify key concepts/ definitions in the literature; to examine how research is conducted on a certain topic or field; to identify key characteristics or factors related to a concept; and to identify and analyse knowledge gaps. The PRISMA-ScR (Preferred Reporting Items for Systematic reviews and Metanalysis extension for Scoping Reviews)[5] methodology was selected.

Literature searches were limited to include full-text publications and government regulations that were available in English. The following selection criterion was used to determine whether the piece of literature was included in the review:

1. Studies involving healthy human adults with no hearing impediments. If the study included individuals from the excluded groups but reported the results for such participants separately, the study would then be included
2. Studies investigating the impact that drone noise has on humans; through:
    a. Subjective effects of drone noise on humans.
    b. Objective effects of drone noise on humans.
    c. Comparisons of subjective or objective effects of drone noise to other noise sources.
3. Studies including a source of noise that is perceived as a drone. This can include recording of drone noise, altering available drone noise, or altering any noise to replicate drone noise.

Three categories of search terms were created for this systematic review. The general search strategy is outlined below and was applied to SCOPUS, Dimensions, IEEE, Proquest, Environment Complete, Web of Science and Aerospace Research Central databases.

Table 1. Search terms used for the systematic review

Search Category	Search Terms Used
Drones	drone* OR rpa* OR "remotely piloted aircraft*" OR uav* OR "unmanned aerial*" OR "unmanned air*" OR "UAM*" OR "Urban air mobility*" OR "advanced air mobility" OR "AAM"
Noise	nois* OR acoustic* OR sound* OR psychoacoustic* OR auditory
Effect	impact* OR effect* OR perception* OR physio* OR objective* OR perform* OR task*

*Note * denotes a wildcard search term*

3. GENERAL FINDINGS

The search and selection process of the publications from the initial search strategy from the year 2000 to 2024 first resulted in the return of 16,024 publications. After removing duplications there were 10,613 publications. After a title search, 321 remained. All 321 abstracts, and if necessary full text, were then checked for relevance. After this final check, 31 papers were identified to be relevant of which 28 involved subjective assessments such as annoyance, loudness, threat, safety, pitch, tone, roughness, and other qualities of noise while 6 studies included objective measurements such as the ability to hear and/or identify sounds whilst drone noise is present. The initial findings highlight the diversity in the approach to the types of noise used to represent the noise from drones which is a reflection of the rapidly growing field. Similarly, there is a diversity in the approach to the methodology of assessing the noise from drones which makes selection of guidance on acceptable limits challenging. Thus, there are conflicting outcomes

indicating there is a need for more studies investigating the effects of noise from drones.

4. CONCLUSIONS

This paper summarises the work done up until the present day on this systematic review. By answering the research questions discussed above, this systematic review will be a significant contribution to the understanding the current research into the effects that the new technology of drones has on noise in the built environment. It will assist with development of regulations on the management of this new technology. Identifying the gaps in knowledge on the subjective and objective responses towards drone noise will assist to direct future research in this field.

A NOVEL PROCEDURE TO MINIMIZE THE ACOUSTIC AND ENVIRONMENTAL IMPACT OF EVTOL VEHICLES FOR INTRA-CITY MISSION PROFILES

Caterina Poggi[1*] **Giovanni Bernardini**[1] **Massimo Gennaretti**[1]

[1] Department of Civil, Computer Science and Aeronautical Technologies Engineering, University of Roma Tre, 00146, Rome, Italy

ABSTRACT

The paper applies a novel procedure to minimize the emitted noise or maximize vehicle performance for advanced air mobility applications. It considers a hexacopter configuration during the whole flight envelope for a typical intra-city mission profile. For a given flight trajectory conceived as a sequence of steady states segments, a trim solver, suitable for vehicle configurations with redundant controls, is applied in each segment to evaluate the optimal combination of control settings and vehicle attitude optimizing selected target functions like, for instance, noise and performance, while guaranteeing the desired flight condition. To this aim the trim solver is coupled with an aerodynamic solver based on the blade element momentum theory method and an acoustic solver based on the compact source version of the Farassat 1A formulation.

Keywords: *Advanced air mobility, noise reduction, eVTOL, trim procedure*

1. INTRODUCTION

Due to the exponential growth of city overcrowding and pollution, academia and industries are making a great effort to develop eco-friendly alternatives to standard urban mobility. Among them is urban air mobility (UAM), e scenario that is conceivable thanks to significant technological advances, including electric propulsion and batteries. Yet, to allow public acceptance and entry into the service of UAM, some critical issues should be addressed [1], such as environmental pollution and acoustic nuisance (mainly during take-off and landing operations).

In recent years, a great amount of research activities have been carried out to investigate viable strategies and technologies aimed at reducing the noise emitted by conventional vehicle designs, while maximizing aerodynamic performance to reduce fuel and electric energy consumption [2].

In typical eVTOL designs, as those commonly exploited for UAM applications, the propulsive system consists of more than one rotor, suitably tilted during the different flight envelope stages, eventually complemented by fixed wings to lift generation. In this perspective, to reduce the acoustic emissions of these concepts, several strategies can be exploited, from optimising each single rotor's geometrical characteristics [3] to defining optimal installation parameters to maximize the destructive interference of the signals radiated by each rotor [4] or the shielding effect of the vehicle airframe [5]. Even though great progress has been achieved so far, these strategies have the drawback of requiring the re-design of the whole configuration through costly optimization processes.

Recently, the authors proposed a novel procedure to minimize the emitted noise or maximize the aerodynamic performance of multi-rotor systems [6]. This approach overcomes the limitation of re-engineering the whole vehicle, by introducing strictly acoustic and aerodynamic

*__Corresponding author__: caterina.poggi@uniroma3.it.

constraints since the earliest design phases, and is applicable as an easy retrofitting of already existing concepts. This strategy is based on the observation that typically eVTOL vehicles are conceived as multi-rotor systems, for which the number of available controls is generally greater than those required to trim the vehicle. In addition to the possible methods available in the literature for the control redundancy management [7, 8], recently the author proposed an alternative approach based on recasting the trim procedure into a constrained cost function minimization problem, which provides the optimal combination of control settings and vehicle attitude that guarantees the desired flight condition while achieving targeted design objectives [6]. It has already been successfully applied to minimize the acoustic emissions in terms of tonal and broadband components for specific flight condition cases [9, 10].

Here, the method is applied to minimize the noise emitted by a hexacopter configuration during the whole flight envelope for a standard intra-city mission profile. Starting from a given flight trajectory conceived as a sequence of steady-state segments, the trim solver is applied in each trajectory segment to evaluate the optimal combination of control settings and vehicle attitude to minimize the emitted noise while guaranteeing the desired flight condition. To this aim, the trim solver is coupled with an aerodynamic solver based on the blade element momentum theory method [11] and an acoustic solver based on the compact source version of the Farassat 1A formulation [12].

2. MINIMUM OBJECTIVE FUNCTION TRIM METHOD

For multi-rotor configurations with redundant controls the trim solution, in terms of attitude and control settings, can be achieved by the control identification method presented and validated through comparison with literature results in [6].

This method minimizes an objective function, $\mathcal{O}(\boldsymbol{z}, \boldsymbol{u})$, depending on the flight state parameters, $\boldsymbol{z}$, and the commands, $\boldsymbol{u}$, under the constraint to comply with the steady-state flight mechanics equations of trimmed flight. To this aim, the Lagrange multipliers, $\boldsymbol{\lambda}$, are introduced and the original minimization problem is recast into the following one

$$\mathcal{H}(\boldsymbol{z}, \boldsymbol{u}, \boldsymbol{\lambda}) = \mathcal{O}(\boldsymbol{z}, \boldsymbol{u}) + \boldsymbol{\lambda}^T \boldsymbol{f}(\boldsymbol{z}, \boldsymbol{u}) = min \quad (1)$$

where the $\boldsymbol{f}$ vector collects the equilibrium equations of trimmed flight. The solution of Eq. (1) requires the solution of the following system of equations:

$$\frac{\partial \mathcal{H}}{\partial \boldsymbol{z}} = 0 \; ; \qquad \frac{\partial \mathcal{H}}{\partial \boldsymbol{\lambda}} = 0 \; ; \qquad \frac{\partial \mathcal{H}}{\partial \boldsymbol{u}} = 0 \quad (2)$$

Thus, for a given steady-state flight condition, the system consists of 5 equations given by $\partial \mathcal{H}/\partial \boldsymbol{z} = 0$, N equations given by $\partial \mathcal{H}/\partial \boldsymbol{u} = 0$, and 9 equations provided by $\partial \mathcal{H}/\partial \boldsymbol{\lambda} = 0$, with $5 + N + 9$ unknowns, $(\boldsymbol{z}, \boldsymbol{u}, \boldsymbol{\lambda})$. Thus, Eqs. (2) yield a consistent nonlinear system that can be solved through the standard Newton-Raphson method. Although simple to implement, the drawback of this approach is the need to evaluate the Hessian matrix of $\mathcal{H}$. For this purpose, a standard finite difference algorithm can be exploited to evaluate the derivatives numerically, or, if available, the solution can be derived analytically. Alternatively, the computational burden of such an approach could be alleviated by using other solution approaches, such as the SLSQP (sequential quadratic programming) [13].

For a given set of kinematic variables and commands, the trim solver combines aerodynamic/propulsive loads, evaluated through a component build-up procedure, with the gravitational and inertial loads. The rotor blade is modeled as a hinged, rigid structure, with lead-lag and flap motion in addition to rotation about the feathering axis. The aerodynamic loads are determined by a quasi-steady Blade Element Momentum Theory, with section aerodynamic loads evaluated through a lookup table approach.

The trim problem is solved through two nested iterative loops, one for the solution of Eq. (1) and the other for the rotor dynamics equations solution through a harmonic balance approach. Specifically, starting from current states $(\mathbf{x}, \mathbf{u})$, the aerodynamic loads of each rotorcraft component are evaluated, including those from rotors given as output of the harmonic balance problem. Then, these are used to define a new value of the functions in Eq. (1) and hence of the unknowns to be applied in the next step of the trim loop. This procedure is iterated until convergence. Once the convergence is reached, the spanwise distribution of the blade section aerodynamic loads is determined.

As already stated, the designer can arbitrarily define the objective function in terms of suitable measures of targeted performance as long as they depend on any of the flight variables and the flight parameters involved in the problem. If the selected target function is an acoustic metric, the trim solver has to be suitably coupled with an aeroacoustic solver. In particular, the blade section aero-

dynamic loads, coming from the trim procedure, become the input of the aeroacoustic solver used to evaluate the vehicle radiated noise. The aeroacoustic solver is based on the compact-source version of the Farassat 1A boundary integral formulation [12]. Indeed, since the latter requires the knowledge only of section loads, it can be easily coupled with the blade element theory method implemented within the trim solver described above for the evaluation of aerodynamic loads. For rotors in a subsonic regime, this formulation yields the aeroacoustic pressure field as a superposition of a thickness noise term depending on the blade geometry and kinematics, and a loading noise term associated with the blade aerodynamic loads. Both can be suitably expressed as a combination of line integrals along the spanwise quarter-chord line of the rotor blades [14].

3. NUMERICAL RESULTS

The configuration considered herein consists of a hexacopter vehicle (schematically depicted in Fig. 1) with a maximum take-off weight of 3000 kg, six coplanar and identical three-bladed rotors, each with a radius, R = 3 m, in a vertex-first configuration. The blades have a linear twist of 12°, a mean chord c_w of 0.2711 m, and the airfoil shape is the VR7 profile. In the reference system depicted

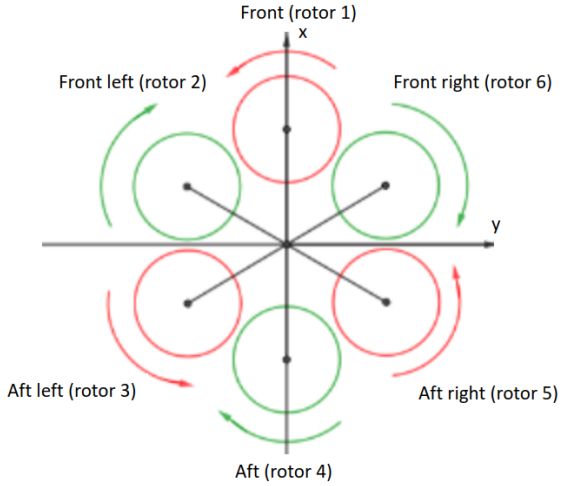

Figure 1. Schematic representation of the hexacopter configuration.

in Fig. 1, the rotors hubs coordinates are listed in Tab. 1.

The mission profile herein considered is schematically depicted in Fig. 2. The transient phases between the

	x [m]	y [m]	z [m]

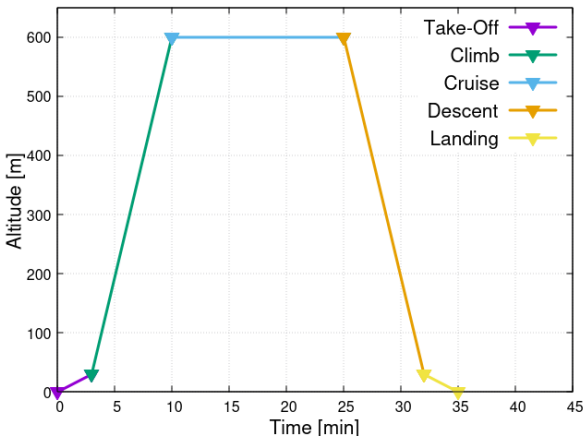

Figure 2. Mission profile.

different segments are ignored (they are assumed to be of short duration and, thus, scarcely affecting the overall nuisance generated).

The steady-state flight operative conditions in each segment of the mission profile are detailed in the following:

- Take-Off (TO): vertical flight from an altitude of 0 m to 30 m at 6 m/s;
- Climb (CL): from an altitude of 30 m to 600 m at 20 m/s, with a flight path angle equal to 12°;
- Cruise (CR): horizontal flight at an altitude of 600 m at 60 m/s;
- Descent (DS): from an altitude of 600 m to 30 m at 20 m/s, with a flight path angle equal to -12°;
- Landing (LN): vertical flight from an altitude of 30 m to 0 m at 6 m/s;

In each segment of the flight envelope, the trim procedure is applied considering two different objective functions to

be minimised:

- Strategy A, minimum torque condition: the objective function is the sum of all the dimensionless rotors' torque, defined as:

$$\mathcal{O}_t = \sum_{i=1}^{N_r} \hat{M}_{z_i}$$

where $\hat{M}_{z_i}$ denotes the dimensionless torque of the i-th rotor and N_r is the number of rotors;

- Strategy B, minimum noise condition: the objective function is the mean Overall Sound Pressure Level (OASPL) evaluated in a selected set of microphones, defined as:

$$\mathcal{O}_{ac} = \frac{1}{N_{mic}} \sum_{i=1}^{N_{mic}} OASPL_i$$

where N_{mic} is the number of microphones.

In particular, in the reference system shown in Fig. 1, the microphones lie over a circle in the xy plane, centred at the origin and having a radius equal to $40R$.

Note that for the evaluation of the radiated noise objective function (here accounting for the tonal contribution only), the frequency analysis required to evaluate the acoustic metric includes a windowing process of the signal recorded during a three-rotor-revolution period to deal with the presence of arbitrary rotor angular velocities. In particular, the Hann windowing is applied, and an energy correction factor is used to maintain the total energy content of the signal.

The blades are assumed to have a fixed pitch set equal to 11° (reference value). Thus, the only available controls are the six rotors' angular velocities. The control settings obtained through the application of strategies A and B are shown in Tab. 2 and Tab. 3, respectively.

The differences in control settings are negligible in all the mission phases except for the cruise. This means that, except for the cruise segment, the controls that minimize noise emissions and rotors' torque are the same. Instead, for the cruise condition, the control settings obtained by minimizing the torque or the noise are significantly different, even if both the minimization processes lead to a set of control settings where the angular velocity of rotor 1 is significantly lower than the others.

For the cruise segment the comparison of the noise and performance objective functions obtained through strategies A and B is reported in Tab. 4. A significant improvement of the value of the specific objective function minimized is obtained: when the torque is the objective function to be minimised, the dimensionless rotors' torque is reduced up to 45% with respect to that obtained through strategy B. On the contrary, when the target function is noise minimization, the average OASPL is reduced by 13 dB. This outcome is confirmed by Fig. 3 which shows the comparison of OASPLs evaluated at the selected set of microphones through the application of strategies A and B.

As already stated, the only active controls used up to this point are the rotor angular velocities, as typically assumed for multirotor control procedures. This means that the collective blade pitch angles are set a priori based on structural and aerodynamic considerations. An alter-

native approach might be considering the blade pitch angles as additional controls. But, being the use of variable blade pitch propellers unrealistic for standard configurations, the idea is to define an optimal pitch angle to be exploited for the whole flight envelope. To evaluate the optimal pitch, the trim procedure is applied considering 12 available commands for a selected flight condition. Once determined, the optimal pitch is kept fixed for the whole mission profile, and the trim procedure is applied with the angular velocities as the only available commands.

To this purpose, strategies A and B are applied in the takeoff condition, to evaluate the corresponding optimal collective angles, considering six angular velocities and six collective angles as available controls. The noise minimization leads to an increase of the collective pitch angle, with an optimal value of $12.7°$ (upper bound of the design space due to aerodynamic constraints), and equal for all the rotors. Instead, the minimization of the rotor torque results in a decrease of the pitch angle, with an optimal value of $9.3°$ (only slight differences are obtained among the rotors, less than 2%). The angular velocity control settings obtained through strategies A and B in combination with the optimal pitch angle setting are shown in Tab. 5 and Tab. 6, respectively.

The objective function obtained through the two strategies when applying the corresponding optimal pitch

angles are compared in Fig. 4 and Fig. 5 for the noise and torque objective functions, respectively. For the sake of completeness, the objective functions obtained by assuming the reference pitch angles are also depicted.

Concerning the rotor torque minimization, using an optimal pitch angle improves the target functions throughout the whole flight envelope. Instead, When the objective function is the emitted noise, the average OASPL is reduced in all the mission profile phases except for the cruise. In the latter case the average noise is 4 dB higher than that obtained by setting the reference pitch. In fact, since the optimal collective pitch angle is identified for a single flight condition, not necessarily it remains the optimal value for all the mission profile phases. Nevertheless, the average OASPL is still lower than the OASPLs resulting from a torque minimization strategy. These results confirm that even if an improved target function can be achieved by setting the same reference pitch angle for all the analyses, the application of a suitably determined optimal collective pitch can provide even better outcomes.

Finally, Fig. 6 shows comparisons between the OASPL directivities evaluated through the two strategies

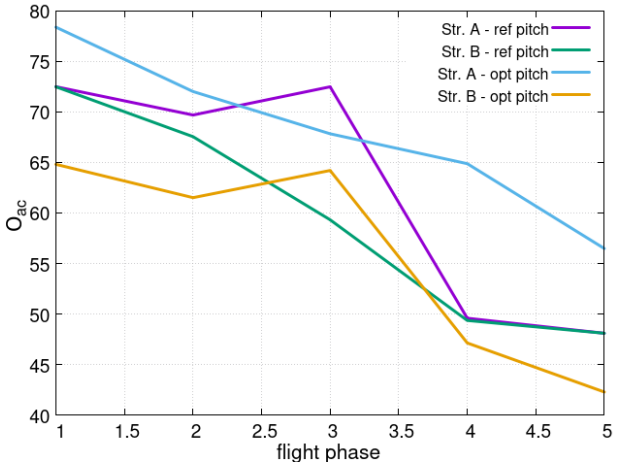

Figure 4. Comparison of the objective function $\mathcal{O}_{ac}$ obtained by application of strategies A and B with the reference and optimal pitch angle.

by the two pitch settings for the whole mission profile.

The reduction in noise emission already observed in Fig. 5 is here confirmed. The decrease in the average OASPL is almost equally distributed among all the observers, with no microphones measuring an undesirable significant increase in noise. As already pointed out, the only exception is the cruise condition, where an increase of noise in all the microphones is observed with respect to

(a) Takeoff (b) Climb

(c) Cruise (d) Descent

that radiated in the case of noise minimization assuming the reference pitch angle.

4. CONCLUSIONS

This paper proposes a novel procedure to determine the trim condition of multi-rotor systems suitably exploiting the control redundancy to optimize selected target func-

tions, here related to noise emissions and aerodynamic performance. The configuration herein investigated is a hexacopter with a typical intra-city mission profile, which is conceived as a sequence of steady-state conditions. To demonstrate the capability of the proposed approach to achieve an effective improvement of the selected objective function, two different strategies are applied and compared which rely on the minimization of the acoustic emissions and the rotors' torque, respectively. The numerical investigations demonstrate that the minimization of both rotor torque objective function and acoustic metric objective function is successful when the rotor angular velocities are the set of controls to be identified. Furthermore, if the blade pitch angle is set a priori without involving any noise constraint, the improvements are limited. Instead, if the pitch angle is set through a preliminary trim analysis involving both the collective pitch angles and the angular velocities as active commands, the improvement strongly increases with a reduction of noise up to 8 dB, and a reduction of rotors' torque up to 5%.

DIFFERENCES IN SOUND EMISSION LEVEL OF MULTI-ROTOR UAS DURING HOVER AND CRUISE

ABSTRACT

UAS noise is an increasing concern in today's society, necessitating effective control and monitoring. One approach to address this issue is the development of reliable UAS noise models. In some studies, the sound emission of multi-rotor UAS was characterized using hover measurements in an anechoic room; however, comparisons with forward-flight measurements revealed discrepancies for certain UAS. To investigate these differences, we conducted measurements during transitions from hover to cruise using an on-board measurement system mounted on the UAS. In addition to recording the emitted sound, the system acquires relevant flight data and the precise UAS position. In this paper, we present initial measurement results comparing the overall emitted sound pressure level (OSPL) at hover and across various flight speeds for two propeller types. For one propeller, the OSPL increases abruptly by 2 dB at low speeds, while a near-linear trend is observed for the other. The constant rotor speed during these changes suggests that aerodynamic factors are likely responsible. Although further analysis is needed, these findings emphasize the importance of assessing different flight conditions when modeling sound emission of UAS.

1. INTRODUCTION

Noise is an increasing concern in today's society and requires careful monitoring and control [1,2]. Depending on the field of investigation, different noise prediction models are necessary, ranging from those that generate overall sound pressure level (OSPL) at receiver positions to auralizations and annoyance models [3–6]. Most of today's existing unmanned aerial systems (UAS) noise models rely on lab measurements in hover mode or stationary ground microphone recordings during cruise.

Wunderli et al. [7] proposed a modeling approach to simulate third-octave band noise emission levels for various types of UAS, derived from lab recordings in hover. For each third octave band, a multi-regression model was developed using (1) rotor rotational speed and (2) emission angle as variables. During a validation study where these models were used to calculate noise levels in cruise flight sections, discrepancies of up to 10 dB were observed compared to models based on lab measurements, independent of rotor rotational speed or cruise speed. To account for this difference, a level correction term for cruise was applied to the OASPL, improving model performance with a maximum standard deviation of 1.8 dB between measurements and simulations. However, the physical cause of this level correction and the flight speed at which it should be applied remained unclear.

We hypothesize that noise emissions in hover and cruise phases may differ significantly, with strong dependence on the UAS and propeller type, and that a mea-

surable transition phase exists where this change occurs. Demonstrating this effect would have important implications for UAS noise measurements and modeling. To investigate this, we measured sound emissions during the transition between hover and cruise for a multi-rotor UAS equipped with two different propeller types. Using an onboard measurement system, we identified significant acoustic differences between these two flight states. In this paper, we present preliminary results from these measurements.

2. METHODS

Since the flight design consists of dynamic maneuvers, the use of stationary microphones would have been challenging. During cruise, the distance between the UAS and the microphone gets large quickly, leading to poor signal-to-noise ratio. Backpropagation of the signal to a fixed distance from the UAS is challenging due to the dynamic changes in geometry. In consequence, we used an onboard measuring system, keeping the distance between microphone and UAS short and constant. In this section, we describe the sound emission measurements with our developed onboard measurement system.

2.1 Experimental Setup

As UAS type, we selected the DJI Matrice 300 RTK [8], recently used in UAS noise studies (e.g. [4, 9]) and a common choice for inspection and mapping tasks. For each measurement, we equipped the UAS with two different commercially available propeller types: the standard R2110, referred to as "Propeller 1," and the R2195, referred to as "Propeller 2." The latter is designed for high-altitude operations, generating more lift per rotation than the standard model. These propellers have distinct shapes (especially the blade tips), as shown in Figure 1.

Table 1. Propeller types installed on the UAS during measurements.

Propeller 1	Propeller 2
	

To measure the emitted sound, the rotational speed of each rotor and the position/velocity of the UAS simultaneously, we used an onboard measurement system called "backpack", developed at the authors' institution (Empa). It has already been successfully used in a recent project, to record UAS sounds for auralization tasks [4] and is described in more detail in [10]. It consists of different parts, described in the following Table 2.

Table 2. Onboard measurement system ("backpack") and its components.

Component	Task
MEMS microphones (attached to arms)	Sound emission recording
Optical sensors	Tracking of rotor rotational speeds
GNSS antenna	Tracking of UAS position
Battery	Power supply
Microcontroller	Data acquisition
SD card	Data storage
Housing	Mounting structure for sensors and microcontroller

We used MEMS microphones (SPH0645LM4H, Knowles Electronics, Itasca, IL, USA) for sound recordings due to their lightweight design. Two microphones were mounted on carbon fiber tubes at a distance of 1.1 m from the nearest propeller tips, positioned symmetrically on either side at two different elevation angles relative to the rotor plane. One microphone was aligned with the rotor plane, while the other was angled 30° downward. To minimize wind-induced self-noise, we installed spherical foam windscreens, which also acted as vibration insulators (not measured). The MEMS microphones contain an AD converter and directly provide digital signals. Recordings were made with a sampling rate of 44.1 kHz and with 16 bit resolution. According to the manufacturers specification, the sensitivity of the MEMS microphones has a large range of 6 dB at 1 kHz. We therefore calibrated the MEMS microphones under free-field conditions. These calibration measurements were performed in an anechoic room with a loudspeaker and a free-field measurement microphone as a reference. The calibration measurements revealed an amplification of high frequencies due to pressure buildup at the added MEMS microphone circuit board. To equalize the frequency response of the microphones, we applied a second order high shelf filter.

To measure the rotational speed of each rotor, we

placed LEDs alongside photodiodes facing each motor. The LED continuously emitted infrared light, and its reflection was measured by the photodiode at a sampling frequency of 1 kHz. To reduce harmonics, we applied a grayscale strip with sinusoidal intensity around the rotating part of the motor.

For precise UAS position tracking, we used two GNSS receivers: one mounted on top of the backpack and one stationary on the ground. This setup enabled real-time kinematic (RTK) positioning in dual-band mode, achieving centimeter-level accuracy. With this configuration, we obtained position updates at a rate of 15 Hz. The complete setup, including the backpack and sensors, is shown in Figure 1.

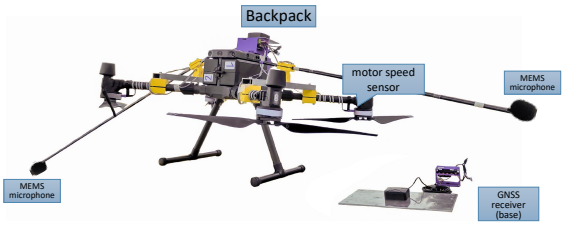

Figure 1. UAS equipped with the backpack and sensors. A second, stationary GNSS receiver (base) enables RTK positioning.

2.2 Flight Test Design

To ensure real-world flight conditions and avoid space limitations, we conducted the measurements outdoors in an open field. The UAS was manually operated, flying extended straight tracks at varying speeds. To minimize ground reflection influences, flights were conducted at an altitude of several 10 meters. The ambient temperature at the measurement site ranged between 5.9°C and 7.1°C, with relative humidity between 56% and 61%, and with low wind conditions (1.4 m/s at the nearest weather station, 10 m above ground).

Since the investigated UAS is designed to carry payloads of up to several kilograms, the attached backpack and sensors had minimal impact on flight performance. The UAS itself weighs 6.3 kg, while the backpack, including all sensors and sensor mounts, adds an additional 1.8 kg.

2.3 Data Processing and Analysis

From the in-flight recordings, time histories of the OSPL were computed, i.e. the unweighted short-term equivalent continuous OSPL with a time window of 1 s ($L_{\mathrm{eq},1s}$). In order to be comparable to the recordings of other UAS types, the obtained levels were scaled to a 1 m reference distance to the UAS's nearest propeller tips, by compensating for geometrical spreading. To obtain a corresponding OSPL assigned to every flight trajectory point, the $L_{\mathrm{eq},1s}$ was interpolated to the sampling rate of the GNSS receivers (15 Hz).

The rotational speed for each rotor was determined by applying Fast Fourier Transform (FFT) to the recorded signals. The rotational speed was then identified using a peak-finding method. For 2-bladed propellers, this corresponds to half the blade passing frequency.

3. RESULTS

This section presents initial measurement results for the UAS at different cruise speeds, equipped with two different propeller types. Figure 2 displays the $L_{\mathrm{eq},1s}$ for both propeller types, covering hover (very low cruise speed) up to cruise at speed of 9 m/s (max. possible speed $>$ 20 m/s). For each 1 m/s flight speed bin, we obtained an average of 75 seconds of flight data for Propeller 1 and 30 seconds for Propeller 2. We fitted the data points with a cubic smoothing spline using a smoothing parameter of 0.1.

Figure 2 shows that within the studied speed range, Propeller 2 exhibits 1 to 2 dB higher emissions compared to Propeller 1. For Propeller 1, a nearly linear increase in sound emission level with increasing cruise speed is observed. In contrast, Propeller 2 exhibits a sudden, sharp increase in emission level by 2 dB at a cruise speed of 3 to 4 m/s. Apart from this abrupt change, the emission levels remain largely unaffected by variations in cruise speed within the observed range. Additionally, the standard deviation of sound levels for Propeller 2 is noticeably higher at lower speeds, reaching almost 2 dB, but decreases at higher speeds. For Propeller 1, the standard deviation remains between 0.5 and 1 dB across all speeds.

Since the modeling approach in [7] uses rotor rotational speed as an input, we compare the emitted sound to the measured rotational speeds. Figure 3 presents the mean rotational speed across all four rotors as a function of cruise speed, with smoothing applied similarly to Figure 2. Within this speed range, the mean rotor rotational speed appears largely unaffected by increasing

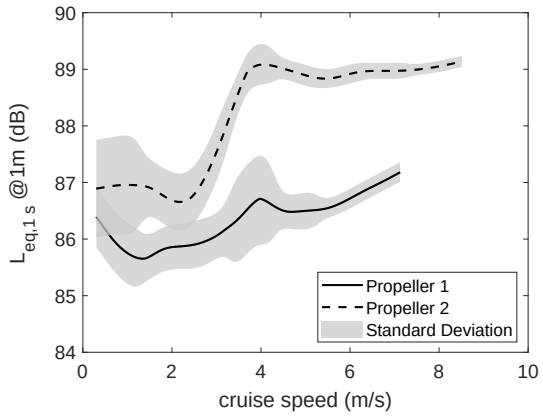

Figure 2. OSPL as a function of cruise speed for two propeller types under an elevation angle of -30° to the rotor plane at a 1 m reference distance to the nearest propeller tips.

cruise speed. As Propeller 2 is designed for higher altitudes, it generates more lift per rotation than Propeller 1, resulting in a noticeably lower rotor rotational speed.

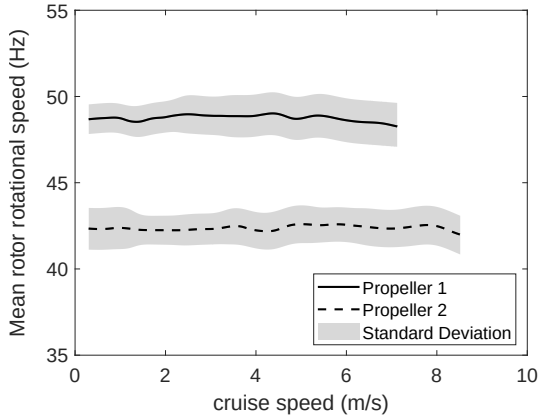

Figure 3. Mean rotational speeds and standard deviation of all four rotors for each measured propeller type as a function of cruise speed.

4. DISCUSSION

Both studied propeller types exhibit distinctly different behavior in terms of sound emission level at different cruise speeds, despite being used on the same UAS type. While the emitted OSPL of Propeller 1 changes only slightly with speed (showing a gradual increase), Propeller 2 displays a pronounced step-like behavior. However, measurements of rotor rotational speeds indicate that this sudden increase in sound level cannot be attributed to changes in rotational speed, as it remains relatively constant within this range. Consequently, we assume that the aerodynamics of the rotors must be influenced by changes in lateral inflow. This is, however, part of future investigations. Additionally the question arises, if a particular shape of the propellers favors this non-linear effect, such as for Propeller 2. Or if for any particular shape, generalizable statements regarding sound emission can be made.

For Propeller 2, applying the modeling approach of [7] would result in a cruise level correction of approximately 2 dB, whereas for the same UAS equipped with Propeller 1, no such correction would be necessary. Additionally, measurements taken within the rotor plane (not presented within this paper) revealed an even higher cruise level correction of 4 dB for Propeller 2. This dependence on the emission angle further indicates that the source directivity of the UAS also differs between hover and cruise.

5. CONCLUSION AND OUTLOOK

In this paper, we measured the emitted sound of a UAS equipped with two different propeller types at various flight speeds to investigate the transition between hover and cruise. Our results show that, depending on the UAS/propeller combination, the sound emission level can increase sharply at relatively low flight speeds, independent of rotor rotational speed. We assume that changes in the aerodynamics are responsible for this phenomena. When developing models for predicting or simulating UAS noise emissions for different flight states, it is therefore essential to measure the emitted sound for each propeller type separately and at both states, hover and cruise at various speeds.

Due to the assumption of aerodynamic changes in cruise flight, not only noise emission levels but also other characteristics of the emitted sound might be affected. Psychoacoustic aspects, as well as measurement data from a smaller UAS equipped with three different propeller types, are currently under investigation and will be presented in a future publication.

ABSTRACT

Recently, demand of UAM has been increasing because of the high versatility. However, there are several technical issues that makes the public acceptance about the UAM operation. One of the major issues is the environmental noise problem. The environmental noise should be quantified for the noise regulations issued by FAA or EASA.
Measurements of the noise in the urban areas would be the most reliable way for the quantification. However, it is impossible on the current step that any UAM vehicles have not got certification from FAA or EASA. Alternatively, numerical methods efficient for the environmental noise prediction could be used
In this study, we use an environmental noise prediction method based on noise hemisphere database (NHD). The NHD for a UAM vehicle is generated with using noise measurement data, which were obtained from flight tests conducted in K-UAM Grand Challenge. The noise propagation in an urban area is simulated to predict the noise data in the area. Then, the noise data is analyzed to estimate whether the noise satisfy the public acceptance in the urban area.

Keywords: *environmental noise, rotorcraft, noise hemisphere method, auralization*

1. INTRODUCTION

Environmental noise refers to sounds people hear in everyday environments, such as vehicle noise, mechanical noise, and conversational noise. Aircraft noise can also be classified as environmental noise, especially when sounds from aircraft operations like take-offs and landings impact daily life. Such environmental noise significantly affects public acceptance of aircraft. Indeed, the limited frequency of helicopter flights in urban areas can be attributed to their low public acceptance, resulting in frequent complaints.
This public acceptance issue is expected to become even more critical with the advent of Advanced Air Mobility (AAM). When dozens of small Unmanned Aerial Systems (sUAS) and Urban Air Mobility (UAM) vehicles fly within urban environments, citizens exposed to unfamiliar environmental noises may experience discomfort. This discomfort could ultimately undermine public trust in aviation systems, becoming a barrier to related industrial advancements.
Psychoacoustics quantitatively analyzes the psychological discomfort caused by audible noise. Although still relatively unfamiliar in the aviation field, psychoacoustics is essential for enhancing public acceptance of the upcoming AAM era. This analysis requires the subjective evaluation of listeners after auralizing the aircraft-generated noise. For accurate auralization, time-domain data is required instead of the frequency-domain data typically used in many aircraft noise studies.
Environmental noise can be analyzed through direct measurements from flight tests or predictive methods using

analytical approaches. The noise hemisphere method is commonly used, storing aircraft noise data on a hemispherical surface to rapidly predict environmental noise by substituting the aircraft noise source with this hemisphere. However, existing noise hemisphere methods typically propagate sound in the frequency domain, complicating accurate auralization (1,2).
Considering these limitations, this study improved the existing environmental noise prediction code, enabling the creation of a noise hemisphere through noise back-propagation and facilitating noise predictions at specific locations in the time domain. The analysis primarily focused on noise back-propagation data.

2. NUMERICAL METHODS

2.1 Noise back-propagation and auralization

Microphones measure acoustic pressure in the time domain. Thus, noise back-propagation from microphone data to the hemisphere surface is performed for each time instance as described by Eqn. (1).

$$p'_{spr} = p'_{mic.} \times \frac{r_0}{r_s} \quad (1)$$

Here, the subscript denotes information on the hemisphere surface, represents information at the microphone, is the distance from the microphone to the hemisphere center, and is the radius of the hemisphere. This back-propagation is conducted for all measured time instances. The back-propagated noise data on the hemisphere surface does not initially account for physical phenomena such as atmospheric absorption and ground effects. To model these phenomena, previously proposed methods operate in the frequency domain. Therefore, back-propagated noise data is converted into narrow-band (NB) frequency-domain data using the Short Time Fourier Transform (STFT). Each modeling method then adjusts the amplitude of NB frequency-domain data for hemisphere construction.

2.2 Auralization through Grifin-Lim algorithm

Noise data converted to NB frequency-domain form via STFT can be returned to time-domain data using the Inverse STFT (ISTFT). However, the phase angle information of this reconstructed data often lacks accuracy. To resolve this, the Griffin-Lim Algorithm (GLA) is employed to reconstruct the phase angle using only the continuous amplitude of NB frequency-domain data. Figure 1 illustrates differences between original sounds restored with and without applying

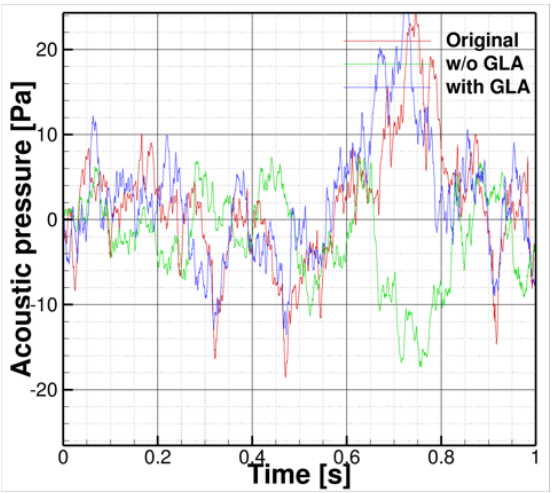

Figure 1. Comparison of restored time-domain data with and without GLA

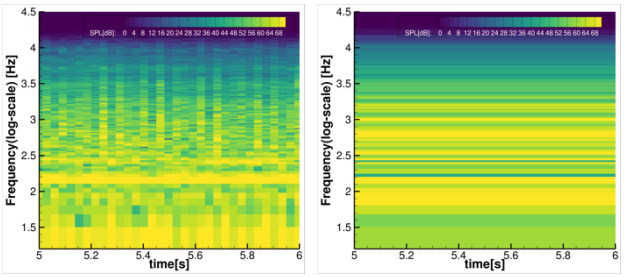

GLA. Although the reconstructed sound slightly differs from the original, GLA prevents critical errors like inverse phase reproduction. Sample points used for noise hemisphere construction are finalized through GLA.

2.3 Noise hemisphere generation using a surrogate model

Traditional noise hemisphere methods utilize grid-based data structures, storing noise data at grid centers or points. Interpolation with pre-generated noise samples often leads to unrealistic sound data due to insufficient grid resolution in time-domain noise prediction and auralization. To overcome this, the current study implements Kriging surrogate models for hemisphere generation, deriving noise information at various radiation angles required by the noise propagation algorithm. Figure 2 shows spectrograms comparing grid-based hemispheres and surrogate model-based hemispheres with the original sound. The surrogate model achieves more accurate restoration similar to the original, unlike the grid-based method, even at high grid resolutions

3. CONCLUSION

This study proposes a method to enable auralization in environmental noise prediction from rotorcraft by transitioning noise hemisphere techniques from frequency-domain to time-domain data. Implementing the Griffin-Lim Algorithm and surrogate models significantly improves the accuracy of sound reconstruction, closely matching original

sounds. Future research will utilize the developed time-domain noise hemispheres for noise propagation and auralization studies in both open and urban areas.

ABSTRACT

The increasing air traffic of small multi-rotor UAVs for urban activities has led to a growing interest in the study of the flight noise emitted by these vehicles. Propeller noise has been recognized as a crucial issue, prompting efforts by the scientific community to search for mitigation strategies to reduce noise without compromising the propeller aerodynamic performance. The current research aims to analyze the effect of the propeller blades surface roughness on their aerodynamic, aeroacoustic and psychoacoustic performances. In order to carry out the study, an experimental campaign is conducted on a propeller, in isolated configuration at different rotational speeds. Tests involved the simultaneous measurements of the propeller thrust and noise, through a load cell and an array of microphones respectively. For each combination of parameters, a time-frequency analysis is performed, and a psychoacoustic annoyance model is used to evaluate five psychoacoustic metrics, loudness, sharpness, roughness, tonality and fluctuation strength.

1. INTRODUCTION

Unmanned aerial vehicles (UAVs) have experienced a significant increase in popularity over the last decade, due to the wide range of applications they can be used in. They are employed in military operations as well as civil applications such as traffic surveillance, packages delivery, wildfire monitoring, medical purposes, exploration of inaccessible areas etc. [1,2] Despite the advantages of using drones, noise is considered a crucial factor that limits their employability on a large-scale in urban environments. The main source of noise in multirotor vehicles is caused by the propulsion system, i.e. propellers. Since propellers are the components responsible for generating lift, in the effort to reduce propeller noise, particular attention must be paid to ensure that the aerodynamic performance of the propeller does not deteriorate. Noise reduction can be achieved by modifying the blade shape and structure, leading to a deep interdependence of noise and propeller efficiency.

Several studies have been conducted in order to achieve a better understanding of the noise generation mechanism of small rotating blades [3] and to explore the relationship between the aerodynamic performance and the acoustic signature of propellers [4]. These two aspects are naturally in competition. Therefore, to avoid that the reduction of noise is obtained to the disadvantage of the efficiency, multidisciplinary optimization algorithms are often employed in order to achieve a trade-off between the two aspects [5,6].

Recent researches have focused on the impact assessment on propeller aeroacoustics of the addition of roughness on the blade surface [7–9]. The application of a microfiber

coating on the propeller blades [7], or the use of propellers with high surface roughness values [8] have been found to lead to a noise reduction if compared with the baseline propeller. Hasegawa et al. [7], in particular, demonstrated that the application of a microfiber coating effectively reduces the broadband noise emitted by the propeller in the frequency range between 3 kHz and 10 kHz. The noise reduction becomes more pronounced as the position of the microfiber coating moves towards the blade tip. This, combined with the fact that the reduction occurs at high frequencies, suggests that the microfiber coating modifies the characteristics of the flow associated with the turbulent boundary layer trailing-edge noise (TBLTE) and the laminar boundary layer vortex-shedding noise (LBLVS).
Moreover, noise generated by UAVs is strongly related to a sense of annoyance in human listeners. The annoyance that people experience when exposed to UAVs noise is found to be greater than the one related to other vehicles, such as road vehicles [10]. Evidence highlights that environmental noise pollution significantly affects public health, well-being, and quality of life [11]. Recent focus on public health, encompassing both physical and mental dimensions, plays a crucial role in directing research and innovation in this area, aiming to ensure an improved quality of life and psychosocial well-being.
The indicators typically used to assess the acoustic behavior of a source, such as the overall sound pressure level (OASPL), calculated by integrating the power spectral density over the audible frequency range (between 20 Hz and 20 000 Hz), although very useful to determine the acoustic efficiency of a vehicle, can not be fully representative of the human perception. To evaluate the annoyance perceived under laboratory conditions, participants were exposed to specific noises and asked to numerically rate their level of annoyance. Statistical indicators were then derived from these ratings [10, 12–14]. Specifically, the mean annoyance indicator (MA) was calculated as the primary parameter, based on the average rating of all those involved in the study. However, the MA obtained from a specific laboratory trial can not be directly compared with the same parameter from another trial, unless additional tests are performed.
For this reason, psychoacoustic models have been developed to mathematically calculate and directly compare the relative annoyance degree of different sounds.
Since the perceived annoyance is found to be strongly dependent on the spectral characteristics of the sound, specific metrics are used to quantify these properties [15–17]. These metrics include loudness, sharpness, roughness, tonality and fluctuation strength. A weighted combination of these parameters enables the calculation of psychoacoustic annoyance (PA). According to Zwicker [18], PA can be described as a function of loudness, sharpness, fluctuation strength and roughness. This model, however, does not take tonality into account. To address this limitation, Di et al. [19] enhanced the model by including tonality as a dependency in the PA function, making it suitable for comparing tonal and atonal noises.
The present study intends to investigate the influence of the surface roughness on the aerodynamic, aeroacoustic and psychoacoustic behaviour of a propeller. The aim is to determine if an improvement can be achieved from the aeroacoustics and psychoacoustics point of view without compromising the propeller aerodynamic performance.
To this purpose, an experimental campaign has been carried out in the Fluid dynamics Laboratory of the University of Roma Tre. A load cell was used to measure thrust under static conditions while a linear microphone array was installed to collect acoustic data and, hence, to perform an analysis in terms of OASPL and psychoacoustic indicators.
The paper is organized as follows. Details about the experimental set-up and the measurement techniques are reported in Sec. 2. The results of the aerodynamic characterization and the acoustic and psychoacoustic measurements are presented in Sec. 3, with the conclusions drawn in Sec. 4.

2. METHODOLOGY

2.1 Experimental Setup

The experimental investigation was carried out in the Fluid dynamics Laboratory of the University of Roma Tre. The propellers used in this campaign are APC 8x6 E, with a diameter D of 20.48 cm and a pitch of 15.3 cm. Each propeller features a different surface roughness value. Apart from the commercial off-the-shelf propeller, the other roughness values were achieved by applying materials with varying grain sizes to the blades near the tip and in correspondence of the trailing edge in the suction side, as in Fig. 1, following the methodology in [7]. The grain sizes are equal to 27 µm, 50 µm, and a mixture of particles ranging from 70 to 110 µm. Tab. 1 provides a summary of the different values of the propeller's surface roughness along with the corresponding labels used in the graphs in Sec. 3.

The propellers were operated in static condition and

Table 1. Values of the propeller's surface roughness and the corresponding labels.

Roughness 1	R1	27 µm
Roughness 2	R2	70-100 µm
Roughness 3	R3	50 µm
Roughness 4	R4	baseline

in a pusher configuration at a maximum chord-based Reynolds number of about 7×10^4, based on the chord at 75% of the blade. The rotational speed of the propellers was set equal to six different values: 5500 RPM – 6000 RPM – 6500 RPM - 7000 RPM – 7500 RPM – 8000 RPM for the current experiment. The RPM control was managed through a LabVIEW program, which ensures that the RPM variation remains within 1.5% of the desired value.

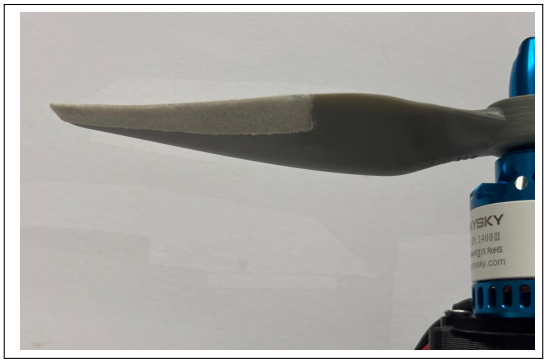

Figure 1. Propeller APC 8X6 E with a roughness value of 50 µm

2.2 Acoustic measurements

Four Microtech Gefell M360 electret microphones were used to perform the acoustic acquisitions. Each microphone has a diameter of 7 mm and has a flat frequency response in a range between 20 and 20 kHz with a maximum sound pressure level of 130 dB. The reference pressure is 20 µPa and the microphones have an integrated preamplifier. Microphone signals were recorded for a total of 10 s at 100 kHz. The microphones were mounted on a linear stand parallel to the propeller rotational axes and positioned at 0.7 m from it, that is equal to 3.5 D. The first microphone was aligned with the propeller plane, the others were positioned at 15°, 30° and 45° with respect to the propeller plane, in the outlet region. Fig. 2 shows in detail the setup used to perform the acoustic measurements. A fifth microphone was then placed in the nearfield of the propeller to perform the RPM control.

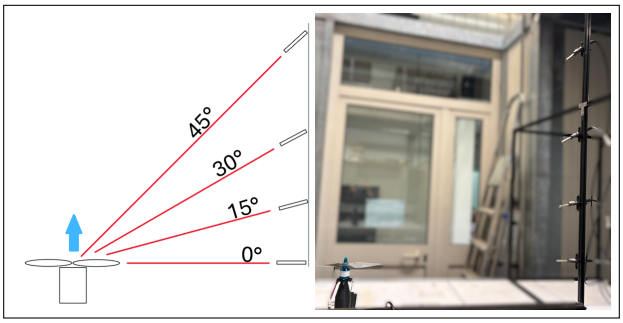

Figure 2. Schematic (left) and photo (right) of the experimental setup.

2.3 Thrust acquisitions

A RoHS low force compression load cell FS20 was used to perform thrust measurements. It can measure up to 1500 Grams-Force and the sensitivity was determined through the utilization of known weights. The signals were recorded for a total of 10 s at 100 kHz and the average values were calculated. The load cell was positioned into the propeller support specifically created to allow the transmission of the force in the x direction. Fig. 3 shows the load cell and the motor support.

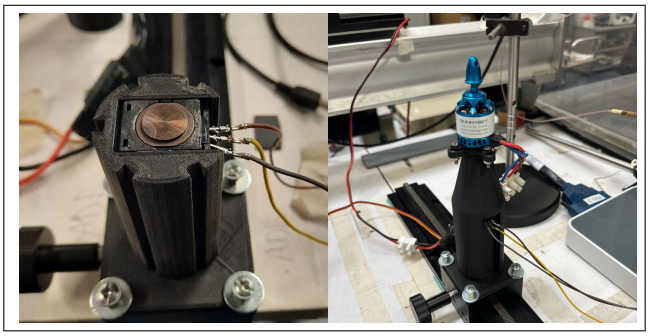

Figure 3. Load cell (left) and motor support (right).

2.4 Analysis

To perform the acoustic analysis, the sound pressure spectrum level (SPL) and the OASPL were calculated according to Eqn. (1) and Eqn. (2), respectively.

$$SPL(f) = 10\log_{10}\frac{PSD(f)}{p_{ref}^2} \tag{1}$$

$$OASPL = 20\log_{10}\frac{\sigma(p_m)}{p_{ref}} \tag{2}$$

where PSD is the power spectral density of the signal, calculated with a frequency resolution of $\Delta f = 3$ Hz, p_{ref} is the reference pressure and it is set equal to 20 µPa and $\sigma(p_m)$ is the standard deviation of the pressure signal from which the mean value has been subtracted.
Moving on to the psychoacoustic analysis, the open-source MATLAB toolboxSQAT (Sound Quality Analysis Toolbox) [20] was used. In particular, the model implemented here to calculate the perceived annoyance is the one proposed by Di et al. [18]. Psychoacoustic annoyance is defined as in Eqn. (3).

$$PA = N_5\left(1 + \sqrt{w_S^2 + w_{FR}^2 + w_T^2}\right) \tag{3}$$

where w_S, w_{FR} and w_T are defined as in Eqn. (4), Eqn. (5) and Eqn. (6).

$$w_S = \begin{cases} (S - 1.75)(0.25\log_{10}(N_5 + 10)), & S > 1.75 \\ 0, & S \leq 1.75 \end{cases} \tag{4}$$

$$w_{FR} = \frac{2.18}{N_5^{0.4}}(0.4F + 0.6R) \tag{5}$$

$$w_T = \frac{6.41}{N_5^{0.52}}T \tag{6}$$

where N_5 is the fifth percentile loudness and S, FS, R and T are the other psychoacoustic metrics: sharpness, fluctuation strength, roughness and tonality respectively.

3. RESULTS AND DISCUSSION

In this section the results are analyzed and commented. Starting from the analysis of thrust, Fig. 4 shows that the two propellers R1 and R2 exhibit better aerodynamic performance than the baseline propeller at all rotational speeds tested, with a maximum thrust gain of 0.3 N at 6000 RPM. The same cannot be said for the propeller R3, which instead shows lower performance than the baseline propeller at low RPM, but recovers from 7500 RPM onward, achieving the best overall performance at 8000 RPM.

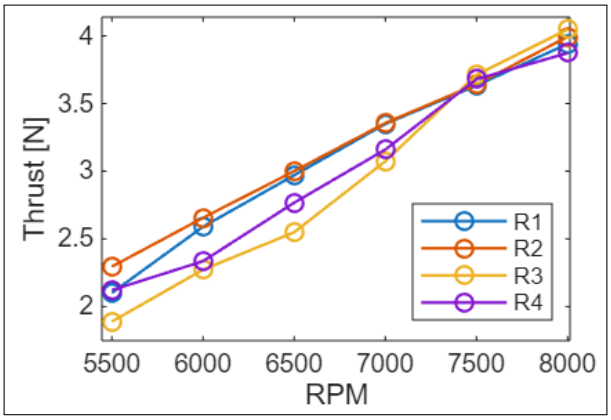

Figure 4. Thrust vs RPM

Fig. 5 shows the sound pressure spectrum level for a rotational speed of 7000 RPM and for all the propellers tested. The propellers with the add-on show a reduced broadband noise contribution than the baseline one, especially at the lower frequencies, up to 5 kHz. The same behavior is observed for all the rotational speeds tested and it is particularly pronounced for the propellers R1 and R2.
A zoom of the first 15 BPFs at 7000 RPM is provided in Fig. 6. In addition to the lower broadband noise, it can be observed that, in correspondence of the harmonics of the BPF, the propellers with the add-on reach higher values of SPL than the baseline (R4), i.e. the tonal noise contribution is higher, especially for R1 and R3.
In agreement with this observation, the values of tonality, the psychoacoustic indicator that evaluates the proportion of pure tones in a noise signal, are found to be higher for the propellers with the add-on compared to the baseline, which exhibits lower values across all RPM, as shown in Fig. 7. The greatest difference is observed at 7000 RPM, where the tonality value of the propeller R1 is 50% higher than the tonality of the baseline. Furthermore, it is worth emphasizing that the R2 propeller exhibits both a significantly reduced broadband noise and a relatively minor increase in tonal noise. This combination of contributions is expected to provide a good trade-off for achieving a better overall acoustic performance.

The OASPL values of the four propellers are com-

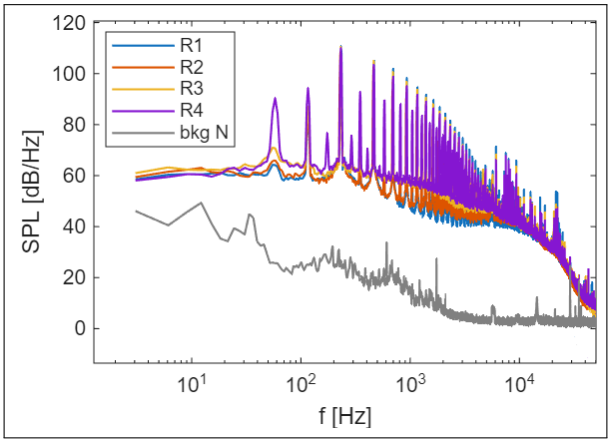

Figure 5. Spectra of the nearfield microphone at 7000 rpm

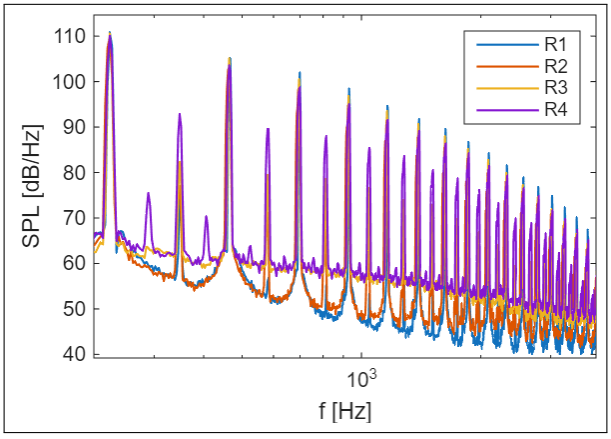

Figure 6. Zoom of the first 15 BPF at 7000 rpm

pared in Fig. 8 for all microphones and all the rotational speeds tested. As a general trend, we observe that the OASPL values tend to increase as the RPM increases, as expected. The baseline propeller has the worst aeroacoustic performance, exhibiting a higher acoustic energy content than the other propellers. Moreover, for most conditions, the R2 propeller appears to have the best acoustic performance, as previously suggested, with an average OASPL reduction of 0.9 dB compared to the baseline, versus an average reduction of 0.6 dB for the R1 propeller and 0.5 dB for the R3 propeller. However, at low speed, around 5500 RPM, and at high speed, around 8000 RPM, the lower value of OASPL is achieved by the R3 propeller. In the range between 6500 RPM and 7500 RPM, the R3

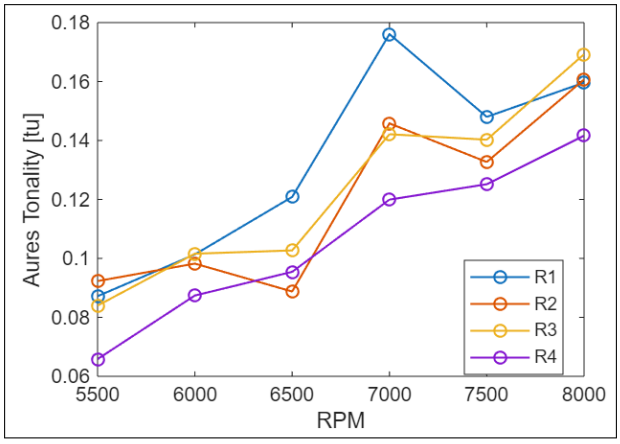

Figure 7. Tonality vs RPM for the microphone on the rotational plane of the propeller

OASPL values became similar to the ones of the baseline, deteriorating its overall acoustic performance. The maximum OASPL reduction, equal to 2.3 dB, with respect to the baseline, is achieved by the R2 propeller in correspondence of microphone 3 at 8000 RPM.

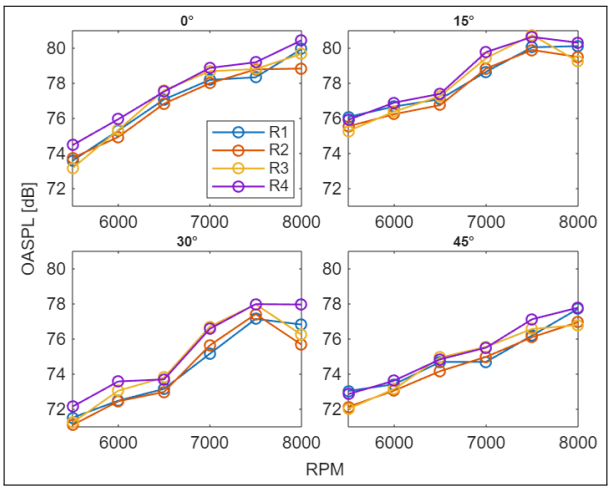

Figure 8. OASPL vs RPM for each microphone

From the psychoacoustic perspective, only the psychoacoustic annoyance (PA) is reported here, as it is calculated as a linear combination of all the other psychoacoustic parameters (see Eqn. 3). In Fig. 9, in particular, the annoyance versus the RPM is plotted for all the microphones. It can be observed that the trend of the PA curves is quite similar to the trend of the OASPL curves,

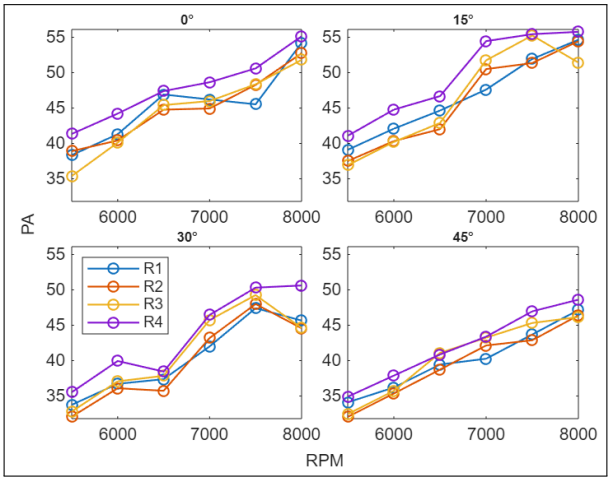

Figure 9. Psychoacoustic annoyance vs RPM for each microphone

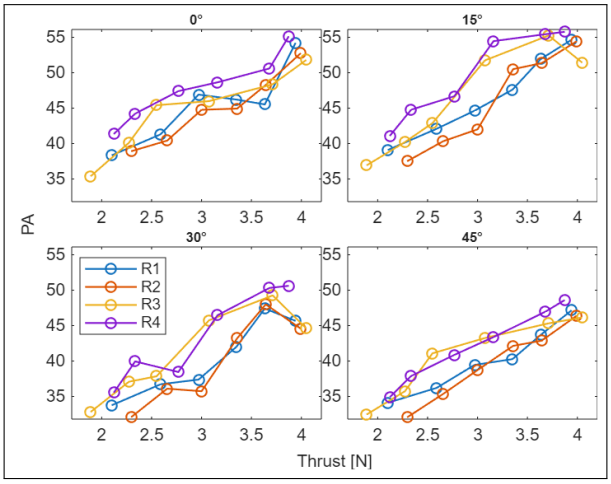

Figure 10. Psychoacoustic annoyance vs Thrust for each microphone

but the differences are more pronounced: the curves of the propellers are more spaced apart, revealing significant differences in terms of the annoyance caused. First, it is clearly visible that the baseline propeller is the most annoying along all the RPM and at all the locations. Regarding the lowest values, the situation is somewhat less clear. At low speed, between 5500 and 6000 RPM, the best psychoacoustic performance is reached by the roughness 3 and roughness 2 propellers. At 7000 and 7500 RPM the roughness 3 propeller became more annoying reaching, in some cases, values equal to the baseline. In this range of RPM, the best performance is prerogative of the R1 and, again, of the R2 propellers. At the maximum speed, 8000 RPM, once again the roughness 3 propeller achieves the best result. Anyway, the propeller with an overall greater average decrease in PA, compared to the baseline, is the R2 propeller, with a decrease of 3.2 units, whereas the other two propellers, R1 and R3, show a decrease of about 2.6 units.

As final comparison, Fig. 10 shows the psychoacoustic annoyance of the four propellers as function of the thrust produced. Here the situation is a bit different. For the same thrust, the most annoying propeller is, quite always, the baseline, but the values are often matched by the R3 propeller. For almost all the cases, the best psychoacoustic performance is achieved by the R2 propeller, followed by the R1. Only at the maximum thrust, the roughness 3 propeller achieves the best performance, since it combines the highest thrust at 8000 RPM (Fig. 4), if compared to the other propellers, and a relatively low psychoacoustic annoyance at 8000 RPM, as highlighted previously (Fig. 9).

4. CONCLUSIONS

An experimental investigation of the influence of the surface roughness on the aerodynamic, aeroacoustic and psychoacoustic behaviour of a propeller was carried out in the Fluid dynamics Laboratory of the University of Roma Tre. Four APC 8X6 propellers were tested: an off-the-shelf propeller and three propellers with an add-on of 27 µm, 50 µm, and a mixture of particles ranging from 70 to 110 µm, respectively. Thrust measurements were performed by means of a load cell, whereas 4 microphones were placed in the farfield, at a distance of 3.5 D from the hub of the propeller, for the acoustic characterization. Moreover, a fifth microphone was placed in the nearfield of the propeller. The psychoacoustic analysis was performed using the open-source MATLAB toolboxSQAT (Sound Quality Analysis Toolbox) that implemented the model proposed by Di to calculate the psychoacoustic annoyance. From the study of the spectra measured by the nearfield microphone, the propellers with an add-on show a reduced broadband noise contribution at the lower frequency, up to 5000 Hz. In the same frequency range, in correspondence of the BPF and its harmonics, the propellers with an add-on exhibit higher peaks than the baseline, showing an increased tonal noise contribution. In particular, the R2

propeller, with the add-on roughness ranging from 70 to 100 µm, displays both a significantly reduced broadband noise and a relatively minor increase in tonal noise, a combination that ensures a good performance overall from an aeroacoustic point of view, as demonstrated by the analysis of the OASPL. From the psychoacoustic perspective, the roughness 2 propeller shows an excellent performance relative to the psychoacoustic annoyance as function of the thrust produced. For the same RPM, R2 produces a greater thrust and a lower psychoacoustic annoyance than the other propellers tested, resulting in the best choice to improve the propeller performances.
Therefore, the addition of material which increases the surface roughness on the propeller's tip trailing edge surface is shown to improve the aerodynamic, aeroacoustic and psychoacoustic performances of the off-the-shelf propeller. In particular, among the particles sizes tested in this study, the best results were provided using the mixed particles ranging from 70 to 100 µm.

MID-FIDELITY FRAMEWORK FOR ROTOR NOISE PREDICTION AND PERCEPTION IN MANEUVERING FLIGHT

Marco Picillo[1*] **Mattia Barbarino**[2] **Francesco Avallone**[1]

[1] Department of Mechanical and Aerospace Engineering, Politecnico di Torino, Italy
[2] Centro Italiano Ricerche Aerospaziali, Capua, Italy

ABSTRACT

The goal of Urban Air Mobility (UAM) is to provide a safe, efficient, and sustainable transportation option to reduce traffic congestion and improve mobility in cities. However, the benefits, such as reduction of pollution and increase of public health, need to face important challenges related to safety, regulatory frameworks and public acceptance; the latter is highly driven by noise emissions. In this paper a mid/low-fidelity framework is used to investigate the effects of the acceleration between two steady conditions at different angular velocities for a small propeller. Far-field noise results are evaluated in terms of physical and psychoacoustic metrics. Differences in amplitude and directivity patterns suggest that in the presence of a fast transient, noise increases. Different angular velocity accelerations have also been investigated, highlighting their impact on noise perception.

Keywords: *Noise, UAM, Maneuver, Perception*

1. INTRODUCTION

Urban Air Mobility (UAM) refers to the use of advanced air transportation systems, including electric Vertical Takeoff and Landing (eVTOL) aircraft, to transport people and goods within urban and suburban areas. Beside this concept, Advanced Air Mobility (AAM) encompasses a range of new and emerging technologies in aviation, including UAM, but also includes larger and faster aircraft that are capable of longer-range flights. The development of these new concepts has been accelerated, in the recent years, thanks to the technological advance of VTOL, which are vehicles capable of take-off and landing in a small space [1] and are mainly driven by distributed propellers. Both AAM and UAM are expected to have significant impact on our future lives. However, the benefits, such as reduction of pollution, increase of public health and so on, need to face some important challenges related to safety, regulatory frameworks and public acceptance.

In the context of public acceptance, the analysis proposed by [2] shows that public acceptance is highly driven by noise. For this reason, it is crucial to correctly predict noise emissions from rotorcrafts in urban environments, which are characterized by non-uniform flows, gusts and turbulence [3], causing a non-uniform inflow condition at the rotor disk that determines a dramatic change in sound pressure levels and directivity [4]. Another important challenge in represented by the correct prediction of noise emissions in maneuvering flight and how noise is perceived by an observer. In order to predict noise emissions, different numerical methods are usually adopted, ranging from high-fidelity to low-fidelity. High-fidelity and low-fidelity approaches share the same philosophy, based on predicting blade loads and fluid displacement around the propeller, using an aerodynamic solver, which are then used to compute the acoustic pressure at a specific observer location. Classification is based on the accuracy of the aerodynamic and acoustic solvers that are used for the simulation. High-fidelity methods adopt high-fidelity Computational Fluid Dynamics (CFD) methods such as Reynolds Averaged Navier-Stokes (RANS) [5], Large Eddy Simulation (LES) [6] and Very Large Eddy

Simulation (VLES) [4] to obtain near field description of noise sources, while the near to far field propagation is carried out by the Ffowcs Williams and Hawkings analogy (FW-H), which is a re-formulation of the linearized Euler equations using Lighthill's acoustic analogy [7]. On the other side, low-fidelity methods adopt low-fidelity CFD methods, such as Blade Element Momentum Theory (BEMT) [8], Lifting Line Theory (LLT) [9] and Potential Flow Methods [10] coupled with simplified versions of the FW-H equation such as Hanson's and Gutin's model in the frequency domain and Farassat 1 and 1A formulations in the time domain.

Although noise prediction for propellers in stationary and uniform-inflow conditions has been extensively studied, noise prediction from maneuvering rotorcraft remains a challenging problem. In practice, VTOLs and drones perform complex maneuvers. Rotorcraft flight, in general, can be described as a sequence of equilibrium states interspersed with transitional maneuvers. These maneuvers are marked by non-stationary and aperiodic effects, leading to noise generation mechanisms that significantly differs from the ones in stationary conditions [11]. This additional noise, which increases as the duration of the maneuver decreases, is not negligible as it is characterized by a time-dependent directivity [12].

The majority of studies in the literature employ a quasi-stationary approach, ignoring the transient that occurs when transitioning from one flight condition to another; only few works consider the effects of a short-time maneuver in terms of physical noise metrics. In [13] the noise of a helicopter transient maneuver is numerically simulated using the formulation 1A of Farassat, while [14] used a BEMT solver coupled with an acoustic solver, based on the formulation 1A of Farassat, to investigate the effects of a typical eVTOL mission on the noise of an observer fixed with the vehicle. However, most of the studies cited above focus primarily on physical noise metrics, such as Sound Pressure Level (SPL), while few address the effects of a short-time maneuver on noise perception. Ref. [15] highlights experimentally the effects of a drone transient flight in terms of sound quality metrics, such as loudness, sharpness and roughness with respect to the hovering case, while [16] focused on the effects of different type of propellers on the psychoacoustic annoyance, suggesting that perception-driven design can be performed by targeting the minimization of the perceived noise annoyance, rather that just reducing SPL. For this reason, with the aim of tackling the challenge of public acceptance, it is important to address the psychoacoustic effects of short-time maneuvers, in a fast and accurate way, due to the variety of eVTOL and drones architectures present in the market nowadays, and to include these metrics with the purpose of guiding future designs.

The purpose of this paper is to analyze the effects of angular velocity acceleration, for a small drone rotor, on physical and psychoacoustic metrics, using a low-fidelity framework. This paper is structured as follows: in Sec. 2 the simulation framework is introduced, in Sec. 3 a validation in uniform and non-uniform inflow conditions is presented, while in Sec. 4 the results of a short-time maneuver in terms of sound quality metrics and physical noise metrics will be discussed.

2. SIMULATION FRAMEWORK

In this section, the simulation framework is presented. The tool is composed of an aerodynamic solver, which is FLOWUnsteady [17], based on Vortex Particle Method and an in-house time-domain acoustic solver for the tonal component of the noise, based on the FW-H analogy [18]. The sketch, shown in figure Fig. 3, presents the workflow. First, the rotor geometry, defined with chord distribution, twist distribution, sweep distribution, rotor diameter, airfoils distribution and number of blades is passed to the aerodynamic solver, together with the operating conditions of the rotor. Then, the time history of the blade loading distribution along the radius of each blade is passed to the acoustic solver, together with the observer position, in order to compute a pressure signal at the observer position and finally the noise, in terms of physical noise metrics such as SPL and perception using the open-source python library MoSQUITo [19]. The acoustic solver is developed in Python, following the object-oriented paradigm, which make the software user-friendly and modular.

Vortex Methods are a class of meshless CFD solving the Navier-Stokes equations in their velocity-vorticity form. In particular, the method uses particles to discretize the Navier-Stokes equations. Each particle represents a Radial Basis Function that constructs a continuous vorticity field by carrying an integral quantity of vorticity that is convected by the velocity field. In FLOWUnsteady, blades are divided into blade elements that include 2D airfoil data, such as lift and drag, calculated by XFOIL. The forces on each blade are then reintroduced into the fluid domain by converting them into equivalent immersed vorticity. In this way, it is possible to compute the performance of one or multiple rotors under different operating conditions.

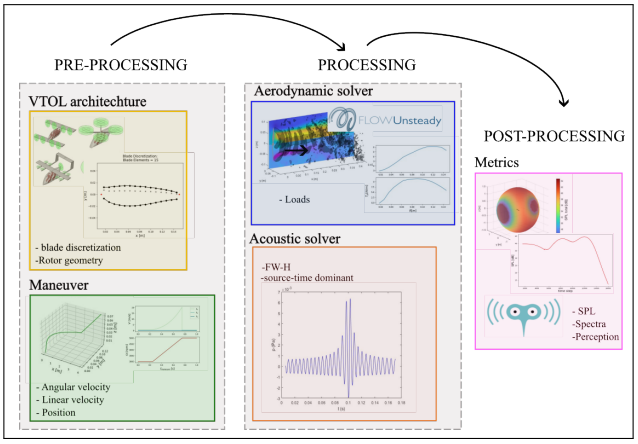

Figure 1. Simulation Framework.

For the acoustic solver we follow the procedure presented in [18]. Only the thickness and loading noise components are computed. More in detail, the FW-H equation, Eqn. (1), is simplified considering two hypotheses: observer placed in the far field and surface integrals calculated on the blade planform.

$$\begin{aligned}\rho'(\boldsymbol{x},t)c_\infty^2 = &\frac{\partial^2}{\partial x_i \partial x_j}\int_{V_0}\left[\frac{\boldsymbol{T}_{ij}}{4\pi r|1-M_r|}\right]_{\tau=\tau^*} dV(\boldsymbol{z}) \\ &- \frac{\partial}{\partial x_i}\int_{S_0}\left[\frac{p_{ij}\boldsymbol{n}_j}{4\pi r|1-M_r|}\right]_{\tau=\tau^*} dS(\boldsymbol{z}) \\ &+ \frac{\partial}{\partial t}\int_{S_0}\left[\frac{\rho_\infty V_j \boldsymbol{n}_j}{4\pi r|1-M_r|}\right]_{\tau=\tau^*} dS(\boldsymbol{z})\end{aligned} \tag{1}$$

Each integrand is then evaluated at the retarded time τ^* which is the time needed to the signal, emitted at time τ, to reach the observer position at time t. The retarded time equation, Eqn. (2), is solved implicitly.

$$t - \tau - \frac{|\boldsymbol{x} - \boldsymbol{y}(\tau)|}{c_\infty} = 0 \tag{2}$$

where $\boldsymbol{y}$ is the blade position in the fixed reference system, $\boldsymbol{x}$ the observer position and c_∞ the speed of sound.

3. VALIDATION

In this section, the noise generated by a rotor in a uniform and non-uniform inflow is compared against high-fidelity and experimental data, in order to partially validate the numerical tool. The geometrical characteristics of the propeller and reference values used for the simulations are summarized in Tab. 1, while geometric characteristics of the propeller can be seen in Fig. 2 and found in previous works from [20] and [4].

Table 1. Propeller parameters and reference values.

Propeller diameter (D)	0.3 m
Hub to tip ratio	0.13
Number of blades (N_b)	2
Blade aifoils	NACA 4412
Air density (ρ_∞)	1.18 kg/m^3
Speed of sound (c_∞)	343 m/s

For uniform inflow distribution we consider a condition in which the free-stream velocity vector, $\mathbf{V}_\infty$, is parallel to the blade rotational axis. On the other hand, a non-uniform inflow distribution consists of a free stream velocity vector which has an inclination, α, with respect to the propeller axis.

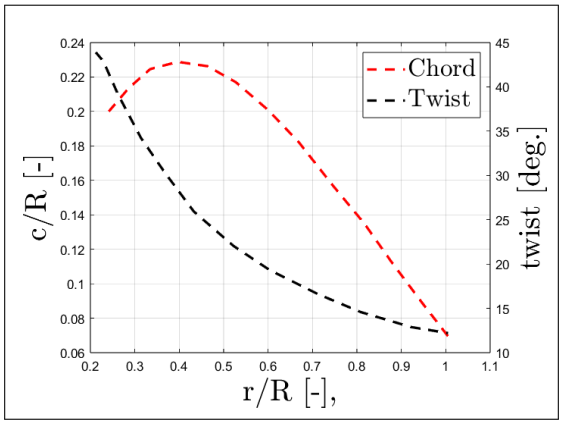

Figure 2. Blade geometry.

First, a comparison of the thrust coefficient C_T, the torque coefficient C_Q and the propulsive efficiency η, for different advance ratios J, calculated as in Eqn. (3), is shown in Fig. 3, Fig. 4 and Fig. 5. Here, the rotor is kept at a constant angular velocity of 4000 rpm, and the results are compared with respect to experimental data [20].

$$C_T = \frac{T}{\rho n^2 D^4} \qquad C_Q = \frac{Q}{\rho n^2 D^5} \qquad \eta = J\frac{C_T}{C_Q} \tag{3}$$

The numerical results match well with the experimental ones. The thrust coefficient is overpredicted for low

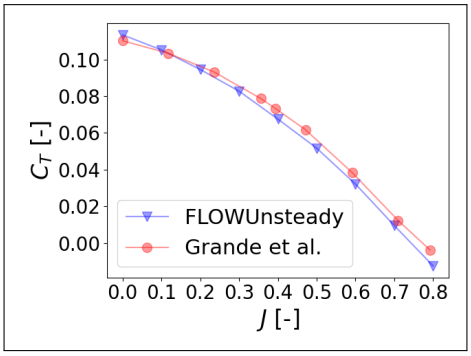

Figure 3. Thrust coefficient as a function of advance ratio.

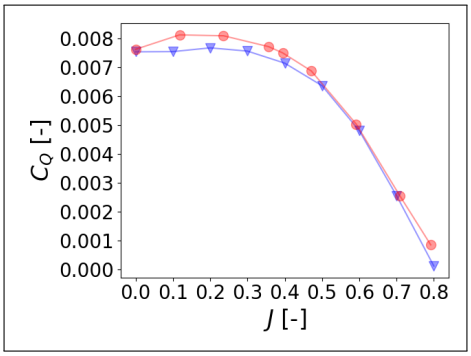

Figure 4. Torque coefficient as a function of advance ratio.

advance ratios, while it is underpredicted for higher ones; while the torque coefficient is underpredicted for low advance ratios in the order of 7%. This behavior reflects in the propulsive efficiency.

Acoustic results are compared with high-fidelity ones from [4] in terms of SPL directivity, for a uniform inflow condition, $\alpha = 0°$, and a non-uniform inflow condition, $\alpha = 15°$, both at $J = 0.4$. Fig. 6 shows the SPL directivity for the non uniform inflow distribution, and we can see that the low-fidelity results, computed with the present framework, match quite well with the high-fidelity data from [4].

4. RESULTS

In this section, the effects of a short-time maneuver are investigated, i.e. an angular velocity variation, between two steady conditions at constant angular velocity, for the rotor geometry described above. The maneuver is shown

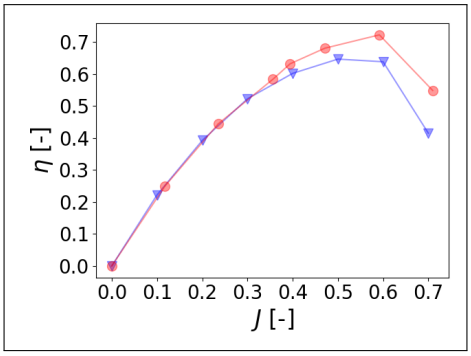

Figure 5. Propulsive efficiency as a function of advance ratio.

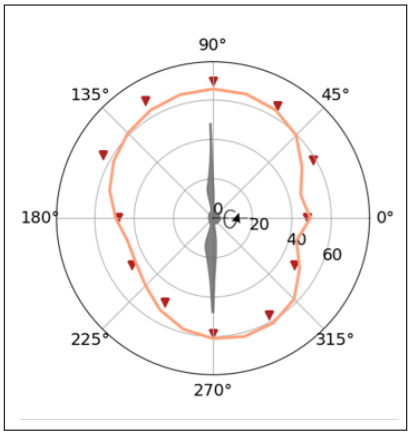

Figure 6. Thickness+Loading noise, $\alpha = 15°$. Solid line represents low-fidelity results. Results are in dB.

in Fig. 7.

Defined $t_{P_3} - t_{P_0}$ as the total time (t_{tot}) of the maneuver, and $t_{P_2} - t_{P_1}$ the transient time (Δt) between the two steady conditions, the transition between the two steady condition is obtained with different laws, a first order polynomial and a third order polynomial, and the transient time is varied in order to study the influence of both on physical noise metrics, such as SPL, and Sound Quality Metrics (SQM). In all the simulations the rotor position is fixed, with a uniform inflow ($V_x = V_\infty$) of 3 m/s, in order to speed up the convergence and eliminate the effects of a possible wake ingestion. The rotational speeds are set equal to $\Omega_{P_1} = 4000$ rpm $\Omega_{P_3} = 5000$ rpm. The selected transient times are $\Delta t = 0.1, 0.5$ s and the total time of the maneuver $t_{tot} = 1$ s. Tab. 2 summarizes the characteristic times, referring to Fig. 7, for each maneuver.

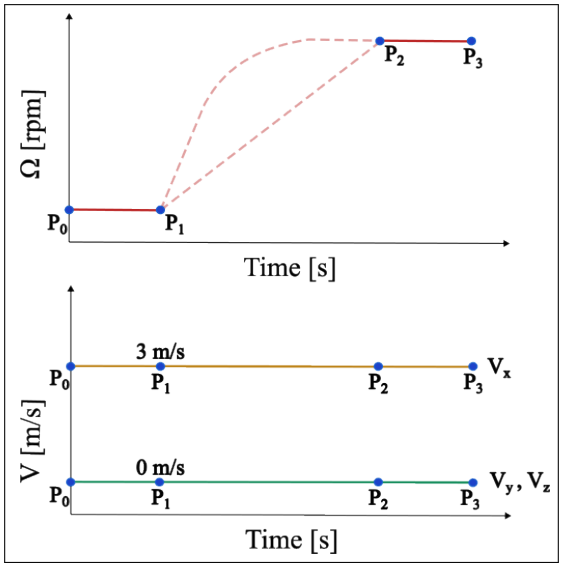

Figure 7. Reference maneuvers.

Table 2. Characteristic times of the maneuver.

Δt (s)	t_{P_1} (s)	t_{P_2} (s)
0.1	0.45	0.55
0.5	0.25	0.75

4.1 Physical Noise Metrics

In this section, the effect of the maneuver will be investigated in terms of SPL and its directivity. Fig. 8 and Fig. 9 show the directivity in time of the first order polynomial maneuver in terms of a difference in SPL, for the two transient times, defined as $\Delta SPL = SPL_{\Delta t=0.1} - SPL_{\Delta t=0.5}$, for the thickness and loading noise, respectively. Θ is the angle between the observer ad the propeller axis, see Fig. 6 for reference. Observing the figures, it can be stated that in the two stationary conditions, the two maneuvers have the same SPL values, but because of the different transient time, these stationary conditions are reached at different times. In fact, observing Fig. 8, the ΔSPL decreases from $0.25s$ to $0.45s$, approximately, becoming zero at $0.5s$, and then starts to increase until $0.55s$, where the maneuver with $\Delta t = 0.1s$ reaches the steady condition. This behavior appears to be independent of Θ, but dependent only on the angular speed value. Focusing on the loading noise, Fig. 9, we can observe an overshoot in SPL at the beginning and end of the transient of each maneuver. The overshoot seems to increase in magnitude and to affect a bigger range of Θ, decreasing the transient time. This behavior is related to the thrust derivative with respect to the retarded time in the FW-H equation, which becomes important approaching the propeller axis, and the effect becomes more evident as the transient time decreases.

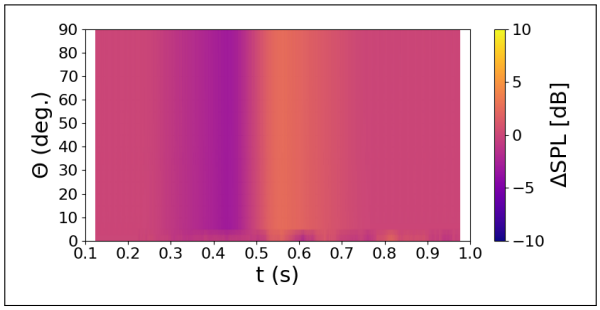

Figure 8. Thickness noise, first order polynomial.

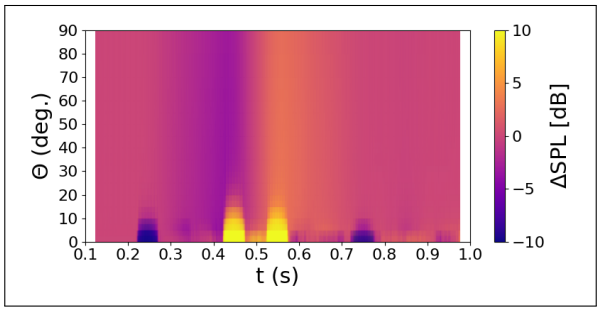

Figure 9. Loading noise, first order polynomial.

This effect can also be observed considering the spectrograms, Fig. 10 and Fig. 11, obtained for the first order polynomial transient with $\Delta t = 0.1s$. We can see that for $\Theta = 20°$, Fig. 11, SPL is higher in two low-frequency bands at the beginning and end of the transient and disappear for $\Theta = 90°$, Fig. 10.

The same behavior appears also for the third order polynomial at the beginning of the transient where the first order derivative of the thrust and angular velocity are greatest, Fig. 12.

Setting the transient time, it is possible to compare different transient laws, that are the third order polynomial and the first order polynomial, as presented in Fig. 7. Fig. 13 and Fig. 14 shows the thickness and loading noise, respectively, for $\Delta t = 0.5s$, in terms of $\Delta SPL =$

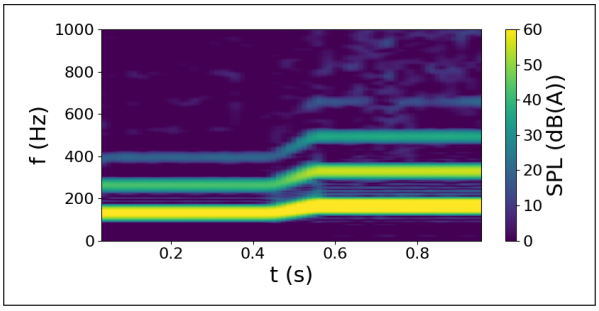

Figure 10. Spectrogram, poly1, $\Theta = 90°$, $\Delta t = 0.1$s.

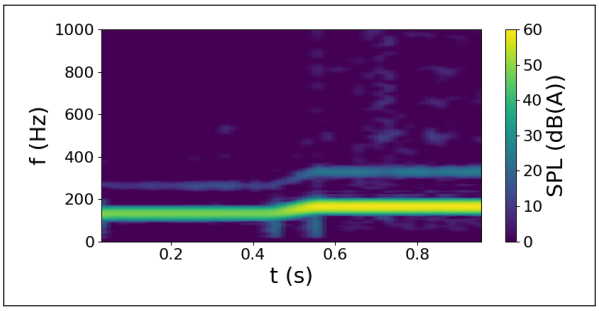

Figure 11. Spectrogram, poly1, $\Theta = 20°$, $\Delta t = 0.1$s.

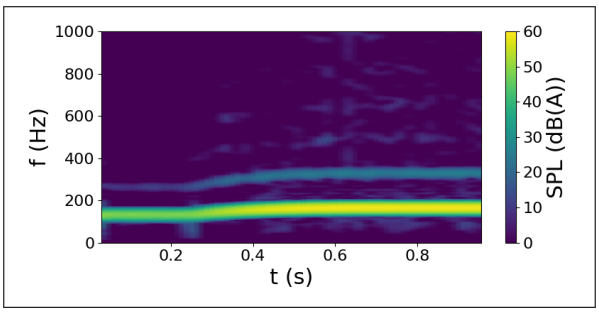

Figure 12. Spectrogram, poly3, $\Theta = 20°$, $\Delta t = 0.5$s.

$SPL_{poly3} - SPL_{poly1}$, which is the difference between the third order polynomial SPL and the first order polynomial SPL. As can be seen, from $t = 0.25s$ to $t = 0.75s$ the ΔSPL is positive, while it is zero during the two steady conditions. That is because the transient of the third order polynomial is characterized by higher angular velocities. The same behavior can be observed for the loading noise, with some differences from $\Theta = 0°$to $\Theta = 90°$. In fact, for $t = 0.25s$ the SPL of the third order polynomial is higher with respect to the first order polynomial; while the opposite behavior is observed for $t = 0.75s$. These results reflect the effect of the thrust derivative, which is higher, for the third order polynomial, at the beginning of the transient, and it is zero at the end of the transient.

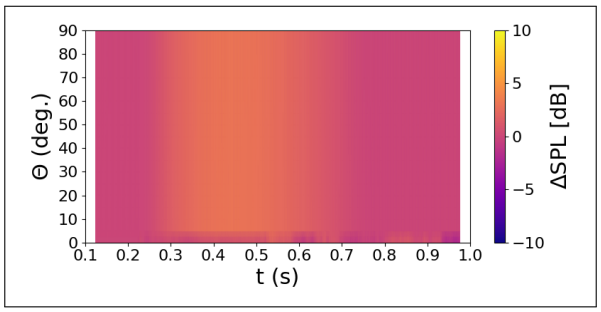

Figure 13. Thickness noise, $\Delta t = 0.5$s.

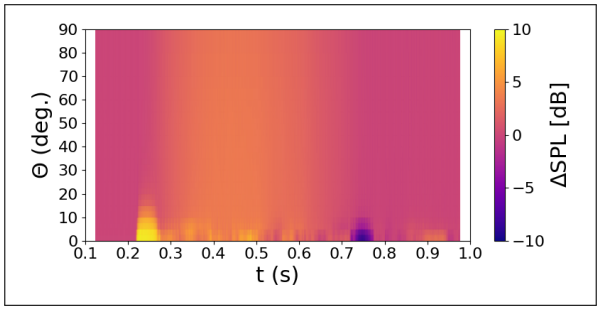

Figure 14. Loading noise, $\Delta t = 0.5$s.

4.2 Sound Quality Metrics

To understand if the effects described above affects the human perception, the SQM are analyzed. Fig. 15 and Fig. 16 show the loudness (ISO 532-1:2017) at $\Theta = 90°$and $\Theta = 20°$, respectively. As can be seen, the loudness increases as the observer approaches the rotor disk and it is dependent on the angular velocity variation law. In fact, the third order polynomial transient is characterized by higher loudness with respect to the first order polynomial, reflecting the angular velocity transient law, while during the two steady conditions the loudness remains constant, as expected.

Looking at the sharpness (DIN.45692:2009), Fig. 17 and Fig. 18, a peak in the transient region of the maneuver is observed. Moreover, the shape of the curve and the

magnitude of the peak seems to be dependent on the time variation of the angular velocity of the rotor. In fact, fixing the transient time, the third order polynomial transient law is characterized by a higher peak and this can be related to the effect of the higher derivative of the angular velocity at the beginning of the transient. The same observation can be made fixing the transient law and reducing the transient time.

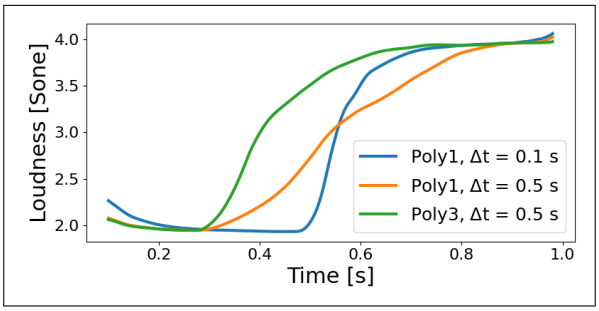

Figure 15. Loudness, $\Theta = 90°$.

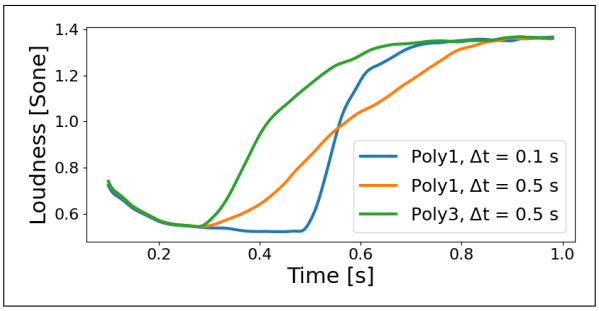

Figure 16. Loudness, $\Theta = 20°$.

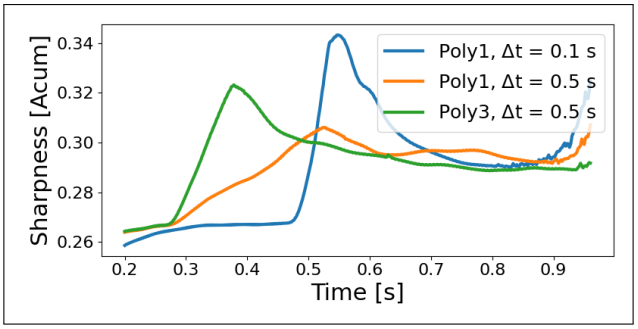

Figure 17. Sharpness, $\Theta = 90°$.

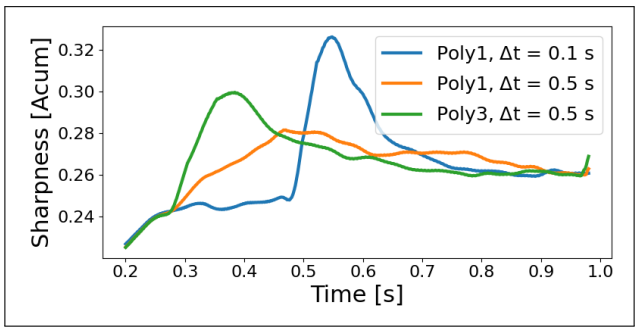

Figure 18. Sharpness, $\Theta = 20°$.

5. CONCLUSIONS

In this paper we presented a mid/low-fidelity tool for noise prediction of eVTOL vehicles. The framework is based on a Vortex Particle Method and a time-domain Ffowks Williams and Hawkings analogy. The framework is validated with high-fidelity and experimental data for a single propeller in uniform and non-uniform inflow conditions. The good agreement of low-fidelity data with respect to the high-fidelity ones gave confidence in employing the tool for the study of a maneuver. The maneuver consists of an angular velocity transient between two steady conditions, and the objective was to understand if the transient time and the angular velocity law affects physical and Sound Quality metrics, for a single two-bladed propeller. In particular, we observed the following features:

- time-dependent SPL directivity: from $\Theta = 0°$to approx. $\Theta = 30°$, we observed two overshoots in SPL at the beginning and end of the transient. These overshoots are carachterized by low-frequency noise, caused by the time variation of the thrust of the rotor, which becomes important as the observer approaches the propeller axis;
- transient time dependence: reducing the transient time, the overshoots increase in magnitude, both for the SPL and the sharpness;
- transient law dependence: how the two steady conditions are reached seems to influence the SPL and the sharpness. Highest time derivative of the angular velocity causes higher overshoots in SPL and sharpness;
- the loudness shape seems to be dependent only by the angular velocity.

In order to understand if these effects affect the noise perception, more in depth studies should be conducted, like sound perception tests on a sample of individuals and more specific maneuvers, representative of real eVTOL flight scenarios.

PSYCHOACOUSTIC CHARACTERIZATION OF AN ISOLATED PROPELLER AT DIFFERENT INFLOW TURBULENCE CONDITIONS AND COLLECTIVE PITCH ANGLES

Roberto Merino-Martínez [1*] **Luca Nicola Quaroni**[1]

[1] Faculty of Aerospace Engineering, Delft University of Technology, the Netherlands

ABSTRACT

The far-field acoustic emissions of a six-bladed propeller were investigated in aeroacoustic experiments in an open-jet wind tunnel. The propeller was operating in different isotropic inflow turbulence conditions generated by turbulence grids placed upstream of the exit plane of the wind tunnel nozzle. In addition, the collective pitch angle of the propeller blades was also varied throughout the measurements. A preliminary directivity analysis of different acoustic and psychoacoustic metrics was performed to investigate the influence of the inflow turbulence intensity and collective pitch angle on the noise emissions and sound perception. In general, increasing the inflow turbulence levels did not modify the conventional metrics recorded, e.g. equivalent sound pressure level. Nevertheless, it considerably increased the broadband noise emissions of the propeller, the loudness, and the overall psychoacoustic annoyance metrics. However, notable reductions in tonality (due to partial tone masking because of the higher levels of broadband noise) and sharpness were reported for increasing turbulence intensities. Overall, this analysis is valuable for the perception-influenced design of devices equipped with propellers, such as drones or urban air mobility vehicles, to account for installation effects.

1. INTRODUCTION

An increasing number of devices employ propellers, such as drones [1] and urban air mobility vehicles [2,3], as well as aerospace technologies (e.g. distributed electric propulsion [4] and boundary layer ingestion systems [5]). Therefore, during the last years, considerable research has been devoted to investigating propeller noise emissions [6, 7] and, from a psychoacoustic point of view, the corresponding human perception [8, 9]. This has led to the use of perception-influence design of propellers to cause minimal noise annoyance during operation [10].

Most aeroacoustic experiments, for simplicity reasons, feature isolated propellers (typically conducted in anechoic chambers [10, 11] or wind tunnels [7]) and consider clean, low-turbulence inflow conditions. However, in practice, the usual installation of propellers close to the airframe (e.g. on aircraft or drones) typically causes turbulent inflow conditions [12]. Despite some studies on this topic [6,13,14], there is currently a lack of knowledge on how inflow turbulence influences propeller noise emissions, especially in terms of broadband noise and sound perception.

Therefore, the present paper provides a psychoacoustic characterization (using psychoacoustic sound quality metrics) based on a fundamental study conducted on an isolated propeller under different isotropic inflow turbulence conditions. In addition, the investigation is extended to different collective pitch angles of the propeller blades.

Section 2 describes the experimental setup employed for the aeroacoustic measurements and the acoustic equipment used. The conventional and psychoacoustic sound metrics used for the characterization are explained in section 3. Lastly, the main results are discussed in section 4, and the conclusions are drawn in section 5.

2. EXPERIMENTAL SETUP

The aeroacoustic measurements of the propeller were conducted at the anechoic, open-jet wind tunnel (A-Tunnel) at Delft University of Technology [15]. The wind tunnel circular outlet (exit diameter of 600 mm) placed on the floor of the facility has a contraction ratio of 15. An additional axisymmetric nozzle with an exit diameter D_{ext} of 420 mm was attached on top of the outlet, see Fig. 1, increasing the overall contraction ratio to approximately 30.

The experiments featured a six-bladed propeller made of steel with a diameter D_p equal to 203.2 mm (8") and a manually adjustable collective pitch angle β. In this study, β values of 25°, 27.5°, 30°, and 32.5° were investigated. This propeller (normally known as X-PROP-S) has been the subject of several publications; for its geometry, including spinner and nacelle dimensions, the reader is referred to [16]. The propeller was placed at a distance of 252 mm ($0.6\,D_{ext}$) from the exit plane of the nozzle. For additional information on the experimental setup the interested reader is referred to [6].

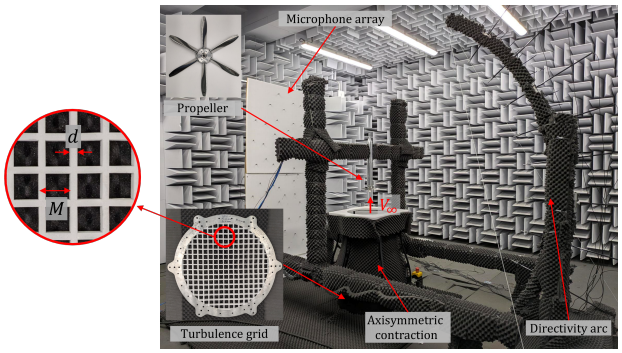

Figure 1: Experimental setup in the A-tunnel.

To investigate different inflow turbulence conditions, three different squared-mesh planar grids made of aluminum plates (thickness 5 mm) were placed at the junction between the axisymmetric nozzle and the wind tunnel outlet, see Fig. 1. The three grids (named A, B, and C) had the same open area ratio of 64% but different values for the bar width d and mesh length M, see Table 1 and Fig. 1. These differences in grid geometries enable various combinations of turbulence intensity TI (defined as the ratio between the root-mean-square velocity fluctuations u'_{rms} and the freestream velocity in the streamwise direction U_∞) levels and streamwise turbulence integral length scales Λ. Table 1 gathers these values for a freestream velocity U_∞ of 30 m/s and a streamwise distance of $x = 0.4\,D_{ext}$ downstream of the nozzle exit. The values for the reference grid-off case are also presented in the same table. All these values were obtained using hot-wire anemometry measurements [6].

Table 1: Bar width d, mesh length M, and turbulence intensity TI for each of the turbulence grids at a distance $x = 0.4\,D_{ext}$ downstream of nozzle exit for U_∞ of 30 m/s [6].

Grid	d, [mm]	M, [mm]	TI, [%]	Λ, [mm]
Off	N/A	N/A	<0.1	N/A
A	7	35	1.97	11.4
B	10	50	2.75	14.1
C	12	60	3.44	16.2

The acoustic measurements were performed using a phased array containing 63 free-field microphones and a directivity arc containing 8 microphones, see Fig. 1, spanning an emission angle range of 70° from $\theta = 70°$ to 140°, with the $\theta = 90°$ corresponding to the rotor disk plane and $\theta = 0°$ to the upstream direction. Both arrays of microphones were positioned at a distance of 1.3 m ($\approx 6.5 D_p$) from the propeller's axis, with the directivity arc centered at the propeller's rotation center. To account for the sound convection due to the flow, the acoustic data recorded was corrected in terms of amplitude and polar emission angle θ, following the guidelines explained in [17]. Therefore, the polar emission angles and amplitudes shown henceforth in directivity plots (Figs. 4-15) already present this correction. A sampling frequency of 51200 Hz and a recording time of 60 s were employed, which corresponds to approximately 10,000 propeller rotations acquired per operating condition.

In order to reduce acoustic reflections, acoustic absorbent materials (melamine and pyramidal polyurethane foam panels) were placed over all exposed surfaces within the anechoic plenum, see light and dark gray surfaces in Fig. 1, respectively. The turbulence grids were also equipped with 20-mm thick melamine foam panels, which were water-jet cut to the respective grid geometry and glued onto the downstream side to suppress both secondary reflections and the generation of tones by vortex-shedding mechanisms [18].

3. CONVENTIONAL AND SOUND QUALITY METRICS

Conventional sound metrics typically used in noise assessment pose challenges for quantifying noise annoyance [9]. Nevertheless, current noise regulations still employ these metrics for enforcing environmental noise laws. Therefore, the current study considers the equivalent sound pressure level $L_{\text{p,eq}}$, as well as the maximum tone-corrected perceived noise level (PNLT) to assess the noise emissions of both propellers. The latter is the base for the effective perceived noise level (EPNL) metric, which is typically employed during aircraft noise certification processes [19].

Unlike the sound pressure level L_{p} metric, which quantifies the purely physical magnitude of sound based on the pressure fluctuations, Sound Quality Metrics (SQMs) describe the subjective perception of sound by human hearing. Hence, SQMs are expected to better capture the auditory behavior of the human ear compared to conventional sound metrics typically employed in noise assessments. The five most commonly-used SQMs [20] are:

- Loudness (N): Perception of sound magnitude corresponding to the overall sound intensity.
- Tonality (K): Perceived strength of unmasked tonal energy within a complex sound.
- Sharpness (S): High-frequency sound content.
- Roughness (R): Hearing sensation caused by modulation frequencies between 15 Hz and 300 Hz.
- Fluctuation strength (FS): Assessment of slow fluctuations in loudness with modulation frequencies up to 20 Hz, with maximum sensitivity for modulation frequencies around 4 Hz.

These five SQMs were calculated for each recording and combined into a single global psychoacoustic annoyance (PA) metric following the model proposed by Di *et al.* [21]. Henceforth, the top 5% percentiles of these metrics (values exceeded 5% of the time) are reported (and hence the sub-index *5*). All the SQMs and the PA metric were computed using the open-source MATLAB toolbox SQAT (Sound Quality Analysis Toolbox) v1.2 [22]. The R and FS metrics evaluate the amplitude modulation and, since the result comparisons are made for the same propeller rotational speed, their variations were not as significant as for the other metrics and are, therefore, not presented in this paper for the sake of brevity.

4. RESULTS

From the different test conditions evaluated, the results presented in this paper correspond to a freestream velocity U_∞ of 30 m/s and a rotational frequency f_r of 166.76 Hz, resulting in a tip Mach number $M_{\text{tip}} = V_r/c_0$ of 0.325, where $V_r = \sqrt{(\pi f_r D_p)^2 + U_\infty^2}$ and $c_0 = 340$ m/s (speed of sound at 16°C).

4.1 Influence of the inflow turbulence intensity

Figure 2 depicts the comparison of the spectra for all grid cases for $\beta = 30°$ and a polar emission angle of $\theta = 140°$, i.e. downstream of the propeller plane. The frequency axis is normalized with respect to the blade passing frequency (BPF $= Bf_r \approx 1$ kHz, where $B = 6$ is the blade count). In general, it is observed that increasing TI causes a substantial raise in the broadband noise up to roughly the 7$^{\text{th}}$ BPF (≈ 7 kHz). On the other hand, a considerable reduction in high-frequency broadband noise is observed for all the grid cases after the 11$^{\text{th}}$ BPF (≈ 11 kHz).

For conciseness, the result comparison of varying turbulence grids in this section is limited here to the cases with $\beta = 30°$, although other collective blade pitch angles presented comparable findings.

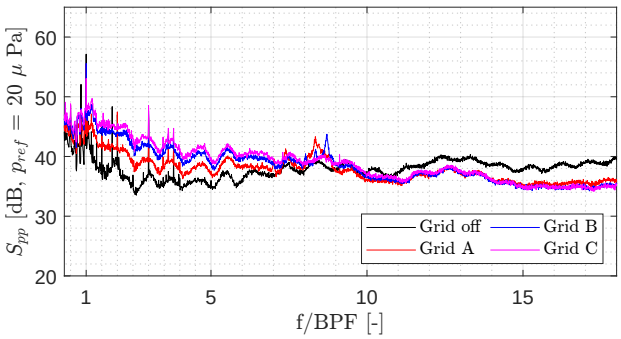

Figure 2: Power spectra S_{pp} of acoustic pressure for $\beta = 30°$ and all grids for $\theta = 140°$ ($\Delta f = 5$ Hz).

The influence of the inflow TI in the propeller far-field noise emissions was evaluated using directivity plots (Figs. 4-9) at the end of this paper for the different sound metrics considered (both conventional and psychoacoustic).

First of all, Fig. 4 depicts an almost omnidirectional (except for an outlier at $\theta \approx 150°$) emission pattern of the $L_{\text{p,eq}}$ metric that is essentially the same for all the four cases. This highlights the fact that this simple metric (lacking any frequency weighting) is not suitable for

making perceptual comparisons [23]. The PNLT_{max} metric (Fig. 5, on the other hand, starts showing larger differences between the four inflow TI cases, with (in general) larger emission values with increasing TI. Overall, larger values and variability are observed for larger polar emission angles θ. Nevertheless, the directivity patterns are not very uniform. Regarding loudness N_5, Fig. 6 presents a more dipole-like radiation pattern typical in propeller applications [6, 10, 11]. Since loudness is (to a certain extent) an energy-based metric, increasing the TI results in higher N_5 values for all emission angles, showing values up to 30% higher than the baseline grid-off case. This is explained by the higher broadband noise levels observed in the mid-frequency range in the spectra of Fig. 2. In terms of sharpness S_5 (see Fig. 7), the radiation patterns are again dipole-like, but in this case, the grid-off case (lowest inflow TI) presents the highest values. This is due to the fact that the sharpness metric employed represents the ratio of high-frequency loudness with respect to the total loudness. High-frequency noise is, in fact, affected by the presence of a turbulence inflow, but rather surprisingly, not by its turbulence intensity. Unexpectedly, its level is greater with a clean inflow and, therefore, the overall sharpness is roughly 10% lower for the cases with higher TI compared to the grid-off baseline. A similar trend (although with a considerably more irregular radiation pattern) is observed for the tonality K_5 (see Fig. 8). In this case, the additional broadband noise observed in the cases with higher TI (see Fig. 2) effectively masks the characteristic tones of the propeller noise signature (BPF and harmonics), providing K_5 values about half the baseline case without inflow turbulence. Finally, the global PA metric (see Fig. 9) combines the results of all SQMs and shows a similar radiation pattern as N_5 (since loudness heavily influences PA [20]). For the larger polar emission angles θ, the estimated psychoacoustic annoyance is up to about 25% higher than for the grid-off baseline case.

4.2 Influence of the collective blade pitch angle

In a similar way as Fig. 2, Fig. 3 compares the far-field noise emissions for all β cases considered when using Grid C and a polar emission angle of $\theta = 140°$. In contrast to the TI variation, increasing β seems to mostly affect the broadband noise emissions for frequencies higher than the 10^{th} BPF, with lower values reported for increasing β. The spectra below that threshold, on the other hand, roughly remained constant for varying β.

The effect of β on the directionality of the different

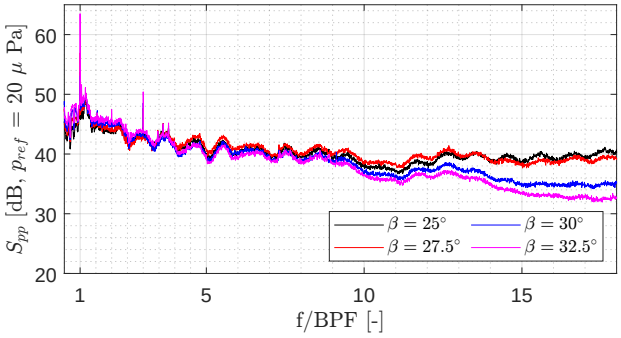

Figure 3: Power spectra S_{pp} of acoustic pressure for Grid C and all β for $\theta = 140°$ ($\Delta f = 5$ Hz).

sound and psychoacoustic metrics for the propeller was evaluated in Figs. 10-15 at the end of this paper. Only the results corresponding to Grid C (i.e. $TI = 3.44\%$) are presented for conciseness, but the conclusions can be extended to other cases.

The results for the $L_{\text{p,eq}}$ metric for this comparison are depicted in Fig. 10, which are essentially the same for all the cases evaluated, like in the TI comparison presented in Fig. 4. In contrast, the PNLT_{max} metric (Fig. 11 presents its largest variations (up to 4 PNTdB) closer to the propeller plane ($\theta \approx 90°$) with higher values for increasing β. This reflects the greater importance of loading noise mechanisms in the propeller's plane, as increasing β results in increased blade loading for a constant inflow velocity and rotational velocity. The loudness radiation patterns presented in Fig. 12 also show this feature, although with a more uniform dipole-like directivity pattern. Near the propeller plane emission angles, differences in N_5 up to 20% are reported, whereas for higher θ values, the results for all cases seem to collapse better. A more consistent variation with β is observed for the sharpness in Fig. 13, where the first two cases ($\beta = 25°$ and 27.5°) follow a very similar trend, but the two higher blade pitch angles present roughly 10% lower S_5 values. This is explained by the aforementioned reduction in high-frequency noise, as seen in Fig. 3. The tonality values for this comparison (with the highly-turbulent Grid C, see Fig 8) are all relatively low, but in the polar plot of Fig. 14, it is observed that the lower β cases present even lower K_5 values (below 0.05 t.u.). Once again, this is likely to be due to the lower masking because of the decrease in broadband noise that these cases present (see Fig. 3). Lastly, the global PA metric presents once again a dipole-like radiation pattern, but with a considerably smaller spread within

the different cases compared to the TI study. In fact, only significant reductions (about 10%) in PA are observed for the smaller β cases close to the propeller disk ($\theta \approx 90°$).

5. CONCLUSIONS

The current manuscript discussed the influence of the inflow turbulence intensity (TI) and the collective pitch angle on the noise emissions of an isolated propeller, evaluated with conventional and psychoacoustic metrics. The experimental data considered was measured using a directivity arc in an aeroacoustic wind tunnel campaign.

In general, it was found that increasing the inflow TI considerably raised the measured values of PNLT_{max} and loudness, whereas, on the other hand, sharpness and tonality decreased. The overall psychoacoustic annoyance metric (PA) roughly followed the same trend as loudness. Overall, larger PA values and variability were observed for higher polar emission angles (i.e. downstream of the propeller plane).

Increasing the collective propeller blade pitch angle β also caused a rise in PNLT_{max} and loudness, but also a moderate increase in tonality. This time, higher variations of these metrics were observed in the propeller plane direction ($\theta \approx 90°$). Conversely, sharpness seemed to decrease for increasing β angles. The combined effect of these changes caused a slight increase of PA with $beta$, but was considerably milder than for the TI comparison.

Future work will involve psychoacoustic listening experiments to confirm the findings in this paper and assess the somewhat contradicting trends between loudness and tonality and sharpness. In addition, applying acoustic imaging to the data recorded by the planar microphone array would also be of interest to localize, if possible, the noise sources responsible for these psychoacoustic features [24].

ABSTRACT

Over the last decade, there has been a marked increase in the use of drones for various applications including emergency and natural disaster response, payload delivery, aerial imaging and surveillance. There are currently many private and public initiatives that aim to further increase the number of drones and diversify their tasks, offering many associated benefits such as reduction in emissions by replacing traditional and more polluting options with electric unmanned aerial vehicles (UAVs). However, several challenges have to be addressed before a broader implementation is accomplished. One of such challenges is the reported noise annoyance produced by UAVs. This study focuses on the development of data-driven models to predict the dynamics of noise metrics during real UAV operations. Extensive outdoor experimental campaigns were conducted, where array-based measurements were recorded during several manoeuvres performed by different types of drones. Beamforming techniques were applied to improve data quality and signal-to-noise ratio (SNR), and to synchronize telemetry and acoustics data streams. Using the improved experimental data, an initial machine learning model was developed to predict the back-propagated $OSPL$ as function of telemetry-derived operational parameters for ascent, hover, and descent. The model managed to accurately predict the experimental data, and it was found that the elevation angle was the most important predictor of $OSPL$ for the considered manoeuvres.

1. INTRODUCTION

Several factors have led to a sharp increase in the number of drones and tasks, some of which are due to the reduction of production costs, the development of more efficient and smaller technologies, critical for the manufacturing and control of these systems, and their versatility performing a large variety of tasks. Among these, photography and video recording capabilities have enabled drones to support, for example, infrastructure development and surveillance and security. Drones have also been employed to provide assistance in emergencies and natural disasters, in agricultural applications, and goods transportation [1]. Generally, they are considered to have great potential to serve as greener and more sustainable options to replace traditional, more contaminating methods. The number of tasks that UAVs can perform exceeds this list, but the critical natures of certain applications signify their importance.

However, one of the main barriers to the broader adoption and applications of UAVs is the reported acoustic annoyance caused by their operation [2–4]. To allow for the sector to sustainably grow, it is essential to address such reported acoustic annoyance. A predictive tool is needed to estimate representative psychacoustic metrics. Given the wide range in drone types and operational conditions, outdoor drone noise measurements are considered an important element in the efforts of working towards such a tool. These need to be developed based on studies of typical real UAV operations to understand the connections between operational parameters and the acoustics, as well as the influence of environmental factors.

The resulting tools will allow for adequate mission planning, manoeuvre optimization, and design improvements to mitigate acoustic annoyance. As the acoustics vary for different drone types and manoeuvres, these differences must be taken into account as well. At the same time, these tools need to remain computationally inexpensive for fast calculations and seamless

integration into optimization frameworks. Studying drone noise with the drone operating under realistic conditions is essential to ensure a realistic overview of the expected noise. Recent studies have explored UAV noise in such realistic and uncontrolled environments [5–7]. These works focused on measuring and characterising noise from specific drones under realistic conditions. In this study, we describe the development and initial results of a data-driven model that managed to predict experimentally measured acoustic features using telemetry-based variables, and identified important operational parameters as main predictors.

2. METHODS

2.1 Experimental campaigns

An experimental campaign was conducted in April 2024 at an airfield on the outskirts of Prague, Czechia. The site was chosen for its isolation from populations centers, and it was only close to a seldom-used road. Additionally, the airspace in the area was not crowded by air traffic, with only a few aircraft flying overhead throughout the campaign. These occurrences were noted in the experimental logs to account for their contributions, or remeasure if necessary. Taken all together, these conditions met the site goal which was to constitute a highly isolated environment in terms of additional noise sources, while still being an outdoor environment with its inherent variability, including occasional wind currents and gusts. The tested flight plan consisted of a series of manoeuvres including ascent, hover, descent, horizontal flights, and sudden changes in direction. All manoeuvres were performed by three different multirotor UAVs.

To start the model development, operations involving ascent, hover, and descent were analysed. Each operation was performed as follows: The drone took off and ascended vertically to 10 m above ground level (AGL), where it hovered for 15 seconds. It then ascended to 30 m where it hovered again for the same duration, and repeated the process at 50 m and 70 m. Once the hover at the last altitude was completed, the drone descended continuously until landing. The altitude profile, as a function of time, for this operation is shown in figure 1.

This operation was repeated for five different take off positions, where the ascent position, relative to the microphone array, was changed. The take off positions were located north, south, west, and east of the microphone array, at approximately 25 m distance, and an additional site at 50 m east of the array, resulting in five total take off positions. The combined altitude profile of these operations can be observed in figure 2. Differences in altitudes corresponding to different operations occurred due to pilot operations. The selected drone was a co-rotational (X8) quadcopter Gorgon, built, developed, and piloted by AgentFly Technologies, which can be observed in figure 3.

To measure the acoustic signal while the manoeuvre was performed, an array of 4 m of aperture, consisting of 64 microphones, with a sampling frequency of 62500 Hz was used. To attenuate ground reflections, a foam was placed under the entire array, and a secondary foam was placed in the central part of the array between the microphones and the array structure to avoid these reflections, had they appeared.

To record the operational parameters of the drone, the autopilot telemetry and ESCs were used. Among several others, these included the GPS-based information, position, velocity, and acceleration, the RPMs of individual rotors, and thrust, all recorded as a function of time.

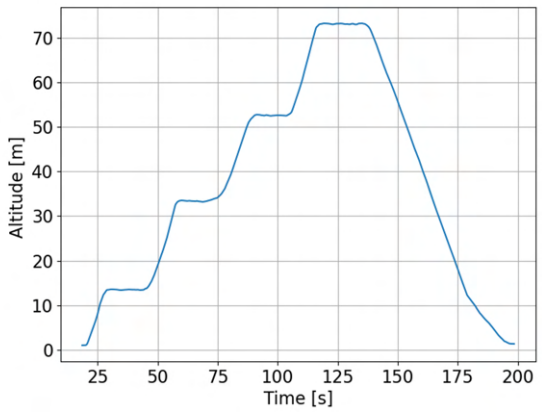

Figure 1. Altitude profile for a single ascent-hover-descent operation performed by the Gorgon X8.

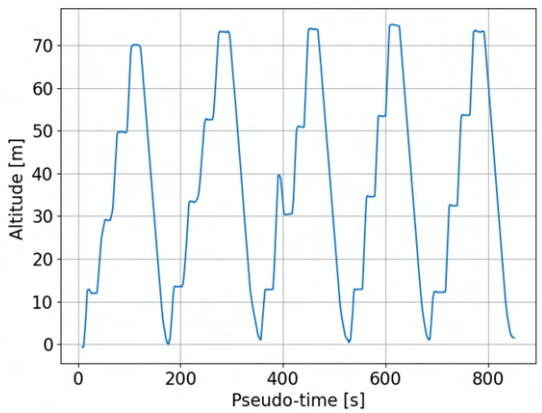

Figure 2. Altitude profile for five ascent-hover-descent operations performed by the Gorgon X8. The horizontal axis represents a sequential arrangement of time-series data rather than the actual time. Variability among signals is evident due to the manual piloting of these operations.

2.2 Beamforming techniques

Given the goal of developing a data-driven model to describe the time dynamics of different acoustic metrics, it is necessary to first address two points. i) As explained in the previous section, different measures were taken to reduce the effect of ground reflections. However, it was impossible to eliminate them entirely during the data acquisition. ii) It is important to accurately synchronize all telemetry variables and acoustic data to increase the model validity. This involves both properly synchronizing the data and correcting the GPS readouts due to their uncertainties. To address the above issues, beamforming was used.

To do this, a beamformer for a fixed source position ξ_j is defined based on the following functional structure [8]:

$$B(r,\theta,\phi) = \frac{\mathbf{g}_j^* \langle \mathbf{p}\mathbf{p}^* \rangle \mathbf{g}_j}{|| \mathbf{g}_j ||^4} \tag{1}$$

where $\langle \mathbf{p}\mathbf{p}^* \rangle$ is the Cross-Spectral Matrix (CSM) of the measured pressures, which is generated by averaging the Fourier transforms of sample blocks of 0.1 s in our case, with no overlap considered, and $\mathbf{g}_j^*$ is the steering vector

$$g_{j,n} = \frac{\exp\left(-2\pi i f \Delta t_{j,n}\right)}{4\pi \, || \, \mathbf{x}_n - \xi_j \, ||} \tag{2}$$

with $\Delta t_{j,n}$ the delay between the emission at the position ξ_j and the receiver position $\mathbf{x}_n$. The beamformer (1) establishes a correlation between the actual location information of the source, contained within the CSM, and the source position considered, represented by the steering vector in Equation 2. By considering many potential source locations ξ_j, the location corresponding to the maximum of Equation 1 is used as the estimate of the source position from the array measurements.

This methodology was used to reconstruct the UAV trajectory, independent from the GPS information. Then, the acoustic localization-based and GPS-based trajectories were compared to estimate the corrections needed in the GPS telemetry data.

Once the corrections were implemented, the steering vector was no longer defined based on the estimated position, but rather in terms of the GPS-corrected trajectory. As the beamforming considers all microphones, while compensating for delays to effectively focus on the source, it generates a much cleaner spectrogram with improved SNR compared to single microphone measurements. Once the beamformed spectrogram was obtained, the signals were back-propagated for each beamformed frequency band according to:

$$SPL_{source}(f,t) = SPL_{ground}(f, t + \frac{r(t)}{c}) \tag{3}$$

$$+20 \log \frac{r(t)}{r_0} + \alpha(f) r(t) \tag{4}$$

where r is the distance between the array and the drone, $r_0 = 1$ m, c the sound speed, and $\alpha(f)$ is the coefficient of atmospheric absorption, which depends on the frequency, and also on relative humidity and temperature, both of which were recorded during the measurement campaign.

This procedure generated a cleaner, back-propagated to the source spectrogram, where ground reflections are attenuated. The single microphone and beamformed spectrograms for a single operation can be observed in figure 4

3. RESULTS

3.1 Correlation study

From the telemetry data, different observables were computed as inputs for the data-driven models. These were:

- Azimuthal angle $\phi(t)$: The angular position between the microphone array and the drone measured on the horizontal plane (on the ground).
- Elevation angle $\theta(t)$: The polar angle between the microphone array and the drone, with $\theta = 0$ when the drone is on the ground, and $\theta = \frac{\pi}{2}$ if the drone is overhead.
- Velocity vector absolute value $|\bar{v}(t)|$
- Acceleration vector absolute value $|\bar{a}(t)|$
- Thrust percentage T
- Each of the eight rotors rpm $\{n_{p,i}(t)\}_{i=1\ldots8}$

As the acoustic metrics were back-propagated to the source hemisphere, the range between the array and drone and altitude were not considered.

Since ascent, hover, and descent were the initially tested maneuvers, it is expected that under isolated, ideal conditions, all rpms should have the same absolute value at corresponding times. In the cases of ascent and descent, the absolute rpm of all rotors should be identical at each moment, whereas for hover,

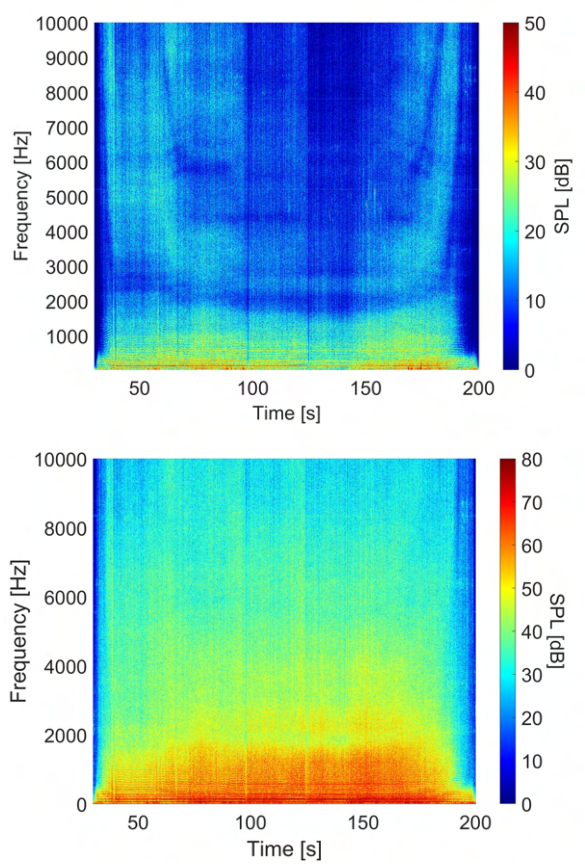

Figure 4. Top: Single microphone spectrogram from an ascent-hover-descent operation. Despite the measures taken during the experiments to attenuate reflections, some effects are still clear. These reflections however, do not appear to be due to ground effects but rather from the outermost parts of the array, which appear to act as spurious sources. Bottom: Beamformed spectrogram from a single ascent-hover-descent operation. Compared with the top, the reflections are greatly attenuated. The dB values increase as this spectrogram is back-propagated to the source. The tones are clearer than the top frame, and in particular, they are present up to 2 kHz. In this range, and for higher levels, the noise is dominated by its broadband component.

the rpm of all rotors would remain constant also during the duration of the manoeuvre. Therefore, the rpms time series were replaced, and the following observables were generated:

$$\langle n_p(t)\rangle = \frac{1}{N_r}\sum_{i=1}^{N_r} \mid n_p(t) \mid \tag{5}$$

$$\sigma_{n_p}(t) = \sqrt{\frac{1}{N_r}\sum_{i=1}^{N_r}(\mid n_p(t) \mid -\langle n_p(t)\rangle)^2} \tag{6}$$

where the average and standard deviations were calculated at equal times, thereby resulting in time series as well.

The $\langle n_p(t)\rangle$ measures the overall rpm, and $\sigma_{n_p}(t)$ is used to quantify how far from the ideal hover, ascent or descent the rpm activities are; a value of $\sigma_{n_p}(t_i) = 0$ indicates that at the time t_i, all the rotors had the same rpm. In other words, variations given by factors such as wind gusts and pilot-induced perturbations will cause this observable to vary from zero. The time over which each effect takes place depends on factors such as pilot reaction time, and wind gust intensity and duration.

The first step towards studying relations between both sets of variables (acoustic metrics and telemetry data) was to compute pair-wise correlations between each of the inputs and $OSPL$, considering a single ascent-hover-descent operation. The Spearman correlation was used as it can test for the existence of general monotonic correlations. The results are shown in figure 5.

As it can be observed from the correlation coefficients, the correlation between the $OSPL$ and the elevation angle θ is significantly increased. To validate the results, Pearson correlation was also used and displayed approximately the same coefficient between both of these variables (data not shown).

This study is a sufficient condition to establish that the elevation angle is a variable of importance to predict the $OSPL$, but it does not necessarily mean that the other variables are not relevant, as this is a pair-wise study and does not capture any coupling between input variables. Additionally, both metrics have limitations, with Spearman correlation allowing for non-linear but monotonic relations, and Pearson looking exclusively to linear relations; both could be excluding the discovery of more complex relations.

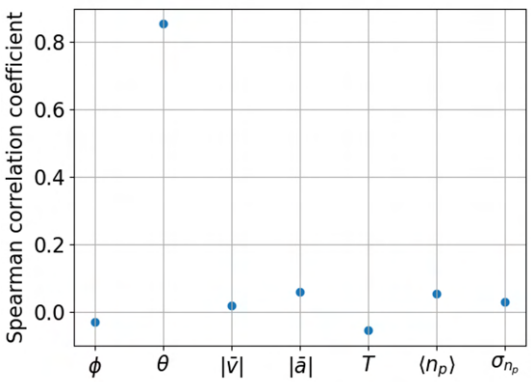

Figure 5. Spearman correlation of the $OSPL$ with each of the tested input parameters. A considerable increase is observed for the elevation angle. This implies the existence of a monotonic relation between both signals.

3.2 Model results

Because drone operations in uncontrolled environments tend to show a higher variability in terms of the drone flight dynamics and therefore in the generated acoustic signals, it is important to understand the model performance in representing this variability. To this end, all five ascent-hover-descent operations were integrated together into the dataset for the model. The altitude profile corresponds in this case with the one observed in figure 2 in the section 2.1.

As the correlation analysis showed that relations exist between at least one of the telemetry variables considered and the measured $OSPL$, the main goal was to find such relations and use them to predict this acoustic metric. To create a model capable of capturing complex relations between the operational parameters and the acoustic metrics, machine learning techniques were employed. In this work, we report the model results for the case of random forest regression (RFR). This method was chosen after comparing the prediction accuracy of different ML regression models, from which RFR proved to be the most accurate while remaining relatively simple. Additionally, Random Forest has also been used in other works related to assesment and prediction of aviation noise [9].

Initially, a series of studies were performed to optimize the number of decision trees. The optimization consisted of generating training, validation, and quality assessment of prediction procedures for each number of decision trees. Randomization and splitting were done before the optimization starts; dividing the randomized data into 80% training and 20% for validation. After the model for each number of trees is trained on the training set, the prediction is computed by applying it to the validation data and generating the model estimation. R^2, $RMSE$, and MAE were calculated based on the prediction and stored for each decision trees number. The optimal number of decision trees was set based on the highest value of R^2. It was also checked that the values of $RMSE$ and MAE have a local minimum at the chosen value. These results can be observed in the figures 6, 7, 8.

The optimization resulted in an optimal number of trees, which was then used to produce the optimal model predictions, which can be observed in figures 9 and 10, and the accuracy in figure 11. From figure 10, the dynamics of the $OSPL$ is accurately recovered by the model. There are sources of deviations arising from extreme values and stochastic experimental noise.

To assess the robustness of the model results, the optimization was repeated for different randomization of the dataset and the R^2, $RMSE$, and MAE were extracted again. No significant difference was observed for the optimized model, presenting similar values up to the 3 decimal place of R^2. The results obtained from the initial optimization are then robust relative to changes in the data randomization. Therefore, the model managed to generate accurately predictions of the experimentally obtained $OSPL$ when all operations are considered together.

To assess the relevance of each of the input variables to predict the $OSPL$, the feature importance of the model was studied, analyzing the mean decrease impurity (MDI). This metric measures how much each input variable reduces the variance of the target values after it is used to split the data. The results from

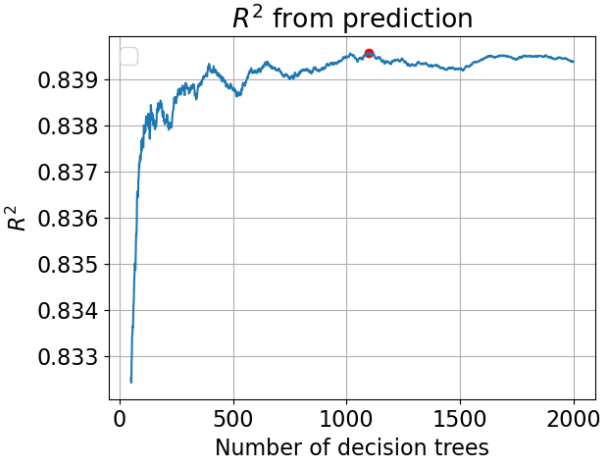

Figure 6. Optimization of the number of decision trees based on the highest R^2. In red, this maximum is shown. It can be observed that the variations on the R^2 are small, as it only changes a maximum of 0.007.

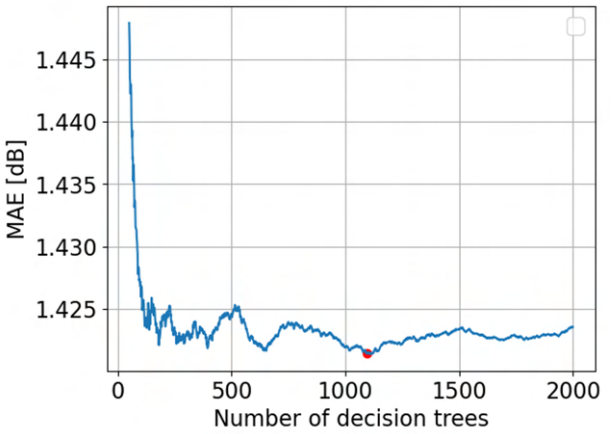

Figure 7. Values of the MAE calculated on the model prediction from each optimization run based on the highest R^2. In red, the number of decision trees for which the highest R^2 is obtained is displayed. It was observed that it corresponded to a local minima of the function. The variation on the MAE is small, with a maximum of 0.025 dB.

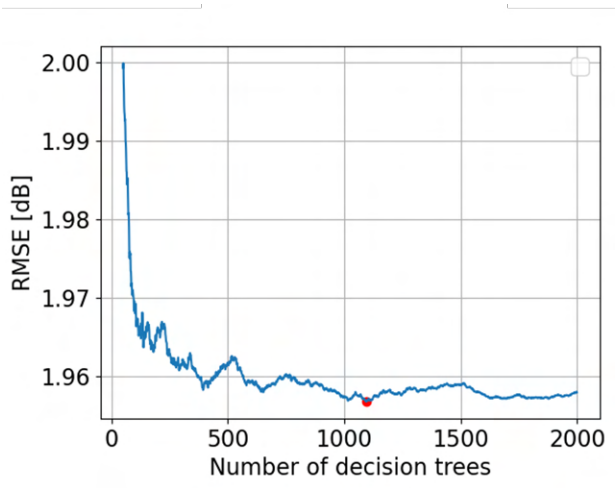

Figure 8. $RMSE$ of the prediction from each optimization run based on the highest R^2. In red, the number of decision trees for which the highest R^2 is obtained is displayed. The variation on the $RMSE$ is small, with a maximum of 0.05 dB across all tree values.

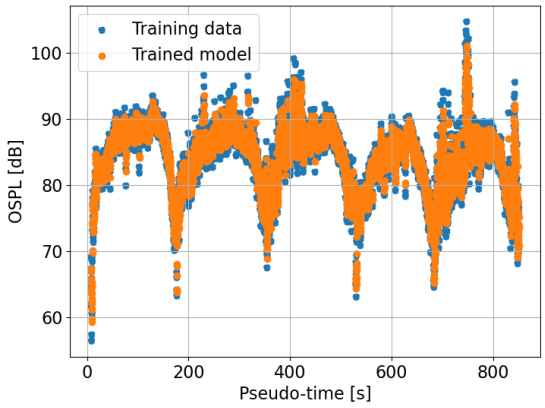

Figure 9. Trained RFR of the $OSPL$ data using the optimal number of decision trees.

this analysis can be observed in figure 12

As the MDI results show, the elevation angle results in the most important predictor of the $OSPL$, which implies that the information of both the $OSPL$ dynamics and intensity can be greatly explained by the elevation angle. Since all acoustic data was back-propagated to the 1 m hemisphere, the elevation angle is the angle between the horizontal plane of the drone and the field point.

This result implies that the $OSPL$ hemisphere behaviour

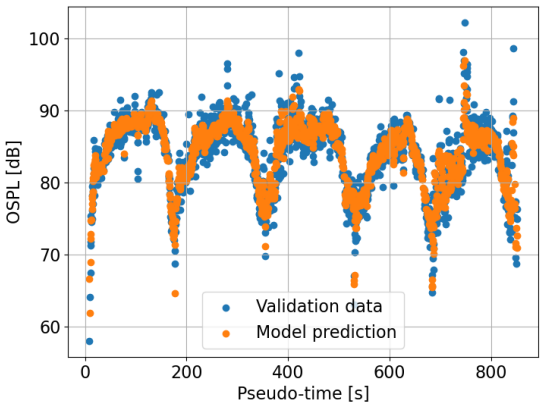

Figure 10. RFR prediction of the $OSPL$ using the optimal number of decision trees.

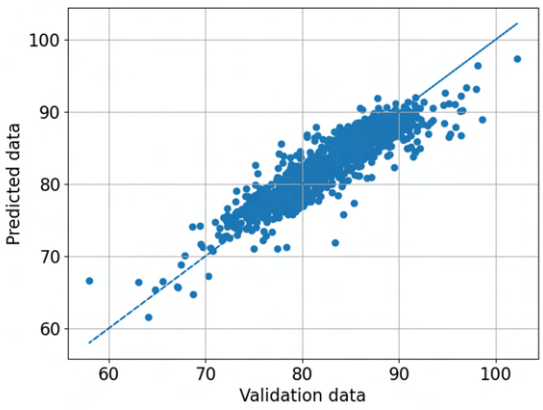

Figure 11. RFR prediction of the OSPL plotted as function of the validation data, for the case where all the operations were used. The model manage to capture most of the behaviour of the $OSPL$, with $R^2 = 0.84$

takes over other sound generating mechanisms when assessing predictor importance during realistic environmental conditions. The observed behaviour of the model in terms of R^2, deviation relative to the validation data, and feature importance, indicate that the prediction is accurate and robust to the high variability allowed. Furthermore, the ascent-hover-descent manoeuvres were performed manually, which adds a level of variability that is not usually present in systematic drone operations. Because of this, the model could show more accurate results when the automatic pilot commands the drone.

To visually verify the behaviour of the elevation angle, it

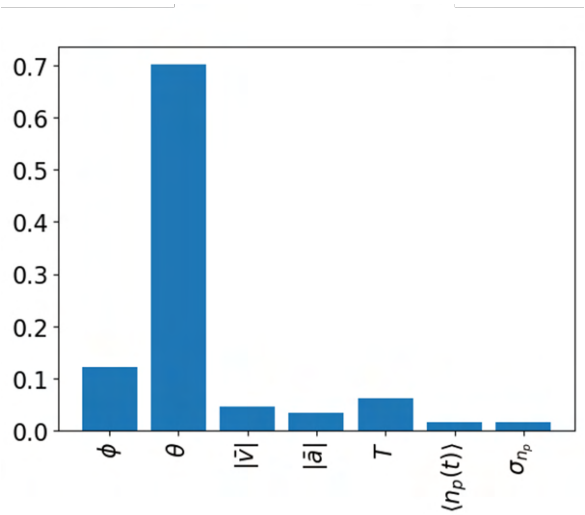

Figure 12. RFR parameter importance. The elevation angle scores the maximum MDI.

can be observed $OSPL$ for all the operations can be observed in figure 13.

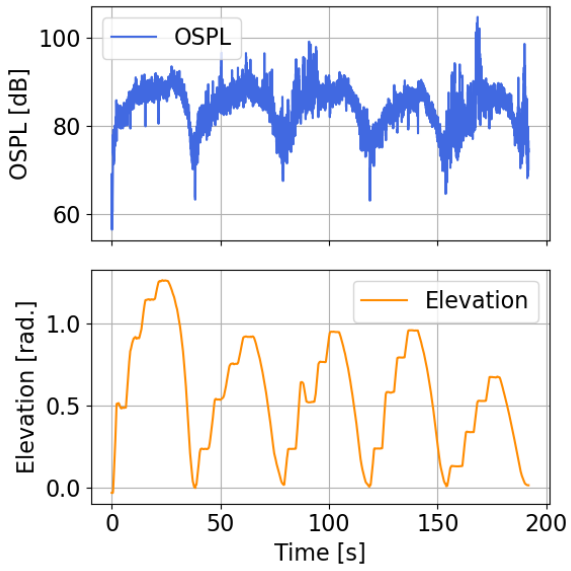

Figure 13. Comparison between the elevation angle (θ) and the $OSPL$ of all the ascent-hover-descent operations.

It is observed that the $OSPL$ increases as the elevation angle increases, which indicates that more frequency-integrated acoustic energy is measured when the field point is located closer to the bottom of the drone. As it can be observed in figure 13, this behaviour is not linear and the $OSPL$ increases more for smaller elevation angles, and it reaches an asymptotic behaviour for larger elevation angles.

4. CONCLUSIONS AND DISCUSSIONS

During the present work a machine learning model was developed and tested to predict the $OSPL$ caused by ascent, hover and descent operations of an X8 multirotor drone. The model managed to predict most of the variation observed in the acoustic metric calculated directly from experimental data, taken in realistic outdoor operational conditions. The elevation angle was found to be the most important predictor of the $OSPL$ in the tested manoeuvres, which indicates that the geometry of the hemisphere is more relevant than the other telemetry-based variables.

Consequently, the model is able to represent an effective geometry of the radiation lobe of the drone's $OSPL$. In particular, based on the observed non-linear behaviour, where the $OSPL$ increases more for smaller angles, and much less for larger angles, the model could indicate a sinusoidal/shifted-cosine dependency on the angle, which points at a dipolar behaviour of the sound propagation. This effect will be validated and further studied for other acoustic metrics in the future, as well as for the other manoeuvres and drones recorded during the experimental campaign.

This paper presents a method to generate predictions of total $OSPL$ prior to operations, involving ascent, hover, and descent. As these are critical manoeuvres for real UAV operations, they are highly relevant for assessing the impact of these operations on human populations nearby. During ascent and hover in real conditions, the drone has to accelerate or maintain an altitude, while adapting the rotors activities to compensate for any wind distortions, which in turn generate a fast variation of the acoustic dynamics. This first model managed to represent most of these variations based on telemetry-based features, accomplishing a good degree of accuracy and robustness, when analyzing all operations together.

Since the input features are directly derived from telemetry data, the model shows the potential to be also used as a way of interrogating the importance of physical drivers and guide the development of physics-based theories that can study from first principles, the dominant sound generating mechanisms in realistic, uncontrolled, conditions.

In a broader aspect, these results represent a first step into the development of a predictive tool to quantify the acoustic impact of drone operations. During the measurements campaign explained in section 2.1, several horizontal flight and changes in directions were measured, which are being used to extend the model to these different manoeuvres, hence more comprehensively studying a full flight envelope. To study how general the

predictors are, other multirotor systems that were used in the measurements campaign will be analysed.

Based on the measured manoeuvres, a series of uncertainty quantification studies are being developed with two objectives. Firstly, to quantify the accuracy of the model as well as its uncertainty for the different studied manoeuvres. Secondly, to study the role of wind gusts in the acoustic metrics and to quantify the effect on the model predictions.

ASSESSMENT OF THE PSYCHOACOUSTIC PERFORMANCE OF THE VENUS PROJECT DISTRIBUTED ELECTRIC PROPELLERS CONFIGURATION

Alessandro Di Marco[1*] **Luana G. Stoica**[1]
Giorgia Capobianchi[1]
[1] DICITA, University of Roma Tre, Roma, Italy

ABSTRACT

The increasing use of aircraft concepts driven by distributed propulsion for urban and regional air mobility raises the issue of new sources of community noise and the prediction of the resultant annoyance. This paper addresses the assessment of the experimental measurements on a distributed electric propellers configuration in the framework of the EU project VENUS from a psychoacoustic point of view, framing the engineering design of these systems in a perception-driven perspective. The VENUS project was aimed to the aerodynamic and aeroacoustic design of a distributed electric propulsion aircraft. Acoustic, aerodynamic and wall pressure measurements were carried out on a wing model equipped with a flap and three propellers powered by electric motors in an open jet wind tunnel. The parameters changed during the tests included five blade pitch settings, an angle of attack sweep, take-off and landing flap configurations, a phase delay between the propellers, different relative distances between the propellers and with respect to the wing. An optimized liner was installed on the wing for acoustic mitigation, in selected configurations. The optimal geometric configuration was determined based on psychoacoustic metrics (i.e. loudness, fluctuation strength, roughness, sharpness and tonality) and psychoacoustic annoyance models.

1. INTRODUCTION

The main objective of the present study is to investigate to what extent a model based on sound quality metrics (SQMs) can predict the noise annoyance caused by a set of distributed electric propulsion layouts. The human perception of noise is influenced not only by personal qualities but also by their aesthetic and cognitive inclinations, along with their psychophysiological condition. While it's challenging to assess the latter factors, one can consider the unique aspects of how sounds are perceived acoustically, defining them through a model based on subjective qualities [1]. In psychoacoustic studies, different subjective qualities independent of each other have been identified: sharpness, fluctuation strength, roughness and tonality. By combining these qualities, a quantitative measure was established: the psychoacoustic annoyance (PA) can be calculated from a global point of view. The benefit of this approach is that it provides an overall estimate of the perceived annoyance level from a recorded sound without identifying the noise annoyance level among public residents through questionnaires. Additionally, the PA performance is compared to commonly used conventional noise metrics. The use of the PA approach in combination with the noise certification metric makes a perception-influenced acoustic design possible, in which the new vehicle design can simultaneously meet noise certification requirements while achieving low annoyance [2].

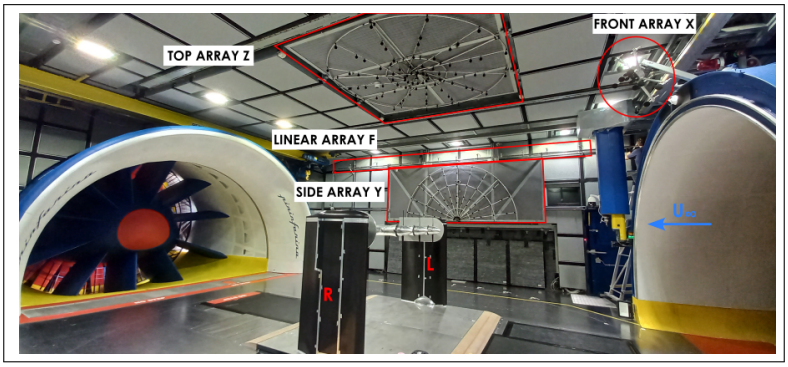

Figure 1. VENUS experimental setup.

2. METHODOLOGY

2.1 Wind Tunnel Aeroacoustic Measurements

Measurements in wind tunnels (WT) have been one of the main methods for aeroacoustic testing for the last decades, as they offer controllable conditions (flow velocity, angle of attack, etc.) repeatability of the results and, in most cases, accurate knowledge of the model position. One of the main challenges for wind-tunnel experiments is to replicate the exact conditions at full-scale. The smaller scale and usually less-detailed geometry of the wind-tunnel models, together with the typically lower flow velocities, can lead to a discrepancy in the Reynolds number. This effect was not taken into account. A model with three wing installed propellers (Fig. 1) was mounted on the floor of the Pininfarina WT test section with the central plane aligned with the WT balance.

Two aerodynamically shaped struts sustained the upside-down wing. The wing consisted in a non symmetric constant chord airfoil (NACA 63(2)415) with a deployable flap. The three propellers could be arranged in different geometrical configurations. The lateral propellers had two degrees of freedom on the wing whereas the central could be translated only in longitudinal direction. The propellers rpm were remotely controlled by an homemade software able to syncrophase the lateral propellers (followers) with respect to the central one (the leader). The model was instrumented with pressure taps, pressure transducers and load cells for thrust and torque measurements. During the test campaign, fluctuating pressure was acquired with four microphone arrays (Fig. 1) and the global aerodynamic coefficients were measured with the WT balance. Different DEP configurations were tested, those of interest are summarised in section 3 The reader is referred to [3] for more details on the experimental set-up.

Table 1. Parameters varied during VENUS wind tunnel tests.

Parameter	Value
AoA α	$-1° \rightarrow 11°$
Flap angle δ	0° (SL), 20° (TO), 35° (LA)
Phase shift $\Delta\varphi$	$0°, 35°$
DEP layout	XY1 $\rightarrow$ XY11
Low noise device	on, off

Tab. 1 provides a description about the tested conditions during the whole campaign. A reduced subset of the VENUS database is used here for to the psychoacoustic analysis. The data analysed herein correspond to an angle of attack (AoA) of $5°$, as it is the design angle in the landing phase. Regarding the nacelles layout, only the geometrical dispositions relevant to the study are selected as individuated in a preliminary numerical aeroacoustic study performed before the realization of the WT model. $XY*$ is a conventional name given to a specific combination of nacelle positions with respect to the baseline configuration, which is indicated with $XY1$.

The phase shift indicates the de-phasing of the lateral propellers with respect the central one. The wind tunnel air speed velocity was set at 20 $\mathrm{m/s}$ and the rotational speed of the three propellers was kept constant at 3300 rpm in all tests in order to guarantee the same advance ratio of $J = 0.65$.

2.2 Aeroacoustic and Psychoacoustic Sound Quality Metrics

Conventional acoustic/aeroacoustic metrics were used as a first ranking discriminant of the most/less annoying DEP configuration. To better assess the actual annoyance experienced by people, more sophisticated SQMs from the field of psychoacoustics were also implemented. In addition to SQMs, the relationship between annoyance of the sounds in this test and aircraft noise certification metrics was explored. Since the sounds were of short duration and constant, (those certification metrics involving summation and integration over time) metrics such as the effective perceived noise level were not analysed. Instead, the constituent metrics of these certification metrics were analysed. These constituent metrics are A-weighted sound pressure level ($L_{p,A}$), Z-weighted (or unweighted) sound pressure level ($L_{p,Z}$), perceived noise level (PNL) and tone-corrected perceived noise level (PNLT). In synthesis, without entering into the definitions, for each sound signal the following metrics were calculated:

- Loudness (N);
- Tonality (K);
- Sharpness (S);
- Roughness (R);
- Fluctuation strength (FS);

In this paper, a subset of these metrics is reported for the sake of conciseness. To reduce amplitude variation in some metrics, the 5 percent excess in the levels of the metrics are used to describe the metric levels for the duration of sound. If an SQM value is nearly constant over the sound duration the exceeded level will be approximately equal to the constant level [4].

From the SQMs, the PA metrics were calculated according to the models introduced by [5] and improved by [6]. The conventional sound metrics, SQMs and PA metrics were computed using the open-source MATLAB toolbox SQAT (Sound Quality Analysis Toolbox) [7].

3. TEST CASES

Three comparison scenarios are considered: (i) clean model versus model with installed propeller blades, (ii) five nacelle layouts for the take-off configuration with respect to the baseline layout, four nacelle layouts for the landing configuration with respect to the baseline layout and (iii) wing with/without noise reduction device for a selected nacelle layout. The clean configuration was obtained from the baseline layout removing the propellers blades and carrying out the tests with motors off. For this specific comparison a side-line (SL) configuration with the flap not deployed was also tested and presented in section 4. Take-off (TO) and landing (LA) configurations were obtained deploying the flap at 20° and 35° respectively. Fig. 2 shows the possible nacelle movements in $X-$ and $Y-$ direction. The central green lines indicate the positions of the baseline configuration. Note that the central nacelle can only translate in the streamwise direction.

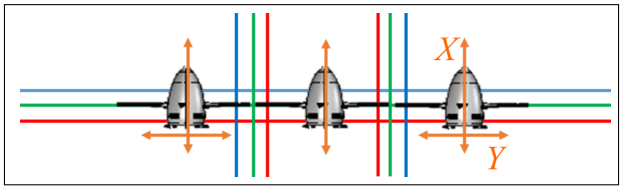

Figure 2. Sketch of the nacelles translation directions.

The nacelle layouts considered in this study are summarised in Tab. 2. ΔX and ΔY corresponds to the position variation with respect to the baseline configuration. Arrows indicate the longitudinal and transversal translation directions of the three nacelles (left L, central C and right R) for each layout. The values of the nacelle translations considered here were set at $\Delta X = 6$ cm for streamwise movements and $\Delta Y = 4$ cm for spanwise movements.

The noise reduction device consisted in a series of micro-perforated inserts mounted on the wing leading edge of the pressure side. The holes distribution and size and the cavities beneath the wing surface were specifically designed through an optimization procedure focused on the attenuation of the propeller tonal noise in a wide range of frequencies.

4. RESULTS

All the results presented in the following sections are obtained analysing the signal acquired by the central microphone from the array on the ceiling of the WT. In this way, the noise is perceived as an observer underneath the wing, similar to a fly-over manoeuvre. Sound propagation effects are not taken into account. All the signals are band-pass filtered in the range of interest of the installed propellers, discarding effects of the low frequency wind tunnel noise and high frequency disturbance due to the microphones and acquisition system. Furthermore, the signals are downsampled at 48 kHz in order to be compatible with psychoacoustic software requirements.

4.1 Clean vs Installed Configuration

Tab. 3 summarises the results of the comparison between the clean wing model and the wing with the propeller blades installed. The $L_{p,A}$ are found to be larger when the propellers are running, as expected, due to the noise contribution from the propeller rotation. The average level of this difference between the configurations amounts approximately to 8.8 dBA. For the clean model, the values increases with the flap deployment angle by 1 dBA when moving from SL to TO to LA. The effect of the flap with the propellers running only causes a rise of the $L_{p,A}$ in landing configuration, due to the greater deflection of the propeller wake. Similar trends are found for the PA. It is worth noting that installing the propellers doubles the estimated annoyance with respect to the clean model, for each manoeuvre setup.

4.2 Noise Mitigation Device Effect

The acoustic and psychoacoustic effects of the noise mitigation devices are summarised in Tab. 4. The results do not indicate a substantial modification of the perceived noise. The best performances are obtained for the in-phase

propellers ($\delta\phi = 0°$). The noise reduction device causes a slight reduction of the loudness, whereas the other metrics remain substantially unchanged.

4.3 Psychoacoustic Sound Quality Metrics of TO and LA setups

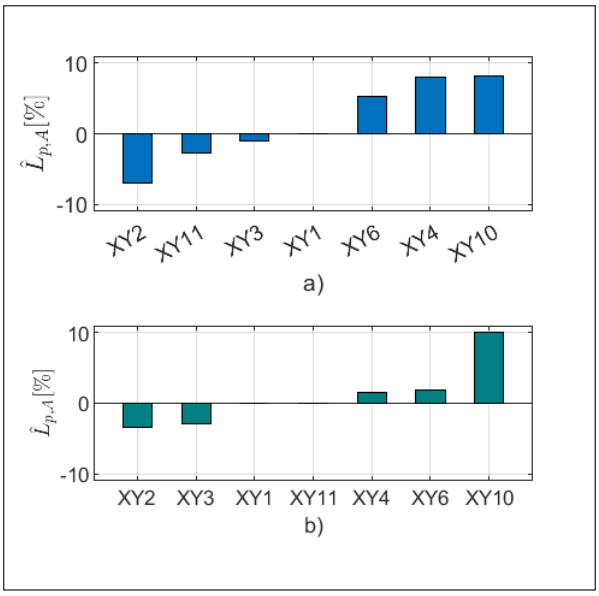

Figure 3. Normalized $L_{p,A}$ in TO for a) $\Delta\varphi = 0°$ and b) $\Delta\varphi = 35°$.

The results presented in this section for both setups are all referred to the baseline $XY1$ configuration. In order to adjust values measured on different scales to a comparable scale, the conventional metrics ($L_{p,A}$) and the psychoacoustic annoyance (PA) values are normalized as follows:

$$\hat{\sigma}_{p,A} = \frac{\sigma_{p,A,XY*} - \sigma_{p,A,XY1}}{\sigma_{p,A,XY1}} \tag{1}$$

and

$$\hat{PA}_{p,A} = \frac{PA_{XY*} - PA_{XY1}}{PA_{XY1}} \tag{2}$$

where XY^* indicates a generic nacelle layout, $XY1$ corresponds to the baseline layout and $\sigma_{p,A}$ is obtained from the A-weighted sound pressure level with the inverse formula assuming a reference pressure of 20 µPa.

The analysis of the conventional metrics and the PA model revealed some differences among the various layouts as illustrated in Fig. 3 and Fig. 4 for TO and in Fig. 5

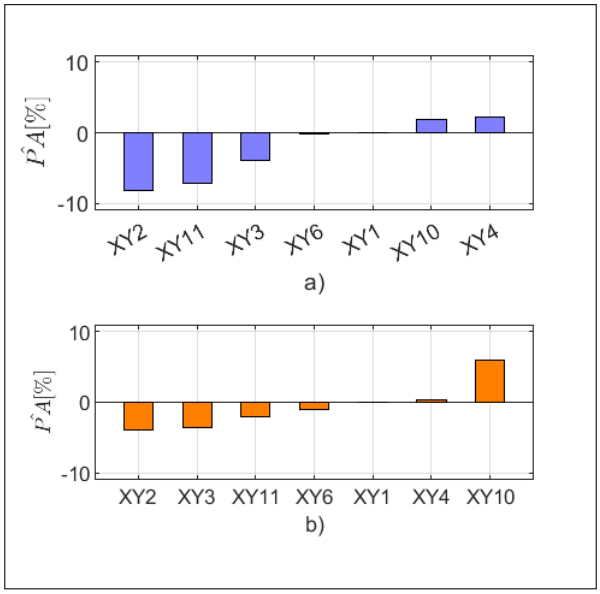

Figure 4. Normalized PA in TO for a) $\Delta\varphi = 0°$ and b) $\Delta\varphi = 35°$.

and Fig. 6 for the LA setup. In the figures, negative values express a reduction in the emitted noise compared to the baseline layout whereas positive values are an increment. On the abscissa, the layout ranks from the quietest to the noisiest; in each figure, results obtained at the two relative phase angles between the propellers are shown.

In TO, the quietest layout is the $XY2$ independently of the phase or the approach used. The layout consists of the three propellers discs aligned with each other at their closest position with respect to the wing. The noisiest configuration is the $XY10$ examining most metrics, although this result is questionable for the PA at $\Delta\varphi = 0°$ (Fig. 4). In this layout, the propeller discs are overlapping, with the two external propellers closest to the wing and the central at the farthest longitudinal position. Comparing the acoustic and psychoacoustic metrics at $\Delta\varphi = 0°$, the layout ranking remains almost unvaried, whereas changes occur when the propellers are not running in phase. A moderate noise reduction is obtained de-phasing the propellers in most cases.

For LA conditions, the worst case in terms of noise with respect to the baseline is represented by layout $XY4$. In this layout, the central nacelle is in the closest and the external nacelles in the farthest streamwise position. The estimated annoyance for this case is considerably lower than the conventional metric $L_{p,A}$. The quietest layout is

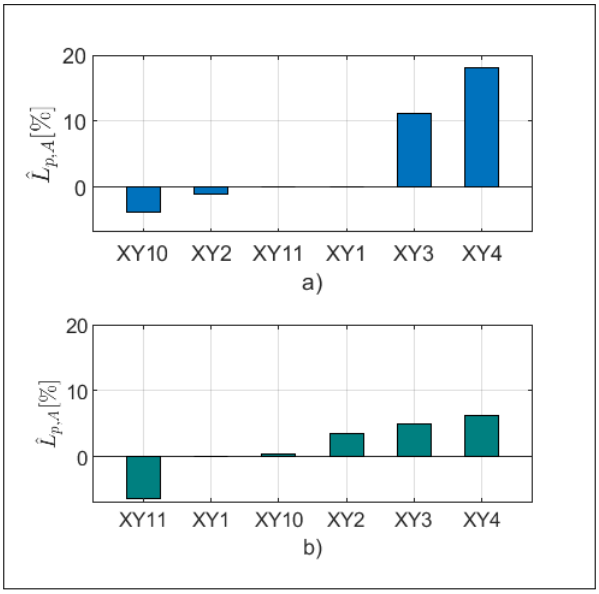

Figure 5. Normalized $L_{p,A}$ in LA for a) $\Delta\varphi = 0°$ and b) $\Delta\varphi = 35°$.

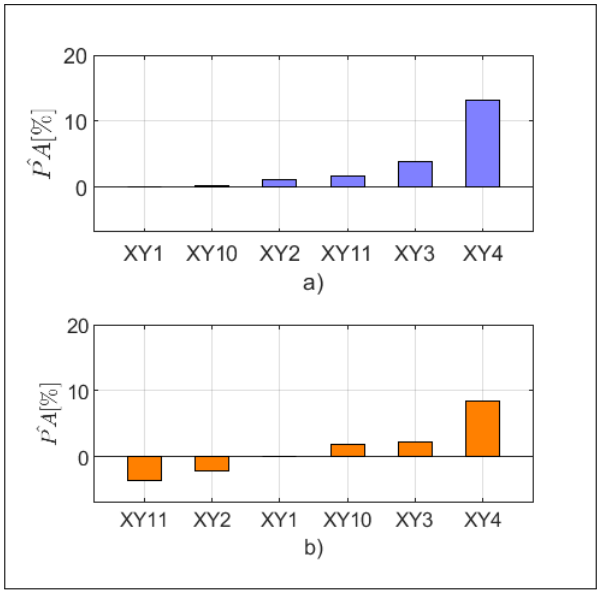

Figure 6. Normalized PA in LA for a) $\Delta\varphi = 0°$ and and b) $\Delta\varphi = 35°$.

not uniquely determined as it is the ranking.

Table 5. Overall ranking.

Tot points	Layout
15	XY2
20	XY11
27	XY1
30	XY3
37	XY10
48	XY4

In order to define the best and worst performing layout, a score was assigned based on the performances in both TO and LA configurations, for all the relative phase angles and for all the metrics used. The total points were counted summing each placement in the different rankings considered. The best overall configuration is thus found to be $XY2$ and $XY4$ as the worst. The overall ranking is reported in Tab. 5.

5. CONCLUSIONS

The aim of the paper is to gain insight into the wide variety of experimental tests performed within the VENUS project from a psychoacoustic perspective and compare it to classical aeroacoustic metrics. The model tested is a wing of a regional aircraft with an optimized distributed electric propulsion system composed of three tractor propellers powered by electric motors. The objective of the study was to compare different methods analysing the annoyance of noise perception. The classical method for annoyance estimation is to apply the A-weighting to the SPL, which roughly corresponds to the perceived loudness level. However, this method may only be suitable for certain types of noise.

Measurements of loudness are used to put policies in place that limit noise levels below reasonable bounds. But because of the informational value of noise and the notable decrease in noise levels that has already been attained, there are now additional techniques for measuring noise-induced irritation that supplement the conventional approaches. These include the rapid and effective computation of short-term psychoacoustic annoyance based on various subjective noise properties.

Results demonstrated that the noise emitted by the model with the installed propellers with respect to the

airframe only notably increases the human annoyance as confirmed by the conventional metrics. The effects of the noise mitigation device showed a moderate impact reduction on both conventional metrics and short-term annoyance. It was shown that the estimated human perception of the noise is different from the conventional approach, leading in some case to different results. A critical role is also held by the phase between the propellers. A deeper study on the phase effect and a hearing experiment would complete and validate this study.

COMPARATIVE DRONE NOISE FLIGHT TEST CAMPAIGN USING CONVENTIONAL PRECISION MICROPHONES AND AN ARTIFICIAL HEAD

Giovanni Fasulo[1*] **Francesco Petrosino**[1] **Mattia Barbarino**[1] **Luigi Federico**[1]

[1] Italian Aerospace Research Centre (CIRA), Capua (CE), 81043, Italy

ABSTRACT

This study investigates the acoustic signatures of a DJI Matrice 300 RTK during LiDAR and photogrammetric mapping missions at the Pianabella UrbanV vertiport in Rome. Utilizing a comprehensive setup that combines conventional precision condenser microphones with an artificial head, measurements were conducted throughout various drone flight phases. Analysis revealed that calculating advanced psychoacoustic metrics with the artificial head can introduce significant errors compared to conventional microphone measurements, for which these metrics were originally designed.

Keywords: *artificial head, psychoacoustic, drone noise, experimental test.*

1. INTRODUCTION

Small drones, known as Small Unmanned Aircraft Systems (sUAS), have become much more common in recent years, being used for commercial, security, and other purposes in areas that were previously unaffected [1]. As sUAS noise differs significantly from that of conventional aircraft [2], predicting resultant annoyance remains challenging. The numerous noise-generating components of sUAS experience constant variations in level, directionality, spectral content, and temporal characteristics during take-off, landing, and overflight maneuvers [3]. Moreover, the propagation of sUAS noise is highly sensitive to operating environment, weather, and wind conditions, complicating attempts to reliably forecast acoustic impacts. To address this, specialized flight tests are now crucial for better understanding sUAS noise and improving prediction models [4]. Within the European U-ELCOME project [5] framework, an extensive test campaign was carried out to investigate the acoustic signatures of different drone operations in real-world scenarios. Observations included different flight phases, such as take-off, overflight, and landing, to better characterize the role of operational aspects and external conditions on noise. A suite of precision microphones and an artificial head were deployed to capture a comprehensive dataset of both conventional and binaural acoustic measurements, which more accurately reproduce the subjective perception of human listeners. Traditional descriptors such as sound pressure level (SPL), along with psychoacoustic metrics including loudness, sharpness, fluctuation strength, roughness, and tonality, were computed for each audio sample. A comparative analysis between conventional microphone recordings and those acquired using an artificial head (both with and without the application of equalization curves) revealed significant discrepancies. These findings underscore the importance of a careful and informed application of psychoacoustic measurement equipment and metrics when assessing the potential disturbance caused by sUAS noise. Moreover, the results highlight the critical role of flight test data in developing robust acoustic impact evaluation methods, which are essential for guiding future regulatory frameworks and design considerations.

2. TEST GROUND AND EQUIPMENT

2.1 Test Ground

The acoustic test campaign was conducted on November 28th 2024 at the Pianabella UrbanV vertiport in Rome, Italy, with the primary objective of capturing and analyzing noise emissions during LiDAR and photogrammetric terrain mapping operations. The experimental setup involved the deployment of precision condenser microphones across the test field (Figure 1) to accurately record the acoustic signatures associated with various drone activities: takeoffs, landings, and flyovers. This approach enabled a comprehensive assessment of the drone's noise profile under realistic operational conditions.

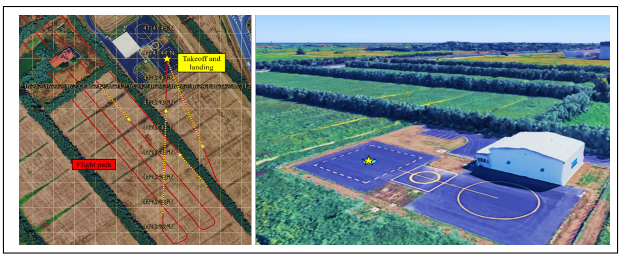

Figure 1. Test ground and planned drone flight path (Google Earth image).

2.2 Acoustic Equipment

Acoustic measurements were conducted using a comprehensive system that integrates data acquisition hardware, precision microphones, signal conditioning components, and calibration tools. The setup comprised a personal computer interfaced with an IMC C-SERIES PL3 analyzer, which provided eight channels at a sampling rate of 50 kHz per channel. Acoustic signal acquisition was achieved using a set of precision pre-polarized condenser microphones coupled with dedicated preamplifiers. Specifically, eight PCB model 377B11 microphones, which feature a pressure-field response were deployed. Each microphone has a nominal 1/2-inch diameter and a typical sensitivity of 50 mV/Pa, with the 377B11 units covering a frequency range of 3.15 to 10000 Hz (±2 dB) and a dynamic range of 146 dB re 20 µPa. Prior to measurements, each microphone was calibrated using a PCB model CAL250 acoustic calibrator that provides a 250 Hz output at 114 dB re 20 µPa (±0.2 dB) with distortion below 2%. Windscreens were employed on each microphone to mitigate wind-induced noise from high-speed airflow. To preserve signal integrity over long cable runs and extend the measurable frequency range, 8 microphone preamplifiers (PCB model 426A30) equipped with 7-pin LEMO connectors were used. These preamplifiers, which produce an output voltage of 28 Vpp, were supplied by 8 preamplifier power supplies (Larson Davis model 2221). These supplies offer selectable polarization settings (0 and 200 V) and weighting options (A, C, or Z), with a frequency response (Z-weighted) from 10 Hz to 100 kHz (±0.2 dB) and 1 Hz to 150 kHz at –3 dB. In addition, CIRA deployed a specialized acquisition system known as an artificial head, which replicates the acoustically significant features of the human ear, head, shoulders, and skin. This design filters incoming sound based on its direction, enabling the recorded signals to be perceived as if the listener were immersed in the original sound field. The artificial head HSU III.2 incorporates two precision pre polarized condenser microphones that have a nominal diameter of 1/2 inch and a typical sensitivity of 50 mV/Pa. These microphones operate over a frequency range of 3.5 to 20000 Hz, offer a dynamic range of 119 dB re 20 µPa, and can handle sound pressure levels up to 135 dB with less than 3% distortion at 1 kHz. Data acquisition and storage were managed using SQobold, a four channel recording and playback system for mobile sound and vibration measurements, providing two channels with a sampling rate of 48 kHz per channel.

Figure 2 is a sketch of the experimental apparatus schematic diagram:

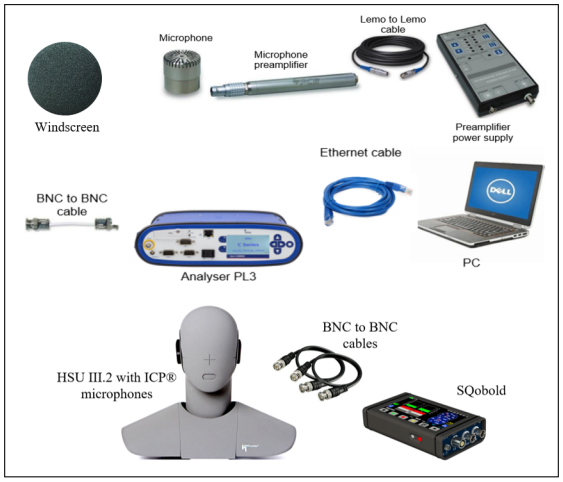

Figure 2. Experimental apparatus schematic diagram.

Microphone placements were determined based on the drone's designated flight paths (Figure 3). Three microphones were arranged in a quarter-circle with a 7-meter radius at a height of 1.5 meters, centered on the drone's takeoff point. A second array, consisting of three microphones, was configured in a quarter-circle with a 14-meter radius, also at 1.5 meters above ground level. In addition, two microphones were positioned along the drone's flight path within the terrain adjacent to the Pianabella vertiport, maintaining the same 1.5 meter elevation. Furthermore, the artificial head was mounted on a tripod and oriented such that its shoulders were perpendicular to the drone's flight trajectories, with the left ear directed toward the takeoff point, aligned with the position of microphone #8 (Ch8). The ear level was set at 1.5 meters from the ground.

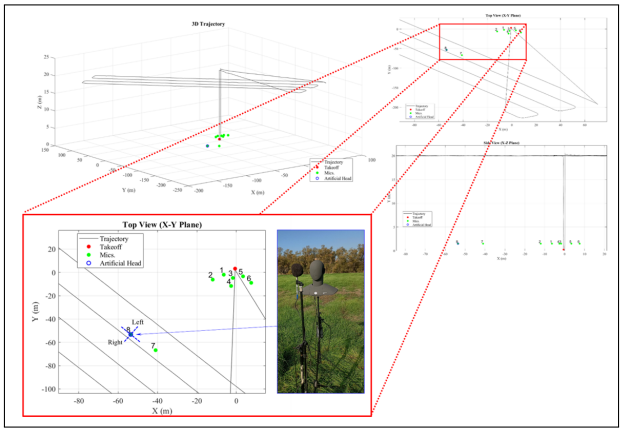

Figure 3. Drone trajectory and acoustic sensors locations.

2.3 Test Article

For the LiDAR and photogrammetric mapping operations, a DJI Matrice 300 RTK quad-rotor (Figure 4) was deployed. This versatile platform is engineered for a wide range of industrial applications and features a robust, foldable design that ensures both durability and ease of transport across various operational environments. Its support for multiple payload configurations allows for tailored setups to meet specific mission requirements, while advanced flight control algorithms and GPS positioning deliver precise navigation, stable hovering, and autonomous operation capabilities. The main technical specifications of the DJI Matrice 300 RTK are as follows: when unfolded (without propellers), its dimensions are 810 × 670 × 430 mm, and when folded (with propellers), 430 × 420 × 430 mm, with a diagonal wheelbase of 895 mm. The drone weighs approximately 3.6 kg without batteries and around 6.3 kg when equipped with batteries, with a maximum takeoff weight of 9 kg. It supports a maximum payload capacity of 2.7 kg and offers a flight time of up to 55 minutes with no payload.

Figure 4. DJI Matrice 300 RTK at UrbanV vertiport.

3. ACOUSTIC MEASUREMENTS AND POST-PROCESSING

This section presents the methodology employed for acoustic measurements at the UrbanV vertiport in Rome. Data acquired from both precision microphones and an artificial head were analyzed to assess the implications of the observed noise signatures.

3.1 Background Noise

Background noise plays a critical role in acoustic measurements as it represents the ambient sound environment in the absence of the primary noise source. In this study, the drone serves as the primary noise source, while the background noise is primarily attributable to operations at a nearby airport. This background noise includes sounds from aircraft takeoffs and landings, ground support equipment, vehicular traffic, and other related activities. Consequently, precise measurement of the background noise is imperative for establishing a reliable baseline that differentiates between ambient environmental noise and the noise generated specifically by the drone. To achieve this, acoustic signals were recorded and analyzed for approximately 150 seconds before to the beginning of the flight

test. The post-processing involved applying a Discrete Fourier Transform (DFT) with a Hanning window and a 50% overlap. Given the signal duration and segmentation, a sampling frequency of 0.01 Hz was achieved. Specifically, the signal was segmented into two overlapping frames, with each frame windowed by the Hanning function to minimize spectral leakage. The 50% overlap ensured that each consecutive frame shared half of its data points with the previous frame, thereby enhancing frequency resolution and yielding a smoother, more reliable frequency spectrum. The DFT was computed for each windowed segment, and the resulting spectra were averaged. To facilitate interpretation, the spectra were converted into 1/3 octave bands and adjusted using A-weighting (Figure 5) to account for the human ear's varying sensitivity across frequencies.

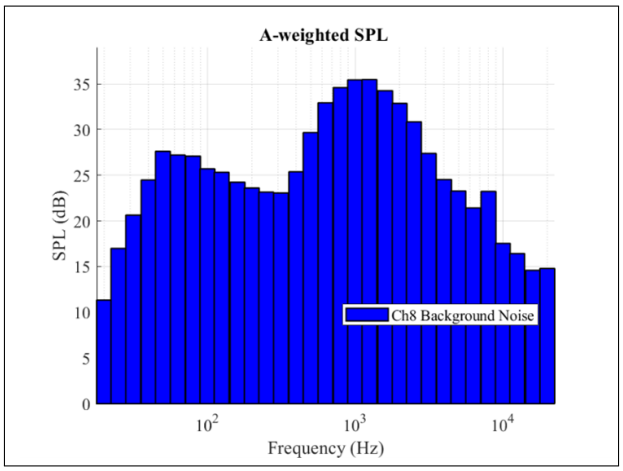

Figure 5. A-weighted 1/3 octave band spectra of background noise recorded by microphone #8.

Additionally, the mean A-weighted Overall Sound Pressure Level (A-OASPL) from all microphone measurements, which represents the mean total sound energy over the measurement duration, was computed. Specifically, two mean A-OASPL values were computed to reflect the distinct environmental conditions at different measurement locations. Microphones #1 to #6, positioned near the takeoff and landing area on rigid asphalt surfaces, exhibited a mean A-OASPL of 47.8 dBA, likely due to increased sound reflections. In contrast, microphones #7 and #8, deployed on grass and other absorptive surfaces, recorded a lower background noise level of 43.8 dBA, resulting from enhanced sound absorption.

3.2 Drone Noise

The acoustic signature of drones substantially differs from that of conventional aircraft. Drone noise is characterized by a complex frequency spectrum featuring multiple tones at harmonics of the blade passage frequency (BPF). Moreover, these acoustic emissions can vary considerably depending on factors such as drone type, size, propeller design, and operational conditions. Consequently, conventional noise metrics like $L_{A,eq}$ or L_{AE} are often inadequate to capture the annoyance of drone noise, thereby necessitating the use of psychoacoustic parameters that more accurately reflect human auditory perception.

Within the framework of the U-ELCOME project, a series of tests were conducted to characterize the noise generated by drones. The main test lasted 755 seconds, with signal acquisition for the eight microphones started and ended manually at the beginning and end of each test session. In contrast, the psychoacoustic head was activated manually prior to the initial test and deactivated after all tests, resulting in a continuous recording from which the relevant sections were later extracted. To analyze the temporal evolution of the drone's spectral content, a spectrogram was computed. This analysis utilized a Hanning window with a 50% overlap. The FFT was computed with a spectrum size of 65536 samples at a sampling rate of 50 kHz, resulting in time and frequency resolutions of 1.31 seconds and 0.76 Hz, respectively. Given the tonal nature of the recorded noise and the absence of impulsive characteristics, a larger FFT size was selected to achieve finer frequency resolution. Figure 6 presents the spectrograms for microphones #7 and #2.

These spectrograms reveal a predominance of continuous low-frequency noise attributable to background noise. In the recordings from microphone #2, peaks in the mid-to-high frequency range were observed at the beginning and end of the test, corresponding to the drone's noise during takeoff and landing. Conversely, recordings from microphone #7 exhibited peaks at regular intervals, characteristic of drone overflights. In the frequency domain, periodic spectral lines corresponding to the harmonics of BPF are clearly discernible. These harmonics are most marked when the drone is close to the microphones but become increasingly diluted by ambient noise as the drone moves farther away.

3.2.1 Artificial Head vs. Conventional Microphone

The artificial head employed in this study inherently incorporates multiple filtering phenomena, namely, pinna

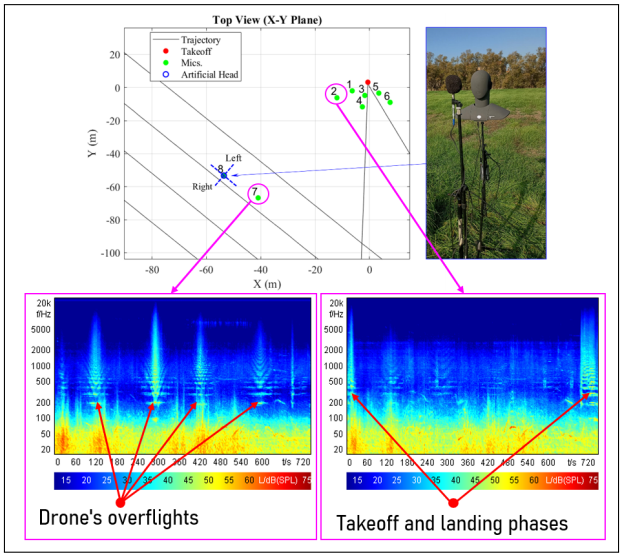

Figure 6. Drone path, placement of acoustic equipment, and corresponding spectrograms.

effects, ear canal resonance, diffraction and reflection due to the head's structure, acoustic shadowing, and skin absorption. These effects result in distortions that make the signals captured by the artificial head incompatible with those obtained from conventional measurement microphones [6]. Consequently, parameters such as the A-weighted sound pressure level and various other metrics cannot be reliably determined using a non-equalized artificial head measurement system. To address this limitation, HEAD Acoustics provides three distinct equalization options for the artificial head based on the direction of sound incidence:

- Free Field (FF): Sound arriving from the front in an anechoic environment, with the sound source located at least 3 meters from the artificial head;
- Diffuse Field (DF): Sound arriving uniformly from all directions;
- Independent of Direction (ID): Equalization tailored to the directional resonances of the cavum conchae and the ear canal entrance.

Since the sound field conditions during measurement rarely correspond exactly to any one of these idealized scenarios (FF, DF, or ID) this study examined the influence of various equalization curves on the evaluation of psychoacoustic metrics. For this purpose, microphone #8 was strategically positioned adjacent to the artificial head along the drone's flight path, specifically between the two ear microphones. A slight spatial displacement was compensated by temporally shifting the microphone pressure time histories by 0.45 seconds. Acoustic levels are presented in Figure 7 without the application of any weighting functions, ensuring an accurate representation of the total acoustic energy and to clarify the underlying noise generation mechanisms. Only a slow time weighting (1000 ms) was applied to smooth the output and enhance the readability of the plot.

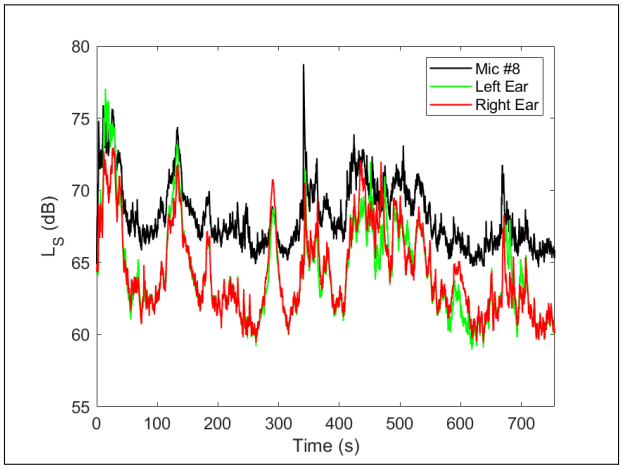

Figure 7. Acoustic levels with slow time weighting for conventional microphone #8 and the artificial head's ear microphones.

Microphone #8 generally records higher levels than the ear microphones, although there are time intervals where the levels converge or where the ear microphones briefly exceed those of microphone #8. Furthermore, the slight mismatch between left and right ear measurements arises from the head's asymmetry relative to the sound source. Refer to Figure 3 for an overview of the flight path and the artificial head's positioning.

The subsequent analysis focuses on a single forward flight segment, specifically, the time interval during which the drone is nearly overhead of the artificial head, as indicated between 200 and 370 seconds in the level graph (Figure 7). Figure 8 compares the spectral content of both recordings within the human auditory range (20 Hz–20 kHz). The spectra were computed using a Fast Fourier Transform (FFT) with a spectrum size of 16384 samples, a Hanning window, and 50% overlap. Given the 50 kHz

sampling frequency, the frequency resolution is approximately 3 Hz. These measurement do not incorporate any equalization curves, thereby representing the spectra of the original recorded sound.

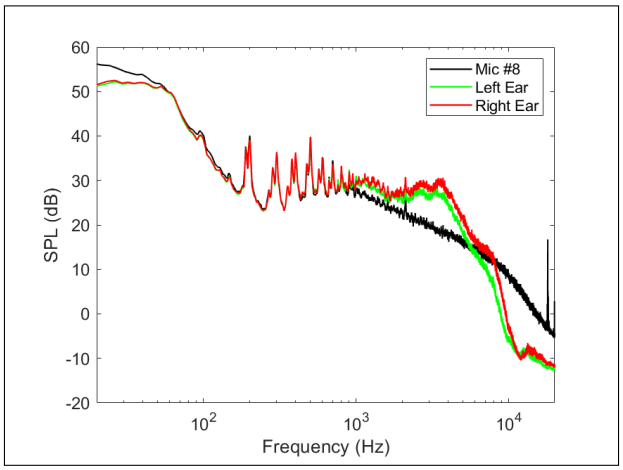

Figure 8. Comparison of the acoustic spectra obtained from conventional microphone #8 and the artificial head's ear microphones during the drone's forward flight.

The tonal components, specifically, the first eight harmonics of the blade passing frequency (BPF), are captured equally by both the conventional microphone and the artificial head. In the forward flight scenario, Figure 8 illustrates the separation of the BPFs between the forward and aft rotors, a result of the differing rotation rates during this flight condition. However, the artificial head also exhibits additional peaks at approximately 3 kHz, which indicate resonance associated with the ear canal's length [7], while a notch across the entire frequency band at 10 kHz can be attributed to the effect of the pinna [8]. The difference in the low-frequency region is likely due to the transition from free-field conditions to a duct configuration, which introduces a change in acoustic impedance that conventional microphones do not account for. This discontinuity may induce partial reflections of the acoustic wave at the entrance of the ear canal, thereby reducing the energy transmitted within the duct and consequently attenuating the signal detected by the artificial head microphones.

The following graphs present the FFT computed using equal input settings and time histories previously employed, incorporating the combined effect of the three equalization curves provided by HEAD Acoustics. In each instance, the resulting spectra are compared with those derived from conventional microphone recordings of the same noise event.

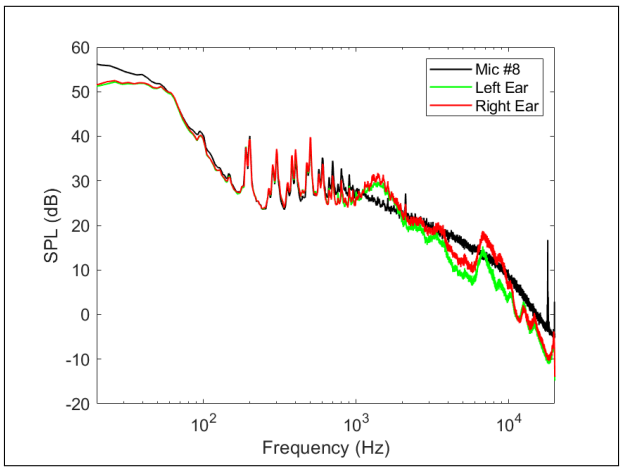

Figure 9. Conventional microphone #8 versus the artificial head's ear microphones (FF equalized).

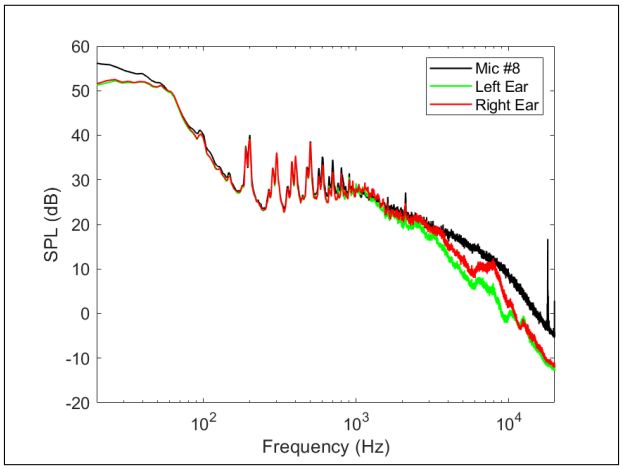

Figure 10. Conventional microphone #8 versus the artificial head's ear microphones (DF equalized).

Analysis reveals that the equalization curves do not reconstruct the spectral content of the conventional microphone signal from artificial head measurements with high fidelity. In this context, the diffuse field equalization appears to be a more suitable option. A quantitative evaluation of psychoacoustic metrics is provided in the subsequent part of this work. Specifically, Sound Quality (SQ)

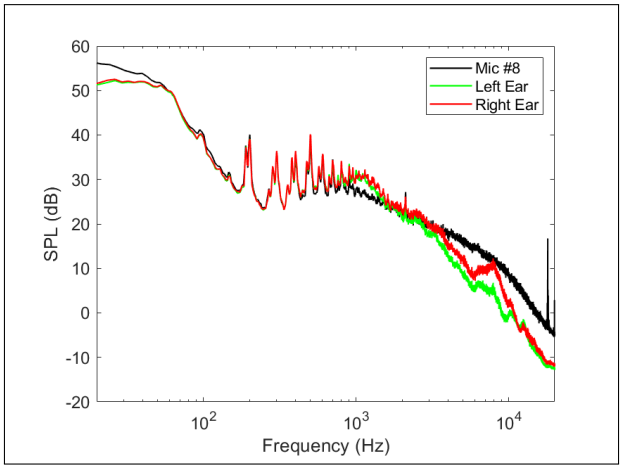

Figure 11. Conventional microphone #8 versus the artificial head's ear microphones (ID equalized).

metrics were computed for the conventional microphone recordings and for the artificial head measurements (both with and without equalization) across distinct phases of the drone mission. For this purpose, the levels shown in Figure 7 were segmented into six sub-signals with time ranges of 1–60, 60–200, 200–370, 370–530, 530–660, and 660–755 seconds. The analyses were conducted using the ArtemiS software from HEAD Acoustics, and the computed SQ metrics include Loudness (N), Roughness (R), Fluctuation Strength (F), Sharpness (S), and Tonality (T).

Loudness, Roughness, and Tonality were calculated according to ECMA-418-2 (2nd Edition), based on the Sottek Hearing Model [9]. In particular, for the computations of Loudness and Roughness, signals from both the right and left ears of the artificial head were combined. The calculation of Fluctuation Strength was derived from that of Roughness, with an adaptation ensuring that its maximum value occurs at a modulation frequency of 4 Hz. Finally, Sharpness was determined using the DIN 45692 standard. The maximum value, along with the 5th and 10th percentiles of each audio sample, was computed and analyzed. For metrics that lack an inherently defined combined left/right ear result (Fluctuation Strength, Sharpness, and Tonality) the arithmetic mean of the left and right ear values was employed as the representative single value metric for the artificial head. To ensure consistency, the mean absolute differences between the conventional and equalized curves, computed across all tests, were normalized by the mean metric value as estimated by the conventional microphone. Consequently, Figure 12 to Figures 15 illustrate the percentage deviation from the expected results for each single value metric and for each equalization curve adopted.

Figure 13. Percentage deviation from the expected results (FF Equalized).

4. CONCLUSIONS

As part of the U-ELCOME project, an acoustic test campaign was conducted on November 28th 2024 at the Pianabella UrbanV vertiport in Rome, Italy. The study aimed to record and analyze the noise generated by a DJI Matrice 300 RTK during LiDAR and photogrammetric mapping operations. To achieve this, CIRA deployed eight 1/2-inch precision condenser microphones alongside an artificial head, strategically placing the sensors across the test field to capture noise during drone take-offs, landings, and overflights. A comparative analysis of psychoacoustic metrics derived from conventional microphone measurements and those obtained from the artificial head, both with and without equalization curve, revealed significant differences. Overall, the application of equalization curves substantially improves loudness estimation.

DF			
	Max	5%	10%
N	7.1	5.5	5.1
R	13.8	12.7	15.7
F	2.6	5.0	3.9
S	37.9	11.3	6.3
T	11.1	14.1	14.5

Figure 14. Percentage deviation from the expected results (DF Equalized).

ID			
	Max	5%	10%
N	3.3	4.2	3.9
R	16.0	19.5	24.5
F	3.2	8.5	4.3
S	39.1	7.5	9.1
T	11.1	14.6	17.8

Figure 15. Percentage deviation from the expected results (ID Equalized).

In particular, the "free-field" equalized curve yields the most accurate loudness estimates when compared with the reference measurement obtained from a conventional microphone. Other metrics did not exhibit a clear or consistent pattern. These results underscore that if the objective of using the head is to estimate psychoacoustic metrics in contexts that differ from the idealized conditions of a free-field or diffuse field, even when applying the "independent of direction" equalization curve as recommended by HEAD Acoustic for that cases, non-negligible errors may arise. Consequently, it may be valuable to develop specialized metrics for head measurements that eliminate the need for equalization by directly quantifying the external hearing effect during testing.

5. ACKNOWLEDGMENTS

The authors would like to thank all the partners of the U-ELCOME project, with special thanks to UrbanV for hosting the test campaign and to TopView for providing the drone.

Exploring the Socio-spatial Pattern of Noise Impact of Advanced Air Mobility – A Case Study in West Yorkshire, England

Like Jiang[1*]
[1] Institute for Transport Studies, University of Leeds, UK

ABSTRACT

Using West Yorkshire in England as the case study area, this study assesses the potential noise impact of advanced air mobility (AAM) at reginal scale, and explores how the impact is distributed across different socio-economic groups. Using agglomerative hierarchical clustering (AHC), possible vertiport locations were identified based on commute travel demand. Then, two types of flying routes were tested: one prioritises distance reduction and one prioritises noise mitigation, each tested with 3 distances of noise footprints. Statistics of people exposed to the potential AAM noise were made with and without considering exposure to existing road and rail noise. The results show that AAM noise is likely to affect a large proportion of the population in West Yorkshire, and most of the affected population are not currently exposed to road and/or rail noise above 55dB $L_{Aeq,\ 16h}$. AAM noise is also likely to make the social inequality in transport noise exposure in West Yorkshire even worse. Using noise-priority routes seems to reduce the inequality, but there is a risk that the more deprived communities who are already exposed to high transport noise will bear disproportionally more burden of the new noise introduced by AAM.

Keywords: *advanced air mobility, vertiport, flying route, noise impact, social equity*

1. INTRODUCTION

Advanced air mobility (AAM), including passenger mobility such as air taxis, is becoming a reality. Real-world demonstrations have been taking place since at least 2017 with air taxi by Volocopter in Dubai, and commercially viable services are expected to be widely available by 2030 [1]. AAM will improve mobility and connectivity, stimulate economic growth, while at the same time reduce carbon emission [2]. However, it also comes with new problems. Despite lower noise emission from the emerging new flying vehicles such as electric vertical take-off and landing (eVTOL) aircrafts as compared to conventional aircrafts, lower flying paths, higher penetration into high density areas and higher frequency of operations mean AAM can potentially cause more noise impacts. According to a survey in Europe, noise is one of the public's most concerned issues regarding AAM [3].

There is a growing body of research addressing the noise issues of AAM. However, most of the focus has been on the modelling of noise emission from individual vehicles, along their flying paths or around vertiports where these vehicles take off and land [4-5], much less attention has been paid to assessing potential noise impact at city or reginal scale [6-8]. Studies at city and reginal scales can be useful in understanding spatial pattern and distribution of AAM noise impact. However, such studies are rare in Europe where land use and urban morphology are very different from those in US or in Asia. Moreover, none of these existing studies considered social distribution of the impact, while social equity could be an issue in public acceptance and AAM's uptake, given that AAM may only serve high value travelers, at least in the early stages. Therefore, this study explores the socio-spatial pattern of potential AAM noise impact using West Yorkshire in England as the case study area.

2. METHODS

To assess potential UAM noise impact, possible vertiport locations were first identified based on commute travel demand. Then, two types of flying routes were tested: one prioritises distance reduction and one prioritises noise

mitigation, each tested with 3 distances of noise footprints. Statistics of people exposed to the potential UAM noise were made with and without considering exposure to existing road and rail noise.

2.1 The case study area

West Yorkshire is a county in North England with a population of around 2.4 million in 2022 and governed by five metropolitan boroughs: City of Leeds, City of Bradford, City of Wakefield, Calderdale and Kirklees.

Analysis in this study was conducted at the spatial scale of Output Areas (OAs) which are the lowest level of geographical area for census statistics in England. Each OA has between 100 and 625 usual residents and there are 7345 OAs in West Yorkshire in the 2021 census. The 2019 English indices of deprivation (IMD) was used to divide the OAs into 10 deciles, with Decile 1 among the 10% most deprived OAs in England and Decile 10 among the 10% least deprived. As shown in Figure 1, there is a mixed levels of deprivation in West Yorkshire with OAs present in all the 10 deciles. However, the majority of the OAs are in the lower deciles and numbers of OAs generally decrease as deprivation decreases.

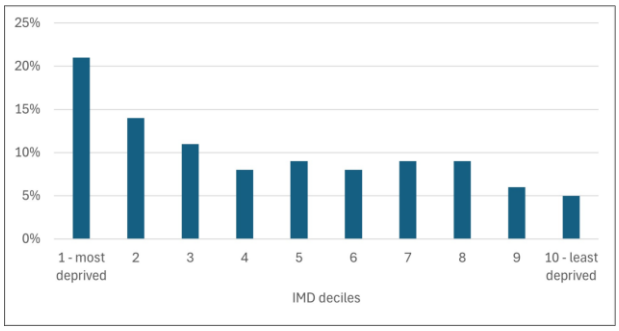

Figure 1. Distribution of West Yorkshire OAs in the English Indices of Multiple Deprivation (IMD) 2019 deciles.

2.2 Vertiport locations

Since one of the most promising use cases of AAM is envisaged to be for commute [6], possible vertiport locations in this study were identified based on travel to work demand. Number of residents as well as workplace population by distance travelled to work in each Middle Layer Super Output Area (MSOA) were obtained from census 2011. Census 2011 was used instead of census 2021 due to impact of Covid lockdowns on census 2021. MSOAs are higher level census geographical areas each containing between 5,000 and 15,000 residents. Given that AAM is unlikely to be appealing for very short distance travels, only residents and workplace population travelled longer than 10km were kept for analysis.

Clustering analysis is a popular approach to identify AAM vertiport locations [9] and agglomerative hierarchical clustering (AHC) was used in this study. To perform AHC, each MSOA centroid was broken down into demand point each representing 500 travellers (residents plus workplace population). Coordinates of the demand points were randomised by applying a random move of up to 500m so points belonging to the same MSOA do not overlap on each other. The resulted demand points are shown in Figure 2. The AHC was conducted in R using the *cluster* package [10] with the Ward.D2 linkage method. Figure 3 shows the resulted dendrogram. Based on the split pattern in the dendrogram and given that [6] used 100 vertiports for 21 million people while West Yorkshire has a population of around 2.4 million, number of vertiports was set to be 11 in this study. Locations of these vertiports was determined by calculating the arithmetic means of the coordinates of demand points within each cluster. Figure 2 shows the locations of the vertiports.

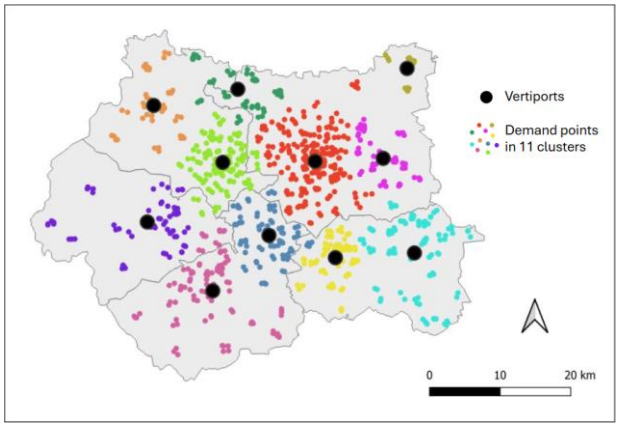

Figure 2. Vertiports and demand points in 11 clusters.

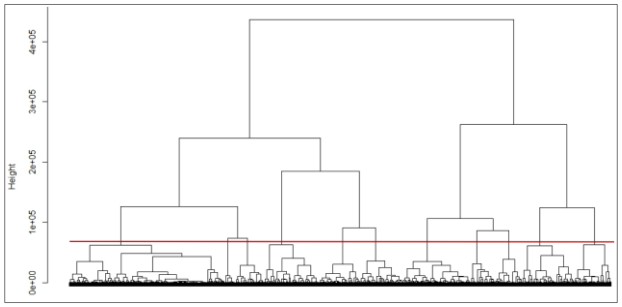

Figure 3. Dendrogram from the agglomerative hierarchical clustering (AHC) analysis with the cutoff line at 11 clusters.

2.3 Flying routes and noise footprints

Flying routes were assigned to provide good connections to the two largest settlements in West Yorkshire: Leeds and Bradfords. Two types of routes were tested: distance-priority routes which connect vertiports using straight lines; and noise-priority routes which follow major roads so the routes are above areas already exposed to high transport noise. The noise metric of $L_{Aeq,\ 16h}$ was used for road noise, as well as for all the noise levels mentioned in the rest of this paper, since AAM for commute is unlikely to operate over night so noise impact over the 16-hour period from 7am to 11pm would be most relevant. Figure 4 shows the two types of routes with road noise map from England Strategic Noise Mapping Round 4 (2022) in the background.

Noise footprints covering areas of within 500m, 1000m and 1500m distances along the flying routes were assumed and tested. AAM noise within these distances were assumed to be above 55dB $L_{Aeq,\ 16h}$. These distances were chosen based on noise maps produced in previous studies [6-8], and the fact that there is still uncertainty in AAM vehicle technologies and operation intensity which could affect noise footprint.

2.4 Noise impact assessment

Whether an OA is exposed to AAM noise is determined by whether the population-weighted centroid of the OA is within the noise footprint. Statistics were made for the 2 × 3 flying route and noise footprint scenarios, with and without considering existing road and rail noise.

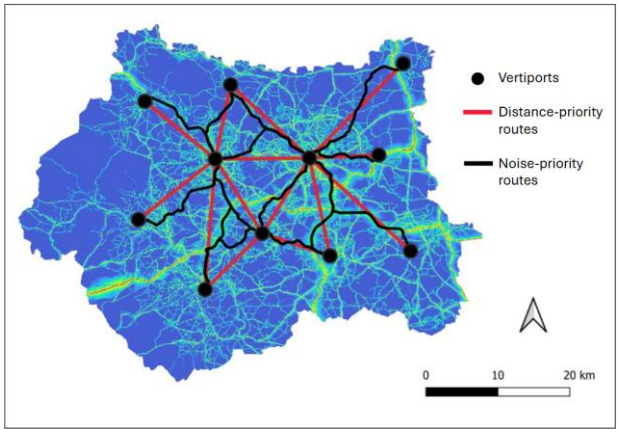

Figure 4. Distance-priority routes and noise-priority routes with road noise map in $L_{Aeq,\ 16h}$ from England Strategic Noise Mapping Round 4 (2022).

3. RESULTS

West Yorkshire is already facing serious transport noise issues, with 38% of the OAs exposed to road and/or rail noise above 55dB $L_{Aeq,\ 16h}$, while it was reported that "only" 27 % and 2.9 % of the adult population in England were exposed to road and rail noise above 53 and 54 dB L_{den} respectively [11]. Introduction of AAM will further increase noise exposure. As shown in Table 1, more than half of the OAs (53%) will be exposed to AAM noise above 55dB in our scenario if distance-priority routes are used and the wide 1500m noise footprint is assumed. Even with noise-priority routes and the narrow 500m noise footprint, the proportion of exposed OAs will still be high, around 1 in 5 (19%).

Table 1. Percentages of OAs in West Yorkshire exposed to AAM noise above 55dB.

	Noise footprint		
	500m	1000m	1500m
Distance-priority route	22%	39%	53%
Noise-priority route	19%	34%	48%

Among those exposed OAs, most are in quiet areas that are not currently exposed to road and/or rail noise above 55dB $L_{Aeq,\ 16h}$. As shown in Table 2, the percentage is highest

(60%) when distance-priority routes are used and the wide 1500m noise footprint is assumed, and lowest (53%) with noise-priority routes and the narrow 500m noise footprint. This indicates that AAM may pose new threat to areas that are otherwise not affected by transport noise, and the geographic coverage could be very wide and challenging.

Table 2. Percentages of OAs in West Yorkshire exposed to AAM noise in otherwise quiet areas (below 55dB $L_{Aeq,\ 16h}$ road and/or rail noise).

		Noise footprint		
		500m	1000m	1500m
% in all OAs	Distance-priority route	13%	23%	32%
	Noise-priority route	10%	19%	28%
% in exposed OAs	Distance-priority route	57%	59%	60%
	Noise-priority route	53%	56%	58%

Impacts of both the existing road and/or rail noise and the potential AAM noise are not evenly distributed across social groups. As shown in Figure 5, the more deprived OAs are more likely to be exposed to road and/or rail noise, with more than 40% of the OAs in Deciles 1, 2 & 3 exposed, while it is less 30% for OAs in Deciles 9 & 10.

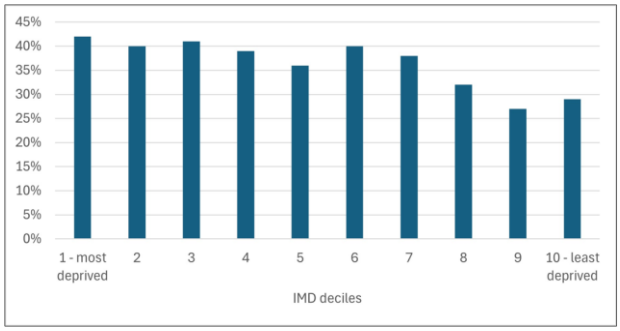

Figure 5. Percentage of OAs in West Yorkshire exposed to road and/or rail noise above 55dB $L_{Aeq,\ 16h}$ in each IMD decile.

The inequality could be even worse with AAM noise. As shown in Figure 6, when distance-priority routes are used, more than 30% of the OAs in Decile 1 will be exposed to AAM noise with 500m noise footprint. The percentages roughly go down as deprivation decreases, and are less than 10% for Deciles 8 & 9. Similar patterns are observed with 1000m and 1500m noise footprints, with OAs in lower deciles more than twice as likely to be exposed to AAM noise as compared to those in higher deciles.

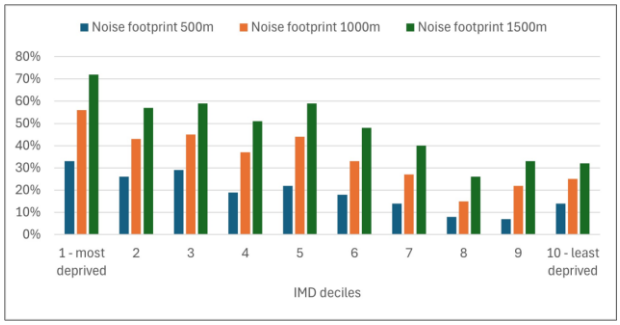

Figure 6. Percentages of OAs in West Yorkshire exposed to AAM noise above 55dB with distance-priority routes in each IMD decile.

Using noise-priority routes reduces the inequality. As shown in Figure 7, while lower deciles are still more likely to be exposed to AAM noise, the divides are not as large as when using distance-priority routes. With 500m noise footprint, around 25% and 10% of OAs are exposed in Decile 1 and in Deciles 8 & 9 respectively.

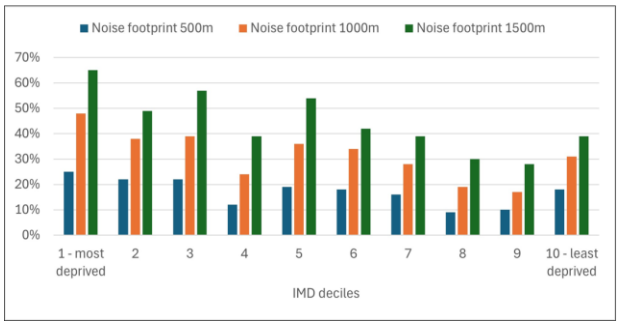

Figure 7. Percentages of OAs in West Yorkshire exposed to AAM noise above 55dB with noise-priority routes in each IMD decile.

When existing road and/or rail noise is considered, i.e., only counting OAs where road and/or rail noise does not exceed 55dB $L_{Aeq,\ 16h}$, the inequality becomes much less significant. With distance-priority routes, there are still higher proportions of OAs exposed to AAM noise in the lower

deciles, but generally less than twice as high as those in the higher deciles, especially when wider noise footprints are assumed (Figure 8). With noise-priority routes, the variation becomes even smaller and OAs in the lower deciles do not show remarkable disadvantages (Figure 9). However, this does not mean that AAM will not further contribute to social inequity in transport noise impact, or noise-priority routes are better at tackling the inequality. Rather, it indicates that the more deprived communities who are already suffering from more transport noise will bear disproportionally more burden of the new noise introduced by AAM.

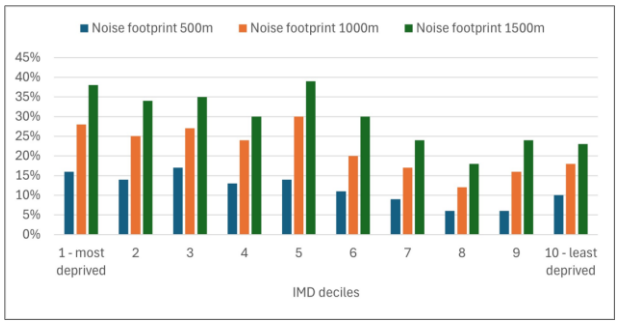

Figure 8. Percentages of OAs in West Yorkshire exposed to AAM noise above 55dB in otherwise quiet areas (below 55dB $L_{Aeq,\ 16h}$ road and/or rail noise) with distance-priority routes in each IMD decile.

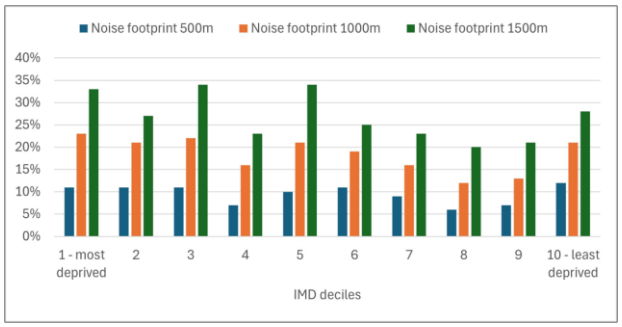

Figure 9. Percentages of OAs in West Yorkshire exposed to AAM noise above 55dB in otherwise quiet areas (below 55dB $L_{Aeq,\ 16h}$ road and/or rail noise) with noise-priority routes in each IMD decile.

4. CONCLUSIONS

This study shows that AAM noise is likely to affect a large proportion of the population in West Yorkshire even in the more conservative scenarios, and most of the affected population are not currently exposed to road and/or rail noise above 55dB $L_{Aeq,\ 16h}$. AAM noise is also likely to further impair social equity in transport noise impact in West Yorkshire, as the more deprived communities are more likely to be exposed to AAM noise. Using noise-priority routes seems to reduce the inequality, but there is a risk that the more deprived communities who are already exposed to high transport noise will bear disproportionally more burden of the new noise introduced by AAM.

This study however has some limitations. Vertiport locations and flying routes were decided only based on travel demand without considering other important factors such as land and airspace availability and land use sensitivity. Potential noise level and footprint of AAM was only roughly estimated. More accurate noise modelling could improve the rigorousness of this study.

UAS-NOISECHECK - A SYSTEM IMPLEMENTING THE EASA GUIDELINES ON DRONE NOISE MEASUREMENT

Martin Blass* **Stefan Grebien** **Franz Graf**
JOANNEUM RESEARCH Forschungsgesellschaft mbH
DIGITAL – Institute for Digital Technologies

ABSTRACT

Unmanned aerial systems (UAS) are on the rise and are about to transform civil aviation. As their proliferation grows, the social and legal acceptance of drones is becoming increasingly important, particularly with regard to noise pollution. So far, the lack of standardized methods and systems to measure in-flight noise emissions of UAS has hindered the creation of legal frameworks. To close this gap, the EASA introduced guidelines for UAS noise measurement in October 2022, for which feedback is currently being collected on their practical implementation and measurement results. In this work, we present *UAS-NoiseCheck*, a prototype system designed to implement these guidelines. It integrates acoustic, visual, GNSS and meteorological components to enable comprehensive, multisensory data acquisition and thus represents a novelty in the multimodal metrological description of UAS. Since our system not only contains a single microphone as a sound level meter but also features a hemispherical 32-microphone array, it can also facilitate the certification and regulation of noise emissions when used in the context of drone detection and localization. In initial field experiments, we analyze noise emissions of different multicopter UAS recorded with a ground-based and an inverted microphone setup as well as the microphone array.

1. INTRODUCTION

Unlike conventional aircraft, UAS produce distinctive high-frequency and tonal noise signatures, which can lead to noise annoyance populated areas. Previous research studies have shown that UAS are likely to be perceived as more annoying than road vehicles, airplanes or helicopters at similar sound levels, in particular when combined with low-altitude flight maneuvers and hovering [1, 2].

In response to growing concerns [3], the European Union Aviation Safety Agency (EASA) introduced guidelines in 2022 [4] aimed at standardizing noise measurement for UAS operating in the *specific* category, which has not been addressed so far. These guidelines mark a significant step in bridging the gap between traditional noise assessment methods [5, 6] and the evolving acoustic profiles of modern UAS [7]. Previous studies have largely focused on controlled environments such as anechoic chambers, wind tunnels or complex and costly outdoor configurations [5, 8]. Nevertheless, field measurements are still essential to capture the complex interplay between UAS noise emissions and environmental factors such as ground effects and meteorological conditions.

In [9], sound pressure level (SPL) and noise variability under different flight conditions was analyzed in an extensive flight test campaign for small UAS, focusing on the comparison between ground-plane and elevated microphones. [10] presents a robust framework for field measurements to accurately characterize UAS noise emissions during flyovers, using multiple measurement positions and backpropagation techniques to calculate directivity noise hemispheres. In this comprehensive work the inverted microphone setup over a ground plate proposed in [4, 6] is used. Similar measurements were performed in [11] with results providing insights into sound pressure, sound power, spectral content and directional patterns.

At the same time, numerous papers have been published on the human perception of drone sounds, with the aim of finding a link between objective noise metrics and psychoacoustic sound quality metrics. [1] used the sound exposure levels (SEL), effective perceived noise level (EPNL), and loudness exceeded 5% of the time (L5) together with subjective listening tests, to compare human annoyance responses to noise from UAS flyovers and road vehicle drive-bys. [2] recommends a combination of qualitative and quantitative methods, including laboratory studies and real-world testing to understand human responses to UAS and to develop the most meaningful noise metrics. In particular, loudness, sharpness, tonality and roughness should be considered, as A-weighted SPL, SEL or EPNL are considered insufficient.

There exist only few works on the noise measurement including SPL estimation with microphone arrays. In [12] the use of microphone arrays is recommended due to their localization capabilities and improved signal-to-noise ratio (SNR) given by possibility of focusing in a desired direction via beamforming (BF). In a previous paper [13], we presented a hemispherical 32-microphone array specifically designed to capture typical UAS noise and investigated its performance in fixed and mobile setups.

In this paper, we present *UAS-NoiseCheck*, a research project and equally named system, designed to implement the EASA noise measurement guidelines [4]. By integrating ground-plate microphones, a sound level meter (SLM) and a microphone array from [13], with visual, GNSS and meteorological components, our system enables a comprehensive, multimodal characterization of drone noise. Based on the results of initial field tests, we show that the system has the potential to combine noise measurement with acoustic drone tracking to enable directional SPL estimation in future regulatory tasks.

2. METHODOLOGY

The guidelines of [4] describe two different approaches for the objective measurement of UAS noise: a level-flight to estimate the A-weighted sound exposure level (L_{AE}) and a hover procedure to compute the A-weighted equivalent continuous SPL (L_{Aeq}) recorded using the inverted setup (INV) with a 1/2" microphone spaced 7 mm above a ground plate [6] and an SLM, both complying with IEC 61672-1 (Class 1). This setup is recommended for its simplicity instead of a ground-based microphone (GND) mounted flush with the plate. In *UAS-NoiseCheck*, we implement both setups to analyze potential SPL differences.

Similar to our previous work [13], we use an acoustic localization algorithm providing DOA estimation (DOAE) of multiple sound sources in order to track potential UAS targets. The algorithm relies on the BF steered response power and adopts a Gaussian Mixture Model (GMM) based approach for the use in 3D with custom frequency and sampling grid settings to enable probabilistic modeling and tracking of an unknown number of sources and signal extraction using masked delay-and-sum beamforming (DSB) [14]. It provides good localization accuracy even with coarse spatial scanning grids with a computational load that enables real-time application.

3. SENSOR SYSTEM

The sensor system consists of the following components that provide data streams a central unit (CORE):

- SPL: *GRAS 67AX* (INV, GND) + *NTi Audio XL2* SLM → 2x audio via USB, 1x JSON message via LAN,
- ARR: *JR-IcoDome32* microphone array + *MOTU AVB* → 32x audio via USB,
- CAM: 2x *FLIR Blackfly GigE* + *NVIDIA Jetson Orin* → 1x JSON message via LAN,
- GNSS: *Holybro H-RTK F9P GNSS* + *Pixhawk 6X* → 1x GNSS message via USB from *RFD868x-EU*,
- METEO: *DAVIS Vantage Pro 2* + *Weatherlink LIVE* → 1x JSON message via LAN.

Figure 1: Measurement setup: SPL with GNSS for positioning (top left), ARR with windscreens (top right), CAM in case (bottom left), and a *ViewCopter V6H* with payload for MTOM (bottom right).

Figure 1 shows the measurement setup during the initial field test in 2024. All components are synchronized in time by an NTP server on an LTE router. For SPL, we use a *GRAS 47AX* (GND) and a *Z-TECH 333-507* (INV) microphone. The audio signal of INV is split with an XLR Y-adapter and used as SLM input. ARR has 32 ICP electret array microphones, 26 of which are arranged on a geodesic dome and 5 as a pentagon, with one in the center of a solid plate. Signal conditioning, A/D conversion and time synchronization is done with *MOTU AVB* USB audio interfaces. CAM only sends position estimates to CORE and stores video data locally. GNSS is used to record sensor positions and is mounted on the UAS during flights.

For our initial field test, we used four UAS [1] [2]:

UAS	**DIM** (cm)	$\mathbf{V_{Gref}}$ (m/s)	**MTOM** (kg)
ViewCopter V6H	150x150x45	10	32
twinFOLD KAT	173x187x30	10	12
twinFOLD GEO	125x115x26	10	5
twinFOLD SCI	52x52x17	15	2

Table 1: UAS with dimensions, reference ground speed V_{Gref} and maximum take-off mass (MTOM).

According to [4], UAS must be operated at V_{Gref}, i.e. at the fastest speed at which the level-flight can be maintained under the atmospheric reference conditions, with their maximum take-off mass (MTOM) at an altitude between 17 m and 150 m and ensuring a lateral deviation of $\pm 10°$ from the vertical above the noise measurement point (SPL). For the hover procedure, the UAS must maintain a stabilized position for 30 s at an altitude between 12 m and 50 m within a cone of 8° from the vertical above the noise measurement point. For both level and hover scenarios at least 6 valid runs must be performed.

4. RESULTS

The first field tests were carried out at *UMFC Stocking* airfield in November 2024. All microphones and the SLM were calibrated with a 1 kHz sine signal at 94 dB. Audio data was recorded at a sampling rate of 48 kHz at 24 bits together with the SLM metrics L_{AF} and L_{AS} logged at 5 Hz for fast and slow time weightings, respectively. For FFT processing in DOAE, we set the size of the time window (square-root Hann) and the FFT to 4096, with a frame overlap of 50% to ensure perfect reconstruction of the DSB signals extracted from the estimated source tracks. Considering the predominant characteristics of drone sound, i.e. rotor noise, the frequency range for DOAE was set to [300 2300] Hz and for DSB signal extraction to the whole range [0 24] kHz. As scanning grid we choose a hemisphere of 200 quasi-uniformly distributed points. The number of initial and maximum sound sources was set to 3 and 16, respectively [13].

In Figures 2 and 3 we show exemplary runs for a level and a hover flight of the *ViewCopter V6H*, respectively. The top two subplots represent the DOAE tracking results of three sound source hypotheses (SRC1-3) compared to the GNSS based position ground truth (TRUE) in terms of azimuth and elevation angles. The respective absolute angle error for each source is shown in the third diagram. The fourth subplot shows the distance and velocity profile of the UAS flight with respect to SPL as origin. The bottom two plots display the SPL recordings of INV as reference (which is also used as input to SLM), GND, ARR as the central microphone on the array base, and DSB as the extracted beamformer output of the SRC closest to TRUE.

The measurement results for the entire dataset are presented as follows: Table 2 provides the calculated noise metrics defined in [4] for each UAS: the arithmetic average sound level L_{AEref_av} and L_{Aeqref_av} for level and hover flight, with the corresponding standard deviation (SD).

UAS	$\mathbf{L_{AEref_av}}$ (dBA)	$\mathbf{L_{Aeqref_av}}$ (dBA)
ViewCopter V6H	77.6 ± 0.81	77.6 ± 0.76
twinFOLD KAT	74.4 ± 0.67	66.4 ± 1.09
twinFOLD GEO	77.3 ± 0.48	57.6 ± 1.73
twinFOLD SCI	66.3 ± 0.39	50.8 ± 1.32

Table 2: UAS noise metrics L_{AEref_av} and L_{Aeqref_av} averaged over runs for level-flight and hover, resp.

Scenario	**GND** (dB)	**ARR** (dB)	**DSB** (dB)
level	0.23 ± 0.06	-0.03 ± 1.84	-2.69 ± 2.63
hover	0.06 ± 0.83	0.50 ± 4.82	-3.86 ± 4.88
level & hover	0.17 ± 0.71	0.16 ± 3.24	-3.11 ± 3.64

Table 3: SPL differences of GND, ARR and DSB w.r.t. INV: mean $\pm$ SD for level-flight and hover.

[1] https://www.vcopter.net/drohnenbau.html
[2] https://www.twins.co.at/multirotorsysteme

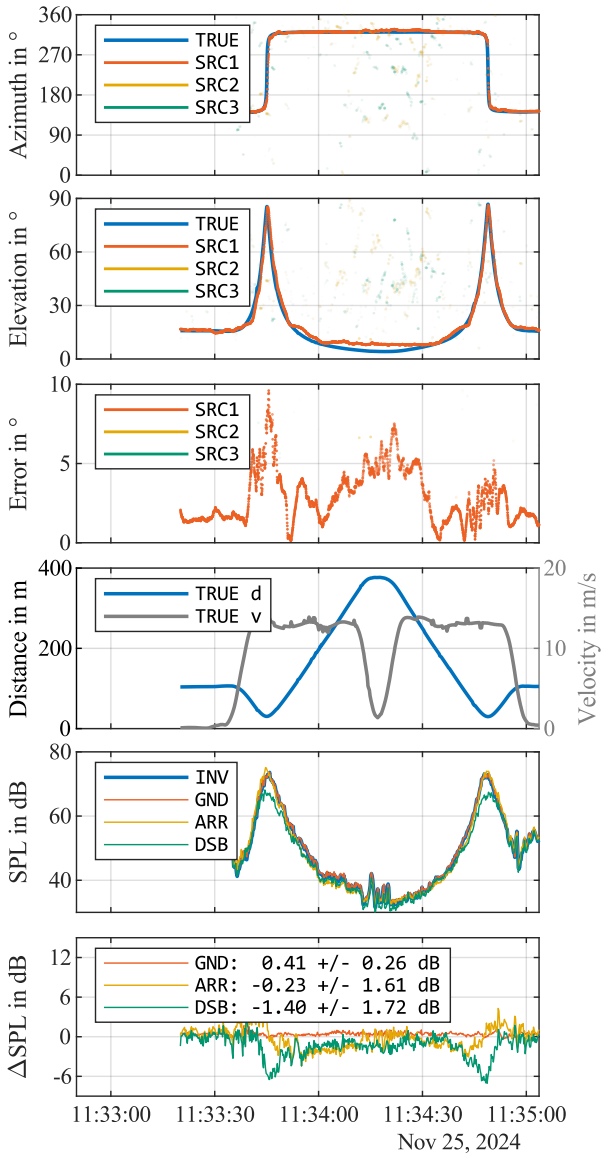

Figure 2: Level-flight example of *ViewCopter V6H*: The UAS is tracked during the entire run up to a distance of 400 m with a DOAE error below 10°. The average SPL differences w.r.t. INV are within 1.5 dB for all signal types. The deviations in ARR and DSB are mainly due to time differences during overflights. The relatively large SPL differences in DSB of -6 dB indicate that the tracker is not able to follow the UAS fast enough, leading to steering errors and unwanted attenuation of the target signal in the BF process.

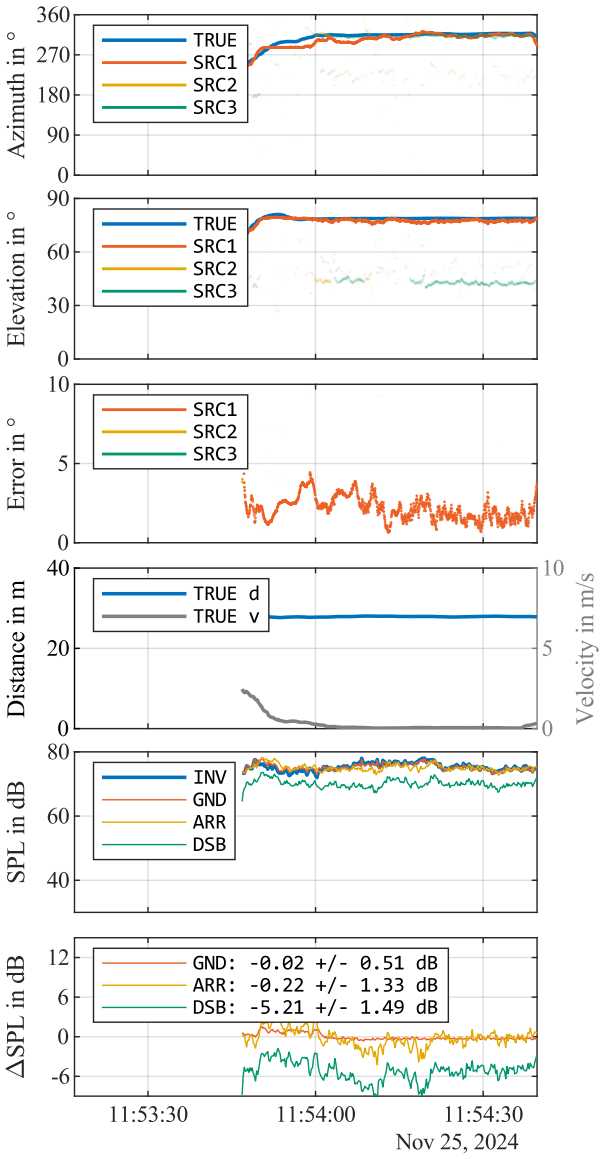

Figure 3: Hover-flight example of *ViewCopter V6H*: The UAS is stabilized at a height of 31 m above the ground plate (SPL) and tracked with a DOAE error below 5°. The average SPL differences w.r.t. INV are within 1 dB for GND and ARR. The deviations at DSB of -6 dB are due to spatial filtering effects, such as suppressed ground reflections, turbulent incoherent noise etc., and possibly also due to the fact that the array mainlobe is too narrow to focus on the UAS as a whole and therefore does not capture its entire frequency content.

Table 3 examines the SPL differences in terms of L_{AF} of GND, ARR and DSB compared to the inverted setup microphone signal (INV) averaged over all runs. To get a more detailed insight, we divide the analysis into the contributions of level, hover, and both scenarios.

Table 4 shows a statistical evaluation of the DOAE in terms of mean absolute error (MAE) including SD and median absolute deviation with the respective interquartile ranges, which represents a more outlier prone error metric. Again, we split the evaluation into level, hover, and both.

Scenario	**MAE** $\pm$ **SD** (°)	**MAD** (°)	**IQR** (°)
level	5.94 $\pm$ 8.27	3.63	[2.08, 7.25]
hover	6.08 $\pm$ 5.36	3.69	[2.34, 8.83]
level & hover	5.99 $\pm$ 7.37	3.65	[2.16, 7.88]

Table 4: DOAE performance: mean $\pm$ SD, median and IQR of absolute error for level-flight and hover.

5. CONCLUSION

We have presented *UAS-NoiseCheck*, a multimodal system for UAS noise measurement. We draw the following conclusions from our results obtained in a first field test:

- Both the inverted and the ground microphone setup are suitable for accurately measuring UAS noise metrics.
- The DOAE performance highlights the effectiveness of microphone arrays to automatically localize UAS.
- To accurately measure SPL based on BF, special care must be taken to ensure robust sound source tracks and to compensate for the spatial array response.

Future work lies in extensive field testing to verify the results on larger datasets and improve DOAE tracking.

6. ACKNOWLEDGMENTS

The project *UAS-NoiseCheck* has received funding from the research, technology and innovation funding program Take Off of the Republic of Austria, Ministry for Climate Action. The Austrian Research Promotion Agency (FFG) has been authorized for the program management.

NOISE MODELING OF UAM AROUND VERTIPORTS BY SOUND BARRIER

Seung-Min Lee[1] **Chan-Hoon Haan**[1*]
[1] Department of Architectural Engineering, Chungbuk National University, South Korea

ABSTRACT

The present study aims to propose practical solutions to control the noise issue, which is a key challenge for the commercialization of Urban Air Mobility (UAM). Noise levels around vertiports during UAM urban operations were predicted using the SoundPLAN program, and the noise reduction effects were assessed through simulation modeling when various heights of noise barriers were applied at different distances and receiver heights. The comparison factors to confirm the noise reduction effect were set to L_{den}, L_{eq}, and L_{max}. The height of the sound barrier was investigated up to 27 m at 3 m intervals. In the present study, for noise prediction, two major vertiports on the K-UAM Grand Challenge phase 2-1 Ara Waterway demonstration route were targeted. As a result, it was found that significant noise reduction was observed at receiver points lower than the sound barrier. However, the noise reduction effect was minimal or absent at receiver points of similar or greater height than the sound barrier. This indicated that as the distance from the vertiport decreased, the noise reduction effect increased with the height of the sound barrier. Thus, it can be expected that the findings of this study could contribute to noise mitigation of UAM.

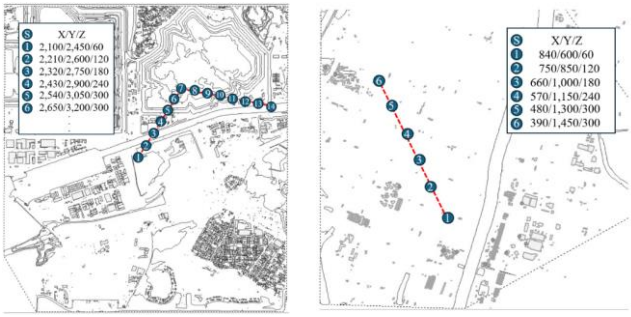
1. INTRODUCTION



A significant challenge in the commercialization of Urban Air Mobility (UAM) is noise.[1] Aircraft like helicopters have caused disturbance to those living near airports due to elevated noise levels, frequently sparking community opposition. Because UAM utilizes electric vertical take-off and landing (eVTOL) technology, it is anticipated to produce less noise compared to traditional aircraft.[2] However, given that UAM operations primarily occur over urban centers, even with reduced noise compared to conventional aircraft, they will operate much closer to where people live and work. Consequently, UAM operation could introduce a new source of noise in existing urban areas, potentially increasing how intensely noise is perceived and raise concerns about sensitive reactions from city dwellers.[3] Therefore, to successfully commercialize UAM, the development and application of UAM-specific noise analysis and mitigation techniques are essential.

Sound barriers are recognized as important elements in decreasing environmental noise. In the transportation sector, they are installed alongside highways and railways to effectively lessen noise impacting nearby residential and commercial zones. [4] Sound barriers function by creating a physical obstruction that prevents sound from traveling directly to the listener. Beyond just traffic noise, these sound barriers are also employed to control noise from industrial activities, aiding in adherence to local noise ordinances and minimizing noise pollution in adjacent areas. This study proposes a method for reducing noise generated by UAM operations through the use of an established technology: sound barriers. To achieve this, SounPLAN software is employed to predict and analyze noise levels by strategically placing sound barriers around vertiports, which are the take-off and landing locations for UAM within the city. The aim is to identify ways to lessen the noise impact of UAM operations on urban environments and to significantly contribute to the protection of the living environment for city residents

(a) V1) (b) V2

Figure 1. Noise reduction rate according to the height of sound barrier.

2. RESEARCH METHOD

Noise maps were generated, and noise levels were predicted using the SoundPLAN program. Sound barriers were positioned along the road adjacent to the vertiport, and the material of the sound barriers was set to be reflective. The area simulated was the vertiport location of the K-UAM Grand Challenge. Table 1 shows the noise level of the UAM input into SoundPLAN. The height of the sound barriers was compared from 12 m to 27 m at 3 m intervals.

3. RESULTS

L_{eq} and L_{max} were predicted at two different points. L_{eq} prediction results showed that the noise level continuously decreased as the height of the sound barrier increased in 3 m increments. Furthermore, when the increase/decrease rate was compared, the noise level reduction was greater as the height of the sound barrier increased. This trend was consistent at both sound-receiving points. L_{max} did not show a decreasing trend up to 18 m. However, when the height of the sound barrier exceeded 20 m, the noise level was reduced by nearly 2% compared to the previous measurement. At R2, the noise level was nearly double that at R1.

4. CONCLUSION

In this study, the noise level according to the height of the sound barrier was predicted and analyzed using the SoundPLAN program. As a result of analyzing the noise reduction effect, there was a difference in the noise reduction rate depending on the height of the sound barrier and the distance from the sound source. Therefore, when determining the height of sound barriers to prevent noise impact on buildings around the vertiport, the appropriate height should be calculated considering the distance between the vertiport and the sound-receiving location. In addition, there was a difference in the noise reduction rate depending on the noise evaluation factors. In the case of UAM, L_{max} is a noise evaluation factor that requires more careful examination than L_{eq}. Therefore, selecting the height of the sound barrier that is most effective for L_{max} reduction will be effective in reducing overall noise.

NONLINEAR BEHAVIOR OF CONDENSER MICROPHONES: ANALYTICAL MODELING AND EXPERIMENTAL VALIDATION

Jan Plaček[1] **Petr Honzík**[1*]

Czech Technical University in Prague, Technická 2, 166 27 Praha, Czech Republic

ABSTRACT

This study investigates the nonlinear behavior of condenser microphones, with a focus on nonlinear capacitance as the primary source of nonlinearity. An experimental transducer was developed, consisting of a circular membrane and a fixed electrode with a central hole leading to a backing cavity. A linear analytical model for membrane displacement was derived using a multimodal approach, while a nonlinear model from the literature was used to relate the membrane displacement to the output voltage of the microphone. Experimental measurements of the nonlinear output of the transducer were conducted. A harmonic correction method from the literature was used to linearize the acoustic pressure incident on the transducer's membrane. These measurements were compared with theoretical predictions. The dependence of the first, second, and third harmonics of the output voltage on the input acoustic pressure level was analyzed. The results show good agreement between theoretical predictions and experimental data, particularly for the first and second harmonics, demonstrating the effectiveness of the proposed model in capturing the nonlinear characteristics of condenser microphones.

1. INTRODUCTION

Condenser microphones offer several advantages, including a flat frequency response, low inherent noise, and relatively high sensitivity. Like many electroacoustic transducers, they exhibit a certain level of nonlinear distortion [1]. Among the various sources of nonlinearity, the nonlinear variation of capacitance is widely recognized as the dominant contributor [2]. This nonlinear distortion can be both measured [3, 4] and, to some extent, reduced [5, 6].

In this paper, we first present an analytical model of an experimental condenser microphone composed of a circular membrane and a fixed electrode with a central hole leading to a backing cavity. A linear formulation is used to determine the membrane displacement, which is then applied to compute the nonlinear output voltage of the microphone. The experimental device is subsequently described, along with a measurement setup based on recent techniques for nonlinear characterization and signal correction [4, 7]. Finally, the measured results are presented and compared with theoretical predictions to assess the accuracy and limitations of the model.

2. ANALYTICAL MODEL

This section presents an analytical model of the electrostatic (condenser) microphone, which consists of a circular membrane of radius R, separated by an air gap of thickness h_g from a fixed electrode of thickness l_h. The electrode contains a central hole of radius R_h, which opens into a backing cavity with volume V_c, as illustrated in Figure 1.

2.1 Nonlinear ouput voltage

First, the model of the microphone output voltage incorporating nonlinearities due to the nonlinear variation of

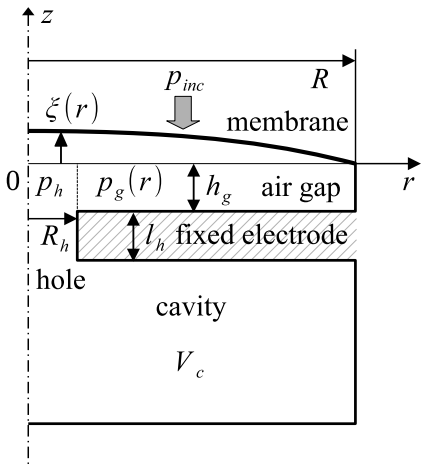

Figure 1. Axisymmetric schematic cross-sectional view of the transducer.

capacitance is summarized from [4]. Since the polarization voltage U_0 is applied to the fixed electrode through a high-value polarization resistor (on the order of GΩ), the charge variation is negligible, and the output voltage can be expressed as

$$u = -U_0 \frac{\mathrm{d}C}{C}. \tag{1}$$

Assuming that the time-dependent capacitance is given by

$$C(t) = C_p + \frac{\varepsilon_0 S}{h_g + \tilde{\xi}(t)} = C_p + C_0 \frac{1}{1 + \frac{\tilde{\xi}(t)}{h_g}}, \tag{2}$$

where $\tilde{\xi}(t)$ denotes the spatial average of the membrane displacement over the active area of the fixed electrode, the capacitance can be expressed as the sum of the parasitic capacitance C_p, transducer's static capacitance C_0 and a time-varying component $\mathrm{d}C(t)$. Applying a Taylor series expansion, the output voltage (1) can be written as

$$u(t) = U_0 \frac{C_0}{C_p + C_0} \left(\frac{\tilde{\xi}(t)}{h_g} - \left(\frac{\tilde{\xi}(t)}{h_g} \right)^2 + \right. \\ \left. + \left(\frac{\tilde{\xi}(t)}{h_g} \right)^3 - \dots \right) \tag{3}$$

The nonlinearities in the output voltage are thus clearly apparent.

2.2 Equations governing the displacement of the membrane

The membrane displacement ξ, required for evaluating the output voltage in (3), is governed by the following wave equation [8–10]

$$T(\Delta_r + K^2)\xi(r) = p_{inc} - p(r), \tag{4}$$

where T denotes the membrane tension, K is the membrane wavenumber, p_{inc} is the incident acoustic pressure, and $p(r)$ represents the $r-$dependent acoustic pressure behind the membrane. The solution to equation (4) is searched for in the form of an eigenfunction expansion

$$\xi(r) = \sum_n \xi_n \Psi_n(r), \tag{5}$$

where the eigenfunctions $\Psi_n(r)$ are given by

$$\Psi_n(r) = \frac{1}{\sqrt{\pi} R J_1(K_n R)} J_0(K_n r), \tag{6}$$

with K_n determined by the membrane boundary conditions $\xi(R) = 0$. The modal coefficients ξ_n are expressed as

$$\xi_n = \frac{1}{T(K^2 - K_n^2)} \iint_S (p_{inc} - p(r)) \Psi_n \mathrm{d}S, \tag{7}$$

where $S = \pi R^2$ denotes the membrane surface area.

2.3 Acoustic pressure inside the transducer

The acoustic pressure behind the membrane comprises two parts

$$p(r) = \begin{cases} p_h = \text{const.} & \text{for } r \in (0, R_h), \\ p_g(r) & \text{for } r \in (R_h, R), \end{cases} \tag{8}$$

where p_h is assumed to be constant over the cross-sectional area of the central hole $S_h = \pi R_h^2$. Following the approach in [9], the acoustic pressure in the air gap is governed by the wave equation

$$\Delta_r p_g(r) + \chi^2 p_g(r) = \zeta\, \xi(r), \tag{9}$$

where ζ is an auxiliary source term and χ is a complex wavenumber that accounts for thermoviscous losses, as described in [9]. The solution to equation (9) is sought in the form

$$p_g(r) = A J_0(\chi r) + B Y_0(\chi r) + \sum_n p_n \Psi_n(r), \tag{10}$$

where A and B are integration constants determined by the following boundary conditions: (i) zero acoustic velocity at $r = R$, (ii) continuity of the acoustic pressure at $r = R_h$, and (iii) continuity of the volume velocity at $r = R_h$.

2.4 Coupling between membrane displacement and acoustic pressure

Substituting the expression for the acoustic pressure $p(r)$ into equation (7), the modal coefficients are obtained as follows

$$\frac{T(K^2 - K_n^2)}{2\pi}\xi_n = b_n + \sum_{mn} \xi_m C_{mn}, \tag{11}$$

which can be rewritten in matrix form as

$$\{[\mathbb{U}] - [\mathbb{C}]\}(\Xi) = (B), \tag{12}$$

where $[\mathbb{C}]$ is the matrix composed of elements C_{mn}, and $[\mathbb{U}]$ is a diagonal matrix with elements $T(K^2 - K_n^2)/2\pi$. The vectors (Ξ) and (B) represent the modal coefficients ξ_n and the excitation terms $b_n = p_{inc}\int_0^R \Psi_n(r) r \mathrm{d}r$, respectively.

2.5 Mean displacement and pressure sensitivity

The mean value of the membrane displacement over the active area of the fixed electrode S_e is given by

$$\begin{aligned}\tilde{\xi} =& \frac{1}{S_e}\iint_{S_e} \xi(r)\mathrm{d}S_e = \\ =& \frac{2\pi}{S - S_h}\sum_n \xi_n \frac{RJ_1(K_nR) - R_hJ_1(K_nR_h)}{K_n\sqrt{\pi}RJ_1(K_nR)},\end{aligned} \tag{13}$$

where $S_e = S - S_h$.

Finally, the acoustic pressure sensitivity of the microphone is expressed as

$$\sigma = \frac{U_0}{p_{inc}}\frac{\tilde{\xi}}{h_g}. \tag{14}$$

2.6 Theoretical results

The results of the linear microphone model are presented in this section. The physical properties of air and the geometrical and material parameters of the microphone used in the theoretical calculations are summarized in Tables 1 and 2, respectively.

Table 1. Properties of the air

Parameter	Value	Unit
Adiabatic sound speed c_0	343.2	m/s
Air density ρ_0	1.2	kg/m^3
Shear dyn. viscosity μ	$1.8{\cdot}10^{-5}$	Pa·s
Thermal conductivity λ_h	$24{\cdot}10^{-3}$	W/(m·K)
Specific heat at constant press. per unit of mass C_p	1005	J/(kg·K)
Ratio of specific heats γ	1.4	-

Table 2. Dimensions of the system and material properties of the moving component

Parameter	Value	Unit
Membrane radius R	$18{\cdot}10^{-3}$	m
Membrane thickness h_m	$25{\cdot}10^{-6}$	m
Air-gap thickness h_g	$230\cdot10^{-6}$	m
Radius of the hole R_h	$0.8{\cdot}10^{-6}$	m
Length of the hole R_h	$1.6{\cdot}10^{-6}$	m
Back cavity volume V_c	$7.74{\cdot}10^{-6}$	m^3
Membrane density ρ_m	1944	kg/m^3
Membrane tension T	116.27	N/m^1
Polarization voltage U_0	165	V

The absolute value of the acoustic pressure sensitivity, expressed in decibels and computed using the linear analytical model described above, is shown in Figure 2 (blue curve). This analytical result is compared with a reference numerical model based on the finite element method (FEM), formulated according to [11] and implemented in the Comsol Multiphysics software (red dots). The comparison demonstrates good agreement between the two models when the first 10 modes are included in the analytical solution.

Using the calculated mean displacement (13), the nonlinear output voltage of the microphone (3) was computed, and the levels of the first three harmonic components were determined at each frequency. These frequency-dependent output levels, calculated for an incident acoustic pressure of $p_{inc} = 1$ Pa, are presented in Figure 3. A relatively large level difference between the harmonic components can be observed at this input pressure.

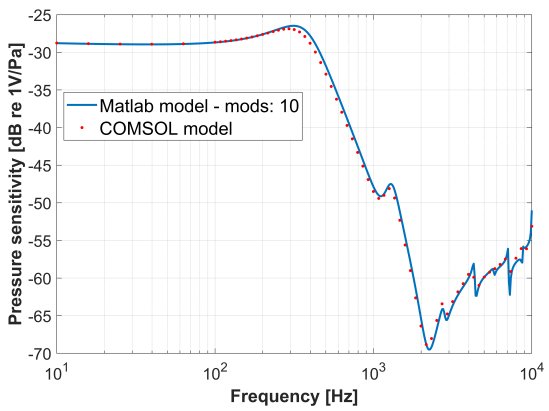

Figure 2. Comparison of the bsolute value of the acoustic pressure sensitivity in dB, calculated analytically (blue curve) and numerically using COMSOL Multiphysics (red dots).

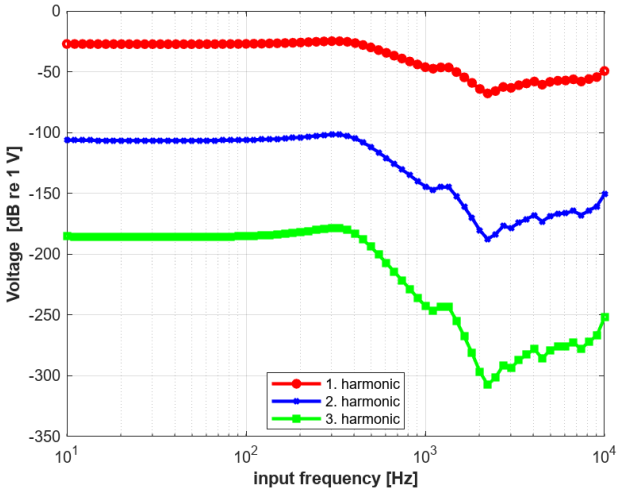

Figure 3. Absolute values of the harmonic components of the microphone output voltage in dB for $p_{inc} = 1$ Pa: 1st (fundamental) harmonic (red curve), 2nd harmonic (blue curve), and 3rd harmonic (green curve).

3. EXPERIMENTAL DEVICE AND MEASUREMENT SETUP

The experimental transducer (see Figure 4) consists of a circular membrane made of aluminum-metallized plastic foil, clamped at its periphery within a rigid 3D-printed frame. The fixed electrode, separated from the membrane by spacers forming the air gap, is fabricated from a printed circuit board (PCB) metallized with copper and coated with a thin gold layer on the side facing the membrane. The opposite side of the PCB hosts electronic components for signal amplification and power supply. A 3D-printed component forms the backing cavity and includes a threaded mechanism, which, when tightened, presses the PCB and spacers against the membrane, thus adjusting its tension. The dimensions of the system correspond to those listed in Table 2.

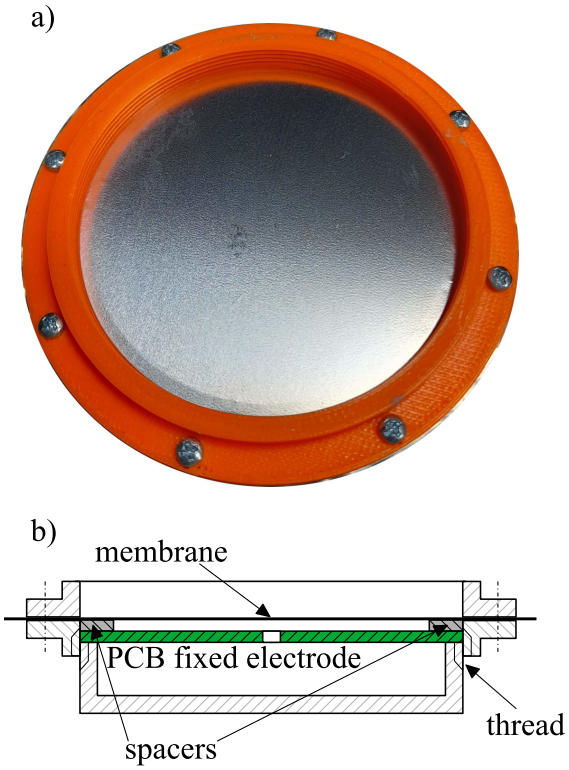

Figure 4. The experimental transducer: (a) top-view photograph; (b) schematic view of the assembly.

The measurement setup is shown in Figure 5. The experimental transducer, together with a reference microphone (B&K 4944-B, 3% THD at 170 dB SPL), is placed inside a measurement chamber between two loudspeakers (Visaton FR 12) arranged in a push-push configuration to generate high sound pressure levels with low distortion. The loudspeakers and both microphones are connected, via amplifiers, to a sound card (RME Fireface

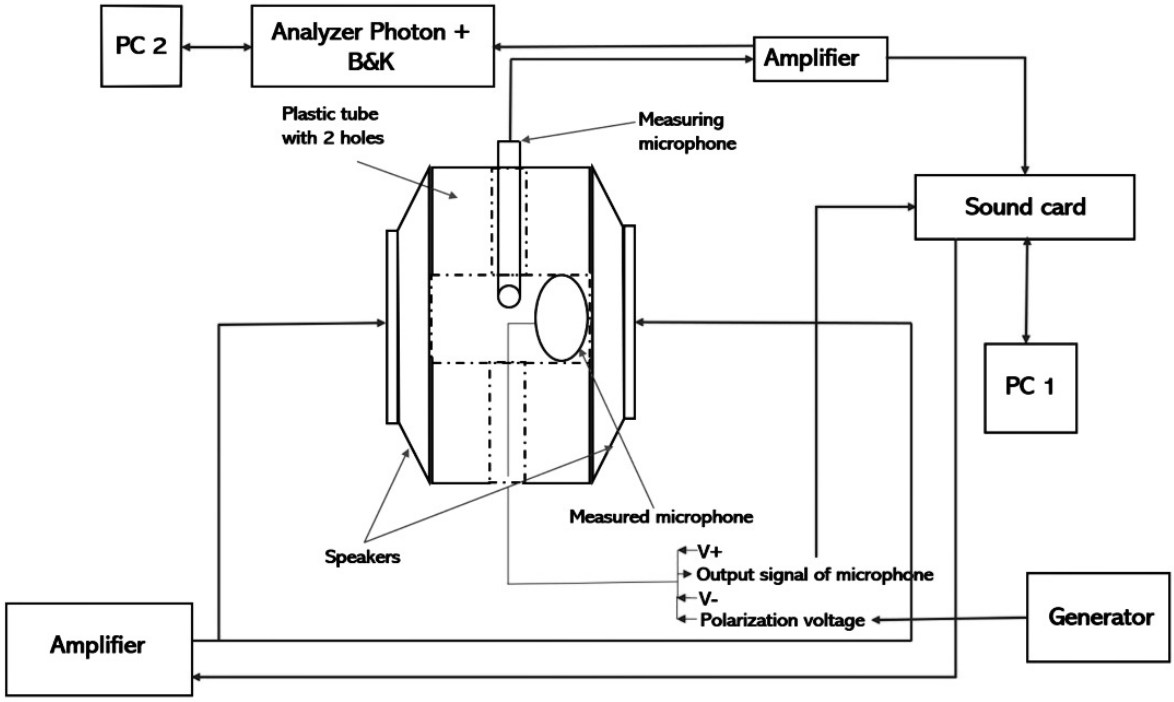

Figure 5. Schematic view of the measurement setup.

UCX), which is interfaced with computer PC1. Additionally, the output of the reference microphone is connected through an amplifier to a B&K Photon+ analyzer, which is linked to computer PC2 to monitor the exact sound pressure level inside the measurement chamber. To ensure purely harmonic excitation, a nonlinear harmonic correction technique was applied [7], effectively suppressing all undesired higher-order harmonics to the noise level. As a result, any nonlinearities observed in the output signal of the tested microphone originate solely from the microphone itself.

4. RESULTS

The measurement procedure described in the previous section was repeated for various levels of incident acoustic pressure and at different frequencies. For each measurement, the levels of the first three harmonics were extracted from the recorded output voltage of the tested microphone using a Fast Fourier Transform (FFT).

Figure 6 presents the results obtained at 110 Hz, which lies below the first resonance frequency of the transducer, for incident acoustic pressure levels ranging from 100 to 140 dB SPL. The points indicate the measured values for the first (blue points), second (orange points), and third (green points) harmonic components. The continuous lines represent the theoretical predictions based on the model described in the preceding sections. Similarly, Figure 7 shows results measured at 1 kHz, which is above the first resonance frequency of the transducer, for pressure levels between 90 and 130 dB SPL.

In both figures, the first and second harmonics are accurately predicted by the model. However, the third harmonic is observed to be between several decibels and approximately 40 dB higher than the levels predicted by the model. This discrepancy indicates that the third harmonic is influenced by additional sources of nonlinearity not accounted for in the analytical model, such as varying damping in the air gap with changing thickness or acoustic nonlinearities at high sound pressure levels within the gap.

5. CONCLUSION

An analytical model of an electroacoustic transducer with a circular membrane and a fixed electrode was developed, incorporating the coupling between membrane displace-

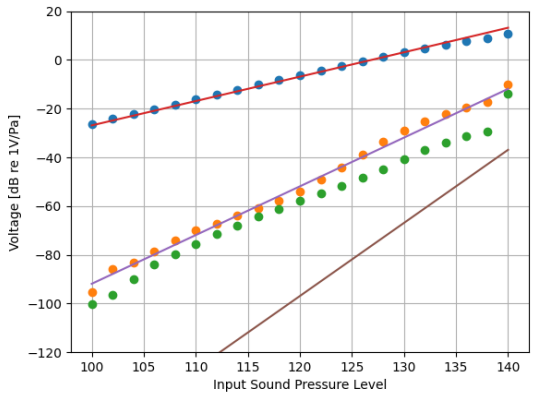

Figure 6. First three harmonic components of the microphone output voltage for different input sound pressure levels at 110 Hz.

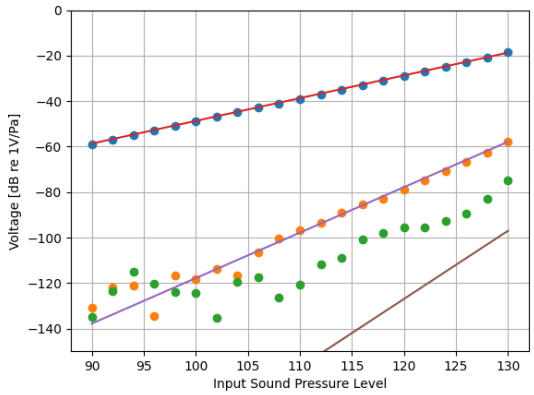

Figure 7. First three harmonic components of the microphone output voltage for different input sound pressure levels at 1 kHz.

ment and acoustic pressure in the air gap, as well as nonlinearities due to time-varying capacitance. The membrane response was expressed via eigenfunction expansion, leading to a formulation of the nonlinear output voltage. The model's predictions of acoustic pressure sensitivity were validated against numerical FEM results from COMSOL Multiphysics, showing good agreement when using the first ten modes.

An experimental transducer was built and measurements were carried out using harmonic excitation with nonlinear correction to isolate the transducer's intrinsic nonlinearities. The results confirmed that the model accurately predicts the first and second harmonic components. However, the third harmonic was significantly underestimated, indicating the presence of additional nonlinear effects, such as pressure-dependent damping or nonlinear acoustics in the air gap, not captured by the current model.

ABSTRACT

Advancements in microphone arrays are transforming acoustic sensing and innovating applications such as speech enhancement, beamforming, source localization, and environmental noise monitoring. On the way to developing low-cost phased arrays with numerous sensors, MEMS microphones have become a preferred solution whose distribution and positioning can boost their acoustic capabilities. The performance of both circular concentric and square grid geometries is characterized. A square grid array prioritizes low-cost scalability for high-efficiency data acquisition, while the circular concentric design optimizes directivity. Both compared arrays use the same MEMS microphone model and electronic configuration, but differ in the number of elements and aperture size. The microphone model used for both arrays allows using Time-Division Multiplexing for streamlined data collection through a single data line with an I^2S interface and integrated PCB design. The frequency response, directivity, and data transfer efficiency are analyzed by conducting experiments with a sound source at various positions within an anechoic chamber. The results demonstrate trade-offs between geometric configurations, providing valuable insight into the design of low-power, flexible, and scalable acoustic sensing systems.

1. INTRODUCTION

The growing demand for low-cost and scalable acoustic sensing systems has fueled advancements in microphone array technology. These arrays are essential tools for applications such as noise source identification, beamforming, and environmental noise monitoring [1, 2]. Among the available technology solutions, MEMS (Micro-Electro-Mechanical Systems) microphones have gained prominence due to their reduced and compact size, low-power consumption, affordability, and integration versatility with development boards. The ease of deployment in various geometric configurations significantly influences the array's spatial resolution, directivity, and overall performance.

A critical challenge in developing massive acoustic cameras is optimizing the microphone distribution while ensuring efficient data capturing [3]. To diagnose noise generation, expensive FPGA-based acquisition systems commonly use the Inter-IC Sound (I^2S) protocol. However, standard I^2S interfaces can only support up to two microphone channels per data line, requiring multiple physical connections for larger arrays [4]. To address this limitation, the Time-Division Multiplexing (TDM) interface extends I^2S capabilities by allowing up to 16 microphone channels to be transmitted on a single data line. Thus, the number of connections can be significantly reduced, streamlining system integration and enabling a cost-effective and scalable architecture. By using

a multiplexed acquisition system, we can systematically assess the performance of different microphone distributions while ensuring consistency in sensor characteristics.

To evaluate the impact of these configurations, we compare two distinct microphone array geometries: a circular concentric array CCA and a square grid array SGA. Both arrays utilize the same MEMS microphone model and electronic setup, differing only in their spatial arrangement, number of elements, and aperture. These configurations are designed as a complete acquisition system intended for use with a low-cost microprocessor development board. The acquired signals must undergo post-processing after acquisition, meaning that all analyses are conducted offline. As it can be seen in Fig. 1, the CCA features a completely solid design, whereas the SGA distributes its microphones along a grid structure, and therfore is expected to behave more transparently concerning wave incidence.

Experiments in this study focus on analyzing the frequency response of each microphone within both array configurations to determine potential variations across the array, and also considering different orientations with respect to the noise source, i.e., the array directivity. Additionally, we assessed whether the multiplexing process impacts measurement accuracy. To demonstrate the synchronization of the multiplexed system, we evaluate its functionality with the worst-case scenario (SGA), where signals are stressed at the maximum trace length recommended by the manufacturer and the one that multiplexes the maximum number of channels supported. These results will provide insights into the reliability of TDM acquisition for scalable, low-power microphone arrays and contribute to optimizing array design for acoustic sensing applications.

The breakout of this document is as follows: Section 2 describes the design of both microphone arrays, explaining the criteria behind their geometries and detailing the composition of the acquisition system. Section 3 outlines the methodology used to evaluate their performance, focusing on three key aspects: frequency response, directivity, and TDM synchronization. In Section 4, the results of these evaluations are presented, supported by graphs and performance parameters. Finally, Section 5 provides a discussion of the findings and summarizes the main conclusions of this work.

2. MICROPHONE ARRAY DESIGNS

2.1 Hardware Development

The modular SGA design has been explained in detail in [5]. Such array follows a scalable architecture consisting of four identical modules, each containing 16 daisy-chain microphones model ICS-52000 [6]. For this study, we assessed the performance of one 16-microphone submodule. Microphones of this array design are evenly spaced and arranged in a 4×4 square grid, with $62.5\,\mathrm{mm}$ between adjacent microphones. To minimize propagation delay mismatches, all electrical connections adhere strictly to the manufacturer's recommendations, with trace lengths set to the maximum allowable limits and matched impedance at clock frequency.

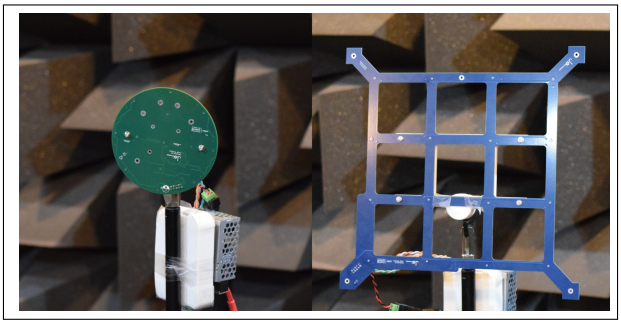

Figure 1. On the left-hand side, the CCA composed of 13 MEMS microphones. The blue printed circuit board corresponds to the SGA with 16 microphones distributed in a Cartesian grid.

Beyond electrical considerations, the SGA's mechanical design was developed to be minimally intrusive to the test environment, reducing the risk of potential airborne disturbances. The printed circuit board occupies a considerable surface area, which could reflect sound energy and introduce pressure variations that degrade acoustic measurements. To counteract this, sections of the structure between microphones have been removed, allowing air to pass freely through the array. This design choice minimizes reflections and potential aerodynamic artifacts. By balancing electrical, spatial, and mechanical constraints, this microphone array optimizes acoustic performance and modular scalability. Moreover, if this microphone array design were used for beamforming applications, its aperture size and microphone separation would impose limitations, e.g., reduced spatial resolution and grating lobes generation, for frequencies under

$f_L \approx 1\,\mathrm{kHz}$ and above $f_H \approx 2.7\,\mathrm{kHz}$, respectively.

A different approach is observed in the CCA, which consists of 13 microphones: one at the center, four distributed along a $2.5\,\mathrm{cm}$ radius, and eight along a $4.5\,\mathrm{cm}$ radius. Compared to SGA from a theoretical point of view, the microphone distribution of this CCA would offer improved directionality and isotropic coverage, making it more suitable for applications requiring omnidirectional sound capture and robust source localization [7], although it is expected that its solid design will affect the directivity in the high frequency range. Furthermore, due to its short and non-uniform spacing, the array may introduce more spatial aliasing effects depending on the frequency range of interest. Additionally, its smaller aperture limits its ability to resolve lower frequency sources as effectively as the larger square array. For this setup, the approximate lower and upper frequency bounds are $f_L \approx 3.8\,\mathrm{kHz}$ and $f_H \approx 8.5\,\mathrm{kHz}$, respectively.

2.2 Data Transmission to BeagleBone Black Board

To handle the signal acquisition, a BeagleBone Black board (BBB) was chosen as the main processing unit. The primary reason for this selection was its Multichannel Audio Serial Port (McASP), which enables seamless interfacing with TDM digital audio streams. Since the MEMS microphones used in both designs output data via this protocol, the acquisition system must be capable of demultiplexing the interleaved audio channels correctly. The BBB, running a Linux-based system, provided this capability while allowing efficient real-time data acquisition.

This transmission format implies that the board manages precisely a bit clock (BCK) and frame synchronization (FS) signals. The data transfer rate is defined by BCK, while FS triggers the start of the first microphone. This means that the following microphone has to wait until the first microphone finishes writing a 32-bit word and commands the word select output (WSO), as shown in Fig. 2.

For a fair comparison between both microphone arrays, the acquisition system was configured to record 16 channels at a sample frequency of $8\,\mathrm{kHz}$. In the case of the 13-microphone CCA, the last three channels were ignored during processing.

3. MEASUREMENT PROCEDURES

Measurements were carried out in an anechoic chamber to ensure a controlled acoustic environment, free from unwanted reflections and external noise. This facility is located at the Signal Theory and Communications Department of the University Carlos III de Madrid. The chamber's interior dimensions of $6.5\,\mathrm{m} \times 4.5\,\mathrm{m} \times 3.85\,\mathrm{m}$, combined with $60\,\mathrm{cm}$-long absorbing wedges, effectively attenuate reflections across a wide frequency range.

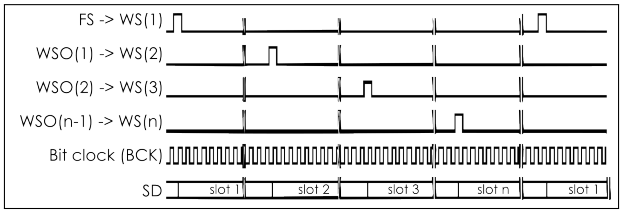

Figure 2. In the microphone datasheet, the terminology describes the Word Select (WS) and Word Select Output (WSO) as the propagation of the Frame Sync (FS) throughout the daisy-chain system. This pulse triggers the bit writing of each microphone to the Serial Data line (SD) at the Bit Clock rate (BCK), sequentially.

3.1 Frequency Response

The frequency response of both microphone arrays was evaluated following two distinct procedures, both using a domestic speaker as a sound source, specifically an Alexa Echo Pop, and generating a white noise signal.

In the first procedure, each microphone was assessed individually at a distance of $1\,\mathrm{m}$ from the sound source. The objective of this measure was to compare the magnitude of the frequency response of each microphone when positioned at the same location relative to the source. To achieve precise positioning, a cross-line laser was used to mark the exact spot on each microphone, always keeping the 1-meter distance throughout the procedure, as shown in Fig. 3. Measurements were conducted sequentially, displacing the arrays in a parallel plane to the source position, and ensuring that only the channel that corresponds to the microphone positioned at the spot is analyzed at a time.

We calculate the deviation in the frequency response of the i-th microphone using $\Delta H_i(f)$ as figure of merit, denoted as

$$\Delta H_i(f) = H_i(f)\ (\mathrm{dB}) - H_{\mathrm{av}}(f)\ (\mathrm{dB}), \qquad (1)$$

where $H_i(f)$ represents the magnitude of the i-th microphone in decibels, and $H_{\mathrm{av}}(f)$ is the reference value to compare, obtained as the average of all the frequency re-

sponses magnitudes across the array, also expressed in decibels.

To ensure the stability of the sound source throughout the measurements, a Brüel & Kjær Type 2250 Light Hand-Held Sound Frequency Analyzer was placed at a fixed reference point within the anechoic chamber (see Fig. 4). This device monitored continuously the level of the sound source to allow a source stability correction in the event of a slight change in the loudspeaker's power efficiency.

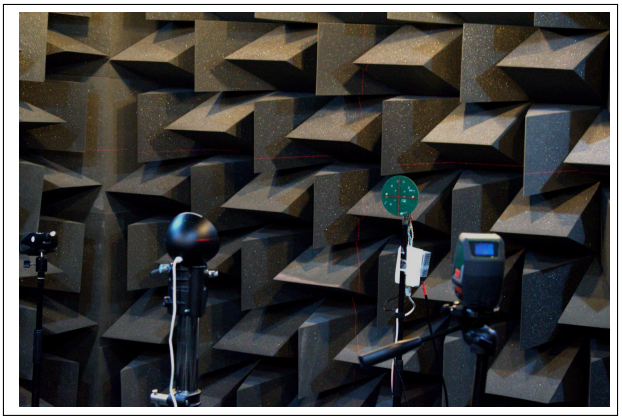

Figure 3. Cross-line laser positioning to maintain the measurement spot at 1 m from the sound source. In the picture, the laser aims at the central microphone of the concentric array.

In the second procedure, the microphone array was positioned at a greater distance of 2.5 m from the sound source. The purpose of this measurement was to assess the collective response of the array, assuming that at this distance, the sound waves would approximate a plane wavefront, meaning that all microphones would receive the signal with minimal differences in amplitude and frequency content due to source directivity. This measurement approach allowed for the characterization of the array's response under conditions where spatial variations in the sound field were minimized, avoiding an iterative relocation of the array. All the recorded signals from the microphones were compared to determine variations in frequency response across the array and to evaluate the consistency of microphone performance.

Figure 4. SGA positioned at one meter from the sound source. A sound frequency analyzer was placed at a fixed position to control the sound source's stability.

3.2 Directivity

The directivity of both microphone arrays was measured by rotating the array in 30-degree increments relative to the sound source in the horizontal plane. The sound-receiver distance was marked at 2.5 m. The frequency response at each angle was normalized by the response measured at 0 degrees (frontal incidence), representing the direction of maximum sensitivity [8]. Specifically, we define the directivity function $D(\phi, f)$, quantified in decibels, as

$$D(\phi, f) = H_{\text{av}}(\phi, f)\ (\text{dB}) - H_{\text{av}}(0^\circ, f)\ (\text{dB}), \qquad (2)$$

where $H_{\text{av}}(\phi, f)$ is the average of the frequency response magnitudes across all microphones at a specific rotational angle ϕ and frequency f, expressed in decibels. The term, $H_{\text{av}}(0^\circ, f)$, represents the reference response measured when the microphone cavities and PCB orifices directly face the sound source ($\phi = 0^\circ$), also in decibels.

3.3 Time-Division Multiplexing Synchronization

An additional experiment was conducted to validate the integrity of the TDM acquisition process and the phase response of the microphones, which consisted of placing the microphone array at a distance of 2.5 m from the sound source, emitting a low-frequency tone through the speaker. Thus, potential time delays between channels can be visualized by comparing the recorded signals across

the microphones. Since the TDM protocol transmits microphone signals sequentially, a key concern was whether the multiplexing process introduced any artifacts or synchronization errors by analyzing the phase alignment of the recorded signals.

4. RESULTS

4.1 Microphone Frequency Response

All presented spectral results were processed using one-third octave band filtering for a clearer comparison and interpretation.

As detailed in 3.1, the individual microphone response was captured at a time and compared to the average, as Equation (1) indicates. Figure 5 displays the range of values in which all the frequency responses are found, observed across the entire set of microphones, as well as selected examples from individual microphones of the CCA. For the SGA, the same experiment was performed for each of its 16 microphones, whose results are displayed in Figure 6.

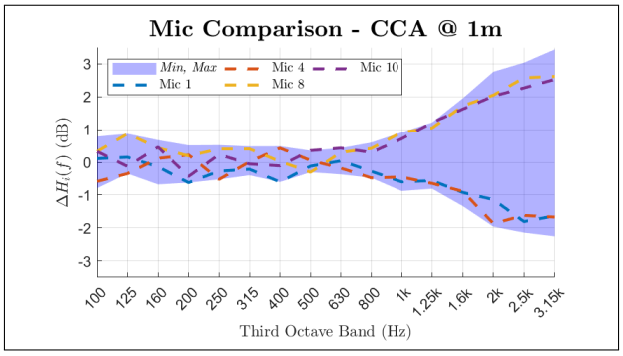

Figure 5. Comparison of the Frequency Response of microphones 1, 4, 8, and 10 of the CCA placed at 1 m from the source. The purple region corresponds to the minimum and maximum frequency response values.

Fig. 7 shows the frequency response evaluated following our second procedure. In this case, with the array positioned at 2.5 m from the source, all microphones were assessed simultaneously, under conditions approximating a plane wavefront. It is important to note that this second procedure was carried out as an alternative to the first one, aiming to reduce its associated uncertainty due to its iterative process which involves the array repositioning for each microphone, and that could be affected by small

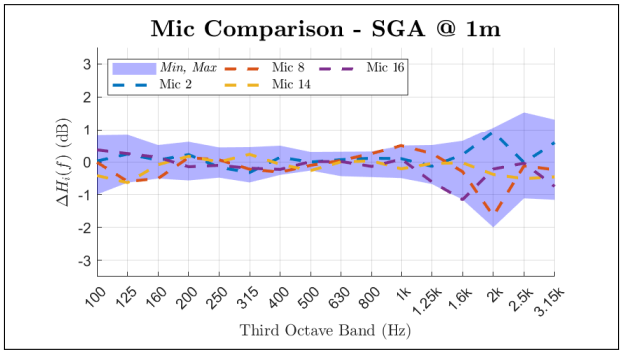

Figure 6. Comparison of the individual frequency response of microphones 2, 8, 14, and 16 of the SGA placed at 1 m from the source. The purple region corresponds to the minimum and maximum frequency response values.

changes in the source stability. For this reason, we only present here the results for the SGA.

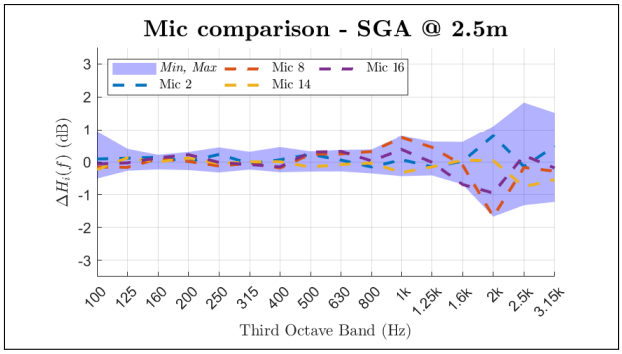

Figure 7. Comparison of the simultaneous frequency response of microphones 2, 8, 14, and 16 of the SGA placed at 2.5 m from the source. The purple region corresponds to the minimum and maximum frequency response values.

4.2 Directivity

The directivity measurement was carried out rotating both arrays in 30° increments over the horizontal axis, keeping a fixed 2.5 m distance to the sound source. The 0° orientation was used as the reference since it aligns with the main axis of sensitivity, as stated in (2). Figures 8 and 9 show the difference between the average response relative

to the reference direction and the rotation angle of ϕ for the CCA and SGA, respectively. Four selected frequency bands are also displayed to ease the visualization.

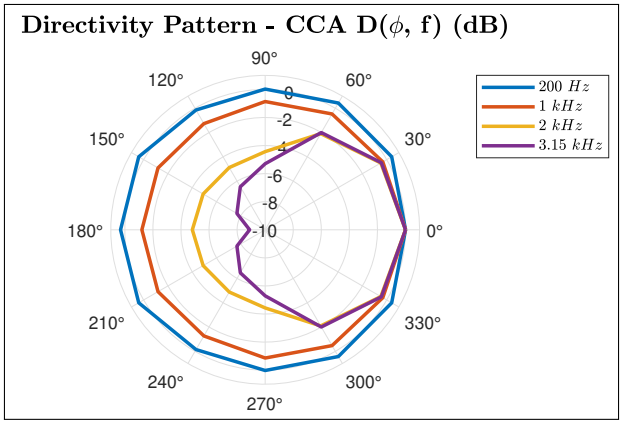

Figure 8. Directivity pattern of the frequency response of the CCA, measured at 2.5 m for the 1/3 octave bands of 200 Hz, 1 kHz, 2 kHz, and 3.15 kHz.

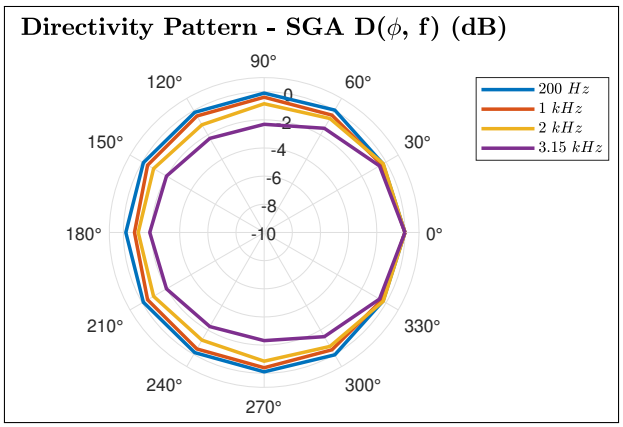

Figure 9. Directivity pattern of the frequency response of the SGA, measured at 2.5 m for the 1/3 octave bands of 200 Hz, 1 kHz, 2 kHz, and 3.15 kHz.

4.3 TDM Synchronization

The integrity of the TDM data acquisition system was examined using a low-frequency signal, which has to be at least higher than the anechoic chamber cut-off frequency, i.e., above 143 Hz. Two sinusoidal signals were tested at 200 Hz and 500 Hz, chosen for its relatively long period (5 ms and 2 ms respectively) compared to the sampling interval (125 µs at the 8 kHz sampling rate). Given that the SGA poses the worst-case scenario, with 16 audio channels and the longest data line traces, it was chosen for this test. The array was positioned at 2.5 m, minimizing the paths differences with respect to the wavelength. To quantify synchronization offsets $\Delta(\tau)$, the signal from each microphone channel was compared against the signal from microphone 1, which served as a stable reference for being the first channel in the TDM data stream. This comparison was performed using a cross-correlation calculated over sliding windows of 600 samples. The analysis was systematically swept along the entire signal length for all microphones. Fig. 10 presents the results of this analysis at 200 Hz, only plotting the calculated time delay evolution of the reference microphone and any detected to be off-sync. For the test using 500 Hz signal, no off-sync was detected.

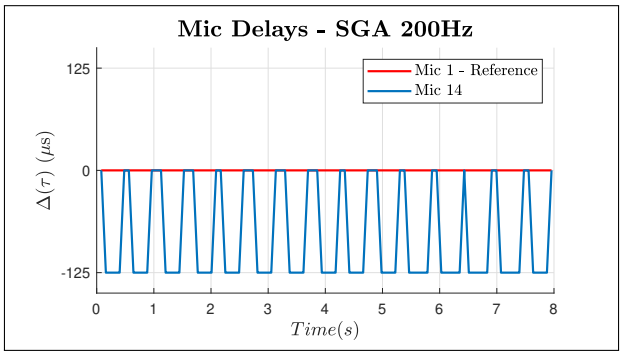

Figure 10. Delay pattern over time using a 200 Hz signal with SGA. Delays are shown in steps of 125 µs due to the sample frequency employed in this acquisition.

As can be seen, only channel 14 shows a fluctuation in synchronization, appearing to drift in and out of phase alignment with the reference channel. Fig. 11 provides a snapshot in the time domain, illustrating a moment when microphone 14's signal is visibly delayed compared to microphone 1, confirming the detected synchronization drift.

5. DISCUSSION AND CONCLUSIONS

This study presents an experimental evaluation of two microphone array prototypes (CCA and SGA), developed using identical MEMS sensor models and the same data transmission protocol to the same BeagleBone Black

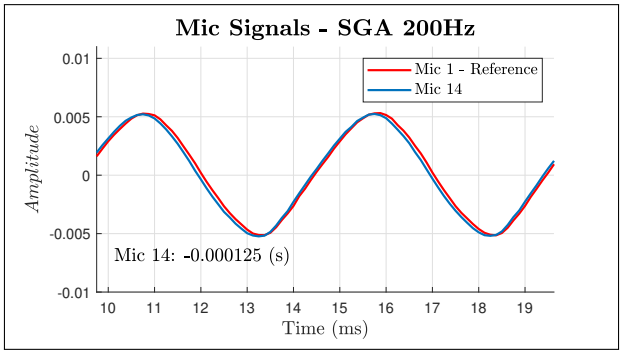

Figure 11. Snapshot in the time domain of waveforms from microphones 1 and 14 when desynchronized. Note that both are overlaid at the moment where the difference becomes most evident.

board, in order to ensure a fair and consistent comparison. The characterization experiments demonstrated the overall functional performance of both the CCA and SGA. Individual microphone frequency responses showed good consistency across both arrays, particularly within the stable 100 Hz to 1 kHz range. Minor deviations observed at higher frequencies are likely due to small positioning variations and inherent microphone differences, while the CCA's response above 1 kHz suggested additional scattering effects, possibly influenced by its solid central mounting board. This structural component may introduce diffraction or reflection that becomes more relevant as frequency increases.

Comparing the former procedure with measurements taken at 2.5 m with SGA, results show a similar behavior, with an even more uniform frequency response, especially when compared to sequential measurements taken at 1 m. Rather than thinking in different frequency responses depending on the distance, we consider that this difference could be caused by a reduced uncertainty in the procedure because of simultaneous measurements that avoids the reallocation of the array and prevent small fluctuations in the emitted sound power of the source. Nevertheless, small differences remained at higher frequencies, indicating that individual microphone characteristics still play a role even under more ideal conditions.

Directivity analysis allows concluding that SGA exhibits a sensitivity with lower dependency on the angle. This behavior seems related to the construction of the arrays (solid design for CCA vs grid structure for SGA). In fact, for the CCA, rotation in 30º increments revealed significant attenuation of high-frequency content when the array was turned around 180º from the source. These results underline the impact of array geometry, construction, and orientation, particularly in aeroacoustic environments where source directionality is a key factor.

The TDM synchronization test for SGA using a 200 Hz signal revealed detectable, periodic time delays for at least one channel relative to the reference. While these delays are bounded by the system's sampling step of 125 µs, their presence suggests that in applications requiring very precise phase alignment, such as beamforming or source localization, potential channel-specific compensation must be applied. That said, the overall results showed that the multiplexing process did not introduce significant artifacts, and most microphones remained well-aligned over time, especially those that are at the end of the stream (microphones 15 and 16), which could have been the most delayed. As a conclusion, a deeper study about the delay evaluation should be performed in order to conclude if this behavior is only related to the phase response of the microphone.

In summary, the experiments provide a solid baseline for understanding the operational characteristics of both arrays. While their overall behavior supports their use in typical aeroacoustic applications, special attention should be given to high-frequency variability, directional response, and synchronization fidelity when designing experiments that rely on fine spatial or temporal resolution.

ABSTRACT

The demand of metrological traceability to the International System of units (SI) for Micro-Electro-Mechanical Systems (MEMS) microphones poses new challenges for the development of reliable, fast, and cost-effective calibration methods. This work proposes novel solutions to meet these requirements, improving the capabilities of secondary calibration methods by pressure-comparison. Specifically, it addresses the effects of acoustic field irregularities and different frequency response of microphones under comparison in the determination of MEMS microphone sensitivity in the reverberation chamber. We present numerical techniques for predicting the sound pressure distribution within the narrow gap between reference and test microphones, along with the experimental evaluation of the deviation of calibration results when microphones of different frequency response characteristics are compared. The validity of the measurements in the reverberation chamber, is demonstrated comparing the calibration results obtained by different implementations of the pressure-comparison method, like in closed pressure-couplers and in the anechoic chamber.

1. INTRODUCTION

MEMS microphones are critical components in various acoustic applications, prized for their compact size, low power consumption, and cost-effective production [1, 2]. They are commonly used in consumer electronics and wireless sensor networks, playing a vital role in urban and natural soundscape analysis [3, 4]. Additionally, their small size makes them ideal for sound source localization in applications like seismic detection, traffic monitoring, and security systems.

Traditional calibration methods, like the pressure-comparison method, struggle to fully account for geometric differences between MEMS and reference microphones, leading to systematic errors, especially at high frequencies. These methods also fail to consider the complex acoustic interactions within pressure-couplers, affecting accuracy and repeatability. To overcome these issues, proper correction methods are essential to handle geometric discrepancies [5, 6].

This study integrates Finite Element Method (FEM) simulations with experimental implementations of the pressure-comparison technique for the calibration of MEMS microphones within a reverberation chamber. It addresses the challenges associated with the compensation of acoustic field irregularities between reference and test microphones using FEM, as well as the comparison of microphones exhibiting significantly divergent sensitivity responses across the frequency interval. The results obtained in the reverberation chamber demonstrate good consistency with those from other applications of the pressure-comparison method, including closed pressure-coupler and anechoic chamber set-ups.

2. PRESSURE-COMPARISON CALIBRATION OF MEMS MICROPHONES

The comparison method is crucial for calibrating non-conventional microphones, including miniaturized MEMS microphones, ensuring traceability to primary standards. It uses a reference microphone with known sensitivity, often determined by the reciprocity technique. For smaller microphones, especially MEMS, calibration under pressure-field conditions has the advantage to replicate real operating environments. Studies highlight the importance of using small-size Laboratory Standard (LS) microphones that can ensure the traceability of measurements.

2.1 Numerical simulation of sound field non-uniformities

FEM is widely used to solve complex acoustics problems, especially in cases where analytical solutions are impractical. It is particularly useful for modeling sound fields between microphones in scenarios involving intricate geometries, such as the small sensing areas of MEMS microphones. The acoustic pressure distribution p is governed by the Helmholtz equation:

$$\Delta p + k^2 p = 0 \tag{1}$$

where $k = \omega/c$ represents the wave number, ω is the angular frequency, and c is the speed of sound in air. FEM effectively handles boundary conditions, including rigid, vibrating with finite acoustic impedance, and sound source boundaries with known particle velocity distributions, which are crucial for simulating real-world microphone configurations.

Recent studies demonstrate the effectiveness of applying FEM with a lumped-parameter approach to model acoustic impedance boundaries [5, 6], simplifying a 3D problem to a 2D axisymmetric one. This approach aids in simulating MEMS microphones during pressure-comparison calibration, ensuring reproducible results. Numerical models have been proposed to correct sensitivity differences caused by acoustic pressure non-uniformity between reference and test microphones, which become more significant at high frequencies and as size dissimilarity of transducers gets more pronounced.

FEM results show the radial distribution of acoustic pressure, influenced by the impedance characteristics of microphones and boundaries, and are validated with experimental data. Fig. 1 illustrates the sound pressure distribution between a reference LS microphone and a MEMS test microphone under pressure-comparison at 6.3 kHz sine-type acoustic excitation, as obtained by FEM. The simulation mesh has a maximum element size of $\lambda/30$, being λ the sound wavelength, with 7214 elements covering an area of $12.12\,\mathrm{mm}^2$. The highest simulation frequency is $f_{max} = 30\,\mathrm{kHz}$.

2.2 Differences in microphones frequency response

The choice of the type of acoustic excitation and signals analysis for microphones calibration by the pressure-comparison method depends on the time efficiency of the measurement procedure, the type of acoustic environment, and the discrepancy of frequency responses of reference and test microphones' sensitivities. Broadband noise sources and third-octave bands analyses are advisable for fast calibrations, but if there are significant differences in microphones frequency responses, the use of sine-type signals and FFT analysis is recommended, especially for MEMS microphones calibration against LS reference microphones. In reverberation chambers, care should be taken in narrowing the bandwidth of the analysis with broadband noise sources, particularly as far as the degradation of the signal-to-noise ratio is concerned. Furthermore, long time-averaging of microphones signals and multi-position measurements should be performed to increase calibration accuracy.

3. REVERBERATION CHAMBER SET-UP

The pressure-comparison method for the calibration of MEMS microphones has been implemented inside the INRiM reverberation chamber of 294 m^3 volume, able to maintain the conditions of an acoustic diffuse field in the frequency range from 250 Hz to 12.5 kHz. The acoustic excitation is provided by two omnidirectional sound sources, placed at specific positions inside the chamber. The reference microphone was an LS2 type (LS microphone of 13.2 mm outer diameter, and 9.3 mm diaphragm diameter) HBK 4180, calibrated by the pressure reciprocity method at the centre frequencies of third-octave bands. The test microphone was an analog MEMS microphone on the evaluation board STMicroelectronics STEVAL-MKI139V5 fit into a custom cartridge that mimics the typical shape of LS2 microphones with a front recessed cavity. Reference and test microphones were coaxially aligned, facing each other with a very small separation gap lower than 2

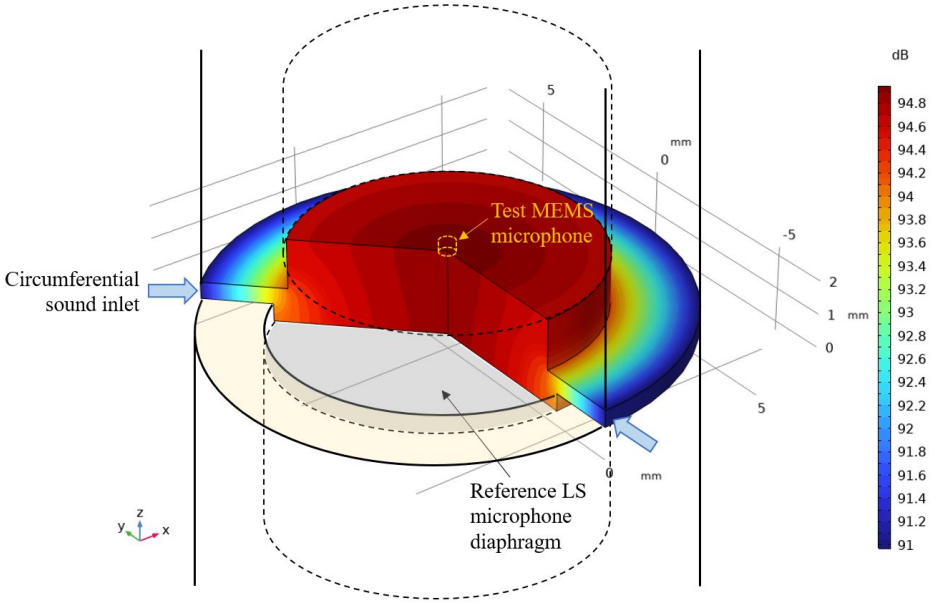

Figure 1. FEM simulation of the acoustic field for pressure-comparison calibration of a test MEMS microphone against an LS2 type reference microphone (LS microphone of 13.2 mm outer diameter, and 9.3 mm diaphragm diameter) with sine-type excitation at a frequency of 6.3 kHz.

mm. The coaxial alignment of the two microphones was realized along a direction non-parallel to any of the walls of the room as show in Fig. 2.

Signal acquisition and analysis were carried out using the ONO SOKKI DS-3200 data station, acting as a spectrum analyzer in third-octave bands. A 15-minute time-averaging was applied, with measurements repeated at various positions within the chamber to account for the diffuseness of the environment. A custom signal conditioner for the MEMS microphone, along with an HBK 2673 preamplifier for the reference microphone connected to the power and polarization module through a custom switch box, allowed applying the insert voltage technique to compensate for gain differences.

4. RESULTS

A broadband noise signal in the frequency range from 100 Hz to 16 kHz, properly amplified and equalized, was supplied to the sound sources to get a uniform sound pressure level (SPL) of about 80 dB over the third-octave bands from 250 Hz to 12.5 kHz. Because of the electro-acoustic characteristic of the sound sources, the SPL at the third-octave band of 16 kHz resulted of around 70 dB, still high enough with respect to the background noise, which was lower than 30 dB in the whole spectrum.

The frequency response of the sensitivity of the MEMS test microphone differs significantly from that of the LS2 reference microphone, as observed in previous calibrations by pressure-coupler and free field implementations of the pressure-comparison method. The dependence of calibration results on the bandwidth of the analysis was investigated by comparing the results obtained in the reverberation chamber with broadband noise stimuli analyzed in third-octave bands, with calibrations in pressure-coupler (active coupler) and free field (anechoic chamber) implementations using sine-type signals at the centre frequencies of third-octave bands. Fig. 3 shows the deviation of the calibration results due to the band-averaging in the reverberation chamber, calculated with respect to the average sensitivity curve of the MEMS microphone normalized to 1 kHz. Results are shown from 500 Hz to 16 kHz.

A marked deviation has been observed at frequency higher than 10 kHz, with a frequency response of about

Figure 2. Reference LS2 HBK 4180 microphone (right) faced to the test STEVAL-MKI139V5 MEMS microphone fit into the custom cartridge (left) for pressure-comparison calibration inside the reverberation chamber.

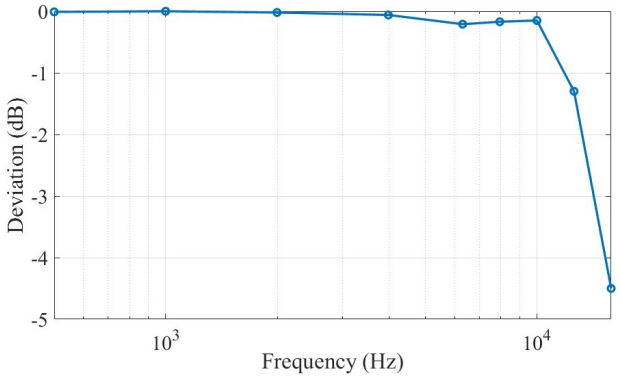

Figure 3. Deviation of pressure-comparison calibration results in the reverberation chamber with respect to the results obtained in pressure-coupler and free field implementations, due to third-octave band-averaging error.

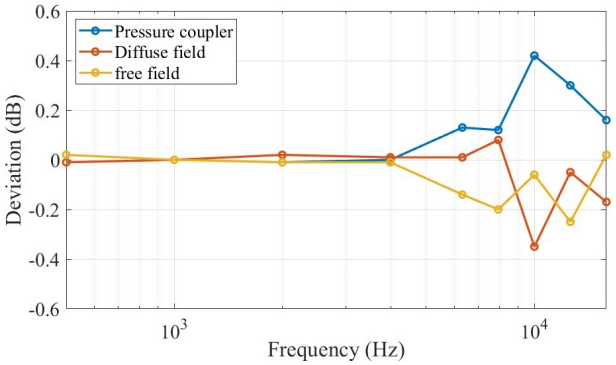

Figure 4. Deviation of pressure-comparison calibration results using sine-type signals in pressure-coupler, free field, and diffuse field implementations.

5 dB lower than those obtained with sine-type excitation. To evaluate the influence of the bandwidth of the analysis on the calibration results, sine-type signals have been used instead of broadband noise, along with the FFT analysis of microphones signals. Despite the possible onset of standing waves would be enhanced by such a tone excitation, the signal-to-noise ratio was higher compared to the case of a broadband noise source with bandwidth analysis narrower than third-octave. Fig. 4 shows the deviations from the mean sensitivity curve of the MEMS microphone normalized to 1 kHz, as obtained from pressure-comparison calibrations with sine-type signals in all acoustic environments: closed pressure-coupler (active coupler), free field (anechoic chamber), and diffuse field (reverberation chamber).

With sine-type signals excitation all calibration results were observed consistent within 0.5 dB. The increasing deviations above 4 kHz are likely due to the worse repeatability of measurements in the reverberation chamber, and to the uncertainty associated to the evaluation of the sound field corrections for the compensation of acoustic field non-uniformities between reference and test microphones.

5. CONCLUSION

This study presents a detailed analysis of pressure-comparison calibration of MEMS microphones

in a reverberation chamber. Although this approach can be time efficient, it is critical to account for significant differences in frequency response between reference and test microphones, which is common for MEMS microphones. In such cases, a trade-off between accuracy and time must be considered, as sine-type excitation provides more accurate results but requires longer measurements. However, sine-type signals can be affected by standing waves in the acoustic field. The results obtained in the reverberation chamber show good agreement with previous pressure-comparison calibrations performed in pressure-coupler and free field implementations. Improvements can be achieved by optimizing the numerical evaluation of sound field corrections and by implementing automatic positioning systems to improve the repeatability of the measurements.

ABSTRACT

Unattended noise monitoring systems can be used to track the sound level over an extensive amount of time and record whenever the level exceeds a threshold. Direction-of-Arrival (DoA) measured with a microphone array can add relevant information about the noise captured.
This paper investigates a prototype application employing novel directional flow-sensing Micro-Electro-Mechanical Systems (MEMS) microphones integrated into a highly compact array for DoA-detecting noise monitoring. Such sensors are supposed to exhibit a consistent directivity over the audible frequency range and to hereby enable frequency-independent DoA estimation for broadband noise sources. An array prototype is designed on an energy efficient micro controller unit (MCU) that runs three different DoA-estimation methods under test.
The resulting prototype uses one omnidirectional and three directional, flow-sensing MEMS microphones. Measurements confirm that a high spatial aliasing limit could be reached without sacrificing low-frequency directivity. Our field study validates applicability to DoA-detecting noise monitoring at cheap computational costs.

1. INTRODUCTION

Compliance with noise regulations typically requires monitoring acoustic emissions from specific sources and the comparison to legal limits [1]. In unattended noise monitoring systems, the sound level is tracked over a long period of time. When the level surpasses a threshold, the system activates an alarm, requiring a human operator to restore order manually. This is time-consuming, especially if the object to monitor is near roads, railways and airports. Using Artificial Intelligence (AI) for unattended noise monitoring systems allows for the automatic classification of triggering events and potential exclusion from the overall measurement [2, 3]. Deep learning methods are remarkably successful in Sound-Event-Detection (SED). However, the current leading models still encounter errors, especially when having to distinguish between different types of vehicles [4] or distinct soundscapes [5]. However, there is more information than what can be contained in single-channel sound. For instance, Direction-of-Arrival (DoA) offers useful additional information. In particular, DoA allows to limit the solid angle/field of view, within which noise shall be monitored. Current methods in DoA estimation for noise monitoring applications investigate arrays incorporating mainly omnidirectional MEMS microphones. The “Noise Compass” [6] is an array that includes eight omnidirectional MEMS microphones and computes the DoA of the dominant noise source using a Time-Difference-of-Arrival method. Another work proposes the design of a 3D sound intensity probe using eight MEMS pressure microphones on the vertices of a 2cm × 2cm cube [7].
This work investigates the performance of novel directional, flow-sensing MEMS microphones [8, 9] that sense acoustic particle velocity. An orthogonal arrangement of velocity microphones combined with an omnidirectional pressure microphone enables the computation of the three-dimensional pseudo-intensity vector, which indicates the direction of sound propagation and, accordingly, the direction of the sound source emitting the sound field. We derive and compare three DoA-estimation methods applicable to the proposed array geometry, which are implemented on a low-power ARM microcontroller. Additionally, the results of directivity measurements used

to verify the figure-of-eight polar pattern of the velocity microphones are discussed. Finally, we present two case studies to demonstrate the array's performance in the field. The proposed array prototype is suitable for noise DoA-estimation applications and produces good results with minimal signal processing. Drawbacks such as the influence of wind on the velocity microphones should be discussed and addressed.

2. SIGNAL MODEL

We assume an acoustic signal $s(t)$ emitted by a sound source that lies at some distance along the unit DoA vector

$$\boldsymbol{u} = \begin{pmatrix} \cos(\varphi)\cos(\vartheta) \\ \sin(\varphi)\cos(\vartheta) \\ \sin(\vartheta) \end{pmatrix}, \tag{1}$$

where $\varphi \in [0, 2\pi[$ is the azimuth angle and $\vartheta \in [-\frac{\pi}{2}, \frac{\pi}{2}]$ is the elevation angle of the source. For our array with 4 microphones located at the center of a coordinate system, let there be K sources at the directions $\boldsymbol{u}_k$ with the signals $s_k(t)$, and an $\mathbb{R}^{4\times 1}$ signal vector recorded by the array

$$\boldsymbol{x}(t) = \sum_{k=1}^{K} s_k(t)\, \boldsymbol{y}(\boldsymbol{u}_k) + \boldsymbol{v}(t). \tag{2}$$

Here, $\boldsymbol{y}(\boldsymbol{u}) \in \mathbb{R}^{4\times 1}$ is the array manifold vector for a continuous direction $\boldsymbol{u}$, and $\boldsymbol{v}(n) \in \mathbb{R}^{4\times 1}$ is a vector that contains the additive zero-mean self noise of each microphone.
Similar to [10], we assume the following conditions:

A) Incident waves are local plane waves at the array, implying (i) far-field conditions characterized by array-to-source distances much greater than a wavelength, and (ii) array dimensions much smaller than a wavelength to avoid both diffraction and time differences of arrival.
B) Band limitation: The signal is bandlimited accordingly, $\omega_{\min} < \omega < \omega_{\max}$, such that both conditions are fulfilled.

The microphone array in this work follows a WXYZ (B-format) layout with three orthogonal velocity microphones and one omnidirectional pressure microphone. The resulting array manifold vector $\boldsymbol{y}(\boldsymbol{u}) \in \mathbb{R}^{4\times 1}$ is defined as

$$\boldsymbol{y}(\boldsymbol{u}) = \begin{pmatrix} 1 \\ \boldsymbol{u}\sqrt{3} \end{pmatrix}. \tag{3}$$

We further assume consistent microphone directivity within the frequency range of interest, which is why $\boldsymbol{y}(\boldsymbol{u})$ is assumed to be frequency-independent.

3. FLOW-SENSING MEMS MICROPHONE

The Soundskrit directional MEMS microphone is the result of a collaboration between researcher Ronald N. Miles, who has extensively studied sound velocity sensing [11–13], and Stephane Leahy from Soundskrit, who designed a new transducer based on capacitive sensing [8]. The sensing element consists of multiple porous plates, fixed beams, and cantilevers, creating a highly flexible membrane designed to enhance the influence of air viscosity on its movement due to its material properties. Two port holes on the front and back of the microphone allow sound to flow through the sensing element. In our array prototype as seen in Fig. 1, we incorporate three of Soundskrit's SKR0410 first-generation digital MEMS microphones in an orthogonal alignment. An omnidirectional microphone by Infineon is brought into the center of the array using a Flex PCB. The coupon board PCBs of the velocity microphones are attached to a hollow 3D-printed housing. The distance between the orthogonal microphone and the three velocity microphones is $d = 6.5$ mm, resulting in a maximum microphone distance of $d_{\max} = \sqrt{2}\, d = 9.2$ mm and consequently a minimum aliasing frequency at $\frac{c}{2d_{\max}} = 18657$ Hz where $c = 343$ m/s is the speed of sound.

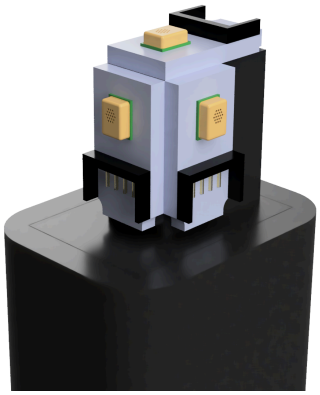

Figure 1: The array prototype. The MEMS velocity microphones are mounted on the white PCB coupon boards. The omnidirectional MEMS microphone is located in the center of the array. The largest distance between any two microphones is 9 mm.

3.1. Directivity measurements of the microphones

The polar pattern of the MEMS velocity microphones is specified as a figure-of-eight (Fo8) and has been verified through directivity measurements. These measurements utilize an array of loudspeakers mounted on a circular frame with radius $r = 1.5\text{m}$ facing the circle's center point where the microphone array specimen is located, as seen in Fig. 2. The array is mounted on a stand on a turntable that rotates the array along the vertical axis in 10° azimuthal steps, resulting in an angular resolution of $\Delta\varphi = 10°$. The elevation resolution is given by the spacing of the loudspeakers, which is $\Delta\vartheta = 11.25°$.

Overlapping exponential sweeps were employed as the measurement signal [14]. The loudspeaker's individual frequency response is equalized by measurements recorded with an *Earthworks* measurement microphone. Spherical surface plots are generated with a MATLAB tool[1] that interpolates the 10° × 11.25° sample grid using 14th-order spherical harmonics and performs far-field extrapolation in the spherical harmonics domain.

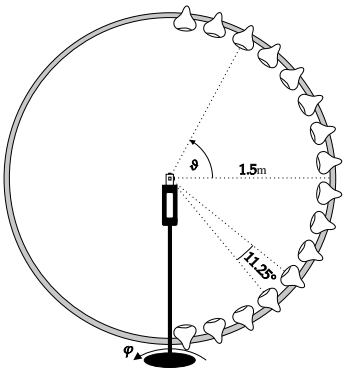
We observed a consistent phase difference of approximately 60° between the omnidirectional MEMS and the Fo8 microphones. This difference must be accounted for to prevent a sign flip of the pseudo-intensity vector. Therefore, the Fo8 microphones are equalized to the frequency response of the omnidirectional microphone.

Furthermore, the orthogonal MEMS microphones exhibit an orientation misalignment, especially the X- and Z microphones (as depicted in Fig. 3). Fortunately, this misalignment can be easily corrected through a change of basis transformation

$$\hat{\boldsymbol{u}}' = \boldsymbol{D}\left(\tilde{\boldsymbol{D}}^{\mathrm{T}}\right)^{-1}\hat{\boldsymbol{u}}. \tag{4}$$

This transformation projects the estimated DoA vector onto the inverse of a matrix containing the actual alignment of the microphones, transforming the vector to lie within the orthonormal Cartesian basis. Here, $\boldsymbol{D} = \boldsymbol{I}$ denotes the Cartesian basis which is an identity matrix and $\tilde{\boldsymbol{D}}$ contains the actual alignment of the Fo8 microphones determined by the measurement.

The measured polar pattern of a cardioid beam steered to $\varphi = 90°$ is shown in Fig. 4 a). In this depiction, the magnitude is normalized for each frequency bin as the MEMS microphones are less sensitive at lower frequencies but that sensitive was also not considered in the simulation. However, the directionality and consequently the beampattern is maintained even for lower frequencies. We do observe inconsistencies in the beampattern with frequencies starting at 4000 Hz which could be attributed to temporal measurement errors or acoustic turbulences within the case. The simulated energy response of a cardioid beamformer steered to $\varphi_s = 90°$ and $\vartheta_s = 0°$ is depicted in Fig. 4 b). Initial interference patterns can be observed at $\frac{c}{4d} = 13192$ Hz. Below that frequency, the beamformer consistently favours the steering direction without spatial aliasing.



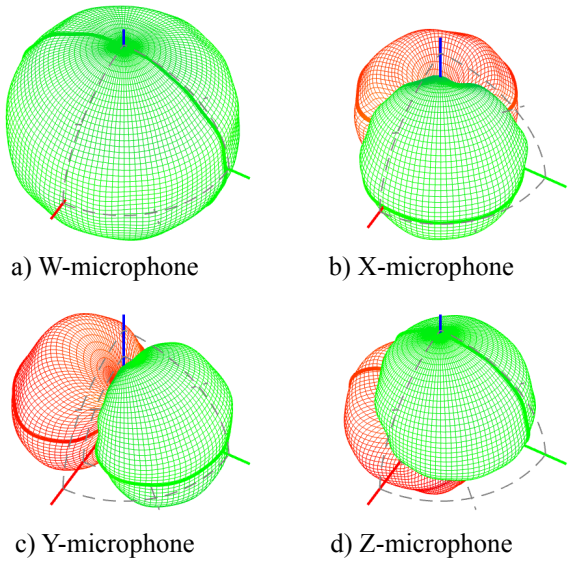


Figure 2: The measurement setup. 16 loudspeakers with a spacing of 11.25°, mounted on a circular frame with radius $r = 1.5\text{m}$, face the microphone array.

Figure 3: Directivity for the W, X, Y, and Z microphone measured at a frequency of 500 Hz. The colors indicate the phase response of the micorphones.

a) Measured polar pattern.

b) Simulated array response.

Figure 4: A cardioid beam (linear combination of the omni- and Fo8 microphones) is steered to a direction of $\varphi = 90°$ and $\vartheta = 0°$. In the measurement in a), the magnitude is normalized per frequency. In reality, the MEMS microphones are less sensitive in the lower frequency range but that sensitivity was also not considered in the simulation depicted in b) which is performed by placing sound sources around the array and evaluating Green's function for planar waves that depends on the distance between the source and receiver.

4. DOA ESTIMATION METHODS

In this section we present three DoA-estimation methods. We extend a simple beamforming approach with a seasoned, well-established subspace algorithm applicable for any kind of array-geometry, followed by a pseudo-intensity method that makes use of the sampling of the sound pressure and velocity vector.

4.1. Steered Response Power (SRP)

The Steered Response Power (SRP) method is fundamentally based on beamforming, utilizing the array response vector $\boldsymbol{y}(\boldsymbol{u})$ as defined in Eqn. (3) and an estimation of the covariance matrix

$$\boldsymbol{C}_{\mathrm{xx}} = \boldsymbol{X}^{\mathrm{T}}\boldsymbol{X} \tag{5}$$

of a N-sample signal block $\boldsymbol{X} \in \mathbb{R}^{N\times M}$. For a set of $\mathcal{G}$ discrete points on the surface of a unit-sphere, sampled using a Fibonacci lattice, we compute

$$P(\boldsymbol{u}) = \boldsymbol{y}^{\mathrm{T}}(\boldsymbol{u})\,\boldsymbol{C}_{\mathrm{xx}}\,\boldsymbol{y}(\boldsymbol{u}). \tag{6}$$

The point that maximizes this power is the estimated direction of arrival

$$\hat{\boldsymbol{u}} = \underset{\boldsymbol{u}\in\mathcal{G}}{\operatorname{argmax}}\, P(\boldsymbol{u}). \tag{7}$$

4.2. Multiple Signal Classification (MUSIC)

Introduced in 1986 [15], MUSIC is a renowned subspace method and extends the aforementioned beamforming technique. It relies on the eigen-decomposition of the covariance matrix $\boldsymbol{C}_{\mathrm{xx}}$ and successive separation of the eigenvectors into a signal- and noise subspace. The signal model claims that the wavefronts received at the M microphones are a linear combination of D incident wavefronts and noise. After the eigendecomposition of the covariance matrix of the signal vector $\boldsymbol{x}$, the D largest eigenvalues and their corresponding eigenvectors span the signal subspace, whereas the eigenvectors corresponding to the $M - D$ smallest, clustered eigenvalues span the noise subspace $\boldsymbol{E}_{\mathrm{n}}$. A pseudo spectrum $\hat{P}_{\mathrm{MU}}(\boldsymbol{u})$ is introduced, which computes to the squared norm of the projection of $\boldsymbol{y}(\boldsymbol{u})$ onto the noise subspace. The direction that maximizes the pseudo spectrum

$$\hat{P}_{\mathrm{MU}}(\boldsymbol{u}) = \frac{1}{\left\|\boldsymbol{E}_{\mathrm{n}}^{\mathrm{T}}\,\boldsymbol{y}(\boldsymbol{u})\right\|^2} \tag{8}$$

is the predicted direction of arrival $\hat{\boldsymbol{u}}$

$$\hat{\boldsymbol{u}} = \underset{\boldsymbol{u}\in\mathcal{G}}{\operatorname{argmax}}\, \hat{P}_{\mathrm{MU}}(\boldsymbol{u}). \tag{9}$$

4.3. Active Intensity Measurement (AIM)

Euler's equation relates the acoustic pressure p to the sound velocity vector $\boldsymbol{v}$

$$-\nabla p = \rho_0 \frac{\partial \boldsymbol{v}}{\partial t} \tag{10}$$

where $\rho_0 \approx 1.2 \frac{\text{kg}}{\text{m}^3}$ is the atmospheric density. For sufficiently far away sources, i.e. plane-wave conditions, the ∇-operator is equal to $\partial(\boldsymbol{u}_\text{s}/c)/\partial t$ and Eqn. (10) becomes

$$\boldsymbol{v} = -\frac{\boldsymbol{u}\, p}{\rho_0 c}. \tag{11}$$

As the B-format signals of a first-order ambisonics microphone are $W = p$ and $[X, Y, Z]^\text{T} = -\rho_o c \sqrt{2}\, \boldsymbol{v}$, the predicted direction by AIM is

$$\begin{aligned} \hat{\boldsymbol{u}} &= -\frac{\rho_0 c\, \boldsymbol{I}}{|p|^2} = -\frac{\rho_0 c\, p \boldsymbol{v}}{|p|^2} = \frac{\rho_0 c\ |p|^2\ \boldsymbol{u}}{\rho_0 c\ |p|^2} = \boldsymbol{u} \\ &= \frac{W\,[X, Y, Z]^\text{T}}{\sqrt{2}\ |W|^2} \end{aligned} \tag{12}$$

and the estimator averaging over one block of samples is

$$\hat{\boldsymbol{u}} = \frac{\mathbb{E}(W[X, Y, Z]^T)}{\sqrt{2}\mathbb{E}(W^2)}. \tag{13}$$

5. HARDWARE IMPLEMENTATION

The microphone array is powered by a *STM32U5A9NJ* ARM microcontroller which also runs the DoA-estimation algorithms and performs 1/1 octave band filtering for eight octave bands with center frequencies from 31.5 Hz - 4000 Hz. The built-in interleaved sampling mode of the Multi-Function-Digital-Filter (MDF) of the ST guarantees precise sampling of the four microphone channels. After acquiring a block of $N = 2048$ samples, that block is filtered eight times by 4$^\text{th}$ order IIR butterworth bandpass filters following the ANSI S1.11-2004 specifications [16], effectively whitening the signal in its respective band. A separate recording mode allows for the transmission of the recordings to a host computer for postprocessing and the results shown in Sec. 6 were obtained by offline analysis of the recordings.

5.1. Computational effort of the algorithms on the chip

The *STM32U5A9NJ* MCU contains a single-core *Cortex-M33* ARM processor operating at a system clock frequency of up to 160 MHz. We benchmarked the algorithms by executing a Monte Carlo simulation comprising 1000 trials and selecting the median number of clock cycles required for the algorithm to finish. We set an external timer to the same system clock rate $f_\text{CLK} = 160$ MHz. Computational improvements could be made using the CMSIS DSP library[2] tailored towards the specific CPU architecture of the *Cortex-M33*.

[2]https://arm-software.github.io/CMSIS_5/DSP/html/index.html

Table 1: Computational effort of the three algorithms for different sample sizes N. The numbers below the algorithm's names denote the number of clock cycles required for the algorithm to finish.

N	SRP	MUSIC	AIM
512	739 384	1 948 476	35 779
1024	808 535	2 039 794	71 133
2048	946 834	2 192 544	141 815

For an efficient processing of the MUSIC algorithm, the property of the covariance matrix $\boldsymbol{C}_\text{xx}$ as real-valued and positive semi-definite was exploited to efficiently use a real-valued Schur decomposition for eigendecomposition $\boldsymbol{C}_\text{xx} = \boldsymbol{E}\,\text{diag}(\boldsymbol{s})\,\boldsymbol{E}^\text{T}$, where $\boldsymbol{E}$ contains all eigenvectors and $\text{diag}(\boldsymbol{s})$ the eigenvalues. The noise subspace $\boldsymbol{E}_\text{n}$ corresponds to the 3 smallest eigenvalues with the signal subspace set to $D = 1$. The number of points for SRP and MUSIC is set to $\mathcal{G} = 1650$ to achieve an angular resolution of approximately $\Delta\boldsymbol{u} = \sqrt{\frac{4\pi}{1650}} \frac{180}{\pi} = 5°$.
Tab. 1 shows the measured clock cycles for different block lengths N. AIM is faster than both MUSIC and SRP, mainly because of their expensive grid search over $\mathcal{G}$ directions. Complexity roughly scales with $\mathcal{O}(N)$ for AIM, in contrast to $\mathcal{O}(N) + \mathcal{O}(\mathcal{G})$ for SRP and MUSIC. The computation of the SRP power spectrum is cheaper than Schur decomposition.

6. CASE STUDIES

Case studies on the array performance in real-world scenarios were carried out, of which two are presented in the following sections. The first scenario demonstrates the array performance on a low-frequency sound source. The second study investigates the influence of wind, which is particularly evident in recordings of the flow-sensing microphones. Direction estimates are performed individually for eight 1/1 octave bands with center frequencies ranging from 31.5 Hz to 4 kHz and additionally for the A-weighted recording. The system's sampling rate is set to 16 kHz. The number of discrete unit vectors $\mathcal{G}$ for SRP and MUSIC is 1650, resulting in an angular resolution of approximately 5°. The number of signals in MUSIC is assumed to be $D = 1$. The individual 5-minute recordings are buffered into blocks of $N = 2048$ samples, each block yielding a direction estimate for segments where a noise source is present with certainty. Given that the true direction of the sound source is unknown, we can only analyse the scattering of direction estimates. For this purpose, we

analyse boxplots containing samples of the angle between an estimate $\hat{\boldsymbol{u}}$ and the mean direction $\boldsymbol{\mu}_{\mathrm{A}}$ of the A-weighted filter bank, i.e. $\arccos(\boldsymbol{u}^{\mathrm{T}}\boldsymbol{\mu}_{\mathrm{A}})$. The boxes in the boxplots shown extend from the first to the third quartile with a line at the median. The whiskers extend from the box to the farthest data point, lying within 1.5 times the interquartile range. Fliers are shown as grey circles. Additionally, histograms counting direction samples estimated by AIM are presented.

6.1. Low-frequency screed silo pump

The first study was conducted next to a construction site during the operation of a silo pump. Free-field conditions could not be fulfilled as the recording area was surrounded by residential houses, as can be seen in Fig. 5. Nevertheless, this example should demonstrate the direction estimation capabilities of the miniature array for low-frequency sources. As can be seen in the spectrogram segment shown in Fig. 6, the silo pump emits a particularly dominant tone at 50 Hz and additional harmonic overtones. For conventional, small-aperture microphone arrays, the accurate detection of a noise source in this frequency range should pose a great challenge. However, as evident in the boxplots presented in Fig. 7, the direction estimates exhibit minimal deviation from the mean direction $\boldsymbol{\mu}_{\mathrm{A}}$ in the 31.5- and 63 Hz frequency bands. Notably, in the 31.5 Hz band, a remarkably precise direction estimate of AIM's histogram for a single frame is discernible in Fig. 8. Comparing the algorithm's performance in this scenario, we can note that SRP, AIM, and MUSIC yield similar estimation outcomes. However, AIM does show greater scattering of its direction estimates in the frequency bands from 250 Hz to 4000 Hz.

Figure 5: In the first scenario, a silo pump next to a construction site in a residential area was recorded.

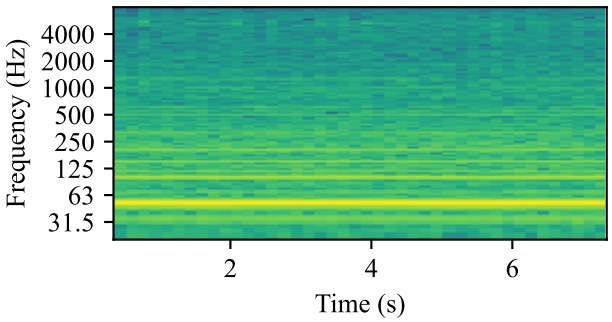

Figure 6: Spectrogram of the pump recording in a segment where an especially dominant low-frequency tone at 50 Hz is present.

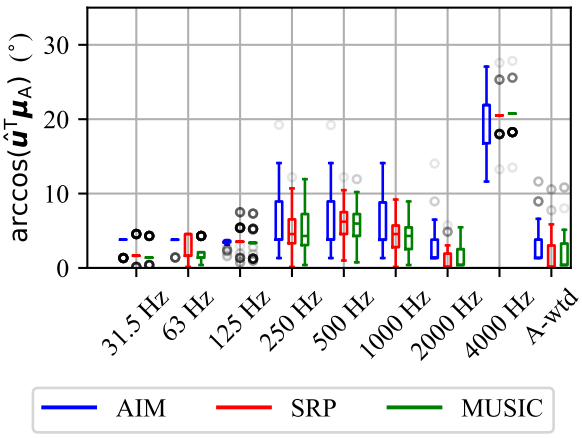

Figure 7: Angle between the direction estimates $\hat{\boldsymbol{u}}$ and the mean direction of the A-weighted filter $\boldsymbol{\mu}_A$ for the silo pump recording.

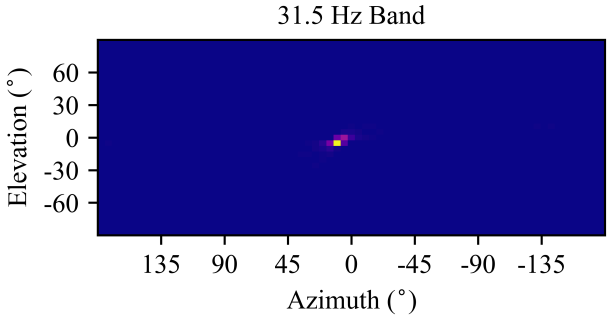

Figure 8: A histogram counting direction estimates for a single block of the silo recording. Computed by AIM, evaluated for the 31.5 Hz octave band.

Such behaviour could be attributed to the reflective recording scenario and, consequently, additive wavefronts from mirror sources, causing more deviations in the per-sample estimates of the pseudo intensity vector. Notably, in the 4000 Hz band, an angular discrepancy of 20° is evident. Further examination of this band revealed that the elevation of the estimation is 20° higher than for $\boldsymbol{\mu}_{\mathrm{A}}$ but with similar azimuth. It is possible that a more prominent noise source, perhaps originating from another point on the silo itself, is present at higher elevations.

6.2. Parked airplane in the presence of wind gusts

For the second study, the array was mounted on a terrace of an airport facing the runway, as shown in Fig. 9. We want to demonstrate the array's performance in non-ideal weather conditions, such as in the presence of wind gusts that interfere with the recording. Occasional wind gusts can be seen in Fig. 10 where they occupy the frequency range of 20 Hz to 100 Hz. We observed that recordings captured by the Fo8, flow-sensing microphones were significantly more influenced by wind compared to recordings captured by the omnidirectional pressure microphone. Evidently, as wind gusts distort the recording, they will deteriorate the performance of the direction estimation. A greater scattering of direction estimates can be seen in Fig. 11, vastly influencing the performance of all algorithms in the 31.5 Hz and 63 Hz band. Turbulent - but optically quite artistic estimations of the direction of the pseudo intensity vector can be appreciated in Fig. 12. This picture further emphasizes the impact of wind at lower frequencies. However, with increasing center frequency, the performance improves for all algorithms. In comparison to the scenario in Sec. 6.1, their prediction performance seems to be even more similar.

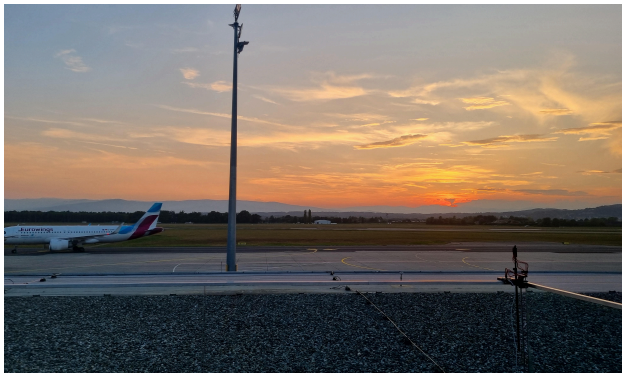

Figure 9: The second recording scenario was conducted at an airport and the sound source was the parked airplane seen on the left.

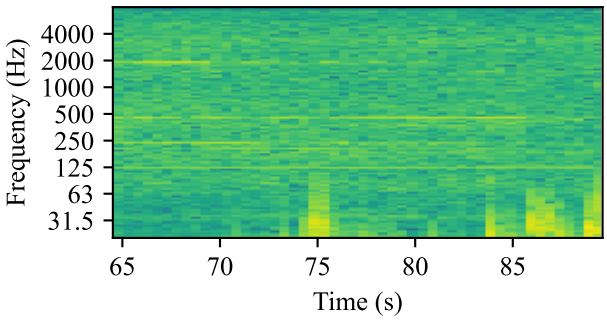

Figure 10: Spectrogram of the airplane source. Occasional wind gusts can be seen occupying the frequency range from 20 Hz to 100 Hz.

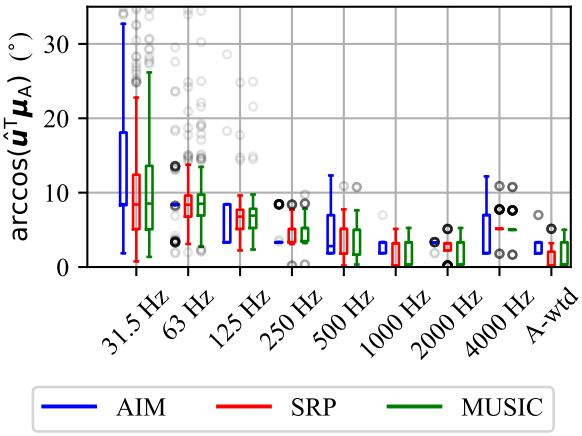

Figure 11: Angle between the direction estimates $\hat{\boldsymbol{u}}$ and the mean direction of the A-weighted filter $\boldsymbol{\mu}_A$ for the airport recording.

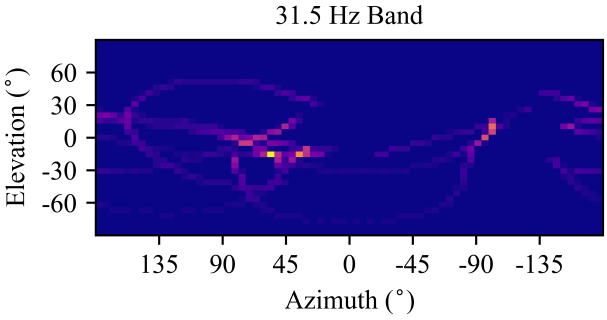

Figure 12: A histogram counting direction estimates computed by the AIM algorithm. Evaluated for the 31.5 Hz octave band for the airplane source.

7. CONCLUSION

We presented a miniature microphone array comprising directional, velocity-sensing MEMS microphones suitable for broadband noise source direction estimation. We verified the individual microphone and array directivities over a broad frequency range, and showed that the small sensor spacing provides a high spatial aliasing frequency limit. For the array prototype, three direction-of-arrival detection algorithms were implemented on an energy-efficient MCU. It was shown that the computational load varied depending on the complexity of the underlying algorithm. Field studies further verified the applicability of the microphone array in real-world scenarios, demonstrating comparable estimation performance for the different algorithms, but also highlighting the influence of wind, primarily on the velocity microphones. Consequently, users should consider their windscreen solution when incorporating flow-sensing microphones. Compared to conventional microphone arrays using non-coincident, omnidirectional sensors, the microphones in this configuration can be brought together as closely as possible without sacrificing low-frequency directivity performance. This not only reduces spatial aliasing but also enables the design of a very small microphone array module, that could potentially be installed directly in a class-1 measurement microphone e.g. with a 1/2″ capsule form factor.

ABSTRACT

For cochlear implant (CI) listeners, speech comprehension relies on sensitivity to amplitude modulation (AM) cues across different electrode channels. For a given channel, envelope sensitivity may be impaired for many reasons, not least due to the spread of electrical current and/or neural degeneration.

We used a psychoacoustic task to explore AM discrimination in adult CI listeners (n=12). Listeners discriminated a 40 Hz sinusoidally amplitude-modulated (SAM) pure tone from a 13 Hz SAM tone in a three-interval task, where the modulation depth was varied adaptively. Testing was conducted in the presence or absence of speech envelope modulated interferer tones targeting neighboring electrode channels (± adjacent+1). Stimuli were delivered through headphones, all front-end noise reduction features were de-activated on the speech processor, and the level of each interval was roved (3 dB). By varying carrier frequencies, we measured AM thresholds across a range of targeted electrodes.

AM discrimination was poorer in the presence of interferers, and poorer at higher carrier frequencies. CI performance is also compared to normal hearing cohort (n=12): Although performance was more variable across CI listeners, both groups achieved comparable mean thresholds. Individual thresholds will be correlated with panoramic ECAPs and measures of speech in noise performance.

1. INTRODUCTION

Cochlear implants (CIs) most commonly function by filtering the acoustic signal into a limited number of frequency channels. The amplitude modulation (AM) envelope within each channel is extracted, and used to modulate a fixed-rate electrical pulse train delivered by a corresponding intra-cochlear electrode. For the perceived sound to correspond meaningfully with the external source, the listener must detect, track, and discriminate temporal envelope cues, both within and across channels. Many factors may limit the transmission of AM cues to a CI listener, but those most pertinent to this research concern the spread of electrical current within the cochlear, and the extent of neuronal survival of the auditory nerve at the corresponding frequency region. Any measure which could estimate these factors on an individual basis would likely prove helpful in guiding implant fitting [e.g., 1, 2, 3].

To this end, we are currently testing and comparing a range of measures to characterize information transmission and selectivity at different electrode sites within the cochlear. These measures include evoked responses to changes in AM rate [4], panoramic ECAP recordings [3], behavioral measures of stream segregation, and behavioral measures of AM discrimination [5]. A overview of the latter measure is presented here, alongside data from two experimental conditions.

2. METHOD

2.1 Listeners

Twelve CI listeners who used Cochlear® devices took part. During the experiment, listeners used their everyday map, but with any noise reduction and automatic scene classification (SCAN) features disabled via clinical software. Twelve normal hearing (NH) listeners also took part and were presented with the default stimuli described below.

2.2 Stimuli

The test signal typically comprised an acoustic tone, of a frequency corresponding to the centre frequency (CF) of electrode 16. This was 1000 Hz for those with maps comprising default electrode-frequency allocations. Listeners discriminated a 'target' test signal from two 'reference' signals. The target rate of sinusoidal AM (SAM) was 40 Hz, and the reference rate of SAM was 13 Hz.

When present, two interferers were presented with frequencies corresponding to the CFs of electrodes 17 and 15 (875 Hz and 1125 Hz by default). Each interferer was modulated with an envelope extracted from an independent sample of speech [6], lowpass filtered at 50 Hz.

Stimuli were presented via an RME Fireface UCX soundcard (Haimhausen, Germany) and Sennheiser HD-600 headphones (Hannover, Germany). Each stimulus component was presented at a random level between 62-65 dB SPL, as calibrated using a Tektronix MDO3024 oscilloscope (Beaverton, OR, USA).

2.3 Method

In a 3I-3AFC adaptive procedure; listeners discriminated a target test signal from two reference signals. There was a 500 ms silence between intervals, and visual feedback was provided.

The experiment used a two-down, one-up adaptive procedure to estimate the 71% correct point on the psychometric function [7]. The depth of SAM applied to the test signal was varied, starting at 80% (i.e., where 100% corresponds to full modulation). The step size was a factor of 1.7 for the first two reversals, reduced to 1.4 for another two reversals, and finally held at 1.15 for four reversals. The geometric mean of the final four reversals is taken as the threshold estimate.

Interferer modulation depth began at 10%, but *increased* when test signal modulation *decreased*, and vice versa. At each step change, interferer modulation depth was scaled by the same factor as that for the test signal.

Listeners completed two runs of each of experimental conditions, and their final threshold estimate was taken as the geometric mean of the estimates derived both each run.

3. RESULTS AND DISCUSSION

Mean thresholds for both CI and NH groups are plotted in Figure 1. Performance was broadly similar across the two groups – both were able to discriminate modulation rates at relatively shallow modulation depths in the absence of interferers, but the presence of interferers markedly impaired performance. A mixed-design ANOVA confirmed a significant effect of interferers [$F(1,22)=161.55$, $p<0.001$, $\eta_p^2=0.88$], but not of group [CI vs. NH, $F(1,22)=2.21$, $p=0.15$, $\eta_p^{2=}0.09$]. The interaction was not significant [$F(1,22)=1.17$, $p=0.29$, $\eta_p^2 0.05$]

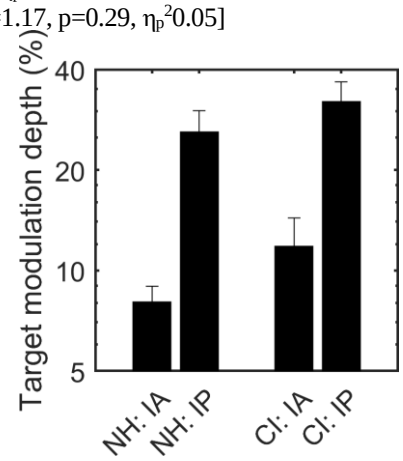

Figure 1. AM discrimination thresholds normal hearing (NH) and cochlear implant (CI) listeners. The task was performed in the absence (IA) or presence (IP) of interferers. Error bars indicate +1 standard error.

Overall, these results show that the task is generally suitable for CI listeners – all performed below ceiling and above floor. The comparable performance between CI and NH groups is consistent with other research showing that CI listeners are broadly as sensitive to SAM as those with NH [8,9]. Further data will be presented which explores 1) changes in performance over carrier frequencies/electrode locations, and the extent to which greater individual variability across frequencies in the CI group may be indicative of poorly functioning electrode regions, 2) correlations between behavioral measures of SAM discrimination and objective measures (ECAPs and EEG-observed cortical evoked responses), and 3) correlations between AM discrimination thresholds and a measure of speech in noise performance [10].

4. ACKNOWLEDGMENTS

This research was supported by an MRC Senior Fellowship in Hearing Research (MR/S002537/1). We thank our CI volunteers for their valuable time and help with this study.

ABSTRACT

The rapid development of sound-absorbing acoustic metamaterials has opened new ideas for their application. Innovations shared in metamaterial designs — such as reduced material thickness compared to traditional solutions and precise control over absorption bandwidth — show promise in the design of loudspeaker enclosures. This presentation will detail recent advancements at AGH University of Krakow, demonstrating the use of acoustic metamaterials to attenuate standing waves within loudspeaker enclosures and to mitigate back-propagation effects from the driver diaphragm. We will discuss the methodologies for designing metamaterial structures using Transfer Matrix Method simulations, optimization techniques, and neural networks to establish a reliable design and manufacturing process. Results from anechoic chamber experiments conducted for test enclosures equipped with metamaterials will be presented. These cavity-based materials, in both broadband and multi-resonance configurations, offer solutions to problematic wave phenomena within enclosures and present advantages over traditional porous materials, such as improved speaker sensitivity by 1 dB and the elimination of VAS increase due to the use of rigid materials instead of porous ones.

1. INTRODUCTION

The utilization of acoustic metamaterials is rapidly expanding across various fields of acoustics. They are particularly noted for their effectiveness in low-frequency absorption when compared to porous or fibrous materials of the same size [1]. This characteristic enables the use of metamaterial absorbers in applications where a low material thickness is essential. One such application is in loudspeaker enclosures, which is the focus of this paper. Previously, acoustic metamaterials in electroacoustics were primarily employed as broadband sound-absorbing structures to mitigate diaphragm back propagation [2], [3]. However, they had not been previously utilized to address the issue of standing waves. This paper presents preliminary research on the application of metamaterial absorbers for standing wave attenuation within loudspeaker enclosures. By employing cavity-based acoustic metamaterials that are tuned to the multiple resonant frequencies of the test enclosure, we demonstrate that metamaterials can effectively reduce standing wave interference. Despite a smooth frequency response in the resonant frequency region, the use of rigid metamaterial structures mitigates the adverse effects of fibrous materials, which usually reduce loudspeaker sensitivity.

2. MULTI-RESONANCE CAVITY-BASED ACOUSTIC METAMATERIALS

Acoustic metamaterials are often designed as cavity-based structures, which may include a combination of quarter-wavelength absorbers [4], [5] or Helmholtz-type absorbers [6], [7]. In this study, we used a set of Helmholtz resonators with a common inlet canal. The desired sound absorption was optimized for the frequency ranges of 215 Hz and 320 Hz, which were previously identified as the first two standing wave frequencies in the measured enclosure. The

sample design process utilized Particle Swarm Optimization (PSO) algorithms alongside the Transfer Matrix Method (TMM), following methodologies established in prior research [8], [9], [10]. The finalized model was encased in a cylinder with a diameter of 100 mm and a depth of 100 mm, ensuring both metamaterial sample and fibrous material used in this investigation had the same depth. Figure 1 illustrates the shape of the canals used in the tested sample and the printed model.

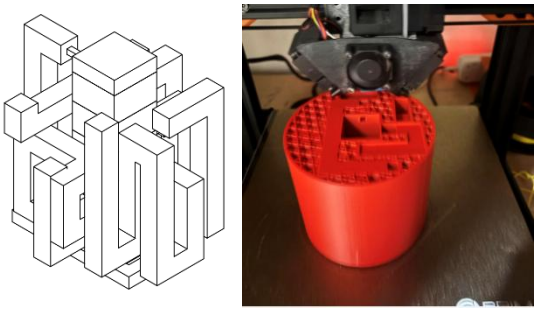

Figure 1. The scheme of the used metamaterial sample (left) and the printed model (right)

To confirm that the manufactured sample met the absorption criteria, its sound absorption coefficient was measured in an impedance tube using the transfer function method. The final sample shape was adjusted to fit into a standard impedance tube with a diameter of 100 mm.

3. MEASUREMENTS OF LOUDSPEAKER ENCLOSURE IN ANECHOIC CHAMBER

To evaluate the influence of the metamaterial samples placed within the loudspeaker enclosure, we conducted acoustic measurements. The enclosure was prepared in three variants: 1) empty, with no absorbing materials inside; 2) with polyester fibers, using a fibrous material of 100 mm depth; and 3) with metamaterials, incorporating six samples of cavity-based metamaterials tuned to the frequency ranges matching the first two modes of air inside the enclosure. Figures 2 and 3 show images of the enclosure's interior with fibrous materials and metamaterials, respectively. Figure 4 depicts the measurement setup.

Acoustic measurements were carried out with a free-field microphone (GRAS46AE) positioned 1 m from the enclosure, aligned with the loudspeaker, similar to loudspeaker sensitivity measurements. A sine sweep signal was utilized to acquire the frequency response of the loudspeaker in the enclosure.

Figure 2. Test enclosure – polyester fibers variant

Figure 3. Test enclosure – metamaterial variant

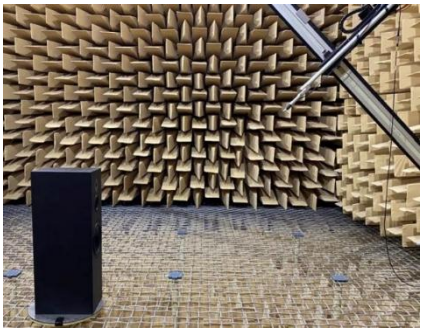

Figure 4. Test enclosure during the acoustic measurements in an anechoic chamber

The frequency response of the loudspeaker was assessed to evaluate the effectiveness of the metamaterial absorbers. The results are presented in Figure 5, which displays the Sound Pressure Level (SPL) measurements alongside the sound absorption coefficients of the metamaterial sample obtained in the impedance tube, which is a common method for this type of material research [11], [12].

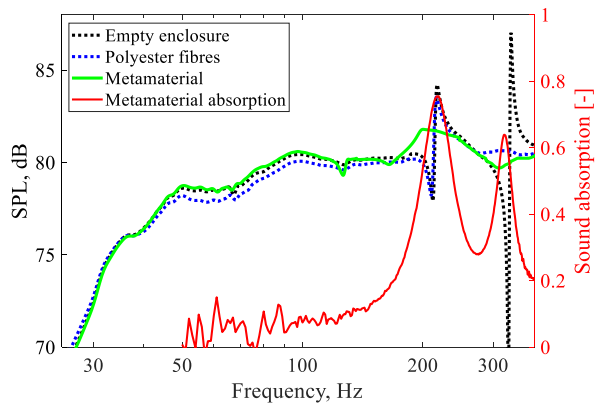

Figure 5. Frequency response of the measured loudspeaker enclosure in three variants

This study aimed to reduce the first two modal frequencies of the air mass confined within the enclosure. It is evident that the metamaterial samples absorbed the resonant frequencies at 215 Hz and 320 Hz, which were observed in the measurements of the empty enclosure, resulting in a smoother frequency response. As shown in Figure 5, the first resonant frequency at 215 Hz was only absorbed with the use of metamaterial samples, while the polyester fibers did not effectively address this low-frequency issue. Moreover, the use of fibrous materials resulted in a significant drop in loudspeaker sensitivity, whereas the incorporation of rigid metamaterial samples allowed for a recovery of the loudspeaker sensitivity.

During the research, it was observed that the absorption bandwidth may be a critical factor for the effective attenuation of standing waves within the enclosure. Designing a single, perfectly tuned resonator would be inefficient as a wider absorption range is typically necessary. This need is evident in the absorption curve, particularly around the 215 Hz point of the tested metamaterial sample. Consequently, an optimized metamaterial design is essential to achieve the desired sound absorption curve.

4. SUMMARY

The preliminary research data presented in this paper demonstrates that cavity-based metamaterial absorbers can effectively reduce the standing wave phenomenon in loudspeaker enclosures. This solution has two main advantages:

- Metamaterials enable absorption of lower frequencies without requiring an increase in the thickness of the absorbing materials.
- The rigid metamaterials used in this research eliminate the sensitivity drop often associated with fibrous materials, resulting in a 1 dB gain in sensitivity.

Metamaterial absorbers hold significant potential for further research in electroacoustics. However, it is crucial to address potential issues that may arise from their application. During the project, it was observed that full-cylinder samples placed inside the enclosure reduced the overall volume, which could negatively impact the loudspeaker's low-frequency response.
Therefore, sound absorption measurements for the samples used are necessary, and it is important to maintain the impedance tube size. It would be beneficial to design samples that do not substantially alter the enclosure volume and could be constructed without an external cylinder. Additionally, further development and testing on various enclosures are required to ensure that the design and manufacturing processes are consistent and that the technology can be successfully transitioned to the development stage.

5. ACKNOWLEDGMENTS

Development of the metamaterial absorbers for loudspeaker enclosures was funded and supported by the Polish Government, National Centre of Research and Development, agreement no. LIDER/11/0065/L-12/20/NCBR/2021.

FLAT AND CURVED PARAMETRIC ACOUSTIC LOUDSPEAKERS MEASURED WITH EXPONENTIAL SINE SWEEPS

Augusto Fantinelli[1] **Marc Arnela**[1*]

[1] Human-Environment Research (HER) group, La Salle, Universitat Ramon Llull, Barcelona, Catalonia, Spain

ABSTRACT

Parametric Acoustic Loudspeakers (PALs) utilise ultrasounds to generate an audible field thanks to a non-linear effect in air. This phenomenon is difficult to simulate, so an alternative is to rely on prototyping devices and test them experimentally. Several options exist to manufacture a PAL, the flat surface being the most common. However, transducers can also be set on curved surfaces to attain specific effects. In this paper, a set of four prototypes with different transducer dispositions on flat and convex surfaces are constructed and tested in free-field conditions at several distances. A methodology based on the Exponential Sine Sweep is used for this aim, which allows us to obtain their ultrasonic and audible frequency responses simultaneously. The results were compared with those of a single transducer, revealing significant differences between flat and curved PALs attributed to constructive and destructive interference patterns that vary with transducer arrangement.

Keywords: *parametric acoustic loudspeakers, frequency response, ultrasonic and audible sound fields, exponential sine sweeps, spatial sound-field sampling*

1. INTRODUCTION

Parametric acoustic loudspeakers (PAL) are devices that generate audible sound using ultrasonic transducers [1, 2]. They rely on the Parametric Acoustic Array (PAA) effect, in which the propagation of two ultrasonic frequencies in a medium generates a secondary field that oscillates with the difference between the frequencies. This difference can be tuned to be audible, allowing these devices to reproduce audio focused through the ultrasonic beam, making them useful for a vast gamma of applications [3].

The PAA effect results from the non-linear behaviour of the propagation media at elevated frequencies, and the equations that describe this phenomenon tend to have elevated mathematical and computational complexity [2, 4–7]. This makes the numerical modelling of this type of device difficult. To circumvent the need for simulations, prototypes of PALs can be constructed at relatively low costs since the ultrasonic transducers are inexpensive and 3D printing is currently an accessible process. Notwithstanding, the differences in the sound fields generated by different prototype models still need to be assessed.

This paper presents a comparison between 4 different prototypes of PAL that differ in shape (flat or curved), size, and amount of transducers. Two of them are flat, with one laying 96 transducers in concentric rings up to a diameter of 195 mm [8], while the other has 19 of them in a compact hexagonal distribution with diameter 82 mm. The other two are curved, with one of them being an omnidirectional source with 750 transducers placed on a sphere of 250 mm of diameter [9], and the other being a spherical cap of 91 mm and 19 transducers with the same curvature than the omnidirectional source. Exponential Sine Sweeps (ESS) were adapted and employed to be used in these loudspeakers, allowing the simultaneous measurement of the frequency response in the audible and ultrasonic ranges [10, 11]. A robotic system was used to

place the transducer at increasing distances from 10 mm up to 2.13 m, and the frequency responses were taken at each point.

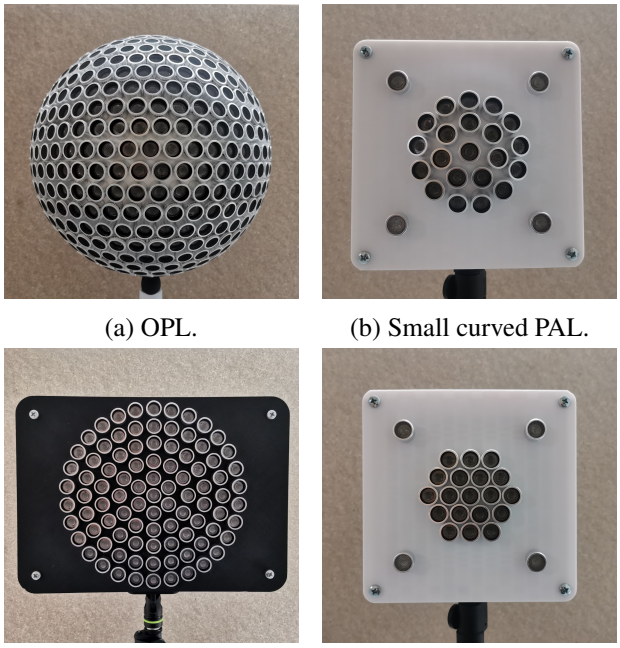
This paper is structured as follows. Section 2 presents the prototypes and the method used to measure the sound field they generate. Section 3 shows the results obtained for each prototype and presents considerations regarding their differences. Section 4 closes the paper with the conclusions.

2. METHODOLOGY

2.1 Exponential Sine Sweep methodology applied to PAL

An Exponential Sine Sweep (ESS) can be defined as [10]

$$s(t) = K \sin\left[K\ (\exp(t/L) - 1)\right], \tag{1a}$$



in which

$$K = \frac{2\pi f_1 T}{\ln(f_2/f_1)}, \tag{1b}$$

$$L = \frac{T}{\ln(f_2/f_1)}, \tag{1c}$$

and f_1 and f_2 are the lower and upper frequencies of the sweep, respectively. This represents a sine function of amplitude K in which the argument exponentially increases in time. This sweep is played through a loudspeaker inside an enclosure and recorded by a microphone. The deconvolution of the recorded signal through an inverse filter corresponding to the sweep results in an impulse response that contains information about the speaker, room and microphone. This technique has been vastly used in acoustics due to its robustness to noise and distortion [12–14].

The utilisation of ESSs in PALs [10, 11] requires the sweep to be modulated into a frequency range appropriate to the ultrasonic transducers that form the PAL. The signals, therefore, go through an upper side-band amplitude modulation (USBAM) with a transmitted carrier component. This, in practice, means that the transducers are constantly emitting the transmitted carrier with frequency f_c and whatever the frequency of the sweep signal at that moment. The simultaneous emission of both frequencies triggers the PAA effect. This allows for the frequency responses in the audible and ultrasonic ranges to be measured simultaneously [10, 11].

(a) OPL. (b) Small curved PAL.

(c) Flat PAL. (d) Small flat PAL.

Figure 1: PALs analysed in this work.

2.2 Prototypes

Four prototypes of PAL are considered. They all employ the same transducer model (Multicomp Pro MCUST16A40S12RO), varying in quantity and/or disposition. These transducers are ultrasonic piezoelectric transducers (PZTs) and are connected in parallel in all models. Figure 1 displays the four parametric loudspeakers analysed in this work. The Omnidirectional Parametric Loudspeaker (OPL) was designed and constructed in [9], characterised in [10, 11] and applied in [15] for measuring the random-incidence sound absorption. It has 750 transducers arranged in a sphere with 250 mm of diameter following an equal-area distribution [9]. The OPL directly inspires the next prototype. It is based on its top spherical cap, with 91 mm of diameter and 21 transducers. Next is the flat PAL described in [8], with 96 transducers laid out in six circular rings up to 195 mm of diameter. The last prototype has its transducers set in a hexagonal manner, with three layers and 19 transducers, and has 82 mm of diameter. In addition to the PALs, the same transducer that composed all prototypes was also analysed.

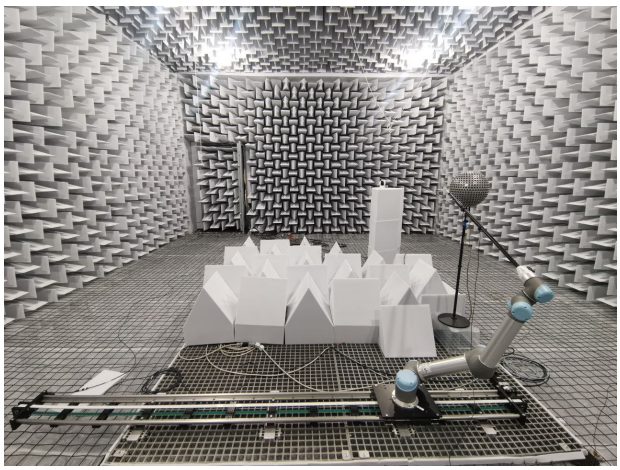


Figure 2: Experimental setup in the anechoic chamber of La Salle - Universitat Ramon Llull, with the robot, the track and the OPL installed.

2.3 Experimental setup

A UR5 (Universal Robots) robotic arm was used to position the microphone aligned with the centre of the irradiation. The robot is mounted over a $2.45\,\mathrm{m}$ linear track (IGUS) so it can be moved around parallel to the x axis of the speaker. The sound field emitted by the prototypes was measured along the centre of the propagation axis for all loudspeakers (aligned with the movement axis of the track) with an interval of $0.04\,\mathrm{m}$, from $0.01\,\mathrm{m}$ to $2.13\,\mathrm{m}$ of distance from the closest transducer. A GRAS 46BF-1 1/4" microphone was attached to the robot by a $1\,\mathrm{m}$ microphone holder, long enough so the robot causes minimal effects in the measured sound field. The generation of the sine sweep and the recordings were made using a Type 3160-A-042 Brüel & Kjaer LANXI module with a UA-3102-041 front end. The signal was amplified using an Ecler XPA3000 amplifier with its gain set in such a way that it provides a peak voltage of $17\,\mathrm{V}$ to avoid damaging the transducers. Fig. 2 displays the experimental setup with the UR5 cobot and the Igus track used to scan the sound field generated by the OPL [9], assembled in the anechoic chamber at La Salle - Universitat Ramon Llull.

The ESSs emitted by the PALs were $1\,\mathrm{s}$ long, from $20\,\mathrm{Hz}$ to $14\,\mathrm{kHz}$, with $2\,\mathrm{s}$ and $3\,\mathrm{s}$ of silence before and after the sweep, respectively. Linear ramps from $20\,\mathrm{Hz}$ to $80\,\mathrm{Hz}$ and $12\,\mathrm{kHz}$to $14\,\mathrm{kHz}$ were added to the sweeps to avoid pre-ringing artefacts, as proposed in [10]. Due to the changes in impedance from one prototype to another and the response of the amplifier, an equalization of the sweep was done to compensate for the change in waveform and maintain the excitation voltage constant [15]. This is specifically important when employing the OPL due to its very capacitive load [15]. In addition, a $1\,\mathrm{kHz}$ modulated pure tone was measured to calibrate the measurement chain. This pure tone was measured at the central position of the array $10\,\mathrm{mm}$ from the loudspeaker. The ESSs were modulated using USBAM with carrier frequency $f_c = 41.4\,\mathrm{kHz}$, selected based on [10]. The same carrier frequency was used for all devices.

3. RESULTS AND DISCUSSIONS

Fig. 3 shows the frequency responses in front of the four PALs and the single PZT transducer for four different distances in the audible and ultrasonic frequency ranges. The first thing of note is that the audible frequency responses have shapes that follow the ultrasonic ones. This is especially noticeable when comparing the frequency responses between the two ranges close to the source, where the highest sound pressure levels (SPLs) occur. It can also be seen that very close to the source, the curved designs produce higher levels than the flat prototypes, except at about $54\,\mathrm{kHz}$, which is the second resonance of this transducer [16]. Note also that they produce the highest levels at low frequencies. This is likely related to the constructive and destructive interaction of the sound waves generated by the arrays, which is modified depending on whether the prototype is flat or curved. With increasing distance, the only PALs that generate over $60\,\mathrm{dB}$ are the flat PAL and the OPL, which have more transducers than the rest. The small flat PAL does not reach large distances compared to other prototypes. This indicates that the constructive and destructive interactions between the individual transducers influence the behaviour of the PAL, and the final resulting emission cannot be estimated with only the amount and the shape of the distribution. As expected, the single transducer also does not generate high level audible sound fields due to insufficient ultrasonic power in the far-field to trigger the PAA.

Fig. 4 displays the generated audible and ultrasonic SPLs along a straight line following the propagation axis in front of the PALs, for $500\,\mathrm{Hz}$, $1000\,\mathrm{Hz}$, $5000\,\mathrm{Hz}$, and $10\,000\,\mathrm{Hz}$. The sound field cast by a PAL can be divided into three zones regarding the distance: a near-field in which there are successive local minima and maxima of

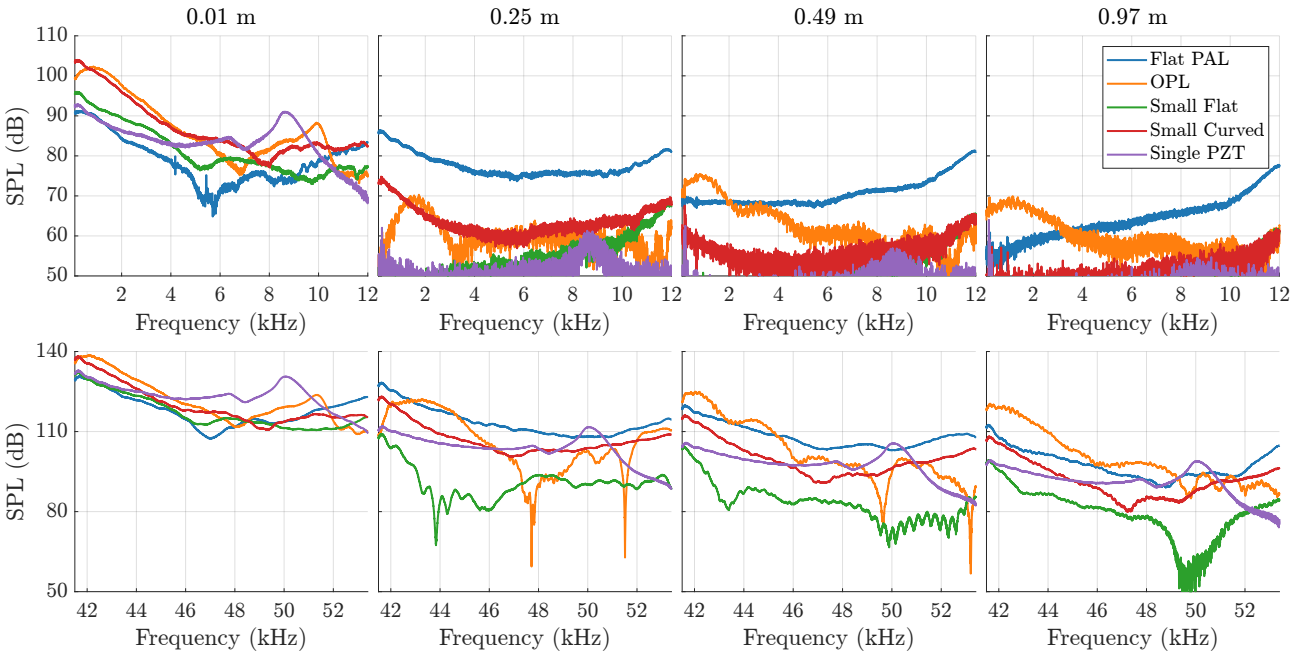

Figure 3: Frequency responses for the four PALs and the single transducer.

sound pressure; the Westervelt far-field, in which the PAL behaves like an infinitely large virtual volume source; and the inverse-law field, in which the inverse-square-law is valid [2]. The inverse-law field typically exists very far from the source, exceeding the dimensions of the anechoic chamber. Therefore, it was not assessed. The transition between near-field and Westervelt far-field can be identified following the criterion introduced by Zhong *et al.* [2]. This transition can be determined by finding the last local maxima of the SPL in the distance. The Westervelt far-field transition distances for the flat circular PAL (F. C. PAL), the flat hexagonal PAL (F. H. PAL), the OPL, and the spherical cap PAL (S. C. PAL) are displayed in Tab. 1. The small flat PAL and the single transducer do not produce high audible SPLs beyond the near-field, likely due to destructive interferences in the former and lack of power in the latter. Another thing of notice is that the flat PAL has a pronounced peak around the transition distance at 500 Hz, 1 kHz, and 5 kHz. Relating with Zhong *et al.*'s analysis [17], this indicates that this corresponds to a region where the sound energy is focused. At 10 kHz, the peak is not as pronounced, and the levels are higher in the Westervelt far-field, indicating the formation of a sound beam despite an initial concentration of energy.

Table 1: Westervelt far-field transition distance (m) at 500 Hz, 1 kHz, 5 kHz and 10 kHz for the flat PAL, the small flat PAL, the OPL, and the small curved PAL prototypes.

	500 Hz	1 kHz	5 kHz	10 kHz
Flat PAL	0.25 m	0.25 m	0.25 m	0.29 m
Small Flat	0.17 m	0.13 m	0.17 m	0.13 m
OPL	0.41 m	0.45 m	0.33 m	0.37 m
Small Curved	0.09 m	0.09 m	0.09 m	0.13 m

Regarding the ultrasonic field generated along the propagation axis (see Fig. 4), observe that the local maxima in the ultrasonic range coincide with the local maxima at the audible range. This indicates that the ultrasonic fields could also be used to determine the transition between near-field and Westerwelt far-field. Another remark is that the ultrasonic levels for the small flat PAL are very low, even lower than the single transducer. This means that, despite this PAL having 19 transducers, their ultrasonic signals suffer destructive interferences, and the generated levels are even lower than for the single transducer. Transducer placement and phase mismatch might be the causes of this phenomenon.

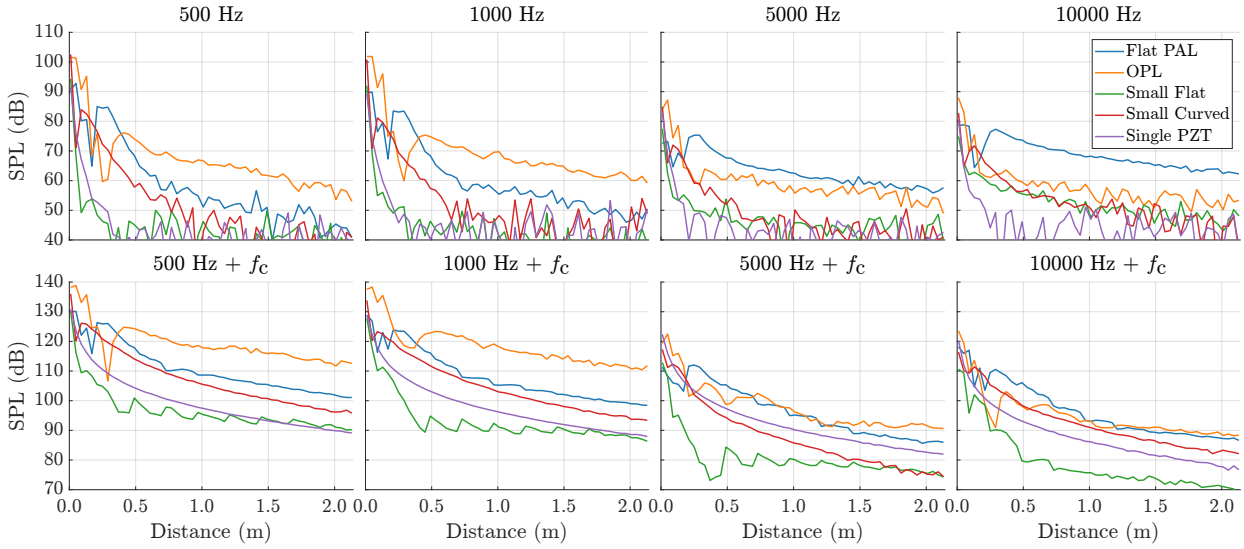

Figure 4: Audible (top) and ultrasonic (bottom) sound pressure levels (SPLs) for each device as a function of the distance from the speaker. $f_c = 41.4$ kHz.

4. CONCLUSIONS

This work has explored the performance of four prototypes of PAL with distinct characteristics: a flat circular PAL (flat PAL), a flat hexagonal PAL (small flat), an omnidirectional PAL (OPL), and a spherical cap PAL (small curved), aiming to assess differences between flat and curved layouts. Their audible and ultrasonic frequency responses were simultaneously measured in free-field conditions using exponential sine sweeps, as well as that of the transducer used to build the arrays. Their behaviour was examined at several distances aligned to their centres employing a robotic system that moved and positioned a microphone.

Results show that the audible and the ultrasonic frequency responses match each other in shape, indicating proportionality between the primary (ultrasonic) and secondary (audible) fields. The curved designs produced higher levels in the near field and reached longer distances compared to the flat prototypes for low and mid frequencies (< 2 kHz), while the flat prototypes have the opposite behaviour and generate the highest values at high frequencies. The flat PAL has a focusing behaviour in lower frequencies, in which the sound energy is concentrated in the transition region of the PAL. The prototypes with curved designs did not present this behaviour and, instead, tended to carry part of the sound energy throughout the distance, although with a pronounced decay at higher frequencies, while retaining part of the energy in the near-field. The small flat PAL generated very low ultrasonic levels in the far-field, which were not enough to trigger the PAA effect. All in all, the above behaviours could be justified by the constructive and destructive interaction of the ultrasonic sound fields generated by each of the transducers that form the array. It seems clear that modifying the number of transducers and their arrangement in the array, whether curved or flat, greatly affects the behaviour of the PAL.

Future work will involve applying near-field acoustical holography (NAH) to these and other prototypes and transducers to investigate the mechanisms of ultrasonic and audible sound generation, as well as the interactions among individual transducers. Their sound fields will also be analysed using pressure maps obtained with the assistance of a robotic measurement system.

ABSTRACT

This work presents an analytical method to determine which material -copper or aluminum- is more suitable for coil winding, based on the initial specifications of the transducer. The proposed approach compares the coil mass to the total moving mass and establishes a threshold value that defines the suitability of each material for achieving maximum efficiency.
Initial method relies on minimal variables, primarily derived from the original loudspeaker model. These variables include the total moving mass (M_{MS}), encompassing all moving parts, such as the air load on both sides of the diaphragm, and the material used for the coil conductor.
The role of the voice coil, however, differs from some perspectives presented in the literature, particularly those equating the coil mass to the total moving mass, a simplification that is not realistic for a transducer characterized by inherently low efficiency.
Additionally, the analysis accounts for variations in the Bl force factor caused by the physical differences between copper and aluminum for the same electrical resistance, due to the alterations in the air gap volume.

Keywords: *Electrodynamic loudspeaker, voice coil, moving mass, transducer efficiency.*

1. INTRODUCTION

This article proposes a novel approach in the development of the electrodynamic loudspeaker, focusing on the optimization of the voice coil. The objective is to achieve results comparable to those obtained through conventional methods but with lower time and costs, as well as a significant reduction in the carbon footprint during the manufacturing process.
To this end, a comprehensive study of the voice coil is presented, analyzing various improvement criteria and refining its performance to achieve an optimal balance between performance and cost. The importance of optimizing the coil mass in relation to the moving masses is discussed, and a solution based on the limit value theory is proposed. This approach allows for performance maximization through changes in the material of the winding wire as well as in the geometry of its cross-section.
As mentioned, equating the coil mass to the remaining moving masses would require a significant increase in the size of the magnetic circuit, which is economically unfeasible [1]. On the other hand, some authors propose reducing the coil size to match the total moving mass [1, 2], but this would introduce technical challenges that are difficult to resolve. Therefore, the approach should focus on maximizing efficiency while retaining the original components, with some modifications in the properties of the voice coil conductor.
For certain types of loudspeakers, copper is traditionally preferred for voice coil construction due to its excellent conductivity and mechanical strength. Consequently, it is the most widely used material in low and mid-frequency direct-radiation models. Conversely, aluminum is recommended in high-frequency loudspeakers and compression drivers, mainly due to its low density [3].
Although this criterion may involve some subjectivity, it is the most applied approach in loudspeaker manufacturing. This study challenges this practice and proposes a method to determine the suitability of one material over another to

achieve maximum loudspeaker performance if that is the objective or to optimize the magnetic circuit for a given performance level.

2. APPROACH

In loudspeaker design, it is not usual to conduct a preliminary study to determine the optimal coil mass to maximize system performance. Typically, the dimensions and construction characteristics of the voice coil -such as diameter, conductor material, winding width, among others- are dictated by parameters such as electrical resistance, power capacity, maximum linear displacement, or peak displacement, etc. However, this study aims to justify the need to refine the coil based on additional criteria that enable maximum performance. This includes improving the *Bl* product with an optimized moving mass and dissipation while also achieving the desired power and efficiency characteristics through magnetic circuit optimization. The latter is a critical component in terms of weight and cost, highlighting its relevance in the overall design and efficiency of the system.

2.1 Voice coil mass versus efficiency

The efficiency of the loudspeaker in the mid-frequency range can be expressed using the following equation:

$$\eta = K\frac{{S_D}^2 B^2 l^2}{R_E M_{MS}^2} \quad (1)$$

Where the terms affected by the change in the coil are the wire length l of the coil and the moving mass M_{MS}.

This expression can be expanded by substituting the electrical resistance R_E in terms of the resistivity of the material ρ, as well as the length l and cross-sectional area s of the conductor. Additionally, M_{MS} can be replaced by the sum of the individual masses that comprise it.

$$\eta = K\frac{{S_D}^2 B^2 l^2}{\rho\frac{l}{S}\cdot(2M_A+M_{MD}+M_{MVC})^2} = K\frac{{S_D}^2 B^2 lS}{\rho(2M_A+M_{MD}+M_{MVC})^2} \quad (2)$$

With M_A being the mass of the air load on the membrane, M_{MD} the mass of the membrane, spider, and dust cap, and M_{MVC} the mass of the coil.

In the numerator, the product of l and S appears, representing the volume of the winding. By mathematical adjustment, the coil mass M_{MVC} is obtained.

$$\eta = K'\frac{{S_D}^2 B^2 M_{MVC}}{(2M_A+M_{MD}+M_{MVC})^2} \quad (3)$$

By taking the derivative of Equation (3) with respect to M_{MVC} and equating it to zero, the condition for maximizing efficiency is found.

$$M_{MVC} = 2M_A + M_{MD} \quad (4)$$

This condition suggests that the coil mass M_{MVC} must equal the mass of the remaining moving components (Fig. 1, solid line).
However, this solution is unrealistic. Compelling the coil mass to match the total moving mass would require an extremely powerful magnetic circuit to maintain a constant *Bl* product, resulting in prohibitively high costs. Nevertheless, even with a variable *Bl* product, there is an optimal value for the coil mass relative to the total moving mass that maximizes efficiency (Fig. 1, dashed line).

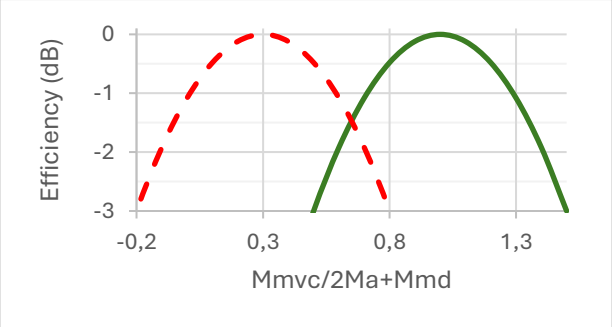

Figure 1. Efficiency versus voice coil mass

2.2 Influence of the conductor material on efficiency

This study aims to determine which of the two analyzed materials (copper or aluminum) is more suitable for voice coil construction to optimize loudspeaker efficiency. To achieve this, the expression for efficiency in Equation (1) is considered, depending on the *Bl* product and the moving mass.
Since efficiency is directly proportional to the first term and inversely proportional to the second- both terms squared- it can be stated that this relationship serves as the determining criterion, as the other terms in the equation remain constant regardless of the material used for the winding.

2.3 Determination of variables affecting efficiency

From the expression for the electrical resistance of the loudspeaker coil:

$$R_E = \rho \frac{l}{S} \quad (5)$$

The ratio of the aluminum wire diameter, w_{DAl}, to the copper wire diameter, w_{DCu}, is obtained:

$$w_{DAl} = 1{,}17 w_{DCu} \quad (6)$$

Using these values and taking μ as the material density, the coil mass M_{MVC} can be calculated as:

$$M_{MVC} = \mu l S \quad (7)$$

From this, it follows that the mass of the aluminum coil M_{MVCAl} relative to the copper coil mass M_{MVCCu} is:

$$M_{MVCAl} = 0{,}355 M_{VCCu} \quad (8)$$

This indicates that, for a coil with the same electrical resistance R_E, voice coil diameter V_{CD}, and winding width w_L, the aluminum wire diameter must be 17% larger than that of copper. Furthermore, based on this relationship, the aluminum coil mass is approximately one-third that of the copper coil.

2.4 Variation of the *Bl* product due to the change in the voice coil material

For magnetic systems such as the one illustrated in Fig. 2, empirical studies have shown that the magnetic flux Φg in the air gap can be calculated using the following expression [4]:

$$\Phi_g = \frac{L_m B_R / 1.07\mu_0}{(L_g/\mu_0 A_g)(27.5\mu_0 L_m R_m + 1.55) + L_m/1.07\mu_0 A_m} \quad (9)$$

Where

B_R Residual induction
R_m Magnet reluctance
A_m Magnet cross section area

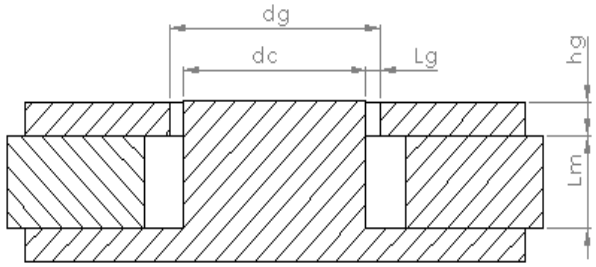

Figure 2. Section of the loudspeaker magnet system

By applying these results, it is possible to determine the variation in the air gap size and, using Eq. (10) and (11), calculate the difference in magnetic induction B between the two coils:

$$B = \frac{\Phi_g}{A_g} \quad (10)$$

Where the air gap area Ag is given by:

$$A_g = \pi(d_c + L_g)h_g \quad (11)$$

Initial calculations performed with the air gap dimensions for the copper coil, and subsequently adjusted for the aluminum coil, reveal a 3.5% reduction in magnetic induction B when switching from copper to aluminum. On the other hand, the reduction in the second term, l, is due to the increase in the wire diameter when using aluminum, which leads to a decrease in the number of turns and, consequently, in the total wire length, according to the following relationship:

$$l_{Al} = 0.854 l_{Cu} \quad (12)$$

Based on these variations, the ratio of the Bl product for the aluminum coil to that of the copper coil can be expressed as:

$$Bl_{Al} = 0.824 Bl_{Cu} \quad (13)$$

3. CONCEPT OF THE LIMIT VALUE BASED ON THE COIL MATERIAL

As discussed earlier, this study aims to select the voice coil wire material based on criteria for either maximizing efficiency or optimizing the magnetic motor. Without requiring prior analysis of the magnetic circuit, the choice between copper and aluminum can be deduced using the criteria outlined below.

3.1 Initial considerations

In the early loudspeaker design, constraints related to the moving mass (e.g., membrane, suspensions, and other moving parts) are established. Similarly, the geometric dimensions of the coil are defined based on power handling, electrical resistance, linear displacement, etc. With these values and Equation (1), the efficiency equivalence for both materials can be expressed as:

$$K \frac{(Bl)^2_{Cu}}{R_{ECu}(M_{MS})^2_{Cu}} = K \frac{(Bl)^2_{Al}}{R_{EAl}(M_{MS})^2_{Al}} \quad (14)$$

Since the electrical resistance is the same (R_{ECu}= R_{EAl}), it cancels out along with other constants. On the other hand:

$$2M_A + M_{MD} = M_X \quad (15)$$

Substituting M_{MS} according to Equations (1) and (15), and simplifying, yields:

$$\frac{Bl_{Cu}}{M_{MX}+M_{MVC_{Cu}}} = \frac{Bl_{Al}}{M_{MX}+M_{MVC_{Al}}} \quad (16)$$

Reordering terms:

$$\frac{Bl_{Cu}}{Bl_{Al}} = \frac{M_{MX}+M_{MVCCu}}{M_{MX}+M_{MVCAl}} \quad (17)$$

Substituting and solving using Equations (8) and (13),

$$\frac{M_{MX}}{M_{MVC_{Cu}}} = 2.66 \quad (18)$$

This implies that when the ratio of M_{MX} to the copper coil mass equals 2.66, both materials yield equivalent performance. For ratios below 2.66, aluminum is better, whereas ratios above 2.66 favor copper (Fig. 3).
It is easy to deduce that, when the ratio in Equation (18) exceeds the indicated value, the weight of the moving parts other than the voice coil becomes predominant. As a result, the coil mass is not as critical, and a higher *Bl* product is preferable.

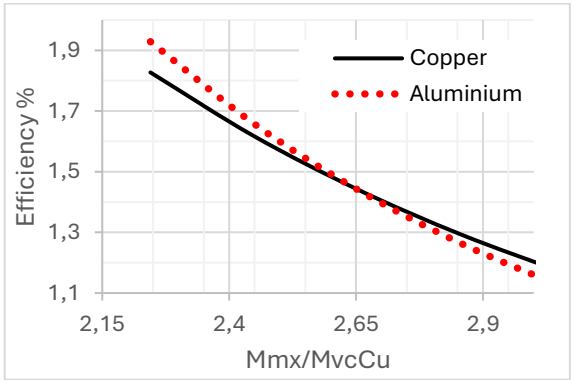

Figure 3. Variation of the efficiency

According to Equation (13), this is achieved with a copper coil. On the other hand, if the value is below 2.66, the coil mass becomes dominant. In this case, the lightest possible coil is desirable, which is achieved with aluminum, despite having a lower *Bl* product.

3.2 Example

A loudspeaker is selected from a well-known manufacturer that provides the following data: Loudspeaker size: 18" (46 cm), with 100 mm voice coil diameter, made of 0.50 mm diameter copper wire. The M_{MX}/M_{MV} value is 1,32, so less than 2.66. According to this, the efficiency will be higher with an aluminum coil. A 30% increase in efficiency has been confirmed by changing the coil wire material, according to the procedure seen above (Tab. 1).

Table 1

Coil Material	M_{MVC} Kg	M_{MS} Kg	M_{MX} Kg	Bl N/A	η %
Copper	0,099	0,23	0,131	29	2,7
Aluminun	0,035	0,166	0,131	23,9	3,5

4. PERFORMANCE VARIATION DUE TO WIRE CROSS-SECTION GEOMETRY

The conventional geometry for the voice coil conductor is circular, from which the packing factor can be obtained. This factor represents the ratio between the actual volume of the wire and the total volume of the winding (Fig. 4a). In this case, the packing factor is 78.5%. It is also possible to use rectangular cross-section wire, which achieves a 100% packing factor (Fig. 4b).

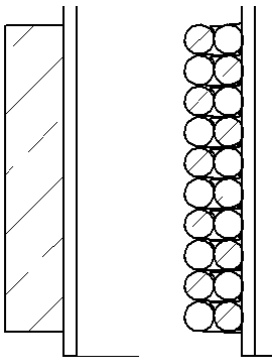

Figure 4a. Difference between voice coil volume (left) and wire volume (right)

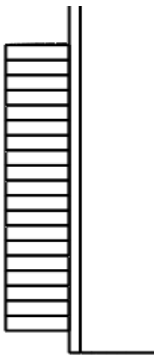

Figure 4b. Voice coil with edge wound rectangular wire

This allows the wire length and cross-sectional area to be increased while maintaining the electrical resistance. Obviously, this configuration enhances the Bl product.

4.1 Calculation of rectangular cross-section voice coil parameters

When switching from one geometry to the other, certain dimensions are preserved, such as the winding length (w_L) and the inner and outer diameters of the winding, which avoids modifications to the air gap dimensions.
Additionally, while the round-wire coil uses two layers in the winding, the rectangular-wire coil only uses one. Consequently, the height of the rectangular-section wire (h) will be equal to $2w_D$.

$$l = \frac{2w_L V c_D \pi}{w_D} \tag{20}$$

By substituting (considering the number of layers n is equal to 1, and the wire thickness denoted as t.

$$l = \frac{w_L V c_D \pi}{t} \tag{21}$$

4.2 Rectangular vs. Circular Cross-Section Conductor

Due to its higher packing factor, the rectangular cross-section coil will have a greater number of turns, thereby increasing the Bl product.
Expressing the electrical resistance based on the rectangular wire cross-section geometry:

$$R_{E\,FLAT} = \rho \frac{w_L V c_D \pi}{h t^2} \tag{22}$$

4.2.1 Calculation of wire thickness

As previously defined, $h = 2w_D$. The thickness can be obtained from the following expression:

$$R_E = \rho \frac{2w_L V c_D \pi}{\frac{w_D{}^2 \pi}{4}} = \rho \frac{w_L V c_D \pi}{h t^2} \tag{23}$$

Solving for t:

$$t = 0{,}44 w_D \tag{24}$$

4.2.2 Determination of rectangular wire coil mass

The mass is expressed as:

$$M_{MVC\,Round} = lS\mu = \frac{2w_L V c_D \pi^2 w_D^2}{4w_D}\mu \tag{25}$$

$$M_{MVC\,FLAT} = lS\mu = \frac{w_L V c_D \pi}{t} h t \mu \tag{26}$$

Resulting in:

$$M_{MVC\,FLAT} = 1{,}273 M_{MVC\,Round} \tag{27}$$

Since the air gap volume remains unchanged, the new value of l is derived using equations (25) and (26):

$$l_{Rect} = 1{,}136 l_{Round} \tag{28}$$

Thus

$$Bl_{FLAT} = 1{,}136 Bl_{ROUND} \tag{29}$$

4.3 Critical value between round and rectangular wire coils

Following the methodology in Section 4.1, equation (16) is adapted by substituting materials with the cross-sections:

$$\frac{Bl_{ROUND}}{M_{MX} + M_{MVC\,ROUND}} = \frac{Bl_{FLAT}}{M_{MX} + M_{MVC\,FLAT}} \tag{30}$$

From this, it results:

$$\frac{M_{MX}}{M_{MVC\,ROUND}} \approx 1 \tag{31}$$

This solution demonstrates that no critical value exists to equalize the performance of voice coils with circular versus rectangular cross-section geometries. In practice, since the rectangular wire coil mass M_{MVC} is significantly smaller than other moving masses, the improvement in Bl product will enhance overall performance. This improvement depends on the ratio M_{MX}/M_{MVC}, with greater benefits as this ratio increases.

5. CONCLUSION

It has been possible to establish the advantages of analyzing the loudspeaker coil to achieve a balance between the mass of moving parts, excluding the voice coil and the voice coil mass itself.
While the optimal solution -equating both masses- is economically unviable or practically unattainable, it has been demonstrated that selecting the appropriate conductor material, copper or aluminum, allows for

either maximizing efficiency or optimizing the magnetic circuit. This approach offers both economic and technical advantages.

Additionally, the feasibility of using alternative wire cross-section geometries to increase the packing factor and consequently, the Bl product, has been outlined. This improvement is universally beneficial, particularly in bigger diameter models. In such cases, the higher manufacturing cost of flat wire voice coil (compared to more economical round wire voice coil) is compensated by the potential to reduce the magnetic circuit volume.

OPTIMIZATION OF CAVITIES AND SUSPENSIONS IN UNDERWATER ACOUSTIC PROJECTORS: ANALYTICAL AND EXPERIMENTAL STUDY

Martínez-Iranzo, José [1*] **Carbajo-San Martín, Jesús**[1] **Poveda-Martínez, Pedro**[1]

ABSTRACT

This paper focuses on the design and analysis of an underwater acoustic projector based on a conventional loudspeaker, with particular emphasis on the role of the intermediate cavity between the loudspeaker and the radiating diaphragm, as well as the suspension properties of both components. The design, which eliminates direct contact between the loudspeaker and the diaphragm, presents unique challenges in efficiently transmitting mechanical energy from the former to the latter while minimizing losses.
The study explores how the cavities volume and suspension characteristics (linearity, stiffness, and damping) influence the low-frequency response by analyzing the first modes of the diaphragm. Using analytical approaches and experimental models, comparative studies are presented to optimize the system configuration.
This arrangement offers a significant advantage by eliminating the need for compensating the fluid pressure exerted on the diaphragm in shallow waters, without affecting the coil rest position within the magnetic gap.

1. INTRODUCTION

The purpose of this work is to analyze the behavior of the cavities that form the projector, particularly their influence on the response and passband. Additionally, it aims to define the type of suspension and dimensions based on the piston size to optimize the low cutoff frequency and performance in water, for submersions up to 3 meters deep, while avoiding nonlinearities caused by the static displacement of the resting point of the coil.
In this type of design, numerous references exist for audio applications [1, 2, 3], highlighting the possibility of varying the passband or efficiency [2, 3], as well as limiting low frequency displacement due to the membrane being loaded on both sides. A vent is typically used because of the ease of tuning the enclosure to the desired frequency. The use of a passive diaphragm has been described on some occasions [3, 4], but no practical or commercial applications are known in this field.

2. PROJECTOR DESCRIPTION

To protect the inside loudspeaker from the effects of hydrostatic pressure when submerged in water, a system has been conceived based on the symmetrical loading system used in some speaker enclosures. This system consists of placing the loudspeaker inside an enclosure formed by two cavities (Fig. 1, 2). The rear cavity (V1) is airtight, while the other (V2) contains a passive diaphragm that allows sound to propagate outward.

2.1 Design of the prototype

This design, reminiscent of one previously presented in an earlier communication [5], differs primarily in the absence

of the element that connected the loudspeaker coil to the external diaphragm. This significantly reduces the displacement of the coil from its resting point due to the hydrostatic pressure exerted on the diaphragm. This aspect is crucial since, as will be discussed later, the aim is to use a loudspeaker with a very short voice coil.

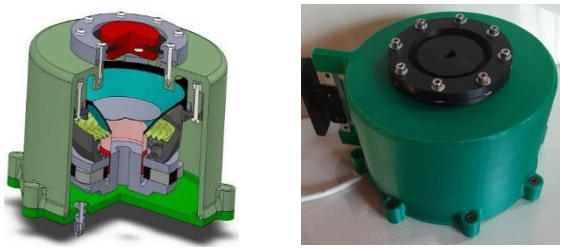

Figure 1. Section of the projector (left), and prototype photo (right)

This type of assembly is derived from the sealed back chamber bandpass enclosure, used in audio systems for very low-frequency applications. It is characterized by a frequency response like a bandpass filter, with a bandwidth of slightly more than two octaves. Since the loudspeaker is loaded on both sides, it exhibits minimal displacement. This allows for the use of a voice coil with a very short winding width. As a result, with all the turns remaining within the magnetic gap, both efficiency and power handling capacity are improved.

2.2 Construction

Obviously, models that radiate into the air require a large loudspeaker size and a significant volume to achieve a low cutoff frequency with high sensitivity. In the case of the described model, due to the difference in radiation impedance between air and water, a small diaphragm with a relatively high mass is used (Fig. 2).

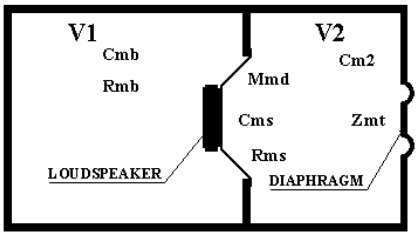

Figure 2. Band pass cabinet

3. ELECTRO-MECHANICAL CIRCUIT

Fig. 3 shows the mechanical circuit, with all the elements involved in it.

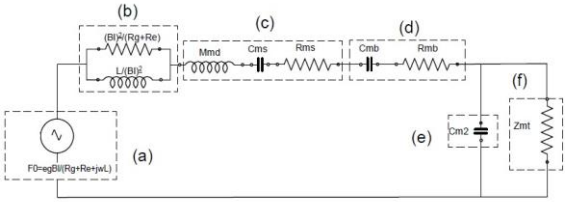

Figure 3. Mechanical circuit of the direct-radiator loaded on both sides: (a) force, (b) electrical components referred to the mechanical side, (c) mechanical elements of the loudspeaker, (d) rear side box, (e.) front side box, (f) mechanical impedance of the passive diaphragm

4. RESULTS AND DISCUSSION

Based on previous model experience, a free air resonance frequency is established around 100 Hz, as the increase in moving mass—due to the added mass of water—will shift the main mode below this value, which is the requested low cutoff frequency for this model.

4.1 Passive diaphragm characteristics

To minimize the efforts induced by hydrostatic pressure, the area is reduced to one-fourth of the total area of the membrane. A suspension with the required stiffness is employed to match the properly required free air resonance, as described above. To confirm this value, a known mass is applied, and the resulting displacement is measured using a laser sensor (Fig. 4).

Figure 4. Measurement of the resting point (left), and the displacement with a known mass (right)

This experiment is conducted using the same piston diameter, but with different suspension areas.
The first suspension, (model C), has a smaller area than model D. This difference has a strong impact on stiffness K and in the free air resonant frequency, (Tab. 1). The diaphragm mass is defined by the material and production conditions, in this case printing 3D techniques.

Table 1

Diaphragm Model	Suspension Area cm^2	K N/m	Diaphragm Mass Kg	Fs Hz
C	4,5	30430	0,038	142
D	9,5	9360	0,038	79

4.2 Parametric study

Different measurements are conducted on both the active and the passive model, while also analyzing the influence of the cavities. Because the nature of the components, an impedance measurement of the 5" loudspeaker (active model), will be done. On the other hand, the passive diaphragm has no way to achieve a direct electrical measure, so a sensor (accelerometer) will be affixed to the piston, to see how it performs.

4.2.1 Influence of the passive diaphragm

The accelerometer is placed on the back side of the piston and is excited by the loudspeaker in all the audible range of frequencies (Fig. 5).

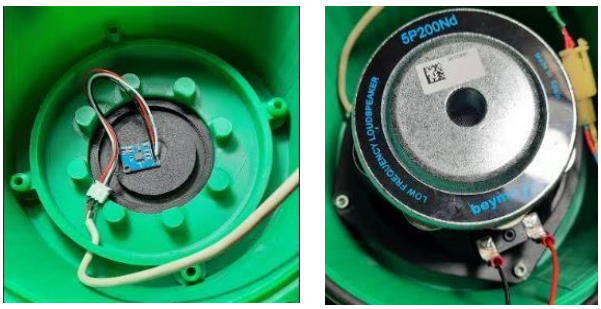

Figure 5. Accelerometer fixed on the back side of the piston (left) with the 5" unit mounted inside the cabinet (right)

Figure 6 shows the shift in the first peak of impedance when replacing the diaphragm. In the case of model C, this peak is located around 200 Hz (solid line), whereas in model D, a downward shift is observed, placing it around 105 Hz (dashed line).

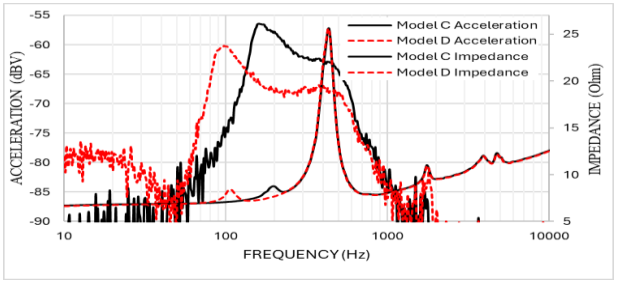

Figure 6. Impedance and Acceleration, with models C and D diaphragms

The first mode has a very low amplitude due to the air load enclosed in both cavities, on both sides of the loudspeaker. The second mode remains unchanged in both frequency and amplitude. The tuning frequency, which is the minimum value between both peaks, is also clearly modified. The acceleration measurements show a broader frequency response for diaphragm D (dashed line), while for model C, the response is substantially reduced at lower frequencies (solid line). As the passband widens, efficiency decreases.

4.2.2 Influence of the front cavity

This cavity, located between the loudspeaker and the diaphragm, behaves as a low-pass filter. Therefore, it should affect the response at the upper cutoff frequency. Figure 7 exhibits the behavior, with the first peak located around 150 Hz, and the second one, at 445 Hz.

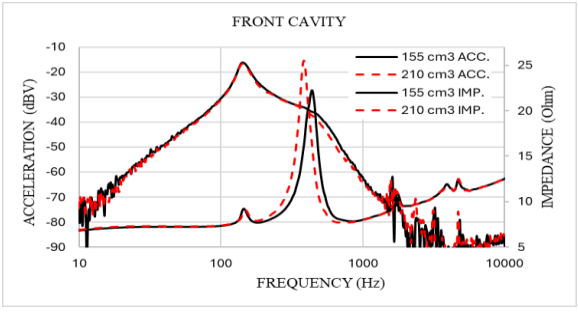

Figure 7. Impedance and acceleration for different volumes

After modifying the volume, increasing up to 210 cm^3, the first peak remains at the same value, meanwhile the second is placed at 390 Hz. The amplitude of the peak rises due to the increase of the air chamber compliance.

4.2.3 Influence of the rear cavity

The rear cavity is completely sealed, loading the loudspeaker from the rear side. The air enclosed inside represents an added rigidity to the loudspeaker suspension. The volume of his cavity increased from 800 cm³ (Fig. 8) to 1300 cm³, while the original front volume of 155 cm³ remains unchanged.
It can be observed a shift in the first two peaks toward the lower frequency region.

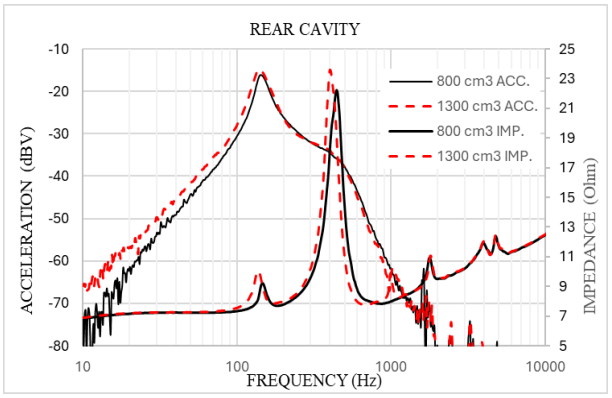

Figure 8. Impedance and acceleration when modifying the rear volume

Additionally, a peak appears at 1 kHz, likely caused by a resonance due to the larger cavity size and the absence of damping material.
The increase in the rear volume V1 affects the low frequency cutoff, and very lightly the higher cutoff frequency.
Meanwhile, the variation in the front volume, that behaves as a low pass filter, has some incidence in the higher cutoff frequency, but none in the low frequency.

4.3 Analytical results

A parametric study, leveraging a MATLAB-based implementation of the mechanical model (Fig. 3), revealed strong agreement between theoretical predictions and experimental outcomes (Fig. 9)

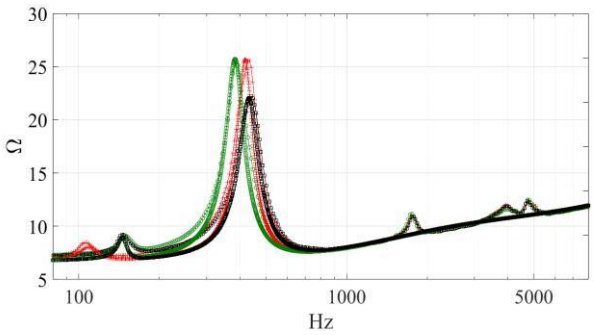

Figure 9. Validation of the analytical model: Diaphragm model D, (lines); 210 cm^3 front volume cavity: (squares); 1300 cm^3 rear volume cavity:
(circles)

4.4 Pressure frequency response

Although this model is intended for underwater applications [6, 7], SPL measurements in free air are carried out to confirm the previously described results (Fig. 10).

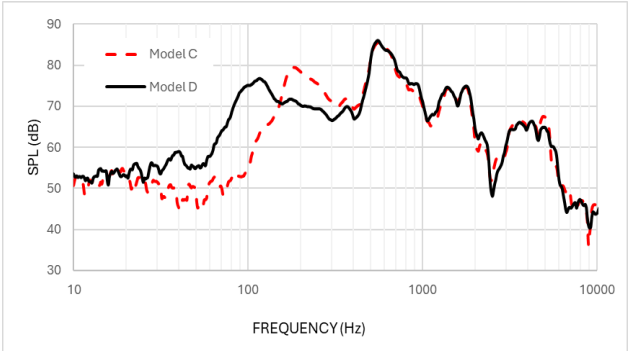

Figure 10. Frequency response at free air

It is possible to verify that the SPL aligns well with the measurements performed with the accelerometer, and verifies the wider response of model D but also the higher efficiency of model C.

5. CONCLUSION

This study has investigated an innovative underwater projector design, inspired by electrodynamic loudspeaker principles, which introduces a novel decoupling mechanism to mitigate hydrostatic pressure effects on the

voice coil at rest. By eliminating direct mechanical coupling between the external diaphragm and the loudspeaker assembly, the proposed configuration demonstrates a marked reduction in static load-induced deformations.

The analysis further reveals that careful optimization of the diaphragm suspension system yields substantial improvements in both frequency response linearity and acoustic sensitivity, while the dimensions of the front and rear cavities exhibit measurable influence on bandwidth behavior, their impact plays a secondary role compared to suspension tuning.

Notably, the striking concordance between experimental measurements and analytical predictions validates the theoretical framework as a robust predictive tool.

The validated model provides a foundation for optimizing similar pressure-resilient projectors, particularly in applications requiring precise acoustic performance in shallow-water environments. Future work should explore the long-term stability of the decoupled assembly under cyclic loading and investigate advanced materials to further enhance sensitivity without compromising structural robustness.

INVESTIGATING SPATIAL ALIASING AND FRESNEL ZONES OF LINE AND PLANAR SOURCES FOR SOUND REINFORCEMENT

Lukas Gölles[1,2*] **Franz Zotter**[1,2]
[1] Institute of Electronic Music and Acoustics, Graz, Austria
[2] University of Music and Performing Arts, Graz, Austria

ABSTRACT

Modern large-scale sound reinforcement systems predominantly utilize line-source arrays and, more recently, planar matrix arrays due to their flexibility in shaping direct sound pressure coverage across the listening area. In these arrays, the received sound pressure level is influenced, not only by the listener's distance, but also by the size of the first Fresnel Zone on the array, particularly around the origin of the earliest wavefront. The size of this zone varies with both frequency and source dimensions, and it can be adjusted through curvature and time delays. However, comb filtering effects inevitably arise, especially at higher frequencies, due to contributions from later Fresnel Zones and the finite size of the array. Additionally, the discrete spacing of drivers in both line and planar sources introduces spatial aliasing. This contribution presents simulations that analyze the impact of Fresnel Zones, driver spacing, and driver arrangements on frequency response and direct sound coverage within the listening area.

Keywords: *line array, planar arrays, spatial aliasing, Fresnel Zones, sound reinforcement*

1. INTRODUCTION

The field of sound reinforcement is fundamentally concerned with the precise reproduction, control, and propagation of sound waves to ensure optimal audio quality and spatial fidelity. Line-source arrays have long been the standard for large-scale sound reinforcement systems, but more recently, planar arrays have also gained prominence. In this context, spatial aliasing and Fresnel Zones play an essential role in shaping the performance of sound systems. These phenomena are central to the design and operation of modern sound reinforcement systems and present significant challenges that must be addressed to guarantee high-fidelity audio reproduction across diverse environments, ranging from concert halls to outdoor venues.
Fresnel Zones, derived from wave interference theory, define regions of constructive and destructive interference that arise as sound waves propagate from a linear or planar source to a receiver. These zones are particularly relevant in large-scale sound reinforcement, where the interaction of wavefronts over extended distances can result in variations in sound pressure levels and phase coherence. The concept of Fresnel Zones, initially developed in optical theory to describe the diffraction of light waves [1], has proven to be an invaluable tool in acoustics for understanding how sound waves interact with physical obstacles and how these interactions influence perceived sound quality. Notably, Kuttruff's work [2] underscores the importance of Fresnel Zones in room acoustics, emphasizing their role in shaping the spatial distribution of sound energy and the clarity of audio signals. In sound reinforcement systems, effective consideration of Fresnel Zones is critical for minimizing interference effects and ensuring uniform coverage, especially in line and planar array configurations.
Spatial aliasing, in contrast, occurs when the spatial sampling of sound sources is inadequate to excite the wave field with sufficient continuity. This issue is particularly prominent in line and planar sound sources, where the discrete arrangement of transducers can introduce artifacts and distortions in the reproduced sound. Berkhout et al. [3] provide a foundational understanding of spatial aliasing in array-based sound systems, demonstrating how

transducer spacing and the frequency content of sound signals contribute to aliasing phenomena. Line arrays, composed of multiple closely spaced transducers arranged in a vertical configuration, are widely used in sound reinforcement for their ability to provide controlled directivity and extended range. However, the discrete nature of line arrays makes them vulnerable to spatial aliasing, particularly at higher frequencies. Heil et al. and Urban et al. offer valuable insights into the properties of arrays composed by multiple sources and outline five essential criteria that line arrays must satisfy [4, 5]. Planar arrays, which extend line arrays into two dimensions, encounter similar challenges, albeit with greater complexity due to the increased number of transducers and the multidimensional nature of wave propagation.

This paper explores the effects of Fresnel Zones and spatial aliasing in the context of linear and planar sound sources, focusing on their implications for sound reinforcement systems. The goal is to offer a comprehensive understanding of the challenges they present and the strategies available to mitigate their impact on the listening area. Through a combination of theoretical analysis and numerical simulations, we will demonstrate how optimizing transducer spacing, array geometry, and signal processing algorithms can enhance sound quality and spatial fidelity in practical applications.

2. PHASED LINE SOURCE

2.1 Line Source Phasing

Recently, a theory for line array curving and phasing has been introduced [6], presenting a nonlinear differential equation for the total inclination $\vartheta_\mathrm{T} = a\,\vartheta + (1-a)\,\vartheta_\mathrm{w}$ which is linearly decomposed into a curving component ϑ and a phasing/beamforming component ϑ_w,

$$\dot{\vartheta}_\mathrm{T} = -\frac{r^{2\,\beta}}{g^2}\,\frac{1}{r^2\,\cos\vartheta_\mathrm{w}} + \frac{\cos\vartheta_\mathrm{w}}{r}\,, \qquad \text{with } r = \frac{z}{\sin\vartheta_\mathrm{T}}\,. \tag{1}$$

Here, r represents the distance between the source and receiver, and z is the current z-coordinate of the source when solving the differential equation stepwise. The parameter g determines the radius of curvature at the highest point, while β is a design parameter controlling the direct sound level roll-off, resulting in a decay of $-6\cdot\beta$ dB per distance doubling (dod) across the listening area. Using the Frenet-Serret formulas, which describe arbitrary spatial trajectories, the tangent at any point on the curved line source is given by $\boldsymbol{t} = \begin{bmatrix}\sin\vartheta & 0 & \cos\vartheta\end{bmatrix}^\mathsf{T}$. The geometry of the source is then computed by integrating along the natural source length parameter,

$$\boldsymbol{x}(s) = \int_0^S \boldsymbol{t}\,\mathrm{d}s + \boldsymbol{x}_0 \qquad \boldsymbol{x}_0 = \begin{bmatrix}0 & 0 & z_0\end{bmatrix}^\mathsf{T}\,, \tag{2}$$

where z_0 defines the mounting height of the line source. The delay introduced along the curve acts as a progressive delay and summing beamformer, with the delay length determined by integrating over the sine,

$$w = -\int_0^S \sin\vartheta_\mathrm{w}\,\mathrm{d}s\,. \tag{3}$$

It has been shown, that this formalism is directly applicable to line-array curvature design after discretization [7]. Furthermore, for optimal frequency homogeneity across distance and a balanced trade-off between preserving the mixing balance and enhancing envelopment in immersive sound reinforcement at off-center listening positions, it is recommended to use line sources with a direct sound level decay of -1.5 dB/dod [8]. Accordingly, the simulations in this study are conducted for sources exhibiting this specific decay characteristic.

2.2 Simulation Procedure

We consider a mid-scale sound reinforcement scenario. To align with the results presented in [6], we employ a linear arrangement of the line array prototype [9] consisting of 12 elements.

The continuous line source contour, along with the phasing profile,cf. Eq. (1), (2), and (3), is computed through numerical simulation, following Algorithm 1 in [6]. The simulation parameters are set as follows: $x_{r,0} = 10\,\mathrm{m}$, $z_0 = 2\,\mathrm{m}$, $g = 0.4093$, and $\beta = 0.25$. The phasing profile is discretized based on the element height of the line array prototype, which measures $8.2\,\mathrm{cm}$ [9].

To simulate a piston-shaped driver, we employ a circular arrangement of ideal point sources positioned at $1\,\mathrm{mm}$ intervals. Each source is described using Green's function, with a total diameter of $6.35\,\mathrm{cm}$ (2.5 inches). A Gaussian filter is applied as an amplitude kernel to each element, under the assumption that the driver's edge contributes less to radiation than its center,

$$K[m,n] = \left[e^{-\frac{m^2+n^2}{2\,\sigma^2}}\right]^5\,. \tag{4}$$

Here, σ^2 represents the standard deviation, defining the width of the Gaussian kernel, and is set to $\sigma = 0.83$.

The exponent of five is chosen based on simulation results from [6, 10], as there the results of the measurement match well to the simulation using the prototype array of [9].
For equalization, a filter is applied whose magnitude increases by 3 dB per octave up to the spatial aliasing frequency, compensating for the pink frequency response characteristic of a line source composed of ideal point sources, as described in [6].
At each observation point, the sound pressure is evaluated over a frequency range from 20 Hz to 24 kHz with a linear resolution of 512 points. To visualize the coverage as a broadband result, the frequency responses are third-octave smoothed, followed by A-weighting before summation.

2.3 Spatial Aliasing

Fig. 1 presents the simulated frequency responses of discrete line sources composed of 12 elements. Due to the driver spacing of 8.2 cm, spatial aliasing is expected to occur at approximately $f_{\mathrm{spat.al}} \approx 4.2\,\mathrm{kHz}$ which is clearly reflected in the graphs.
The impact of spatial aliasing can potentially be mitigated through the use of waveguides, f.e. DOSC (Diffuseur d'onde sonor cylindrique [11]), HRW (Hyperbolic Reflective Waveguide [12]), or multi-driver systems. A key advantage of a multiway system incorporating smaller drivers for high frequencies is, that the required curvature of the outlet for near-field sound reinforcement can be more effectively achieved due to the closer spacing of the drivers.
Fig. 2 illustrates the simulated on-axis frequency responses at various distances for a two-way system. In this setup, 2.5-inch drivers spaced at 8.2 cm intervals are used for the lower frequencies, while 1-inch drivers positioned at 2.9 cm intervals handle the higher frequencies. The crossover frequency is set at 2 kHz, and each filter (high-pass and low-pass) is a 4th-order Butterworth filter with a cutoff frequency at 2 kHz. Notably, the two-way system increases the spatial aliasing frequency to approximately 14 kHz due to the reduced driver spacing.

2.4 Fresnel Zones

Figures 3 and 4 illustrate the sizes of the various Fresnel Zones for a discrete line source with 12 elements at the observation points $\boldsymbol{x}_\mathrm{r} = \begin{bmatrix}1 & 0 & 0\end{bmatrix}^\mathsf{T}$ and $\boldsymbol{x}_\mathrm{r} = \begin{bmatrix}2 & 0 & 0\end{bmatrix}^\mathsf{T}$. The regions marked in black represent the first Fresnel Zone, which is the most significant. As the zone number increases, the regions become progressively brighter. For clarity, only the first five Fresnel Zones are depicted.

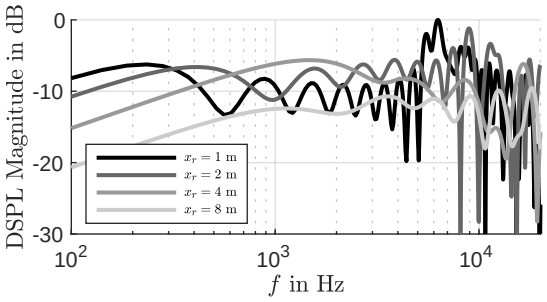

Figure 1. On-axis frequency responses of a 12-element discrete line array at different distances to the source.

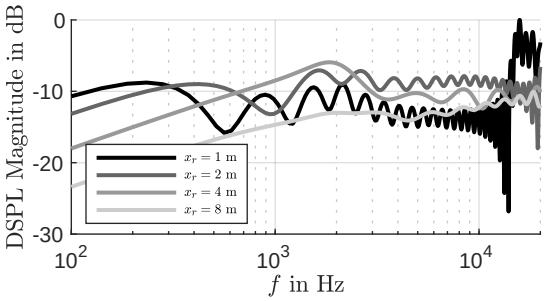

Figure 2. On-axis frequency responses of a 12-element discrete line array (two way system) at different distances to the source.

At both observation points, the Fresnel Zones exhibit asymmetry. At $x_\mathrm{r} = 1\,\mathrm{m}$, the second Fresnel Zone becomes evident at 500 Hz, contributing to the first notch in the frequency response, as shown in Fig. 1. As the frequency increases, the Fresnel Zone diminishes in size, resulting in comb filtering effects in the frequency response. At $x_\mathrm{r} = 2\,\mathrm{m}$, the entire source lies within the first Fresnel Zone. The size of the first Fresnel Zone at 1 kHz at $x_\mathrm{r} = 2\,\mathrm{m}$ is comparable to that at 500 Hz for $x_\mathrm{r} = 1\,\mathrm{m}$. This causes a shift in the first notch to approximately 1 kHz, resulting in an additional comb filter pattern.
Tapering, a well known technique from phased antenna theory [13] and also known as shading in the theory of constant-beamwidth transducer in acoustics [14], can be applied to the array to mitigate the effects of comb filtering. Fig. 5 presents the on-axis frequency responses at different distances of the dual-driver array, consisting of 12 low-frequency drivers and 33 high-frequency drivers, with amplitude tapering applied. For amplitude tapering,

we used a Hann window

$$a[n] = \frac{1}{2}\left(1 - \cos\frac{2\,\pi\,n}{M-1}\right)\,, \tag{5}$$

where the window length M is chosen such that the outermost element is attenuated by 10 dB. This condition is expressed as $a\left[\frac{(M+1)}{2} - \frac{N}{2}\right] = 10^{\frac{-10}{20}}$, where N denotes the number of array elements. By rearranging Eq. (5), the required parameter M is determined

$$M = \mathrm{rd}\left\{\frac{\pi\,(N+1) - \arccos\left(1 - 2\cdot 10^{\frac{-10}{20}}\right)}{\pi - \arccos\left(1 - 2\cdot 10^{\frac{-10}{20}}\right)}\right\}\,. \tag{6}$$

Subsequently, only the symmetric section centered around the peak of the window function is utilized, ensuring it aligns with the number of array elements N. While this tapering results in a noticeable reduction of the notches in the frequency response, it also limits the coverage area, leading to excessively small levels at close observation points, as seen in Fig. 7.
To increase coverage (with $g = 0.38$) while maintaining tapering such that the closest desired observation point is closer to the source, i.e., $x_r = -0.14\,\mathrm{m}$, frequency responses similar to those in Fig. 5 are achieved, c.f. Fig. 6. Additionally, the A-weighted sum of the direct sound level over the distance is comparable to the setup without tapering, as shown in Fig. 7.

3. PHASED PLANAR SOURCES

3.1 Planar Source Phasing

The formalism introduced in [6] has been extended to planar arrays in [10] by introducing a horizontal spread parameter a and a lateral distance range parameter b as design parameters in addition to g and β. Since implementing a two-dimensional curved source is challenging, the proposed method relies on flat planar sources, where delays are used to achieve the desired $-6\cdot\beta$ dB/dod in the listening area. The formalism employs a set of three differential equations to calculate the delay length $w = c\cdot\tau$, where c represents the speed of sound and τ denotes the equivalent delay:

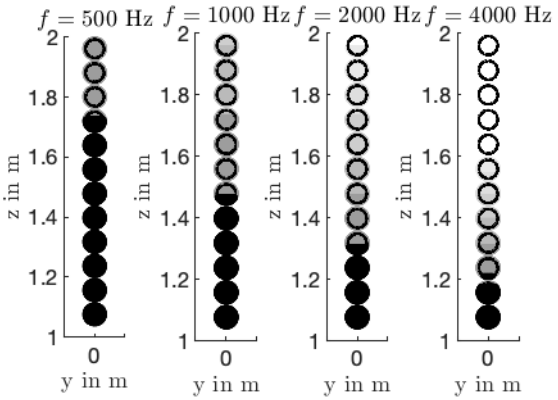

Figure 3. Fresnel Zones (1st=black) on the source at observation point at $x_\mathrm{r} = 1\,\mathrm{m}$ for different frequencies.

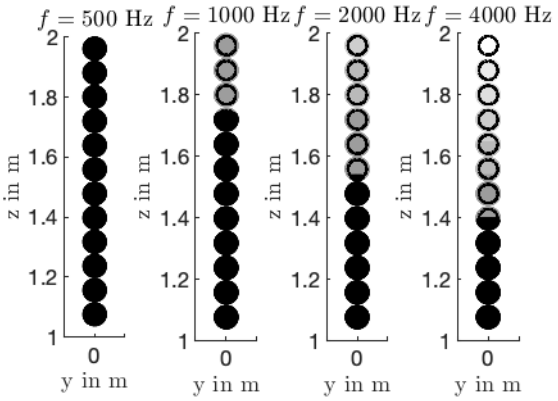

Figure 4. Fresnel Zones on the source at observation point at $x_\mathrm{r} = 2\,\mathrm{m}$ for different frequencies.

$$\frac{\partial^2 w}{\partial h^2} = a + \frac{1}{r}\left(\frac{\partial w}{\partial h}\right)^2 \tag{7}$$

$$\frac{\partial^2 w}{\partial h\,\partial v} = b + \frac{1}{r}\frac{\partial w}{\partial h}\frac{\partial w}{\partial v} \tag{8}$$

$$\frac{\partial^2 w}{\partial v^2} = \frac{1}{r}\left[\frac{g^{-2}\,r^{2\beta} + r^2\,b^2}{1 + r\,a} + \left(\frac{\partial w}{\partial v}\right)^2 - 1\right] \tag{9}$$

$$\text{with } r = \frac{v\,\cos\eta + z_0}{-\frac{\partial w}{\partial v}\,\cos\eta + \sin\eta\,\sqrt{1 - \left(\frac{\partial w}{\partial h}\right)^2 - \left(\frac{\partial w}{\partial v}\right)^2}}\,.$$

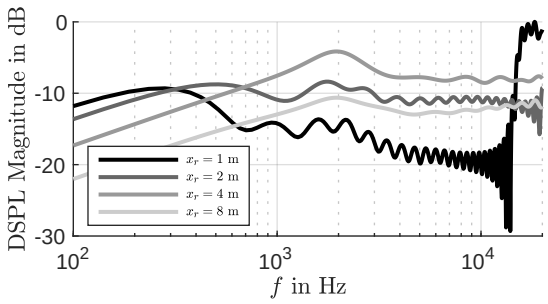

Figure 5. On-axis frequency responses of a 12-element discrete line array (two way system) at different distances to the source with applied tapering.

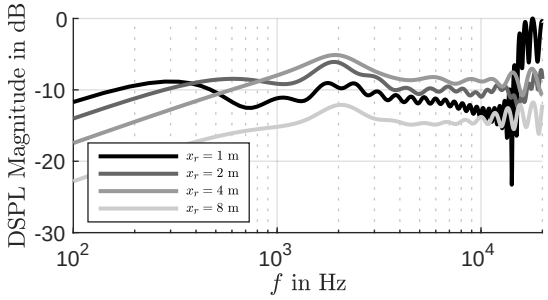

Figure 6. On-axis frequency responses of a 12-element discrete line array (two way system) at different distances to the source with applied tapering and modified coverage.

Here, η denotes the inclination of the planar source, v defines the source length in the vertical direction (i.e., $v \in [0, -V]$), and h represents the width in the horizontal direction ($h \in \left[-\frac{H}{2}, \frac{H}{2}\right]$). z_0 is the mounting height of the planar source, which corresponds to the distance between the highest point of the source and the listening area (assumed to be on the x-y plane). The geometry of the planar source is described using the unit vectors $\boldsymbol{e}_\mathrm{h} = \begin{bmatrix}0 & 1 & 0\end{bmatrix}^\mathsf{T}$ and $\boldsymbol{e}_\mathrm{v} = \begin{bmatrix}\sin\eta & 0 & \cos\eta\end{bmatrix}^\mathsf{T}$,

$$\boldsymbol{x}_\mathrm{s} = \boldsymbol{x}_0 + h\,\boldsymbol{e}_\mathrm{h} + v\,\boldsymbol{e}_\mathrm{v} \qquad \text{with } \boldsymbol{x}_0 = \begin{bmatrix}0 & 0 & z_0\end{bmatrix}^\mathsf{T}. \tag{10}$$

3.2 Simulation Procedure

To make the results from both sources comparable, a planar source with 9×10 elements of size $8.2\,\mathrm{cm} \times 8.2\,\mathrm{cm}$ is chosen. The differential equations (7), (8), and (9) are solved numerically, following Algorithm 3 from [10], using the parameters $x_{\mathrm{z},0} = 10\,\mathrm{m}$, $z_0 = 2\,\mathrm{m}$, $\eta = 11.3°$, $\beta = 0.25$, $g = 0.2492$, $a = 1.9684$, and $b = 0.3902$. The parameters a and b control the coverage width, while η defines the total inclination of the source. In this case, an outermost observation point at $\boldsymbol{x}_\mathrm{r} = \begin{bmatrix}5 & 5 & 0\end{bmatrix}^\mathsf{T}$ is targeted. The values of a and b are derived from a fixed-point iteration as described in Algorithm 1 of [10]. Subsequently, the phasing profile is discretized as proposed in [10].
The individual elements are simulated in the same manner as the linear sources described earlier.

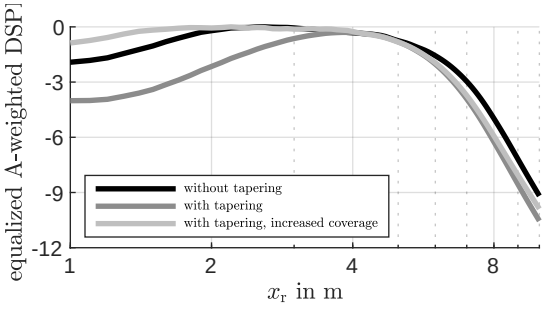

Figure 7. Equalized A-weighted direct sound level in ox-axis direction.

3.3 Spatial Aliasing

Spatial aliasing presents challenges similar to those encountered with linear sources. The top panel of Fig. 8 displays the frequency responses at various observation points. However, for practical reasons, employing an array with smaller, more densely spaced drivers is not a viable solution, as smaller drivers are generally less effective at reproducing lower frequencies. Additionally, a two-way system with an auxiliary array of smaller, denser drivers positioned in front of the main array is not feasible, as it would adversely affect the radiation of lower frequencies. A possible approach to mitigate spatial aliasing effects, at least along the depth dimension, involves placing a vertical array of smaller, densely packed drivers in front of each vertical loudspeaker line. Fig. 8 compares the frequency responses of an array using 2.5 inch drivers across the entire frequency range to an alternative array that employs 2.5 inch drivers for lower frequencies and 1 inch drivers for higher frequencies. The crossover frequency is set at 2 kHz, with each filter (high-pass and low-

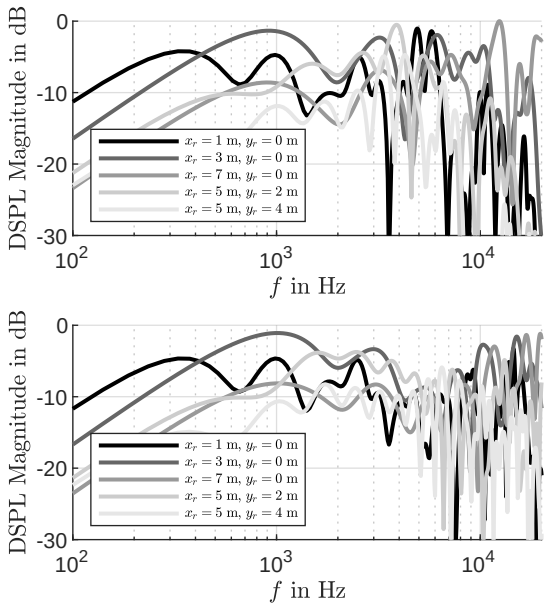

Figure 8. Comparing the frequency responses of a planar array as one-way system (top) and a two-way system (bottom) at different observation points that lie within the desired coverage region.

pass) implemented as a 4th-order Butterworth filter with a cutoff frequency of 2 kHz. Notable improvements in the frequency response are observed in the range of 3 kHz to 6 kHz. However, spatial aliasing at high frequencies remains unavoidable.

3.4 Fresnel Zones

Figures 9 and 10 depict the Fresnel Zones on the planar source at various frequencies for two different observation points. As with the line sources, it is observed that nearly the entire source lies within the first Fresnel Zone at 1 kHz for both observation points. For other frequencies, the size and shape of the Fresnel Zones vary with distance. The observed discontinuities in the zones arise from the fact that the phase profile of an element has been discretized, and the Fresnel Zone is calculated for multiple points on the driver. Consequently, only part of the driver falls within one Fresnel Zone, while the remainder belongs to the next higher Fresnel Zone.
As previously conducted for line sources, tapering is applied to mitigate the effects of comb filtering. The top panel of Fig. 11 illustrates the frequency responses at various observation points for the phased planar source without tapering. The center panel presents the corresponding results after tapering is applied. The same window function as for line sources was selected for tapering, but the outermost elements were attenuated only by 6 dB in both

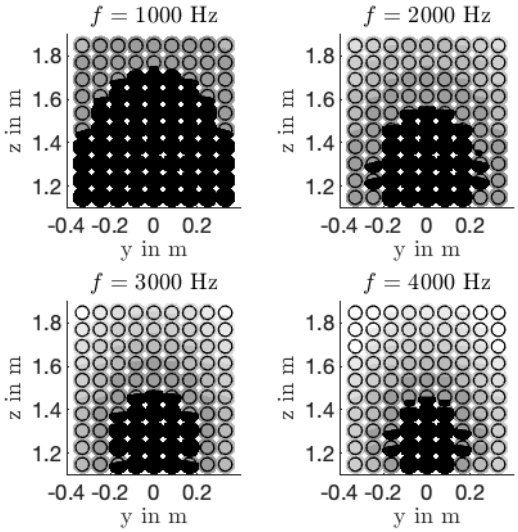

Figure 9. Fresnel Zones on the source at observation point at $\boldsymbol{x}_\mathrm{r} = \begin{bmatrix} 2 & 0 & 0 \end{bmatrix}^\mathsf{T}$ for different frequencies.

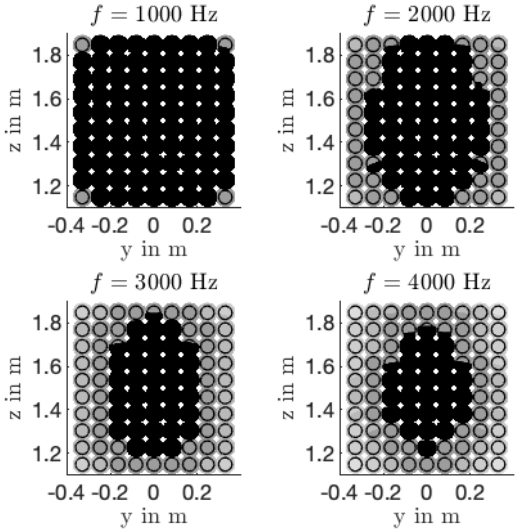

Figure 10. Fresnel Zones on the source at observation point at $\boldsymbol{x}_\mathrm{r} = \begin{bmatrix} 4 & 0 & 0 \end{bmatrix}^\mathsf{T}$ for different frequencies.

the horizontal and vertical directions.
Similar to line sources, the implementation of tapering enhances the frequency response below the aliasing frequency but simultaneously reduces the coverage area, comparing the top and center panels of Fig. 12. To address this limitation, the coverage can be strategically designed for a broader region by adjusting the parameters defining the horizontal coverage to $a = 2.295$ and $b = 0.2919$, thereby targeting an outermost observation point at $\boldsymbol{x}_\mathrm{r} = \begin{bmatrix}5 & 8 & 0\end{bmatrix}^\mathsf{T}$. Additionally, the nearest observation point is repositioned to $x_\mathrm{r} = 0.22\,\mathrm{m}$. A comparison of the results indicates that the coverage achieved with these modifications is comparable to that of the untapered source, cf. Fig. 12. The frequency response characteristics of the tapered source exhibit noticeable improvements, cf. Fig. 11.

4. CONCLUSION

This contribution investigated the effects of spatial aliasing and Fresnel Zones for both line and planar sources in sound reinforcement systems. To improve the frequency responses, tapering can be applied; however, this comes with the trade-off of restricting the coverage area. It was demonstrated that designing for an extended area yields similar results in terms of the covered region when compared to the source without tapering, but with the added improvements in the frequency response achieved through the application of tapering.
Further research should focus on measuring the prototype array and comparing the simulation results with practical applications. Additionally, the impact of individual filtering of the array enclosure should be explored to determine whether further improvements in coverage and frequency homogeneity over distance can be achieved.

A SIMULATION FRAMEWORK FOR PIEZOELECTRIC MEMS SPEAKERS: MODELING, INTEGRATION, AND VALIDATION

Fabian Bachl[1*] **Samu Horváth**[1]
[1] USound GmbH, Gutheil-Schoder-Gasse 8-12, Vienna, Austria

ABSTRACT

We present a simulation framework for piezoelectric, cantilever based Micro-Electro-Mechanical-Systems (MEMS) Speakers. Contrary to electrodynamic speakers, those speakers present a capacitive electrical load, necessitating a modified modeling approach.

Using measurements from a Laser-Doppler-Vibrometer (LDV) we determine a set of parameters derived from the well known Thiele-Small-Parameters (TSP) using the Known Mass Method.

The acoustic load on the back of the membrane is strongly influenced by the cavity structure within the speaker. We use Finite-Element-Analysis (FEA) to calculate the acoustic impedance acting on the membrane back side. A lumped element representation of this impedance is included in the full model.

We present the integration of a MEMS speaker into an earphone design using a simulation driven approach based on the previously described model.

The acoustic effects of the enclosure, as well as the artificial ear are simulated using the finite element method. The results are validated against acoustic measurements of a 3D printed version of the earphone. We show that the models can accurately predict the frequency response of the MEMS speakers, also under complex acoustic load conditions.

1. INTRODUCTION

1.1 Piezoelectric MEMS Speakers

Cantilever based piezoelectric Micro-Electro-Mechanical-Systems (MEMS) Speakers are transducer elements utilizing the force provided by the inverse piezoelectric effect to actuate a moving surface, leading to the radiation of sound. There are two distinct approaches. While some designs use the surface of the piezoelectric MEMS device itself [1], our work concerns itself with designs that utilize an additional membrane component that is connected mechanically to the piezoelectric cantilever element.

Figure 1 shows a cross cut through such a MEMS speaker. The acoustically active area (membrane) is shown in yellow. The MEMS device is shown in light gray. The two elements are mechanically connected to each other.

The MEMS device is the active motor unit of the

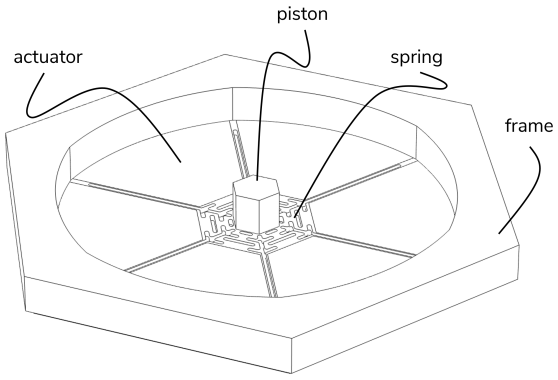

Figure 2. Architecture of the MEMS device

speaker. It consists of four main structural building blocks. (Figure 2)

The frame supports the MEMS device and provides mechanical and electrical connection towards the base of the speaker assembly.

The actuators are piezoelectric cantilevers that provide the driving force. The composite layer stack of the actuators consists of the electrodes, the active piezoelectric layer and the passive structural layer. Due to the inverse piezoelectric effect, applying a voltage at the electrodes across the active layer leads to a deformation, this results in a bending motion of the cantilever. Moving the central region of the device upward and downward where the piston and springs couple the movement to the membrane element of the speaker.

The active piezoelectric layer is made from Lead zirconate titanate (PZT), specifically, epitaxial PZT with highly ordered crystal structure, providing self-poling and high linearity. [2] The passive structural layer is a polymeric film. It provides a large elastic reserve for the structure, which is especially crucial for the device to withstand not only normal operation but also extreme events such as drops while handling.

Generally, there are many similarities between this type of piezoelectric MEMS speakers and "traditional" electrodynamic (micro-)speakers. While the motor principle is fundamentally different, both rely on a moving membrane, the movement of which can be described by a single degree-of-freedom oscillator. This is why a slightly modified version of the Thiele-Small Model [3,4] can also be used for piezoelectric MEMS speakers.

The difference is in the transformation between the electrical domain and the mechanical domain. While the force output of an electromagnetic motor is proportional to the current flow through the voice coil, the force output from a piezoelectric element is proportional to voltage. [5]

1.2 TSP Measurement

Traditional parameter measurement involves adding a known mass or enclosing the speaker in a small, known, volume, both altering the resonance frequency. The change in resonance frequency is then used to conclude the values of the TSP [6]. Since resonance appears as a clearly visible peak in electrical impedance, commercial systems typically use impedance measurements for both methods.

However, the usage of this approach is limited for piezoelectric MEMS speakers due to two factors. First, their impedance is predominantly capacitive. Figure 3 shows the difference to the impedance of an electrodynamic (ED) speaker. Common algorithms are designed for ED speaker impedance profiles. Making them incompatible with the capacitive impedance of piezoelectric MEMS devices.

Secondly, the very small internal dimensions of piezoelectric MEMS speakers (as shown in Figure 1) have a significant influence on the acoustic speaker performance. These internal cavities act as acoustic impedance, influencing all moving surfaces within the speaker, and therefore the speaker's movement.

1.3 Ear Simulators

Ear simulators, or couplers, play a crucial role in the accurate and standardized assessment of auditory devices by mimicking the acoustic impedance of the human ear. The IEC 60318 series defines various coupler types, among which the occluded ear simulator specified in IEC 60318-4 is the most widely used in earphone design. However, its specification is limited to the 100 Hz to 10 kHz frequency range.

The RA0403 (GRAS Sound Vibration A/S, Holte, Denmark) is compatible with the IEC 60318-4 standard but includes design modifications that extend its operational frequency range up to 50 kHz. [7]

2. METHODS

2.1 Model Structure

The piezoelectric MEMS speaker is modeled as a damped mass spring resonator with one degree of freedom. This corresponds to the membrane moving as a piston. All

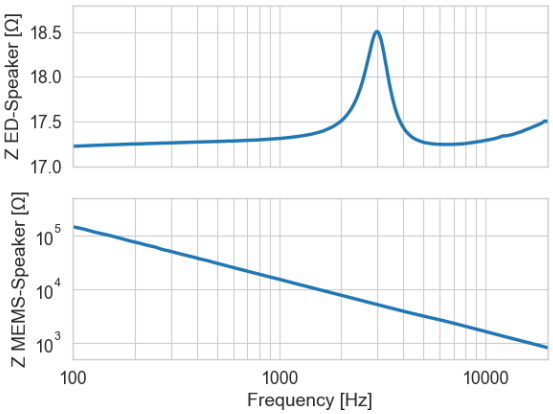

Figure 3. Comparison between the typical impedance curve of a electrodynamic (ED) speaker (RB-E06016F-007R) and a piezoelectric MEMS speaker (USound UA-C0503-3T)

higher order modes, like membrane deformation, are not considered.

The response of a dampened mass-spring resonator is given by the equation of motion. (1)

$$F_p = M_{ms}\frac{d^2x}{dt^2} + R_{ms}\frac{dx}{dt} + K_{ms}x \tag{1}$$

Expressing the frequency response

$$\begin{aligned} x = A\frac{1-T^2}{(1-T^2)^2+(2\zeta T)^2} \\ +jA\frac{2\zeta T}{(1-T^2)^2+(2\zeta T)^2} \end{aligned} \tag{2}$$

where A is the deflection per voltage, T is the tuning and ζ is the damping ratio.

$$T = \frac{2f\pi}{\omega_0} \tag{3}$$

$$\omega_0 = \sqrt{\frac{K_{ms}}{M_{ms}}} \tag{4}$$

$$\zeta = \frac{R_{ms}}{2\sqrt{K_{ms}M_{ms}}} \tag{5}$$

$$a = x \cdot (2j\pi f)^2 \tag{6}$$

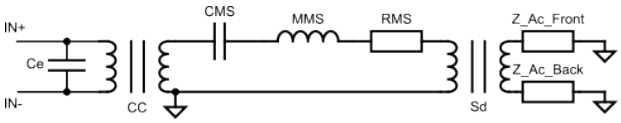

Figure 4. The basic equivalent circuit used to describe the MEMS speaker. $C_{MS} = {}^1/_{K_{MS}}$

The model is represented using and lumped parameters with the equivalent circuit shown in Figure 4. We use the Force-Voltage (FU) analogy for the mechanical domain. As the force provided by the MEMS device is directly proportional to the voltage applied, the effort variable voltage in the electrical domain is directly transformed into the effort variable force in the mechanical domain.

To model this relation a parameter referred to as the Coupling Constant (CC) is introduced. It replaces the Force Factor (B_L) typically used in loudspeaker models. The Coupling Constant is given in ᴺ/ᵥ.

$$A = \frac{CC}{K_{ms}} \tag{7}$$

Allowing the use of a ideal transformer to interface the two domains in the equivalent circuit. The mechanical spring stiffness K_{ms} is represented by its inverse, the compliance C_{ms}

The full model and any Finite-Element-Analysis (FEA) is set up and solved in COMSOL Multiphysics 6.3 (COMSOL Inc. Stockholm, Sweden). We use the lumped electrical circuit physics interface to model the mechanical and electrical domains of the lumped representation. Acoustical simulations are done using FEA.

As with the majority of other transducer principles, the piezoelectric MEMS speaker in question (USound UA-C0504-3T) features an active area (membrane) that is moved to create acoustic pressure. The membrane separates the acoustic front from the acoustic back. An acoustic impedance acts on both sides. The impedance on the front (Z_Ac_Front) is dominated by the ear simulator and the earphone. But, the acoustic impedance on the back (Z_Ac_Back) mainly arises in the small air cavities within the speaker. (Assuming a reasonably open ventilation towards the back)

We calculate Z_Ac_Back using FEA. A 3D representation of the cavity within the speaker is created based on technical drawings. ⅙ of the speaker is used for the sim-

ulation as it is rotationally symmetric and this makes the model computationally less expensive. Due to the small structure sizes found inside the speaker, the calculations are done in the "Thermoviscous Acoustics, Frequency Domain Interface" of the COMSOL Acoustics Module. This interface calculates the viscous and thermal losses occurring in close vicinity to the boundaries. [8]

The external back volume of the speaker is assumed to be infinitely big. In this model, the membrane is moved with a constant velocity for each frequency point. This allows the calculation of the acoustical impedance by evaluating the acoustic pressure on the membrane surface.

$$Z = \frac{p}{q} \tag{8}$$

Where p is the average acoustic pressure at the active area ("membrane") and q is the volume flow rate. This is equal to the integral of the mechanical velocity over the active area. The calculated impedance is a complex valued function of frequency. Discrete frequency points are exported.

The frequency points are then included for "Z_Ac_Back" as seen in Figure 4. As described before, this circuit is implemented in the COMSOL model. "Z_Ac_Back" is integrated as a "User Defined" impedance in the Lumped Speaker Boundary Condition. "Z_Ac_Front" however is dependent on the acoustical load from the ear(-simulator) and the coupler adapter/earphone.

2.2 Added Mass Method

The TSP are typically measured in free air, where results are affected by acoustic impedance. To eliminate these external acoustic influences and accurately determine the intrinsic mechanical parameters of the speaker assembly, measurements were carried out in a vacuum using a Laser-Doppler-Vibrometer (LDV) (PSV 500, Polytec GmbH, Waldbronn, Germany). The vacuum environment effectively isolates the system from acoustic loading, allowing for the characterization of its purely mechanical behavior.

Equation 1 to 6 describe the frequency response function of a dampened mass spring resonator. The least_squares function of Scipy v1.15.2 is used to determine a set of parameters that satisfactorily describe the loaded and unloaded cases.

2.2.1 *Known Mass*

We cut circular pieces of adhesive copper tape. The pieces used had a mass of 2.5 mg each. The front cover was removed from the speakers to reveal the whole membrane. The speakers were then measured under vacuum ($< 8.7 \cdot 10^{-2} hPa$), so as to remove effectively all influences from the air load (unloaded case). The copper pieces were attached, as shown in Figure 6, and the measurements were repeated within the same conditions (loaded case).

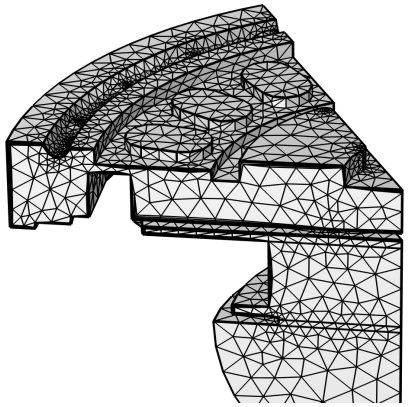

Figure 5. Mesh used to calculate the acoustic impedance of the volume within the speaker packaging

2.3 Acoustic Validation

The predictive quality of the model is validated acoustically by comparing the output to measurements of two scenarios. We use a 1.8 mm long coupler adapter with a diameter of 3 mm to connect the speakers acoustic output to the coupler input. The coupler is used without the conical earmould adapter.

Also, the speaker model is compared to the speaker performance within an earphone prototype. The earphone in question is shown in Figure 7. The piezoelectric MEMS speaker is used as a tweeter. Hence, the design features space for the integration of a ring-shaped electrodynamic woofer, which is outside the scope of this paper. A detailed description of the earphone is provided in [9].

We use a RA0403 (GRAS Sound & Vibration A/S, Holte, Denmark) "High-Resolution" ear simulator to do all reference measurements. The ear simulator is represented in the model by a slightly modified version of the "generic_711_coupler" available in the COMSOL appli-

Figure 6. A circular piece of copper tape is attached to the speaker membrane. Increasing the moving mass by 2.5 mg

cation library. An acoustic impedance of $9000^{Pas}/_{m^2}$ is added to the central, tube shaped, volume of the coupler. Figure 8 shows the alignment of this model and the calibration data provided by the manufacturer.

3. RESULTS

3.1 TSP Measurement

The TSP are calculated with a least squares fit of Equation 2, to both the loaded and unloaded cases. Figure 9 shows the alignment of the fit to the acceleration measured using LDV.

From fitting Equation 6 to the measurement data we can extract the modified TSP, resulting in the values shown in Table 1.

Table 1. The calculated modified TSP

Parameter	Value
M_{ms}	$1.57mg$
K_{ms}	$1.86 \cdot 10^{3N}/_{m}$
R_{ms}	$4.2 \cdot 10^{-3Ns}/_{m}$
CC	$818 \cdot 10^{-6N}/_{V}$

3.2 Acoustic Measurements

The simulation model is compared with the acoustical test results gathered in a G.R.A.S RA0403/04 ”Hi-Res” Ear Simulator. The comparative plot is shown in Figure 10. The deviation up to 20 kHz is below $\pm 1\,dB$.

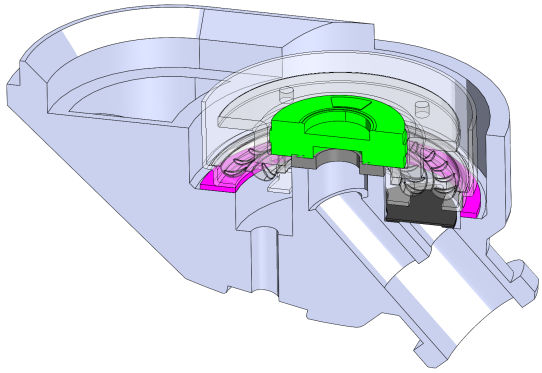

Figure 7. Cross cut of the earphone Design used for model validation. The piezoelectric MEMS speaker is shown in green. The woofer is shown in transparent gray. The silicone rubber eartip is not shown.

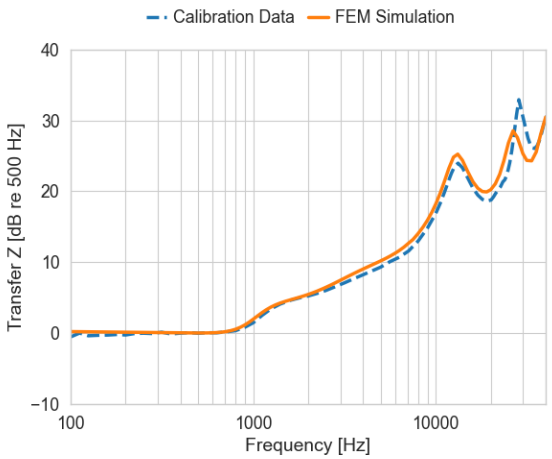

Figure 8. Relative transfer impedance of the used FEM Model of the G.R.A.S RA0403 ”Hi-Res” Ear Simulator and the corresponding calibration data provided by the manufacturer

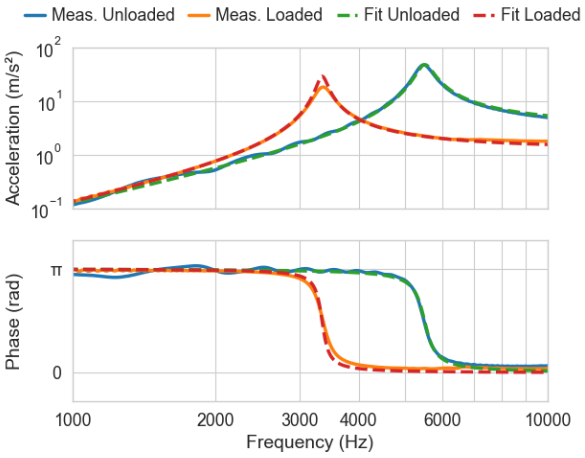

Figure 9. Result of the least squares fit in comparison with the LDV measurement results. The loaded case has a lower resonance frequency.

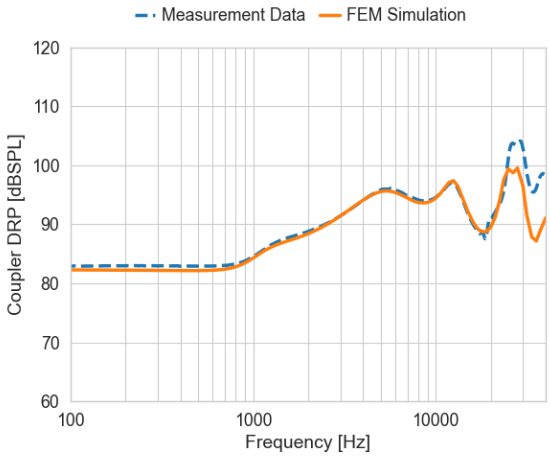

Figure 10. Comparison between the simulation result and the measured performance of the piezoelectric MEMS speaker in the G.R.A.S RA0403/04 "Hi-Res" Ear Simulator. With two different adapter systems

Above the audible range, the deviation increases continuously. Showing the limit of the single degree-of-freedom approach.

In addition, speakers are evaluated in an application-focused way using a previously developed earphone design. The predictive performance of the model is shown in Figure 11. Within the audible range, the deviation is below $\pm 1.5\,dB$. The position of the resonances is accurate to $\pm 300\,Hz$

4. DISCUSSION

The simulation framework presented addresses the unique characteristics of piezoelectric Micro-Electro-Mechanical-Systems (MEMS) speakers, particularly their capacitive electrical load, which requires a modified modeling approach compared to traditional electrodynamic speakers. We show the adaption of the Thiele-Small-Parameters (TSP) for these speakers and present a way to measure them using Laser-Doppler-Vibrometer (LDV) measurements under vacuum with the Known Mass Method, effectively eliminating the influence of acoustic impedance. The calculated TSP values appropriately describe the speakers mechanical behavior in the audible frequency range.

The integration of the MEMS speaker model into an earphone design was achieved using a simulation-driven

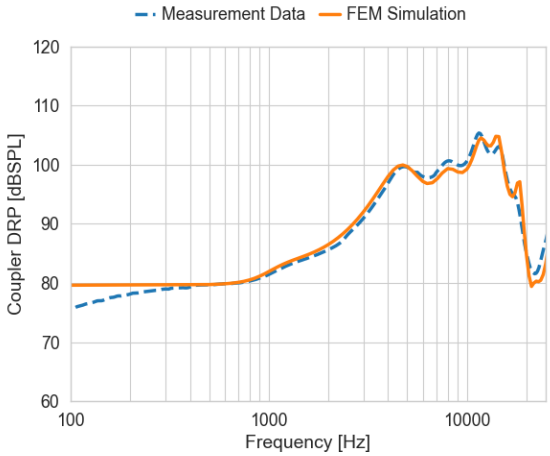

Figure 11. Comparison between the simulation result and the measured performance of the MEMS speaker in the earphone design.

approach incorporating Finite-Element-Analysis (FEA) to model enclosure and artificial ear acoustics. The significant influence of internal acoustic impedance, calculated via FEA of the speaker's cavities, was included in the model.

Acoustic validation demonstrated good agreement between simulation and measurements using a GRAS RA0403/04 "Hi-Res" Ear Simulator and an earphone prototype. Deviations were generally below ±1 dB up to 20 kHz for the ear simulator and below ±1.5 dB within the audible range for the earphone, with accurate resonance prediction. The increased deviation at frequencies above the audible range shows a limitation of the single degree-of-freedom model.

In conclusion, this simulation framework provides a valuable tool for the design and optimization of piezoelectric MEMS speakers and their integration into audio devices by accurately predicting frequency response under various acoustic loads while considering their unique electrical and acoustic characteristics.

Future work could focus on more complex mechanical models. A promising approach would be to go towards lumped representation of a multi degree of freedom model. We would expect this to improve the high-frequency accuracy.

5. ACKNOWLEDGMENTS

We would like to thank our colleagues at USound GmbH for all their previous contributions that went into this paper. Although they are too many to mention individually, we would like to especially thank Paul Heyes for his help with the Laser-Doppler-Vibrometer measurements and Jascha Blinzer for providing the cross sectional view from Figure 1.

ABSTRACT

MEMS loudspeakers for in-ear applications have been attracting a growing interest in recent years, promising to overcome the limits in terms of form factor, power efficiency and cost of non-MEMS loudspeakers. The piezoelectric actuation principle is one of the most investigated, thanks to the introduction of high precision piezoelectric thin films with high electro-mechanical coupling coefficients in the microfabrication processes. This work presents a new set of high-performance piezoelectric MEMS speakers, consisting of PZT-driven thin plates properly shaped through a set of narrow slits. The latter serve the twofold purpose of enhancing the mechanical compliance of the speaker diaphragm and limiting the acoustic short-circuit between the speaker front and rear side. The diaphragm geometry, evolution of a design previously proposed by the Authors, is properly modified to improve the acoustic output and power efficiency. The proposed devices feature a Sound Pressure Level (SPL) at 30 V_{pp} greater than 108 dB SPL in the whole audible range, a Total Harmonic Distortion (THD) at 1 kHz at 94 dB SPL lower than 1% and a compact footprint of 4.5x4.5 mm^2. Experimental results are compared with a FEM-assisted lumped element model demonstrating a good match between them.

1. INTRODUCTION

The integration of loudspeakers into devices such as smartphones, laptops, earphones, and hearing aids underscores their critical role in modern audio technology. The miniaturization of these systems into MEMS loudspeakers offers several advantages, including a compact form factor, low power consumption, and cost-efficient manufacturing, facilitating their widespread adoption in true wireless systems and in-ear applications, where power and space constraints are increasingly stringent.

To date, diaphragm actuation in MEMS loudspeakers can be achieved through electrodynamic (see *e.g.* [1, 2]), electrostatic (see *e.g.* [3, 4]), thermoacoustic (see *e.g.* [5, 6]), or piezoelectric (see *e.g.* [7–10]) forces. Among these, piezoelectric actuation has emerged as the most viable approach due to its ability to generate high driving forces at relatively low voltages. That is due to key technological advancements, including the development of piezoelectric materials with high electromechanical coupling, refined sputtering techniques enabling precise deposition in complex patterns, and the introduction of the mechanically-open and acoustically-closed (MOAC) design concept [8, 11]. This design strategy involves integrating a series of openings into the diaphragm to reduce its mechanical stiffness, thereby allowing for greater displacements. Simultaneously, these openings are designed so that the viscosity of the air within them limits the acoustic short-circuit between the front and rear side of

the MEMS loudspeaker. Piezoelectric MEMS loudspeakers have achieved Sound Pressure Levels (SPL) exceeding 100 dB SPL in all the audible range, starting to close the performance gap with widely adopted non-MEMS loudspeakers. However, their sound pressure output per unit area has not yet reached its full potential.

This work presents a new set of high-performance piezoelectric MEMS speakers, whose diaphragms consists of PZT-driven thin plates separated by narrow slits. The devices were designed with the support of a FEM-assisted lumped element model [12], whose predictions are compared with in-ear acoustic measurements carried out on prototypes fabricated by STMicroelectronics (Cornaredo, Italy).

2. DESIGN CONCEPT

For a single-degree-of-freedom loudspeaker radiating in a cavity, the output pressure can be computed as [8]:

$$\Delta p = \gamma P_0 \frac{\Delta \mathcal{V}}{V_0} = \gamma P_0 \frac{d_{\max} S_{\text{eff}}}{V_0}, \tag{1}$$

where $\Delta\mathcal{V}$ is its volume displacement, given by the product of the speaker maximum displacement $d_{\max}$ and the speaker effective area S_{eff}, while γ is the adiabatic index (equal to 1.4 for dry air at 20 ° C), P_0 the ambient pressure and V_0 the volume of the cavity. The effective area of the speaker is computed as:

$$S_{eff} = \int_{\partial\Omega_f} \mathbf{\Phi} \cdot \boldsymbol{n} \, dS, \tag{2}$$

where $\mathbf{\Phi}$ is the modal shape function, $\partial\Omega_f$ is the surface area of the front side of the speaker and $\boldsymbol{n}$ its outward normal. Consequently, the parameters to address to maximize the speaker's acoustic performance are its maximum displacement and effective area, which are related respectively to the diaphragm mechanic stiffness and its movement type. The first can be reduced by implementing the MOAC design principle while the second can be maximized by encouraging the central part of the membrane to move like a piston. Following these design guidelines led to the diaphragms presented in Fig. 1, where a schematic cross-section of their structure is also given (Fig. 1c). The first design (Fig. 1a) consists of eight trapezoidal plates fabricated from a 13 µm-thick Epi-Poly silicon layer, partially coated with a 2 µm-thick Lead Zirconate Titanate (PZT) layer. These plates are connected to the central region of the MEMS loudspeaker through a

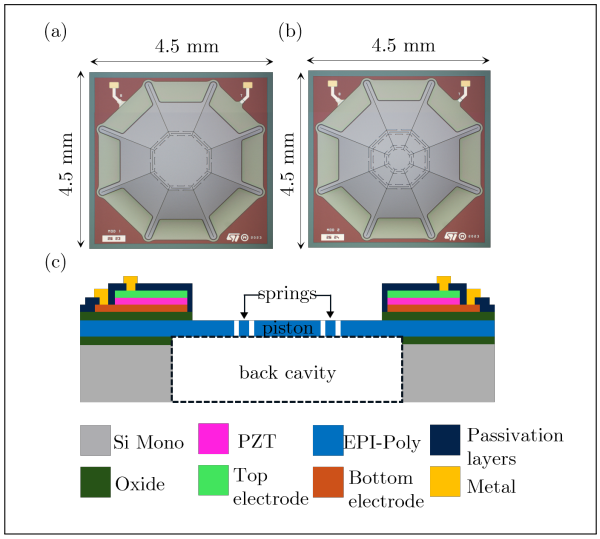

Figure 1. (a) Microscope optical images and (b) cross-sectional view of the proposed MEMS loudspeakers.

network of elastic springs and are anchored to an external fixed frame. The eight plates are designed to be actuated synchronously, moving the diaphragm central part that they keep suspended like a piston. The mechanical gaps between adjacent trapezoidal plates extend from the fixed frame to the central region, effectively segmenting the PZT patches, which remain interconnected at the fixed frame. This distinct separation between plates, combined with the low stiffness of the elastic springs at their extremities, allows to mitigate the hardening effect that a clamped-clamped configuration would otherwise experience. The second device (Fig. 1b) features a reduced central region, leaving space for an additional set of elastic springs positioned along the extended trapezoidal plates. This modification aims to further enhance the maximum displacement of the diaphragm, albeit at the cost of deviating from an ideal piston-like motion. The two devices features a footprint of $4.5 \times 4.5\,\text{mm}^2$.

The proposed diaphragm geometries are an evolution of the design previously proposed by the Authors in [8]. Compared to the previous generation, the diaphragm structure is properly modified to improve the acoustic output with a halved piezoelectric capacitance, which is directly related to the power consumption. In particular, the air-gaps are reduced from 10 µm to 5 µm, to improve the sound pressure at low frequency by limiting the acous-

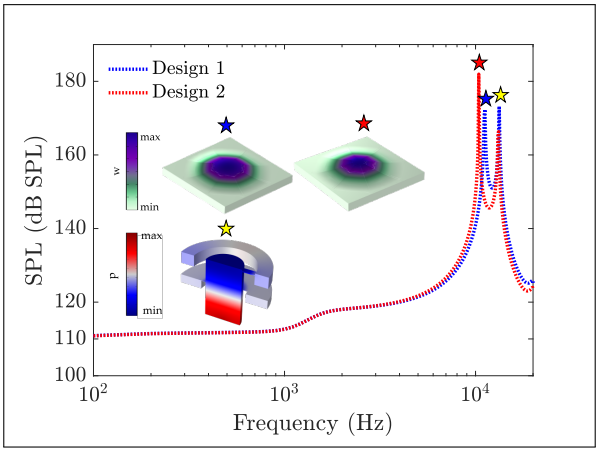

Figure 2. Equivalent circuit SPL predictions for design 1 and 2 at a bias voltage of 15 V_{DC} plus an alternating voltage of 30 V_{pp}. The insets report the loudspeakers deformed shape at their resonance frequency and the acoustic pressure distribution at the half wavelength resonance of the ear simulator.

tic short-circuit. The piezoelectric capacitance is reduced from 70 nF to 35 nF.

3. NUMERICAL RESULTS

The acoustical performances of the proposed loudspeakers are simulated through the FEM-assisted lumped element model reported in [12]. In particular, a FEM prestressed eigenfrequency analysis is exploited for the derivation of the electro-mechanical parameters whereas acoustical parameters are computed through analytical formulas.

The acoustic performance for a bias voltage of 15 V_{DC} plus an alternating voltage of 30 V_{pp} are reported in Fig. 2. The actuated loudspeaker mode, occuring at 11.6 kHz for design 1 and at 10.7 kHz for design 2, determines the first peak of the SPL curves. The second peak is instead due to the half wavelength resonance of the ear simulator. The simulations predict a SPL greater than 110 dB SPL from 100 Hz onwards and a relatively flat response at low frequency, due to the reduced slit width.

4. EXPERIMENTAL RESULTS

The numerical SPL predictions are compared with experimental measurements carried out on nine prototypes of

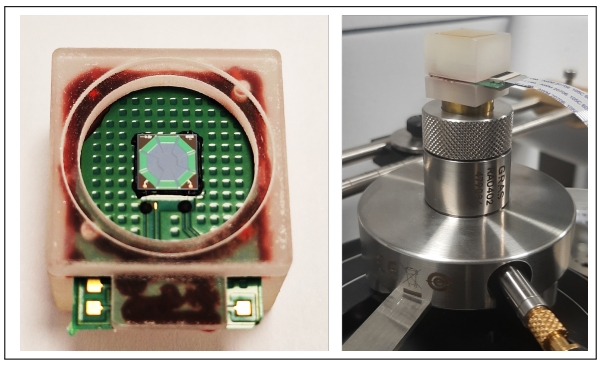

Figure 3. Fabricated microspeaker mounted on a custom PCB and coupled with the package for in-ear acoustic tests (left). Device Under Test (DUT) mounted on the ear simulator G.R.A.S. RA0402 (right).

the proposed microspeakers, fabricated by STMicroelectronics. For experimental tests, the device is mounted on a custom printed circuit board (PCB) and coupled with an acrylonitrile butadiene styrene (ABS) thermoplastic package composed of a back chamber of 1 cm^3 and a front adapter of 1 mm height to connect the speaker with the ear simulator (Fig. 3).

The experimental SPL curves for a bias voltage of 15 V_{DC} plus an alternating voltage of 30 V_{pp} is reported in Fig. 4, for design 1 and 2. The acquisition is stopped at 10 kHz to avoid the break-up of the prototypes. Overall, the numerical vs experimental matching is good (overestimation at 100 Hz of 2.3 dB SPL for design 1 and 2.7 dB SPL for design 2). As reference, the experimental SPL curve for the design of the previous generation [12] is reported in the same figure with black solid line. It can be confirmed that the reduction of the slit width from 10 µm to 5 µm leads to a significant SPL improvement at low frequency (+5 dB SPL at 100 Hz). Moreover, despite the halved piezoelectric surface area, the output pressure is overall higher for the new devices.

The THD has also been evaluated at 1 kHz at 94 dB SPL, obtaining 0.68% for design 1 and 0.72% for design 2 (previous design 1.5%).

5. CONCLUSIONS

Two full-range piezoelectric MEMS loudspeakers for in-ear applications are designed, simulated, fabricated and experimentally characterized. The good match between

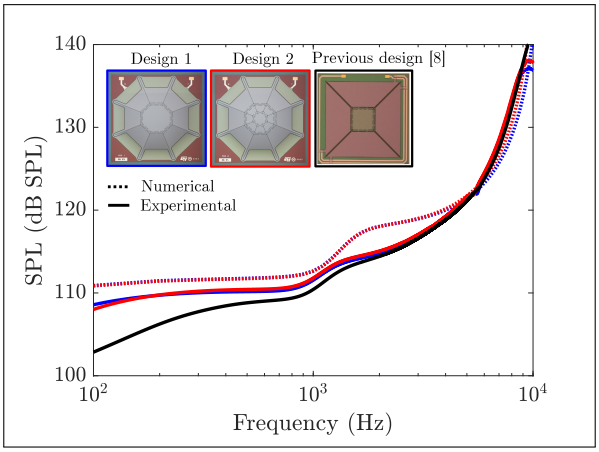

Figure 4. (a) Comparison between numerical (dotted lines) and experimental (solid lines) SPL frequency spectra for a bias voltage of 15 V_{DC} plus 30 V_{pp}, for design 1, design 2 and the design reported in [8].The acquisition is stopped at 10 kHz to avoid the break-up of the prototypes.

simulations and experiments demonstrates that, with respect to the previous generation, the proposed designs gain up to 5 dB SPL at low frequency and more than halve the previous THD, while keeping the same device footprint and a halved piezoelectric surface area.

ABSTRACT

Crosstalk Cancellation (CTC) is an audio technology designed to deliver binaural sound from loudspeaker arrays. Recently, its application has been extended to portable devices with miniature loudspeakers, hereafter referred to as micro-speakers. This paper investigates the effect of manufacturing inconsistencies causing variations in micro-speaker characteristics on CTC performance using numerical simulations. A lumped element model, based on measured electrical impedance of several identical micro-speakers, is used as the transfer functions between the array input signals and the loudspeaker diaphragm velocity. This, together with a rigid sphere acoustic head model or measured Head-Related Transfer Functions (HRTFs), is used to simulate the pressure signals at the listener's ears. Key findings reveal the sensitivity of CTC to specific parameter variations.

Keywords: crosstalk cancellation, micro-speakers, binaural audio, electroacoustic modeling, head-related transfer function

1. INTRODUCTION

The widespread use of mobile devices, including smartphones, laptops and tablets, has led to a significant increase in the integration of miniature speakers, or micro-speakers, to deliver high-quality audio in portable electronics. Advances in digital signal processing have led to the testing of sound and noise control technologies in portable devices with embedded micro-speakers [1], including binaural 3D audio reproduction over loudspeakers – a technique known as Crosstalk Cancellation (CTC) [2–4].

A potential challenge in using micro-speakers for such applications is the variability introduced by manufacturing inconsistencies, which can lead to discrepancies between expected and actual performance [5, 6]. This paper investigates the effect of micro-speakers manufacturing variations on CTC performance by analysing a set of micro-speakers of the same model, produced by the same manufacturer. These variations are assessed by measuring the electrical impedance of the micro-speaker voice coils, and a lumped element model is used to estimate key parameters such as voice coil resistance, inductance, suspension damping, compliance and the electrodynamic transduction coefficient (force factor). The effect of parameter variations on the transfer function relating input voice coil voltage to diaphragm velocity is analysed and the resulting impact on CTC performance is assessed. This is done by combining the transfer function with both rigid sphere and measured Head-Related Transfer Functions (HRTFs) to investigate how variations in micro-speaker parameters affect the reproduced pressure at the listener's ears.

2. THEORETICAL FRAMEWORK

2.1 Micro-speaker lumped element model

The electrical impedance of the blocked voice coil, Z_{EB}, at a given frequency ω is modelled as

$$Z_{EB} = R_E + j\omega L_E, \tag{1}$$

where R_E is the DC voice coil resistance, and L_E is its ideal inductance without considering the losses generated

by eddy currents at higher frequencies [7]. The mechanical impedance describing the diaphragm and voice coil dynamic is computed as:

$$Z_{MD} = R_{MS} + j\omega M_{MD} + \frac{1}{j\omega C_{MS}}. \quad (2)$$

In Equation (2), the parameter M_{MD} models the mechanical mass of the diaphragm and voice coil assembly, C_{MS} defines the mechanical compliance of the diaphragm suspension, and R_{MS} models the mechanical losses in the suspension [8]. The micro-speaker is mounted in a closed-box enclosure. Therefore, the total mechanical impedance, Z_M, can be modelled by introducing the rear-acoustic loading radiation impedance as follows [9],

$$Z_M = Z_{MD} + j\omega M_A + S_D^2 \frac{\rho_0 c^2}{j\omega V_c}. \quad (3)$$

where ρ_0 is the air density, c is the speed of sound, S_D is the effective radiating area of the micro-speaker diaphragm, V_c is the cabinet's volume, and M_A represents the effective mass of acoustic loading on the speaker diaphragm. By combining Equations (1) and (3), the electrical voice coil impedance is given by [8, 9]:

$$Z_E = Z_{EB} + \frac{(Bl)^2}{Z_M}, \quad (4)$$

where the force factor, Bl, is the electro-mechanical transduction coefficient representing the force exerted on the diaphragm by the magnetic motor [8]. It can be further shown [9] that the ratio between the velocity of the diaphragm and voice coil assembly, u_D, and coil input voltage, v_E, is given by:

$$\psi \triangleq \frac{u_D}{v_E} = \frac{Bl}{Z_{EB}Z_M + (Bl)^2}. \quad (5)$$

Assuming that the loudspeaker radiates sound omnidirectionally, Equation (5) can be used to express the ratio of acoustic pressure, p, to input voltage [9]:

$$\frac{p}{v_E} = j\omega\rho_0 S_D \psi \cdot G(\boldsymbol{r}, \boldsymbol{r}_s) \triangleq \Gamma \cdot G(\boldsymbol{r}, \boldsymbol{r}_s), \quad (6)$$

where $G(\boldsymbol{r}, \boldsymbol{r}_s)$ is the Green's function modelling the acoustic field produced by the speaker located at $\boldsymbol{r}_s$ at point $\boldsymbol{r}$. In this work, Equation (6) and the transfer element Γ are used to model the micro-speaker transfer function and investigate the effect of parameters variations on Crosstalk Cancellation.

2.2 Crosstalk Cancellation

Crosstalk Cancellation (CTC) is a method for reproducing binaural audio over loudspeakers, achieved by sound field control via inverse filtering [4, 10]. A single listener, L-channel CTC system ensures accurate binaural reproduction by controlling the sound pressure at two control points (the listener's ears) using L loudspeakers. The system may be described in the frequency domain as [4]

$$\boldsymbol{p} = \boldsymbol{C}\boldsymbol{H}\boldsymbol{d}, \quad (7)$$

where $\boldsymbol{p}$ is the pressure reproduced at the listener's ears, $\boldsymbol{C}$ is the $2 \times L$ plant matrix describing the system's complex frequency responses between the L loudspeakers and the left and right ear, $\boldsymbol{H}$ is the $L \times 2$ matrix of the CTC filters, and $\boldsymbol{d}$ is the target pressure to be reproduced. The CTC filters $\boldsymbol{H}$ are typically obtained by minimising the squared error norm $\|\boldsymbol{p} - \boldsymbol{d}\|^2$. To ensure causality, a modelling delay is usually introduced during filter design [3]; for simplicity, this delay term is omitted here. Solving this minimisation problem involves inverting the plant matrix $\boldsymbol{C}$. Since $\boldsymbol{C}$ is generally non-square, the filters are computed using the Moore-Penrose pseudoinverse [10].

The computation of the CTC filters, $\boldsymbol{H}$, with an accurate plant matrix, $\boldsymbol{C}$, is often impractical as it requires a thorough calibration and measurement process. Therefore, system models are commonly used, making assumptions about the listener's Head-Related Transfer Function (HRTF) and loudspeaker radiation. For instance, loudspeakers could be modelled as monopole sources [2, 11]. However, errors in the reproduced signals and a degraded binaural effect can result from inaccurate plant models [4]. Moreover, at certain frequencies, the plant matrix undergoing inversion may be ill-conditioned. Thus, to control the loudspeaker gains and the sensitivity of the pseudoinverse solution to errors in the plant matrix, Tikhonov regularisation is used to compute the CTC filters as [11]

$$\boldsymbol{H} = \boldsymbol{C}^H[\boldsymbol{C}\boldsymbol{C}^H + \beta\boldsymbol{I}]^{-1}, \quad (8)$$

where β is the regularisation parameter, $\boldsymbol{I}$ is the 2×2 identity matrix and $[\cdot]^H$ denotes the Hermitian transpose. In Equation (8), β determines the relative weight assigned to the electrical power required to drive the loudspeakers – referred to as control effort and defined as $\|\boldsymbol{H}\boldsymbol{d}\|^2$. As β changes from zero to infinity, the solution changes from minimising only the performance error to minimising the control effort [3].

In this paper, Equation (8) is used to calculate the CTC filters employed to drive L micro-speakers arranged

in a linear configuration, adopting a rigid sphere head model for the plant matrix, $\boldsymbol{C}$, as outlined in [12]. To include the micro-speaker characteristics, Equation (7) is modified as follows,

$$\boldsymbol{p} = \boldsymbol{G}\boldsymbol{\Gamma}\boldsymbol{H}\boldsymbol{d}, \tag{9}$$

where $\boldsymbol{\Gamma}$ is a $L \times L$ diagonal matrix populated with transfer elements Γ as defined in Equation (6), $\boldsymbol{G}$ is the matrix of Green's functions modelling the acoustic field between the array speakers and the listener's ears, and $\boldsymbol{d} = [1, 0]^T$ is the target binaural signal [4]. In this work, $\boldsymbol{G}$ contains the transfer responses associated with a rigid sphere head model or Neumann KU 100 HRTFs [13], and is hereafter referred to as *forward* plant matrix.

2.3 Crosstalk Cancellation system description

The CTC system under consideration consists of $L = 5$ sources and two control points corresponding to the ears of a dummy head. The sources considered, all of the same model and from the same manufacturer, are rectangular microspeakers with diaphragm dimensions of 9.2 mm $\times$ 32.2 mm, giving an area of $S_D = 2.9$ cm^2. Each transducer is mounted in a cabinet with a volume of approximately $V_C = 13.0$ cm^3. Figure 1 illustrates the listener and loudspeakers configuration.

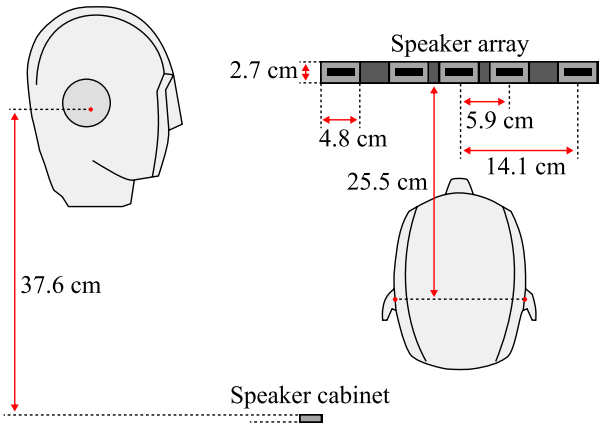

Figure 1: Graphical representation of the CTC system (side and top view).

3. SENSITIVITY ANALYSIS OF PARAMETERS

This section illustrates how the parameters of the model introduced in Equation (4) are estimated from measured voice coil electrical impedances and how they affect the transfer function ψ defined in Equation (5).

3.1 Parameter estimation

The voice coil impedance of 12 micro-speakers was measured between 100 Hz and 20 kHz using the method described in [14]. The resulting data were then analysed using the function introduced in Equation (4) for the least-squares estimation of the Thiele-Small (T-S) parameters of the micro-speakers. Table 1 presents the mean value of the fitted parameters, along with their corresponding percent Relative Standard Deviation (RSD), and maximum mismatch ($m_{\%}$), equivalent to three deviation standards. The total mass $M_{MT} = M_{MD} + M_A$ represents the mechanical mass of loudspeaker diaphragm assembly including air load and voice coil, and f_0 the resonance frequency of the micro-speakers.

Table 1: Estimated mean, percent Relative Standard Deviation (RSD), and maximum mismatch ($m_{\%}$) of model parameters.

Parameter	Mean value	RSD (%)	$m_{\%}$
R_E	3.7 Ω	3.3%	9.9%
L_E	0.025 mH	0.8%	2.4%
Bl	3.5 N/A	2.5%	7.5%
R_{MS}	4.8 Kg/s	6.4%	14.4%
C_{MS}	0.015 mm/N	5.9%	17.3%
M_{MT}	3.7 g	4.8%	14.4%
f_0	678.8 Hz	2.3%	6.9%

The table shows that the estimated parameters with the largest variation are the suspension resistance and compliance, followed by the mechanical mass and electrical resistance. This result is consistent with the level of manufacturing imperfection reported in other studies [6, 9, 15, 16], where it is observed that C_{MS}, R_{MS}, and R_E are typically the micro-speaker parameters that are the most subject and sensitive to variations in the production line. It is further noted that the estimated voice coil DC resistance, resonance frequency, and mechanical mass align with the specification provided in the micro-speaker data sheet.

Figure 2 shows the measured voice coil impedance and the reference impedance curve calculated using the mean values from Table 1. The figure clearly illustrates the manufacturing inconsistencies in micro-speakers across the entire frequency range. It should also

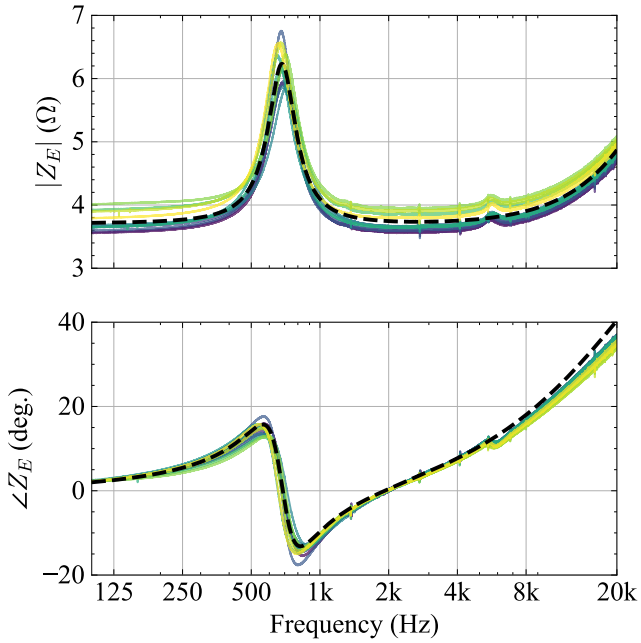

Figure 2: Measured (coloured, solid) and average (black, dashed) voice coil electrical impedance. The average curve is computed using the mean parameters of Table 1.

be noted that the lumped element model considered replicates the impedance curve well, but is unable to reproduce the resonance peak at 5.5 kHz, which might be a higher-order mechanical vibration mode of the micro-speaker [7].

3.2 Effect of parameter variations on ψ

Each parameter of the micro-speaker model has a different effect on the transfer function ψ (Equation (5)) and thus on the radiated acoustic pressure (Equation (6)). Figure 3 illustrates the effects caused by variations of individual parameters on the magnitude and phase of ψ. The black solid and dashed lines respectively represent the magnitude and phase of ψ calculated using the mean parameter values from Table 1, with $\rho_0 = 1.204$ kg/m^3 and $c = 343$ m/s. Deviations from the mean are indicated by the shaded areas, transitioning to blue for negative variations and red for positive variations.

The variation of the voice coil resistance R_E is inversely proportional to the variation of the magnitude of ψ. Without altering the system's resonance frequency, increasing R_E reduces both the magnitude of ψ and the radiated acoustic pressure. Significant phase variations primarily occur at high frequencies. The electrical inductance L_E affects ψ only at high frequencies, with a smaller effect compared to R_E. Conversely, the variation of the magnitude of ψ is directly proportional to the variation of the force factor Bl, with limited phase variations. The suspension resistance R_{MS} modifies the sharpness of the resonance peak without changing its frequency, where higher mechanical losses due to the suspension reduce the radiated sound. The phase response is only slightly affected by large variations in R_{MS}. Differently to the previous cases, the resonance frequency of the system is significantly influenced by changes in C_{MS} or M_{MT}, as expected. An increase in these parameters will lower the resonance frequency and alter the phase response of ψ. These observations align with the results discussed in [17].

4. EFFECT OF PARAMETER VARIATIONS ON CROSSTALK CANCELLATION

This final section examines how mismatches in loudspeaker impedance – resulting from variations in selected T-S parameters between different micro-speakers – affect the CTC level achieved by the system, based on the model introduced in Equation (5). The tuning of the regularisation parameter, the modelling of the inverse filters, and the evaluation of CTC performance are discussed, followed by simulation results based on two forward plant matrices, $\boldsymbol{G}$.

4.1 CTC filters and CTC level

The CTC filters are computed as shown in Equation (8), using a rigid sphere head model to design the plant matrix. This choice is motivated by the variability introduced by micro-speaker manufacturing variations, as observed in Figure 2. Such inconsistencies can lead to inaccurate plant models when using speakers different from those used during the calibration process. In these cases, regularisation would improve the robustness of the system to loudspeaker variations, but also reduces the CTC performance in the ideal case. Additionally, previous research has shown that CTC levels obtained with measured HRTFs and those derived from rigid sphere head models are comparable [4]. Therefore, for simplicity, in this work the plant matrix elements used for the CTC filter design utilise a rigid sphere head model. The mathematical formulation for the responses follows [12], with the head radius set to 87.5 mm.

To determine the appropriate level of regularisation, the control effort was analysed. Specifically, a frequency-independent regularisation parameter of $\beta = 0.00023$ was

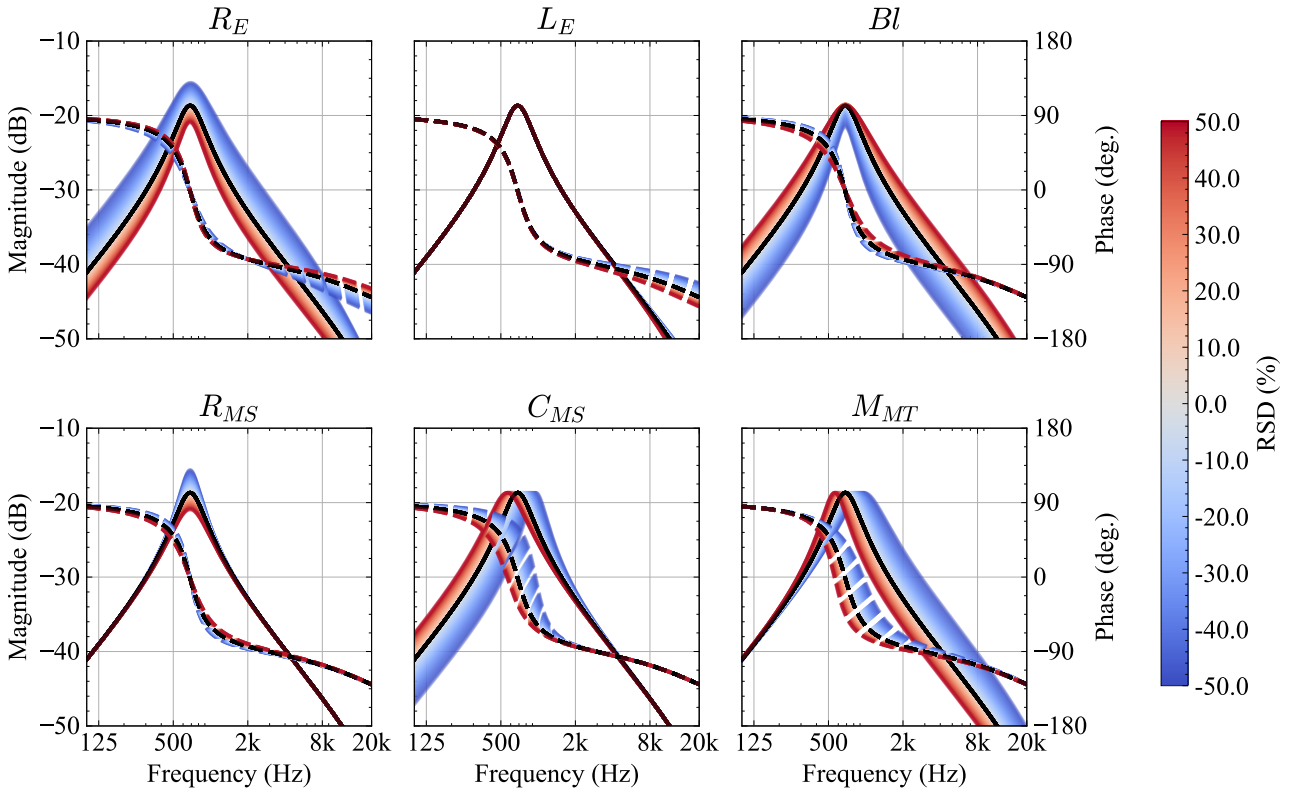

Figure 3: Effect of parameter variations on the magnitude and phase of the transfer function ψ. The black line represents ψ computed using mean parameter values (solid for magnitude, dashed for phase). Shading transitions toward blue for negative variations, measured in terms of the percent Relative Standard Deviation (RSD), and red for positive variations.

chosen to ensure that the control effort variation remained within 18 dB over the 100 Hz to 20 kHz range.

The performance of the system is evaluated using the CTC level, defined as the ratio of the squared reproduced pressures at the listener's ears for a target binaural signal $\boldsymbol{d} = [1, 0]^T$ [4]:

$$\text{CTCL} = 10 \log_{10} \left(\frac{|p_1|^2}{|p_2|^2} \right). \tag{10}$$

The CTC level quantifies the amount of CTC achieved between the listener's ears. In general, a minimum CTC level of 20 dB is required to achieve the desired binaural effect [4].

4.2 Simulation outline

The behaviour of the system under parameter variation was simulated for different levels of percentage mismatch. Previous studies [9,15,16] indicate that the parameters most subject to manufacturing variations in microspeakers are C_{MS}, R_{MS} and R_E. Specifically, these studies suggest that the suspension compliance has an imperfection tolerance of about $\pm 30\%$, while the mechanical and electrical resistances typically vary within $\pm 10\%$. For these reasons, and given the levels of variation reported in Table 1, the T-S parameters R_E, R_{MS}, C_{MS} and M_{MT} are selected for analysis.

The simulation follows this procedure: a single T-S parameter is selected, and a set of $L = 5$ random values is generated for a given percentage mismatch level. The manufacturing imperfections are assumed to follow a normal distribution with a mean μ – the nominal values from Table 1 – and a standard deviation σ given by

$$\sigma = \frac{m_{\%}}{3 \cdot 100} \mu. \tag{11}$$

In Equation (11), $m_{\%}$ represents the maximum deviation from the mean that the random value of the T-S param-

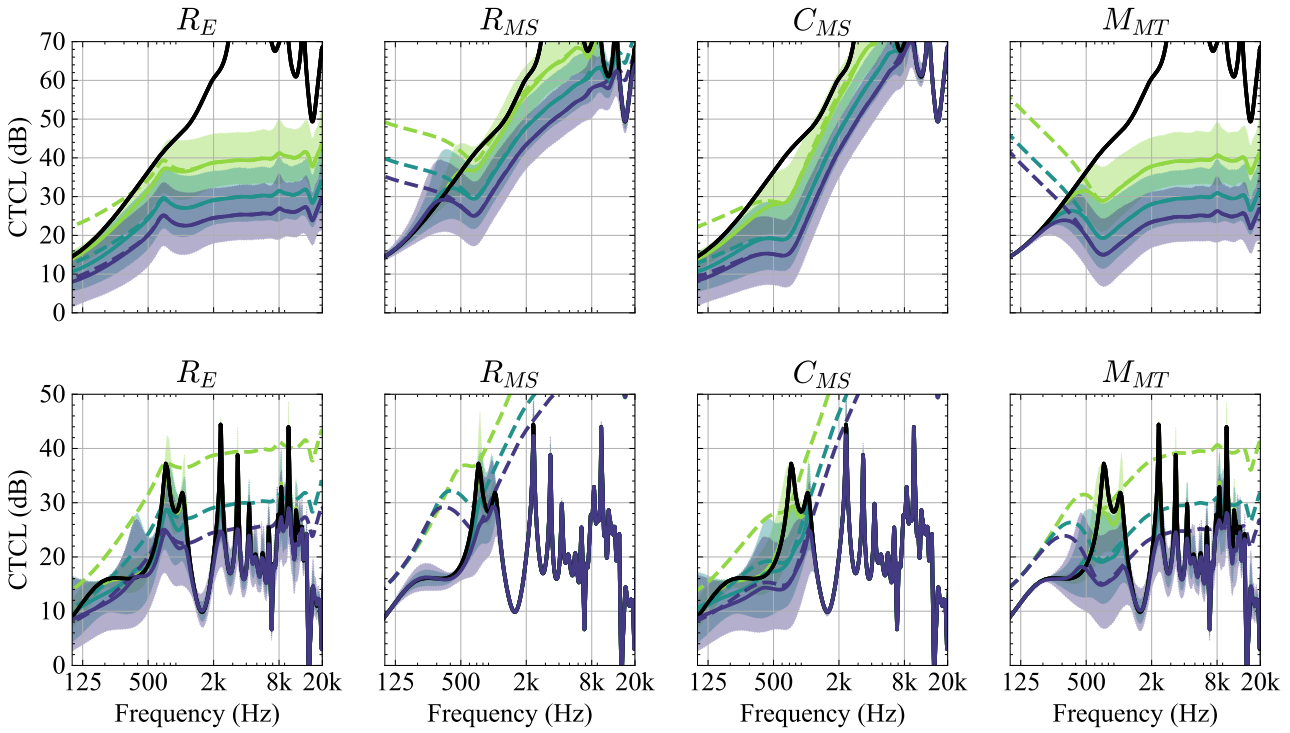

Figure 4: Average CTC level for different parameter mismatch values and forward plant matrix choices. Top: forward plant modeling with rigid sphere HRTFs; bottom: forward plant modeling with KU 100 HRTFs. Mismatch values: 0% (—), 10% (—), 30% (—), 50% (—). Dashed lines show CTC levels with reduced regularisation ($\beta = 10^{-9}$) in the first row and with rigid sphere forward plant matrix in the second. Shaded regions indicate the 10th to 90th percentiles.

eter can assume. Therefore, 'thirding' $m_{\%}$ ensures that nearly all randomly generated values are within three standard deviations. The selected values for maximum mismatch are $m_{\%} = 10\%$, 30% and 50%. This latter value is considered because, in addition to discussed manufacturing imperfections, further variations can occur during sound reproduction due to the non-linear and time-variant behaviour of micro-speakers, which significantly affects their response [5, 7, 18]. While keeping all other parameters fixed at their nominal mean values, the generated random parameters are used to compute five distinct transfer functions, ψ and Γ. These modified transfer functions populate the diagonal transfer function matrix $\mathbf{\Gamma}$. In this way, the effect of parameter variations on the CTC level can be examined by computing and analysing the reproduced pressure, as described in Equations (9) and (10). This procedure is repeated 10^4 times for the four selected parameters and across all percentage mismatch values to ensure statistical reliability of the results. Finally, the retrieved CTC levels are averaged.

4.3 Performance Analysis

The results of the simulation are illustrates in Figure 4, which shows the average CTC level obtained for the three different parameter mismatch values and four model parameters, for the two distinct forward plant matrix choices. The top row of the figure displays the results corresponding to the choice of a rigid sphere forward plant matrix, while the bottom row corresponds to the KU 100 HRTF plant matrix. Dashed lines are introduced in the plots. In the first row they represent the CTC levels obtained by reducing the regularisation parameter to $\beta = 10^{-9}$. In the second row, they show the CTC level obtained using the rigid sphere forward plant matrix (with $\beta = 0.00023$). The averaged CTC level is compared with the performance level obtained without introducing any parameter variation (black line). Moreover, the statistical dispersion of the CTC level obtained for each simulation

is illustrated with shaded regions, whose boundaries define respectively the 10th and 90th percentiles.

4.3.1 *Forward plant modeling with rigid sphere HRTFs*

Figure 4 shows that when the same rigid sphere head model used to compute the CTC filters is also used to design the forward plant matrix, the CTC level achieved by the system, when no mismatch is considered, is well above the 20 dB threshold over most of the frequency range considered. At low frequencies, especially below 200 Hz, the plant matrix is highly ill-conditioned, resulting in poor CTC levels regardless of parameter mismatch. In this range, β regulates the stability of the solution and prevents energy loss, but at the cost of reduced control performance. When parameter variations are introduced, a reduction in the CTC level is observed. The reductions are consistent with the variations in the transfer function ψ observed in Figure 3. In particular, changes in R_E and M_{MT} affect the CTC level over the entire frequency range, especially above the resonance frequency, where losses of more than 20dB occur above 2kHz. Variations in mechanical resistance mainly affect and reduce the CTC level about and below the resonance frequency, while variations in C_{MS} lead to reductions at frequencies below resonance. The results obtained with reduced regularisation (dashed lines) highlight an important property of the system: at low frequencies, the performance degradation is driven by regularisation rather than impedance mismatch. This proves that regularisation imposes a performance limit on the system, regardless of parameter variations.

4.3.2 *Forward plant modeling with KU 100 HRTFs*

When the reproduced pressure is derived by modeling the forward plant matrix with KU 100 HRTFs, the CTC level significantly reduces compared to the case in which the rigid sphere head model is employed. The forward plant matrix is not accurate and the system results in a lower CTC performance, in line with what is observed in [4]. Nonetheless, similar trends to those observed in the previous case occur. T-S parameter variations reduce the CTC level in proportion to the parameter mismatch, matching the variations in the transfer function ψ. It is further noted that at certain frequencies the CTC level matches that of the rigid sphere (dashed lines), indicating that the reduction is driven by the largest mismatch – whether from regularisation, head model differences, or variations in micro-speaker parameters. For the chosen level of regularisation, errors from mismatched head models dominate over most of the frequency spectrum, while CTC degradation due to parameter mismatch is mainly confined to mid-low frequencies, especially below 1 kHz and about resonance. At these frequencies, the performance loss due to parameter mismatch is less severe than in the previous case, even for large variations. This suggests that in practice, even with extremely poor manufacturing tolerances, parameter mismatches have a negligible effect on CTC performance, provided that the CTC filters and the forward plant matrix are designed with different models.

5. CONCLUSIONS

The increasing integration of miniature loudspeakers in mobile devices has enabled the use of advanced audio technologies, such as Crosstalk Cancellation (CTC), to improve the audio experience on these devices. However, manufacturing inconsistencies in micro-speakers can introduce variability that affects performance. This paper has investigated the effect of these variations on CTC using a lumped element model to design two transfer functions: one for diaphragm velocity to voice coil input voltage, ψ, and the other for acoustic pressure to input voltage. Manufacturing variations in 12 micro-speakers were measured, revealing a maximum variation of up to 20% in the Thiele-Small parameters. The effect of parameter mismatch on CTC was investigated by analysing different model parameters considering typical manufacturing variations.

The CTC filters have been designed using Tikhonov regularisation with a rigid sphere head model. The reproduced pressure was computed using a forward plant matrix whose entries are populated either with the same rigid sphere responses used for the CTC filters, or with measured HRTFs. The results have shown that when a rigid sphere head model is used, the CTC level variations due to parameter mismatch are more pronounced, as the ideal CTC level is very high and there are no errors in the sound path transfer responses. The variations are consistent with those observed in the transfer function ψ. At low frequencies, the degradation in performance is driven by regularisation rather than impedance mismatch, highlighting that regularisation sets a performance limit independent of parameter variations. When KU 100 HRTFs are used, the CTC level is significantly reduced due to the differences in the head models. At some frequencies, the CTC level is equal to that of the rigid sphere, indicating that the reduction is dominated by the largest mismatch – whether from regularisation, head model differences or micro-speaker

parameter variations.

The results presented in this paper suggest that CTC performance may be further compromised when multiple mismatches are combined. Future research could also explore the effects of extending the micro-speaker model to account for non-linear behaviour, as well as analysing the effects of varying the number of loudspeakers in the array, or testing the system's robustness across different listener positions.

DEVELOPMENT OF AN OMNIDIRECTIONAL CYLINDRICAL SOUND SOURCE WITH A CORONA DISCHARGE TRANSDUCER

Hervé Lissek[1*] **Tirui Wang**[1] **Rahim Vesal**[1]

[1] Laboratory of Wave Engineering, Ecole Polytechnique Fédérale de Lausanne, Switzerland

ABSTRACT

The Corona Discharge Transducer (CDT) relies on the electroacoustic actuation of a ionized layer of air through an oscillatory electric field. This device allows sound generation without an intermediate mechanical radiator such as a membrane, making it an almost perfect particle velocity source, with ideal impulse response. Thanks to its membrane-less and construction and its continuous arrangement of uniform linear acoustic antennas, it also permits the development of ideal monopolar sources. This paper presents a cylindrical CDT concept, its design and optimization through numerical models (COMSOL), in a view to the realization of a future experimental prototype. The discussion on the acoustic performance obtained on the models will lead to concluding remarks on its applicability to acoustic metrology.

Keywords: *Plasma physics, corona discharge, directional loudspeakers*

1. INTRODUCTION

In their vast majority, loudspeakers rely on the acoustic radiation of a mechanical component (circular or rectangular diaphragm) or through an acoustical radiator (horn), actuated by an electromechanical driver, most often electrodynamic (although electrostatic, piezoelectric, or pneumatic transducers also exist) [1]. Therefore, the whole electro-acoustic transduction cannot happen without an intermediate, likely to degrade the response to transients (due to the inertia of the membrane), thus yielding audible phase distortions [2].

Besides their limitations in the time domain, loudspeakers relying on mechanical membrane do not allow the effective construction of actual omnidirectional sources, unless through the faceting of polyhedrons, such as dodecahedrons used in room acoustic measurements [3]. These sound sources present directivity pattern close to ideal pulsating spheres at low frequencies (as long as the wavelength remain much larger than the polyhedron dimensions [4]), but become nonetheless directive at higher frequencies.

The development of electroacoustic transducers relying on the Corona Discharge mechanism has been reported back to the 1970's, but the 2000's have seen a surge of interest with the work of Béquin et al with mathematical models [5, 6] allowing their design in different configurations ("point-to-grid", "wire-to-grid", etc.). More recently, a planar loudspeaker relying on a "wire-to-grid" Corona Discharge configuration has been developed by Sergeev et al [7, 8] for applications to active noise control, but also as an "ideal" source of sound (transparent, massless, resonant-free, ideal flow velocity source...).

One interesting property of this device is the combination of two colocated sound sources. A first monopolar source results from the heat release around the ultra-thin electrode (designated "corona electrode") responsible for the ionization of the surrounding medium. The second dipolar source is linked to the electrostatic force responsible of the bulk acceleration/decelaration of positive ions and their consecutive non-elastic collisions with the surrounding (neutral) fluid medium in the "drift region" between the corona electrode and a grounded coarsely perforated metallic electrode (designate "collector electrode").

In short, the two processes are responsible of the simultaneous generation of two flow velocities, one symmetric and the other anti-symmetric with respect to the median plane of the transducer. It has also been shown that the ratio between the two flow velocity sources was of the order 1:5 (the dipole source being about 5 times stronger than the monopole source), depending on the transducer geometry.

While constructing an ideal spherical source with a corona discharge transducer represents an obvious challenge with the "wire-to-grid" configuration, the cylindrical geometry is much more straightforward to design, and should allow validating the concept of an ideally omnidirectionnal sound source. This paper aims at presenting the development of a cylindrical loudspeaker based on the corona discharge principle with a wire-to-grid configuration, allowing achieving an omnidirectionnal source in the plane perpendicular to its axis of symmetry. In a first section, the principle of the corona discharge and its application to electroacoustic transducers will be shortly reminded, followed by the description of a very simple numerical model on COMSOL Multiphysics, allowing its further design. Finally, preliminary simulation results will be presented, justifying the timeliness of the proposed design, and paving the way to future experimental validations.

2. THE CORONA-DISCHARGE ELECTROACOUSTIC TRANSDUCER

2.1 Reminder of the principle in a "wire-to-grid" configuration

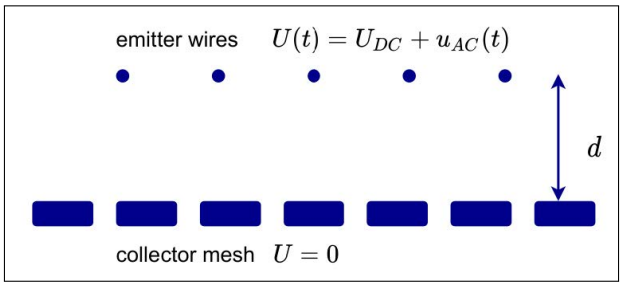

Figure 1. Sketch representing a cut view of the electrode pair: corona electrode (emitter wires)/collector electrode (grounded perforated grid)

Corona discharge loudspeakers allow for sound generation due to the ionization of molecules in the surrounding fluid, moved by an intense oscillating electric field. In the "wire-to-grid" configuration, the transducer is constituted by a pair of electrodes (forming two parallel planes, as illustrated in the sketch of Fig. 1): the first one is a perforated metallic grid connected to the ground, and is designated the "collector electrode"; the second one, designated "corona electrode", is made of an ultra thin wire (diameter of the order of 100 μm), arranged in a pattern of parallel lines along a same plane parallel and distant of d to the collector plane, put at a sufficiently high voltage so as to trigger the extraction of electrons from surrounding molecules. The breakdown voltage, above which ionization is possible, is designated U_0 and is of the order of a few kV.

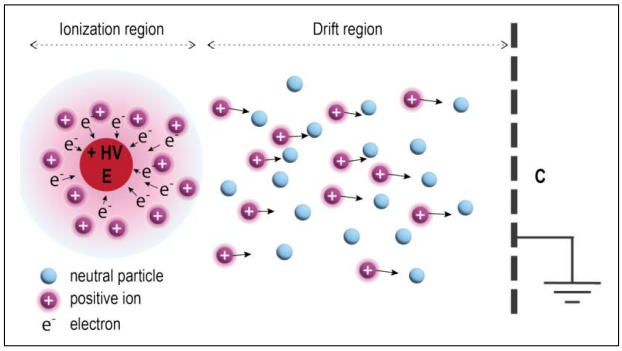

Figure 2. Corona discharge principle

When applying an offset voltage U_{DC} higher than U_0, positive ions are accelerated inside the ionization region towards the collector electrode. They then collide with the neutral particles present in the drift region, which are then moved, giving rise to an "ionic wind" (constant flow).

If an alternating voltage $u_{ac}(t)$, of the order of 1 kV, is superimposed to U_{DC} (while total voltage $U_{DC} + u_{ac}$ still remains higher than the breakdown voltage, as well as not exceeding a value above which arcing may occur), the transducer generates acceleration/deceleration of the surrounding fluid layers, responsible for sound generation.

The preceding studies show that this corona discharge transducer configuration could be modelled as the combination of two volumic sound sources, one monopolar "heat" source H (due to the heat release at the corona electrodes), and another dipolar "force" source F (relative to the electrostatic force moving the surrounding fluid back and forth).

An extremely simple electroacoustic model can be deduced from the coupling equations between the plasma

generation and actuation, and the generated sound field. Indeed, it has been shown that the offset voltage U_{DC} can be linked to the current I flowing through the corona wire according to the Townsend formula:

$$I = CU_{DC}(U_{DC} - U_0) \tag{1}$$

where C is a constant that depends on the transducer geometry, and that can be experimentally determined. It is then possible to express the two sources H and F as a function of the voltage feeding the transducer [7, 8]:

$$\begin{aligned} H &= C(3U_{DC}^2 - U_{DC}U_0)u_{ac} \text{ [W]} \\ F &= \frac{C.d}{\mu_i}(2U_{DC} - U_0)u_{ac} \text{ [N]} \end{aligned} \tag{2}$$

where μ_i designates ions mobility, and d is the distance between the two electrodes (or the plasma thickness).

Equation (1) can then be used to express the "Heat Source" power density (in W/m^3), and the "Dipolar Domain Source" force density (in N/m^3), by dividing these two expressions by the plasma volume ($S.d$, where S is the transducer effective area) in the COMSOL model.

2.2 Case of a cylindrical "wire-to-grid" configuration

In this study, we investigate a alternative geometry of the corona discharge electroacoustic transducer, where the collector electrode is composed of a cylindrical perforated metallic grid (alternatively, composed of cylindrical rods arranged to form a cylinder shape around the symmetry axis), of height h, bounded by two rigid plates on both sides, over which an ultrathin wire can be arranged to form a network of parallel wires distant of e from each others, and distant of d from the collector. Fig. 3 illustrates the proposed configuration.

It seems quite obvious that, in this configuration, the dipolar force source is cancelled by the axisymmetry of the transducer, giving rise to the only monopolar heat source. It should then behave as an ideal omnidirectional sound source in the horizontal plane, or in azimuth (according to the convention of Fig. 3, the symmetry axis being along the vertical). Note that the transducer directivity in elevation (with respect to the z axis) should correspond to the one of a finite radiating cylinder, according to Williams et al [9].

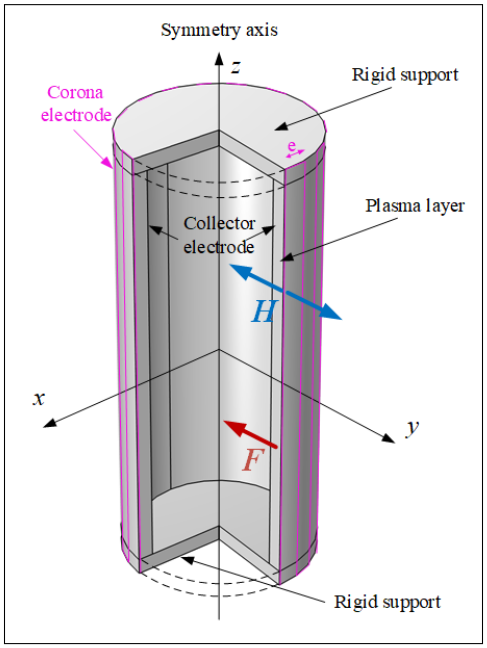

Figure 3. Cylindrical plasma loudspeaker geometry

3. NUMERICAL MODEL

3.1 Description of the COMSOL model

A COMSOL Multiphysics model has been developped to verify the acoustic properties of the transducer elaborated before. The model uses the only *Pressure Acoustics, Frequency Domain* (acpr). We have chosen to develop a full 3D model of the transducer in a view to assess further configurations in the future, not only the axisymmetric one (for which the only 2D Axisymmetric Space Dimension would have been sufficient). Especially, we will be interested in investigating a dipolar transducer configuration in the future (not presented here). However, in order to save computational time, we assumed the horizontal plane xOy and the vertical plane xOz are planes of symmetry, thus limiting the 3D model to a quadrant of a sphere.

We start by modeling the geometry in the xOz plane, and generate the 3D model by semi-revolution along axis z. In this plane, we draw the propagating domain as a quadrant of a circle of radius $D = 1$m, surrounded by a Perfectly Matched Layer of depth $D/5 = 0.2$ m. The cylindrical loudspeaker is represented by a rectangular layer of height $h/2$ and width d, shifted by distance R from the axis of symmetry z. This plasma layer is capped by a rigid frame of width $R + d$ and height t, which is

substracted from the propagation domain, the remaining boundaries being set as "Sound Hard Boundary".

Here, we will consider the plasma layer model presented by Sergeev et al [7, 8], namely considering the plasma layer of volume $V = \pi(d^2 + 2d.R).h$ as an homogenous air medium embedding one "Heat Source" domain (power density $Q_{heat} = H/V$, to which we should precise the isobar heat capacity C_p and adiabatic coefficient γ), and a "Dipolar Domain Source" (power density $q_d = -F/V$ along the xOy plane, the - sign indicating that the corona electrode is located on the exterior side of the cylinder, although this component should have no effect in this geometry). Fig. 4 illustrates the chosen model geometry in 2D.

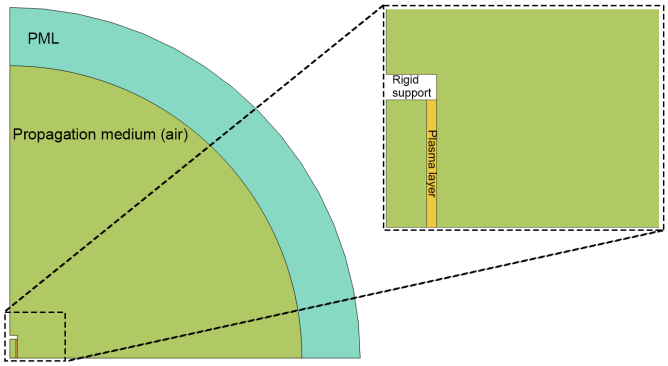

Figure 4. Intermediate 2D COMSOL model

The parameters used to design the COMSOL model are given in Tab. 1. Note that the dimensions have been chosen to meet the ones of a planar version of the corona discharge loudspeaker, assuming the electroacoustic properties (especially coefficient C) is only dependant on the transducer dimensions (inter-electrode distance d, corona wire diameter, and overall corona wire length, linked to the effective area of the transducer S). With these assumptions, there is no need to build a prototype to evaluate the electroacoustic model parameters, which simplifies the modeling and design phase. The following parameters mostly refer to a former design reported in [10].

Table 1. Model parameters

Parameter	Symbol	Value	Unit
Medium (air) properties			
Density	ρ_0	1.23	kg.m^{-3}
Speed of sound	c	343	m.s^{-1}
Isobar heat capacity	C_P	1015	J.kg^{-1}K^{-1}
Adiabatic coefficient	γ	1.4	-
Ions mobility	μ_i	1.1.10^{-4}	m^{2}V^{-1}s^{-1}
Transducer dimensions			
Plasma thickness	d	5	mm
Wires spacing	e	10	mm
Height	h	13	cm
Internal radius	R	2.5	cm
Support thickness	t	13	mm
Electrical characteristics			
DC voltage	U_{DC}	8	kV
Breakdown voltage	U_0	6.16	kV
Current/voltage constant	C	1.8 10^{-11}	A V^{-2}

Last, the 2D model drawn in the xOz *Work Plane* is extruded in semi-revolution to obtain the 3D model of Fig. 5.

The simulations are performed in the frequency domain, for ISO frequencies split in 1/24th octave spanning the [125 Hz - 2000 Hz] range. The tetrahedral meshing was limited to one sixth of a wavelength at 2000 Hz. Presented results will limit to octave bands central frequencies.

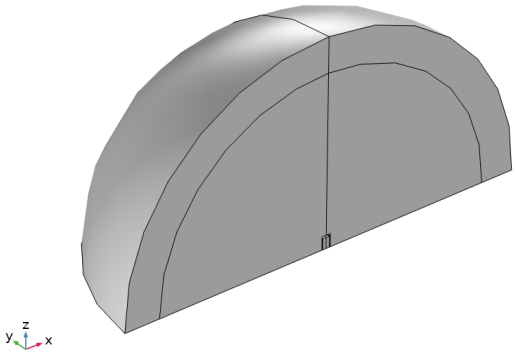

Figure 5. Full 3D COMSOL model

3.2 Simulations results

We present the directivities of the cylindrical plasma loudspeaker in azimuth (Fig. 6) and elevation (Fig. 7). Regarding the directivity in azimuth, it is obvious that the transducer is perfectly omnidirectionnal in the xOy plane, which justifies the chosen geometry. Moreover, the achieved directivities in elevation confirm that the sound radiation conforms to the one of a finite pulsating cylinder, as described by Williams et al. [9].

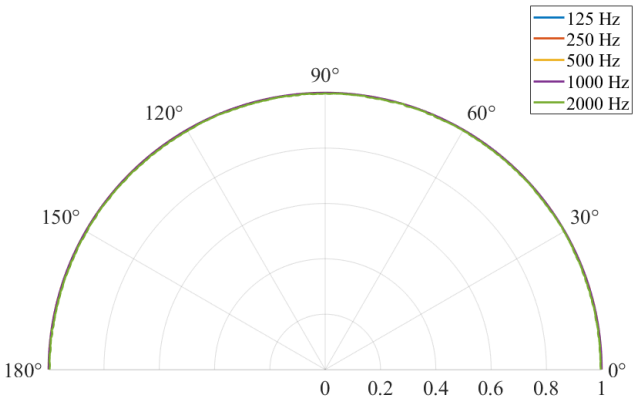

Figure 6. Directivity in azimuth

Moreover, the acoustic pressure along the Ox axis, illustrated on Fig. 8 corresponds to the sound radion model of a finite cylinder reported in [9].

Last, the radiation impedance of the cylindrical plasma transducer is obtained by first integrating the sound pressure and the normal velocity over the plasma outter boundary to derive the net pressure force and flow velocity, and then expressing their ratio normalized by $Z_c = \rho_0.c_0$. The normalized radiation impedance is illustrated on Figure 9.

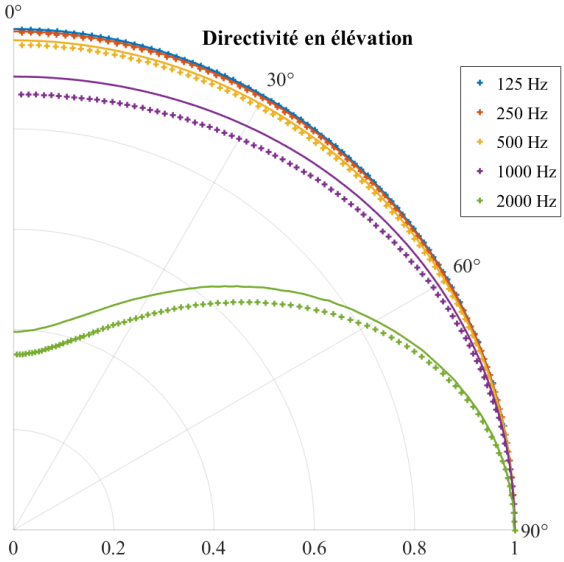

Figure 7. Directivity in elevation (lines: COMSOL simulations; + markers: theoretical results after Williams et al [9])

4. CONCLUSIONS AND PERSPECTIVES

We have been able to verify, with the COMSOL model, the hypothesis after which a corona discharge loudspeaker following a cylindrical geometry behaves as a monopolar sound source in a first approximation (ie. considering the cylindrical plasma layer generates the same amount of monopolar / dipolar sound sources than a plane geometry of same dimensions), the dipolar force source being cancelled by symmetries. The main drawback is the lower sound pressure amplitude radiated by the monopolar source compared to the dipolar (about 5 times less), explaining the low acoustic efficiency of the transducer. Another drawback (also visible on other geometries) is its high-pass filter behaviour, linked to its ideal flow velocity source characteristics, associated to the radiation impedance of a pulsating cylinder. Last, the finite dimension of the transducer yields a directivity in elevation similar to the one of a finite pulsating cylinder of radius R and

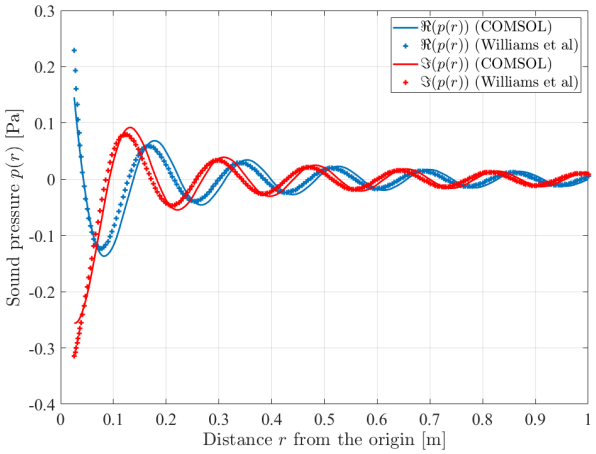

Figure 8. Acoustic pressure along Ox, at 2000 Hz: lines: COMSOL simulation results (blue: real part, red: imaginary part); markers: theoretical results after Williams et al [9] (blue: real part, red: imaginary part)

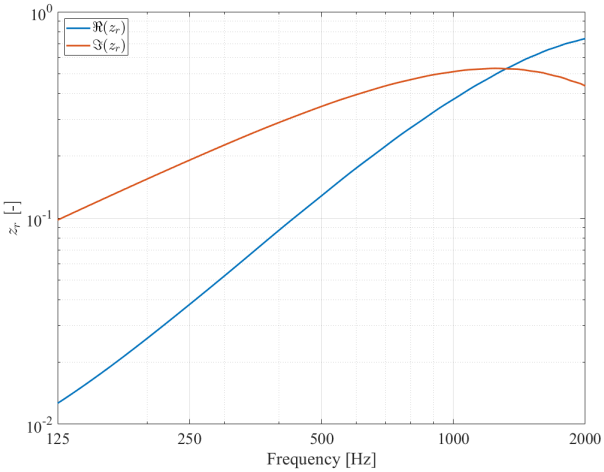

Figure 9. Normalized radiation impedance derived with the COMSOL model (blue: radiation resistance; red: radiation reactance)

height h [9].

The next step will consist in constructing a prototype based on the proposed geometry, and the assessment of its acoustic radiation in an anechoic facility. Moreover, we anticipate to test some alternative transducer configurations, for example in a "dipolar-only" version, where the transducer would be made of two half-cylinders, each fed with its own voltage amplifier, one with voltage $u_{ac,1}$ and the other with out of phase voltage $u_{ac,2} = -u_{ac,1}$. These planned experiments should confirm the results of this preliminary simulation study and open the way to new controllable directionnal sound sources, allowing changing the directivity from omnidirectionnal to bidirectionnal (two-sided), and beyond, multipolar by further partitions of the cylinder.

The applications of such an omnidirectionnal source are manifold: it first allows verifying sound radiation models used for the design of ideal sound sources, such as pulsating spheres and cylinders, which are accessible to experiments only through the simplification of their geometry as polyhedrons. Besides this theoretical interest, having effective omnidirectionnal sound sources could be an important asset for acoustic metrology, more specifically for room acoustics measurements, as a substitute to state-of-the-art dodecahedrons.

5. ACKNOWLEDGMENTS

The authors would like to honor the memory of Tirui Wang, a student in Micro-Engineering at EPFL, having collaborated to the development of the cylindrical plasma loudspeaker, who tragically passed away in China, his home country, on February 14, 2025.

ABSTRACT

Acoustic tagging is one of the primary resources for tracking marine species and understanding their behaviors within these protected zones. However, traditional acoustic tags have several limitations, resulting in data loss or inaccuracies, complicating ecological studies. In this work, we describe the deployment of BTAGs in high-density and elongated array configurations, alongside USBL-based direction and range measurements, providing a versatile toolset for ecological studies, improving the ability to monitor marine species, assess Marine Protected Areas (MPAs), and contribute to the sustainable management of marine ecosystems.

Keywords: *acoustic biotelemetry, bidirectional acoustic tag, usbl*

1. INTRODUCTION

Marine and oceanic ecosystems face significant threats from climate change and overfishing, necessitating continuous monitoring to assess and mitigate their impact [1]. Marine Protected Areas (MPAs) have been introduced to counteract these challenges, but their effectiveness depends on robust data collection methods [2]. Acoustic tagging is one of the primary resources for tracking marine species and understanding their behaviors within these protected zones [3].

The use of acoustic tagging in marine research dates back to the mid-20th century. Early acoustic tags were relatively simple, relying on ultrasonic pulses that could be detected by hydrophones placed in strategic locations. [4]. By the 1970s and 1980s, advancements in electronics and miniaturization enabled the tagging of smaller fish, broadening the scope of research beyond large commercial species. Acoustic telemetry soon became a widely used tool for studying fish behavior, habitat use, and population dynamics, contributing to the development of Marine Protected Areas (MPAs) as a key conservation strategy [5].

Despite its success, traditional acoustic tagging technology has had several limitations. The most significant drawback is the unidirectional nature of data transmission, where tags send signals to receivers but cannot receive information or be reprogrammed remotely [6]. This constraint limits real-time data retrieval, which can be time-consuming and resource-intensive to process.

To solve those unidirectional constraints, a bidirectional acoustic tag has been developed, enabling the acoustic transceivers to send commands to the tags, compute the time of flight (ToF) and receive real-time feedback, thereby improving data accuracy and monitoring efficiency [7].

In this work, the bidirectional acoustic tag (BTAG) system and its deployment options are presented alongside its main specifications.

2. SYSTEM IMPLEMENTATION

The BTAG system is a miniaturisation of a common modem system with tailored solutions to system specifications; these specifications are i. full encapsulation to withstand depths of 500 m, ii. miniaturised design to be able to be carried by a *Nephrops Norvigecus* (i.e., Norway Lobster) following the 2% tag mass to body mass rule [8] and iii. an ultra-low power design to maintain the operativity for a minimum of 3 months up to a 1-year life.

*Corresponding author: gerard.batet@upc.edu.
Copyright: ©2025 Gerard Batet et al. This is an open-access article distributed under the terms of the Creative Commons Attribution 3.0 Unported License, which permits unrestricted use, distribution, and reproduction in any medium, provided the original author and source are credited.

The system has been designed to comply with these requirements, as seen in Fig.1, with three main blocks in mind, i. the power electronics, which comprises a high energy density lithium thionyl-chloride, a hall effect sensor working with a power switch, enabling the tag's activation and deactivation via an external magnet, ii. the microcontroller from ST Microelectronics, which has the ability to access an ultra-low power sleep mode and a low-power dynamic run mode and iii. the transmission and reception circuitry composed by the input and output amplifier and the piezoelectric transducer.

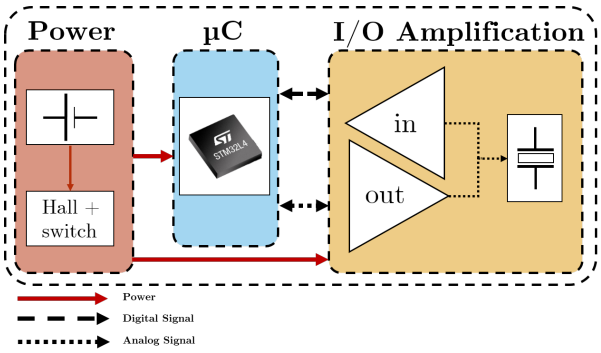

Figure 1. Basic electronic building blocks graphical representation being i. power with the battery and a magnet activated hall sensor with the power switch, ii. ST Microelectronics's ultra-low power microcontroller, and iii. electronic instrumentation with output and input amplification to the piezoelectric element

The output amplifier is a common type D audio amplifier to reduce the power consumption, the input amplifier has been tailored to bandpass 69 kHz which is the most used in the acoustic tagging, being the carrier of the pulse position modulation (PPM) used to transmit the ID of the tag, the polling message from the transceiver station and the response of the BTAG.

The BTAG is encapsulated in a hard resin to ensure the mechanical and water ingress protection (See Fig. 2), and for this size, the battery life in days can be estimated using battery tests resulting in the Table 1.

3. DEPLOYMENT TOPOLOGY

Receivers are typically deployed using two primary configurations: i. a high-density array designed to precisely monitor a specific area and ii. an elongated array or straight-line arrangement used for tracking movements along coastlines, migration routes, or changes in marine habitats. The BTAG system is compatible with these deployment strategies, complementing traditional methods while incorporating transceivers to obtain range measurements.

Table 1. Battery life in days depending on the cycle time and the reception window on the cycle

Cycle time	60 s	120 s	180 s
No Rx	3650	3650	3650
Rx 7.45 s	121	230	326
Rx 12.45 s	75	145	210

Additionally, recent tests utilizing Ultra-Short Baseline (USBL) technology from Evologics have demonstrated the capability to determine both the direction of arrival (bearing) and the range through time-of-flight measurements, enhancing the accuracy and efficiency of tracking efforts.

To ensure full compatibility with the other systems, the BTAG employs the Open protocol developed by the European tracking network (ETN) (https://europeantrackingnetwork.org/en) [9] [10].

Figure 2. Bidirectional acoustic tag transparent test encapsulation showing i. the piezoelectric element (white cylinder), ii. the electronics (blue board), and iii. the battery (purple cylinder)

4. CONCLUSIONS

The introduction of the BTAG technology represents a significant advancement in marine species monitoring. The BTAG system addresses key limitations of traditional acoustic tags by enabling real-time data retrieval and range measurements, thus enhancing tracking accuracy and efficiency.

The miniaturized design, coupled with ultra-low power consumption, ensures extended operational life, up to 10 years when unidirectional mode and 1 year when bidirectional.

Additionally, the integration of an open communication protocol allows for seamless compatibility with existing tracking networks, facilitating broader adoption in marine research.

The deployment of BTAGs in high-density and elongated array configurations, alongside USBL-based direction and range measurements, provides a versatile toolset for ecological studies. These innovations improve the ability to monitor marine species, assess MPA effectiveness, and contribute to the sustainable management of marine ecosystems.

Future developments may focus on further miniaturization, enhanced battery performance, and the incorporation of additional environmental sensors to expand the system's capabilities.

LOW ORDER LATERAL MODES OF PLATE TRANSDUCERS AS BASIS FOR EFFECTIVE AND REPRODUCIBLE ACOUSTOFLUIDIC DEVICES

Andreas Fuchsluger[1*] **Annalisa De Pastina**[2] **Bernhard Jakoby**[1]
[1] Institute for Microelectronics and Microsensors, Johannes Kepler University Linz, Austria
[2] Microsystems, Silicon Austria Labs, Villach, Austria

ABSTRACT

Acoustofluidics is a contactless and thus gentle method for handling objects from the sub-micrometer to the millimeter length scale. Making use of the radiation force, small objects can be aligned at the pressure nodes or antinodes of a stationary acoustic field generated inside microfluidic structures. Besides the intensity and frequency of the acoustic field, the acoustic force on an object purely relies on its mechanical properties, and therefore, no special requirements or treatments are necessary. We designed and built numerically optimized acoustofluidic devices consisting of microfluidic silicon-glass chips actuated by attached piezoelectric plate transducers. The specialty in our design is the utilization of a low order lateral width mode of the plate transducer, which stands in contrast to the usually used thickness mode. A glycerol layer between the transducer and the chip ensures weak coupling of the lateral mode, meaning that the resonance frequency of the transducer is barely altered when attached to the chip. Together with low patch-to-patch variation of the used components, this altogether leads to very reliable and reproducible operating devices. We will demonstrate the performance of our concept by manipulating objects in millimeter-sized structures and in the milliseconds-timeframe, reaching acoustic energy densities close to $3000\,\mathrm{J/m^3}$.

1. INTRODUCTION

Small particles suspended in a fluid and exposed to a standing acoustic plane wave experience a force that, depending on the mechanical properties of the involved materials, will either drive them toward the pressure nodes or antinodes of the acoustic field, where the particles accumulate. This force is known as the acoustic radiation force [1]

$$F_{\mathrm{rad}} = 3V\,\Phi\,E_{\mathrm{ac}}\,k\sin(2kx), \tag{1}$$

which depends on the particle volume V, the acoustic contrast factor Φ, and on the acoustic energy density E_{ac} and the wave-number k of the standing pressure-wave $p_0\cos(kx)$ oriented along the x-direction with the pressure amplitude p_0. The acoustic contrast factor Φ characterizes the influence of the mechanical properties of both the fluid and the particle. Its sign determines the direction of the force. The particles used in our experiment have a density similar to that of the surrounding fluid but lower compressibility, resulting in a positive Φ. Consequently, F_{rad} directs the particles toward the pressure nodes of the wave.

2. THE DEVICE

The core elements of our device are formed by the microfluidic silicon-glass chip and the piezoelectric plate transducer for ultrasonic actuation shown in Fig. 1. The chip is mounted into our custom-made chip holder [2], where the transducer is clamped towards the bottom of the chip using a thin layer of glycerol in between as an acoustic coupling medium.

The chip geometry is numerically optimized for particle focusing in the center of the channel relying on the second-order lateral extensional width mode of the plate

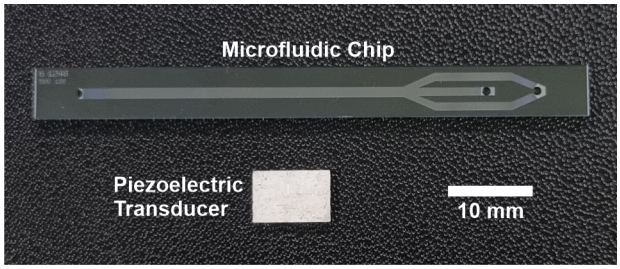

Figure 1. The core elements of the device are formed by a microfluidic chip made out of silicon and glass, and a piezoelectric plate transducer that is attached to the bottom of the chip for ultrasonic actuation.

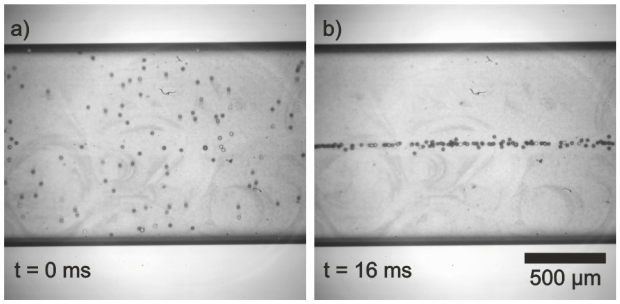

Figure 2. Particle focusing in a 1240-μm wide channel within 16 milliseconds, corresponding to an acoustic energy density of $E_{\mathrm{ac}} = 2770\,\mathrm{J/m^3}$. The actuation frequency and the actuation voltage are $547\,\mathrm{kHz}$ and approximately $70\,\mathrm{V_{pp}}$, respectively.

transducer. Minimizing the focusing time and improving the setup is ongoing work [3,4]. As a final goal, using the trifurcation at the end of the channel, the system should operate as an effective flow-through separator using the lateral mode of the transducer instead of the usually employed thickness modes, e.g., as implemented in [5].

The lateral mode of the transducer, which is fundamental to our actuation, exhibits only a weak coupling with the microfluidic chip. Consequently, the lateral resonance of the transducer remains nearly unchanged when the transducer is attached to the microfluidic chip. Conversely, the thickness mode demonstrates strong coupling, resulting in significant alteration of the behavior at resonance [4].

3. RESULTS

With an actuation voltage of approximately $70\,\mathrm{V_{pp}}$, we cleared the outer region of a 1240-μm wide channel of 20-μm polystyrene (PS) particles, focusing them at its center within $16\,\mathrm{ms}$. By measuring the focusing time and using the method from [6], which is based on equating the acoustic radiation force to the drag force experienced by a particle when moving through the fluid, we obtained an acoustic energy density of $E_{\mathrm{ac}} = 2770\,\mathrm{J/m^3}$.

ACOUSTIC LEVITATION IN AIR: NOVEL TECHNIQUES AND APPLICATIONS

Asier Marzo[1*]
[1] Department of Computer Science, Universidad Publica de Navarra, Spain

ABSTRACT

Acoustic levitation can hold different material in mid-air. Typically, an emitter and an opposed reflector form a standing wave. Millimetric particles significantly smaller than the wavelength can be trapped in the nodes of the standing wave. Despite the limitations on particle size, the diversity of supported materials enables multiple applications. Metals, liquids, gases, plastics or small living beings can be trapped with acoustic levitation. Some applications are contactless spectroscopy or the study of crystallization of levitated samples. In this presentation, novel techniques beyond standing waves will be presented such as acoustic vortices or bottle beams that provide positional and orientation control on the levitated particles. We will highlight emerging applications in additive manufacturing, particle agglomeration, aerosol control, patterning, or pick and place of fragile samples. Finally, we will present some opportunities to get started in mid-air acoustic levitation using devices that can be built at the lab or even at home with off-the-shelf components.

Keywords: acoustic levitation, radiation force, acoustic traps, beamforming

1. INTRODUCTION

Sound can held in mid-air small particles made of different materials [1]. Acoustic levitation in air typically uses an ultrasonic emitter and an opposed reflector [2] to create a standing wave, with particles levitating at its nodes. Other setups use two opposed emitters [3], an array of emitters and reflectors to enable transportation, and recently, phased-arrays [4] are used to levitate multiple particles independently [5]. Trapping on a standing-wave node limits the particle size to half-wavelength, and emitters should be around the particle. Recent research showed that single-beams can trap particles [6, 7] and that particles larger than the wavelength can be trapped in vortices [8] and special acoustic bottles [9].

More advances can be found in acoustic levitation reviews: general [10, 11], liquids [12], biomaterials [13], airborne chemistry [14] or soft matter [15].

2. HOMEMADE LEVITATORS

Lab equipment can be expensive and hard to access, thus limiting exploration and accessibility to acoustic levitators. In the past decade, various levitators that can be built with off-the-shelf components have been shown and successfully used for research activities. Homemade devices are not as accurate or powerful as lab equipment, but they are available to a wider range of researchers, including hobbyists and schools.

TinyLev [16] is a single-axis standing-wave levitator, it has two opposed bowls made of 36 emitters each. The emitters are off-the-shelf $40\,\mathrm{kHz}$ transducers that are arranged around a sphere of 13 cm diameter. This gives the setup a natural focus, and can levitate liquids and samples of densities up to $2.4\,\mathrm{g/cm^3}$ and $3\,\mathrm{mm}$ diameter. The electronics are simplified and use an Arduino Nano and a motor driver (L298N). The levitator and some levitated samples are shown in Figure 1. Modifications of TinyLev make it more compact (Mk3 [17]) or able to levitate denser particles (MightyLev [18]).

SonicSurface [19] is an integrated $40\,\mathrm{kHz}$ phased-array of 16×16 emitters, with individual control of phases

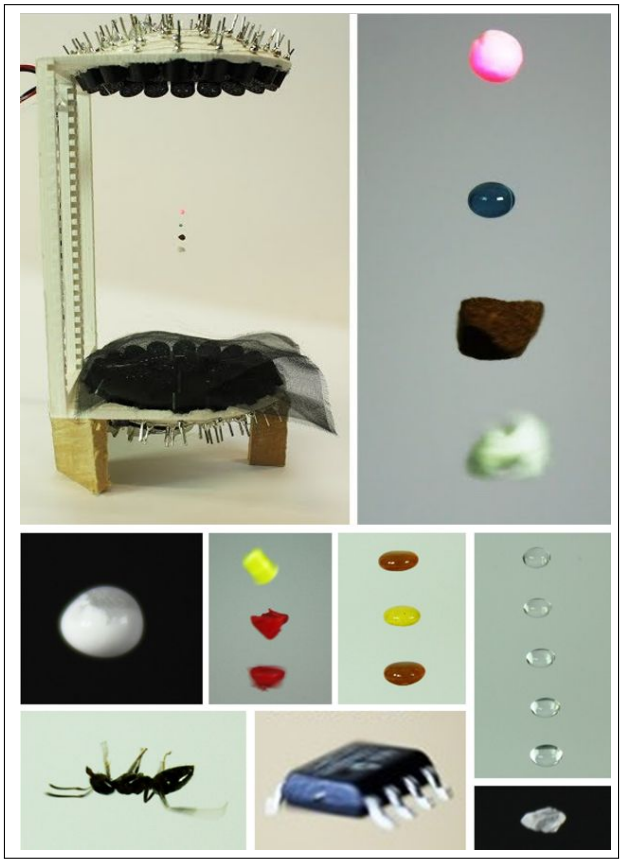

Figure 1. TinyLev is made of two opposed bowls with 36 ultrasonic emitters each, the bowls have a separation of 10 cm. Bottom) some levitated samples, left to right: titanium dioxide in water, plastics, ketchup and mustard, water, ant, integrated circuit and salt.

(see Figure 2). It has been used in various research projects [5, 20–22]. Other open phased-arrays have been published [23–25].

3. EMERGING APPLICATIONS

Apart from the applications referenced in the introduction, we describe some recent explorations that go beyond containerless and contactless processing.

Aerosols falling into a substrate get patterned along the high-amplitude areas where an acoustic field is applied [26]. The variety of aerosols enables application in bio-fabrication but also for printed electronics when conductive powder is mixed with the liquid medium.

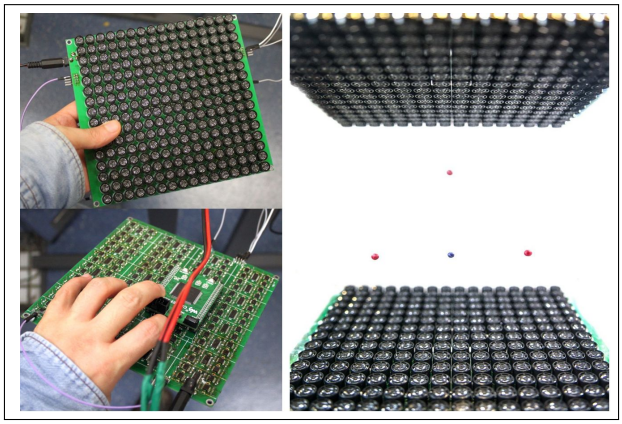

Figure 2. SonicSurface is an integrated phased-array with 256 emitters of 1 cm-diameter. It can levitate multiple particles and control them individually.

LeviPrint [20] explores the levitation of droplets of glue, solid particles and elongated thin objects to build structures in a contactless way. Traditional standing waves can hold droplets and spherical particles whereas other fields are optimized to held in position and orientation elongated sticks. The assembly can be done without touching the pieces to avoid cross-contamination, and the structure can be built inside a container as long as there is a small aperture for the parts to enter. Figure 3 shows a structure built with levitated sticks.

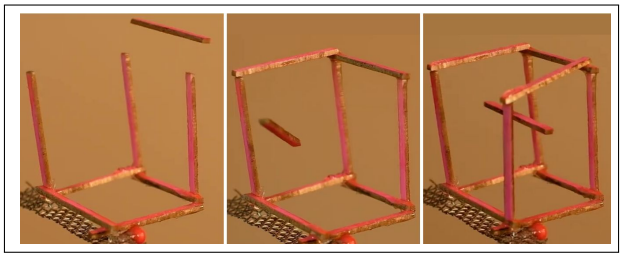

Figure 3. A cube built with sticks connected with UV-curable glue. The cube has 5 cm side, the sticks and the glue were levitated in a contactless way.

Electric sparks can be guided with ultrasound [27]. Electric sparks heat up the air, it expands and becomes less dense. This lower-density air gets shaped by the ultrasonic field due to the acoustic contrast in comparison with the surrounding ambient air. Also, less dense air

has lower breakdown voltage and is a preferred discharge path. The process repeats and the ultrasonic field can guide the sparks along the high-amplitude areas. Being able to guide electric sparks enables new applications in high-voltage switching and selective welding. A guided electric spark is shown in Figure 4.

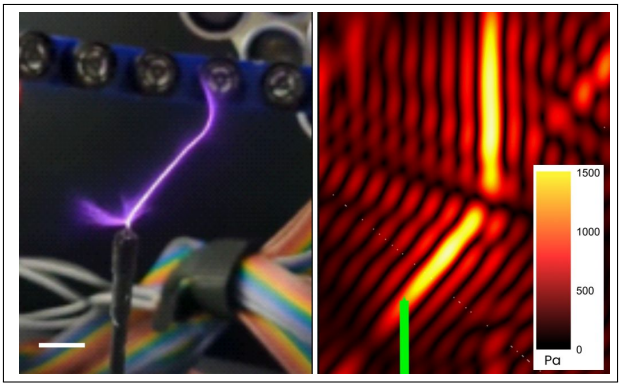

Figure 4. An electric spark is guided along the high-amplitude region of a 40 kHz ultrasonic field. left) guided spark. right) amplitude field. scale bar is 1 cm.

4. CONCLUSION

Acoustic levitation keeps evolving both in techniques and applications. Its low cost and larger scale of manipulation when compared with optical trapping makes acoustic levitation an active research topic.

ABSTRACT

Piezoelectric sensors based on acoustic waves propagating into micro electro-mechanical systems (MEMS) are a lively research area, with devices based on flexural plate waves (FPW) finding applications across various fields, including industrial and biological sectors. In this paper, a temperature sensor based on a piezoelectric MEMS that exploits the first antisymmetric mode, denoted as the A_0 or FPW mode, of Lamb waves generated in a diaphragm is presented. The micromachined diaphragm is composed of a stack of doped silicon and an aluminum nitride (AlN) piezoelectric layer with aluminum interdigital transducers (IDTs) employed for wave generation and detection. The proposed MEMS sensor exploits the variation of the FPW propagation velocity in the diaphragm due to temperature. The sensor expected working temperature range is at least 20 to 80 °C and in this preliminary phase has been tested from 25 to 45 °C by means of a tailored PID controlled temperature chamber including a Peltier cell and a Pt100 sensor while measuring the electrical admittance of a single IDT. The working principle has been validated within the frequency range from 11.185 to 12.88 MHz. Measurements have confirmed the sensor working principle, demonstrating a sensitivity of -426.5 Hz/°C and highlighting its potential for extending the operating temperature range.

1. INTRODUCTION

MEMS-based sensors are extensively employed in several research fields [1], including environmental monitoring [2], biomedical diagnostics [3], and industrial automation [4]. MEMS temperature sensors play a critical role in various applications where precise temperature monitoring is essential, such as tracking the internal temperature of smartphones [5], measuring human body temperature [6], or regulating indoor environments in heating, ventilation, and air conditioning (HVAC) systems [7]. Given the widespread adoption of MEMS temperature sensors, significant efforts have been made to develop and optimize different transduction principles, including resistive [8], optical [9], and piezoelectric [10], the latter being particularly notable for its high responsivity to temperature variations and suitability for harsh environments [10]. Specifically, among piezoelectric sensors, acoustic wave-based sensors have gained attention due to their high sensitivity and reliability [11]. Typically, acoustic wave MEMS temperature sensors are based on surface acoustic wave (SAW) [12], bulk acoustic wave (BAW) [13], and flexural plate wave (FPW) [14]. Among acoustic wave sensors, FPW MEMS exploit the propagation of Lamb waves in thin diaphragms and exhibit several advantages, including the operating frequency range typically in the tens of MHz and the ability to operate in contact with liquids with low losses [15,16]. In this context, this work presents a novel piezoelectric MEMS temperature sensor based on flexural plate waves, specifically exploiting the first antisymmetric mode (A_0) of Lamb waves. The sensor exploits the variation in the propagation velocity of FPWs in a micromachined piezoelectric diaphragm as a function of temperature, enabling thermal measurements.

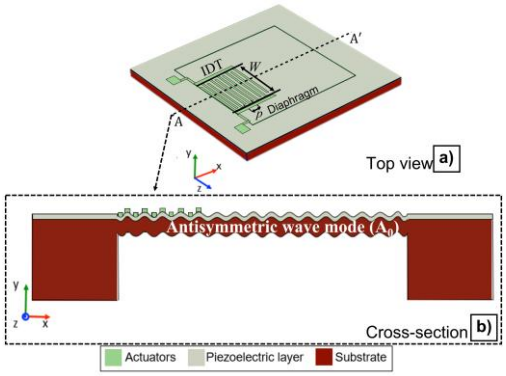

Figure 1. Top (a) and cross-section (b) schematic views of the proposed piezoelectric temperature sensor.

2. DESCRIPTION AND WORKING PRINCIPLE OF THE PROPOSED MEMS TEMPERATURE SENSOR

Fig. 1a shows a schematic representation of the top view of the proposed MEMS. The device is composed of a square diaphragm with an interdigital transducer (IDT), positioned close to the edge of the diaphragm, which comprises two interleaved comb-shaped electrodes. Each electrode consists of equally spaced fingers with a pitch p and aperture W, located on top of a piezoelectric layer. By applying a sinusoidal voltage across the IDT fingers, a perturbation in the thickness of the AlN layer, and consequently in the diaphragm, is induced, as schematically shown in the cross-section view A-A' of Fig. 1b. At specific frequencies, this perturbation induces mechanical vibrations in the diaphragm in the form of Lamb waves. Specifically, the first antisymmetric mode (A_0) has been excited at the synchronous frequency $f_{A0}=v_{A0}/p$ where v_{A0} represents the propagation velocity of the A_0 mode. The proposed MEMS has been manufactured by means of the PiezoMUMPs process [17]. The device features overall dimensions of 9 mm × 9 mm and incorporates a 6 mm × 6 mm squared composite diaphragm. The top and bottom views of the manufactured device are shown in Fig. 2a and 2b, respectively. The diaphragm consists of a material stack composed of a 10 µm thick silicon (Si) layer and a 0.5 µm thick piezoelectric aluminum nitride layer. The AlN layer on the composite diaphragm can be actuated by eight IDTs, positioned on the inner and outer edges of the diaphragm and arranged symmetrically with respect to its center.

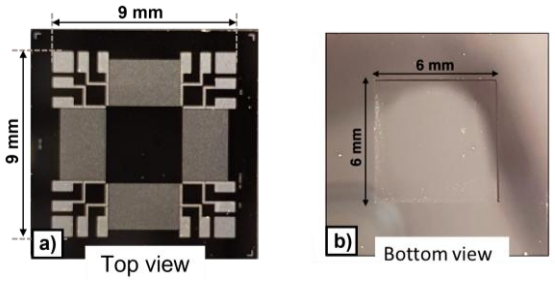

Figure 2. Top (a) and bottom (b) views of the fabricated piezoelectric MEMS sensor.

Each IDT comprises two interleaved comb-shaped electrodes. Each electrode consists of $N = 10$ equally spaced fingers, with a pitch $p = 112$ µm and an aperture $W = 3.5$ mm. By considering the tolerances of the fabrication process the frequency f_{A0} is expected to be between 11 and 15 MHz [15]. The proposed MEMS sensor exploits the variation of the FPW propagation velocity v_{A0} in the diaphragm due to thermal expansion and changes in the Young's modulus of the materials as a function of temperature [18,19]. The device was configured as a one-port transducer and the electrical admittance $G(f)$ of a single IDT has been analyzed as a function of temperature. This is expected to produce a frequency shift in the IDT admittance pattern centered at f_{A0} of the A_0 mode [14, 20], with a downshift in frequency as the temperature increases. The expected working temperature range is at least 20 to 80 °C as observed in similar AlN-based MEMS devices, [21] while in this preliminary phase it has been tested within 25 and 45 °C.

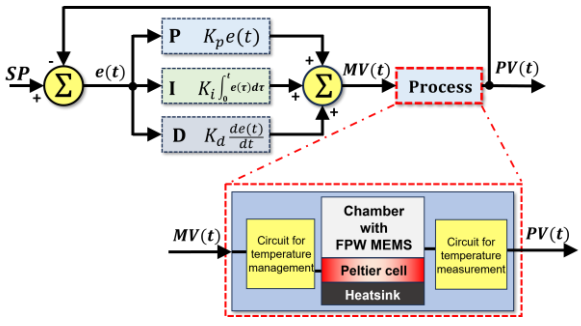

Figure 3. Schematic representation of the implemented PID controller. The enlarged view shows a detail of the controlled process, embedding the FPW MEMS temperature sensor, the actuator (Peltier cell), and auxiliary circuits.

3. EXPERIMENTAL SETUP

The operating principle was experimentally investigated using an HP4194A impedance analyzer and a custom experimental setup, including a thermal chamber regulated by a proportional-integral-derivative (PID) controller. Fig. 3 shows the block diagram of the implemented PID controller. The time-dependent process variable *PV(t)* corresponds to the chamber temperature *T*, which is measured using a dedicated temperature sensing circuit and compared with the setpoint variable *SP*, representing the desired operating temperature. The error $e(t) = SP - PV(t)$ is processed by the PID control algorithm, which incorporates proportional, integral, and derivative control actions with gains K_p, K_i, and K_d, respectively. The resulting manipulated variable *MV(t)* feeds a thermal management circuit to control the chamber temperature *T*. The system is specifically designed to establish and maintain predefined temperature profiles, enabling a precise characterization of the proposed MEMS temperature sensor. Fig. 4a illustrates the developed thermal chamber, which has been built using insulating foam layers. A Marlow TG12-6 Peltier cell has been employed as the heating element and is positioned at the bottom of the chamber, with a heat sink attached to its outer surface as shown in Fig. 4b. The Peltier cell is driven by a Pulse-Width Modulation (PWM) controller, which facilitates power regulation.

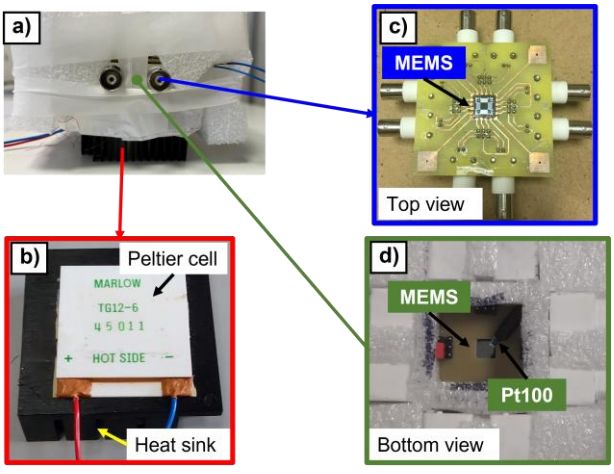

Figure 4. Experimental setup. Thermal chamber made of insulating foam (a). Peltier cell and the heat sink used to control the chamber temperature (b). Top view of the PCB adapter for the proposed MEMS sensor (c). Bottom view of the PCB adapter and Pt100 reference sensor positioned inside the chamber (d).

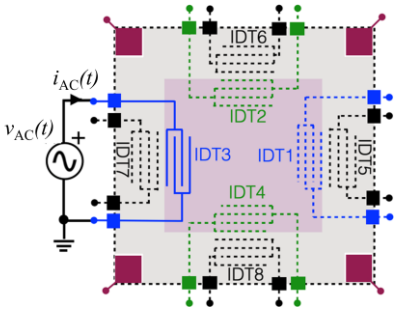

Figure 5. Simplified schematic representation of the proposed MEMS sensor configured for electrical admittance measurements.

The PWM driver is controlled via the PID algorithm, implemented through a LabVIEW interface. The chamber temperature *T* is measured using an HP34401A multimeter connected to a Pt100 resistive temperature detector (RTD) temperature sensor located inside the chamber, with a sampling time of 1 s. The FPW MEMS temperature sensor was fixed on a printed circuit board, as shown in Fig. 4c and Fig. 4d.

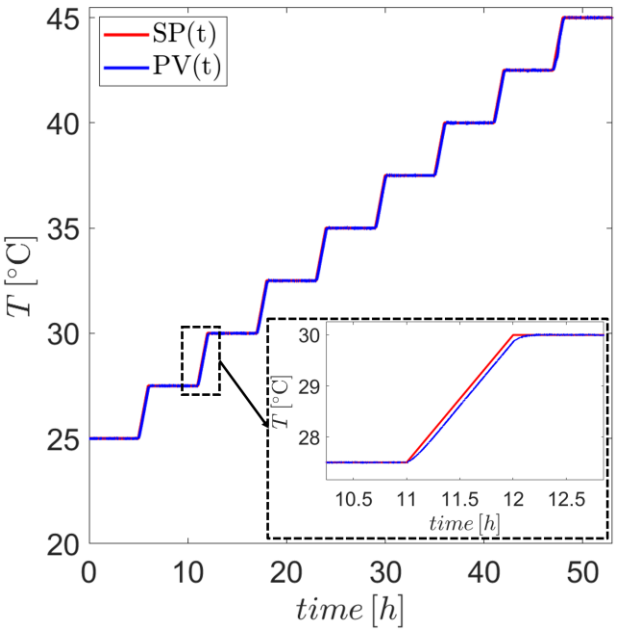

Figure 6. Setpoint (*SP*) and measured chamber temperature (*PV*) as a function of time. The inset shows the transient response to a heating step of 2.5 °C.

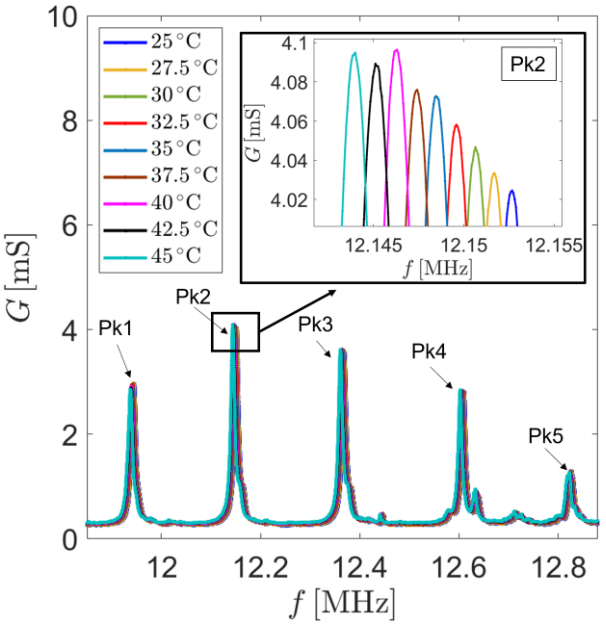

Figure 7. Measured conductance *G(f)* of a single IDT as a function of the excitation frequency *f* at different temperature *T*. The inset shows an enlarged view of the second peak Pk2 of *G(f)* at different temperatures.

4. EXPERIMENTAL RESULTS

To validate the proposed MEMS temperature sensor, the electrical conductance *G(f)* of a single IDT, namely IDT3, was measured according to the schematic diagram shown in Fig. 5, while the remaining IDTs were left floating, i.e., electrically unconnected. A sinusoidal excitation with a rms amplitude V_{AC} of 1 V was applied, while the frequency *f* was swept between 11.185 and 12.88 MHz with a step size of 70 Hz at different temperatures. The proposed sensor has been tested within the temperature range of 25°C to 45°C, while varying the setpoint *SP* with a 2.5°C step as shown in Fig. 6. The time required to achieve steady state after each 2.5°C step was set as 1 hour, as illustrated in the inset of Fig. 6. An additional delay of 30 minutes after the beginning of the steady state was introduced before conducting admittance measurements. Thanks to the continuous real-time temperature control implemented via the PID, the *PV* accurately followed the *SP* ensuring precise thermal regulation, as shown in the inset of Fig. 6. Measurements were performed while maintaining a stable temperature over time, with a variation of approximately ±0.02 °C. Fig. 7 shows the measured *G(f)* of IDT3 as a function of the excitation frequency *f*. The obtained conductance patterns show five distinctive main peaks within the considered bandwidth caused by the IDT3 location on the diaphragm and by the diaphragm dimensions [15, 22]. A conductance peak is obtained when the wavelength is an integer submultiple of the propagation path, defined as twice the distance between the center of the IDT and the outermost constraint of the diaphragm [22]. The obtained series of peaks (Pk1-5) exhibits a rigid downshift in frequency as the temperature *T* increases, as visible in the inset of Fig. 7, where the second peak of *G(f)* is shown. Fig. 8 illustrates the frequency shifts Δf as a function of ΔT, where $\Delta T = T - T_0$ with T_0 = 25 °C. The frequency shift is defined as $\Delta f = f_m - f_{m0}$, where f_m represents the frequency at which the conductance *G(f)* reaches its maximum for the five measured conductance peaks, and f_{m0} the corresponding values at the reference temperature T_0. The dashed line represents the linear fitting of the average frequency shifts obtained by averaging the individual shifts of the conductance peaks as a function of ΔT. For ΔT = 25 °C, a frequency variation of -8.628 kHz has been measured. The proposed MEMS sensor exhibits a sensitivity of -426.5 Hz/°C, with a maximum nonlinearity error, referred to the full scale, of 1.18%.

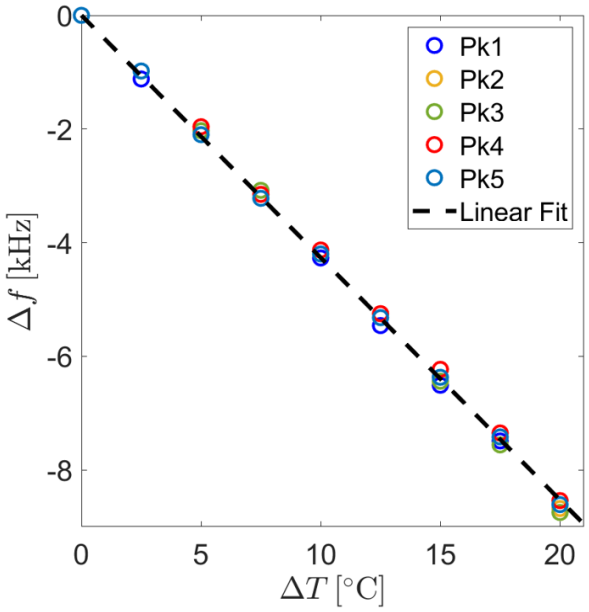

Figure 8. Frequency shifts Δf as a function of ΔT for the five conductance peaks. The dashed line represents the linear fit of the average frequency shifts obtained for the five peaks.

5. CONCLUSIONS

In this work, a piezoelectric FPW MEMS temperature sensor was presented. The proposed sensor exploits the first antisymmetric (A_0) vibration mode of Lamb waves to measure the surrounding temperature. The operating principle was experimentally validated using a custom PID-controlled temperature chamber, ensuring precise measurement conditions, accurate characterization, and minimal external interferences. The sensor was validated over the temperature range of 25 °C to 45 °C within the 11.185 to 12.88 MHz frequency range. For ΔT = 25 °C, a frequency shift of -8.628 kHz was measured. The proposed MEMS sensor exhibits a sensitivity of -426.5 Hz/°C with a maximum nonlinearity error of 1.18% referred to the full scale. The results obtained demonstrate the feasibility of using FPW-based piezoelectric MEMS for temperature sensing applications, confirming the expected downshift in frequency of the conductance pattern as the temperature increases and highlighting its potential to operate over an extended temperature range.

ABSTRACT[*]

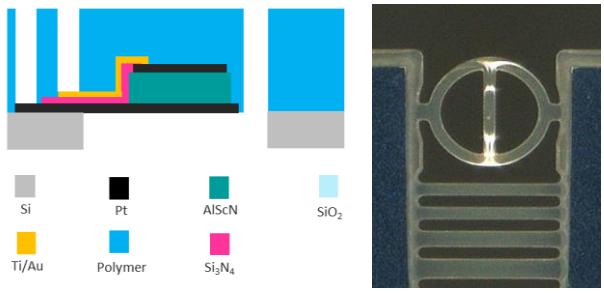
Silicon-based MEMS technologies for acoustic transducers are mature, widely available and have enabled a strong industry for consumer and niche markets while fulfilling the More-than-Moore promise. Nevertheless, mass production faces continuous innovation, manufacturability and testing challenges that prevent a higher market implantation of proof-of-concept acoustic MEMS devices. In response to these challenges, this paper discusses new integration trends involving the hybrid integration of polymeric materials into the flow of MEMS manufacturing. New test and modeling methodologies to address corresponding performance and data handling challenges are also discussed in this paper.

Keywords: *polymer acoustic MEMS, wafer temporary bonding, thin wafer handling, non-ideal MEMS modeling, manufacturing of acoustic MEMS devices.*

1. INTRODUCTION

Nowadays, majority of micro electromechanical system (MEMS) devices in industrial production have leveraged on pure silicon-based processes. More recently, thin-film piezoelectric materials have enabled a whole new range of miniaturized acoustic MEMS devices, from microphones to speakers, from audio to ultrasound bands, and to serve a wide variety of consumer and industrial applications. While conventional sets of materials and silicon-based processes used in these devices demonstrate proof-of-concept feasibility and functionality, performance for industrialization and mass production is not yet there. To address performance practical implementation issues, recent trends in acoustic MEMS device development have seen increasing efforts in polymeric materials integration (moving on from pure-silicon processes to heterogeneous polymer-MEMS materials) [1-5]. Nevertheless, and while polymers bring in a whole new range of convenient mechanical properties that enable new and competitive applications, it also poses new challenges to micromachining and wafer handing for mass production environments. In the following sections, we compare techniques for polymer film transfer as well as properties crucial for manufacturability and device reliability, which involve crucial temporary bonding and debonding processes, to enable safe and reliable processing of thin wafers. We highlight advantages and disadvantages of state-of-the-art techniques like thermal slide-off, UV and IR laser debonding.

Stress control and tunability is another key challenge faced by MEMS devices, which greatly impact manufacturability and device performance. In Section 4 we discuss the impact of stress performance and methods to carry out stress control to accomplish specific performance goals. Finally, Section 5 proposes a brief discussion on testing challenges associated with non-linear and non-ideal behavior of MEMS devices, and handling, analysis and postprocessing of large amount of test data required in production.



2. POLYMER INTEGRATION TO MEMS PROCESS FLOW

2.1 Polymer film and challenges

Figure 1 shows an example process of an acoustic MEMS device integrating a polymer layer and more *conventional* stacked structure and micromachining techniques. Polymer

Figure 1. Example process of an acoustic MEMS device integrating polymer: (a) Schematic of a cross section; (b) realization o of a polymer-based piezo cantilever and Guckel ring stress test structures

integration in the flow of acoustic MEMS devices is challenging as polymers are usually sensitive to temperature. Requirements involve thick layers that are usually in the range of a 10-100 µm, and that require coating of the polymer on a micromachined surface with high aspect ratio features and finally patterning of the thick polymer layer should be achieved while keeping reachable critical dimensions (CD) as low as possible and side walls as vertical as possible. In the following sections, we discuss the best coating techniques and polymer materials candidate for MEMS integration.

2.2 Polymer selection and coating technique

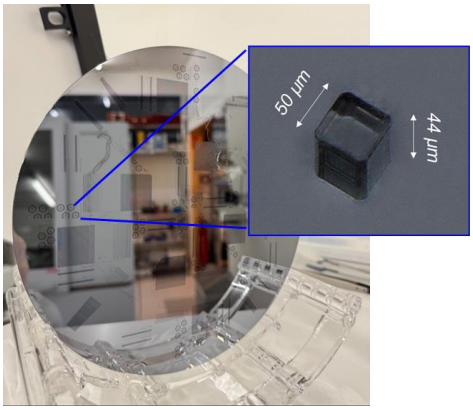
Specifications and constraints were given for the polymer. This polymer needed to be patterned with a required CD of 10 µm, a minimum reachable aspect ratio of 1, a Young's Modulus higher than 3 GPa, a glass transition temperature (Tg) >150°C, a total thickness of 45 µm. Coating should be conformal on a substrate with surface features consisting in steps of 1 to 4 µm and aspect ratio below 1. And lastly all processes need to be compatible with mass production.

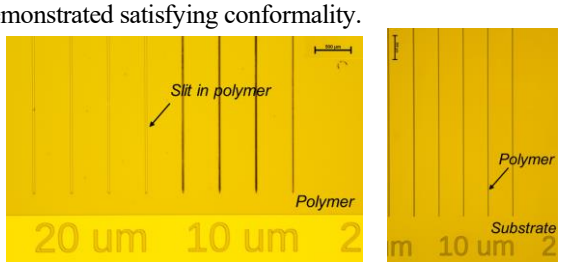
2.3 Polymer dry film

Different coating techniques can be used to realize the dry film, including spin coating, dip coating, spray coating, lamination and vacuum bonding. Among all the different coating techniques, thick layers are mostly coated using dip coating, lamination or vacuum bonding. In general, only lamination and vacuum bonding are mostly used with batch processes. In the end, we selected vacuum bonding to perform conformal coating and potentially reduce the number of trapped air bubbles between the substrate and the polymer. Vacuum bonding is performed with polymer dry films. For this process we selected a 45 µm SU8-based dry-film from Nippon with an expected Young's Modulus of 3.5 GPa and Tg of 280°C. This polymer dry film is a negative photoresist.

2.4 Dry film adhesion and patterning

After substrate plasma O_2 treatment and dry-film vacuum bonding with the EVG 520IS bonder we processed the dry-film using post bonding bake, then UV-exposure, post exposure baking and development using PGMEA. Hard bake was finally performed in an oven at 170°C for at least 80 min. First trials demonstrated vertical sidewalls -see **Figure 2.**





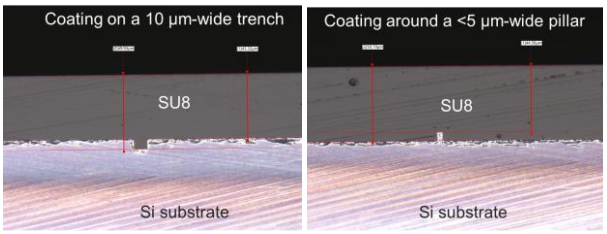


Figure 2. Bird's eye view of a patterned polymer square on 200mm wafer for sidewall characterization.

Error! Reference source not found.3 shows a successful i mplementation example, which reaches a maximum aspect ratio of 2.25 in polymer (**Error! Reference source not f ound.**3a), and a minimum CD of 10 µm see **Error! Reference source not found.**b. On the other hand, **Figure 4** shows test structures with conformal coating on steps with a width of 10 µm and depth of 5 µm were also validated as well as conformal coating of pillars down to a width and height of 5 µm. No trapped air bubbles were noticeable near the patterned features in the silicon substrate. The coating demonstrated satisfying conformality.

2.4.1 Adhesion test and Mechanical Properties

To be noted that the substate was coated with a 100 nm-thick SiO_xN_y layer, as for the final device, thus we performed a pull-off adhesion test using a Zwick/Roell Z2.5 apparatus to validate adhesion of the polymer film on the substrate, see **Figure 5**.

Adhesion loss, delamination occurred at ~ 0.31 MPa between the dolly and the double-sided tape used to fix the sample. The 3M LSE-160WF double-sided tape has a theoretical pull-off adhesion limit at 0.47 MPa. We failed to de-bond the polymer layer from its substrate and concluded to a satisfying adhesion of the polymer to the SiO_xN_y layer. The reduced Young's Modulus of the SU-8-based dry-film was measured using the FT-104 Femto-Indenter from Femtotools. We obtain a reduced modulus equal to 5.3 GPa, meaning a Young's Modulus of 4.8 GPa assuming for dry film a poisson coefficient, ν, close to 0.32 [6].

We measured the Young's Modulus, *E*, 137 % higher than

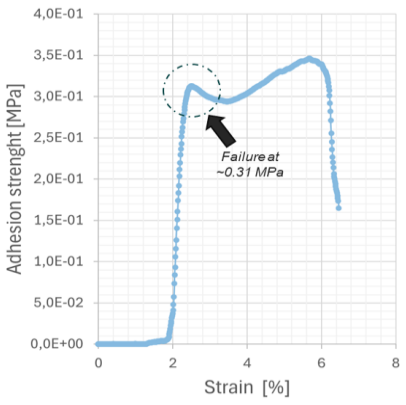

Figure 5. Pull-off test showing dry film adhesion strength vs strain.

what was expected from the datasheets. The discrepancy still needs to be investigated and could be attributed to different characterization techniques and scale between this work and the dry-film manufacturer. However, a higher Young's Modulus than expected is beneficial for the final MEMS device as E > 3 GPa leading to a stiffer structure.

Using our FT-104 Femto-Indenter, we performed continuous stiffness measurement (CSM) nanoindentation from ambient temperature up to 200°C and observed a drop of around 35% of the storage Young's Modulus at 170°C, thus we could assume a Tg close to 170°C which is higher than 150°C, but lower than expected from datasheet. Finally, we measured relatively low residual tensile stress in the blanked polymer layer close to 27 MPa. Ultimately, we selected the dry film polymer from datasheets provided by the manufacturer, development of the processing recipes was performed, and we confirmed its mechanical properties and productization. The next step will be grinding and polishing the silicon substrate to obtain small form factor and thin devices. More details are given in the next section.

3. THIN WAFER HANDLING AND PROCESSING

3.1 Why is temporary bonding needed?

Current mainstream in industrial applications requires miniaturized and cost-effective solutions. Thus, the demand for thin and ultrathin wafers is growing. Temporary bonding is a crucial process that enables safe and reliable processing of thin or to-be-thinned wafers [7, 8]. Thin wafers are very fragile, and as a result chips and cracks can easily occur. Thus, the final yield is at a high risk since these wafers should pass through processing steps like lithography, etching, deposition and others. The industry seeks reliable batch solutions in temporary bonding and debonding that ensures repeatability and high productivity at reasonable cost [9].

3.2 Temporary bonding technologies

A first technique involves direct bonding of MEMS device wafers and a carrier wafer using a special Temporary Bonding Material (TBM) [10] as shown in Figure 5(I). This material is an organic thermoplastic or thermoset adhesive spin coated on a carrier or device MEMS wafer. This process is suitable for simple chemical release debonding. A more complex process combines TBM with a thin Layer Release Material (LRM) [11, 12], intended for UV or IR debonding process -see Figure 5(II).

Typically, the bonding step occurs via thermocompression in vacuum or, in some cases, using UV radiation. The TBM is selected tailored to the intended application considering ease of coating, shorten processing time and simplified cleaning. Ideally, it is applied using single coat step ensuring uniform, void free and low stress interface between carrier and device MEMS wafer. The thickness should be enough to cover all topography on device MEMS wafer. The adhesive should be compatible with the intended thermal budget for subsequent process steps. The choice of carrier wafer is based on the target debonding process and CTE match with the device MEMS wafer to minimize induced thermomechanical stress. For example, silicon carrier is a perfect match for silicon device MEMS wafer. However, the technique such as UV laser debonding is not an option in this case since it requires transparent carriers such as glass.

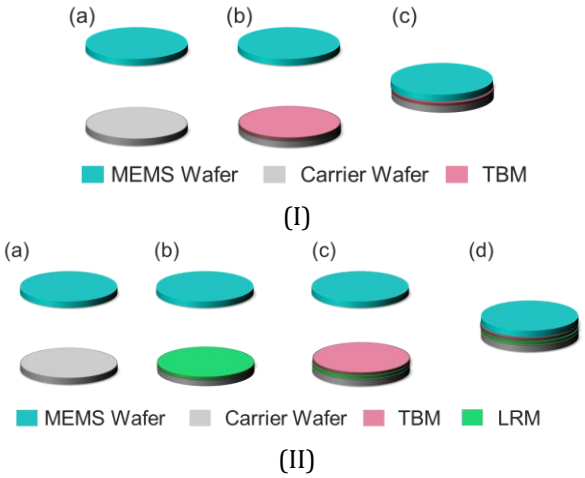

Figure 5. Temporary bonding process designed for: (I) chemical release debonding or thermal slide off; (II) UV or IR laser debonding.

3.3 Chemical release debonding

The chemical release debonding is established and reliable technique for temporary bonded wafers. The temporarily bonded stack is placed in a solvent bath to separate carrier and device MEMS wafer, and then a second bath is used to clean off any remaining adhesive. One can expect an approximate throughput of 25 wafers per debonding cycle that can be up to 4 hours. The main advantage of this technique is low induced stress. However, this technique is comparably slow and, in the end, expensive for high volume production. This pushes industry to develop new temporary bonding materials and corresponding processes.

3.4 Thermal slide-off debonding

In case of thermal slide off debonding, the wafer stack is heated up and separated by sliding wafers apart as Figure 6 illustrates. There is a trade-off between temperature, mechanical force and sliding rate. The maximum throughput is higher, up to 15 wafers per hour. Unfortunately, the stress induced by this debonding technique can be critical for fragile MEMS devices, limiting total yield.

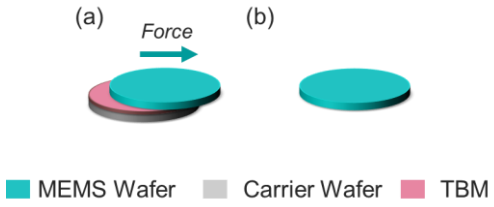

Figure 6. Thermal slide-off debonding process.

3.5 Laser debonding

Laser debonding technique offers high throughput up to 50 wafers per hour and low induced stress that is required to maximize yield in case of sensitive MEMS devices. This technique requires a special inorganic LRM layer [11, 12] that has high absorbance at specific wavelengths in UV (254 nm, 308 nm, 355 nm) or IR (1064 nm) band. This material is decomposed due to photochemical or photothermal effects leaving almost no residues. These residues can be later cleaned using oxygen plasma or an oxidizing solvent. After laser exposure happens, the temporary bonded stack can be separated with almost no force that is a great advantage for fragile structures. Figure 7 illustrates a simple laser debonding process involving (a) laser rastering and heating of the LRM layer; (b) wafers separation; (c) TBM removal.

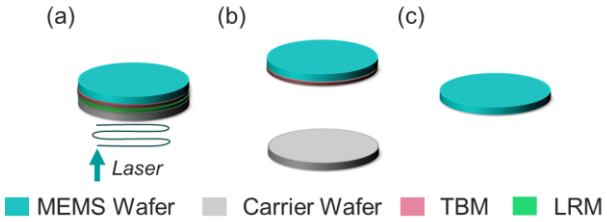

Figure 7. UV or IR laser debonding process.

4. STRESS TUNING FOR ACOUSTIC PERFORMANCE AND MANUFACTURABILITY

4.1 Why is stress control needed?

Stress becomes an important factor for acoustic performance, as it impacts both the geometry, the small and large signal performance and functionality, and the long-term reliability of the device. Geometric parameters include residual deflection of a cantilevered structure, or mismatch of deflections in arrays, buckling, and offsetting of key layout features. Functionality is also affected as losses, electrical, dielectric and piezoelectric performance rely on stress. This has direct consequences on key figures of merit of the device like sensitivity, SNR, resonance frequencies, and electromechanical coupling coefficients, among others. On the other hand, it is worth clarifying that stress is, rather than a problem, a physical situation intrinsic to stacked-layer devices. Also, that stress engineering problems become visible when MEMS manufacturing leave the early R&D proof-of-concept phase, typically done on small wafers, and move to large 200mm wafer format. Therefore, there is a need to tune stress to the performance goals of the MEMS device. This is discussed in the next paragraphs.

4.2 Stress tunability in c-axis textured piezoelectric AlScN thin films

The stress in polycrystalline and textured thin films can be controlled by adjusting various factors. These factors include both extrinsic and intrinsic components. Extrinsic stress is primarily influenced by the processing temperature, known as thermal stress. Intrinsic stress is more complex and arises from the kinetics of film growth, grain boundary densification, and the generation of point defects in the bulk. Chason *et al.* [13] have proposed a kinetic model for stress, which describes *total stress* as the sum of three components, namely growth-related stress, grain boundary energetics-related stress, and bulk energetics-related stress. This model suggests that by controlling the RF bias power of the tools carrying out physical deposition or growth of the acoustic MEMS layers and that affects the kinetic energy of incoming ions, one can manipulate all three components of stress.

As an example, we deposit scandium-doped aluminum nitride (AlScN), a piezoelectric thin-film that we use as active transducer layer of the acoustic MEMS device. Deposition is carried out by physical vapor deposition (PVD) using an industrial cluster tool Cluster 200E from Evatec. In our work, we tune the residual stress of c-axis textured AlScN films by applying an RF bias power to the chuck during deposition. The RF bias power varies from 50 W to 250 W, which leads to a linear increase in compressive stress with increasing power. The residual stress was measured using a Toho Stress measurement system, which employs Stoney's equation to relate the wafer curvature to the film stress [14]. The standard Stoney's equation used is:

$$\sigma = \frac{E \times t_s^2}{(1-\nu) \times t_f}\left[\frac{1}{R_f} - \frac{1}{R_s}\right] \qquad (1)$$

Where E and ν are the Young's modulus and Poisson's ratio of the substrate, t_s and t_f are the thicknesses of the substrate and film, and R_f and R_s are the radii of curvature after and before film deposition, respectively. Our experimental results show that for 500 nm thick Al0.64Sc0.36N films on Pt/AlN/Si100 electrodes, the average biaxial compressive residual stress is linearly dependent on the applied RF bias power. After laser exposure happened, temporary bonded stacks can be separated with almost no force that is a great advantage for fragile structures.

The plot in Figure 5 shows how stress control is a function of RF bias power. Selected bias point is defined by the target value defined by the application and stack of layers in the acoustic MEMS device.

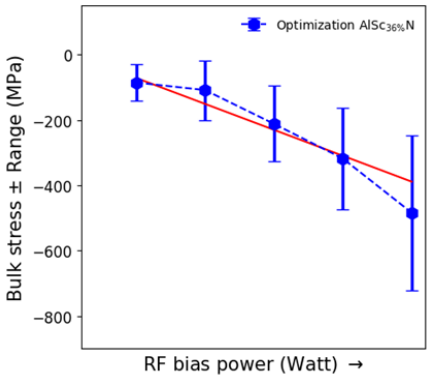

Figure 5. Dependence of RF power chuck bias to the residual stress of the AlScN thin film deposited on a 200 mm silicon wafer.

5. FEW WORDS ABOUT TESTING CHALLENGES

Testing of MEMS devices in the production environment poses several challenges. First of all, foundry setup is typically prepared for pure electrical testing, while MEMS devices generally require multi-physical domain environment. Adapting fab resources away from conventional *e-test* (electrical testing) is far from trivial.

This issue has direct impact in the cost of final application, as MEMS yield has to be characterized, modeled and improved at reasonable cost. Later stages of production will involve singulation of MEMS devices and testing them either integrated with electronic components in a module, or as stand-alone chips. Then, events such as crosstalk due to acoustic waves interfering in the data acquisition, robustness of die bonding using flexible glues, or even clamping losses will affect performance. A fully manufacturable flow will need test methodologies that integrate seamlessly in the manufacturing setup of standard foundries.

6. CONCLUSION

This paper has reported on relevant technologies needed for industrialization and successful inception of MEMS technologies in markets, namely polymeric dry film integration, handling of thin wafers as part of flow, MEMS stack stress management and tuning, and testing methodologies. Dry film integration enables new applications and performance of acoustic devices. MEMS wafer temporary bonding to carrier wafers in turn enables polymer processing, while debonding enables final MEMS device release for acoustic performance. Batch testing finally enables new wafer sorting methodologies.

ABSTRACT

Smartwatches are wearable devices designed for continuous and precise data collection, ensuring minimal disruption or discomfort for the user. Their ability to monitor movement makes them particularly effective for applications such as health monitoring or workplace risk evaluation. However, the inertial sensors embedded in these devices may exhibit inaccuracies in data acquisition, which could compromise the quality of the results. Therefore, thorough characterization is essential to understand their response under specific excitation conditions.

This study evaluates the performance of accelerometers in four commercially available smartwatches, by assessing their frequency responses using two different calibration methods. Method 1, considered the reference method and involving individual sensor calibration, produced minimal deviations, validating the reliability of the devices within the tested ranges. In contrast, Method 2, intended for quicker calibration of multiple devices, showed greater deviations due to limitations in the calibration process.

The results revealed discrepancies in performance based on the calibration method used, highlighting the importance of selecting an appropriate technique to ensure more reliable and accurate measurements, especially for critical human movement monitoring applications.

1. INTRODUCTION

Wearable technology has experienced significant growth in recent years, driven by the integration of advanced sensors into portable devices such as smartwatches, smart glasses, or biometric rings. These systems are widely adopted due to their ease of use, portability, and real-time data collection capabilities. Their main applications include occupational risk assessment, human movement and physical activity analysis [1], with increasing potential in healthcare [2]. Nevertheless, despite their advanced capabilities, multiple studies [3-5] have identified critical technical limitations in the embedded sensors of these devices, particularly regarding the accuracy and reliability of data acquisition.

Smartwatches are among the most common and widely adopted wearable devices [1] due to user familiarity and their integration into daily life. These devices are equipped with inertial sensors, including triaxial accelerometers and gyroscopes. The combined use of these sensors enables a detailed analysis of the user's dynamic behavior.

Periodic calibration or verification of sensors is essential, as factors such as environmental variations, temporal drift or device configuration changes can affect measurement reliability. To address this challenge, a thorough analysis of the sensor's dynamic behavior is required, focusing on its frequency and amplitude response under controlled vibratory excitation conditions [5]. This evaluation allows for the identification of the ranges where the sensor performs with maximum accuracy, while also revealing potential limitations in its measurement capabilities.

This study focuses on the characterization of accelerometers integrated into four commercial smartwatches of the same specific model. In healthcare and other movement monitoring studies, it is common to work with multiple identical devices. Therefore, ensuring that all devices

exhibit a similar and consistent response is essential for making reliable comparisons between the recorded data.

It is essential to determine the relevant amplitude and frequency ranges associated with human movement dynamics (hand-arm), with the aim of aligning the procedure with the specific operating conditions of the sensor. In this context, the frequency ranges extend up to 10 Hz, corresponding to physiological tremors [6], while typical amplitudes reach 4 m/s², as observed during human gait [7]. These parameters enable the assessment of smartwatch accelerometers in real-world applications.

This study employs two approaches for characterizing accelerometers to compare and analyze sensor performance variations under different calibration procedures.

The first method uses a uniaxial vibration bench, which allows for individual sensor characterization by applying precise vibratory excitation at different frequencies and amplitudes. While effective in terms of accuracy, this method can be time-consuming when calibrating multiple devices sequentially, making it less efficient for large-scale applications. This method was validated in [5], and is therefore considered the reference approach for comparison.

The second method utilizes a vibration platform, which generates vibrations on a surface. Unlike the previous approach, it allows for the simultaneous evaluation of multiple sensors, significantly reducing calibration time.

The study focuses on the comparative evaluation of the two calibration methodologies mentioned, employed to characterize accelerometers in smartwatches [8]. Through this analysis, the aim is to identify the advantages and limitations of each method in assessing sensor performance within the frequency and amplitude ranges associated with human movement. The ultimate goal is to optimize the calibration procedure, enhancing the reliability of measurements in biomechanical applications.

2. CALIBRATION METHODOLOGY

In studies related to human movement monitoring, particularly in healthcare or in safety fields such as risk assessments, multiple devices of the same type and model are typically used. Therefore, it is crucial that the data recorded by these sensors are comparable, meaning that all sensors must exhibit a precise and consistent response when subjected to the same mechanical vibration signal.

Consequently, this study focuses on characterizing the integrated accelerometers of four commercially available smartwatches of the same model by analyzing their frequency and amplitude response and verifying the consistency of their behavior. The sensors were configured with a sampling rate of 50 Hz and a maximum amplitude range of ±2 g, values considered appropriate for recording typical human movement dynamics in real-world scenarios.

Considering that the main objective of this study is not to fully characterize the accelerometer but to compare two calibration methodologies and evaluate their effectiveness, the analysis was intentionally limited to examining the frequency response of the Z-axis of the sensor. The axes orientation in the employed devices is shown in Figure 1.

Figure 1. Axes orientation in the employed sensor.

A vibratory excitation source is a device specifically designed to generate controlled vibrations, adjustable in terms of both frequency and amplitude, with the aim of subjecting sensors to defined testing conditions. The input signal applied is a sinusoidal waveform, as shown in Figure 2, whose characteristics are defined according to the sampling plan specifically designed for each study.

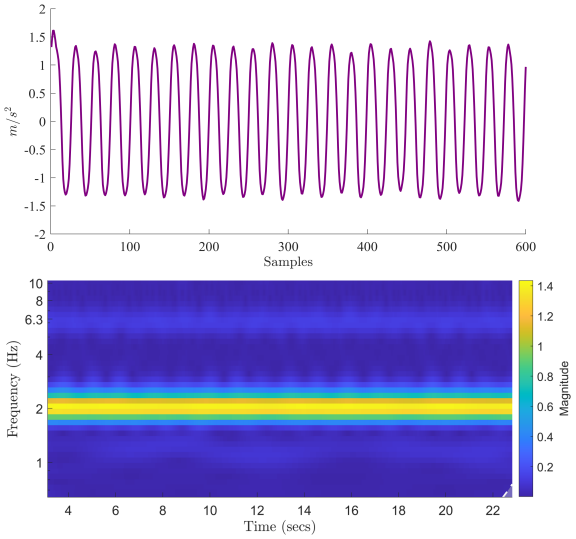

Figure 2. Signal captured by the accelerometer in a 2 Hz and 1 m/s² test. Top: time signal; Bottom: scalogram.

The quality of the calibration process is highly dependent on the performance of the excitation source. This study

employs two methodologies, each involving a different excitation source: Method 1, based on a uniaxial vibration bench, which enables the individual calibration of accelerometers through the application of precise and controlled vibrations; and Method 2, which utilizes a vibration platform capable of subjecting multiple sensors to uniform oscillations simultaneously, with the vibrations applied at a 45º angle relative to the horizontal plane.

The characterization of accelerometers is performed following the ISO 16063-21:2003 [9], which establishes a comparison methodology based on the use of a reference transducer. This method consists of rigidly coupling a calibrated reference accelerometer, which is presumed to function with a high level of accuracy, to the structure of the smartwatch, ensuring that both sensors are simultaneously exposed to the same controlled mechanical vibration.

2.1 Sampling plan

It is essential to establish a sampling protocol that clearly defines the specific frequencies and amplitudes to be used during the calibration process. It should guarantee that the characterization of the sensors is performed under controlled conditions that accurately replicate typical real-world hand-arm vibration scenarios.

Regarding the frequencies to be used for calibration, ISO 16063-21:2003 [9] recommends performing sensor characterization using vibratory excitations at standardized one-third octave frequencies, defined by ISO 266:1997 [10]. In the context of accelerometers designed for human movement analysis, it is crucial to adapt the excitation parameters to the typical frequency range characteristic of human activities in a variety of real-world contexts, which remains below 10 Hz [6, 11]. Accordingly, this study selected the frequencies of 1 Hz, 2 Hz, 4 Hz, 6.3 Hz, 8 Hz, and 10 Hz to evaluate the sensors' frequency response.

Concerning amplitude, the calibration was performed within an acceleration range of 1 m/s² to 4 m/s², reflecting the magnitudes encountered during common activities such as walking, running, or manual operations [7].

However, to develop a sampling plan suited to each calibration method, it is essential to carefully determine the operating range of the vibration sources used. In this context, multiple tests were conducted, establishing the operational interval for each method, as shown in Figure 3.

The common range shared by both calibration methods reaches up to 4 m/s² within the frequency band of 4 Hz to 6.3 Hz and decreases to 1 m/s² at 2 Hz. Method 1 offers the advantage of enabling excitations at higher frequencies (above 6.3 Hz), whereas Method 2 is particularly suitable for excitations at lower frequency ranges (below 4 Hz).

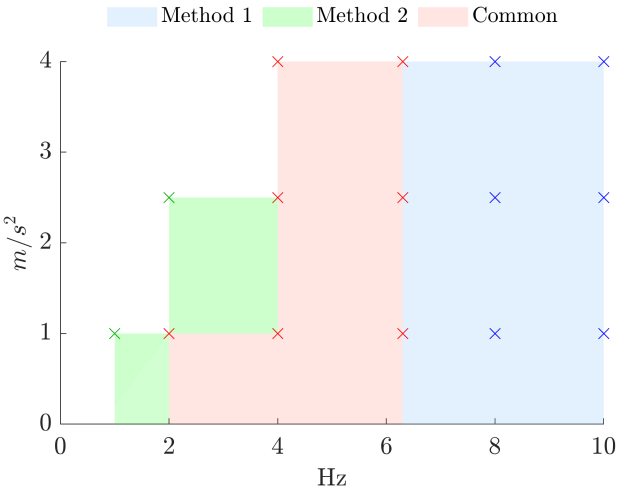

Figure 3. Specific operating range of the excitation sources in Method 1 and Method 2, including the common interval.

2.2 Setup

The calibration test setup is characterized by notable variations between both methods. In Method 1, the excitation source generates vibrations in a uniaxial configuration and, due to its geometric and dimensional constraints, it allows for the placement of only one device at a time, as shown in Figure 4 (left). Consequently, the smartwatch is positioned to ensure that the induced vibrations are applied exclusively along the Z-axis of its accelerometer. Additionally, the device is placed on a rigid and properly fixed holder, preventing the introduction of any undesired vibrations, guaranteeing the reliability and repeatability required for the calibration process.

In Method 2, the vibration excitation source consists of an actuator that induces vibrations on a platform at an angle of 45° relative to the horizontal plane, as illustrated in Figure 4 (right). Due to the dimensions of the surface where the vibration is generated, it is possible to place multiple devices simultaneously for calibration, thus facilitating a more efficient calibration process compared to Method 1.

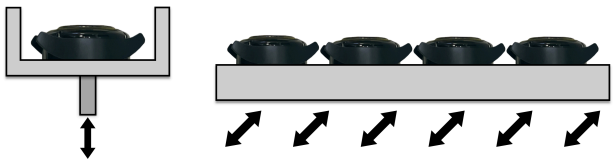

Figure 4. Movement induced by the excitation sources and placement of the smartwatches. Left: Method 1; right: Method 2.

Considering the characteristics of the excitation source in Method 2, there are two possible mounting configurations for placing the devices on the vibrating surface. The first option involves positioning the devices directly on the horizontal plane of the vibratory platform, as illustrated in Figure 5 (left). However, under this particular configuration, the excitation generated would simultaneously affect both the Z-axis and Y-axis of the device's accelerometer, resulting in a biaxial excitation. Although the mechanical implementation of this configuration is simple, it is not suitable for reproducing the Z-axis specific excitation carried out in Method 1.

Furthermore, to achieve the acceleration levels previously defined in the sampling plan, a, positioning the devices on the horizontal plane would necessitate that the platform generates an excitation with an amplitude equal to $\sqrt{2}a$, exceeding the acceleration levels intended for analysis during the calibration procedure. This requirement could lead to nonlinear behavior of the excitation source, particularly at low frequencies where higher amplitudes are required. Such nonlinearities may compromise the accuracy of the calibration and even pose a risk of structural damage to the platform due to excessive excitation levels.

In light of these considerations, the horizontal mounting option was deemed unsuitable for the intended calibration process. Instead, it was proposed to design and manufacture a custom support that holds the devices at a 45° inclination, aligned with the direction of excitation imposed by the actuator, as shown in Figure 5 (right). This approach ensures that the smartwatch experiences a uniaxial excitation along its Z-axis, replicating the conditions of Method 1 and thus enabling a direct comparison between both calibration methods.

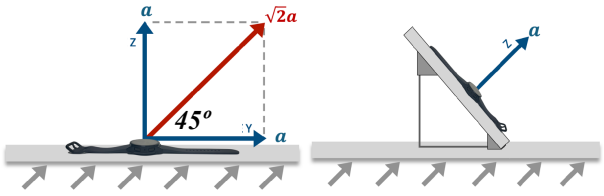

Figure 5. Smartwatch setup in Method 2. Left: horizontal plane, solution excluded from consideration; right: 45º, adopted solution.

The design of a custom fixture to support the devices must be carefully addressed, as several factors may influence the validity of the results. Among these, special attention must be given to the rigid attachment of the fixture to the vibrating platform and to the mounting of the devices on the fixture itself. Any looseness, misalignment, or insufficient clamping force could generate unwanted movements, resulting in distortion of the transmitted accelerations and, consequently, in erroneous calibration data.

Moreover, it is essential to consider that all mechanical structures subjected to dynamic excitations inevitably experience some degree of elastic deformation. If the fixture's natural frequencies fall within or close to the study's frequency range, undesired resonances may occur, potentially amplifying the input vibrations and introducing unwanted acceleration components into the measured signals. This phenomenon could significantly compromise the calibration process, leading to incorrect and unreliable estimations of the acceleration levels in the sensors.

Therefore, to mitigate this risk, it is necessary to ensure that the fixture behaves as a rigid body within the working frequency range, without exhibiting local modes or flexural deformations. To address these concerns, a modal analysis of the fixture was performed. The results revealed that the first resonance frequency is located at 56 Hz (Figure 6), which is above the operational frequency range of interest, since the calibration tests do not exceed 10 Hz. Based on these findings, it can be concluded that no significant resonances that could compromise the accuracy of the calibration results are present within the working interval.

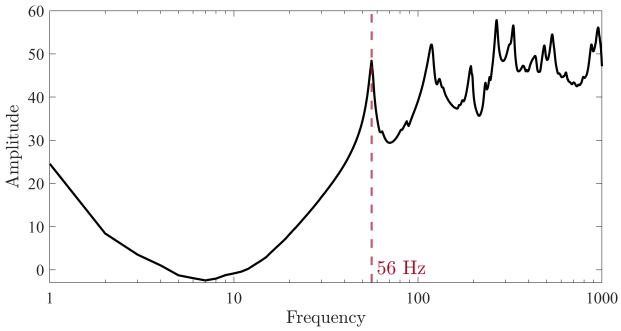

Figure 6. Fixture's global frequency response.

Regardless of the calibration method employed, since the comparative methodology is followed, a reference accelerometer was mounted onto the structure where the devices under evaluation were placed. This setup ensures that both the smartwatches and the reference sensor are exposed to the identical mechanical vibration signal.

2.3 Calibration procedure

In accordance with ISO 8041:2007 [12], for the calibration of hand-arm vibration measuring systems, each test had a duration of 30 seconds. This period was extended as needed to ensure that the excitation source reached a steady-state condition. To guarantee the validity and reproducibility of

the results, three measurements were performed for every combination of frequency and amplitude assessed. Following the sampling plans, Method 1 involved a total of 13 tests, while Method 2 consisted of only 9 tests.

The input signal was adjusted according to the specific test being conducted, with the frequency and amplitude modified as needed to align accurately with the defined sampling plan. This adjustment ensured that the reference accelerometer recorded root mean square (RMS) values of 1 m/s², 2.5 m/s², and 4 m/s², with the signals filtered through a second-order Butterworth bandpass filter.

2.4 Data processing

After completing the tests, the data recorded by the sensors were processed using an identical procedure for both calibration methods, thereby ensuring the comparability of the results. This step involved filtering the raw data from the Z-axis, which is critical to isolate the frequency range of interest and eliminate any unwanted noise that could distort the vibration signal. The filtering was performed using the same filter settings as applied to the reference accelerometer during the tests; specifically, a second-order Butterworth bandpass filter with a one-third octave bandwidth, centered on the relevant frequency band for each specific test.

In addition to removing noise from the source and the measurement environment, filtering also eliminates the effect of gravity. The accelerometer measures the sum of all forces acting on the sensor, which includes both the acceleration due to movement and due to gravity (a low-frequency signal, below 0.5 Hz, that is nearly constant). To focus specifically on the motion-induced data, it is necessary to filter out this low-frequency component.

Figure 7 presents an example of the signal recorded by the accelerometer of a smartwatch during a 1 Hz and 1 m/s² test, both before and following the filtering process.

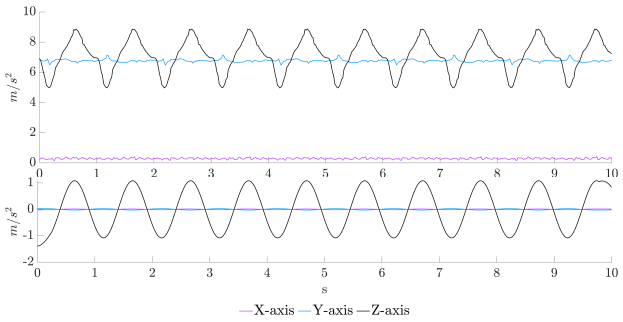

Figure 7. Signal captured by the smartwatch in a 1 Hz and 1 m/s² test. Top: before filtering; Bottom: after filtering.

Following the filtering process, the RMS value, which reflects the total energy of the input signal over a defined period, was calculated. The primary parameter under evaluation during the data processing phase is the error, which quantifies the deviation between the measurements from the test devices and the reference accelerometer.

3. RESULTS

A comparative analysis was performed to evaluate the results obtained with both calibration methods. This comparison considered the RMS values recorded by the smartwatches and their deviations relative to the reference accelerometer, which, during the tests conducted, recorded RMS-filtered accelerations of 1 m/s², 2.5 m/s², and 4 m/s².

Figure 8 presents the frequency and amplitude response of the smartwatches using calibration Method 1. The results indicate that, for all tests conducted, the values recorded by the accelerometers of the four smartwatches are almost identical. This consistency demonstrates that the devices are responding similarly to the applied vibrations. Furthermore, the measurements obtained from the smartwatches align with the recorded values from the reference accelerometer, demonstrating a high level of accuracy.

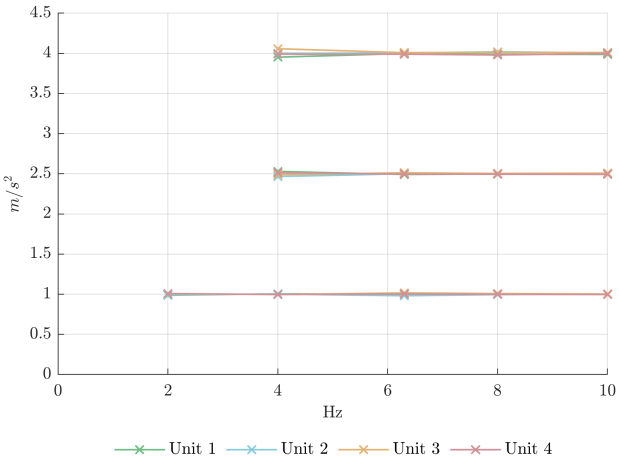

Figure 8. RMS values recorded by the smartwatches in Method 1.

Figure 9 presents the frequency and amplitude response obtained in Method 2. In contrast to Method 1, these results show some differences between the devices tested. The most significant discrepancies between smartwatches in Method 2 are observed when the input signal amplitude is 2.5 m/s², with deviations reaching up to 0.14 m/s². In comparison, the maximum deviation recorded across all tests in Method 1 was notably lower, 0.06 m/s². This

demonstrates that, despite using the same devices, their accelerometers respond differently depending on the applied calibration methodology. These differences suggest that the reliability of the measurements depends not only on the smartwatch hardware but also on the calibration method employed, which may contribute to additional variability and impact the overall validity of the collected data.

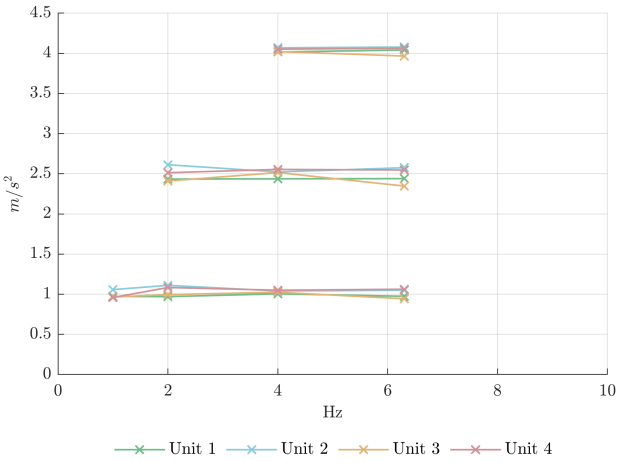

Figure 9. RMS values recorded by the smartwatches in Method 2.

According to ISO 8041:2007 [12], a smartwatch can be used for monitoring human movement and measuring hand-arm vibrations only if its frequency and amplitude response deviation remains within defined limits. These thresholds are defined as percentage-based limits, meaning that higher input amplitudes allow for a greater margin of error. They are set at 0.06 m/s² for an input of 1 m/s²; 0.15 m/s² for 2.5 m/s²; and 0.24 m/s² for an excitation of 4 m/s². Tables 1 through 4 present the absolute deviations of smartwatches relative to the reference sensor. Tests exceeding the limits defined by the standard are highlighted in red for clarity.

In Method 1, all smartwatches fully complied with the required specifications, showing deviations significantly below the established limits. The most notable discrepancies occurred with an input excitation of 4 m/s² at 4 Hz, with deviations of 0.05 m/s² in unit 1 and 0.06 m/s² in unit 3. However, these values fall well within the 0.24 m/s² limit and do not present any significant issue.

In most conducted, the deviations between the smartwatches and the reference sensor remained below 0.01 m/s², which corresponds to an error of less than 1% for all three input amplitudes. These results clearly demonstrate the high level of consistency and accuracy achieved by calibration Method 1 for hand-arm vibration measurements.

Focusing on Method 2, the deviations relative to the reference sensor remained within the permissible error margin in almost all cases, with only two exceptions. For the excitation of 1 m/s² at 2 Hz, units 2 and 4 showed errors of 0.09 m/s² and 0.08 m/s², respectively, slightly exceeding the 0.06 m/s² limit. However, considering that, using this method, a total of 36 tests were conducted across 4 smartwatches, and only 2 tests exceeded the established limit (representing less than 6% of the total tests), these discrepancies can be regarded as isolated incidents. Therefore, they do not compromise the overall reliability or effectiveness of the proposed method.

A comparison of the deviations between methods shows that, in most cases, the error is slightly greater in Method 2. This suggests that, while Method 2 provides reliable results, there is still potential to refine the methodology and achieve the level of accuracy demonstrated by Method 1.

4. DISCUSSION

This study assesses the performance of smartwatch accelerometers subjected to two distinct calibration procedures. The following analysis reviews the main results and identifies factors that may have contributed to any variations observed between the two methods.

The response obtained from the four smartwatches using Method 1 indicates that the deviations are minimal and can be considered negligible. This suggests that the behavior of the devices is highly precise and reliable within the tested frequency and amplitude range. Consequently, the devices do not introduce significant errors in their measurements relative to the excitations they are exposed to.

It is important to emphasize that Method 1 was validated in [5], thereby establishing it as the reference method for this study. Consequently, the outcomes derived from this approach are considered both reliable and accurate.

When analyzing Method 2, the deviations obtained by the tested devices are noticeably larger compared to those in Method 1. As concluded in the validated reference method, the performance of the smartwatches closely mirrors that of the reference accelerometer. Therefore, the errors observed in Method 2 are not attributable to the smartwatches' behavior itself. Instead, these discrepancies are more likely the result of errors inherent in the calibration process of this method. This suggests that improvements in the calibration procedure are necessary for Method 2 to achieve accuracy comparable to Method 1.

The differences observed in Method 2 can largely be attributed to the mounting procedure. Despite efforts to secure the devices as firmly as possible, the fixation method used was relatively rudimentary. This approach may have resulted in imperfect attachment of some smartwatches, causing slight displacements during the measurement process. These movements could have occurred not only along the Z-axis but also along the other two axes that were not considered in the analysis. These uncontrolled shifts in position may explain the variations in error observed among the different smartwatches, with some exhibiting more significant deviations related to the reference sensor.

The limitations associated with the manual fixation method suggest that a more precise, automated mounting system would be beneficial in future experiments to minimize these sources of error and improve the reliability of the results.

In addition to the calibration methodologies and mounting procedures, environmental factors could have also contributed to the observed variations between the two methods. Fluctuations in temperature and relative humidity, as well as vibrations in the surrounding environment may have influenced the measurements, particularly in Method 2, where the manual fixation may have been more susceptible to external disturbances. Future studies could address this by conducting tests in more controlled environments, where these factors are continuously monitored and regulated.

5. CONCLUSIONS

Smartwatches are increasingly utilized in applications such as healthcare or occupational risk assessment, where precision and reliability of data are critical. Consequently, a deeper understanding of the behavior of their inertial sensors is essential to accurately interpret the data they generate. For this purpose, this study presents a comparative analysis of two calibration methods used to characterize the frequency and amplitude response of the accelerometers embedded in four smartwatches of the same model.

Method 1 used a uniaxial vibration bench, which allows for individual sensor characterization, while Method 2 used a vibration platform that generates vibrations on a surface, allowing the simultaneous evaluation of multiple sensors. Method 1, previously validated, was established as the reference for evaluating sensor performance. As the goal is to calibrate multiple devices in the shortest time, this study, along with future research, focuses on refining Method 2 based on the comparison with Method 1.

In this research, only the Z-axis was analyzed. However, once the calibration method is optimized, the procedure should be extended to evaluate all three axes of the triaxial sensor, in order to fully characterize the smartwatch for acceleration measurement applications.

Since these smartwatches are used for collecting data related to human movement, it is essential to characterize their accelerometers within the amplitude and frequency ranges typical for these activities. These ranges include amplitudes up to 4 m/s² and frequencies up to 10 Hz. However, each calibration method has its own limitations in terms of excitation sources. Method 1 enables high-amplitude excitation at higher frequencies but is more restricted at lower frequencies. In contrast, Method 2 can generate larger excitation amplitudes at lower frequencies, but it is less effective at reaching higher frequencies.

The results from Method 1 showed that the smartwatches exhibited minimal deviations relative to the reference sensor, demonstrating their precise behavior under vibratory excitations. This suggests that the smartwatches' accelerometers can provide reliable measurements within the tested frequency and amplitude ranges, supporting their potential for high-precision human motion analysis.

Method 2 revealed larger deviations from the reference method, primarily due to limitations in the calibration

process. These discrepancies are not attributed to inherent issues with the smartwatches' sensors but are likely caused by the mounting procedure. The manual fixation of the devices may have caused uncontrolled movements during measurements, which contributed to the observed errors.

While these unwanted displacements did not significantly impact the overall accuracy and reliability of the method, they highlight the need for a more robust and automated mounting system to enhance the consistency of results. In future studies employing this calibration method, a more controlled mounting procedure will be adopted to minimize uncertainties and guarantee more repeatable measurements.

Additionally, environmental factors, such as temperature and vibrations, may also influence sensor performance and should be carefully considered in future evaluations.

In summary, the precise calibration of smartwatch accelerometers is crucial for their reliable application in human movement analysis and related fields. This study highlights the need to select a calibration method that optimizes both accuracy and efficiency. Future work will focus on refining the accelerometer characterization procedure to minimize uncertainties and, thereby, improve the reliability of inertial sensor measurements.

ABSTRACT

Plane-marching PSE wavepackets for a supersonic twin-jet operating at perfectly-expanded conditions are compared against near-field pressure measurements with the purpose of validating the modelling strategy. Two streamwise phased-microphone arrays distributed close to the external mixing-layer boundary of each jet are employed to obtain pressure measurements in the linear hydrodynamic fluctuation region. PM-PSE calculations are performed for the symmetric toroidal mode (mode SS0) based on a tailored twin-jet mean flow constructed via an analytical profile fitted from PIV measurements. Comparisons of the amplitude evolution in the streamwise direction for different frequencies reveal a very remarkable agreement between the SS0 PSE prediction and the symmetry-decomposed pressure signals, particularly when SPOD-filtered experimental measurements are considered. These results constitute a new validation of PM-PSE for modelling twin-jet wavepackets related to mixing noise.

Keywords: *jet noise, wavepackets, twin jets, supersonic*

1. INTRODUCTION

Twin-jet-powered aircraft and launch vehicles generate noise footprints with significant impact on both civil and military applications. The control of such systems at an aeroacoustic level requires a fundamental understanding of the noise-generation mechanisms in the turbulent flow. Under the knowledge gathered from the study of planar mixing layers and single round jets in the past decades [1], it is well established that the machinery of noise generation in turbulent shear flows is mainly powered by the large-scale coherent structures present in the flow [2–6], and that such structures can, in most cases, be predicted by linear stability theory in the form of what is commonly known as wavepackets [7]. On the modelling side, linear parabolized stability equations (PSE) have been found to deliver excellent wavepacket predictions for both subsonic and supersonic jets [8–10].

The existence wavepackets (and their significant role) in twin jets is expected by extension of the insights accumulated for single jets. In fact, late modelling efforts based on plane-marching PSE calculations [11, 12] have produced wavepacket models for twin jets that exhibit similar characteristics to those for single jets, but which no longer feature axisymmetric structures. However, experimental works aimed at their validation and characterization in twin-jet systems are recent and still very sparse, and mainly focused on the screech resonance phenomenon [13]. Following the need for experimental characterization of mixing-noise wavepackets in twin jets, in a recent work [14] we employ high-speed schlieren visualizations to educe coherent structures present in twin jets at perfectly-expanded conditions, and compare them against PM-PSE modes for validation purposes. While good agreement is found in terms of fluctuation structure, the comparison of PSE models with the schlieren images has inherent limitations due to the implicit line-of-sight integration: one of the symmetry planes of the system is inaccessible and the identification of the different oscillation modes (toroidal, flapping) is non-trivial. For this reason, the use of discrete-point experimental techniques

such as microphone pressure measurements has also been recently considered as a complementary source of empirical data [15].

Using phased microphone arrays positioned just outside of the turbulent mixing layer, combined with cross-correlation techniques such as spectral proper orthogonal decomposition (SPOD), has proven effective to analyze coherent fluctuations in natural subsonic single jets [8, 9, 16–18]. By placing the microphones near the mixing-layer boundary, the measured pressure fluctuations mainly reflect linear irrotational components, with nonlinear perturbations linked to small-scale turbulent structures being, in turn, negligible. Applying SPOD to the phased measurements from multiple microphones enables the successful extraction of the wavepackets, which agree well with PSE predictions [9, 18]. In the case of supersonic jets, the use of the same idea to study mixing noise is virtually non-existent (mainly due to the ubiquity of screech), let alone its application to twin-jet configurations. Recently, we performed an experimental investigation [15] of near-field twin-jet pressure fluctuations employing an azimuthal array of microphones distributed following the mixing layer contours from RANS simulations. Although good agreement was obtained between the experimentally-determined amplitudes and the predicted wavepackets in a significant number of cases, the limitation of measuring one streamwise position at a time prevented the application of SPOD to filter the streamwise wavepacket structure.

The aim of this work is to provide a new quantitative validation of PM-PSE wavepacket models for supersonic twin jets against near-field pressure measurements obtained using a linear microphone array distributed in the streamwise direction, thus enabling the application of SPOD to educe the coherent information contained in the pressure signals. These comparisons complement the aforementioned quantitative analyses based on schlieren visualizations and on an azimuthal microphone array. The manuscript is organized as follows. Section 2 describes the twin-jet experimental apparatus and the adopted processing strategy, section 3 summarizes the numerical methodology employed for the calculation of PM-PSE wavepacket models, section 4 presents the results for the measured pressure signals and the comparison against the computed PM-PSE modes, and section 5 provides concluding remarks.

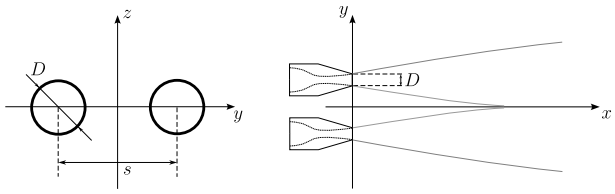

Figure 1. Sketch of the studied twin-jet configuration.

Figure 2. T200 experimental setup: (left) twin-jet system with linear microphone arrays installed; (right) twin-jet system with the 3D-printed part used for microphone positioning.

2. EXPERIMENTAL SETUP

The studied twin-jet configuration consists of two round convergent-divergent nozzles separated by a distance $s = 1.76D$ operating at perfectly-expanded conditions ($M_j = 1.54$), see Fig. 1. The jets are not isothermal and are subject to a total temperature equal to the ambient temperature ($T_0 = T_\infty = 300$ K).

The employed experimental setup is illustrated in Fig. 2, which is built on the T200 wind tunnel facility at Institut Pprime (Poitiers, France). Near-field pressure measurements are carried out using two symmetric streamwise arrays of microphones distributed near the outer mixing-layer boundaries of the twin-jet system. The microphones are located at the symmetry plane containing both jets (xy plane at $z = 0$), with 8 microphones mounted on each array. The left pic-

ture on Fig. 2 shows the microphone arrays mounted on the experimental model. The respective streamwise positions of the microphones on each array are $x/D = [0.5, 1, 1.5, 2, 3, 4, 5, 6]$. Their relative position with respect to the twin-jet mixing layers can be observed in Fig. 3.

A 3D-printed part designed using streamwise velocity contours of RANS calculations is employed for adjusting the position of each microphone (see the right picture in Fig. 2). The geometry of this part approximately follows the evolution of the mixing-layer boundary of the twin jet for the conditions under study, such that microphones located right at its surface would be placed in the desired near-field region. More details on the strategy employed for microphone positioning can be found in [15].

2.1 Processing of microphone signals

The symmetries of the twin-jet geometry can be exploited to decompose the microphone signals into symmetric and antisymmetric fluctuations. For the current experimental setup, the symmetry of the configuration across the xz plane allows the calculation of the following symmetry-decomposed pressure signals:

$$p_{0\mathrm{S}} = \frac{p_t + p_b}{2}, \quad p_{0\mathrm{A}} = \frac{p_t - p_b}{2}, \tag{1}$$

where p_t refers to those pressure signals measured by microphones located near the top mixing layer ($y > 0$) and p_b to those measured near the bottom mixing layer ($y < 0$).

The power spectral density (PSD) of each signal is calculated following Welch's method. First, the pressure fluctuation is obtained by removing the mean from the measured signal:

$$p'(t) = p(t) - \frac{1}{N}\sum_{i=1}^{N} p_i. \tag{2}$$

Then, the power spectral density is computed as:

$$P_{xx}(f) = \frac{1}{\Delta f N_b G_w}\sum_{j=1}^{N_b} |\hat{p}_j(f)|^2, \tag{3}$$

where $\hat{p}_j(f)$ denotes the windowed Fourier-transform of the pressure fluctuation signal for block j, expressed in terms of the fast Fourier transform (FFT) as:

$$\hat{p}_j(f) = \frac{1}{N_{\mathrm{FFT}}}\mathrm{FFT}[w(t)p'_j(t)], \tag{4}$$

where $w(t)$ is a window function and N_{FFT} denotes the block size. The quantity Δf is the frequency bin size, N_b denotes the total number of blocks, and G_w is the energy correction associated to the applied window function (a Hamming window in this case), defined by

$$G_w = \frac{1}{N_{\mathrm{FFT}}}\sum_{i=1}^{N_{\mathrm{FFT}}} w_i^2. \tag{5}$$

The pressure fluctuation signals are split into 487 blocks of 8192 samples each featuring a 50% overlap. The PSD results are converted to dB using the auditory threshold pressure ($p_{\mathrm{ref}} = 20$ µPa) as a reference, i.e. $P_{xx}\,[\mathrm{dB\ SPL}] = 10\log(P_{xx}/p_{\mathrm{ref}}^2)$.

Since all microphone signals are recorded at the same time and the twin-jet dynamics are assumed to be statistically stationary, the spatio-temporal coherence present in the data can be extracted via spectral proper orthogonal decomposition (SPOD). In this case, the SPOD eigenvalue problem takes the form [19]:

$$\mathbf{S}_k\mathbf{\Psi}_k = \mathbf{\Psi}_k\mathbf{\Lambda}_k, \tag{6}$$

where $\mathbf{S}_k$ is the 8×8 cross-spectral density tensor for the kth frequency, defined as:

$$\mathbf{S}_k = \frac{1}{\Delta f N_b G_w}\hat{\mathbf{Q}}_k\hat{\mathbf{Q}}_k^H, \tag{7}$$

with $\hat{\mathbf{Q}}_k$ being the matrix of frequency-domain realizations. $\mathbf{\Psi}_k$ is the matrix containing the eigenvectors for the kth frequency and $\mathbf{\Lambda}_k$ denotes the diagonal matrix containing the associated eigenvalues λ_i, which represent the PSD associated with the ith SPOD mode. The superscript H denotes the complex-conjugate transpose.

The same block size, overlap and window function used for the calculation of the PSD are employed for the SPOD. Since for the current analysis the number of blocks is much larger than the number of spatial points, the formulation of the SPOD problem given by equation (6) requires much less computational effort than the more typical snapshot method formulation [20].

3. NUMERICAL METHODOLOGY

3.1 Mean flow

In this work, the twin-jet mean flow is constructed from the linear superposition of two single-jet mean flows, usually known in previous investigations [11, 12] as a tailored

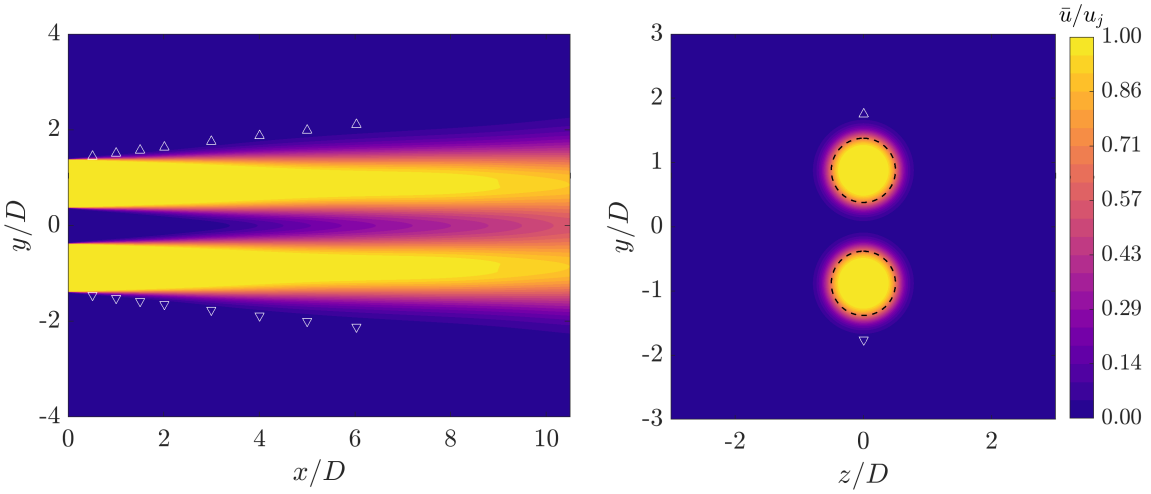

Figure 3. Contours of the tailored twin-jet mean flow employed for the PM-PSE calculations: (left) symmetry plane at $z = 0$; (right) cross-stream plane at $x/D = 3$. The white symbols illustrate the measurement position of the microphones with respect to the mean flow solution.

twin-jet model. The tailored twin-jet mean streamwise velocity component $\bar{u}$ is obtained as the sum (linear combination) of the streamwise velocity fields of two single jets with centers respectively located at $y = \pm s/2$. Here, the velocity components in the y and z directions are neglected. The mean temperature field of the twin jet is estimated from the constructed streamwise velocity field through the following Crocco-Busemann relation:

$$\frac{\bar{T}}{T_j} = \left[1 + \frac{\gamma - 1}{2} M_j^2 \left(1 - \frac{\bar{u}}{u_j}\right)\right] \frac{\bar{u}}{u_j} + \left(1 - \frac{\bar{u}}{u_j}\right) \frac{T_\infty}{T_j}, \tag{8}$$

where T_j and u_j refer to the isentropic jet-exit conditions fixed by M_j and T_0, while the mean density field is obtained from the perfect gas equation of state under the assumption of a constant static pressure field $\bar{p} = p_\infty = 10^5$ Pa.

To obtain the single-jet mean flow, an analytical profile based on the Gaussian function introduced by [21,22] is fitted to PIV measurements of the xy twin-jet symmetry plane. This profile has been used in recent studies of single jets [9] and twin jets [11, 12] with satisfactory results. It is defined as follows:

$$\bar{u}(x,r) = \begin{cases} \bar{u}_c(x), & r < R(x), \\ \bar{u}_c(x) \exp\left[-\dfrac{(r - R(x))^2}{\delta(x)^2}\right], & r \geq R(x), \end{cases} \tag{9}$$

where r denotes the radial coordinate. The parameters $\bar{u}_c$, R and δ respectively represent the mean streamwise velocity of the jet along the nozzle axis, the radial extent of the potential core and the thickness of the mixing layer, which are functions of the streamwise coordinate. These parameters are fitted from the PIV data using a cubic spline, similarly to [9, 12]. More details on the employed PIV measurements can be found in [23]. Although the PIV data corresponds to a twin-jet mean flow and therefore contains both the outer and inner shear layers of each jet, only the external mixing layer of one of the two jets is used for the estimation of $\delta(x)$.

Fig. 3 depicts contours of the tailored twin-jet mean flow obtained following the aforementioned procedure. The triangular symbols represent the position of the different microphones involved in the experimental pressure measurements, showing that they are placed right outside of the external mixing layer of each jet.

3.2 Wavepacket modelling via plane-marching PSE

Twin-jet wavepackets under perfectly-expanded conditions are modelled by means of linear plane-marching parabolized stability equations (PM-PSE). This extension of the classical PSE formulation accounts for mean flows featuring a strong inhomogeneity in two spatial directions, namely, the cross-stream planes in this case. Details on the employed PM-PSE formulation can be found in [11]. In brief, a perturbation ansatz of the following form is considered:

$$\hat{\mathbf{q}}_\omega(x,y,z) = A_\omega \tilde{\mathbf{q}}_\omega(x,y,z) \exp\left(\mathrm{i}\int_{x_0}^{x} \alpha_\omega(\xi)\mathrm{d}\xi\right), \tag{10}$$

where $\hat{\mathbf{q}}_\omega$ denotes the fluctuation at the angular frequency $\omega = 2\pi f$, which is split into a three-dimensional shape function with a slow evolution in the streamwise direction, given by $\tilde{\mathbf{q}}_\omega$, and a wave function featuring a rapid variation along x, given by the exponential term. A_ω represents the initial amplitude and $\alpha_\omega = \alpha_r + \mathrm{i}\alpha_i$ corresponds to the streamwise wavenumber, for which a slow variation with x is also assumed.

The substitution of (10) into the linearized Navier-Stokes equations, together with an order of magnitude analysis that neglects terms of order $1/Re^2$, yields a parabolized initial value problem that can be solved by marching in the streamwise direction.

4. RESULTS

4.1 Measured pressure spectra

The obtained PSD of the symmetry-decomposed pressure signals is displayed in Fig. 4, which shows maps of P_{xx} as a function of x and St for $p_{0\mathrm{S}}$ and $p_{0\mathrm{A}}$. These maps illustrate the range of frequencies at which mixing noise is dominant in the studied twin jet, namely $St \approx [0.1, 1]$. This is the range of interest for comparison against the wavepackets predicted by PM-PSE. As expected in the near-field region where hydrodynamic fluctuations remain important, the streamwise range of linear amplitude growth becomes shorter as the frequency is increased.

Both the symmetric and antisymmetric pressure signals reveal similar spectral signatures, indicating that both kinds of fluctuations are present and are equally important in the twin-jet system.

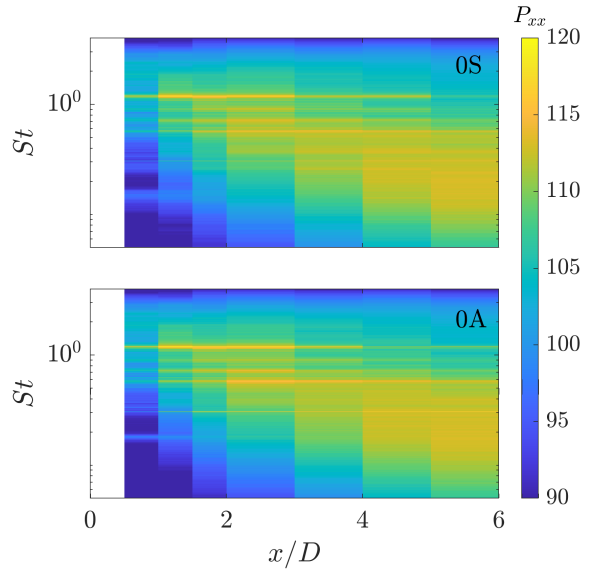

Figure 4. PSD (in [dB SPL/Hz]) of the symmetry-decomposed pressure signals ($p_{0\mathrm{S}}$ and $p_{0\mathrm{A}}$) as a function of x and St.

4.2 Comparison of modelled wavepackets against measured signals

The results presented herein focus on the comparison between the symmetric pressure signal $p_{0\mathrm{S}}$ and the PM-PSE mode SS0, which corresponds to a wavepacket that is symmetric with respect to both twin-jet symmetry planes and represents toroidal Kelvin-Helmholtz instabilities which are analogous to those of $m = 0$ modes in axisymmetric single jets. To illustrate its three-dimensional structure, Fig. 5 displays contours of the PM-PSE mode SS0 for $St = 0.7$ in two different cutplanes: the twin-jet symmetry plane at $z = 0$ and the cross-stream plane at $x/D = 3$. The ring-like structures are clearly visible in the cross-stream plane, which are not axisymmetric owing to the close spacing between the two jets. The fluctuation contours in the symmetry plane highlight the Mach-wave radiation associated with the wavepacket that is typical of mixing noise in supersonic jets. The relative position of the microphone probes with respect to the predicted wavepacket structure are indicated by the triangular symbols.

The initial amplitude of wavepackets calculated via linear stability theory is defined up to an arbitrary constant. For the purpose of comparison against experimen-

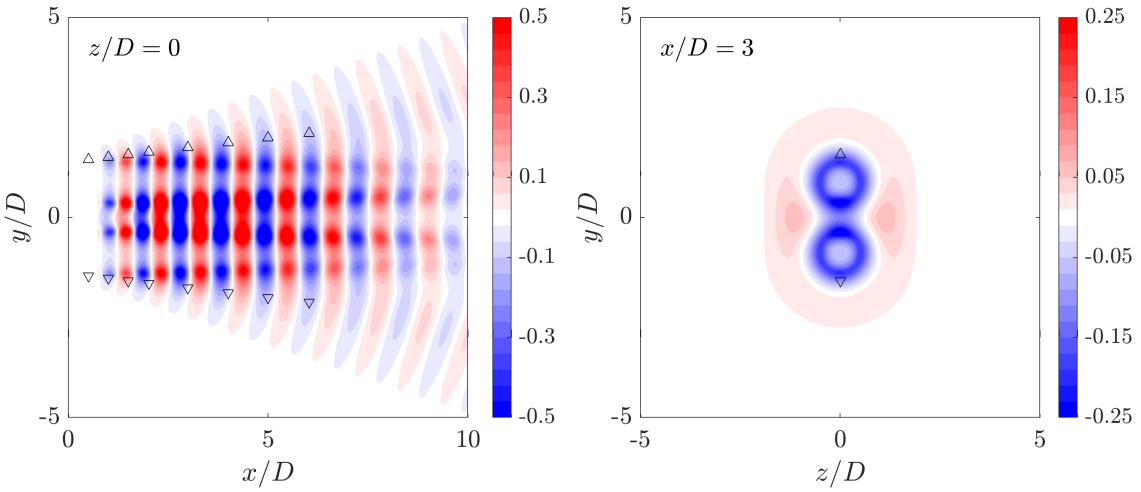

Figure 5. Contours of the real part of the pressure fluctuation for PM-PSE mode SS0 at $St = 0.7$: (left) symmetry plane at $z/D = 0$; (right) cross-stream plane at $x/D = 3$. The contours are normalized with respect to the maximum value of the real part of $\hat{p}$. The black symbols denote the measurement positions of the microphones.

tal measurements, the value of A_ω for a given PM-PSE mode at a given frequency is calibrated by means of a least squares fit to the amplitude of the measured pressure signals, resulting in the following estimation:

$$A_{\omega,p} = \frac{\sum_{j=1}^{N_{\text{mic}}} |\hat{p}_\omega(x_j, y_j, z_j)| \sqrt{P^j_{xx,\omega}}}{\sum_{j=1}^{N_{\text{mic}}} |\hat{p}_\omega(x_j, y_j, z_j)|^2}, \qquad (11)$$

where $\hat{p}_\omega(x_j, y_j, z_j)$ denotes the PM-PSE pressure fluctuation for frequency ω evaluated at the measurement position of microphone j, while $P^j_{xx,\omega}$ represents the PSD of the pressure signal measured by microphone j for frequency ω. This is also the approach followed by previous works on single jets (see e.g. [9]).

The comparison between the measured symmetric pressure signal and PM-PSE mode SS0 is presented in Fig. 6, which shows the evolution of the amplitude as a function of the streamwise coordinate for different frequencies spanning the previously identified range of interest. Two different sets of experimental data are included for each case, namely, the original symmetric pressure signal, marked with star symbols, and the first SPOD mode obtained from the SPOD-filtered symmetric pressure signal, marked with square symbols. Correspondingly, two different curves are represented for mode SS0: that with the initial amplitude calibrated with the original measurements (solid lines, labelled A_p), and that with the amplitude calibrated using the first SPOD mode extracted from the measurements (dashed line, labelled A_Ψ). Overall, a very good agreement is obtained between the PM-PSE wavepacket predictions and the experimental measurements for most of the studied frequencies. Except for the lowest frequency ($St = 0.1$), the match between the PM-PSE model and the measured amplitudes is significantly improved when the SPOD-filtered measurements are considered, especially near and downstream of the saturation point for higher frequencies.

These results suggest that, even though no azimuthal mode decomposition is applicable in the twin-jet case, and therefore the measured signals are expected to contain contributions from multiple modes, the SS0 wavepacket is one of the most dominant contributions to the dynamics of the system, since by itself it can represent the measured amplitude evolution with remarkable accuracy for most frequencies. This comparison constitutes a new quantitative validation of the ability of PM-PSE to model mixing-noise wavepackets in twin jets, which complements our previous quantitative comparisons based on the coherent structures educed from high-speed experimental measurements [14].

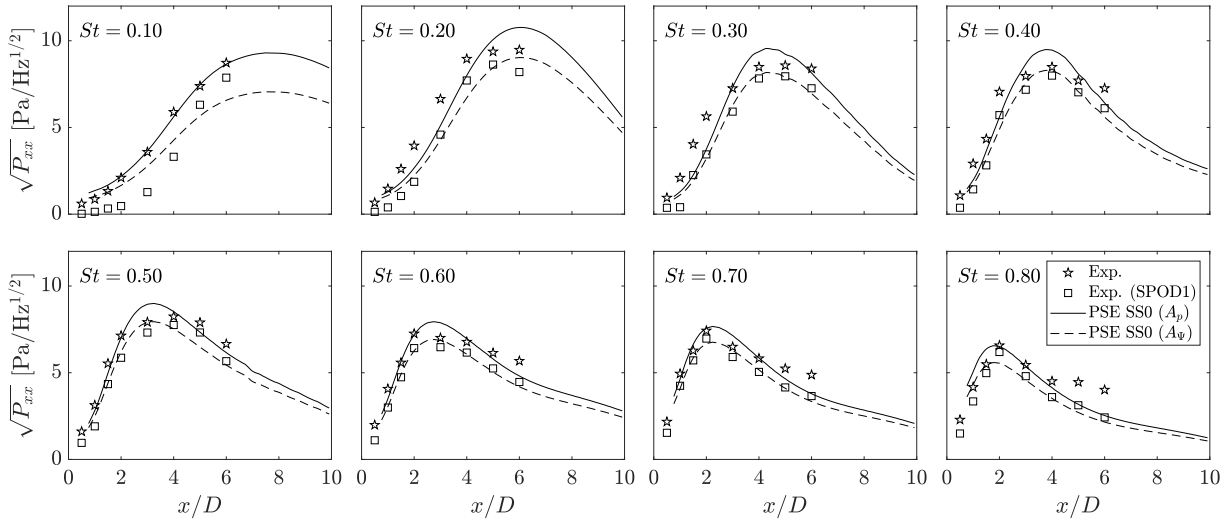

Figure 6. Amplitude comparison between the measured symmetric pressure signal (p_{0S}) and the PM-PSE wavepacket for mode SS0 as a function of the streamwise coordinate for different frequencies. The star symbols denote the experimental measurements; the squared symbols represent the first SPOD mode extracted from the experimental signals; the solid lines indicate the PM-PSE amplitude evolution calibrated directly with the experimental measurements (A_p); the dashed lines correspond to the PM-PSE amplitude evolution calibrated with the first SPOD mode of the experimental results (A_Ψ).

5. CONCLUSIONS

Wavepacket models for mixing noise in twin jets are still premature and require comparison against experimental measurements to assess their validity and accuracy. In this work, wavepackets predicted by plane-marching PSE for a supersonic twin jet operating at perfectly-expanded conditions have been compared against experimental pressure measurements in the near field.

Two streamwise arrays with 8 microphones each are employed to obtain phased measurements in the symmetry plane containing the two jets, with the microphones positioned right outside of the external mixing layer of each jet to target the linear region of the hydrodynamic fluctuation field. The spectral characteristics of the obtained measurements exhibit the desired features expected in the linear hydrodynamic regime and reveal the range of frequencies at which mixing noise is dominant ($St \approx [0.1, 1]$), which in turn guide the wavepacket modelling.

PM-PSE calculations are performed based on a tailored twin-jet mean flow obtained by fitting an analytical axisymmetric jet profile to PIV measurements of the twin jet system. The analysis focuses on the symmetric toroidal mode SS0, for which the predicted wavepackets feature three-dimensional Kelvin-Helmholtz instabilities which deviate from the familiar axisymmetric structures known from single jets.

The comparison between the amplitude of the symmetry-decomposed pressure measurements and the PM-PSE mode SS0 yields a very good agreement for most frequencies in the studied range, particularly when the SPOD-filtered pressure measurements are considered. The obtained results provide a new quantitative assessment of the capability of plane-marching PSE to model twin-jet wavepackets associated with mixing noise. Future work should involve the linear combination of multiple PM-PSE modes in the comparison, as well as the validation of antisymmetric fluctuations.

MATCHING PURSUIT DECOMPOSITION OF JET NEAR-FIELD PRESSURE DATA

Roberto Camussi[1*] **Matteo Mancinelli**[1] **Elisa de Paola**[1]

[1] Department of Civil, Computer Science and Aeronautical Technology Engineering, University Roma Tre, Via della Vasca Navale 79, 00146 Roma, Italy

ABSTRACT

The Matching Pursuit (MP) decomposition is applied to an extensive set of pressure data obtained in experiments carried out in two distinct laboratories, at the University Roma Tre and at the École Centrale de Lyon. Both data sets contain pressure signals measured simultaneously in the near and in the far-field of free stream compressible circular jets of different diameters and different subsonic Mach numbers. The MP method provides a decomposition of the pressure time series into a linear combination of waveforms selected from a dictionary composed of Gabor atoms. A subset of these waveforms is chosen to provide a Reduced Order Model of the original pressure signals that matches at best the energy content at the frequencies of interest. It is demonstrated that the reconstructed signals preserve significant features related to the near-field hydrodynamic pressure field and the far-field noise generation mechanisms. Additionally, it is shown that relevant statistical properties are universal and can serve as a valuable foundation for future modeling.

1. INTRODUCTION

The far-field noise in compressible jets arises from the high-speed flow exiting the jet, which is inherently unsteady and spatially random. In fact, acoustic analogies that model pressure wave radiation in subsonic jets identify the turbulent flow—represented by the Reynolds stress tensor—as the primary source of noise [1]. According to this view, experiments targeted to characterize the jet noise sources, necessities the measurement and processing of non-deterministic signals characterized by time-localized events and time-varying frequency content. To this extent, the application of Time-Frequency decomposition techniques is crucial to overcome the limitations of standard Fourier analysis that is not well-suited for extracting time-localized features.

In the present approach, to the purpose of analyzing efficiently complex signals with time varying characteristics, we propose the use of the Matching Pursuit (MP) method, a technique that has not been used extensively in aeracoustics so far, except for a few applications for beamforming analyses [2] and [3]. The MP procedure provides the decomposition of a given signal (time series) into a linear combination of waveforms taken from a predefined set of functions called Dictionary. The algorithm selects the best basis, not necessarily orthogonal, that efficiently approximates the signal of interest overcoming the limitations of other more traditional approaches, such as the Short Time Fourier Transform, or the Wavelet Transform.

The objective of this work is to demonstrate the method's capability to provide a reliable reduced order modeling of jet noise data while preserving relevant physical properties related to both the evolution of near-field

pressure and its correlation with the far field. Additionally, potential advancements in jet noise modeling are outlined, along with examples of statistical outcomes that highlight universal features.

2. THE PROCESSING METHOD AND THE EXPERIMENTAL DATABASE

The main features of the MP technique are briefly worked out in the following, while details can be found in the literature. This method has been introduced by Mallat & Zhang [4] and has been successively applied for the analysis of temporal signals or images in several fields out of aeroacoustics or aerodynamics (e.g. [5-7]). The MP decomposition provides an optimal non-linear approximation of a signal by adaptively choosing the proper basis depending on the signal nature. The basic idea is to construct an optimal basis, not necessarily orthogonal, that approximates efficiently the signal of interest. The MP algorithm iteratively constructs an approximation by selecting a set of elementary waveforms, called *atoms*, chosen from an over-complete set of functions, called Dictionary, such that they represent at the best the inherent signal features. To the purpose of the present application, the dictionary is composed of Gabor atoms that provide optimal joint time–frequency localization. The Gabor dictionary indeed contains functions obtained by the combination of a Gaussian envelope of variable time location and extension, with a cosine function of variable frequency. The extraction of the atoms is based on an iterative process that maximizes the correlation between the signal reconstructed through the combination of the atoms and the original signal. We remind to the literature for the details on the procedure and the implementation of the algorithm.

In the present analysis, the MP processing procedure has been applied to two distinct data sets obtained in experiments carried out in two different facilities, hereinafter denoted as ECL and UR3.

The experimental database ECL consists of near and far-field pressure signals synchronously measured in the anechoic wind tunnel of the Laboratoire de Mecanique des Fluides et d'Acoustique (LMFA) of the Ecole Centrale de Lyon. The setup provided near field pressure measurements using a linear array of microphones and far-field pressure measurements through a microphone array displaced on a circular arc. Details about the experimental setup can be found in [8].

The experiment denoted as UR3, has been carried out in the semi-anechoic chamber available at the Laboratory of Fluid Dynamic "G. Guj" of the University Roma Tre of Rome. Also in this case near field measurements have been carried out through a linear array of microphones whereas only one microphone was located in the far field. Details about this second setup are given in [9].

We underline that in both experiments the Mach numbers were subsonic and varied between M=0.6 and M=0.9. On the other hand, the jet diameters in the two experiments were significantly different therefore corresponding to different Reynolds numbers.

3. RESULTS

As pointed out above, the Dictionary used in the present analyses is composed of Gabor atoms obtained by a combination of a trigonometric function with a Gaussian envelope. Figure 1 reports examples of those atoms corresponding to different scales. It is pointed out that the minimum and maximum time-scales are selected in order to be compatible with the frequency range of interest for the present applications.

An example of a signal reconstructed through the combinations of atoms selected from the Dictionary is given in Figure 2. It is shown that the reconstructed signal consists of a few selected atoms randomly distributed in time (thus with a random phase), having different frequencies and amplitudes. Indeed, to the purpose of providing a reduced order modeling of the measured pressure signals, in the present analysis the reconstruction is accomplished using only a few thousand atoms. It is also important to point out that the frequency, amplitude, and timing of the selected atoms are not predetermined, but rather derived as outputs of the MP algorithm. In this sense the MP method is considered an *adaptive* approach.

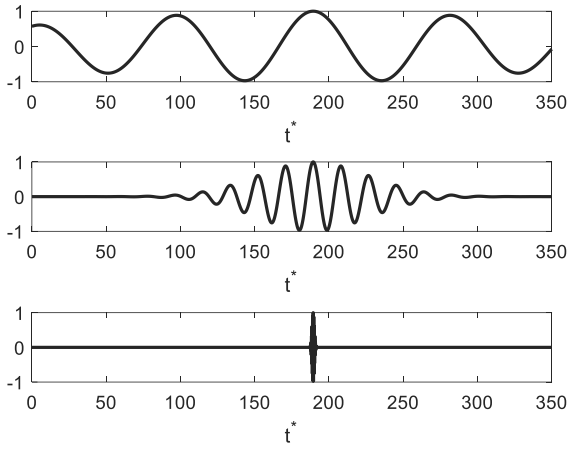

Figure 1. Examples of Gabor functions composing the Dictionary. Amplitudes are normalized in order to vary between -1 and 1.

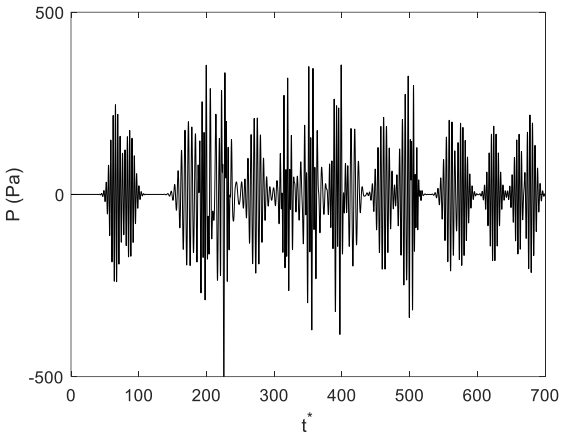

Figure 2. Examples of signal reconstruction. The case reported refers to the UR3 experiment at M=0.7 and x/D=2.

The adaptive nature of the algorithm is demonstrated by the spectral content of the reconstructed signals. An example is given in Figure 3 along with the spectrum of the original signal. The two spectra look very similar in the region where an energy bump related to the Kelvin-Helmholtz (K-H) instability mechanisms, is present. According to the nature of the algorithm, a greater number of atoms results in a more accurate reconstruction of the original signal. However, this analysis demonstrates that a limited number of atoms can still yield a satisfactory reproduction of the signal, particularly within the frequency range that is of primary interest from a physical perspective.

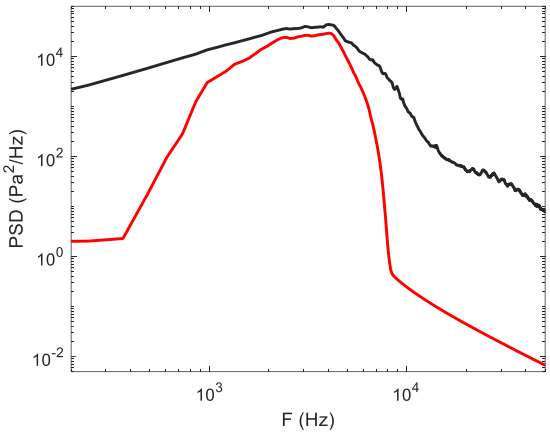

Figure 3. Examples of PSD of the original (black) and reconstructed signal (red). Same case as Figure 2.

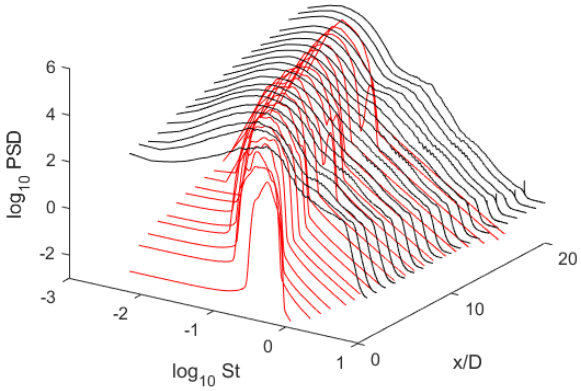

Figure 4. Fourier auto-spectra of the original (black curves) and reconstructed (red curves) signals. Data refers to the UR3 database at M=0.9.

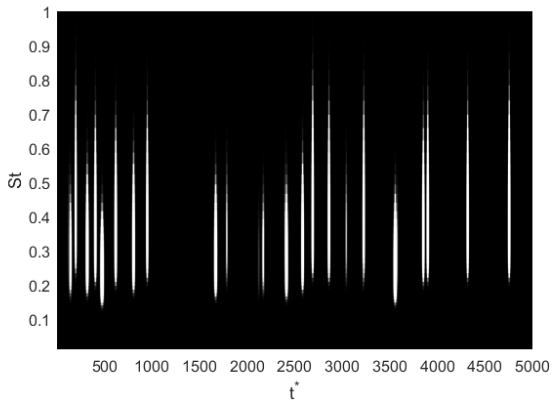

Figure 5. Modulus of the Wavelet Cross-Spectrum between near-field reconstructed signals at x/D=1 and x/D=3. Data refers to the ECL database at M=0.9.

The capability of the method to preserve the physical properties of the original pressure field is examined by analyzing the evolution of atoms in the near field and their correlation with the far field.

The evolution of the auto-spectra in the streamwise direction is examined and examples are reported in Figure 4. It is shown that even though more narrow-banded, the spectra of the reconstructed signals reproduce correctly the energy content of the original signals in the region corresponding to the K-H instability frequency. The reconstruction is satisfactory not only in terms of amplitude but also in terms of its evolutionary behavior along x/D. Similar results are obtained in all the other cases and not reported here for brevity.

Another way to assess the physical significance of the extracted atoms is to verify their *convective* nature, that is to verify whether their trace is presented over different distances from the jet exit. Indeed, atoms that are artifacts generated by the algorithm should not exhibit any coherence in the streamwise direction. Due to the local nature of the atoms in the time frequency domain, the only way to extract a localized coherence is to compute the Wavelet Cross Spectrum (WCS) and an example is reported in Figure 5. The WCS is obtained using a consolidated algorithm [10] and the example reported refers to near-field microphones separated by a distance of 2D. The trace of the atoms is clearly visible (white stripes) showing that most of them are physically correct and are not artifacts generated by the algorithm. It has been checked that the percentage of atoms showing zero correlation length, and thus originated by spurious effects of the algorithm, is less than 10%.

In order to maximize the reliability of the results, all the reconstructed signals are distilled from the spurious atoms and only those showing a non-zero coherence over a distance of at least two diameters are preserved.

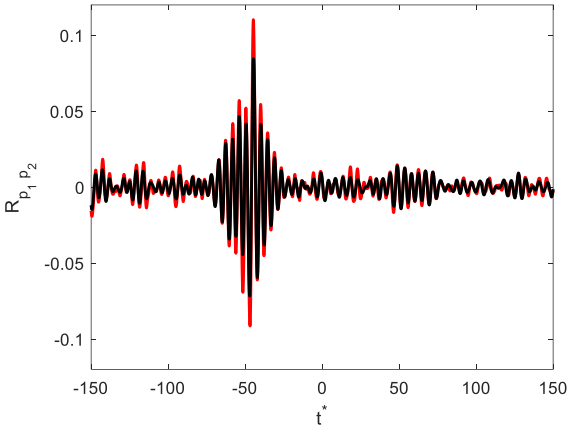

Figure 6. Examples of near- far-field cross-correlations of the original (red) and reconstructed signal (black). Same case as Figure 4.

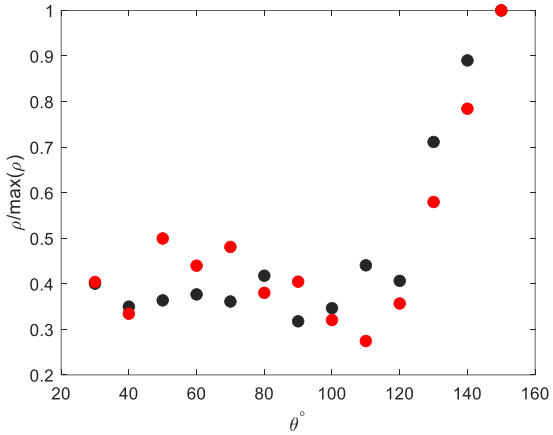

Figure 7. Normalized cross-correlation maxima computed between a near-field microphone located at x/D=1 and all the microphones in the far-field. Black dots refer to the original signals, red dots to the reconstructed ones. The analysis refers to the ECL database at M=0.9.

The set of reconstructed near field pressure time series are correlated with the far field signals in order to verify their

connection with the radiated noise. An example of correlations obtained from the UR3 database is given in Figure 6. The original and reconstructed signals exhibit a very similar behavior both in terms of amplitude and in terms of the time location of the correlation maxima. This time delay, when converted to space using the speed of sound, reproduce exactly the distance between the near field and the far field microphone.

The ECL database allowed us to better clarify the correlation between near and far field microphones thanks to the availability of a polar arc in the far field. In order to characterize the directivity patterns, correlations between near field microphones and all the far field sensors have been computed. To this purpose, the normalized amplitudes of the correlation maxima have been extracted. Results obtained at M=0.9 are reported in Figure 7 and 8 considering a reference near-field microphone located within the jet potential core and in the turbulent region, respectively. A normalization has been employed in both cases to emphasize the dependency upon the polar angles rather than the differences in amplitudes, which are inevitably significant due to the limited number of atoms used to reconstruct the signals.

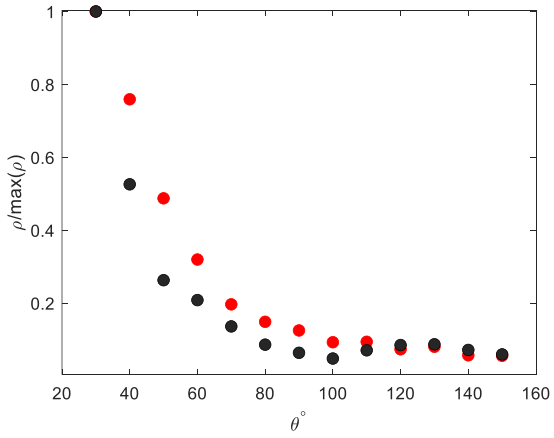

Figure 8. Same as Figure 5 but considering a near-field microphone at x/D=8.

The amplitudes are normalized with respect to the one exhibiting the maximum correlations. As expected, for the microphone located close to the jet exit (Figure 7) the maximum directivity is achieved at around 150° and the trend is very similar for the original and reconstructed cases. When the far field is correlated with a near-field microphone located far from the jet exit, the trend completely changes and the maximum correlation corresponds to very small angles. This is shown in Figure 8 where, again, reconstructed and original cases exhibit very simal behaviors.

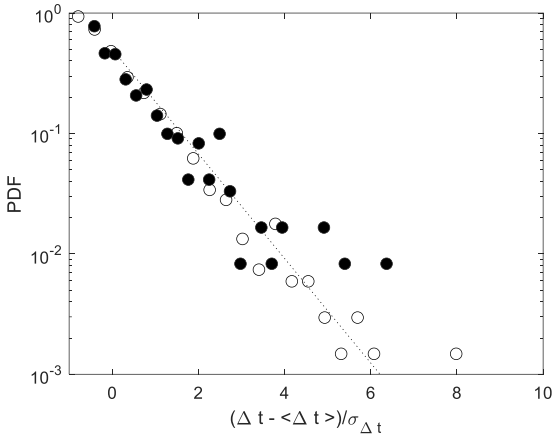

Figure 9. PDFs of the waiting time computed from the UR3 (empty symbols) and the ECL (full symbols) datasets. Both cases are referred to M=0.9 and x/D=3.

The results presented thus far highlight the physical significance of the reconstructed signals, as they accurately reproduce the near-field pressure properties and exhibit proper correlation with the far-field pressure, thereby maintaining the connection with the radiated noise.

The temporal behavior of the extracted waveforms is further explored by extracting the statistics of the time delay between successive atoms. This quantity is often denoted as the waiting time and its statistics is connected with intermittency, an intrinsic property of the turbulent flow. The analysis provides the Probability Distribution Functions (PDF) reported in the so-called reduced form, i.e. by subtracting the mean value from the analyzed random variable and dividing by the standard deviation. Examples are given in Figures 10 where explanatory results obtained in the two experiments are reported. According to the larger number of acquired samples, a better statistical convergence is achieved from the UR3 database but a very good agreement among the normalized PDFs is observed in all cases. For the cases reported, the PDFs exhibit a pure exponential decay, and the exponential fit reported in the figures is very simple, its analytical expression being $F(x) = 0.5\, e^{-x}$.

The same result has been obtained from all the other cases confirming that the time of appearance of the atoms follows a universal statistics.

This universal form of the PDF, together with other statistical properties of the waveforms, can be used to set up a model for reproducing the jet dynamics responsible for the noise emission. This task remains an objective for future studies currently being conducted by the authors, and preliminary results will be presented at the conference.

4. CONCLUSIONS

The MP procedure has been applied to a comprehensive database comprising pressure signals from two distinct laboratory experiments. Both experiments provide pressure signals in the near and far field of circular compressible jets operating at subsonic Mach numbers. The main outcomes obtained can be summarized as follows:

- The MP procedure offers a reduced-order representation of the original signals by reconstructing them through the superposition of a limited number of Gabor atoms extracted from a specified dictionary.
- The overall properties of the near-field pressure are correctly preserved by the reconstructed field. The modelled signals reproduce correctly different features: the energy contained by the pressure spectra around the Kelvin-Helmholtz frequency; the spectra evolution along the streamwise direction; the convective nature of the selected atoms.
- The correlation between near and far field signals is preserved. According to the expected behavior, the reconstructed signals close to the jet exit exhibit good correlations with far field microphones at aft angles. Also, the measured time delay is in line with the distance between the near and far microphones.
- The statistics of the waiting time between successive atoms are universal, supporting the notion of using the reduced-order representation of the signals as potential components for developing predictive models of jet noise.

We emphasize that the similarity of the results obtained across various configurations demonstrates their independence from flow conditions and, more importantly, from the experimental facility. This outcome represents the basis for setting up a reliable model of the atoms' properties that can be used for jet noise predictions. Further studies on this aspect are currently underway by the authors and, hopefully, will be available by the time of the conference.

ABSTRACT

This study provides an analysis of the impact of temperature on the near pressure field of three subsonic jets, using data from well-resolved compressible Large-Eddy Simulations. The jets have nozzle-exit temperatures equal to 1, 1.5, and 2.25 times the ambient temperature, an acoustic Mach number of $M_a = 0.9$ and a Reynolds number of $Re_D = 10^5$. Pressure time series were extracted from several virtual probes distributed in the near field of the jets, covering a region extending up to 20 jet diameters in the streamwise direction and 3 jet diameters radially, repeating this planar distribution across different azimuthal angles. The data were analyzed in both the Fourier and Wavelet domains, facilitating simultaneous representation in the time-frequency domain. The analysis focused on evaluating the influence of nozzle exhaust temperature on pressure fluctuations in the near field of the single-stream jets. In addition, a wavelet-based acoustic decomposition technique was applied to assess the effects of nozzle exit temperature on both the acoustic and hydrodynamic pressure fields. The parameters of a wave-packet model for subsonic jet noise were finally analyzed and systematically optimized.

1. INTRODUCTION

The noise generated by high-speed turbulent jets remains a critical challenge in the design of modern civil aircraft, particularly during take-off when engine thrust is maximized. Since Lighthill's pioneering formulation of aeroacoustic theory [1], extensive research has sought to unravel the physical mechanisms through which turbulent jet flows produce sound. Seminal contributions by [2, 3], and [4], among others, have established that coherent turbulent structures within the jet shear layer act as primary noise sources. Recent advances in modeling, particularly through wavepacket-based approaches and linear stability analysis, have significantly improved the predictions of jet noise radiation. Studies such as those by [5,6], and [7,8] demonstrate the efficiency of these frameworks in linking hydrodynamic instabilities to far-field acoustics.

Despite these advancements, the existing models often rely on simplifications, such as assuming steady base flows, neglecting temperature variations, or linearizing sound propagation that limit their applicability to idealized configurations. While analytical studies such as those of Kam et al. [9] and the experimental analysis by Vishwanathan [10] have explored heated jets, most numerical and experimental efforts focus on jets at ambient temperatures, leaving

a gap in understanding how elevated exhaust temperatures, typical of aeronautical engines, influence noise generation and propagation.

This work addresses these limitations by investigating the generation of acoustic waves in high-speed turbulent jets with temperature ratios ranging from 1 to 2.25 relative to ambient conditions. The jets have an acoustic Mach number of 0.9 and are highly disturbed at the nozzle exit. They have been computed using compressible Large-Eddy Simulations (LES). The LES datasets allow for a comprehensive analysis of both acoustic and hydrodynamic fields through a combination of Fourier and wavelet-based techniques. A wavelet-based acoustic decomposition method [11, 12] is applied to the jet near pressure field to highlight the effects of temperature on jet noise radiation.

Furthermore, this study systematically optimizes the parameters of a wavepacket noise prediction model, based on the methodology of [7,8]. Although earlier work demonstrated strong agreement with experimental data for cold subsonic jets, the extension to heated flows presented here aims to increase the fidelity of the model.

Details on the numerical setup and the wavelet-based processing procedure are given in Sections II and III, respectively. The main results are reported in Section IV while concluding remarks are given in Section V.

2. NUMERICAL SETUP

The LES simulations were performed by solving the three-dimensional compressible Navier-Stokes equations in cylindrical coordinates, using low-dissipation and low-dispersion explicit schemes [13]. The computational grid extends up to $x/D = 20$ in the axial direction and up to $r/D = 7.5$ in the radial direction, where D if the jet nozzle diameter.

For this analysis, we considered three jets with nozzle exhaust temperatures $T = T_a$, $T = 1.5T_a$, and $T = 2.25T_a$, where T_a is the ambient temperature. The jet acoustic Mach number are fixed at $M_a = 0.9$, resulting in jet Mach numbers decreasing with the nozzle-exhaust temperature. The jet Reynolds number is equal to 10^5 in all cases. Finally, the turbulence levels at the nozzle exit has been fixed to $TI = 9\%$ by tripping the boundary layers inside the nozzle.

More information on the LES and properties of the jet flow and acoustic fields can be found in previous papers [13, 14]

3. POST-PROCESSING PROCEDURE

3.1 Wavelet-based analysis

The data processing relies on separating the acoustic component of the pressure signals from the hydrodynamic counterpart. This goal is achieved by applying the procedure proposed by [15] and [11, 12, 16] that is briefly worked out in what follows.

The method is based on the wavelet transform of pressure signals and an appropriate filtering of the resulting wavelet coefficients. It is known that the wavelet transform performs well in identifying and isolating intermittent or time-dependent features. For a pressure time series $p(t)$, the wavelet transform can be formally represented by the following expression [17–21]:

$$w(s,t) = C_\psi^{-\frac{1}{2}} s^{-\frac{1}{2}} \int_{-\infty}^{\infty} p(\tau)\psi^*\left(\frac{t-\tau}{s}\right)d\tau, \quad (1)$$

where s is the wavelet scale, τ is a time shift, $C_\psi^{-\frac{1}{2}}$ is a constant that takes into account the mean value of $\psi(t)$ and $\psi^*\left(\frac{t-\tau}{s}\right)$ is the complex conjugate of the dilated and translated mother wavelet $\psi(t)$.

To perform the acoustic/hydrodynamic separation, the wavelet coefficients can be separated by assuming that the hydrodynamic contribution, being related to localized eddy structures, compresses well onto the wavelet basis so that it originates, in the transformed domain, few but with large amplitude wavelet coefficients [11,12]. Thus, the so-called pseudo-sound (i.e., the hydrodynamic component of pressure fluctuations) can be extracted by selecting

the wavelet coefficients exceeding a proper threshold. In the present approach, the threshold is identified through the so-called WT3 technique. The procedure is based on an iterative process originally developed for signal denoising [22] and then applied to the analysis of coherent structures in turbulence [23]. Details about the procedure have been reported in [11]

Specifically, the chosen method is based on single-point statistics. Thus it does not require any additional signals taken from other virtual probes. Furthermore it has been applied successfully also to configurations out of jet noise (e.g. [24–26]). In the present approach, the application of the decomposition procedure provides the reconstruction in the physical domain both of the hydrodynamic and acoustic pressure in the near field of the jet.

The two time series are then processed separately and the statistical properties are eventually computed.

3.2 Wave-packet modeling

The wavepacket approach considered in this work follows the method described in [7, 8]. Specifically, the wave-packet noise source introduces some parameters whose value can be adjusted to match the pressure fluctuations from the reference jet using LES. A wave-packet describing the pressure fluctuations for a free jet is obtained by optimizing its parameters with near-field data on co-axial lines at two radial distances from the jet axis, namely $r/D = 2$ and 2.5. The radial distance of the near field probes has been chosen considering that the wavepacket model is valid for lines that are outside of the jet stream, and at the same time sufficiently close to the jet to sense and provide information about the hydrodynamic component of the pressure fluctuation. In the following, the data at the mentioned lines are referred to as *training* set, meaning that the model is informed by these data, while a *test* set is composed of the pressure field at other monitoring points.

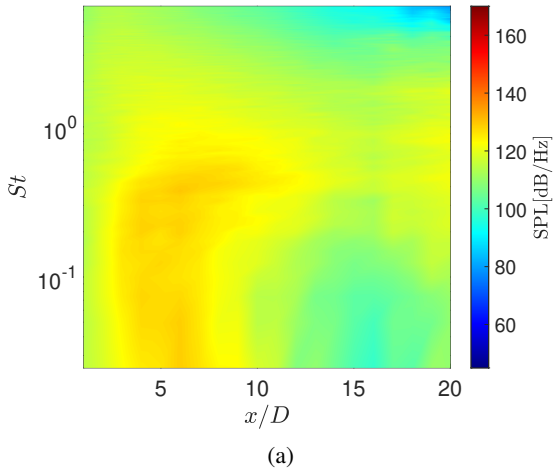
4. RESULTS

A frequency-domain analysis of the wavelet-decomposed near-pressure field is first presented. The frequency dependence of the near-field acoustic component is evaluated through the spectra of both hydrodynamic and acoustic pressure, expressed in terms of the Sound Pressure Level (SPL) using the following equation:

$$SPL = 10\log_{10}\left(\frac{\mathrm{PSD}\Delta f_{\mathrm{ref}}}{p_{\mathrm{ref}}^2}\right), \qquad (2)$$

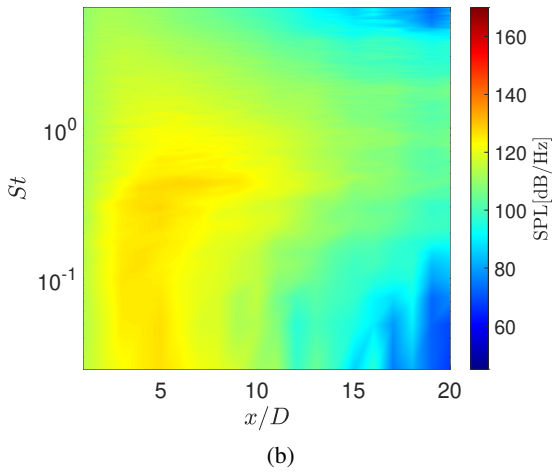
where PSD denotes the power spectral density evaluated using Welch's method setting Nyquist frequency at St = 12.8, with 256 samples per bin, and applying a Hanning window.

The SPL of the acoustic pressure field obtained at a radial distance of $r/D = 2$ in the jet near pressure field are shown in Figure 1 . It reveals a reduction in the acoustic component across all frequencies with increasing temperature, with the attenuation being more pronounced at higher axial distances.



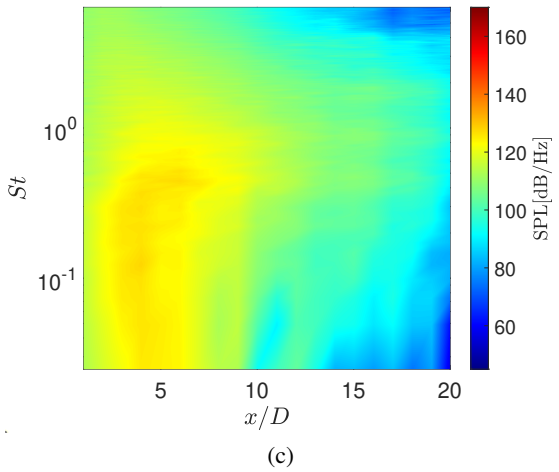
The SPL frequency peak is also significantly reduced with the increase in nozzle exhaust temperature. This can be attributed to the more rapid development of the Kelvin-Helmholtz shear-layer wave instabilities in the hot jets.

Conversely, in Figure 2, the SPL of the hydrodynamic pressure field appear to weakly depend on the jet temperature. Notably, a significant difference between Figures 2(a) and (c) is only observed at low x/D.



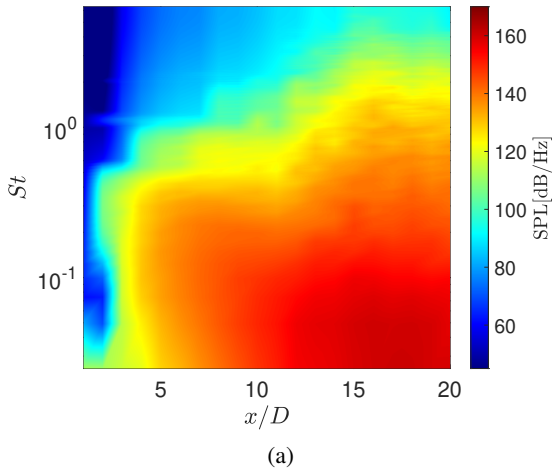
The variation in acoustic pressure field intensity indicates a change in directivity. To illustrate this, the OASPL maps obtained for the acoustic field, evaluated using the following equation:

$$\mathrm{OASPL} = 20\log_{10}\left(\frac{\sigma}{p_{\mathrm{ref}}}\right), \qquad (3)$$

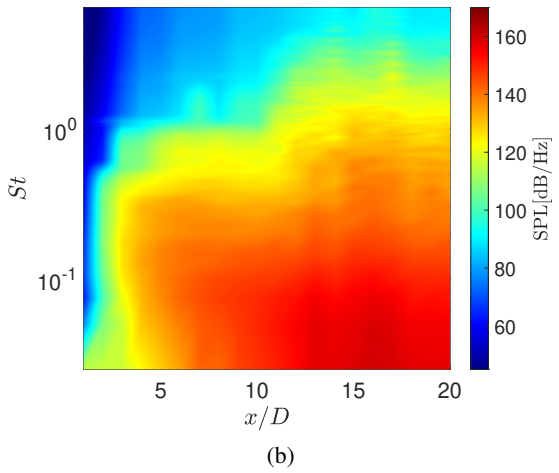


are presented in figure 3, where σ is the standard deviation of the pressure signal and p_{ref} is a reference pressure whose value is $20\mu Pa$.

(a)



(b)



(c)

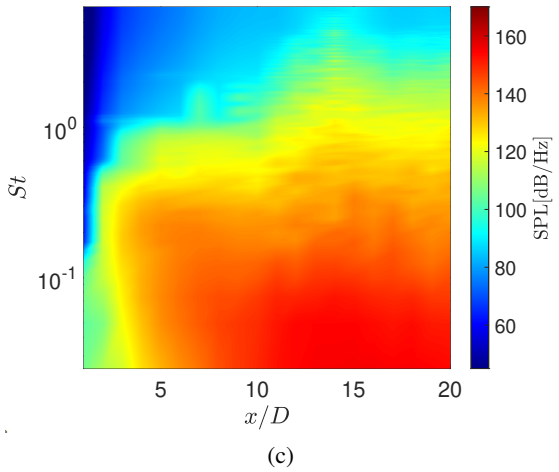


Figure 1: SPL of the acoustic pressure field at $r/D = 2$: : (a) $T = T_a$; (b) $T = 1.5T_a$; (c) $T = 2.25T_a$.

(a)

(b)

(c)

Figure 2: SPL of the hydrodynamic pressure field $r/D = 2$: (a) $T = T_a$; (b) $T = 1.5T_a$; (c) $T = 2.25T_a$.

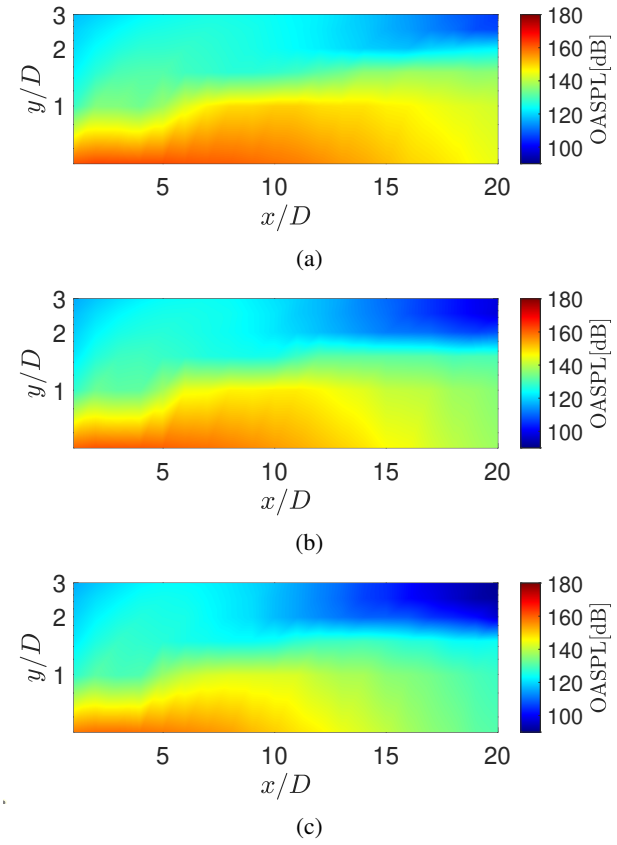

Figure 3: OASPL of the acoustic pressure field: (a) $T = T_a$; (b) $T = 1.5T_a$; (c) $T = 2.25T_a$.

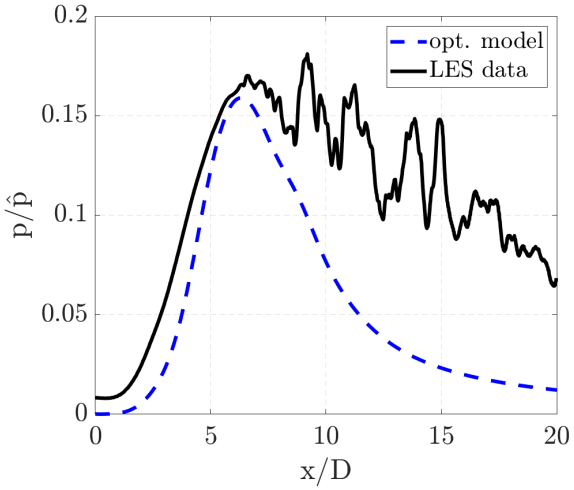
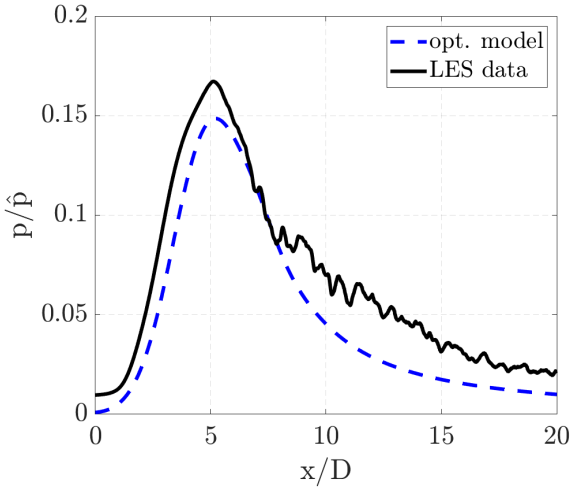


It clearly appears that the amplitude and the directivity of the acoustic pressure field are both significantly affected by the jet temperature, especially further downstream of the jet. Specifically, a reduction in OASPL is observed at high x/D values. Additionally, the OASPL distribution indicates a progressive sideline spread of the noise field as the temperature increases. This can be ascribed to the faster breakdown of large-scale structures as they develop more rapidly.

It is interesting to note that the high-intensity region near the jet axis (represented by the dark red areas in Figure 3) extends from the nozzle exit to a distance between 10 and 15 diameters, depending on the temperature. More specifically, as the nozzle exhaust temperature increases, the axial extent of this high-intensity region contracts, reaching approximately $x/D = 10$ for the highest temperature. This is due to the faster breakdown of large-scale structures.



Comparisons of the LES pressure field and that predicted by the optimal wave-packets (see [8] for the approach used) for $T = T_a$ and (b) $T = 2.25T_a$, at a Strouhal number of $St = 0.25$, are finally provided in Figure fig:enter-label. The predictions closely match the shape of the reference data along the near-field lines, but only up to the axial position where the lines begin to interact with the jet flow for the considered Strouhal number. The modification in jet structure due to the higher temperature enhances the effectiveness of wavepacket optimization.

5. CONCLUSIONS

This paper presented an analysis of the effect of nozzle-exit temperature on the near-field acoustic pressure of compressible subsonic jets. The study is based on a high-fidelity, well-resolved large-eddy simulation (LES) database, conducted at fixed acoustic Mach and Reynolds numbers, and turbulence intensity. The acoustic and hydrodynamic pressure components were separated using an established wavelet-based procedure, enabling the reconstruction of both pressure time series with high accuracy. The OASPL maps show a shortening of the high-intensity region observed which suggests a faster breakdown of large-scale coherent structures, shifting the dominant noise sources upstream. A key finding is the shift in noise directivity with increasing temperature. While lower-temperature jets predominantly radiate noise in the aft direction, higher-temperature jets exhibit a more pronounced sideline directivity. The SPL frequency peak is also significantly reduced with increasing nozzle exhaust temperature, likely due to the more rapid development of the Kelvin-Helmholtz instabilities. Finally, the optimized wavepacket approach better predicts the jet pressure field for higher temperature.

REVISITING THE EFFECTS OF MEAN VELOCITY PROFILES SHAPE ON SOUND PROPAGATION THROUGH TWO-DIMENSIONAL DUCTS

Lucas A. Bonomo[1*] **Julio A. Cordioli**[1] **Edward J. Brambley**[2]
[1] Federal University of Santa Catarina, Florianópolis, Brazil
[2] University of Warwick, Coventry, United Kingdom

ABSTRACT

Previous publications suggest that the acoustic attenuation rate in lined two-dimensional ducts with grazing flow depends on the shape of the boundary layer's mean velocity profile. Nayfeh et al. (1974) showed that for downstream-propagating waves, similar attenuation rates can be achieved for different profile shapes if the boundary layer displacement thickness remains constant. However, for upstream propagation, the attenuation rate also varies with the boundary layer shape factor. This study revisits Nayfeh et al.'s work, focusing on small ducts, particularly within the typical Helmholtz number range used in acoustic liner impedance eduction test rigs. Three profile shapes are considered: the sinusoidal flow profile, the hyperbolic tangent profile, and the universal law of the wall, which represents a more realistic turbulent boundary layer. The exact wavenumbers from the Pridmore–Brown equation for these flow profiles are compared with the approximation obtained using a uniform flow and the Ingard–Myers boundary condition applied to the lined wall with slipping grazing velocity.

Keywords: *duct acoustics, acoustic liners, sheared flow profile, impedance eduction.*

1. INTRODUCTION

Acoustic liners are essential noise-reducing treatments applied to the nacelles of turbofan engines. They typically consist of a perforated facesheet, a honeycomb core, and a hard backplate. These liners are characterised by their acoustic impedance, $\tilde{Z}(\omega) = \theta + \mathrm{i}\chi$, where θ is the resistance and χ is the reactance. The impedance, which depends on both liner geometry and operational conditions such as grazing flow velocity and incident Sound Pressure Level (SPL), serves as a boundary condition in noise propagation models, enabling accurate noise predictions while circumventing the computational cost of explicitly modelling the liner.

Liner impedance is typically characterised using experimental methods under conditions as close as possible as those in turbofan engines, with impedance eduction being the most widely used approach [1]. These techniques often assume uniform mean flow and apply the Ingard–Myers boundary condition to describe liner interaction with acoustic and flow fields. However, recent findings challenge these assumptions.

One key issue is the dependence of educed impedance on the wave propagation direction relative to the mean flow, which contradicts the locally reacting hypothesis. This discrepancy has been consistently observed across different experimental facilities, suggesting a fundamental limitation in the standard modelling approach. Initial studies [2] attributed this behaviour to a failure of the Ingard–Myers boundary condition, prompting alternative formulations that introduce additional degrees of freedom, such as viscosity [3], shear stress [4,5], or boundary layer effects [6]. These modifications aim to remove the directional dependence of the educed impedance. However, experimental validation remains inconclusive, as adjustments to the model fit experimental data regardless of the specific physical mechanism introduced.

An alternative line of research replaces the uniform flow assumption with a sheared velocity profile. While several studies have employed one-dimensional shear flow models [5,7,8], results indicate that incorporating sheared

flow alone does not fully resolve the impedance mismatch [9]. A recent parametric study [8] found that shear effects become more significant at higher frequencies and larger Helmholtz numbers but remain a reasonable approximation for small ducts at low frequencies.

Beyond one-dimensional shear models, some studies have explored the impact of fully three-dimensional flow. Numerical experiments comparing solutions from the Convected Helmholtz Equation (CHE) with those from the Linearised Euler Equations (LEE) [10] indicate that assuming uniform flow introduces a bias error. This bias appears to be a significant contributor to the upstream-downstream impedance mismatch observed experimentally. Furthermore, when impedance eduction is performed using wavenumbers derived from a more physically accurate flow representation, the mismatch is significantly reduced, especially at higher frequencies [11].

A common assumption in the literature is that the specific formulation of the boundary layer profile does not significantly influence acoustic propagation, provided that the displacement thickness remains unchanged. However, early investigations [12] suggest that while this holds for downstream propagation, upstream propagation is sensitive to the boundary layer shape. Despite this, the influence of boundary layer shape on impedance eduction remains largely unexplored.

In this work, we propose a numerical experiment to evaluate how different boundary layer formulations affect impedance eduction. We use the Pridmore–Brown equation [13] to obtain axial wavenumbers for a sheared mean flow and apply these wavenumbers in a traditional impedance eduction routine [14] assuming uniform flow. By comparing realistic turbulent boundary layer profiles with simplified formulations commonly used in the literature, we assess the extent to which small variations in wavenumbers influence the educed impedance. Our findings aim to provide further insight into the limitations of current eduction methods and their sensitivity to flow representation.

2. GOVERNING EQUATIONS

For this study, we consider the infinite 2D duct depicted in Figure 1. The duct has width W and an axial flow $\mathbf{u}_0 = U_0(x)\hat{\mathbf{e}}_z$, assumed invariant in the axial direction. The wall at $x = -W/2$ has a locally reacting impedance $Z(\omega)$, while the other wall is rigid.

Acoustic propagation of a wave with $\exp(\mathrm{i}\omega t)$ time-dependence follows the Pridmore–Brown Equation (PBE)

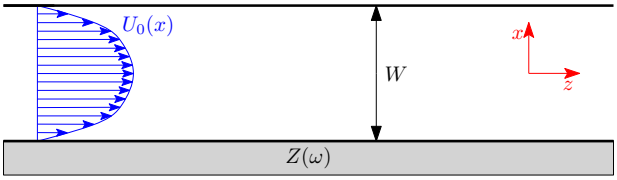

Figure 1. Schematic duct and coordinate system.

[13], given by

$$(\mathrm{i}\omega + \mathbf{u}_0 \cdot \nabla)\left(\frac{1}{c_0^2}(\mathrm{i}\omega + \mathbf{u}_0 \cdot \nabla)^2\tilde{p}' - \nabla^2\tilde{p}'\right) + 2\frac{\partial}{\partial z}\left(\nabla\tilde{p}' \cdot \nabla U_0\right) = 0. \quad (1)$$

Assuming an axial modal solution of the form $\tilde{p}'(x,z) = \tilde{p}'(x)\exp(-\mathrm{i}k_z z)$, with k_z the axial wavenumber, we obtain

$$0 = \left(\nabla_\perp^2 + \frac{\omega^2}{c_0^2} - k_z^2\right)\tilde{p}' - k_z\left(\frac{U_0}{\omega}\nabla_\perp^2 - \frac{2}{\omega}\nabla_\perp U_0 \cdot \nabla_\perp + \frac{3\omega U_0}{c_0^2}\right)\tilde{p}'. \quad (2)$$

For boundary conditions, at the rigid wall $x = W/2$, the normal acoustic velocity vanishes, while at $x = -W/2$, the impedance boundary condition is

$$\frac{\mathrm{d}\tilde{p}'}{\mathrm{d}x} = -\frac{\mathrm{i}\omega}{Z}\tilde{p}'. \quad (3)$$

For a uniform flow, the PBE simplifies to the Convected Helmholtz Equation (CHE), and the impedance boundary condition reduces to the Ingard–Myers condition [15]. The problem is discretised using Chebyshev polynomials [16] and solved as a generalised eigenvalue problem.

3. VELOCITIES PROFILE SHAPE FUNCTIONS

The simplest formulation considered in this work is the sinusoidal flow profile, as presented by Ref. [17]. In this case,

$$\frac{U_0(x)}{c_0} = \begin{cases} M_s \sin\left(\dfrac{\pi\xi}{2\delta_s}\right), & 0 \le \xi \le \delta_s \\ M_s, & \xi > \delta_s, \end{cases} \quad (4)$$

where M_s is the free-stream Mach number, and δ_s is the boundary layer thickness.

A commonly employed formulation nowadays is the hyperbolic tangent profile introduced by Ref. [18], given by

$$\frac{U_0(r)}{c_0} = M_c \Bigg[\tanh\left(\frac{1-r}{\delta_t}\right) + (1 - \tanh(1/\delta_t)) \times \left(\frac{1+\tanh(1/\delta_t)}{\delta_t} r + (1+r)\right)(1-r) \Bigg], \quad (5)$$

where M_c is the centreline Mach number, r is the radial position, and δ_t is a shape factor. In this work, we use the coordinate transformation $r = 2|x|/W$ to obtain the flow profiles in the x coordinate system.

For a realistic boundary layer velocity profile, we employ the universal wall law [19]

$$U^+ = \Pi + \int_0^{y^+} \frac{2}{1 + \sqrt{1 + 4\kappa^2 {y^+}^2 (1 - \exp(-y^+/A^+))^2}} \mathrm{d}y^+, \quad (6)$$

where Π is given by

$$\int_0^{y^+_{\max}} \frac{2}{1 + \sqrt{1 + 4\kappa^2 {y^+}^2 (1 - \exp(-y^+/A^+))^2}} \mathrm{d}y^+ \times (y^+_{\max} - y^+) \left(\frac{y^+}{y^+ \max}\right)^2 = \Pi. \quad (7)$$

where $y^+_{\max,x} = W u_\tau / \nu / 2$. This formulation ensures continuity in the velocity profile derivative at the duct centreline.

4. MATERIAL AND METHODS

In this work, we consider a small rectangular duct representative of traditional liner impedance eduction facilities. The initial dimensions follow the Liner Impedance Test Rig from UFSC (LITR/UFSC), with a width of $W = 40\,\mathrm{mm}$, and a parametric study on the effect of duct width is planned.

For the lined wall impedance, we adopt an SDOF-like impedance given by

$$Z_{\mathrm{SDOF}}(\omega) = 2 - \mathrm{i}\left(\cot(k_0 h) - (0.03 k_0)^2\right), \quad (8)$$

with $h = 35\,\mathrm{mm}$, $k_0 = \omega/c_0$ is the free-field wavenumber, with ω the frequency in $\mathrm{rad\,s^{-1}}$ and c_0 the speed of sound in $\mathrm{m\,s^{-1}}$, which is representative of a typical liner in the considered frequency range and Mach number. The frequency range considered is 500–3000 Hz. The reference impedance is shown in Figure 2.

Velocity profiles are examined using three formulations presented: the turbulent universal wall law, Eqn. (6), a hyperbolic tangent profile, Eqn. (5), and a sinusoidal profile, Eqn. (4). The wall law parameters are fitted to experimental data from LITR/UFSC, yielding an average Mach number of $M = 0.279$, boundary layer thickness $\delta_{99\,\%} = 15.72\,\mathrm{mm}$, and displacement thickness $\delta^* = 1.70\,\mathrm{mm}$.

To assess the impact of velocity profiles on impedance eduction, we fit the hyperbolic tangent and sinusoidal profiles to match either the same bulk Mach number and boundary layer thickness or the same bulk Mach number and displacement thickness. The considered flow profiles are depicted in Figure 3

The number of points in the computational domain used for the pseudospectral solver was determined based on the critical case, which, for this study, corresponds to the universal wall law due to its high gradient near the walls.

For the numerical experiment eduction, we consider the traditional straightforward wavenumber based impedance eduction first proposed by Ref. [14]. Applying the Ingard–Myers boundary condition on the lined wall the CHE solution, it leads to the eigenvalue problem

$$k_x \tan(k_x W) - \frac{1}{\mathrm{i}k_0 Z}(\mathrm{i}k_0 - \mathrm{i}M k_z)^2 = 0, \quad (9)$$

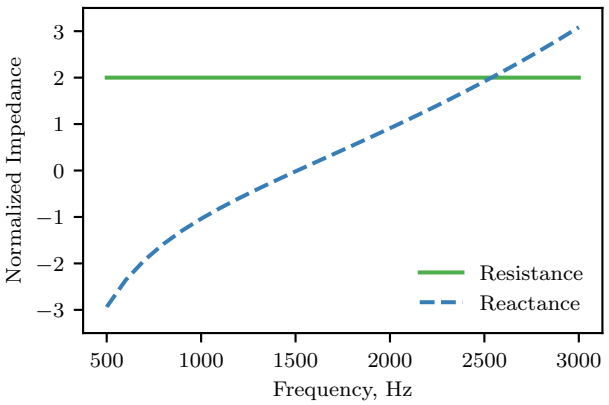

Figure 2. Reference impedance for the numerical experiments.

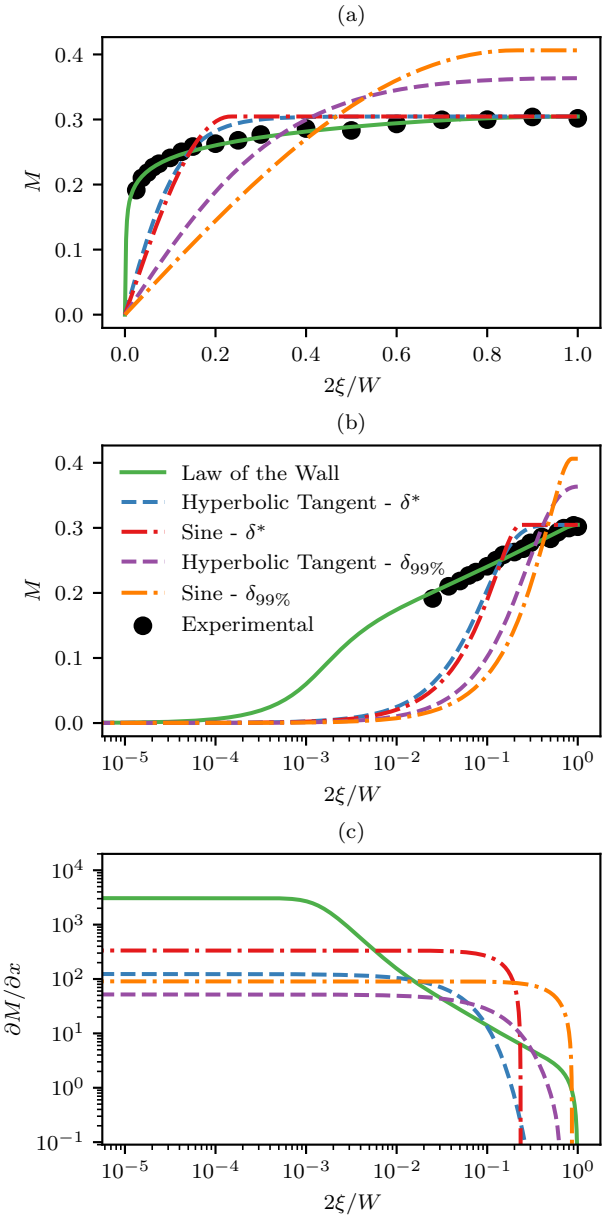

Figure 3. Flow velocities profiles in linear (a) and logarithmic (b) and velocities gradient (c) considered in the first step of this work.

where k_x is the transverse wavenumber, and the dispersion relation given by

$$k_x^2 = (k_0 - Mk_z)^2 - k_z^2. \tag{10}$$

Once the axial wavenumber is known, it is straightforward to calculate the liner impedance from Eqn. (9) and Eqn. (10).

5. RESULTS AND DISCUSSION

First, we examine the wavenumbers obtained from the Pridmore–Brown equation for different velocity profile shapes, all with the same boundary layer thickness, $\delta_{99\,\%}$, and average Mach number M. These results are compared with the wavenumbers derived from the Convected Helmholtz equation with the Ingard–Myers boundary condition, which models the refraction at the boundary layer considering the average Mach number. The wavenumbers for the least attenuated mode, for both upstream (k_z^-) and downstream (k_z^+) propagation (corresponding to upstream and downstream sources, respectively), are presented in Figure 4.

Results suggest good agreement between all considered velocity profiles and the predictions from the CHE-IMBC for the real component of the wavenumber in both propagation directions. However, for the imaginary component of the wavenumber, which corresponds to the attenuation rate, significant differences are observed between the wavenumbers obtained for the hyperbolic tangent and sinusoidal flow profiles, compared to those obtained for the more realistic distribution given by the universal wall law, particularly for upstream propagation. Good agreement is observed between the CHE-IMBC solution and both the wall law and PBE solutions. This suggests that the IMBC may provide a good approximation for the typical range of impedance eduction. A possible explanation is that, due to the high gradient near the wall, even though the velocity distribution extends nearly across the entire duct half-width, the region where refractive effects are significant is confined to a much thinner region, making the infinitely thin hypothesis of the IMBC reasonable

Next, we consider the case where the different velocity distributions are adjusted to match the average Mach number and the boundary layer displacement thickness, δ^*, rather than the boundary layer thickness, $\delta_{99\,\%}$. This approach is expected to improve the agreement between the acoustic attenuation predicted by the different flow profiles, particularly for downstream propagation [12]. The wavenumbers for the least attenuated mode in both upstream and downstream propagation are shown in Figure 5.

As expected, a better agreement is observed for the

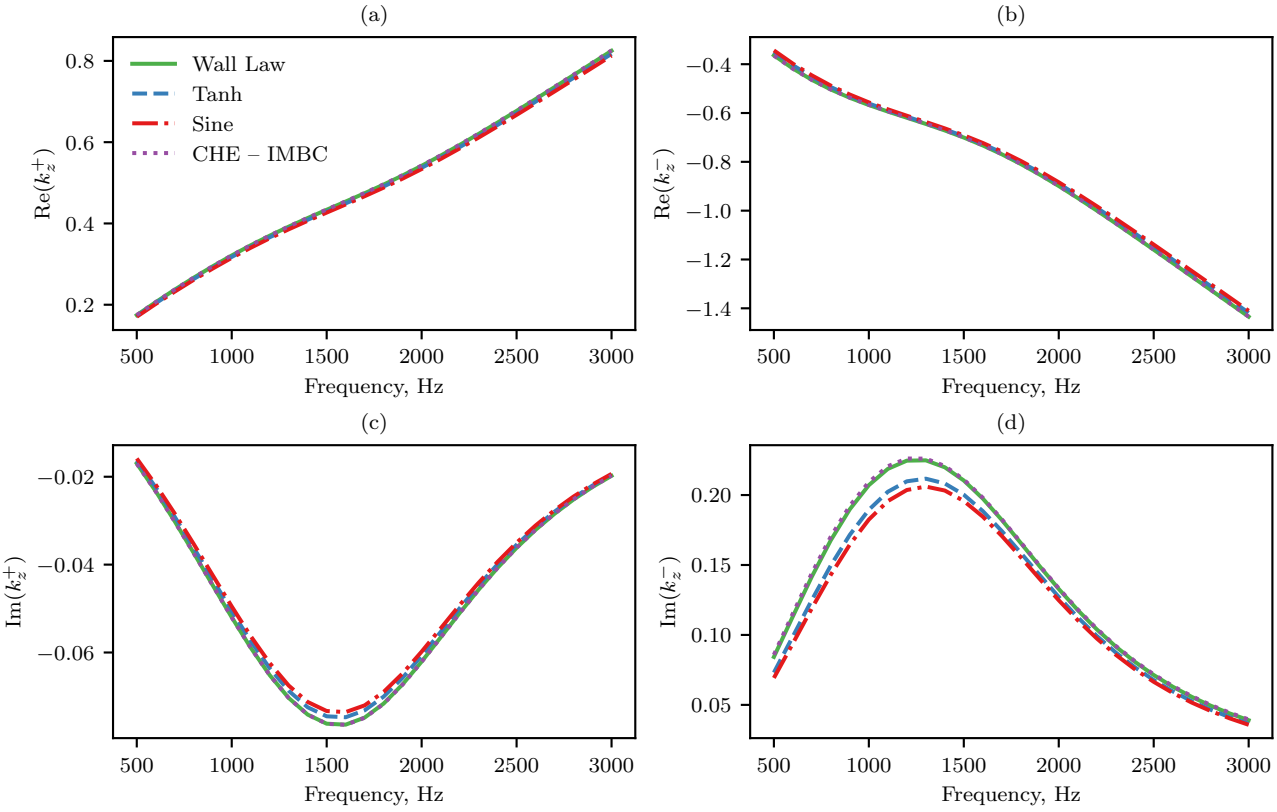

Figure 4. Wavenumbers obtained with different velocities distributions for the same M and $\delta_{99.9\,\%}$.

wavenumbers obtained for the different velocity distributions, especially for downstream propagation. However, for upstream propagation, the wavenumbers for the hyperbolic tangent and sinusoidal flow profiles agree well with each other, but diverge from the solution for the wall law and the prediction for the CHE-IMBC. These initial results suggest that assuming a uniform flow and compensating for the refraction within the boundary layer using the Ingard–Myers boundary conditions provides better estimates of the acoustic field in impedance eduction facilities under typical test conditions, compared to solving for an explicit velocity distribution that is not representative of realistic conditions.

The next step, which is the main goal of this study, is to evaluate the impact of considering different flow velocity distribution shapes on the evaluation of the acoustic field in impedance eduction. We use the wavenumbers obtained for the least attenuated mode, considering the different velocity profile formulations, in the classical straightforward impedance eduction routine. This routine assumes uniform flow and the Ingard–Myers boundary condition to model the slip velocity at the wall. The impedances educed with the proposed numerical experiment, along with the wavenumbers obtained for the different velocity profiles in the PBE, are shown in Figure 6.

The impedances educed using the wavenumbers obtained from the exact solution of the hyperbolic tangent and sinusoidal flow profiles exhibit a similar trend regarding the mismatch observed experimentally between upstream and downstream acoustic sources (downstream and upstream propagation, respectively). At the lower frequency end, the upstream source case results in a lower resistance, with the opposite trend observed at higher frequencies. This behaviour is similar to what has been observed by Ref. [10]; however, in our case, the reference impedance is not the midpoint between the two curves. For the most realistic flow profile, the wall law, the conclusions differ significantly. At the lower frequency end,

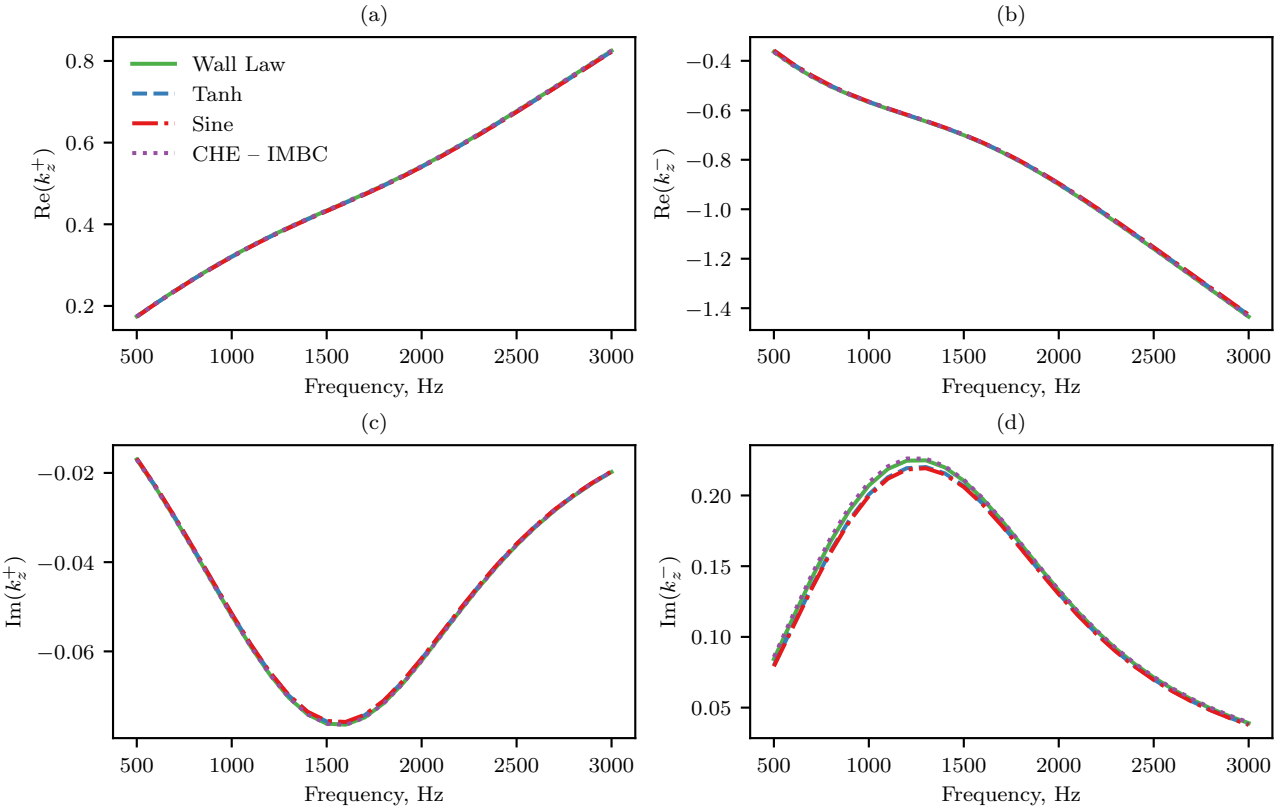

Figure 5. Wavenumbers obtained with different velocities distributions for the same M and δ^*.

the assumption of uniform flow with the IMBC introduces a small bias for both acoustic source positions, with good agreement observed between them. At higher frequencies, the curves diverge, with the upstream source (downstream propagation) surprisingly showing a greater deviation from the reference impedance.

6. CONCLUDING REMARKS

This work revisited the influence of sheared flow profiles on acoustic propagation in a 2D duct, extending Ref. [12] to impedance eduction. Comparing wavenumbers from the Pridmore–Brown equation with those from the Convected Helmholtz equation using the Ingard–Myers boundary condition (IMBC) showed that the IMBC performs well when the velocity profile is realistic, with improved agreement when matching the boundary layer displacement thickness.

A numerical experiment confirmed that IMBC-based eduction may introduce errors for non-realistic profiles but remains accurate for realistic flows. Iterative eduction with experimental data supported the findings of Ref. [5], showing reasonable agreement with the IMBC solution.

Overall, the IMBC is a reasonable simplification for low Mach number, small-duct impedance eduction in 2D ducts. Future work should extend this approach to realistic 3D ducts, as in Ref. [10], while preserving accurate flow profile representation.

GPU-BASED AEROACOUSTIC SIMULATION OF LOW-SPEED AXIAL FANS ACROSS THEIR CHARACTERISTIC FAN CURVES

Alessandra Verza[1*] **Peter Altmann**[2] **Lars Erbig**[2]
[1] Siemens Digital Industries Software, Spain
[2] Siemens Digital Industries Software, Germany

ABSTRACT

Over the past years, several papers dealt with numerical simulations of EAA's axial fan benchmark at its design point. Since all these publications used different simulation techniques and mesh types, but still delivered meaningful results, we assess how different levels of mesh resolution on the fan surfaces and motion modeling approaches impact the accuracy of the simulations when looking at more extreme operating conditions close to stall or free flow. Our simulations are based on constant-density Large Eddy Simulation coupled to a Perturbed Convective Wave equation and are run on 8 Nvidia A100 GPUs, which allows us to return results significantly more quickly than on CPUs. We find that accurately predicting aerodynamic quantities on all considered operating points requires a fine normal, and surface resolution on the fan blades as well as accurate motion modeling. In contrast, the acoustic far field predictions on all operating points except the free-flow condition are significantly less dependent on meshing and motion modeling decisions.

Keywords: *fan noise, large eddy simulation, les, pcwe, gpu.*

1. INTRODUCTION

Fast and reliable aeroacoustics simulation methods are key to enabling manufacturers to develop fan designs for a broad set of applications, such as automotive, wearable technology and appliances. Lowering the noise from components is one of the main concerns for fan manufacturers.

The most common approach in literature to this kind of problem mainly focuses on finding the best set up to accurately resolve the design operating point. This can be observed in numerous papers, for example by Ghodake et al. [1] and Antoniou et al. [2] show results on different meshes both at 1.4 m^3/s, and Erbig et al. [3] solved for the same mass flow rate on very coarse and fine grids. All these papers present good correlation with the experimental results, but so far there have been significantly less research efforts on the robustness of a simulation across a range of operating conditions.

The purpose of this study was to understand the variation in accuracy of the results when key aspects of the simulation and operating conditions were changed. In particular, changes in mesh resolution and motion modeling methods were studied to understand their effects on both aerodynamic and acoustic fields.

The experimental benchmark data that this study refers to, was based on a test series run by Krömer at the Friedrich-Alexander Universität Erlangen-Nürnberg on low-pressure axial fans [4].

Both aerodynamics and acoustic results are compared to the test data across the different mass flow rates to provide better insight into the requirements needed for the set up according to which quantities are of interest for the user.

2. THEORY

In this section, the theoretical background of the simulations is introduced, distinguishing between flow and acoustics modeling, and modeling of the fan motion itself. Finally, the evaluated quantities of interest are introduced.

2.1 Flow and Acoustic Modeling

The simulations follow a hybrid finite-volume approach that splits the aeroacoustic problem into a constant-density Large Eddy Simulation (LES) that is one-way coupled to a Perturbed Convective Wave Equation (PCWE) that uses instantaneous flow fields to model convective effects, as originally introduced by Piepiorka and von Estorff [5]. Both flow and acoustics use a 2nd order discretization in space and an implicit 2nd order temporal discretization. For flow, the temporal discretization is based on backward differencing, and the PCWE is discretized using a Newmark Alpha scheme [3]. It is worth noting that a constant density flow simulation allows fixing the volumetric flow rate at the inlet and is therefore particularly well suited to simulate a range of operating points across an unknown characteristic fan curve.

2.2 Motion Modeling

There are different approaches to model motion or to be more precise fan rotation in numerical simulations. The so-called moving reference (MRF) method was originally developed for axial flows and utilizes momentum equation source terms to approximate rotation [6]. Since no real rotation takes place, it is a numerically cost efficient, pragmatic approach, but with limitations in terms of accuracy. A high-fidelity simulation requires the real motion of the fan. This aspect is enabled with the so-called rigid body motion (RBM) model. The simulation domain gets divided into two parts/regions: the stationary region is the test chamber fluid volume, and the rotating region is the fluid volume surrounding the fan. The latter gets the fan rotation rate assigned and is normally modelled as a cylinder and contains the fan and in case of an axisymmetric shroud the entire shroud fluid volume. Consequently, the interface between the two regions must be re-calculated at every time-step. Past publications [3, 7] used intersection algorithms that lead to topologically valid cells, this paper is based on a more lightweight, "metrics-based", intersection algorithm that does not generate new polygonal faces [6]. While this approach is potentially less accurate, it also minimizes the memory footprint of the intersection and is better suited for running on GPUs.

2.3 Quantities of Interest

The aerodynamic performance of the fan is characterized by its total-to-static efficiency η_{ts} and its total-to-static pressure coefficient ψ_{ts}. Let Q denote the volume flow rate through the fan, and Δp_{ts} its total-to-static pressure difference. Then, the total-to-static pressure coefficient is defined by

$$\psi_{ts} = \frac{2\Delta p_{ts}}{\rho(\pi n d_{\text{fan}})^2} \quad , \tag{1}$$

where ρ is the fluid density, n is the number of blades, and d_{fan} the fan diameter. The total-to-static efficiency is given by

$$\eta_{ts} = \frac{Q\Delta p_{ts}}{M_s 2\pi n} \quad , \tag{2}$$

where M_s is the shaft torque. The acoustic performance of the fan is presented at far field microphones by evaluating its Sound Power Level (SWL) from the A-weighted time signals at the 7 microphones following the standard procedure outlined in DIN EN ISO 3746:2011-03.

3. TEST CASE

3.1 Experimental Setup

The original case was published by the European Acoustics Association [4] including both acoustics and aerodynamics experimental data. The fan was tested in a standardized inlet test chamber with a flow straightener upstream, and the exact volume flow rates were achieved by using an auxiliary fan in the inlet section. The acoustic experimental data was collected across 7 microphones located in an arc 1 m away from the inlet nozzle of the fan, as can be seen in Figure 1.

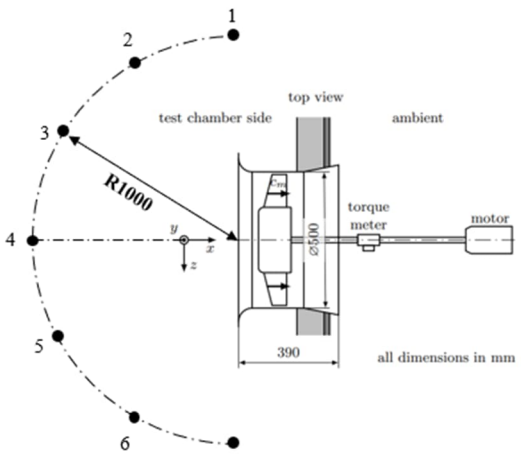

Figure 1. Detail of experimental setup with microphone arc [4].

The geometry here considered consists of an axial fan with a diameter of $d_{\text{fan}} = 0.495\,\text{m}$ and with $n = 9$ blades (referred to as "S1U" by Krömer [8]), mounted inside a duct 0.5 m in diameter, showed in Figure 2. The fan was tested across its complete operating curves, from stall to free flow, which means the inflow rate varied between 0.2 m^3/s to 2.1 m^3/s. Additional equipment was used to provide more

data on the flow behavior, such as time signals from differential pressure transducers to measure wall pressure fluctuations in the duct, and Laser Doppler Anemometer measurements on both sides of the fan.

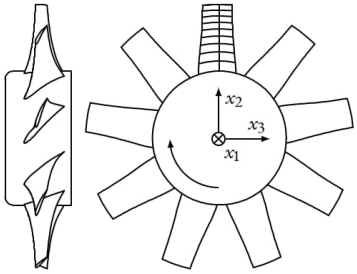

Figure 2. Tested axial fan with unskewed blades [4].

3.2 Numerical Setup

The computational setup replicates the experimental test facility and consists of two large rectangular chambers that are separated by a partition and the duct which hosts the axial fan. The top, bottom and side surfaces and the partition are modeled as non-reflecting, rigid walls. Inlet and outlet boundaries are parallel to the partition and prescribe a mass flow rate at the suction side and enforce a pressure on the pressure side of the fan (as shown in Figure 3). A hex dominated, so-called trimmed mesh in combination with prism layers at the surfaces was used to discretize the simulation domain. In total four different volume meshes were generated to analyze the impact of spatial discretization on runtimes and accuracy. The global mesh size (base size) for all meshes was 13.6 mm. Table 1 provides an overview of the relevant mesh parameters, relative to the base size if applicable, to create the different volume meshes. The total cell count varies between 55 M for the finest and 29 M for the coarsest mesh.

Table 1. Investigated volume meshes.

	Fan prism layers	Prism layer thickness (mm)	Fan target surface size (mm)	Fan minimum surface size (mm)	Volume cells (× 1E6)
Mesh 1	8	0.50	0.43	0.11	55
Mesh 2	2	0.75	0.43	0.11	40
Mesh 3	2	0.75	0.85	0.21	30
Mesh 4	2	0.75	1.70	0.43	26

A hemisphere was used to refine the mesh from the fan up to the far-field microphone locations. To capture the propagating sound waves, a uniform mesh size of 6.8 mm was used. This spatial resolution ensures 12 cells per wavelength up to 4 kHz.
The following image of Mesh 1, the finest volume mesh with around 55 M cells, visualizes the simulation domain, the overall mesh topology and refinement level around the fan and the fan tip gap.

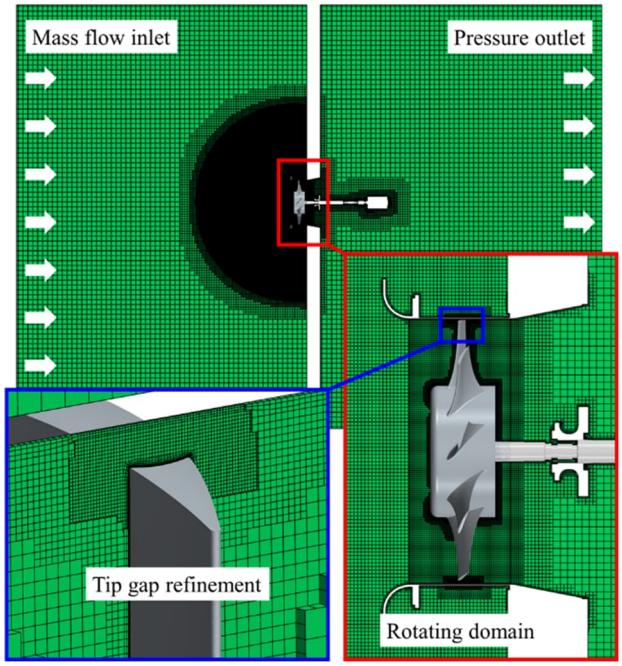

Figure 3. Finest volume mesh, topology and details.

All simulations were performed with Simcenter STAR-CCM+ version 2502. The unsteady, scale-resolving runs were initialized with a steady state Reynolds-averaged Navier-Stokes solution and utilize a segregated solver based on the SIMPLEC algorithm to solve the transient flow equations in an uncoupled manner. Fan motion was modelled with MRF for the steady, initial step and RBM for the unsteady part. The latter uses a wall-modelled Large Eddy Simulation (WMLES) approach based on the Wall-Adapting Local Eddy-Viscosity (WALE) subgrid-scale model [9] for turbulence modelling.
Each run featured eight fan revolutions with 2,000 time-steps per rotation, which equals 12.5 time-steps per period at 4 kHz. The convective wave equation is activated after the first rotation and the Newmark Alpha scheme uses $\alpha = -1/3$. Acoustics data sampling took place over the last six rotations.

4. RESULTS

In this section, we will analyze simulation results obtained on several operating points distributed over the entire characteristic fan curve. We will particularly investigate the dependency of these results on the spatial discretization on the fan blades, as well as the impact of the different motion modeling approaches. The key enabler for performing these numerous simulations were 8 NVIDIA A100 GPUs, each with 40 GB GPU memory. On this hardware, elapsed simulation times varied between 16.8 hours on Mesh 1 with RBM, and 6.8 hours on Mesh 3 with MRF, where MRF motion modeling accelerated the simulations by about 35% compared to RBM.

4.1 Analysis of different operating points

Typically, the degree of resolution of LES simulations of wall-bounded flows are judged upon the sizes of the dimensionless wall distance y^+, and the dimensionless cell sizes in the streamwise direction Δx^+, and the spanwise direction Δz^+ of the flow. These quantities are governed by

$$y^+ = \frac{u_\tau y}{\nu}, \Delta x^+ = \frac{u_\tau \Delta x}{\nu}, \text{and } \Delta z^+ = \frac{u_\tau \Delta z}{\nu}, \quad (3)$$

where u_τ is the friction velocity and ν the kinematic viscosity of the fluid, y is the wall distance of the cell center of the first cell next to the wall, and Δx and Δz denote the local edge lengths in the respective flow directions. Usual criteria [10] consider an LES simulation to be properly wall-resolved if

$$y^+ \sim 1, \Delta x^+ < 100, \text{and } \Delta z^+ < 30, \quad (4)$$

and wall-modeled if

$$y^+ > 30, \Delta x^+ \approx \Delta z^+ < 500. \quad (5)$$

In day-to-day engineering applications, the flow is usually not following a single, well-defined direction, and meshes are often isotropic on the wall. Hence, it is particularly difficult to judge the validity of the dimensionless cell sizes. In this paper, we approximate these quantities by evaluating

$$\Delta^+ := \frac{u_\tau \sqrt{A}}{\nu} \approx \Delta x^+ = \Delta z^+, \quad (6)$$

where A denotes the local face area at the walls.

The obtained upper limits for these values on the leading edges of the blades, and the blades themselves are presented in Table 2. It is evident that Mesh 1 can be considered a classical representative of a wall-resolved LES, whereas Mesh 4 is a clear representative of a wall-modeled LES, while Meshes 2 and 3 are hybrid states that independently vary y^+ or Δ^+.

Table 2. Realized wall discretization on the four considered volume meshes.

	Mesh 1	Mesh 2	Mesh 3	Mesh 4
Max. y^+ Leading Edge	1.2	4	6	14
Max. Δ^+ Leading Edge	22	14	26	50
Max. y^+ Blade	2.5	27	32	32
Max. Δ^+ Blade	98	85	166	320

In an initial attempt, the volumetric flow rate at the inlet was varied from 0.6 m³/s to 2.0 m³/s on the same grid and the mean total-to-static efficiency and total-to-static pressure coefficient were evaluated over the last sampled revolution of the fan. Figure 4 shows that especially the total-to-static pressure coefficient on Mesh 1 aligns very well with the test data.

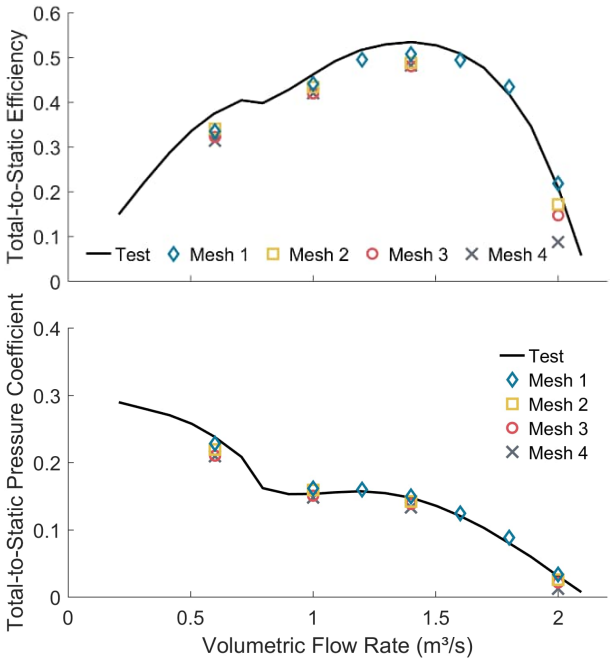

Figure 4. Mesh dependency of the total-to-static efficiency and pressure coefficient.

The efficiency shows slightly larger deviations, with a slightly flatter area around the design point and an underprediction at 0.6 m³/s. Based on these results, we decided to focus the further analysis on the limits of the expected fan operating range, 1.0 m³/s, and 2.0 m³/s, the design point 1.4 m³/s and the case at 0.6 m³/s. It is clearly visible that each individual mesh coarsening, including the independent increase of only y^+, leads to an increased under-prediction of the aerodynamic predictions. And even though this effect is most pronounced for the highest mass flow rate, the data points still follow the measured curves.

By inspecting the wall shear stress on Mesh 1 in Figure 5, one can identify the difference between the various volumetric flow rates: particularly at the lowest considered volumetric flow rate of 0.6 m³/s the flow is highly turbulent on the entire fan blade, and the vortical structures extend upstream throughout the whole shroud, typical for the stall regime. As the volumetric flow rate increases, the upstream vorticity drops, and the flow at the design point of 1.4 m³/s is dominated by the tip gap dynamics and becomes less turbulent on the blade.

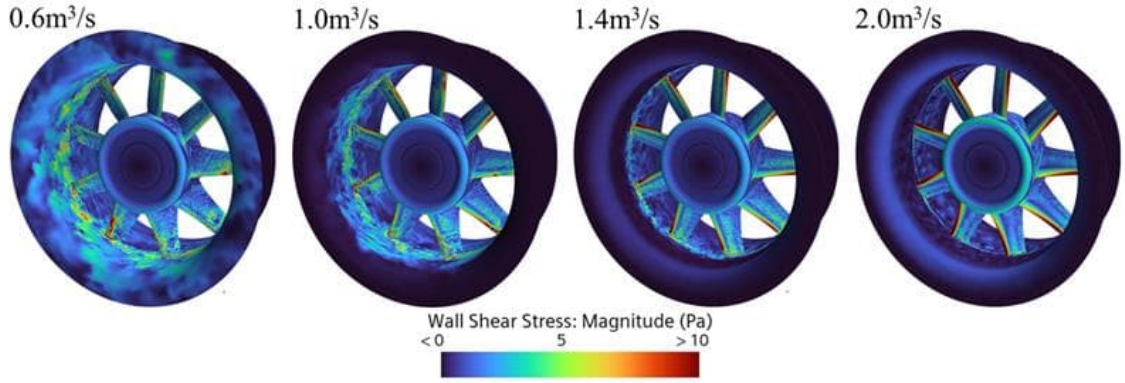

Figure 5. Instantaneous wall shear stress from Mesh 1 on fan and shroud.

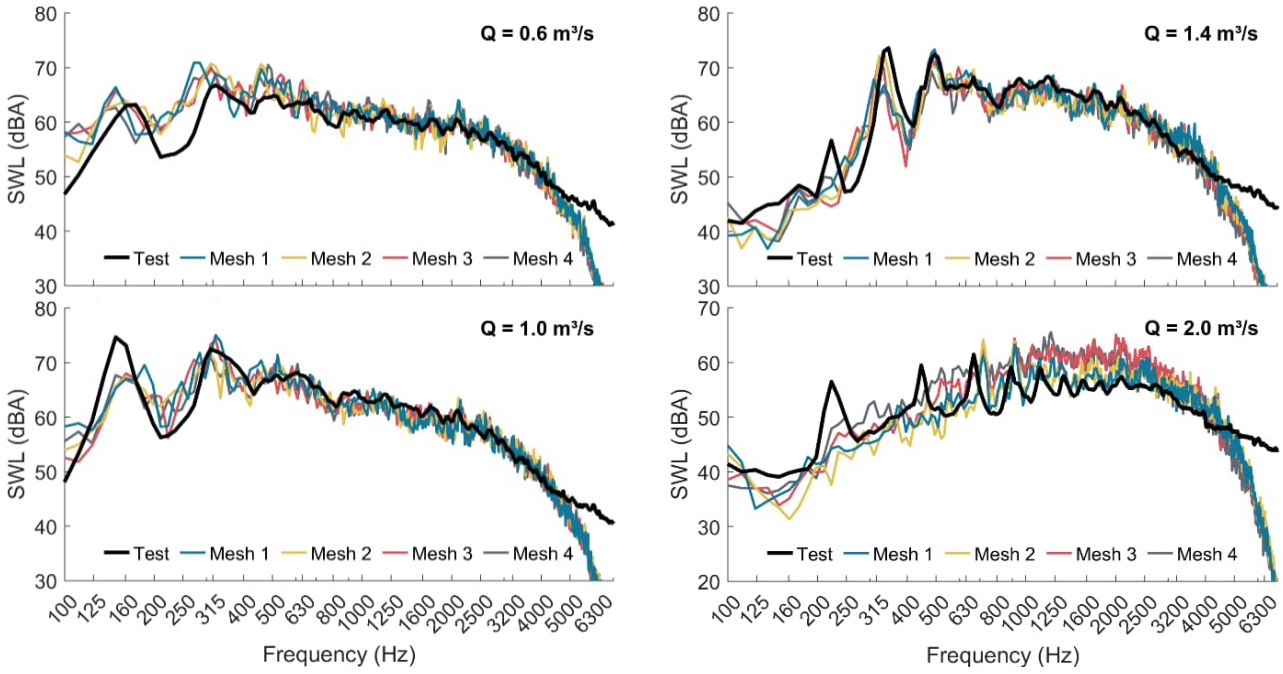

Figure 6. Mesh dependency of the Sound Power Level obtained from the 7 far field microphones.

Finally, at 2.0 m³/s, the trace of the tip gap vortex becomes much more localized and the flow around the blades transitions significantly later, a typical characterization of free flow conditions.

In this context, we can attempt to analyze the Sound Power measured at the 7 far field microphones which are shown in Figure 6. The test data from Krömer's experiments [8] shows a clear dependency on the considered operating point. The spectrum at the design point has already been analyzed in much detail [1, 8], and it is characterized by low low-frequency levels, which are followed by a relatively subtle peak at the blade passing frequency and two strong subharmonic peaks due to the tip gap dynamics. The highest frequencies above 2 kHz are then dominated by trailing edge noise of the blades. In comparison, the spectra at lower volumetric inflow rates show subharmonic peaks that are shifted to lower frequencies, and similar high frequency characteristics. In contrast, the spectrum at the highest volumetric inflow rate appears highly different: The subharmonic peaks vanish entirely, but the blade passing frequency with several harmonics is strongly excited. Furthermore, the overall level of the broadband high frequency content decreases by more than 5 dBA and finally remains more stable towards the highest frequencies.

The simulation results at the design point and the mass flow rate of 1.0 m³/s are highly consistent across all considered meshes and agree well with those reported in the literature, i.e. they show sensitivities at the subharmonic peaks, and they don't capture the blade passing tones. The results at the lowest volumetric inflow rate are also highly consistent and match excellently above 300 Hz, but they overpredict the noise due to the vortex dynamics at the lowest frequencies.

Overall, these results indicate that the acoustics predictions at these volumetric flow rates are much less sensitive to any meshing considerations than the aerodynamic quantities – which are presumably dominated by the strong tip gap vortex dynamics. In agreement with the aerodynamic results, the spectra at the highest volumetric inflow rate show the greatest dependency on the meshes: While the results from the finest mesh (Mesh 1) match the test results quite well, apart from the missing blade passing tones, the results on the coarsest grid leads to a strong offset of more than 5 dBA in almost the entire frequency range. However, it should be noted that the independent modification of y^+ does not affect the acoustic results, it is only the increase of Δ^+ that leads to deteriorated results. Hence, the aerodynamics seem to depend much more on the wall normal resolution in the vicinity of the wall, than the acoustics, which rely much more on the surface resolution. To understand the reasons for these differences, we can analyze the instantaneous wall shear stress and the surface trace of the acoustic source term of the PCWE in Figure 7. In these images, it is clearly visible that the flow structure around the blades changes immediately with increasing y^+, whereas the increase of Δ^+ in Mesh 3 and Mesh 4 only coarsens the flow pattern found on Mesh 2.

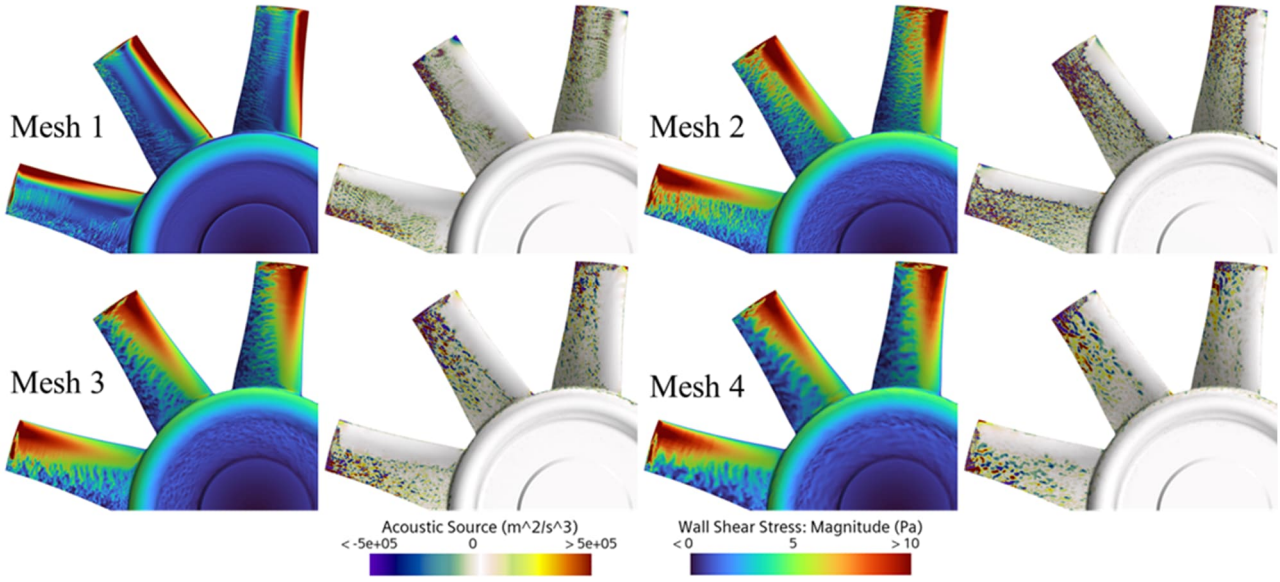

Figure 7. Wall shear stress and trace of the volumetric acoustic source term of the PCWE of the fan.

In contrast, it can also be seen that the acoustic source term changes going from Mesh 1 to Mesh 2, but we still see sources everywhere on the downstream parts of the blades. But with increasing Δ^+ on Mesh 3 and Mesh 4, the sources on the blade itself become weaker and the source term accumulates around the tip gap, which likely indicates a shift of the dominant noise generation mechanism.

4.2 Influence of Motion Modeling

Separately from coarsening the mesh or the time-step it is also possible to consider switching the motion modeling from RBM modeling with a rotating and a stationary domain, to MRF modeling that keeps a stationary mesh but introduces a moving reference frame. While this clearly reduces the computational costs per time-step, the individual impact on aerodynamics and acoustics predictions in a scale-resolving simulation is relatively unclear. To address this question, Meshes 1 and 3 were additionally simulated with MRF. In Figure 8, one can see the aerodynamics results on the different meshes and it can be clearly seen that the MRF motion modeling has a significant impact on both meshes, leading to bigger deviations from the test results. Again, particularly the volumetric inflow rate of 2.0 m³/s is most sensitive to these changes. Very much in contrast to this, especially the broadband acoustic results at the fan's design point shown in Figure 9 are consistent across the entire frequency range. Again, a big deviation is visible on Mesh 3 for the first subharmonic peak, which correlates well with strong sensitivity of the aerodynamic results on the motion modelling approach. The results on the other volumetric inflow rates were highly consistent with those from the design point.

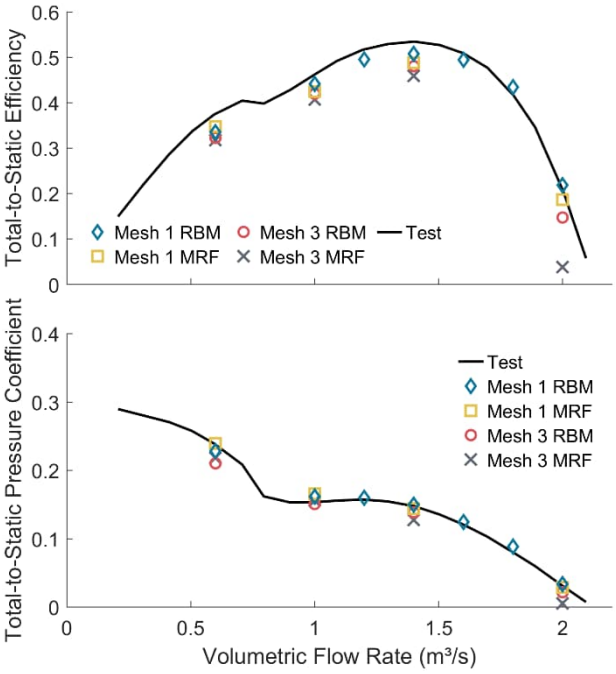

Figure 8. Dependency of the total-to-static efficiency and pressure coefficient on motion modeling.

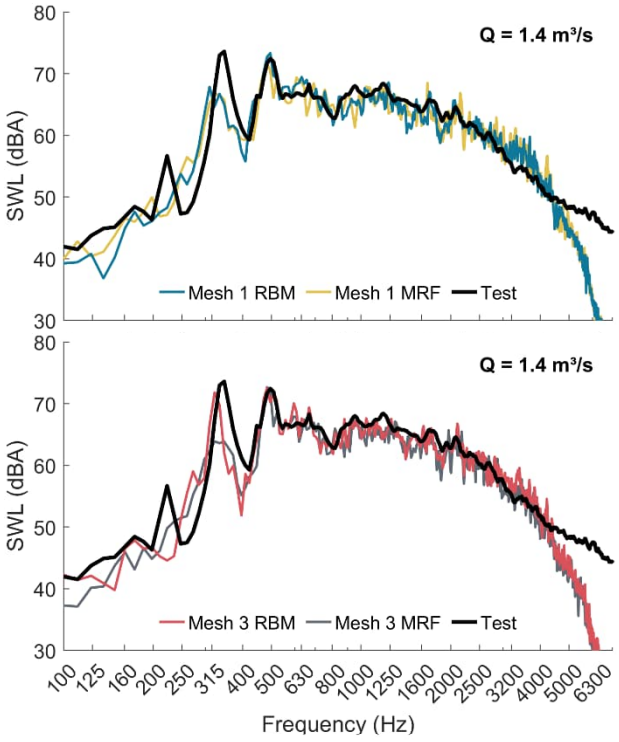

Figure 9. Dependency of the Sound Power Level obtained from the 7 far field microphones on motion modeling.

5. SUMMARY & CONCLUSION

In this paper, scale-resolving hybrid aeroacoustic simulations of the EAA benchmark fan across almost its entire operating range were performed on 8 NVIDIA A100 GPUs. The GPUs helped to reduce the computational costs of each simulation to significantly less than a day. In the simulations, we particularly studied the sensitivity of the aerodynamic and acoustic results on y^+ and Δ^+, as well as on different motion modelling approaches. The operating points were varied by modifying only the volumetric inflow rate. Overall, good results were achieved for all operating points without changing the mesh. It was found that the aerodynamic

predictions rely much more on highly resolved y^+ values and RBM than the acoustic results in the far field. Only the tones due to the subharmonic tip gap vortices as well as the free-flow operating point showed sensitivities to the Δ^+ mesh resolution and the motion modelling approach. Overall, this demonstrates that acoustics and aerodynamics converge at different rates towards their mesh-converged values.

Hence, one can potentially conduct comparably pragmatic acoustic simulations that do not attempt to answer aerodynamics and acoustics at the same time. Such an approach could be considered feasible in most of the fan's operating range. Such a split would be another step towards efficient utilization of the different length and timescales of aerodynamics and aeroacoustics.

To further investigate such splitting the authors intend to better understand the reasons for the mesh dependency at the free flow condition and look deeper into the vortex shedding mechanism at the blade tip. Furthermore, we intend to test these procedures on additional fan designs, such as those simulated by Ghodake [1] and further investigate the validity of MRF motion modelling in cases with more significant rotor stator interactions.

6. ACKNOWLEDGMENTS

ABSTRACT

In the present paper, a non-Lighthill approach based on first principles is developed. The physical sound sources were clearly defined, and two acoustic radiation mechanisms were investigated. The sound field spectrum obtained by calculation was found to be in relatively good agreement with previous study.

Keywords: *jet noise; hybrid methods; equivalent sound source; acoustic radiation mechanism.*

1. INTRODUCTION

Turbulent jets at high subsonic Mach numbers account for a significant proportion of commercial aircraft noise. Despite considerable advances in the characterisation and reduction of jet noise, this subject persists as a salient issue, primarily due to a lack of understanding of the physical mechanisms underlying sound generation.

A turbulent jet is composed of two distinct structures: large orderly coherent structures (CS) and fine-scale random fluctuations [1]. A substantial corpus of research has indicated that the generation of noise is predominantly associated with the evolution and interaction of coherent structures [2-4].

Computational aeroacoustics, defined as solving the full compressible Navier-Stokes equations numerically within a sufficiently large domain encompassing both the near and far fields, is an extremely challenging task, even for the most powerful computers at present.

Theoretical approaches based on reduced equations are indispensable, and two theoretical methods have been developed by taking different perspectives to generation of noise by unsteady flows. The primary approach to aeroacoustics is acoustic analogy, a concept initially proposed by Lighthill [5].

A methodology that differs from the acoustic analogy is the asymptotic approach, which examines the sound waves radiated to the far field as the asymptotic behaviour of the near-field hydrodynamic fluctuations. The mechanism of acoustic radiation was initially investigated using matched asymptotic expansion by Tam & Burton [6]. Building upon this, Zhang and Wu [7-10] have extended the analysis to study the nonlinear evolution and acoustic radiation of coherent structures in subsonic turbulent jets. The physical sound source can be derived directly.

The objective of the present study is to formulate a hybrid method based on first principles. The near/hydrodynamic field is simulated numerically, while the far acoustic field integrates with asymptotic theoretical analysis. The physical sound sources were calculated, and two acoustic radiation mechanisms were identified.

2. HYBRID METHOD

The two-dimensional compressible Navier-Stokes equations in cylindrical coordinates are solved by a finite-difference DNS code. The axial and radial derivatives are computed with sixth-order center difference scheme, while the second-order total-variation-diminishing (TVD) Runge-Kutta scheme is used for time integration.

According to latest research, we know that the nonlinear evolution of large-scale coherent structure produces the

equivalent sound source $\widehat{a_M^+}$ consist of three parts, namely $\mathcal{U}$, $\mathcal{S}$ and $\mathcal{Y}$. The formula is as follows, and only the upper half of the solution of the free shear flow is considered:

$$\widehat{a_M^+}(\omega,k)=\frac{\hat{\mathcal{E}}_-(\omega,k)}{\hat{\mathcal{E}}_+ +\hat{\mathcal{E}}_-}\left[\frac{ik\hat{\mathcal{U}}(\omega,k)}{c(k-\omega)^2}+\int_{-\infty}^{\infty}\frac{\hat{\mathcal{S}}(\omega,k,y)}{(\bar{U}k/c-\omega)^2}dy\right]-\frac{\hat{\mathcal{Y}}(\omega,k)}{\hat{\mathcal{E}}_+ +\hat{\mathcal{E}}_-} \quad (1)$$

where $\mathcal{U}$ is contributed by the interactions in the critical layer, corresponding to the streamwise velocity jump across the critical layer, $\mathcal{S}$ is reflected in the effect of the small-scale structure on the coherent structure, $\mathcal{Y}$ represents the back action from the sound field acted on the source, corresponding to the pressure jump, k is the axial wavenumber, c is the phase speed, y represents the transverse direction, $\mathcal{E}_+$ and $\mathcal{E}_-$ are functions related to the boundary conditions, $\hat{\blacksquare}$ means the Fourier transform of the corresponding quantity. More details can be found in [9].

Then the acoustic pressure $\tilde{P}^+$ can be obtained by integrating the sound source. Here, we directly give the final far-field pressure at any equivalent distance $\bar{R}$ and angle θ to jet axis as follows,

$$\tilde{P}^+\sim\frac{1}{2\pi^2\bar{R}}\int_{-\infty}^{\infty}e^{sgn[\phi''(\omega,k_s,\theta)]i\pi/4-i\pi/4}D_P(\omega,k_s)\widehat{a_{Ml}^+}(\omega,k_s)e^{i\phi(\omega,k_s,\theta)\bar{R}-i\omega\tau}d\omega \quad (2)$$

3. NUMERICAL RESULTS

In present study, the parameters of disturbance waves were listed in table 1, and ω_1, ω_2 are the two inflow primary waves. It should be noted that this simplified "double-wave" model was proposed by Sandham [11-12], and they pointed out there would be a strong nonlinear interaction creating the difference mode wave. Therefore, we calculated these classic cases to verify the feasibility of our hybrid method on the one hand, and on the other hand to analysis the mechanisms of sound radiation of this simplified model in detail.

The dimensionless parameters, Mach number and Reynolds number, are chosen the same as the experimental parameters of Stromberg *et al*. [13], which are *M=0.9* and *Re=3600* respectively.

Table 1. Parameters of inflow.

ω_1	ω_2
2.2	3.4

Figure 1 shows the instantaneous dilation rate field calculated by the present method. The sound radiation is highly directional, and noise is emitted from the vortex roll-up position, implying that the sound sources are just hidden here. The wavelength of the emitted sound corresponds to the difference mode frequency $\Delta\omega=1.2$, which means that the difference mode generated by the nonlinear interaction between two inflow disturbances dominates the acoustic radiation.

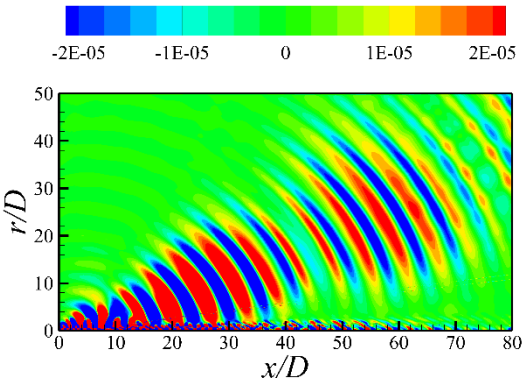

Figure 1. The instantaneous dilation rate field.

By integrating the equivalent sound source, the far-field pressure can be easily obtained. For an intuitive description, the sound pressure level was calculated and compared with the results of DNS, see in Figure 2. And the results of DNS are calculated by the empirical formula

$$SPL=20log_{10}\left(\frac{p'_{DNS}p_s}{p_c p_{ref}}\right), \quad (3)$$

where p'_{DNS} is the calculated pressure of DNS, the relative pressure $p_{ref}=2\times10^{-5}N/m^2$, p_s is the standard atmospheric pressure and $p_c=0.0072p_s$.

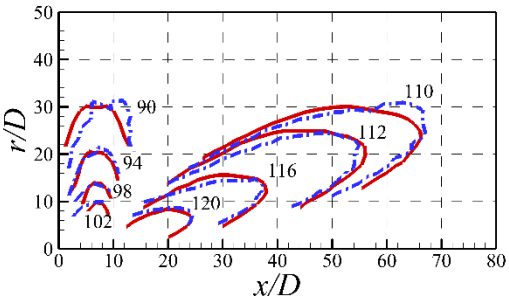

Figure 2. The sound pressure level contours. (red line for present result; blue dashed line for DNS)

It is evident that the results of the present method are exactly congruent with those of direct simulation. For the low angle region, the sound radiation exhibits super-directive characteristics at an angle of nearly *30* °relative to the jet axis. This radiation mechanism can be considered as an extension of the Mach-wave radiation.
In addition, there is another direction of radiation at an angle approximately *90* °to the jet axis. This finding is an indication of the presence of an additional high angle radiation mechanism. The nonlinear interaction of the instability waves gives rise to a mean-flow distortion. This distortion is slowly modulated in both time and space and acts as an emitter, radiating low-frequency sound waves on the scale of the wavepacket envelope at a high angle. This phenomenon is so called envelope radiation.

4. CONCLUSION

This paper presents a novel non-Lighthill hybrid method for the study of the acoustic radiation of axisymmetric modes in subsonic jets. The results, of our hierarchical hybrid methodology, exhibit a remarkable agreement with experimental observations and those obtained from DNS. It is therefore concluded that the non-Lighthill hybrid method is a feasible approach for predicting acoustic noise in subsonic jets.
The findings also indicate the presence of two distinct sound sources and two sound radiation mechanisms: general Mach-wave radiation and envelope radiation.

ABSTRACT

The study delves into the characterisation of the aeroacoustic response of low-Reynolds number propellers subjected to blade spacing angle modification. A numerical investigation was carried out on two-bladed propellers featuring blade spacing angles from 30 to 150 degrees, in 30-degree increments, as well as a conventional propeller with 180-degree blade spacing. The non-uniform blade spacing can mitigate tonal contributions at the blade passing frequency and its harmonics while introducing non-zero contributions at odd multiples of the shaft frequency. The objective of this work is to determine the effect of the blade spacing angle on the distribution of the acoustic energy spectrum and the aerodynamic quality of the propeller. The numerical analyses were performed by a potential aerodynamic solver based on a boundary integral method and an aeroacoustic solver based on the Farassat 1A formulation. The predictions were validated against experimental measurements for conventional and 90-degree blade spacing propellers. The time-averaged propeller thrust and tonal overall sound pressure level were accurately predicted. Propellers with uneven obtuse blade spacing angles displayed the largest addition of the acoustic energy towards the lower frequency domain while preserving the aerodynamic performance of the reference propeller.

1. INTRODUCTION

The prevalence of unmanned aerial vehicles (UAVs) utilising low-Reynolds number propellers is increasing, leading to the establishment of new economic sectors. The perception of noise pollution by humans and the subsequent public acceptance of UAVs represent one of the major barriers to the widespread adoption of these aircraft [1]. The optimisation of propeller designs aimed at mitigating the adverse effects of noise pollution presents significant advantages to emerging aerial robotics services. For this reason, academia and industry are making considerable efforts to investigate and design innovative solutions aimed at reducing the acoustic nuisance of these vehicles [2–4]. To this aim, it is evident that a profound understanding of the mechanism governing noise generation is essential to characterise the acoustic footprint of low-Reynolds number propellers, a topic that has become the focus of extensive literature [5–9].

This study investigates an approach to mitigate acoustic emissions, by manipulating the blade spacing angle that eliminates radial symmetry. Under the assumption of identical and evenly spaced blades, the tonal components of the emitted noise emerge at frequencies that are multiples of the blade passing frequency (BPF) [10]. Contrarily, with blades that are not equally spaced, the tonal noise components manifest at harmonics of the revolution frequency. Therefore, the premise is to utilise this redistribution of the energy content resulting from the uneven blade spacing to diminish the noise emitted at the multiples of the BPF, while recognising that the drawback is the onset of tonal contributions at the revolution frequency and its odd harmonics. It is critical to emphasise that the blade spacing, in principle, influences the aerodynamic perfor-

mance. Hence, a balance between acoustic benefits and performance deterioration should be found.

In this context, a characterisation of the aeroacoustic response of uneven-blade spaced propellers was conducted. Six distinct propeller configurations were examined, featuring blade spacings of 30, 60, 90, 120, 150, and 180 degrees. Due to the apparent radial asymmetry due to uneven blade spacing, these propellers can be referred to as "asymmetric" propellers. The numerical analysis was performed through the application of an aerodynamic solver based on a boundary integral formulation for potential flows and an aeroacoustic solver based on the Farassat 1A formulation for tonal noise prediction. Numerical simulations were supplemented by the experimental measurements of a conventional propeller configuration described by blade spacing of 180 degrees, referred to as VP-R, and a non-conventional design with blade spacing of 90 degrees, denoted by VP-9.

2. NUMERICAL METHOD

The aerodynamic analysis was performed through a Boundary Element Method (BEM) solver based on the boundary integral formulation introduced in [11], able to take into account the effects of significant body-wake interactions. Under the assumption of potential and incompressible flows, the potential field was defined as the superposition of an incident field, generated by doublets over the wake portion not in contact with the trailing edge (far wake), and a scattered field, generated by sources and doublets over the body and doublets over the wake portion very close to the trailing edge (near wake). This procedure allows the removal of the numerical instabilities arising when a doublet wake comes too close to or impinges on the body. Recalling the equivalence between the surface distribution of doublets and vortices, the contribution of the far wake was expressed as a net of thick vortices (i.e., Rankine vortices). In this approach, the wake shape can be either assigned (prescribed-wake analysis) or obtained as a part of the solution (free-wake analysis) by a time-marching integration scheme in which the wake points move according to the local velocity field.

Once the potential field was obtained, the Bernoulli theorem yielded the pressure distribution on the body that, in turn, was used both to determine the aerodynamic loads and to predict the radiated noise, being the input of the aeroacoustic solver. The aeroacoustic analysis was performed by a prediction tool based on the linear Farassat 1A boundary integral formulation [12]. Specifically, the acoustic pressure field was given as the superposition of only the thickness noise depending on body geometry and kinematics and the loading noise related to the pressure distribution over body surfaces (being the quadrupole term negligible in the analysed flight condition).

3. VALIDATION

The numerical aerodynamic and aeroacoustic solvers used in this study have undergone extensive validation against empirical data [13–15]. However, due to the unconventional propeller geometries examined herein, an additional validation set involving a propeller with unequal blade spacing angles has been presented.

All the numerical results presented in the paper were obtained by discretising each propeller blade in $6,000$ panels, whereas $43,200$ panels are used over the corresponding wake surface, which was assumed to be eight revolutions long, with 60 panels distributed along the radial direction. A schematic representation of the discretised geometry is shown in Figure 1 for the baseline propeller configuration. A free-wake algorithm was used for the aerodynamic solution. A non-dimensional time-step of 3 degrees was used for the aerodynamic analysis, whereas a step of $1/2$ degrees was used for the aeroacoustic one. It was verified that these computational mesh characteristics and time discretisation guaranteed converged numerical results.

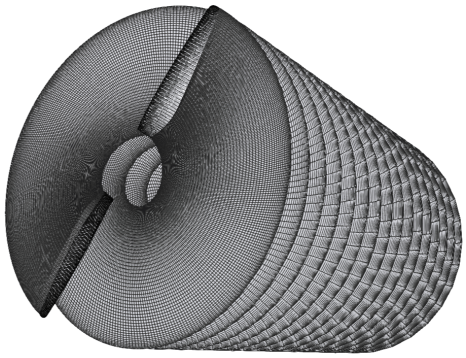

Figure 1. Discretisation of the reference propeller, VP-R.

3.1 Propellers

For validation of the numerical solver, two fixed-pitch, 16×5.5 inches lifting propellers were examined: the con-

ventional, reference off-the-shelf propeller (VP-R) and a custom propeller with 90-degree blade spacing (VP-9), as illustrated in Figure 2. The designation "VP" refers to V-Propeller, named for its characteristic shape. Both propellers had equivalent blade geometry, solidity and tip radius, and were fabricated by a company specialising in the low-Reynolds number propellers manufacturing. To address the inertial imbalance in the plane of rotation for the VP-9 configuration, a finely tuned counterbalance pellet was fitted into the elongated hub of the propeller.

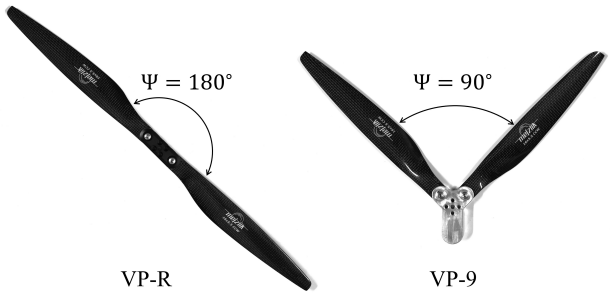

Figure 2. Propeller set. Reference propeller, VP-R, and propeller with 90-degree blade spacing angle, VP-9.

3.2 Test procedure

The aeroacoustic response measurements were carried out in an anechoic chamber with a cut-off frequency of 50 Hz at the University of Salford, instrumented to measure far-field aeroacoustic response for different observation angles. In particular, nineteen 1/2-inch far-field pressure microphones – nine Brüel and Kjær 4963 and nine GRAS 46AO – were installed on a two-and-half meter arc centred in the propeller hub and lying in the plane orthogonal to the propeller plane of rotation. The microphones were uniformly spaced across observation angles, θ, ranging from 0 to 180 degrees, in 10-degree increments, with the microphone at a 180-degree observation angle located within the propeller wake. The microphone signals were recorded at a sampling rate of 50 kHz.

3.3 Aerodynamic response

The comparison of the time-averaged static thrust predictions with the experimental data is presented in Figure 3 for the VP-R and VP-9 propeller. The agreement between simulated results and test data was deemed satisfactory, particularly in the $3,500$ to $5,000$ rpm domain. At rotational speeds below $3,500$ rpm the Reynolds number at 75% tip radius falls below $50,000$, leading to augmented effects of viscosity terms. At speeds exceeding $5,000$ rpm, the influence of compressibility becomes substantial. These effects are not captured by the governing equations of the aerodynamic solver, resulting in a slight decline in the level of agreement within these speed domains. Nonetheless, the observed discrepancies remained marginal. At a speed of interest, $5,000$ rpm, the percentage error between predicted and mean measured thrust for VP-R and VP-9 propellers were 2.9% and 1.6%, respectively. Regarding the effect of the blade spacing, it only

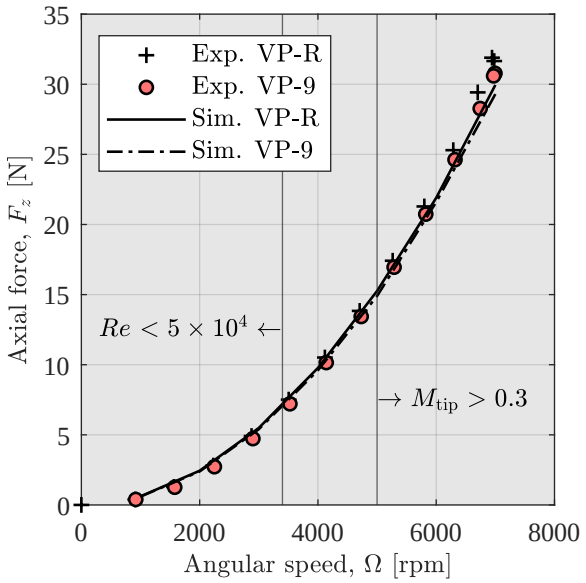

Figure 3. Validation of the predicted time-averaged static propeller thrust.

slightly affects the aerodynamic performance, and mainly for angular velocities higher than $6,000$ rpm. In particular, a thrust decrease as the propeller blade spacing decreases is observed, as captured both numerically and experimentally.

3.4 Aeroacoustic response

For the spectral analysis of the experimental data, a Hanning window was used, characterised by a constant partition size of 2^{17} and 75% overlap, giving a frequency resolution of 0.38 Hz. The power spectral density was

obtained using Welch's method. The reference acoustic pressure level was assumed at 20 µPa.

The noise directivity in terms of zero-weighted overall sound pressure level (OASPL) is shown in Figure 4. The simulated OASPL had a tonal nature and solely incorporated the first ten harmonics of the rotational frequency. Consequently, only the tonal contributions of the measured sound pressure level spectrum were extracted and truncated at a fifth BPF harmonic, $0 < f^+ \leq 5$, to ensure that the experimental results remained directly comparable to the simulation output. The acoustic response was not reported for emission angles between 170 and 180 degrees due to the contamination of the recorded sound pressure signal by the propeller wake. In the case of a conventional propeller, VP-R, the mean discrepancy between the measured data and the simulation for all reported emission angles was found to be 3.9 dB. The most considerable discrepancies were observed at the emission angles corresponding to the suction side of the propeller, ranging from 0 to 20 degrees. In contrast, the OASPL predictions for the propeller with 90-degree blade spacing, VP-9, displayed a strong agreement with the experimental data, yielding a mean difference of 2.3 dB, with discrepancies consolidated in the domain from 60 to 110 degrees.

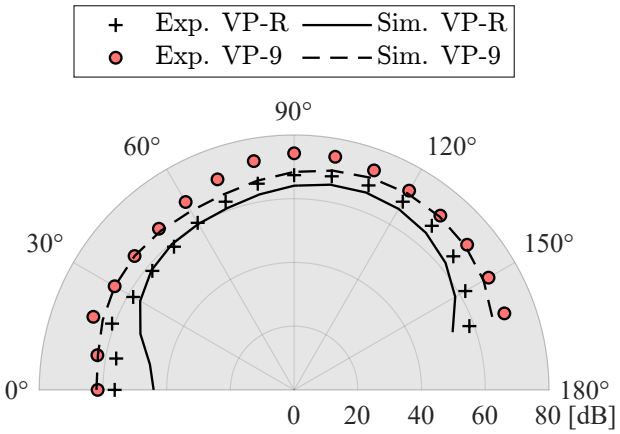

Figure 4. Tonal **OASPL** polar.

4. RESULTS

Upon validating the numerical solver against the experimental data corresponding to both the VP-R and VP-9 configurations, the solver was subsequently employed to asses the influence of the blade spacing angle on the aerodynamic and aeroacoustic responses of the propeller. Figure 5 shows the effect of the blade spacing angle on the time-averaged propeller thrust coefficient – computed at 5,000 rpm in static flight conditions. In agreement with the experimental observation for the VP-R and VP-9 propellers, as well as findings reported in prior publications [16, 17], a decrease in blade spacing angle corresponded with a reduction in time-averaged propeller thrust. Especially, at a blade spacing angle of 30 degrees, a thrust reduction of approximately 9% was observed, a trend that displayed lesser impact for obtuse angles, with thrust reduction diminishing to less than 1% for blade spacing angles greater than 120 degrees.

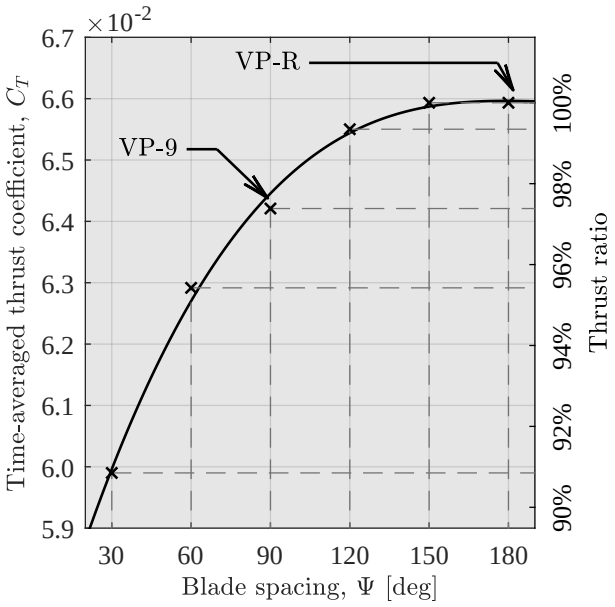

Figure 5. Variation of time-averaged propeller thrust coefficient as a function of the blade spacing angle.

The predicted tonal components of the sound pressure level are illustrated in Figure 6. As anticipated, propellers featuring uneven blade spacing demonstrated the emergence of tones at odd multiples of the shaft frequency. This observation suggests that the uneven blade spacing angle has indeed facilitated a redistribution of acoustic energy within the frequency spectrum. Furthermore, as the blade spacing was reduced a greater amount of acoustic energy was added to the spectra within the analysed frequency interval, $0 < f \leq 833$ Hz. However, it would be a misinterpretation to assert that reduced blade spac-

ing negatively affects acoustic performance, as only the first five BPF harmonics were identified. The observed increase in peak amplitudes may be correlated with a shift in tonal energy toward the lower frequency domain, which must occur at the expense of the higher frequency energy content, thereby the total radiated acoustic energy must be preserved – subject to further investigation.

5. CONCLUDING REMARKS

A numerical and experimental study was conducted to analyse the aerodynamic and aeroacoustic characteristics of a two-bladed low-Reynolds number propeller with uneven blade spacing under static flight conditions. The correlation found between the measured experimental data and the numerical results enhances the fundamental understanding of the key factors affecting both the aerodynamic efficiency and the sound signatures linked to these configurations, while also confirming the effectiveness of the numerical solver for unconventional propeller designs.

A parametric analysis was performed to investigate how different blade spacing angles affect aerodynamic and aeroacoustic behaviours in propellers. The blade spacing angles considered were 30, 60, 120, and 150 degrees.The purpose of this study was to explore the possibility of optimising the blade spacing angle to shift acoustic energy content toward the lower frequency domain while also minimising negative effects on aerodynamic performance.

The implementation of uneven blade spacing facilitates a redistribution of the acoustic energy content towards the lower frequency domain. The uneven blade spacing added more energy into the spectrum in the frequency interval up to the fifth BPF harmonic. Understanding whether this increase in acoustic energy at the lower end of the frequency spectrum occurs at the expense of the higher frequency content remains a topic for further investigation.

ABSTRACT

Accurately measuring the self-noise of unmanned aerial vehicles (UAVs) is crucial for acoustic characterisation, noise reduction optimisation, and gaining public acceptance and certification of these aircraft. An on-board measurement setup allows direct and flexible detection of acoustic phenomena in different flight conditions, without the need for external sensor installations with the problem of continuously changing measurement distance and a complex measurement setup. For reliable measurements, especially at higher flight or wind speeds, an effective microphone windscreen is essential. This windscreen should ideally shield the microphone from ambient and propeller airflow while introducing minimal additional turbulence noise, which could otherwise mask the UAV's self-noise and reduce measurement accuracy. In this study, the airflow around the microphone of a quadrocopter UAV was experimentally analysed for different flight conditions using stereo PIV measurements and a wind tunnel. Based on the results, optimisation possibilities for the microphone windscreen solution were investigated in an aeroacoustic wind tunnel. Starting from commercially available windscreens, different designs were investigated and refined to effectively suppress hydrodynamic pressure fluctuations that overlap with the UAV self-noise. The results illustrate how airflow patterns change in different flight situations and highlight practical optimisation strategies to improve the accuracy of UAV self-noise measurements.

1. INTRODUCTION

Multirotors, commonly known as drones or Unmanned Aerial Vehicles (UAVs), have evolved rapidly from futuristic concepts to practical tools used in diverse commercial and public service applications. Examples of their widespread adoption include autonomous package deliveries already operational in regions such as Australia [1] and upcoming implementations planned in the United Kingdom and elsewhere [2]. Additionally, their inherent flexibility has enabled them to perform various specialized tasks, ranging from media production, such as aerial photography and videography, to medical logistics like the rapid transport of blood samples [3], and critical roles in rescue and reconnaissance missions [4–6] or in the agriculture [7]. The increased use of UAVs introduces significant challenges, most notably the issue of noise emissions [8]. Drone-related noise pollution has become a contentious issue, often leading to public concern and regulatory scrutiny. Engineers and developers thus face the dual challenge of effectively reducing noise emissions while si-

multaneously adhering to regulatory acoustic limits, similar to those established for other technical equipment like heat pumps [9]. Moreover, enhancing energy efficiency remains crucial, as it directly affects the operational range and flight duration of multirotor systems. Prior research at the Chair of Fluid Mechanics (LSTM) has investigated correlations between propeller-generated thrust and noise emissions under controlled hover conditions, confirming a strong link between aerodynamic performance and acoustic output [10]. However, to thoroughly characterize and understand UAV acoustics, it is essential to expand analyses beyond hover conditions. Realistic flight operations, including horizontal, climbing, and descending maneuvers, involve complex aerodynamic interactions that significantly influence the acoustic footprint of the aircraft. The reason for this is that each of these flight maneuvers exhibits specific aerodynamic characteristics [11] and phenomena also known from helicopters. These include the vortex ring state in vertical flight, blade-vortex interactions, flow separations, or Mach number effects [12]. In order to capture the noise emissions of multirotors, there are essentially two approaches: external measurements using microphone(s) on the ground or direct onboard measurements with microphone(s) on the drone itself. However, external measurements are associated with drawbacks, as they usually require a multitude of specifically arranged microphones [13], entail complex evaluations, and the variability of the drone's position during flight as well as atmospheric sound propagation effects [14] limit the measurement accuracy. An on-board measurement using one or more microphones offers a flexible and practical alternative, allowing acoustic data to be recorded directly and continuously during flight. Nevertheless, other challenges arise, particularly due to hydrodynamic pressure fluctuations caused by the propeller flow as well as the self-motion of the multirotor and ambient wind. Previous studies have shown that, especially at higher flight speeds, significant masking effects due to hydrodynamics impair the measurement of the actual self-noise [10]. Furthermore, it has been demonstrated that the positioning of the microphone has a significant impact on the measured sound spectrum. While other publications have positioned microphones on lateral arms [15], future placement is intended to be centrally above the drone, near the horizontal center of mass and without altering the moments of inertia about the horizontal axes. This positioning reduces unwanted influences on flight stability and agility, enables better comparability of the measurements. Furthermore, as demonstrated in the volumetric PIV investigation by Wolf [16], is that in the suction area, where significantly less turbulence occurs compared to a placement beneath the drone. This study clearly illustrated not only the reduction in turbulence but also the behavior of the flow—including blade vortices and other flow phenomena during various flight maneuvers—in different regions around the drone. For our purposes, it is particularly important to analyze how the flow behaves in the suction area, especially in terms of flow direction and turbulence levels, where the effects of the drone's body flow are most pronounced. Therefore, the subsequent analysis will focus on characterizing the flow in this critical region.

2. FLOW CHARACTERIZATION

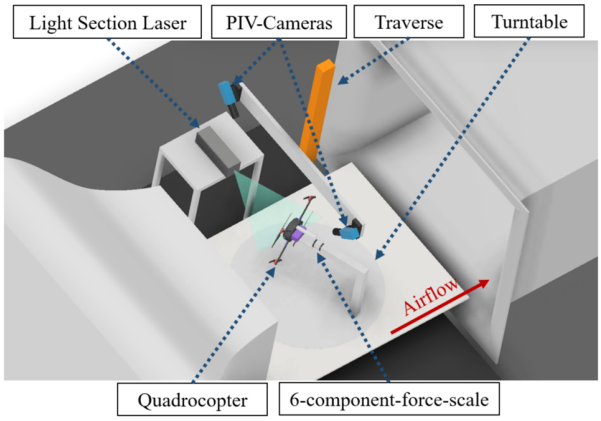

Figure 1. The measurement setup.

To enable future investigations of wind protection variants under realistic conditions, a detailed flow analysis using Stereo-PIV is conducted. The measurements were carried out in the wind tunnel of the Chair of Fluid Mechanics (LSTM). This wind tunnel has a cross-sectional area of $B = 1.87\,\mathrm{m} \times H = 1.40\,\mathrm{m}$ and a test section length of $L = 2.4\,\mathrm{m}$, featuring a central test table and an integrated turntable. A schematic picture of the measurement setup is shown in Fig. 1.

The quadrocopter used for the measurements was equipped with $D = 15$-inch propellers (T-Motor NS15x5) and has a flight weight without payload of $m_{\mathrm{Quadrocopter}} = 3.1\,\mathrm{kg}$. This UAV represents a typical 5-kg class system with a payload capacity of 2 kg, providing an excellent research platform. As shown in Fig. 2, the quadrocopter has canopy with an oval planform and proper extrusion to facilitate a better characterization of its surrounding airflow. Most of the onboard electronics, are housed within

the canopy and the battery hangs under it, so there is a minimal influence to the flow above, with only the electronic speed controlers slightly outside the canopy.

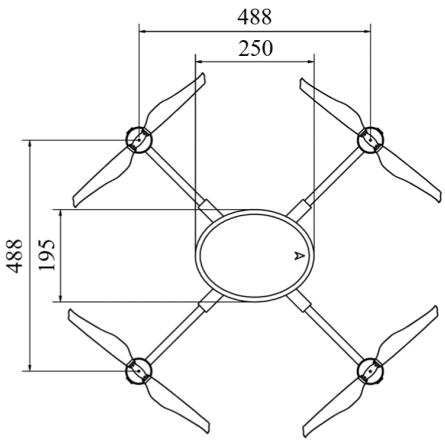

Figure 2. Dimensions of the investigated quadrocopter.

For the Stereo-PIV measurements, two *PCO.2000* cameras with *Sigma* lenses (f = 18–35 mm F1.8) and Scheimpflug adapters were employed. The system was calibrated and aligned using a specialized calibration device and an optical calibration plate. Scheimpflug optics ensured that both cameras shared the same focal plane, allowing reliable three-dimensional (XYZ) measurements. Particular care was taken to ensure that the seeding particles (propylene glycol) were accurately assigned throughout the measurement volume. The flow was illuminated by a pulsed Nd:YAG laser (*Quantel Twins BSL 200*), and data evaluation was performed using the software *PIVView3C*. The measured plane was located centrally between the rotors of the multirotor, as illustrated in Fig. 3. This plane is particularly relevant for understanding the flow, as the measurement microphone will be positioned here in the future.

The current and rotational speed were individually set and monitored for each motor. The multirotor was mounted on a 6-component force balance for the simultaneous measurement of aerodynamic forces on the turntable. The propeller thrust for each flight condition was validated using the 6-component force balance. The relative deviation between the experimentally measured thrust F_{meas} and the theoretically required thrust for weight compensation at a tilt angle θ was calculated as:

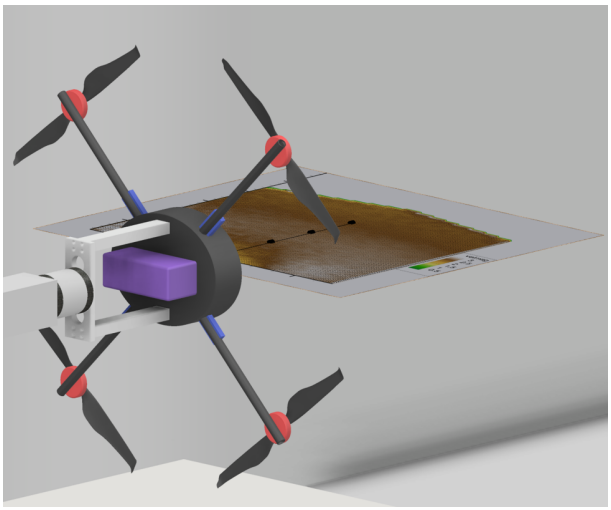

Figure 3. Illustration of the investigated measurement plane.

$$\Delta F_{\%} = \left(\frac{F_{\text{meas}} \cos(\theta)}{m\, g} - 1 \right) \times 100\,\%. \qquad (1)$$

The rotor speeds were determined experimentally during several test flights, with each relevant flight maneuver being performed multiple times and the recorded rotational speeds and currents averaged. These averaged rotor speeds were then precisely reproduced for each motor seperately in the wind tunnel.

2.1 Hover Case

In a hover case no external airflow is applied, which poses a challenge for PIV measurements since, without additional flow, the seeding particles are not sufficiently transported to characterize the velocity field. To overcome this, the airflow generated by the propellers was utilized. The thrust produced by the rotating propellers induces a passive airflow in our closed-loop wind tunnel (Göttinger design), that transports the particles. However, this passive flow leads to a circulation that establishes a relative airflow of approximately $v_{passive} = 1.86\,\text{m/s}$. This passive flow reduces the inflow angle on the propeller blades and consequently diminishes the generated thrust, so that the expected $T = 30.5$ N for hover is not fully reached, as seen in Fig. 4. To compensate, the propeller speed was increased by 200 rpm, which in turn raised the passive airflow to about $v_{passive} = 1.94\,\text{m/s}$. As a result, instead of a pure hover, the condition is more akin to a slow climb

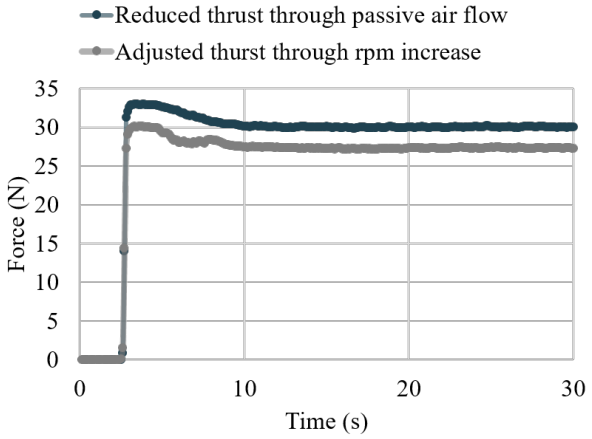

Figure 4. Thrust curve in hover case through passive air flow after turning on the motors at 2 s.

at $v_{vertical} = 1.94\,\mathrm{m/s}$. Analysis of the flow field in Fig. 5 shows that at a distance of the Z-coordinate in the body-fixed frame, $Z_{UAV} = 100\,\mathrm{mm}$ from the drone a stagnation zone with low velocities between $1\,\mathrm{m/s} \leq u \leq 1{,}5\,\mathrm{m/s}$ exists; at $Z_{UAV} = 200\,\mathrm{mm}$ and $Z_{UAV} = 300\,\mathrm{mm}$ the velocity increases to $v \approx 2.5\,\mathrm{m/s}$, and then decreases again to about $v = 2\,\mathrm{m/s}$ at $Z_{UAV} = 400\,\mathrm{mm}$. Furthermore, the flow direction remains largely consistent with only minor deflections very close to the drone at $Z_{UAV} \approx 50\,\mathrm{mm}$, where slight redirection components are observed.

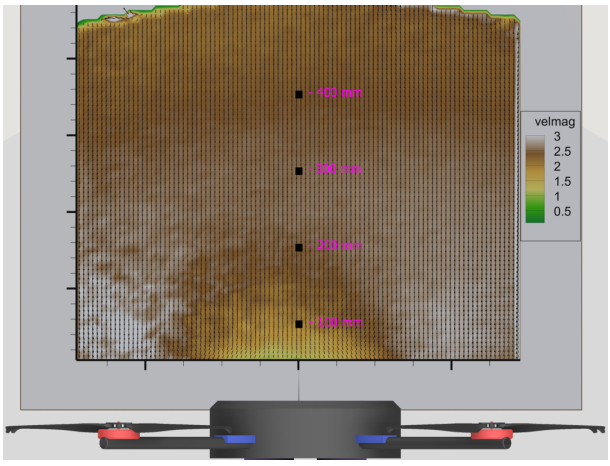

Figure 5. Averaged flow field at $v_{horizontal} = 5\,\mathrm{m/s}$ with the Z-coordinate indicated in the body-fixed frame.

2.2 Horizontal Flight with a Speed of 5 m/s

The conditions for the case of $v_{\text{horizontal}} = 5\,\mathrm{m/s}$ are summarized in Table 1.

Parameter	$v_{\text{horizontal}} = 5\,m/s$
Tilt Angle, θ [°]	4.1
Thrust Deviation, $\Delta F\%$	1.08%

Table 1. Flight conditions at $v_{\text{horizontal}} = 5\,m/s$.

Figure 6 illustrates the averaged flow field obtained under these conditions. The analysis reveals a pronounced stagnation zone in the immediate vicinity of the multirotor body, where the local flow velocity drops to approximately $v = 3.5\,\mathrm{m/s}$. At a distance of around $Z_{UAV} = 100\,\mathrm{mm}$ from the vehicle, distinct velocity peaks emerge, reaching up to $v = 8\,\mathrm{m/s}$. As the distance from the multirotor increases further, the flow velocity gradually diminishes, converging to the nominal flight speed of $v_{\text{horizontal}} = 5\,\mathrm{m/s}$. Moreover, while the flow direction near the body exhibits significant deviations, it increasingly aligns with the flight trajectory at larger distances.

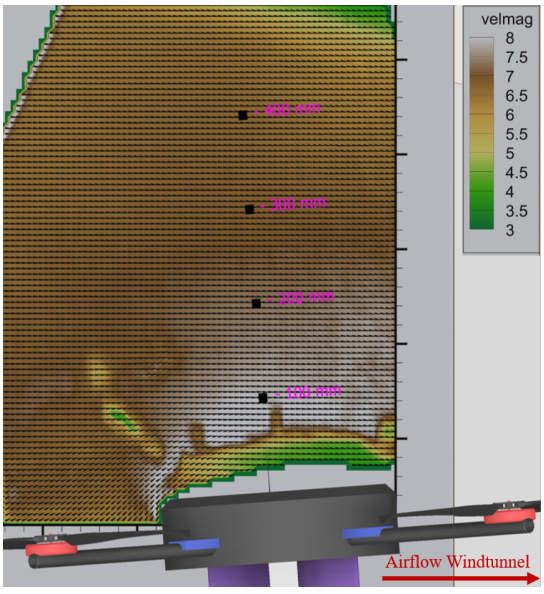

Figure 6. Averaged flow field at $v_{\text{horizontal}} = 5\,\mathrm{m/s}$ with the Z-coordinate indicated in the body-fixed frame.

2.3 Horizontal flight with a speed of 10 m/s

The conditions for the case of $v_{\text{horizontal}} = 10\,\text{m/s}$ are summarized in Table 2.

Parameter	$v_{\text{horizontal}} = 10\,m/s$
Tilt Angle, θ [°]	10.0
Thrust Deviation, $\Delta F\%$	2.98%

Table 2. Conditions at $v_{\text{horizontal}} = 10\,m/s$.

A similar flow pattern is observed at a higher horizontal flight speed of $v_{horizontal} = 10\,\text{m/s}$, as shown in Fig. 7. Here is also a strong stagnation zone was observed immediately at the multirotor body, which, at a distance of $Z_{UAV} = 100$ mm, exhibits strong flow velocity peaks of up to $v = 12\,\text{m/s}$. This increased velocity then continuously decreases with further distance and approaches the actual flight speed. Again, it is evident that near the multirotor body there are significant deviations in the flow direction from the actual flight direction, while at greater distances the flow direction corresponds to the flight trajectory.

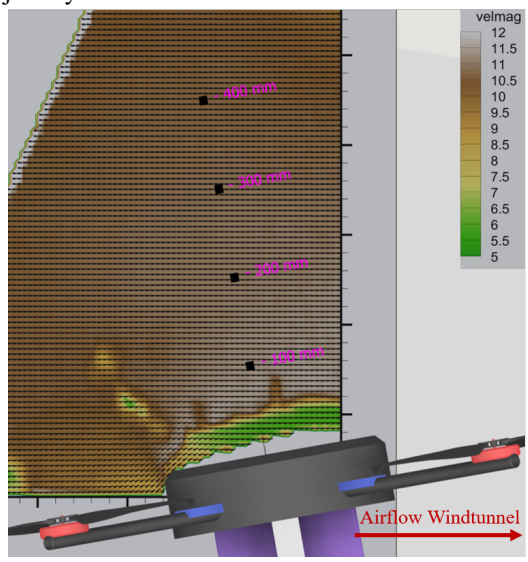

Figure 7. Averaged flow field at $v_{horizontal} = 10\,\text{m/s}$ with the Z-coordinate indicated in the body-fixed frame.

2.4 Horizontal Flight with a Speed of 15 m/s

For the case of $v_{\text{horizontal}} = 15\,\text{m/s}$ the conditions are shown in Table 3.

Parameter	$v_{\text{horizontal}} = 15\,m/s$
Tilt Angle, θ [°]	16.6
Thrust Deviation, $\Delta F\%$	-2.98%

Table 3. Flight conditions for $v_{\text{horizontal}} = 15\,m/s$.

In the $v_{horizontal}$ = 15 m/s case (see Fig. 8), a similar behavior is observed as in the previously investigated horizontal flow fields at different speeds. Very close to the drone, within less than $Z_{UAV} = 100$ mm, a stagnation zone with considerably reduced flow velocities $v \approx 8$ m/s is present, accompanied by strong flow deflections near the drone body. At a distance of around $Z_{UAV} = 100$ mm, a pronounced velocity peak is observed, reaching $v \approx 15$ m/s. With increasing distance from the drone, the flow velocity gradually decreases and eventually converges to the nominal flight speed of $v_{horizontal}$ = 15 m/s at about $Z_{UAV} = 400$ mm. Moreover, the flow direction progressively aligns with the flight trajectory of the drone.

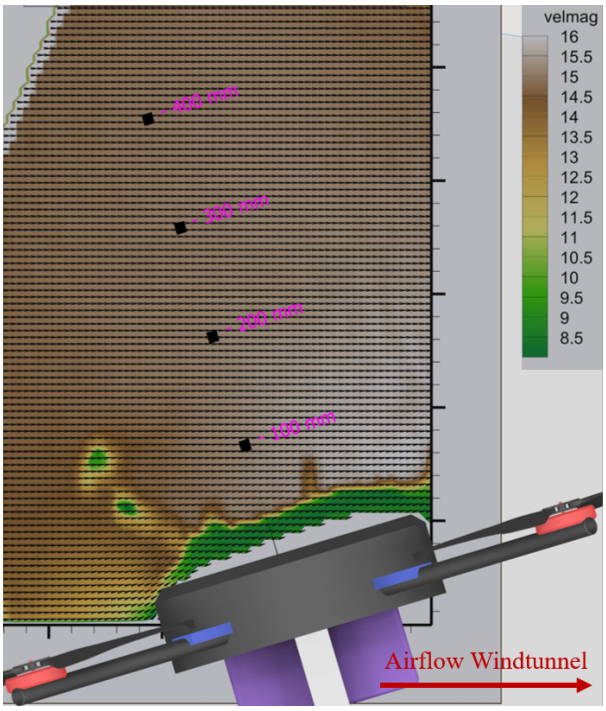

Figure 8. Averaged flow field at $v_{horizontal} = 15\,\text{m/s}$ with the Z-coordinate indicated in the body-fixed frame.

2.5 Summary of Flow Conditions

The present measurements reveal that in all investigated flight maneuvers, a pronounced stagnation zone develops in close proximity to the drone body. At approximately $Z_{UAV} = 80\,\text{mm}$ from the drone, the flow field exhibits significantly increased velocities, with local speeds exceeding the nominal flight speed of up to 60%. As the distance from the drone increases, the flow gradually aligns with the flight trajectory and approaches the vehicle's actual speed. At $Z_{UAV} = 200\,\text{mm}$, the velocities remain slightly elevated compared to the flight speed, while from around $Z_{UAV} = 300\,\text{mm}$ onward, the measured flow velocity essentially matches the nominal flight speed. Although a larger separation, such as $Z_{UAV} = 400\,\text{mm}$, would provide even more favorable flow conditions, it would necessitate a considerably larger mounting structure for the microphone.

These findings are critical for the future design of the wind protection system. The windscreen should be strategically positioned to avoid the stagnation zone, where elevated flow velocities are very close to and the directions the flow are changing. It is also expected that there is higher turbulence intensity within the stagnation region. So it is advisable to place the microphone in an area where the flow has already aligned with the flight trajectory and speed. Future investigations will focus on a detailed analysis of the turbulence distribution and its impact on the measurements, ultimately guiding the optimal positioning of the wind protection.

3. INVESTIGATION OF VARIOUS WIND PROTECTION VARIANTS

In future investigations, the characterized flow conditions will serve as the basis for evaluating various wind protection variants under realistic conditions. To illustrate the potential of these designs, preliminary results from experiments conducted in an aeroacoustic wind tunnel are presented in Fig. 9. These measurements were performed at an approach velocity of $v = 10\,\text{m/s}$ with a 90° incidence angle (i.e., perpendicular to the microphone). The following wind protection variants were tested:

- *MTG* Standard Foam Wind Protection 50 mm (referred to in the spectrum as *Foam*)
- *Rycote Baseball* (referred to in the spectrum as *Baseball*)
- *Rycote Cage with foam + Deadcat* (referred to in the spectrum as *Deadcat*)
- *Rycote Classic Softie* (referred to in the spectrum as *RCS*)
- *Rycote Super Softie* (referred to in the spectrum as *RSS*)

Figure 9 provides a comparison of the different wind protection variants at $v = 10\,\text{m/s}$. Additionally, two microphones were placed outside the primary flow region, and their averaged measurements (denoted as 'outside' in the spectrum) were used as reference values to account for the baseline hydrodynamic influence. The external measurements consistently showed low flow-induced noise, whereas significant differences became apparent when evaluating the wind protection variants.

Notably, the standard foam wind protection (*Foam*) exhibited average sound pressure levels of approximately $L_{p,\text{Mittel}} \approx 48\,\text{dB}$, similar to those observed for the *RSS* and *Baseball* variants. In contrast, the *Deadcat* demonstrated a considerable advantage over the foam by reducing overall sound pressure levels by roughly $\Delta L_{p,\text{Mittel}} \approx 4\,\text{dB}$. This improvement is particularly pronounced in the low-frequency range ($f < 500\,\text{Hz}$), where hydrodynamic pressure fluctuations are most influential. The *Deadcat* achieves a sound level reduction of about $\Delta L_p \approx 11\,\text{dB}$ compared to the foam there. Moreover, the frequency responses of the variants differ significantly in certain ranges. For instance, a switching behavior is observed where the *Foam* variant outperforms *RSS* in specific frequency bands, and vice versa. In some cases, characteristic spectral peaks, presumably due to flowinduced effects or structural noise from the wind protectors, were also detected and warrant further investigation.

At a higher approach velocity of $v = 20\,\text{m/s}$, even more pronounced differences emerge (see Fig. 10). Under these conditions, the classic foam variant performs the poorest. Although its performance up to about $f > 100$ Hz remains comparable to that of the other variants, from around $f < 200$ Hz onward its sound pressure levels increase dramatically by at least 10 dB compared to all other wind protection types a trend that continues well into the high kHz range. Of course it is not made for such flow velocities, it is more like a reference in this case. In contrast, the *RCS* variant performs best in the low-frequency range $f < 300$ Hz but exhibits a significant level increase at higher frequencies. Overall, when the entire frequency spectrum is considered, the *Deadcat* consistently shows

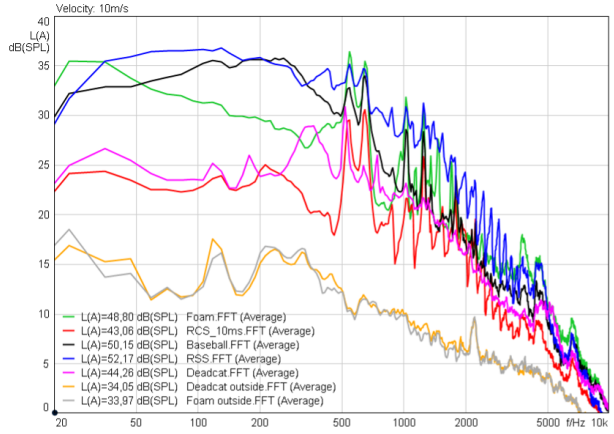

Figure 9. Comparison of the different wind protection variants at a flow velocity of $v = 10\,\mathrm{m/s}$.

the best performance, achieving an overall improvement of $\Delta L_p \approx 17\,\mathrm{dB}$ compared to the classic foam. The presence of characteristic peaks in some of the spectra suggests specific flow-induced components or inherent structural noise from the wind protectors, aspects that will be examined in more detail in future studies.

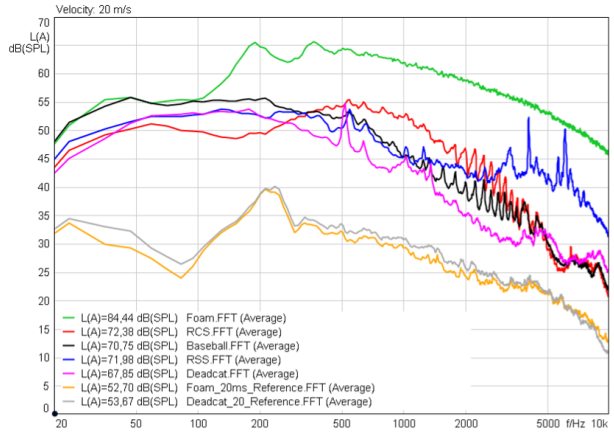

Figure 10. Comparison of the different wind protection variants at a flow velocity of $v = 20\,\mathrm{m/s}$.

Lastly, it is important to note the varying sizes of the wind protection variants. In drone applications, where size and weight are critical parameters, finding an optimal balance between effective wind protection and minimal impact on the vehicle is essential. Future work will focus on refining this balance under realistic flow conditions.

4. CONCLUSION AND OUTLOOK

By employing Stereo-PIV measurements in a wind tunnel, we characterized the complex airflow around a quadrocopter under various flight conditions. Our analysis revealed that, regardless of the maneuver, a pronounced stagnation zone develops in close proximity to the drone body, with local velocities exceeding the nominal flight speed of up to 60%. As the distance increases, the flow gradually aligns with the flight trajectory and converges to the actual movement speed, highlighting the importance of sensor placement for accurate noise measurements. Furthermore, we evaluated several wind protection variants in the aeroacoustic wind tunnel. Preliminary results indicate that commercially available windscreens, particularly the *Deadcat* variant, can significantly reduce the impact of hydrodynamic pressure fluctuations on the measured sound pressure levels. Notable differences in the frequency response among the tested variants emphasize the need for an optimized design that minimizes additional turbulence and noise while maintaining a compact form factor. Looking ahead, future work will focus on a more comprehensive analysis of the turbulence distribution within the stagnation zone and its impact on acoustic measurements. This will enable further refinement of the wind protection design, ensuring optimal microphone placement. The goal is to develop a universally applicable windscreen that reliably isolates the UAV's self-noise, thereby improving measurement accuracy and facilitating broader acceptance of UAV operations in both commercial and regulatory contexts.

ABSTRACT

The rapid development of multi-rotor drones has accelerated the growth of the low-altitude economy (LAE), yet expanding applications demand rigorous noise evaluation and regulation due to varying acoustic characteristics across different sizes and configurations. This study investigates the acoustic emissions of sub-7 kg multi-rotor drones during hovering, using both curved and planar phased microphone arrays in an anechoic chamber. Five drone models (0.25 kg to 6.5 kg) were tested to analyze directional noise radiation and spectral behavior. Results show a shift from tonal to broadband-dominant noise as drone size increases, along with lower blade-passing frequencies and smoother directivity patterns in larger platforms. Notably, the heaviest model exhibited lower overall noise than a lighter one, highlighting the impact of aerodynamic design. A logarithmic-linear model incorporating disk area ratio (DAR) was proposed to predict A-weighted sound pressure levels, with strong accuracy ($R^2 > 0.95$) for broadband and overall sound pressure level (SPL). These findings contribute to drone acoustic databases and offer a practical framework for noise prediction, aiding standardization, low-noise design, and regulatory development in urban air mobility. Future work will expand to dynamic flight conditions and other configurations to further enhance model robustness.

1. INTRODUCTION

With the rapid development of the low-altitude economy (LAE), small multi-rotor drones are increasingly used in logistics, surveillance, and urban mobility [1] . As their deployment expands in urban environments, aerodynamic noise emerges as a key barrier, affecting both human well-being and public acceptance [2] . Accordingly, both the component level and full-vehicle level should be considered, as noise characteristics differ significantly between them. In addition, a standardized noise database and evaluation framework are essential to support drone development, manufacturing, and operational management.

Numerous studies have investigated the aerodynamic noise of drones, particularly from rotor systems. Some have focused on modeling and experimental validation of tonal and broadband noise generated by individual or paired rotors [3, 4] . Others have examined multi-rotor configurations—including coaxial [5, 6] and side-by-side layouts [7–9] —to understand how geometric parameters such as rotor spacing and relative phase affect acoustic performance. In addition, full-vehicle level interactions, including rotor-airframe and rotor-flow coupling effects, have been shown to play a significant role in shaping the overall acoustic behavior of small drones [10–12].

To better reflect realistic flight conditions and capture system-level acoustic effects, recent studies have conducted full-vehicle noise measurements of drones using microphone arrays in both anechoic and outdoor environments. These works typically evaluate key metrics such as

overall sound pressure level (OASPL), blade-passing frequency (BPF) harmonics, broadband noise components, and radiation directivity. Controlled indoor experiments have examined how factors such as observer position, payload, and rotor geometry affect acoustic signatures, while also addressing far-field criteria to ensure the validity of measurements [13, 14] . In contrast, outdoor studies focus on capturing noise during realistic flyover conditions and often employ 3D acoustic field reconstruction techniques [15] . Some investigations further incorporate Geographic Information Systems (GIS)to assess the large-scale environmental impact of drone operations [16] . Together, these efforts underscore the importance of spatially resolved, system-level acoustic measurements and highlight the need for standardized evaluation frameworks to support drone noise regulation and sustainable low-altitude integration.

Although existing studies have improved the understanding of drone noise and informed regulatory efforts, most measurements remain limited to one or two models with narrow variations in size or configuration. To better reflect real-world operations, testing should include larger and more capable drones, as maximum takeoff mass (MTOM) is closely linked to rotor size, configuration layout, and rotational speed—all of which directly influence acoustic performance. For instance, many FAA-approved platforms for advanced operations exceed $5\,\mathrm{kg}$, highlighting the need to study noise behavior in this practically relevant range [17] . While classification systems by EASA, FAA, and CAAC use MTOM thresholds, the category intervals are often too broad to capture meaningful acoustic trends. For example, EU Class C1 includes drones up to $0.9\,\mathrm{kg}$, while C2 extends to $4\,\mathrm{kg}$ [18, 19] . The relationship between drone mass and noise output within these ranges remains poorly understood, motivating higher-resolution measurements across MTOM levels. For untested platforms, anechoic chamber measurements provide a controlled baseline for early-stage acoustic assessment, minimizing environmental interference and supporting consistent noise modeling, design decisions, and policy development [20].

This paper presents a series of acoustic measurements conducted in the anechoic chamber of the Aerodynamics and Acoustics Facility (AAF) at the Hong Kong University of Science and Technology, focusing on typical multi-rotor drones with varying maximum takeoff mass (MTOM) and configurations. The tests were performed under hovering conditions using a curved microphone array to capture noise radiation. Drones under the $7\,\mathrm{kg}$ threshold were selected to span finer MTOM intervals, representing the majority of platforms used in industrial and logistics applications. This work aims to support the sustainable development of the low-altitude economy (LAE), which encompasses drone-based services in logistics, inspection, and urban mobility. To enable cross-platform comparison, dimensionless acoustic parameters were employed to describe noise characteristics within a unified framework. In addition, a logarithmic-linear scaling model incorporating MTOM and disk area ratio (DAR) was developed to predict A-weighted sound pressure levels with high accuracy. The resulting database enhances the understanding of drone acoustics and provides a foundation for future research, regulatory development, and environmentally responsible design.

2. METHODOLOGY

This section outlines the experimental setup for measuring the acoustic emissions of multi-rotor drones under controlled conditions. Five platforms, including both commercial and custom-built models, were selected to represent a range of takeoff weights and configurations relevant to low-altitude operations. Experiments were conducted by using a curved microphone array to capture noise during steady hovering. Measurement feasibility and reliability considerations are also discussed.

2.1 Drone platforms and configurations

Five multi-rotor drones with takeoff masses ranging from approximately $0.25\,\mathrm{kg}$ to $6.5\,\mathrm{kg}$ were selected to represent typical configurations under the $7\,\mathrm{kg}$ threshold. The set includes both commercial and custom-built quadcopters commonly used in consumer, industrial, and commercial applications. All feature a standard X-type layout with two-blade propellers, ensuring structural consistency while varying in frame size, rotor geometry, and propulsion systems. Key physical parameters—such as takeoff mass, propeller diameter, motor spacing, and vertical clearance—are summarized in Tab. 1 . Since most tested platforms are commercial products, only the two custom-built models, X 450 and ZD 680, are shown in Fig. 1.

The selection aligns with regulatory classification systems from EASA, FAA, and CAAC, which define drone categories based on weight. For example, EU categories range from $250\,\mathrm{g}$ (C0) to $4\,\mathrm{kg}$ (C2) [18, 19], FAA defines small UAS under $25\,\mathrm{kg}$ [21], and CAAC classifies drones under $7\,\mathrm{kg}$ as light [22] . This selection increases sam-

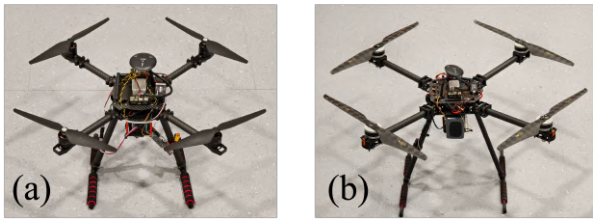

Figure 1. Photographs of the two custom-built platforms: (a) X 450 and (b) ZD 680.

pling density across MTOM levels and configurations, enabling more detailed analysis of acoustic characteristics.

Table 1. Physical parameters of the five tested multirotor drones. "Diag." denotes the diagonal motor-to-motor spacing, "Prop." indicates the propeller diameter, and "Area" refers to the area bounded by the motor layout.

Model	Mass [g]	Diag. [mm]	Prop. [mm]	Clear. [mm]	Area [mm²]
Mini 3	249	247	152	24	39950
Mavic 3	895	380	239	50	74400
X 450	1395	450	254	272	101250
ZD 680	3784	680	432	380	231200
Matrice 350	6470	895	538	239	542700

To better characterize the aerodynamic and geometric properties of the tested drones, the disk area ratio (DAR) was calculated as a dimensionless parameter reflecting the spatial efficiency of the propulsion system. It is defined as the ratio of total rotor swept area to the area enclosed by the motors:

$$\mathrm{DAR} = \frac{n \cdot \frac{\pi D_{\mathrm{prop}}^2}{4}}{A_{\mathrm{enclosed}}} \tag{1}$$

where n is the number of rotors (four in this study), D_{prop} is the propeller diameter, and A_{enclosed} is the area bounded by the motor layout just shown in Tab. 1. Related parameters, including disk loading and layout ratio—which are based on the same core variables such as takeoff mass, propeller diameter, and frame geometry—are also listed in Tab. 2 but are not further analyzed in this study. DAR was later used to develop a scaling model for A-weighted sound pressure levels.

Table 2. Derived parameters of the five tested multirotor drones.

Model	Disk area ratio (DAR)	Disk load	Layout ratio
Mini 3	1.82	10.78	0.62
Mavic 3	2.41	15.67	0.63
X 450	2.00	21.62	0.56
ZD 680	2.54	20.28	0.64
Matrice 350	1.68	22.35	0.60

2.2 Test environment and acoustic measurement setup

All experiments were conducted in the anechoic chamber room. The chamber, measuring $8.1\,\mathrm{m} \times 6.0\,\mathrm{m} \times 5.1\,\mathrm{m}$, is fully wedge-lined and provides free-field conditions above $100\,\mathrm{Hz}$. A nylon safety cage was installed to define an internal working volume of $6.8\,\mathrm{m} \times 4.8\,\mathrm{m} \times 4.0\,\mathrm{m}$, ensuring a minimum $600\,\mathrm{mm}$ clearance from all walls. A net was also placed at the bottom for failsafe protection. High-contrast ground markers were used to support visual-based positioning, especially for lightweight drones operating in GPS-denied indoor environments.

To capture radiated noise under steady hovering, a semi-circular microphone array was deployed at a $2.5\,\mathrm{m}$ radius from the chamber center. The array spanned a $120°$ vertical arc and consisted of thirteen GRAS 46BE 1/4-inch microphones, spaced at $10°$ intervals. The vertical angle of each microphone is denoted by θ, measured from the downward vertical direction ($\theta = 0°$) upward toward the drone's front axis. This angular configuration allows for directional analysis of noise radiation.The array was tilted $60°$ from the chamber's short axis, with the central microphone aligned to the drone's nominal hovering position. Each microphone was fitted with a windscreen to reduce flow-induced noise. A schematic and chamber photo are shown in Fig. 3 and Fig. 2 , including microphone locations, coordinate systems, and marker placement. Drone position and yaw were tracked by a VICON

system with eight Vero V2.2 cameras operating at 50 Hz , using reflective markers beneath each rotor and on the airframe. The system was synchronized with acoustic measurements acquired via NI cDAQ-9189 and NI-9231 modules at 50 kHz . To minimize acoustic interference, metal components of the safety cage were acoustically treated with foam.

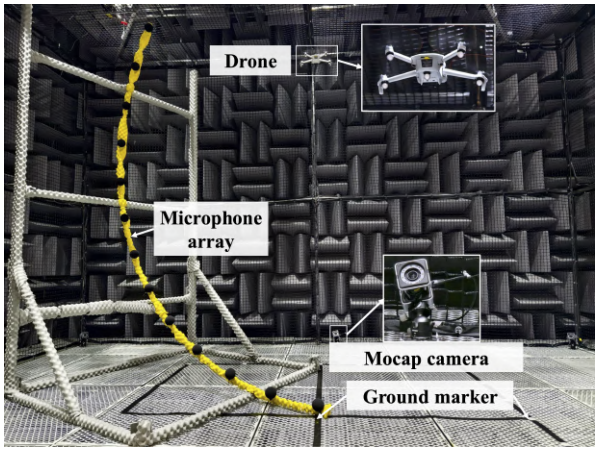

Figure 2. Experimental setup in the AAF anechoic chamber room.

2.3 Test procedure and evaluation of measurement validity and repeatability

Each drone was tested under consistent procedures to characterize its directional acoustic behavior. The drone hovered at the geometric center of the chamber, 2.5 m above the floor (Fig. 3), and was rotated about its vertical body axis (z_b) from 0° to 180° in 15° increments. At each orientation, a 20 s recording was made using synchronized systems: acoustic signals were captured at 50 kHz by the 13-microphone array, while position and yaw were tracked at 50 Hz via the VICON system. Each drone completed three full test cycles to evaluate repeatability.

Measurement validity was ensured through chamber background noise checks and array configuration validation. Ambient noise levels were maintained below 20 dB across the frequency range of interest to achieve sufficient signal-to-noise ratio. The microphone array design was evaluated against ISO 3745:2012 [23] far -field criteria. For the largest drone, Matrice 350 RTK ($L = 1.433$ m), the array radius fell slightly short of the $2L$ condition but exceeded other requirements [14], with a 13 % deviation

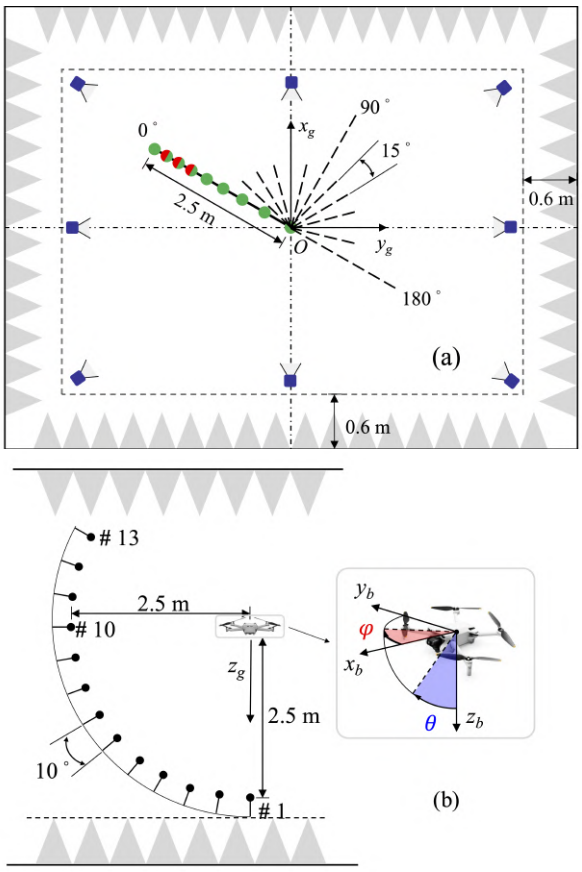

Figure 3. Schematic diagrams of the acoustic measurement setup: (a) top view showing the microphone array orientation; (b) side view including the drone body coordinate system.

deemed acceptable. All smaller drones fully met the criteria. Additionally, the influence of rotor downwash and recirculating flow was considered. Previous studies [24] indicate that such effects cause minor spectral shifts and entropy changes, but their impact on A-weighted broadband SPL remains within 2 dB , and thus does not compromise measurement reliability.

3. RESULTS AND DISCUSSIONS

This section presents the acoustic analysis of all tested multi-rotor drones during steady hovering. Each platform was incrementally rotated in yaw, and sound pressure levels were recorded at 13 microphone positions along a 120°

vertical arc. The signals were post-processed to extract A-weighted overall sound pressure levels (OASPL), narrowband SPL spectra, and directional features, including 2D directivity plots and interpolated 3D fields. The analysis focuses on identifying shared acoustic characteristics across platforms, yaw-dependent frequency behaviors, and trial-to-trial consistency. In addition, scaling relationships between A-weighted OASPL and maximum takeoff mass (MTOM) are evaluated to investigate how noise radiation evolves with platform size.

3.1 Hovering stability evaluation via motion capture

To assess the hovering stability of the tested multi-rotor drones, we analyzed the standard deviation of body center positions and yaw angles during a steady 20-second hover at $0°$ yaw, as summarized in Tab. 3. All five platforms maintained sub- $6\,\mathrm{mm}$ deviations across all spatial axes. The Matrice 350 exhibited the most stable performance, with variations under $3\,\mathrm{mm}$ and minimal yaw fluctuation ($0.77°$). In contrast, the ZD 680 showed the largest vertical ($3.42\,\mathrm{mm}$) and yaw ($1.16°$) deviations, which may be attributed to increased inertia or less refined control tuning. The Mini 3 displayed slightly larger vertical fluctuation ($5.16\,\mathrm{mm}$), likely due to its lower mass and greater susceptibility to recirculating flow , although further testing would be required to confirm this. Overall, all platforms demonstrated sufficient stability to support repeatable and reliable indoor acoustic measurements.

Table 3. Standard deviation of motion capture measurements under hovering at $0°$ yaw for each drone model (unit: mm / °).

Model	X std [mm]	Y std [mm]	Z std [mm]	Yaw std [°]
Mini 3	3.47	2.56	5.16	0.92
Mavic 3	3.13	2.61	2.69	1.06
X 450	3.65	2.96	3.71	0.93
ZD 680	5.06	3.31	3.42	1.16
Matrice 350	2.66	1.99	2.12	0.77

3.2 Acoustic characteristics analysis

Acoustic analysis was based on signals recorded at a microphone positioned at $\theta = 30°$, oriented perpendicular to the drone's forward axis. This angle was selected because the bottom-mounted microphone, affected by rotor downwash, failed to clearly capture tonal components such as the first blade-passing frequency (BPF) . The $30°$ position provided a more representative signal across platforms. Given the presence of multiple tonal peaks around BPFs due to rotor asymmetry and aerodynamic interactions, each BPF in this study is defined as a frequency band rather than a single frequency. The reported SPL values represent the A-weighted energy integrated over each corresponding band.

The A-weighted narrowband SPL spectra of the five drones under hover are shown in Fig. 4 . The Mini 3 exhibits the lowest SPL, with acoustic energy concentrated in the low-frequency region, while the Mavic 3 and X 450 display stronger tonal peaks in the mid-frequency range. The heavier ZD 680 and Matrice 350 generate higher SPL across a broader spectral range (1–6 kHz), consistent with their greater thrust demand and more complex aerodynamic interactions. As maximum takeoff mass (MTOM) increases, the spectra become increasingly broadband, with relatively diminished tonal peaks, broader spectral ridges, and lower blade-passing frequencies. These trends suggest more distributed and diffuse acoustic signatures in larger drones. Design asymmetries such as staggered rotor heights or center-of-mass offsets may further suppress tonal coherence and reduce directional radiation. All spectra remain well above the background noise floor, confirming measurement fidelity.

Fig. 5 illustrates the relationship between maximum takeoff mass (MTOM) and A-weighted SPL across multiple frequency bands, including 1BPF, 2BPF, 3BPF, broadband, and overall. In general, SPL increases with MTOM across all bands, with the most pronounced growth observed at 1BPF and 2BPF, reflecting stronger tonal components in heavier platforms. Broadband and higher-order components exhibit a more gradual increase, suggesting a more distributed energy spectrum. An exception to this trend is the Matrice 350, which, despite its higher MTOM compared to the ZD 680, exhibits slightly lower A-weighted SPL across all metrics—likely due to noise reduction measures such as optimized propeller geometry and a more aerodynamically refined fuselage.

The observed trends in A-weighted SPL are further visualized in Fig. 6 , which presents 3D directivity maps

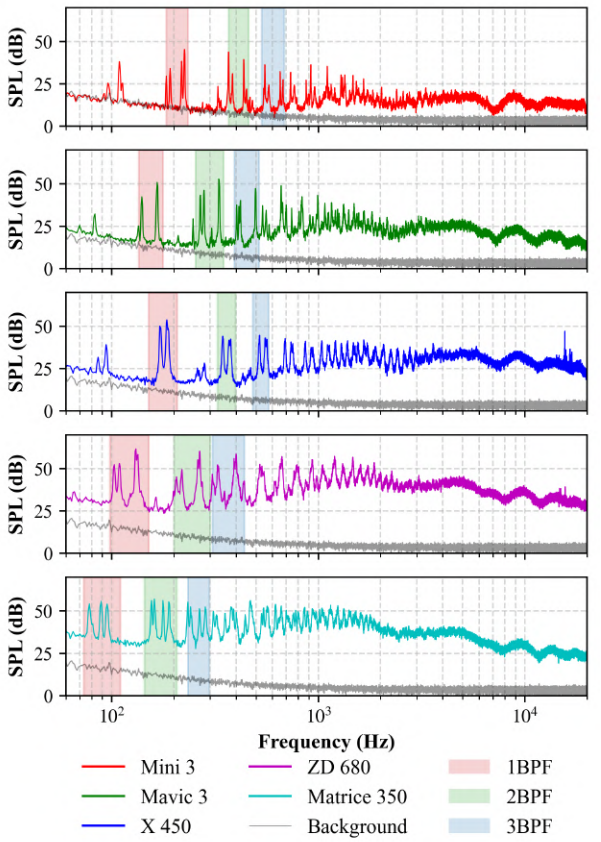

Figure 4. Comparison of SPL spectra measured at the $\theta = 30°$ microphone for all drones under hover condition. The shaded regions represent the respective BPF bands.

of A-weighted OASPL for all five platforms. The X 450 exhibits a fragmented and irregular radiation pattern, likely resulting from structural resonance and less coherent rotor interaction. In contrast, the ZD 680 shows a well-defined downward lobe with elevated levels, reflecting high rotor loading and more focused downward radiation. The Matrice 350, despite its larger size, displays a smooth and symmetric pattern with noticeably lower peak levels, consistent with its overall reduced SPL observed in Fig. 5 . These results suggest that aerodynamic refinements—such as smoother fuselage contours and optimized propeller design—can effectively mitigate directional noise radiation even in larger multirotor systems.

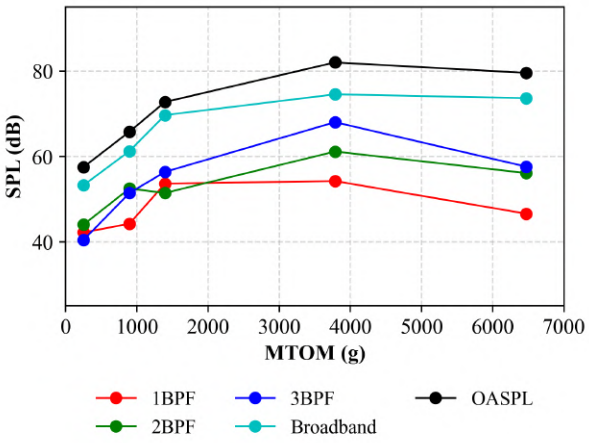

Figure 5. Variation of A-weighted Sound Pressure Level (SPL) with Maximum Takeoff Mass (MTOM) across different frequency bands: 1BPF, 2BPF, 3BPF, Broadband, and OASPL.

3.3 Model fitting and data analysis

To characterize how A-weighted SPL varies with platform mass and configuration, we adopted a logarithmic-linear model incorporating disk area ratio (DAR). This model provides a more accurate representation of the noise emissions across different frequencies using the following equation(2):

$$\mathrm{SPL} = a \cdot \ln(\mathrm{MTOM}) + b \cdot \mathrm{MTOM} + c \cdot \mathrm{DAR} + d \quad (2)$$

Due to the higher variability and less consistent results at blade-passing frequencies (1BPF–3BPF), and given that OASPL is easier to manage and unify in regulatory contexts, we focused our analysis on Broadband SPL and OASPL. The fitted parameters for all frequency bands are summarized in Tab. 4.

4. CONCLUSION

This study examined the acoustic characteristics of multirotor drones with varying maximum takeoff masses and configurations under controlled hovering conditions. Results show that A-weighted sound pressure levels (SPL) scale with drone mass. To quantify the influence of mass and geometry, a logarithmic-linear model incorporating disk area ratio (DAR) was developed to predict A-weighted SPL across frequency bands, achieving strong

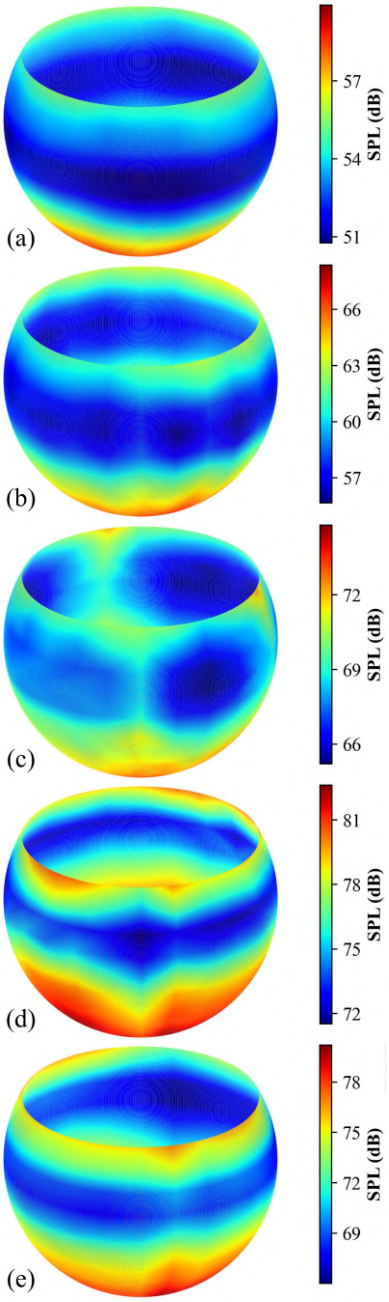

Figure 6. A-weighted OASPL directivity maps from a 45° view: (a) Mini 3, (b) Mavic 3, (c) X 450, (d) ZD 680, (e) Matrice 350.

accuracy for broadband and overall levels. These findings contribute a standardized acoustic dataset and modeling approach that support low-noise drone design, regulatory development, and integration into urban air mobility. Future work will extend to dynamic flight conditions, transitional states, and a broader range of configurations to improve the generalizability of the predictive model and facilitate sustainable development of the low-altitude economy.

ABSTRACT

The potential of distributed electric propulsion to mitigate noise environmental impact has been increasingly explored for UAV and UAM applications. However, when rotors are placed in close proximity, strong aerodynamic interactions and complex acoustic phenomena are induced. Phase synchronization has been proposed as a tonal noise mitigation strategy. Significant reductions in tonal levels have been reported under various configurations, though the extent and nature of such reductions remain debated. Previous assessments have relied on sparse sound pressure measurements, potentially misrepresenting global noise attenuation due to altered directivity. To address this experimental limitation, high-fidelity simulations are carried out for a multi-propeller configuration, focusing on the effects of phase synchronization. The influence of a 30°-phase offset between three co-rotating six-blade rotors is evaluated against an in-phase configuration. A spherical microphone array was used to determine the spatial directivity and total radiated sound power. Results show that phase-angle differences substantially redistribute the acoustic energy toward different spatial locations. Nevertheless, it also impacts the global noise emission, mitigating the sound power level of the opposite-phase configuration by 7.47 dB in acoustic power for the first BPF harmonic and 4.79 dB for the second.

1. INTRODUCTION

The emergence of urban air mobility (UAM) and small-scale unmanned aerial vehicles (UAVs) has spurred interest in novel propulsion systems that reduce environmental impact while improving efficiency. Distributed electric propulsion (DEP) systems, comprising arrays of electrically driven propellers, are promising for enhancing aerodynamic performance and lowering pollutant emissions [1]. When propellers are positioned nearby, as is common in DEP systems, their interactions give rise to complex aerodynamic and acoustic phenomena [2]. These interactions not only affect the aerodynamic loads, leading to increased tonal and broadband noise [3], but also alter the spatial directivity of the blade passing frequency (BPF) harmonics. One proposed method for mitigating such noise is the synchronization of adjacent rotors, typically by imposing a constant phase angle between them. Recently, several studies have investigated the potential of phase synchronization to reduce tonal noise, particularly in hover:

- Pascioni et al. [4] found a 6 dB reduction at the BPF for a 3-bladed, 16-inch propeller at 5100 rpm.
- Shao et al. [5] reported 1–11 dB reductions using 2-bladed, 12-inch propellers at 4000 rpm.
- Guan et al. [6] observed 11–30 dB reductions under hover and low-speed flight (advance ratio 0–0.1) using 2-bladed, 12.5-inch rotors at 6000 rpm.

In forward-flight conditions:

- Turhan et al. [7] measured a 24 dB reduction at the first BPF harmonic with a 90° phase offset between

2-bladed propellers.

- De Paola et al. [8] reported a 5 dB reduction using 4-bladed rotors.

These studies suggest that phase synchronization can suppress tonal emissions without compromising thrust, and they often attribute this effect to acoustic interference between the propellers. In contrast to aerodynamic installation effects, which depend on unsteady flow phenomena, acoustic interference stems from phase-coherent sound fields overlapping and interfering destructively or constructively in the far field [9]. However, reported noise reductions vary widely, from 1 dB up to 30 dB for a single-observation microphone. A key limitation of many studies is that only a few microphones are deployed to capture sound pressure levels (SPL) at discrete positions due to limitations in space, time, and cost. Since phase synchronization drastically alters the directivity of tonal components, local SPL measurements may misleadingly suggest strong attenuation, even though sound is merely redirected elsewhere in space. Without capturing the full spatial radiation pattern, it's unclear whether noise is truly reduced or just redistributed. To address this ambiguity, the present study uses high-fidelity numerical simulations to compute the full 3D directivity patterns of DEP systems and to determine the sound power level (SWL), which integrates radiation over all directions. Unlike isolated SPL measurements, SWL offers a global, physically meaningful quantification of noise reduction. This work, therefore, aims to re-evaluate the noise mitigation claims found in the literature by examining the extent to which phase synchronization alters both the directionality and total radiated acoustic power.

2. MATERIALS AND METHODS

2.1 Computational Setup

The simulations replicate the TUD-XPROP-S propeller setup from de Vries et al. [10], involving three six-blade rotors (diameter $D = 0.2032$ m) spaced along the Y-axis, as depicted in Figure 1a. The present work focuses exclusively on two specific phase-synchronized distributed-propulsion configurations, namely with a relative phase angle $\Delta\phi = 0°$ and $\Delta\phi = 30°$, corresponding to the in-phase and opposite-phase rotation, respectively. The simulations analyzed here are the same as those originally introduced in [11] and further extended in [12], to which the reader is referred for additional details on the numerical setup and methodology. The propeller geometry involves a pitch angle of 30° at 70% span and root chord of 16.3 mm, and it was provided by TU Delft. The system rotates anticlockwise with an inflow velocity of $V_\infty = 30$ m/s, and advance ratio $J = 0.8$. The flow around propellers is simulated using SIMULIA PowerFLOW® (version 6-2021-R2), a commercial CFD that employs the Lattice-Boltzmann (LB) method. It solves the LB equation for the particle distribution function $f(\boldsymbol{x}, \boldsymbol{v}, t)$, describing the probability density of particles with velocity $\boldsymbol{v}$ at location $\boldsymbol{x}$ and time t. The simulation uses a D3Q19

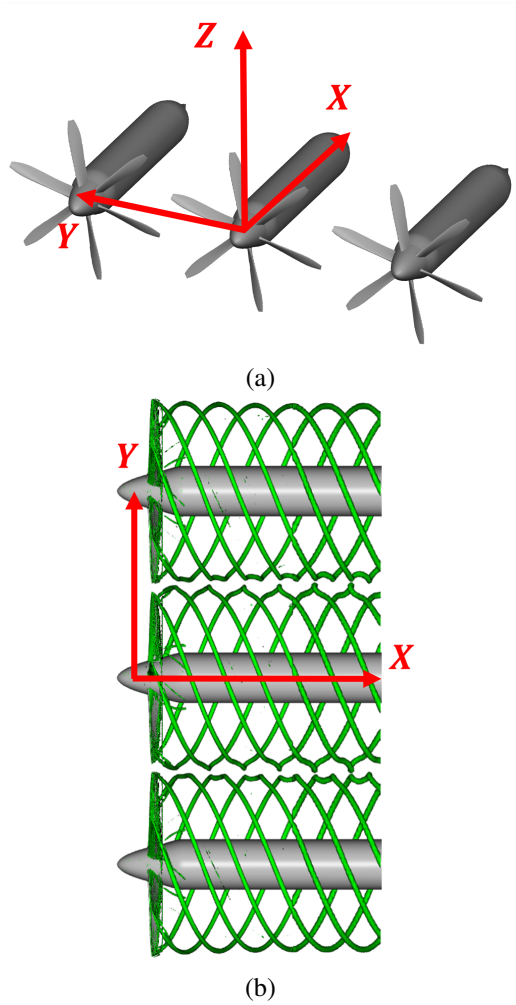

Figure 1: (a) View of the simulated setup with three distributed propellers and the GRS. (b) Visualization of vortex structures with $\lambda 2$ method for the in-phase configuration (b).

stencil for 19 discrete velocity directions and a regularized Bhatnagar-Gross-Krook collision operator. The LB equations are solved on a Cartesian grid with cubic volumetric elements (voxels) and solid objects discretized with planar surface elements (surfels). The solver incorporates a very large eddy simulation (VLES) approach, utilizing a k-ϵ turbulence model. A pressure-gradient extended wall model approximates the no-slip boundary condition. The grid contains approximately 225.5 million voxels, ensuring $y^+ \approx 15$ over the blade surfaces. CPU costs reach roughly 112,000 hours per case. The flow solution can be visualized *via* λ_2 method in Figure 1b.

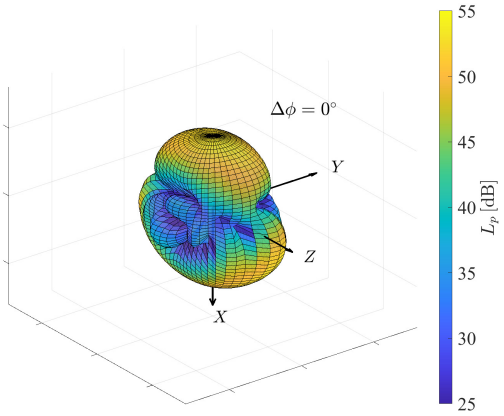
2.2 Far-Field Noise Computation

The far-field noise formulation used in this work is described and validated in [12]. It exploits the axial and tangential forces computed on the propeller disks as dipole sources radiating sound to the far-field. These forces include the aerodynamic interactions caused by the propellers' proximity. The SPL of the BPF harmonic tones is determined from the measured amplitudes ($p_{\mathrm{BPF_n}}$) using the following equation:

$$L_p(f) = 10\log_{10}\frac{0.5p^2_{\mathrm{BPF_n}}}{p^2_{ref}}, \tag{1}$$

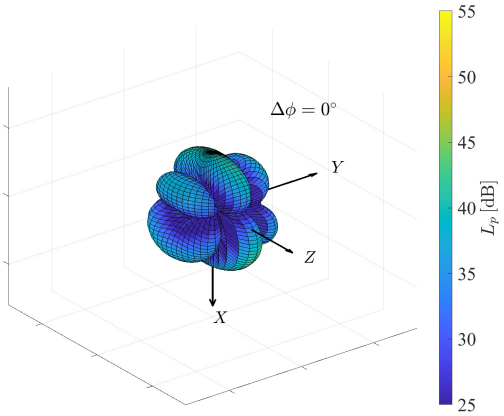
which results in the output in acoustic decibels. In this equation, $p_{ref} = 20\,\mu\mathrm{Pa}$ is the reference pressure, while the subscript n indicated the chosen BPF harmonic. For the calculation of the SWL, a spherical microphone array consisting of 2500 microphones is arranged around the propeller at a distance of $100D$ from the global reference system (GRS) origin, ensuring a comprehensive capture of the sound field in all directions. It was confirmed that increasing the number of microphones and the distance from the origin did not affect the SWL. The root mean square (RMS) pressure was computed at all microphone locations. The RMS pressure squared, p^2_{rms}, is the average of the square of the pressure levels at the selected BPF harmonic over all microphone positions. The emitted sound power is then calculated as:

$$\mathrm{W} = p^2_{\mathrm{rms}} A_m / \rho_\infty\, c_\infty, \tag{2}$$



where ρ_∞ is the air density, c_∞ is the speed of sound in air, and the area $A_m = 4\pi R^2_m$ represents the surface area of the sphere formed by the microphone array, with $R_m = 100D$ being the distance from the source to each microphone. Finally, the SWL is computed as:

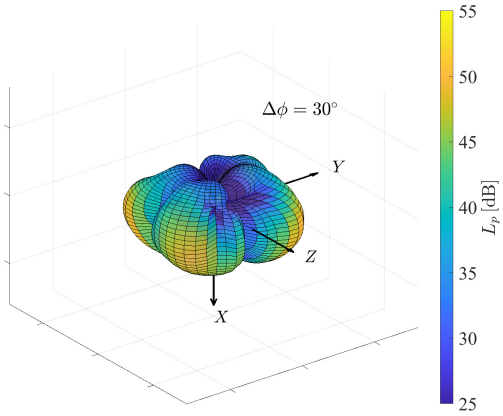
$$L_w = 10\log_{10}\left(\frac{\mathrm{W}}{\mathrm{W_{ref}}}\right), \tag{3}$$



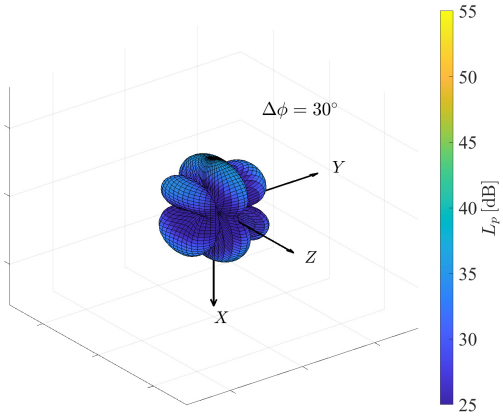
where $\mathrm{W_{ref}} = 1\times10^{-12}\,\mathrm{W}$ is the reference sound power. This formula yields the SWL in decibels, which quantifies the total acoustic power radiated by the source in all directions.

3. RESULTS

The spatial distribution of sound emissions from a system of three rotors is examined. This distribution is determined by the aerodynamic interaction resulting from the proximity of adjacent propellers, as well as by the interference among the acoustic fields generated by each of the three propellers. In Figure 2a, the $\Delta\phi = 0°$ configuration at the first BPF harmonic is analyzed, and the spatial distribution of the SPL around the propellers' GRS is presented. The SPL mostly contributes around the XY plane and reaches its maximum along the X-axis, with values around $52.7\,\mathrm{dB}$. Along the Y-axis, a lobed pattern is observed, with reduced amplitudes not exceeding $19\,\mathrm{dB}$. In contrast, as shown in Figure 3a for the $\Delta\phi = 30°$ configuration, the directivity pattern of the first BPF harmonic is significantly altered, particularly along the X and Z directions. For instance, if the SPL is measured by a microphone placed along the X-axis, at a distance of $100D$ from the GRS, a substantial reduction of approximately $43\,\mathrm{dB}$ is observed. While this reduction can be attributed to the effect of phase synchronization, an inspection of the directivity in Figure 3a reveals that certain regions still exhibit emissions reaching about $48\,\mathrm{dB}$; however, these regions are located differently compared to those observed in the $\Delta\phi = 0°$ case. For this reason, a less ambiguous method for evaluating the effect of noise reduction caused by the phase angle is employed by computing the SWL, as explained in Section 2.2, and by interpreting results in terms of acoustic power levels expressed in decibels. For the first BPF harmonic, values of $L_w = 85.71\,\mathrm{dB}$ and $L_w = 78.24\,\mathrm{dB}$ are obtained for the in-phase and opposite-phase cases, respectively. This corresponds to a reduction of $\Delta L_w = 7.47\,\mathrm{dB}$ in acoustic power due to the phase angle effect. Turning to the second BPF harmonics, these are shown in Figure 2b for $\Delta\phi = 0°$ and in Figure 3b for $\Delta\phi = 30°$. Unlike the first harmonic, the tonal directivity is found to be very similar and is characterized by a lobed spatial distribution that peaks along the X-axis in both cases. When the SWL is computed, values



(a) 1st BPF harmonic.



(b) 2nd BPF harmonic.

Figure 2: Three-dimensional L_p directivity of the BPF harmonic tones for the $\Delta\phi = 0°$ configuation.

(a) 1st BPF harmonic.

(b) 2nd BPF harmonic.

Figure 3: Three-dimensional L_p directivity of the BPF harmonic tones for the $\Delta\phi = 30°$ configuration.

of $L_w = 73.76\,\mathrm{dB}$ and $L_w = 68.97\,\mathrm{dB}$ are obtained for the two configurations, respectively. This indicates a reduction of $\Delta L_w = 4.79\,\mathrm{dB}$ in acoustic power due to the phase angle for the second BPF harmonic.

4. CONCLUSIONS

In recent years, significant tonal noise attenuation has been reported in several experimental studies on phase synchronization in DEP systems. However, these conclusions have often been based on discrete SPL measurements taken at isolated locations, which may not fully capture the three-dimensional nature of acoustic radiation. As a result, the spatial redirection of tonal components may have been misinterpreted as global attenuation, raising questions about the generalizability of the findings. To address this limitation, a methodology has been employed in the present study, relying on high-fidelity numerical simulations already available in the literature [12], combined with a dipole-based far-field noise formulation and a

dense spherical microphone array. Through this approach, the spatially integrated SWL can be computed, providing a global and physically meaningful metric for quantifying tonal acoustic emissions. A three-propeller DEP configuration has been considered in the analysis, with a comparison made between in-phase ($\Delta\phi = 0°$) and opposite-phase ($\Delta\phi = 30°$) operation under forward-flight conditions. It has been shown that in-phase rotation produces highly directional radiation patterns at the first BPF harmonic, particularly along the X and Z axes, whereas the opposite-phase configuration yields a markedly different spatial distribution, with peak emissions occurring elsewhere. This suggests that tonal energy is drastically redistributed by phase synchronization, resulting in either mitigation or amplification depending on the spatial location considered. Nevertheless, notable reductions in SWL have been observed in the $\Delta\phi = 30°$ case, with decreases of $\Delta L_w = 7.47\,\mathrm{dB}$ in acoustic power for the first BPF harmonic and $\Delta L_w = 4.79\,\mathrm{dB}$ for the second. In future studies, a broader range of phase angles, rotor counts, and operating conditions should be explored, and hybrid strategies that combine synchronization with aerodynamic optimization should be considered for more effective and scalable noise control.

5. ACKNOWLEDGMENTS

This research was carried out within the framework of the H2020 Research and Innovation Actions ENODISE (ENabling Optimized DISruptivE airframe-propulsion integration concepts) and eVTOLUTION (eVTOL Multi-fidelity Hybrid Design and Optimization for Low Noise and High Aerodynamic Performance), both funded by the European Commission under Grant Agreement numbers 860103 and 101138209, respectively. Furthermore, the authors would like to acknowledge Prof. Daniele Ragni and Prof. Damiano Casalino from TU Delft (The Netherlands) and Prof. Francesco Avallone (Politecnico di Torino, Italy) for the inspiring discussions about aeroacoustics and computational fluid mechanics.

ABSTRACT

In this paper, the effects of boundary layer ingestion on the noise emitted from an academic ducted propeller are evaluated using lattice Boltzmann simulations and wind tunnel experiments. The boundary layer is generated by an aggressive S-plate placed upstream of the propeller and its impact is assessed by comparison with an isolated ducted propeller configuration. Three operating conditions are studied, which correspond to a free-stream velocity of 32 m/s and rotational speeds of 6000, 8000, and 11,000 rpm. Aerodynamic results are compared between simulations and experiments and show a good agreement. They highlight the increase in flow asymmetry and turbulence ingested by the ducted propeller in the presence of the S-plate. Direct acoustic results are extracted from the simulations at the position of the two experimental microphone arrays and compared against experiments in terms of tonal and broadband contributions. Similar trends are observed despite some quantitative discrepancies. In the presence of the S-plate, the stronger flow distortion is responsible for an increase of tonal noise at the blade passing frequencies, while the higher turbulence intensity generates increased broadband noise levels.

1. INTRODUCTION

In order to reduce aircraft fuel consumption, alternative propulsion systems are investigated, such as open fan [1], distributed electric propulsion [2], or boundary layer ingestion (BLI) [3] architectures. The present paper focuses on the latter configuration, which has been the subject of several concepts of aircraft in recent years [3–5].

The principle of BLI is to minimize the net drag force of the airframe-propulsion arrangement by ingesting and re-energizing the airframe wake through the propulsion system [3]. Some concepts have already shown promising results in terms of fuel savings [5], but they also highlight challenges in terms of noise emissions. In particular, the engines ingest an incoming flow with high turbulence intensity and strong azimuthal mean flow distortion. These characteristics are expected to affect both the tonal and broadband components of the noise emitted by the engines [6, 7].

The present study aims to understand the main mechanisms of noise emission in a BLI configuration by focusing on an academic setup composed of a ducted propeller and a S-plate, as investigated in the European Union's Horizon 2020 ENODISE project (`https://cordis.europa.eu/project/id/860103`). Numerical simulations based on the lattice Boltzmann method (LBM) and wind tunnel experiments are conducted at different operating conditions on this so-called "A2-ducted" configuration. A large database has been generated and is available on Zenodo (`https://doi.org/10.5281/zenodo.14041712`). In this paper, we focus only on a few illustrative results.

The configuration and experimental setup are first described in Sec. 2, before detailing the numerical methodology in Sec. 3. Some aerodynamic results are then pre-

sented in Sec. 4, followed by some acoustic results in Sec. 5. Finally, conclusions are drawn in Sec. 6.

2. CONFIGURATION AND EXPERIMENTAL SETUP

The configuration studied in this paper is composed of a ducted propeller which can be placed above an S-plate to investigate the effects of boundary layer ingestion. The setup, tested in the aeroacoustic wind tunnel facility at the University of Bristol [8], is briefly described below (see the paper of Ahmed *et al.* [9] for a complete description).

The propeller is composed of three blades based on X22A NACA23012 profiles and has a diameter D of 0.254 m. It is placed inside a 0.175 m long duct with inner and outer diameters of 0.255 m and 0.279 m respectively, leaving a tip clearance of 0.5 mm. The position of the propeller inside the duct is such that the distance x_{LE} from the tip leading edge to the duct inlet plane equals $0.0627D$. Three struts are positioned downstream of the propeller to maintain the assembly. Other tip clearance and propeller position values have been tested in the experiments but they are not detailed in this paper. In installed configurations, an S-plate with a total length of 1.69 m and a total width of 1 m is added. It is characterized by an height variation of 0.2 m over a length of 1 m, with a maximum local curvature of 75%. The S-plate is placed in direct continuation of the bottom part of the wind tunnel nozzle. The ducted propeller is located 0.8 m downstream of the nozzle exit plane and touches the plate. As a result, the propeller axis is shifted downwards from the nozzle axis by 0.3 m. The setup in the presence of the S-plate is illustrated in Fig. 1.

In this paper, only one wind tunnel velocity U_∞ of 32 m/s and three rotation speeds N of 6000, 8000 and 11,000 rpm are investigated, but other conditions have been tested experimentally. The three studied regimes are characterized by a tip Mach number M_{tip} of 0.22, 0.33 and 0.44, an advance ratio J of 1.26, 0.94 and 0.69, and a blade passing frequency f_{BPF} of 300, 400 and 550 Hz respectively. These conditions are summarized in Tab. 1.

Many measurements are included in the setup. Pressure taps and microphones are incorporated in the S-plate and hotwire measurements at different axial positions allow an assessment of the flow field development. Regarding acoustics, two farfield microphone arcs are used. One is placed along the plane of the plate (top arc) while the other is in the transverse direction (side arc), as shown in Fig. 1. One microphone is put every 5 degrees but the

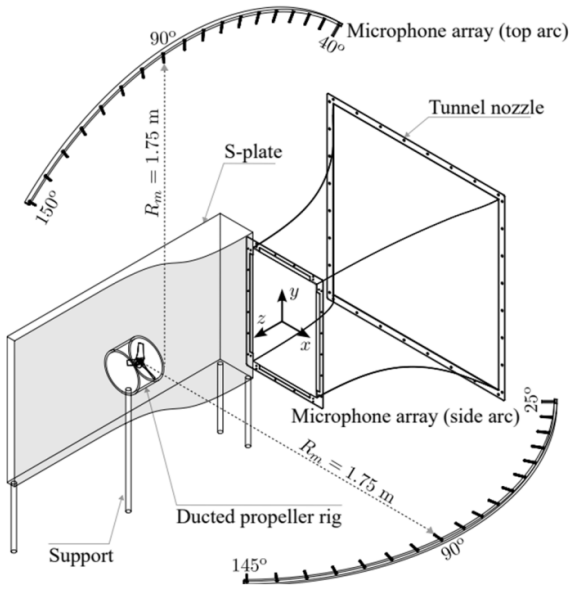

Figure 1. Experimental setup in the presence of the S-plate.

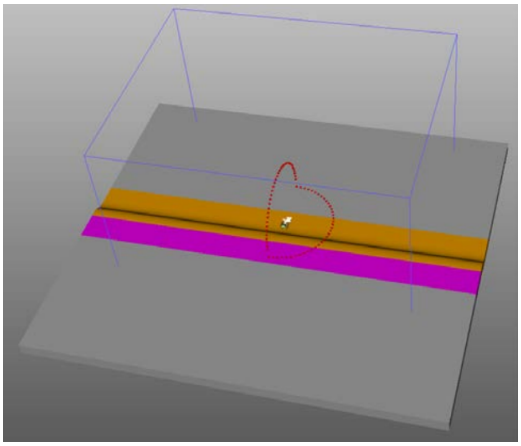
Table 1. Operating conditions investigated in this paper.

U_∞ (m/s)	N (rpm)	M_{tip}	J	f_{BPF} (Hz)
32	6000	0.22	1.26	300
32	8000	0.33	0.94	400
32	11,000	0.44	0.69	550

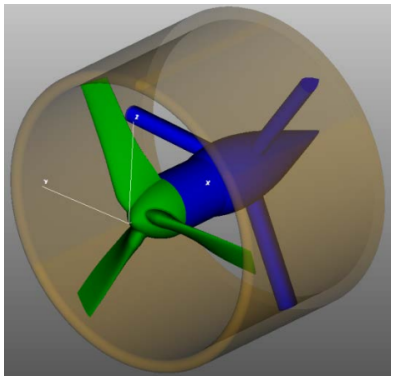
polar range of the two arcs differ because of installation reasons. The top arc goes from 40 to 150 degrees while the side arc covers the 25-145 degrees range.

3. NUMERICAL METHODOLOGY



In addition to the experiments, numerical simulations based on the lattice Boltzmann method are performed with the *ProLB* solver (`http://www.prolb-cfd.com/`) which is developed by a French consortium composed of universities, research institutes, and industries. The hybrid recursive regularized Bhatnagar-Gross-Krook (HRR-BGK) collision model [10] is used and the lattice is composed of 19 velocities (D3Q19 lattice). The shear-improved Smagorinsky model of Lévêque *et al.* [11] is chosen for turbulence modeling, while the transfer of in-

formation from rotating to fixed parts is managed by an arbitrary Lagrangian-Eulerian approach.



Only part of the setup is included in the simulations for limitation of the computational cost. The isolated cases are thus only composed of the ducted propeller and do not include the wind tunnel nozzle nor the propeller support. The propeller is placed at the center of a cubic fluid domain of size 10 m x 10 m x 10 m. Outlet pressure conditions (with $p_\infty = 101325$ Pa) are prescribed at all external fluid boundaries, except on the one that face the duct inlet where an inlet velocity condition (with $U_\infty = 32$ m/s) is imposed. In order to avoid reflections, absorbing regions are also added close to these external boundaries. Finally, wall boundary conditions (with the use of a wall function) are applied on all solid surfaces. The setup of installed cases slightly differs because it additionally accounts for the S-plate which is assumed to be infinite along its width. The domain is therefore no longer cubic with the replacement of one lateral fluid boundary by the plate. The position of the upstream fluid boundary face is also adjusted to account for the plate length. Note that in order to get a correct boundary layer development over the plate, an artificial plate with a 2 m length is added upstream of the real plate. The first part (1 m) is considered as a frictionless wall while the second part (1 m) is considered as a real wall. A view of the setup defined in installed configurations is given in Fig. 2.

The meshes are done such that the region with the smallest cell size of $\Delta x = 0.1$ mm encompasses the propeller blades, which leaves the place for 5 cells in the radial direction in the tip gap area. The maximum cell size up to the farfield microphones is set to 6.4 mm in order to have least 10 points per wavelength associated to $10 f_{\mathrm{BPF}}$ in the most restrictive case (highest rotation speed), thus allowing for direct noise evaluation. In the installed setup, the plate is added with a prescribed cell size of 0.2 mm in its vicinity. As a result, the isolated setup comprises 500 million nodes and 125 million fine-equivalent nodes (*i.e.* the number of nodes effectively updated at each time step) while the installed setup totalizes 884 million nodes and 330 million fine-equivalent nodes.

The smallest time step is of 168.35 ms, making one full rotation to be described by 59,400, 44,550 and 32,400 iterations at 6000 rpm, 8000 rpm and 11,000 rpm respectively. In all cases, 20 propeller rotations are computed to get converged statistics. The isolated simulations are launched on 1056 processors and last between 60 and 100 h depending on the case, while the installed ones use 2112 processors and last between 100 and 120 h and 100 h. The 11,000 rpm case in installed setup failed to converged, probably because of the appearance of too high local velocities, hardly reachable with such an athermal version of the LBM.

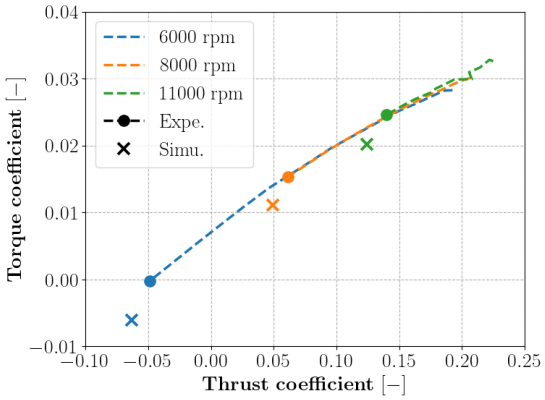
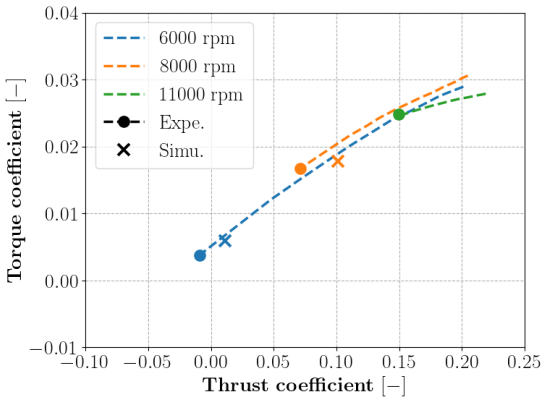
4. AERODYNAMIC RESULTS



Some aerodynamic results are given in this section. The performance map is given for all engine rotation speeds but the flow profiles are only illustrated on the intermediate case ($N = 8000$ rpm) for conciseness, noting that

similar behavior is obtained at other regimes.



We first focus on aerodynamic performance by plotting in Fig. 3 the thrust and drag coefficients obtained in the experiments and in the simulations (averaged value on the last ten rotations). Lines are drawn for experimental results where the wind tunnel speed is varied from 8 m/s to 32 m/s. The points highlight the 32 m/s condition which is the same as the one used in the simulations. For isolated ducted propeller, we observe slightly different operating conditions between experiments and simulations, with an underestimation of both thrust and drag coefficients at all rotation speeds. The tendency is reversed for the installed ducted propeller at 6000 rpm and 8000 rpm where these coefficients are overestimated in the numerical results (recalling that there is no simulation result for the 11,000 rpm case). As a consequence, the effect of BLI on aerodynamic performance (thrust and torque increase) is more marked in the simulations than in the experiments. These observations should be kept in mind when comparing absolute levels between experiments and simulations in the following.

To get an overview of the flow field topology, simulation contour maps of the axial velocity averaged over the last rotation are given in Fig. 4 for both setup at 8000 rpm. In the isolated configuration, the flow is symmetric and we can notice the potential effect of the duct in the vicinity of the inlet plane, as well as the wakes that develop past the hub and duct ends. In the installed case, we clearly see the development of the boundary layer over the plate and its impact with the propeller around $x = 0$ m. The velocity field inside the duct is no longer symmetric as are the duct end wakes. It is interesting to note that the averaged flow velocity ingested by the propeller is slightly lower in the BLI configuration.

In order to provide more insights into the flow field ingested by the propeller, mean and root mean squared (RMS) velocity profiles are extracted at $x = -0.02$ m (just upstream of the inlet plane) and are compared against experiments in Figs. 5 and 6 respectively. We observe a good agreement in both setups in terms of mean flow velocity. In particular, the lobes due to the hub and shroud potential effect are recovered in the isolated case, and the boundary layer development is correctly reproduced in the installed configuration. This result highlights the asymmetry of the mean flow in the presence of the plate. Regarding the RMS profiles, the agreement between simulations and experiments is less good in terms of absolute values, probably because of a small background residual turbulent level in the experiments, but the trends are correctly reproduced. We indeed observe a strong increase of the turbulent levels ingested by the ducted propeller in the installed configurations, especially in the bottom part of the duct.

(b) Installed ducted propeller

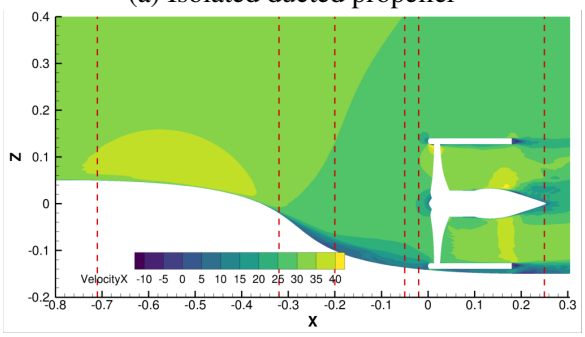

Figure 3. Thrust and drag coefficients from experiments and simulations. Experimental lines show the evolution for different wind tunnel velocities ($U_\infty = 8 - 32$ m/s), with the dots corresponding to the $U_\infty = 32$ m/s condition.

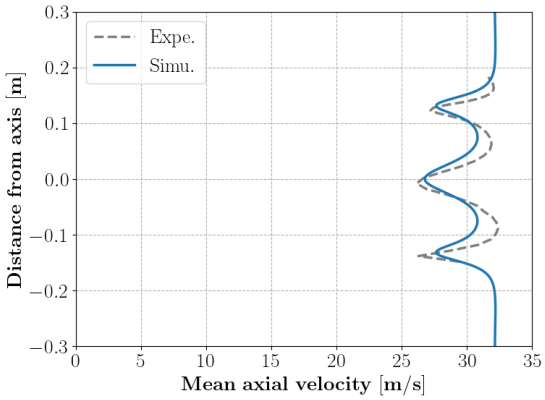
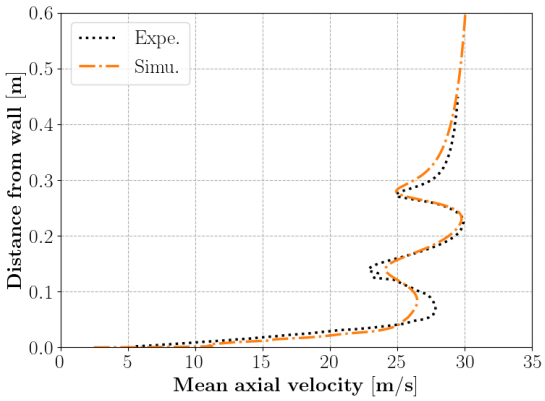
5. ACOUSTIC RESULTS

The main acoustic results are now provided in this section, by first focusing on the broadband noise and then considering the tonal noise.



(a) Isolated ducted propeller



(b) Installed ducted propeller

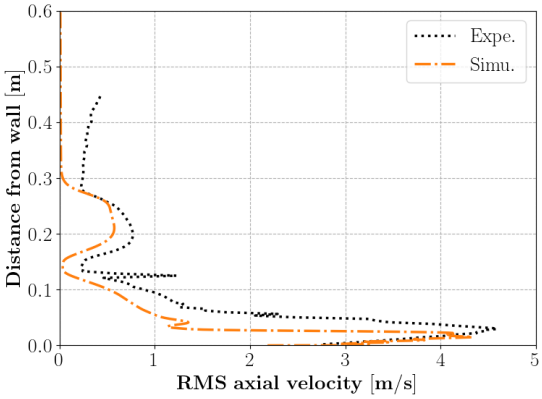
(a) Isolated ducted propeller



(b) Installed ducted propeller

Figure 5. Mean axial velocity profiles extracted at $x = -0.02$ m from experiments and simulations (case $N = 8000$ rpm).

In order to assess broadband noise, power spectral densities (PSDs) are computed from experimental and numerical time series recorded at the microphones/probes. The time series are first filtered by removing the blade passing phase average in order to remove the tonal component. In the simulations, the PSDs are computed from the last ten rotation signals using the Welch's method with 10 blocks and 50% overlapping. In the experiments, around 30 s of signal (equivalent to $\sim$ 3000 to $\sim$ 6000 rotations depending on the speed) is recorded, thus giving a very small frequency step compared to the numerical one. However, no top tour was included in the setup, which makes the phase average removing quite inefficient. In order to compare broadband noise with a minimal pollution by tonal peaks, only the last ten rotations from experimental measurements are also kept for experimental PSD computations, using again the Welch's method with 10 blocks and 50% overlapping. The tonal component is indeed incorrectly captured in these 10 last rotations because of the engine speed fluctuations, making the tonal contribution much more attenuated. The results for one representative microphone, the one at 90 deg of the side arc (along the propeller plane, see Fig. 1), are given for both setups and for the three rotation speeds in Fig. 7. The low frequencies (lower than $0.5 f_{\mathrm{BPF}}$) are not reliable as there are strong discrepancies between numerical and experimental results, probably because of installation effects in the experiments and/or short statistics in the simulations. In the mid-frequency range (between $0.5 f_{\mathrm{BPF}}$ and 1.5 kHz), the agreement between simulations and experiments is correct, which allows driving some conclu-

(b) Installed ducted propeller

Figure 6. RMS axial velocity profiles extracted at $x = -0.02$ m from experiments and simulations (case $N = 8000$ rpm).

sions on the effects of BLI. The levels in the installed configurations are indeed much stronger than in the isolated setup, with 10 to 15 dB increase in average. This increase is probably due to the interaction of incoming turbulence with the rotating blades (rotor leading edge noise), which is to be added to the two other main expected broadband noise sources *i.e.* rotor self noise (trailing edge noise) and wakes/struts interaction noise. Above 1.5 kHz, there is a strong mismatch between numerical and experimental levels for the isolated configurations only. Parametric studies performed experimentally (not shown in this paper for conciseness) have shown that this increase is caused by the tip gap noise, a mechanism that is badly captured in the simulations with only 5 points along the radial extent of the tip gap. This noise mechanism seems to be predominant at high frequencies in the isolated setup only. Indeed, in the installed setup, the agreement between experiments and simulations is correct in this frequency range, thus indicating the predominance of the other acoustic sources mentioned above.

The focus is now put on the tonal noise results. The tonal noise is extracted from time signals recorded at the microphones/probes by doing the blade passing phase average over the whole available signals (*i.e.* the last ten rotations in the simulations, and the whole 30 s in the experiments). The directivities of the overall sound pressure level (OASPL) obtained by integrating the contribution from f_{BPF} to $6f_{\mathrm{BPF}}$ are given in Fig. 8. We can observe significant differences in terms of absolute levels between experiments and simulations, with no clear trend. The OASPL is indeed globally overestimated in the simulations at 6000 rpm and 11,000 rpm, while it is underestimated at 8000 rpm. Still, the relative effect of BLI is coherent between measurements and computations, with an average increase of the OASPL by about 10 dB at 6000 rpm and 8000 rpm. There is no simulation for the installed case at 11,000 rpm, but the penalty induced by BLI found experimentally seems to be slightly lower at this condition. This tonal noise increase is to be mainly caused by the propeller unsteady loadings due to the asymmetric flow in the installed configuration (distortion/rotor interaction noise). The other contributors to tonal noise *i.e.* the propeller steady loading and thickness noise and the wakes/struts interaction noise might also be altered by the boundary layer ingestion.

6. CONCLUSION

The effects of boundary layer ingestion are investigated in this paper on an academic setup composed of a ducted propeller that can be placed over an aggressive S-plate. Experiments have been made in the wind tunnel of the University of Bristol and numerical simulations have been performed using the *ProLB* solver based on the lattice Boltzmann method. Many operating points have been measured in the experiments, but we focused in this paper on the three ones that have been considered in the simulations (wind tunnel speed of 32 m/s and propeller rotation speeds of 6000, 8000 and 11,000 rpm). A large database has been generated and is available on Zenodo. Only a few illustrative results have been presented in this paper.

We have shown in particular that the flow ingested by the ducted propeller is largely asymmetric in the presence of the S-plate, which creates an important flow distortion that interacts with the rotating propeller blades. This creates unsteady loading on the blades, an additional source of tonal noise radiation at the blade passing frequencies. The two other main mechanisms, *i.e.* propeller steady loading and thickness noise and propeller-strut interaction noise, might also be altered by the boundary layer ingestion. As a result, the tonal noise levels are significantly increased at all engine rotation speeds, with a 5 to 10 dB penalty.

In addition, the flow ingested by the propeller is also shown to be significantly more turbulent in the bottom part of the duct. The interaction of this turbulence with the rotating blades adds a contribution to broadband noise, which is caused by the rotor trailing edge and tip gap noise and the propeller-strut interaction noise in the isolated setup. The broadband noise levels in the farfield are therefore strongly increased in the presence of the S-plate, with about 10-15 dB in the mid-frequency range. After 1.5 kHz however, the penalty is no more visible in the measurements, probably because of the predominance of tip gap noise. This mechanism is poorly captured in the simulations which explains the discrepancies in this frequency range.

Those results highlight the strong effect of boundary layer ingestion on both tonal and broadband noise. They also show that the tip gap noise is an important contributor to broadband noise in such a setup, which was not necessarily anticipated in the preparation of numerical simulations. Further analyses should be made to better understand the impact of boundary layer ingestion on the different acoustic sources.

WALL PRESSURE FLUCTUATIONS AND IMPACT ON THE NOISE FROM DISTRIBUTED ELECTRIC PROPELLERS

Luana G. Stoica[1*] **Elisa de Paola**[1] **Giorgia Capobianchi**[1]

ABSTRACT

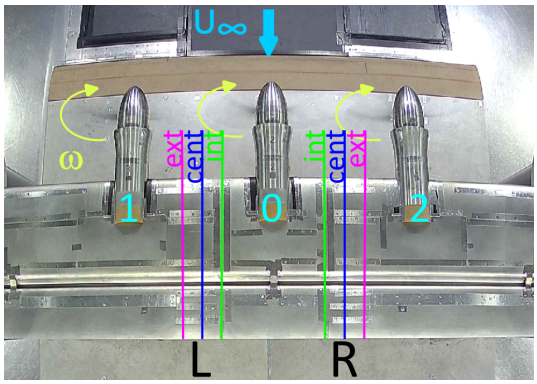
In the pursue of new urban air mobility solutions, the VENUS project served as a test bench for a real-world application of distributed electric propulsion aircraft. Experimental investigations were carried out on a wing model, equipped with three tractor propellers, derived from a realistic regional aircraft configuration inside an open jet acoustically treated wind tunnel. Wall pressure fluctuations induced by the multiple propeller configuration on the wing were investigated, in particular on the leading edge of the wing, on the flap, and inside the gap between the flap and the wing. Measurements of the acoustic footprint and of the polar directivity were carried out using three far-field microphone arrays. The parameters varied during the measurements included propeller blade pitch angle, flap deflection angle and wing angle of attack, as well as the distances between the propellers and with respect to the wing. The importance of the different generation mechanisms on the far-field noise and their dependency on the position along the wing and test parameters was assessed applying two-point statistics.

Keywords: *wall pressure fluctuations, DEP, propellers, wind tunnel.*

1. INTRODUCTION

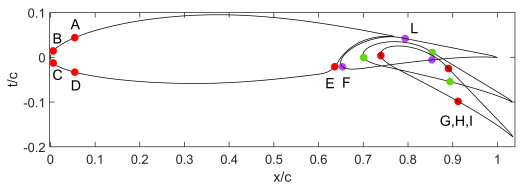
In recent years we witnessed the increased popularity of the distributed electric propulsion (DEP) with a variety of new technologies and aircraft concepts being developed. DEP aircraft concepts feature multiple electric propulsors around an airframe and one or more independent electric generators or energy storage devices [1].

Experimental investigations using high resolution PIV, force and aeroacoustic measurements were carried out in [2] finding that the noise distribution for twin-rotor configurations is a function of azimuthal angle and separation distance. Systematic testing on different dual propeller configurations were conducted both numerically and experimentally in [3] in order to gain insight in the mutual interaction effect on thrust and noise levels. In these two latter papers, two-bladed propellers for UAV applications were considered. A benchmark experiment on wake-ingesting propellers is discussed in [4], including fluctuating pressure and aeroacoustic analysis.



Realistic wing models with multiple bladed propellers were investigated in three different EU funded projects. In [5] we find the results of the study of a wing model equipped with three propellers with three blades each, both in tractor and pusher configuration in the framework of the ARTEM project. The project ERaCLE was focused on the aeroacoustics of a wing model propelled by two five-bladed pusher propellers [6]. In the current paper, the experimental database of the VENUS project was investigated with a focus on the wall pressure fluctuation analysis, and its correlation to the emitted far-field noise.

2. EXPERIMENTAL SET-UP



The VENUS model is inspired by a short range regional aircraft, with each wing powered by three distributed propellers to be used mainly in take-off and landing. Each propeller is composed of four blades. The blade geometry and the propellers positions along the wing were op-

timized with aerodynamic and aeroacoustic constraints. The experimental set-up is described in detail in [7].

(a) Upper view model - pressure side wing

(b) Cross-section view

Figure 1: Fluctuating pressure sensors positions. The wing is seen from the pressure side.

A picture of the wing with the baseline DEP relative position and the position of the sensors is shown in Fig. 1 a, as seen from the pressure side of the wing, as the wing model was installed upside-down inside the wind tunnel. The unsteady pressure sensors (Knowles FG-23629-P16 capsule electret microphones) were installed on both sides of the central propeller, named left (L) and right (R) as seen when facing the flow, on three lines (internal, central and external with respect to the centre of the wing) with the aim of covering the interaction area between the propellers. Along the airfoil, the positions are marked with different letters and are mainly gathered around the leading edge, on the flap and in the gap between wing and flap. All the propellers spin counter-clockwise as seen from the flow, with a blade pitch angle of 17°. In the baseline position, the propeller blades are aligned on the same plane, at a distance from the wing of $0.52D$ and a hub to hub distance of $1.05D$. The wing chord is equal to $1.14D$. All the tested propellers positions can be found in Tab. 1. The wing is also equipped with a high lift device: the flap deflection angles are $\delta = 20°$ in take-off and $\delta = 35°$ in landing position. The wing pitch angle is set to 5° in both cases.

Table 1: Propellers' position in the DEP configurations tested.

	$\Delta Y/D$ 0-1, 0-2	$\Delta X/D$ 1, 2	$\Delta X/D$ 0
XY1	1.05	0.52	0.52
XY2	1.05	0.41	0.41
XY3	1.05	0.41	0.63
XY4	1.05	0.63	0.41
XY5	1.05	0.52	0.63
XY6	0.984	0.41	0.63
XY7	0.984	0.63	0.41

3. RESULTS AND DISCUSSION

The fluctuating pressure signals from the wall microphones on the wing are analysed in this section. The tests analysed herein are performed in take-off wing configuration (AoA=5°, flap deflection 20°) with all three propellers running in-phase at an advance ratio of $J = 0.654$. The Reynolds number of the incoming flow is $Re_\infty = 0.81 \cdot 10^6$, whereas for the propeller, $Re_{0.75} = 1.3 \cdot 10^5$, based on the propeller chord at the 75% propeller-blade station. The fluctuating pressure coefficient is defined as $c_{p,rms} = \frac{\sigma_p}{q}$, where σ_p is the standard deviation of the fluctuating pressure and q is the dynamic pressure measured in the wind tunnel test section.

An interesting feature is that sensors on the central lines show a notable difference in the spectra on both sides of the wing as we can see from the spectra measured in the baseline configuration in Fig. 2. We notice that the sensors on the external and internal lines of microphones exhibit tonal components up to around the 12th shaft frequency, whereas the central line of microphones exhibits an additional set of tonal spikes at higher frequency, in some cases up to the 36th BPF in some cases. This effect may be ascribable to the interaction between the vortices from the two adjacent propellers, and it is registered on both right and left side of the wing (see convention in Fig. 1). As the AoA is increased, this effect remains evident only on the pressure side of the wing, as probably

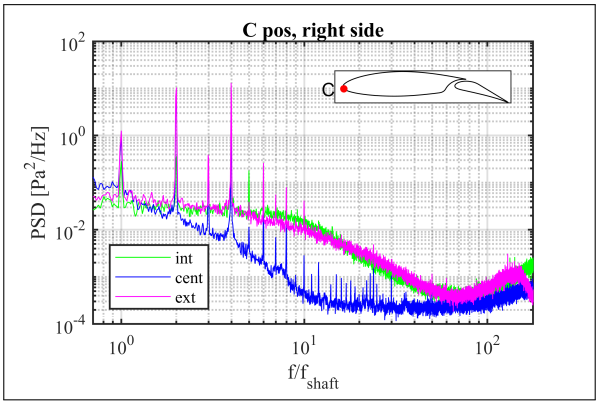

Figure 2: PSD of the fluctuating pressure from sensors in position C, right side of the wing - baseline.

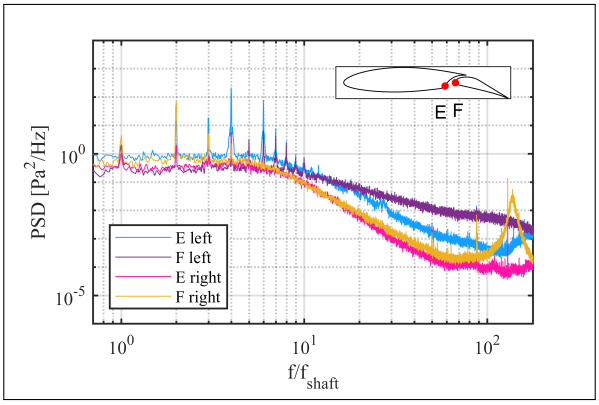

Figure 3: PSD of the fluctuating pressure from sensors in the gap between flap and wing - baseline.

the sensors on the upper side are screened by the airflow separating at the leading edge.

In Fig. 3, the spectra of the wall pressure in the gap between wing and flap are shown for the baseline configuration. These sensors are only installed on the line denoted as internal (green line in Fig. 1). On the right side of the wing, where we expect the disturbed wake of the central propeller to be impinging on the pressure side, the high frequency decay of the spectra has the same rate in E and F, around $f^{(-7/2)}$. On the left side of the wing, where the tip vortices from the central propeller are not impinging on these sensors, we have different features in the E and F positions. For the sensor E, we notice that the tone at the shaft frequency is not present, whereas the successive harmonics have a higher amplitude than in the F position.

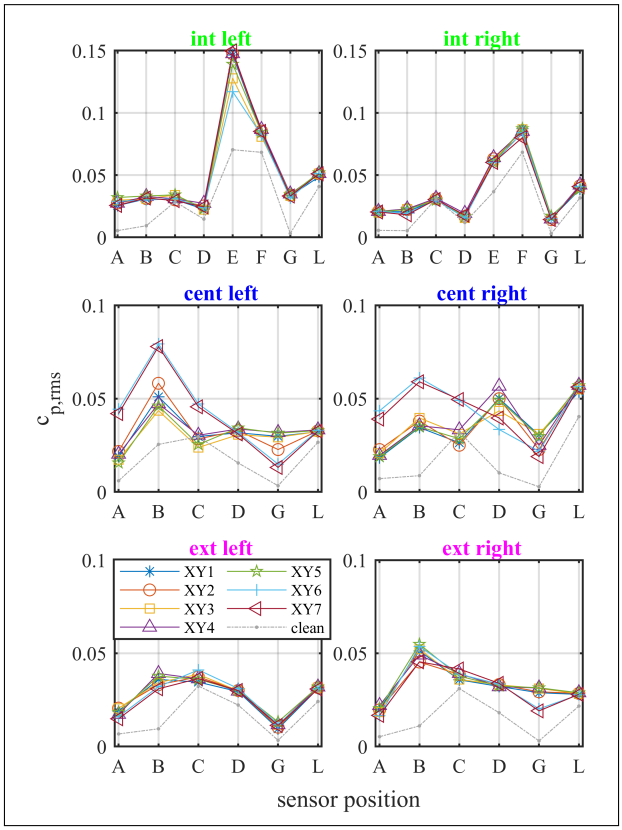

Figure 4: Trends of $c_{p,rms}$ along the wing model in different DEP configurations.

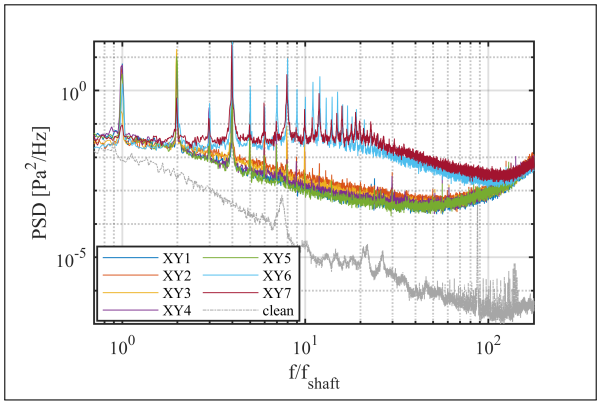

Figure 5: PSD of the fluctuating pressure from sensor B, central line, right side - DEP configuration effect.

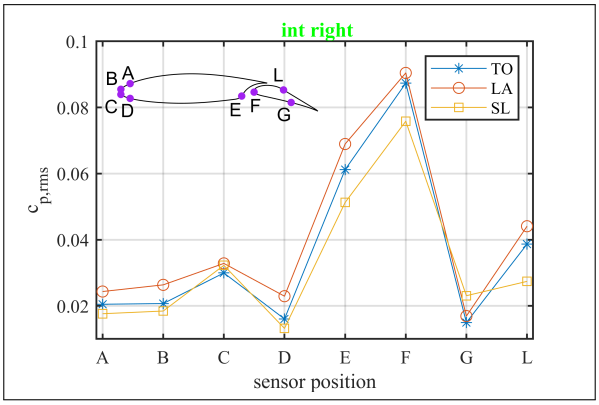

Figure 6: Trends of $c_{p,rms}$ along the wing model with different flap deflection angles.

Also the high frequency decay has a lower rate in F with respect to E, and in both cases is lower than the right side.

The effect of the different DEP configurations on the fluctuating pressure is investigated in Fig. 4, where also the results on the clean wing (i.e. without propeller blades) are included. Notable differences may be observed on the central lines of microphones, where the interaction between adjacent propellers is captured. In particular, configurations $XY6$ and $XY7$ exhibit the highest maximum value in position B and the lowest minimum in position G. This effect may be ascribed to the propellers planes overlapping or to the increased distance between the propellers axes. An intermediate value is found for position $XY2$, which has the three aligned propellers in their closest position with respect to the wing. The trends of the $c_{p,rms}$ on the external and internal lines are quite similar, with a local maximum on the leading edge, in position B or C depending on the line, and with another local maximum in position L on the upper side of the flap. The pressure fluctuations in the gap between the flap and the wing exhibit the highest values, with differences with respect to the other sensors up to 0.05 on the right side and up to 0.1 on the left side. This latter value may be be affected by the impinging wake from the propellers. Similar results are obtained in take-off and landing configurations.

In order to further investigate the origin of the maximum value of the fluctuating pressure, in Fig. 5, the spectra in position B from the central (blue) line on the right side of the wing are shown, for all the DEP configurations tested. The difference between the overlapping discs configurations and the others becomes obvious looking at the mid-high frequency part of the spectra, where a substantially higher level of energy is observed. The high frequency decay of the spectra from configurations XY6 and XY7 is approximately $f^{(-7/3)}$, typical value for the turbulent boundary layer acoustic-transition [8]. For the configurations with no overlap, the slope of the spectra decreases rapidly after the second shaft frequency.

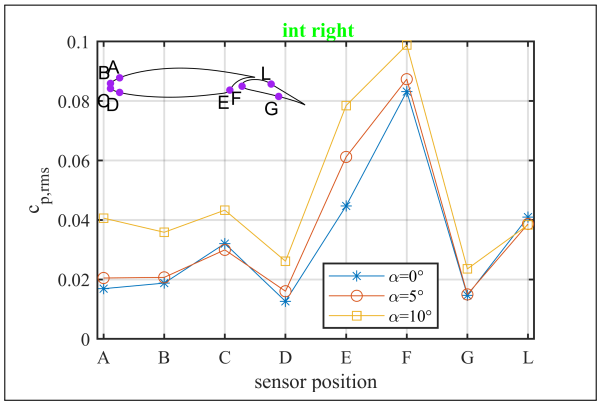

Figure 7: Trends of $c_{p,rms}$ along the wing model with different wing pitch angles.

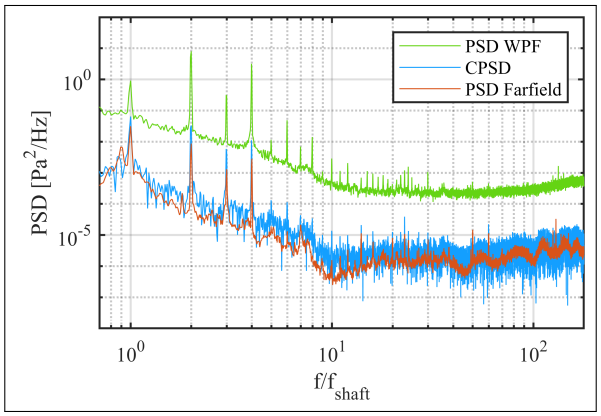

Figure 8: Comparison between PSD of the fluctuating pressure, farfield noise and cross-spectrum.

The effect of the flap deflection on the fluctuating pressure is shown in Fig. 6 for the baseline configuration in take-off, with the results from the sensors located along the internal line on the right side as an example. The landing configuration ($\delta = 35°$) exhibits the higher fluctuation, followed by the take-off and the side-line, with differences in the order of 0.005. This is especially true

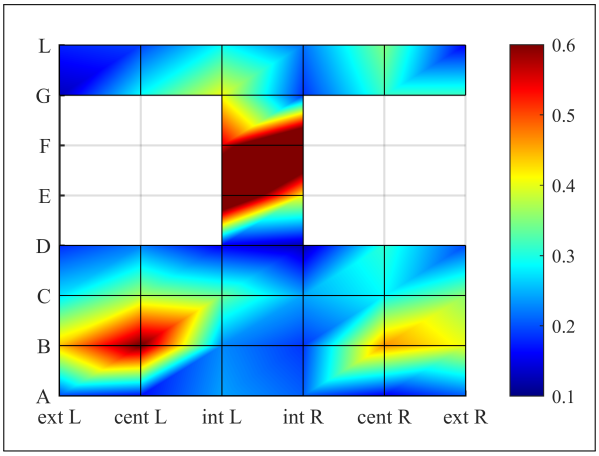

Figure 9: Covariance between the fluctuating pressure sensors and farfield noise.

for the sensors in the gap between the wing and the flap.

In Fig. 7, the results from the same sensors are plotted at different wing pitch angles. At $10°$, there is a $c_{p,rms}$ up to 0.02 higher, due to separation effects. For angles between $0°$ and $5°$ the values are similar, whereas for exceeding angles the fluctuations increase with the AoA, indicating a flow separation occurring. For the sensors in the gap between wing and flap the situation is different, with the fluctuations increasing with the AoA at all angles.

The cross-spectra were computed between the pressure sensors on the wing and one farfield sensor located at the centre of the acoustic footprint of the wing, near the propeller plane. An example is shown in Fig. 8, for the sensor in position C on the central line on the right side of the wing. The baseline configuration in take-off is considered. We can see a strong correlation on the first four shaft frequencies. The cross-spectrum also unveils the higher frequency tonal components which are more evident in the wall pressure spectra. The broadband component maintains the same shape as the far-field noise.

The covariance between the signals was then obtained integrating the cross-spectra, in order to understand which positions affect mostly the emitted noise (Fig. 9). The maximum correlation between the signals is found in the gap between the flap and the wing, although there are other areas concurring in a notable manner to the noise emission. In particular, we find a second maximum at the sensors in position B on the central lines, where the vortices from the adjacent propellers are interacting and impinging on the wing. In this position, flow separation may occur at the examined AoA of $5°$. A lower local maxima is also found at sensors in position C on the internal lines, which are closest to the central propeller. When comparing different flap positions, we find a higher correlation on sensors positions D and L when the flap is deflected with respect to the sideline configuration. As the the angle of attack is increased, the maximum correlation moves towards positions C and D on the left side of the wing, i.e. where the outflow from the propeller is impinging on the wing. Also the correlations measured on the flap in G and L increase with the AoA.

4. CONCLUSION

Wall pressure fluctuations on a DEP configuration were analysed in order to find the underlying mechanisms leading to noise generation. Signals are acquired from 44 fluctuating pressure sensors installed at different stations along the wing, surveying different areas on the airfoil, such as the leading edge of the wing, the gap between wing and flap and the flap.

The interaction between the adjacent propellers has a visible effect on the wall pressure fluctuations and is highly correlated with the acoustic footprint. Regarding the propellers relative position, the configurations with overlapping propellers discs and the greatest distance between their axes are responsible for the highest wall pressure fluctuations impinging on the wing. An influence of the flap deflection angle is also visible, with pressure fluctuations increasing with increasing deflection. The wing angle of attack is in its turn responsible for increasing the fluctuations, especially above $5°$, due to separation effects.

The cross-correlation between the wall pressure fluctuations on the wing and the farfield emitted noise was then examined. The highest correlation with the farfield noise is found in the gap between the wing and the flap, which is also responsible for the highest contribution to the pressure fluctuations on the wing. In addition, the points where the interacting tip vortices from the adjacent propellers are impinging on the wing are the second highest correlated with the acoustic footprint.

ANALYTICAL INVESTIGATION OF ROTOR-STRUT POTENTIAL INTERACTION NOISE

Riccardo Zamponi[1,2*] **Alessandro Zarri**[1] **Julien Christophe**[1]
[1] von Karman Institute for Fluid Dynamics, Sint-Genesius-Rode, Belgium
[2] Technische Universiteit Delft, Delft, The Netherlands

ABSTRACT

This paper presents a methodology to predict the tonal noise radiated by a propeller-strut configuration by modeling the potential inflow distortion induced by the strut. The approach combines a theoretical description of the potential flow around a circular cylinder with the force distribution and induced velocity computed using an unsteady panel method. The analytical results show satisfactory agreement with measurements from previous studies, demonstrating the suitability of the proposed methodology as a fast and effective prediction tool.

Keywords: *Propeller noise, potential interaction noise, noise prediction, urban air mobility.*

1. INTRODUCTION

A significant part of the aerodynamic noise radiating from an unmanned aerial vehicle (UAV) arises from the interaction between the turbulent wake and the acoustic field produced by the rotors and the supporting strut located downstream. The intensity of such interaction depends on the proximity between these components and encompasses several noise generation mechanisms, including the sound emitted by the rotor operating in the potential distortion of the strut. Clarifying these mechanisms can offer guidelines for the future design of quieter UAVs and foster the development of analytical noise prediction tools to exploit in the early design stage, where the detailed geometry of the propulsion systems is still unknown.

Several studies in the literature have focused on the analytical modeling of propeller-strut potential interaction noise [1–6]. However, most of these relied on measurement data or high-fidelity numerical simulations to provide input to the prediction models, particularly for the propeller-induced velocity. Low-fidelity methods, such as blade element momentum theory (BEMT), have been regarded as subject to significant uncertainties [4]. In this study, we propose an alternative approach, making use of a fast mid-fidelity simulation framework coupled for the estimation of the aerodynamic data required by the model.

2. METHODOLOGY

2.1 Experimental setup

The analytical results presented in this study are intended to reproduce the measurements performed by Gallo *et al.* [3] in the JAFAAR anechoic room of the von Karman Institute for Fluid Dynamics. Acoustic measurements were performed using a 7-microphone directivity arc (with radiation angles ranging from $0°$ to $90°$ relative to the propeller axis) to investigate the noise emitted by a propeller operating upstream of a cylindrical rod (see Figure 1). A two-bladed Mejzlik 13”x4.2 propeller, driven by a T-motor AT 2814 KV1050 and controlled by a Scorpion Tribunus II 12-80 A, was tested for different rod diameters and propeller-strut distances. For comparison with noise prediction results, the case with the propeller operating at $6000\,\mathrm{RPM}$ and with a strut radius of $a_c = 0.02\,\mathrm{m}$ located at $d = 0.01\,\mathrm{m}$ from the rotor plane is selected.

2.2 Analytical model

The analytical flow-distortion model used in this paper is based on the classical incompressible solution for the flow past a circle. The two-dimensional nature of the model of-

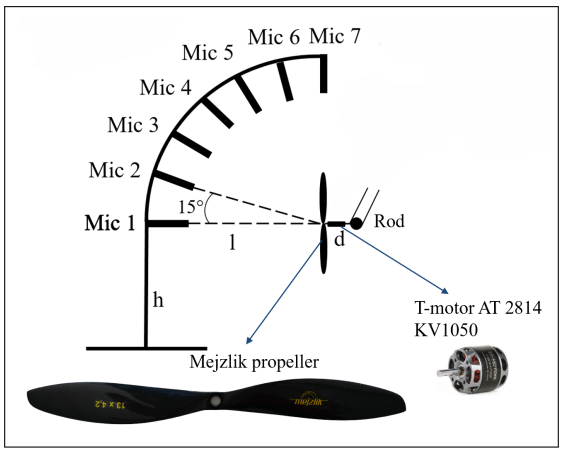

Figure 1. Propeller-strut experimental setup [3].

fers an advantage when dealing with struts of non-uniform cross-section, as it allows the structure to be divided into segments in accordance with a strip-theory approach for rotor noise prediction. Following Roger *et al.* [7], the expression for the upwash velocity w in the direction normal to the blade chord in the polar coordinates (r, ϕ) along the mean circle of the considered blade strip reads

$$\frac{w(r,\phi)}{U_z(r)\,a_c^2} = \sin\alpha\sin\alpha_0\,C_d(r,\phi) - \sin\alpha\cos\alpha_0\,D_d(r,\phi) + \cos\alpha\cos\alpha_0\,A_d(r,\phi) + \cos\alpha\sin\alpha_0\,B_d(r,\phi), \quad (1)$$

where

$$A_d(r,\phi) = \frac{(d^2 - r^2\sin^2\phi)}{(d^2 + r^2\sin^2\phi)^2};\; B_d(r,\phi) = \frac{2d\,r\sin\phi}{(d^2 + r^2\sin^2\phi)^2}$$
$$C_d(r,\phi) = \frac{\cos\phi(d^2 - r^2\sin^2\phi)}{(d^2 + r^2\sin^2\phi)^2};\; D_d(r,\phi) = \frac{d\,r\sin 2\phi}{(d^2 + r^2\sin^2\phi)^2}.$$

Here, α, and α_0 are the blade pitch angle and the flow swirl angle with respect to the rotor axis, respectively, while U_z is the propeller induced velocity. Since the strut only extends on half of the rotor disk plane, w is set equal to zero for $\phi \in [3\pi/2; \pi/2]$ [6]. Although w is stationary, the blade experiences periodic distortion in its reference frame, whose k-th harmonic can be computed through a Fourier series:

$$w_k(r) = \frac{1}{2\pi}\int_0^{2\pi} w(r,\phi)e^{ik\phi}d\phi, \quad k \geq 1. \quad (2)$$

The harmonics of lift per unit span can be subsequently derived from the coefficients w_k by means of Sears' theory [8], according to

$$L_k(r) = \pi\rho_0 c U_r w_k(r) \times \left[C(\sigma)(J_0(\mu) - iJ_1(\mu)) + \frac{i\sigma}{\mu}J_1(\mu)\right]^*, \quad (3)$$

with

$$\sigma = \frac{k\Omega c}{2U_r}; \quad \mu = \frac{ikc}{2r}e^{-i\gamma},$$

where U_r is the velocity at the blade section, C is the Theodorsen function, Ω is the rotational speed, c is the chord of the blade section, γ is the blade stagger angle, and * denotes the complex conjugate. L_k can now be decomposed into an axial and tangential force distribution and used in Hanson's model [9] to calculate the tonal far-field noise radiated at the m-th harmonic of the blade passing frequency (BPF). It is important to specify that the formulation of Hanson's model implemented in this paper is valid for acoustically compact cases, which limits the investigation presented here up to the 5th BPF harmonic.

2.3 Unsteady panel method

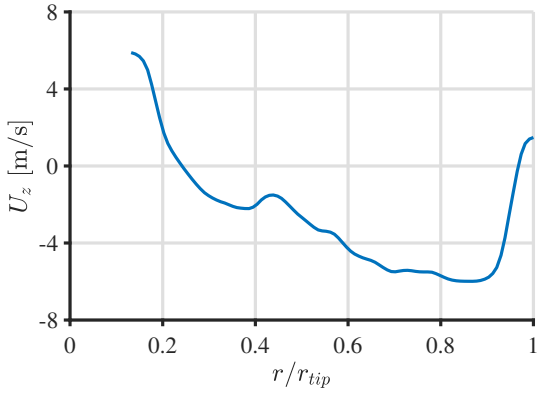

Figure 2. Induced velocity of the isolated propeller extracted 0.01 m from the rotor disk.

The model presented in Section 2.2 relies on the distributions of force per unit span along the propeller blade and the rotor-induced velocity, as well as the flow swirl angle. In the present study, these

quantities are computed using the commercial unsteady panel method software FlightStream, which employs a surface vorticity approach augmented with a Prandtl–Glauert correction to account for compressibility effects and a viscous correction that couples the potential flow solution with a numerical boundary layer. The simulation comprises 2568 surface elements, with a mesh resolution of 2.1 mm at the blade tip and along the leading and trailing edges, and 4.2 mm elsewhere. The numerical calculation is performed for the isolated propeller spinning at 6000 RPM, and the data are averaged over 8 propeller revolutions. An example of an induced velocity profile extracted downstream of the propeller is shown in Fig. 2, whereas an overview of the inflow distortion induced by the strut and experienced by the blades is illustrated in Fig. 3.

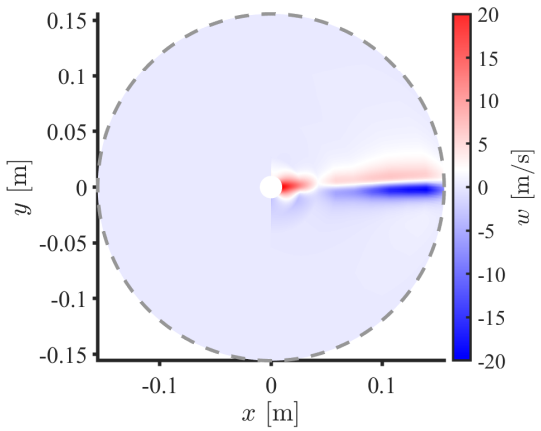

Figure 3. Upwash velocity distortion induced by the strut on the rotor disk.

3. RESULTS AND DISCUSSION

The analytical prediction of the potential interaction noise radiated by the propeller up to a frequency of 5 × BPF is compared to the experimental results of Gallo *et al.* [3] in Fig. 4. The data refer to a radiation angle of 0° (see Fig. 1).

In general, the prediction results agree satisfactorily with the measurements for the considered tonal

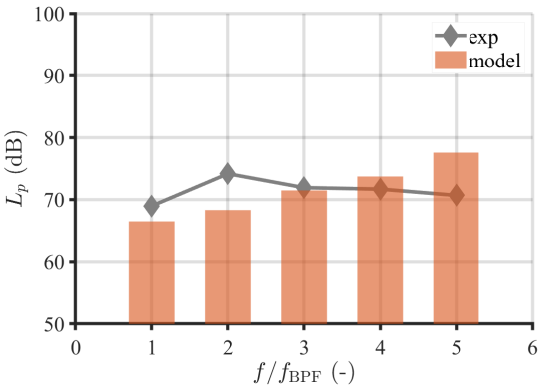

Figure 4. Analytical and experimental sound pressure levels computed with a reference pressure of 20 µPa and referred to the main BPF and its harmonics.

peaks. The model successfully captures the increase in unsteady loading noise due to the inflow distortion, although the first harmonic is under-predicted. This effect may be due to the diffraction of rotor noise by the strut, which is not taken into account in the analytical model and has been shown to play a significant role at low frequencies [4, 5].

These results confirm that a reasonable potential interaction noise prediction can be achieved without relying on experiments or high-fidelity simulations. In particular, the use of an unsteady panel method, such as FlightStream, provides the input data required for the analytical model with sufficient accuracy and little computational effort, making it an attractive tool for the early-design and optimization stages of UAVs. Further developments of this research will involve the inclusion of sound diffraction effects in the noise prediction model, as well as the potential interaction noise that arises from the unsteady loading of the strut due to the passage of the blade [2].

ABSTRACT

The sound radiation of small-scale low Reynolds number rotor in interaction with a beam is measured in anechoic room in hovering condition. The experimental setup is composed by a farfield acoustic instrumentation, a directivity antenna and an array of 45 microphones, and nearfield acoustic intrumentation, a microphone and an array of 16 microphones located near the rotor and flush-mounted on the beam. Both nearfield and farfield microphones are used to characterize the different rotor-beam noise source components, tonal noise associated to the blade passing frequency (BPF) and its harmonics which increases in the presence of the beam, and high frequency broadband noise. The coherent output power (COP) spectral analysis is also used to obtain sound source maps coherent or anti-coherent with nearfield signals. This methodology is first assessed on loudspeakers in anechoic room before to be applied to the rotor-beam test case. Nearfield and farfield acoustic signatures show similar radiation patterns. Tonal noise components are very coherent with nearfield signals and their evolution along the beam differs between low frequency and high frequency BPF harmonics. The high frequency broadband noise is contrarly anti-coherent with nearfield signals and its evolution along the beam shows a maximum level near the blade tip.

1. INTRODUCTION

The sound generated by bodies in interaction with an airflow is a concern for many applications, especially for noise pollution due to transportation in cities [1]. Transportation noise present often multiple aeroacoustic sources and/or complex interaction phenomenon with possible correlation between sources. This is the case of new unmanned aircraft systems for which the developement leds to many aeroacoustic studies last years [2–8].

In order to reduce the noise coming from these equipments, it is necessary to understand the physical mechanisms responsible for their generation. An interesting way of improving aeroacoustics noise sources understanding is the use of microphone array measurements associated with source localization methods. Indeed, such approach allows to discriminate the different sources while providing a ranking of each of them for the frequencies of interest. The most famous source localization algorithm is the conventional beamforming (CBF) method developed by Billinglsey et al. [9], which is based on the assumption that the sound field radiated by the sources under study follows a certain source model (uncorrelated monopoles). The principle is to localize the sound sources from farfield microphone array measurements by interpreting the propagation delays measured between each microphone of the array and knowing the source-array distance. Parallely, coherent output power (COP) spectral analysis has been developped and was recently applied to microphone array measurements for denoising or source separation purposes [10–12].

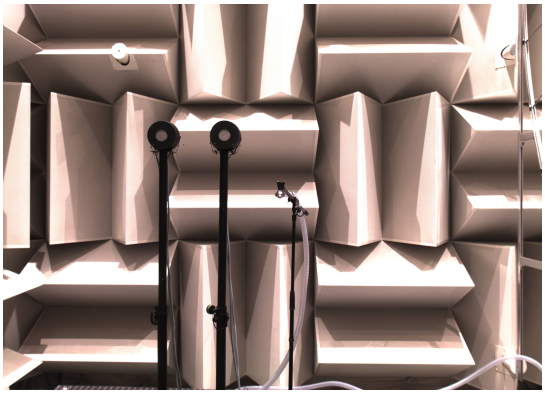

Figure 1. Loudspeakers configuration: S1 (center) and S2 sources (upper left).

This paper proposes to use the degree of coherence of farfield microphone signals with nearfield microphone ones to improve the characterization of complex aeroacoustic noise sources. First, the experimental campaign and associated post processing methodology is presented. Then, the results of preliminary tests on loudspeakers with different degree of coherence are discussed. Finally, the methodology is applied to an aeroacoustic test case: a hovering small-scale low Reynolds number UAV rotor in interaction with a beam.

2. EXPERIMENTAL CAMPAIGN

2.1 Sources configurations

Measurements are performed in ISAE-SUPAERO anechoic room, which is acoustically treated in the frequency range $80 - 16000\ Hz$, and has wedge-tip to wedge-tip dimensions of $5.02 * 5.24 * 5.34\ m^3$ $(L * W * H)$.

A first set of measurements was performed on loudspeakers: a monopolar source Siemens Q-MHF, called $S1$, and two compression drivers BMS 4592, called $S2$. A white noise signal on the frequency range $100-20000\ Hz$ is sended to this three sources. The generation setup allowed to send uncoherent signal, in-phase signal and signals in phase opposition to the two sources $S2$. The positionning of the three sources is shown Figure 1.

A second set of measurements was performed on a hovering small-scale low Reynolds number UAV rotor in interaction with a beam. The rotor has two blades with a NACA0012 blade cross section profile extruded in the radial direction, a constant chord of 0.025 , a constant pitch of $10°$ and a radius $R = 0.1\ m$. The beam is a cylinder

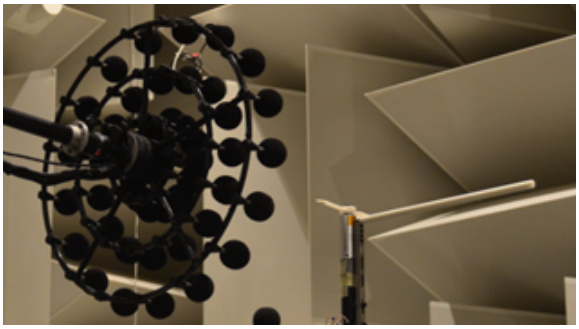

Figure 2. UAV rotor-beam configuration with the 45-channels microphone array.

of diameter $0.02\ m$ and length $0.4\ m$ whose axis is located $0.02\ cm$ below the rotor disk plane. The rotor-beam setup is visible Figure 2 and is described in more details in [6]. Measurements were performed at a rotational speed of $8000\ RPM$.

2.2 Acoustic measurements

The farfield noise radiated by sources is measured by a 2D array of 45 microphones and diameter $0.5\ m$ developed by MicrodB. This array is composed by GRAS 40PH microphones located on 3 concentric circles with irregular spacing (see Figure 2). The array plane was located at a distance of $1\ m$ from the loudspeakers plane and $0.56\ m$ from the rotor-beam setup. For the rotor-beam test case, a directivity antenna of 13 microphones, covering elevation angles $[-60 : 10 : 60]°$, $0°$ being the rotor disk plane, located $1.62\ m$ from the rotor center and perpendicular to the beam was also used. More details about the farfield acoustic instrumentation can be found in [8].

For this study, nearfield measurements were also performed in both cases. The volume acceleration sensor integrated at the exit nozzle of the S1 source is used for the loudspeakers configuration. A microphone GRAS 48LX-1 located on the top of the beam at a distance of $0.8R$ from the rotor axis was used for the rotor-beam configuration. Additionally, a small array of 16 MEMs microphones ICS-40619 was developed to study specifically to study nearfield noise. MEMs were located any $0.005\ m$ between $0.35R$ and $1.1R$ and positionned at the top of the beam instead of the nearfield microphone for some measurements.

Both data acquisition and post-processing were perfomed using Siemens Simcenter Testlab software. Mea-

surements were performed at a sampling frequency of 51.2 kHz during 16.16 s. The fast Fourier transform (FFT) on those signals was computed with a Hanning window applied on 100 segments and a sample overlap of 50%, leading to a frequency resolution of 3.125 Hz. Source maps have been computed with a sample overlap of 50% for FFT in order to have a frequency resolution of 10 Hz with a source grid cells of size 0.01 m.

3. METHODOLOGY

3.1 Conventional beamforming

The conventional beamforming source localization algorithm is based on the propagation delays measured between each microphones that are related to the source-microphone distance. It uses the cross-spectral matrix C, which contains microphones auto-spectra on its diagonal and cross-spectra outside its diagonal, and the free space Green's function g to estimate the sources' position and amplitude q in Pa^2 from the farfield sound pressure measurements p':

$$q = \frac{g^H C g}{||g||^4} \quad \text{with} \quad g = \frac{e^{jkr}}{r} \quad \& \quad C = p' p'^H \tag{1}$$

where ^{H} the complex conjugate transpose, j the imaginary unit, k the wavenumber and r the distance between microphones and focal points.

The cross-spectral matrix diagonal removal technique is used for maps averaging computation to obtain a single acoustic map from a time selection including multiple FFT time segments, while removing the noise contained associated to microphones auto-spectra. This allows to obtain source maps for each frequency or frequency range of interest.

3.2 Coherence with nearfield data

When reference data are available near sources they can be used to separate the different sources' contributions at other microphone's locations. This can be done by calculating the coherent or anti-coherent output power (COP or ACOP) spectra [10]:

$$COP_{rm} = \gamma_{rm}^2 * S_{mm} \tag{2}$$

$$ACOP_{rm} = (1 - \gamma_{rm}^2) * S_{mm} \tag{3}$$

with

$$\gamma_{rm}^2 = \frac{|S_{rm}|^2}{S_{rr} * S_{mm}} \tag{4}$$

where γ_{rm} and S_{rm} are respectively the coherence and the cross-power between a microphone, denoted m, and the nearfield reference signal, denoted r, and S_{mm} and S_{rr} arer respectively the auto-spectra of the microphone and the reference signal. This methodology was used recently to denoise microphone array signals or to separate different noise source contributions [11, 12].

Reference nearfield data can also be used to distinguish different sources' contributions on beamforming source maps. This is obtained using the COP and ACOP principles by weighting microphone averaged auto-spectra S_{mm} and by adding a phase relationship related to this reference:

$$S'_{mm} = COP_{rm} * \frac{{S_{rm}}^2}{|S_{rm}|^2} \quad \text{or} \quad ACOP_{rm} * \frac{{S_{rm}}^2}{|S_{rm}|^2} \tag{5}$$

The beamforming processing is then applied to those new microphone averaged autospectra S'_{mm}, to obtain source maps coherent or anti-coherent with the reference signal.

3.3 Assessment on loudspeaker test case

Measurements were performed with the three loudspeakers in three cases: sources S2 uncoherent, coherent in phase and coherent in phase opposition. Coherent and anti-coherent beamforming maps are then obtained by using S1 volume acceleration sensor as reference.

As expected, the coherent beamforming map obtained for the case of three uncoherent sources highlights the source S1, whereas the anti-coherent beamforming maps highlights S2 sources. This allows to identify the contribution of the source S1 even if its amplitude is lower. Figure 3 shows as example source maps obtained at 2000 Hz. Symbols indicate sources locations, S1 source being at the center. Others cases are not presented here but confirmed the ability of the methodology to separate coherent and anti-coherent sources contributions.

4. ROTOR-BEAM NOISE CHARACTERIZATION

4.1 Farfield spectra

Previous papesr shows that the rotor noise is characterized by tonal noise at the blade passing frequency (BPF) and its harmonics as well as a high frequency broadband noise (BBD), and that the presence of the beam increases the magnitude of BPF harmonics leading to a hump with a maximum level around $5 * BPF$ [4, 6].

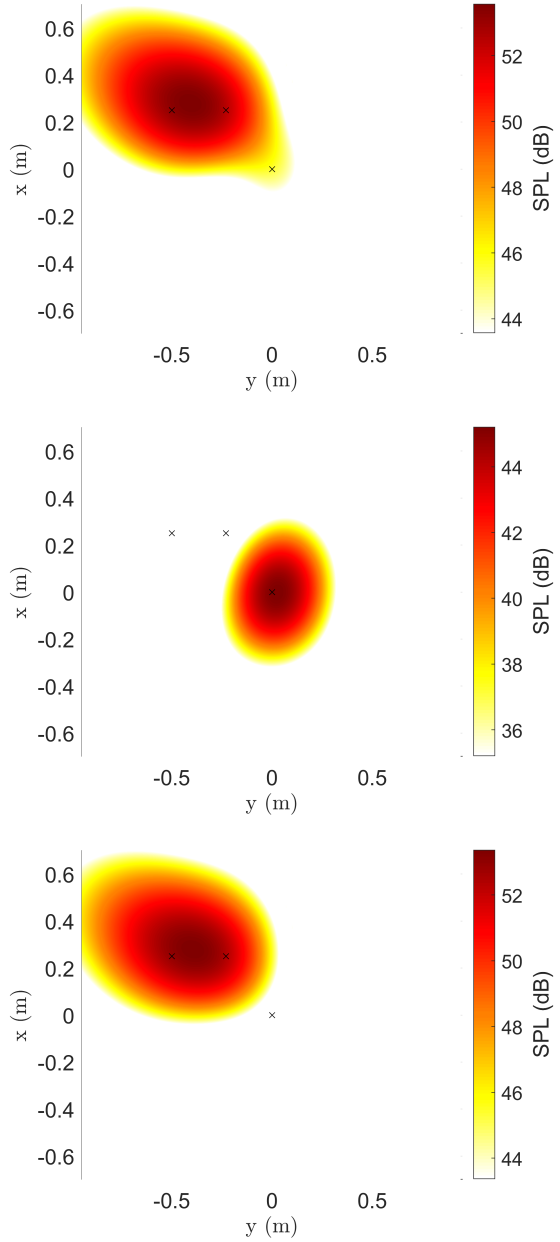

Figure 3. Maps obtained for 3 uncoherent sources at 2000 Hz: CBF (top), coherent CBF (center) & anti-coherent CBF (bottom).

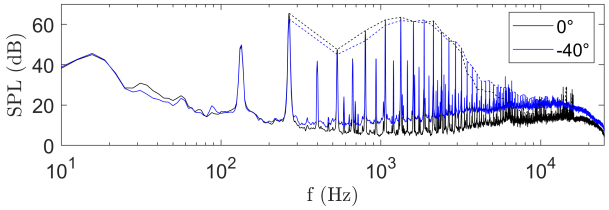

Figure 4. Spectra obtained for rotor-beam in the rotor disk plane $0°$ & toward the ground $-40°$.

A numerical study [8] showed that the BPF harmonics increase seems to be mainly due to the beam radiation, suggesting a noise generation mechanism related to unsteady loading when the blade passes above the beam. Figure 4 highlights those noise components, with the hump of BPF harmonics and the impact of the elevation angle on the high BPF harmonics and broadband noise levels.

4.2 Source maps

Source maps were here obtained using conventional beamforming based on fixed sources to focus on the intetaction noise with the array plane parallel to the beam as described in [8]. Coherent and anti-coherent source maps targeting the different noise components have been computed taking nearfield microphone on the beam as reference sensor. Locations of the rotor, the beam and the test stand are indicated by black lines on the source maps. To complete the source maps, farfield directivity diagrams with and without coherent or anti-coherent with the reference beam microphone are plotted for tonal components $5 * BPF$, $22 * BPF$ and the high frequency broadband noise (BBD) Figure 5.

For the highest BPF harmonic of the hump, $5 * BPF$, the CBF source map is identical to the CBF source map coherent with the beam nearfield microphone, whereas the anti-coherent source map is several orders of magnitudes below. This confirms the relationship between this BPF harmonic level and the periodic blade passing above the beam, and source maps indicate an omnidirectional radiation which corresponds to the farfield directivity perpendicular to the beam (see Figure 5).

Then, it was chosen to study the BPF harmonic $22 * BPF$ which corresponds to a frequency for which the tonal level is decreasing but the broadband level is increasing. In this case, source maps highlight that the main source remains here the one coherent with the beam

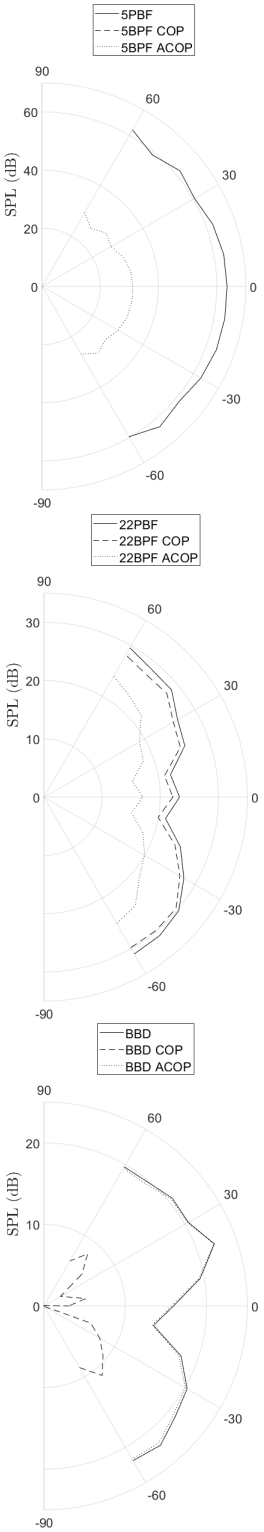

Figure 5. Farfield directivity obtained for rotor-beam at $5*BPF$, $22*BPF$ & BBD with and without coherent or anti-coherent weighting with nearfield data.

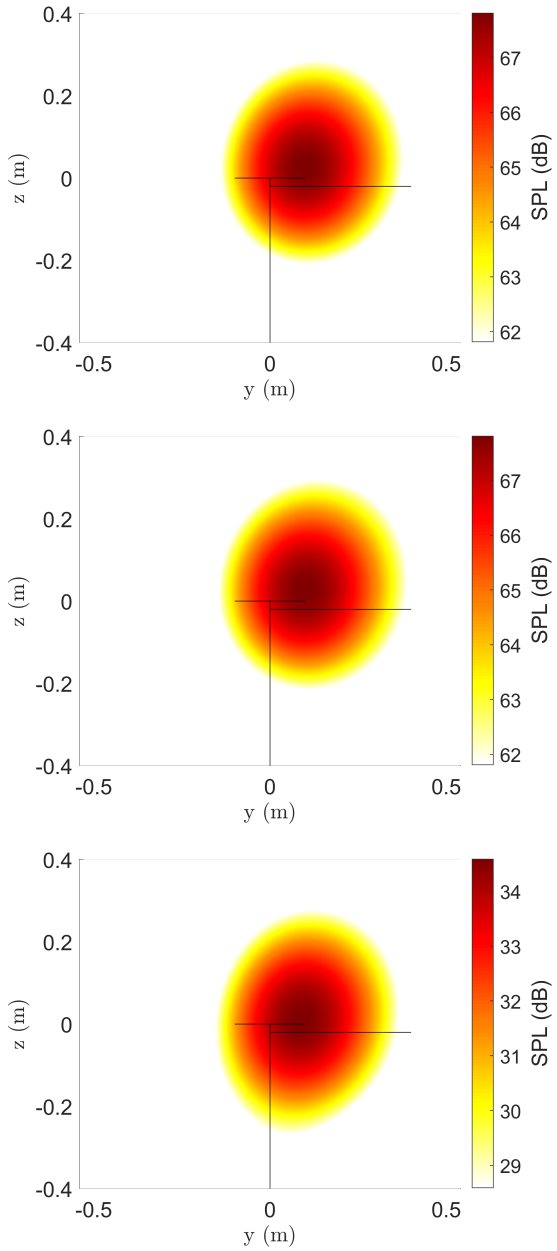

Figure 6. Source maps obtained for rotor-beam at 5*BPF: CBF (top), coherent CBF (center) & anti-coherent CBF (bottom).

nearfield microphone, but the anti-coherent source map allows to identify another source component slightly lower in terms of level and with a different radiation pattern. Looking at the corresponding farfield directivity (Figure 5) we can see that both noise components seem to dipole-like patterns.

Finally, the high frequency broadband noise in the frequency region without tones is studied (frequency of 13000 Hz was chosen). For this noise component we can observe that source map is entirelly determined by the anti-coherent source map, confirming that the sources anti-coherent with the reference beam microphone are associated to the broadband part of the spectrum. The shape of the corresponding source maps indicates a dipolar radiation, as well as the directivity diagrams Figure 5, which is consistent with the trailing edge broadband noise directivity previously identified [6].

4.3 Noise components evolution along the beam

Additionnally, the MEMs linear array was used to plot sound pressure levels (SPL) evolution of each noise component along the beam. COP and ACOP SPL evolutions respect to the MEMs located at $0.8R$ to be consistent with the beam nearfield microphone location.

For the main BPF harmonic an increase along the beam is observed with a maximum at $0.9R$ which is consistent with previous numerical simulation results, and the coherence of this phenomenon with the reference MEMs is confirmed. A previous numerical study showed that the beam was the main contributor to the farfield noise radiation at this BPF harmonic and that the main beam radiating area was around $80 - 90\%$ of the blade radius [7], which is similar to the maximum level location. The $22 * BPF$ harmonic present a diffrent behaviour with a first increase until $0.6R$, then a minimum, and after a second increase with a maximum at $0.95R$, with again the part coherent with the reference MEMs being the main one.

In the case of the high frequency broadband noise the evolution is quite flat between $0.4R$ and $0.9R$ and a peak is observed at $1.05R$. The level of this noise component along the beam is mainly anti-coherent with the reference MEMs but the trend along the beam is the same for both coherent and anti-coherent parts. Anti-coherent parts of tonal noise components present very similar behaviour with a peak at $1R$. The location of those peaks seems to suggest that this noise component might be due to blade tip wake impingement on the beam.

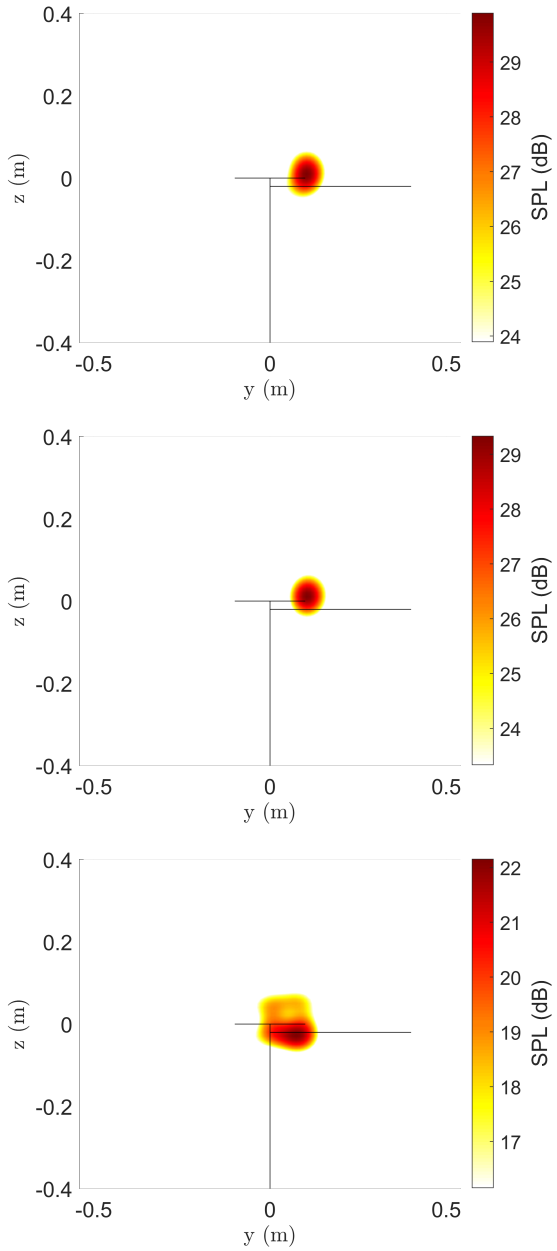

Figure 7. Source maps obtained for rotor-beam at 22*BPF: CBF (top), coherent CBF (center) & anti-coherent CBF (bottom).

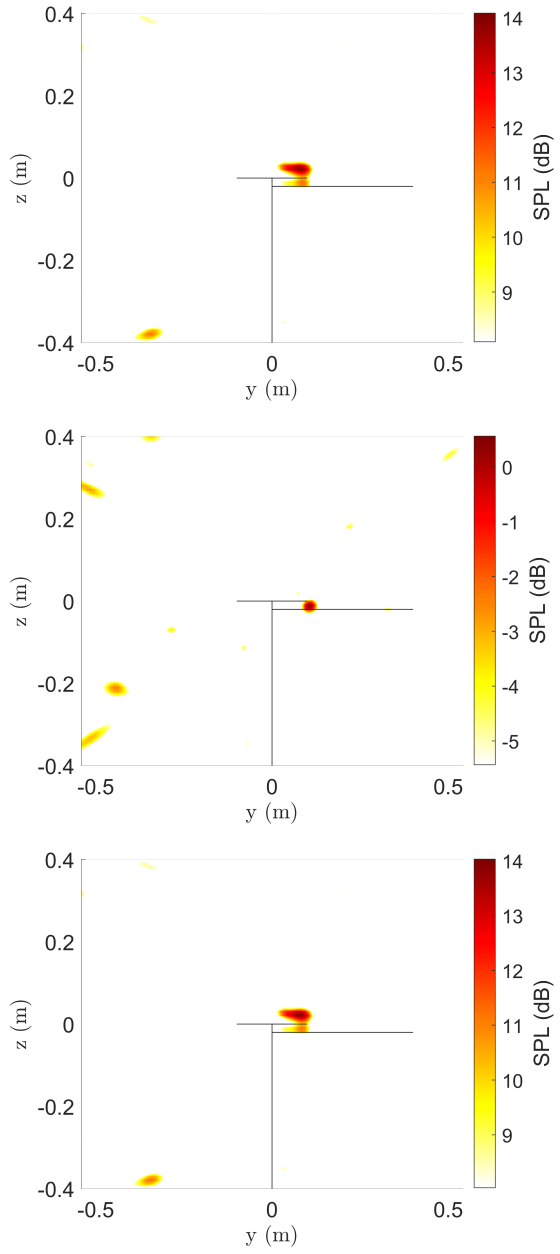

Figure 8. Source maps obtained for rotor-beam at BBD: CBF (top), coherent CBF (center) & anti-coherent CBF (bottom).

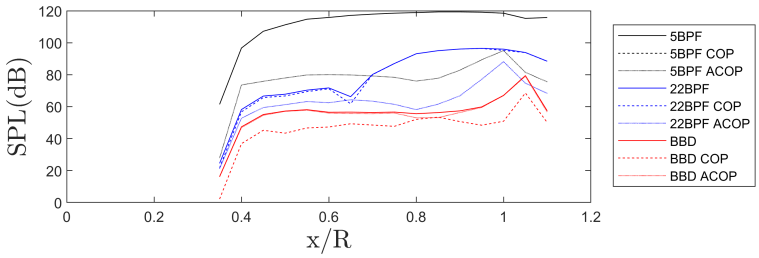

Figure 9. SPL along the beam for $5 * BPF$, $22 * BPF$ & BBD: total, coherent & anti-coherent with the MEMs located at $0.8R$.

5. CONCLUSIONS

Microphone array measurements were performed in anechoic room synchroneously with other acoustic nearfield and farfield measurements in order to help the identification of the different noise components associated to complex aeroacoustic sources. The proposed methodology is to compute beamforming source maps coherent or anti-coherent with nearfield reference signals using the coherent output power (COP) spectral analysis.

Preliminary tests on loudspeakers with different degree of coherence were first performed. The ability of the proposed methodology to distinguish source contributions coherent or anti-coherent with a nearfield reference signal was demonstrated, even when there is a significative difference of levels between the two contributions.

The methodoloy was then applied to an areoacoustic test case: a hovering small-scale low Reynolds number UAV two-bladed rotorof diameter $0.2\ m$ and NACA0012 blade profile in interaction with a cylindrical beam of diameter $0.02\ m$. Previous studies showed tonal noise at the blade passing frequency (BPF) and its harmonics, increased by the presence of the beam with a maximum around $5 * BPF$, and high frequency broadband noise.

Conventional beamforming was used to obtain source maps coherent and anti-coherent with a nearfield microphone located on the beam at 80% of the blade radius. The strongest BPF harmonic appeared to be coherent with the beam nearfield microphone, confirming the relationship between this BPF harmonic level and the periodic blade passing above the beam. High frequency BPF harmonics in the frequency region where the broadband increases appeared to be coherent with the beam nearfield microphone too, but another anti-coherent source with a dipolar radiation pattern and lower level was also identified. The high frequency broadband noise is contrarly

perfectly anti-coherent with the beam nearfield microphone with a dipolar radiation pattern associated to trailing edge noise. Farfield directivity diagrams coherent or anti-coherent with the beam nearfield microphone allowed to confirm the radiation patterns visibles on source maps.

Additionally, a linear MEMs array located on the beam was used to determine the sound pressure levels (SPL) evolution of each noise component along the beam, coherent and anti-coherent respect to the MEMs located at 80% of the blade radius. The evolution of the low frequency BPF harmonic level along the beam leads to one hump coherent with the reference MEMs, whereas the one of the high frequency BPF harmonic leads to two humps also coherent with the reference MEMs. For the high frequency broadband noise a flat evolution, mainly anti-coherent with the reference MEMs, with a maximum level near the blade tip is found.

Complementary post processing are planned and this methodology will be also used to study the different noise source components evolution with the rotational speed, the beam diameter, and the rotor-beam distance. It is also envisaged to apply it to more realistic configurations: different airflow conditions, rotor-airframe and/or multiple rotors interactions for instance.

ABSTRACT

Ingested turbulence affects propeller noise at frequencies higher than the 2nd blade passing frequency. The extension of Amiet's model to rotating blades represents a useful tool for predicting this phenomenon. However, it relies on assumptions that are not fully valid in reality, e.g., it neglects the distortion of turbulence. This paper investigates how the propeller-induced flow field alters incoming turbulence paving the way, in future studies, to extend Amiet's model with these features. Lattice Boltzmann Very Large Eddy Simulations of a reference propeller, for which experimental data exist, operating at low-Reynolds number and subject to turbulent inflow are performed. The spatial and temporal evolution of isotropic grid-generated turbulence approaching the propeller plane is characterized. It is found that the propeller leading edge interacts with anisotropic turbulence. This is due to the rotational flow induced by the propeller, stream tube contraction, and leading-edge distortion. In addition, the impact of the inflow turbulence on the laminar separation bubble on the propeller suction side, whose dynamic affects the acoustics at high frequencies, is analyzed. Finally, the aerodynamics flow features are linked to the far-field acoustic spectra, obtained through the Ffowcs-Williams and Hawkings analogy applied to the propeller surface.

1. INTRODUCTION

The growing interest in small Unmanned Aerial Vehicles (UAVs), driven by a wide range of potential applications, poses the need to integrate this technology into an urban environment. Given their impact on public acceptance [1], it is crucial to account for the aerodynamic noise generated by these devices when operating in an urban environment, which is characterized by different scales of turbulence.

From an aerodynamic point of view, small UAVs' propellers typically operate at low Reynolds numbers, resulting in a transitional regime extremely susceptible to inflow disturbances and characterized by complex phenomena such as the presence of laminar separation bubble (LSB) [2]. Furthermore, incoming turbulence interacting with the propeller produces an unsteady pressure field over the surface, that is radiated as broadband and/or quasi-tonal noise in the far field [3, 4]. LSB, whose presence on a small propeller was assessed for the first time by Grande et al. [5] under clean inflow, plays an important role in the far-field noise in the high-frequency [6]. It causes laminar boundary layer vortex shedding noise with frequency varying along the propeller radius, thus resulting in a high-frequency hump. Casalino et al. [2, 3] showed that, under clean inflow conditions, the mean behavior of the LSB is mostly determined by the propeller advance ratio; furthermore, in hovering, the mean LSB is

unaffected by the recirculating flow in the testing environment.

Most of the work on rotors in turbulent inflow focuses on helicopter and engine rotors, typically operating at higher Reynolds numbers, and they do not consider the effect of turbulence on LSB. Sevik [7] proposed a prediction method of turbulence ingestion noise based on the two-dimensional aerodynamic response function and dipolar radiation pattern of the unsteady loading. This retrieved the broadband component of the acoustic spectrum but missed the quasi-tonal content. Blake [8] recovered the latter by introducing blade-to-blade correlation. Hanson [9] attributed the quasi-tonal noise to the streamwise elongation of the eddies that, chopped several times by the rotor, produce blade-to-blade coherence in the unsteady loading. This is reflected in the narrow-band content around the BPF harmonics in the acoustic spectrum.

Amiet extended the prediction model for airfoils in turbulent inflow [10] to the case of rotating blades [11] approximating the circular motion to a rectilinear motion in the limit of acoustic frequencies much higher than the rotational one. The model obtains the acoustic spectrum from the characteristics of incoming turbulence through an acoustic transfer function, neglecting the effects of turbulence distortion. Capobianchi et al. [12] employed two analytical models based on Amiet's theory for noise prediction: the first one considers turbulence characteristics at a specific representative radial location while the second accounts for blade geometry and turbulence parameters along the blade and exploits the inverse strip theory [13], providing better results. Raposo et al. [14] proposed a prediction model that includes the effects of rotation and spanwise coherence. They proved that Amiet's model recovers the haystacking tones when revised with a correct calculation of the time between two consecutive chops of the same eddy. They highlighted that haystacking is underpredicted when the integral length scale of the flow is large compared to the blade, likely because of the lack of spanwise correlation in the direct strip approach adopted. In these studies, the effect of including turbulence distortion in Amiet 's model is not considered.

The purpose of this study is two-fold. First, the analysis of turbulence near the leading edge reveals the effect of the propeller-induced flow field on the turbulent inflow, inspecting the validity of the assumptions of Amiet 's model. The effect of including turbulence distortion in Amiet 's model prediction will be presented in future work. Additionally, the solid formulation of the FWH analogy, applied to the propeller surface, allows to characterize the effects of ingested turbulence on the aerodynamic sources across different frequency ranges. To address these points, three different setups (only turbulence, propeller in turbulent inflow, and propeller in clean inflow) have been simulated in PowerFLOW 6-2022-R1 3DS.

The paper is structured as follows: the numerical setup is described in sec.2.2 and validated in sec.2.3. In sec.3 the main results are discussed, and sec.4 summarizes the conclusions of this work.

2. METHODOLOGY

2.1 Computational method

The study is based on data obtained with PowerFLOW 6-2022-R1, based on a Lattice-Boltzmann Method (LBM). Here, the only unknown quantity is the particle-probability distribution function $f(\mathbf{x}, t, \mathbf{v})$, representing the probability for a particle at location $\mathbf{x}$ and instant t to have velocity $\mathbf{v}$. The macroscopic quantities are retrieved from the statistical moments of f. The evolution of $f(\mathbf{x}, t, \mathbf{v})$ is described by the Boltzmann equation, which relies on gas-kinetic theory. The discrete Boltzmann equation is then solved on a Cartesian mesh, whose base elements are called voxels, whose size halves from a resolution region to the next finer one. Since reaching a y^+ lower than 1 in a Cartesian mesh is computationally prohibitive, a fully turbulent wall function model, extended to include the effects of pressure gradient, is adopted in this work.

2.2 Numerical setup

The computational domain is a cube with a side length of 100 D_{prop}. The region of interest with the turbulence grid and the propeller is located at the center of the computational domain, which is discretized into 17 Variable Resolution (VR) regions, numbered from 0 to 16, gradually increasing the resolution from the outer region to the area of interest. VR11 resolves the turbulence from the grid to $2D_{prop}$ downstream of the propeller plane, to enclose the nacelle. The voxel size in this region is 0.88 mm. 5 inner levels, defined as offsets of the blades, are introduced to achieve a $y^+_{MAX} \approx 9$ at the wall to capture the separation bubble [2, 3]. The total number of voxels in the computational domain is approximately 1.2×10^7, with the smallest voxel size equal to 0.03 mm. The numerical setup (fig.1) reproduces the experimental one [12]. The flow exits from a cylindrical pipe with a diameter $D = 0.6m$, whose wall is treated as frictionless. The turbulence grid

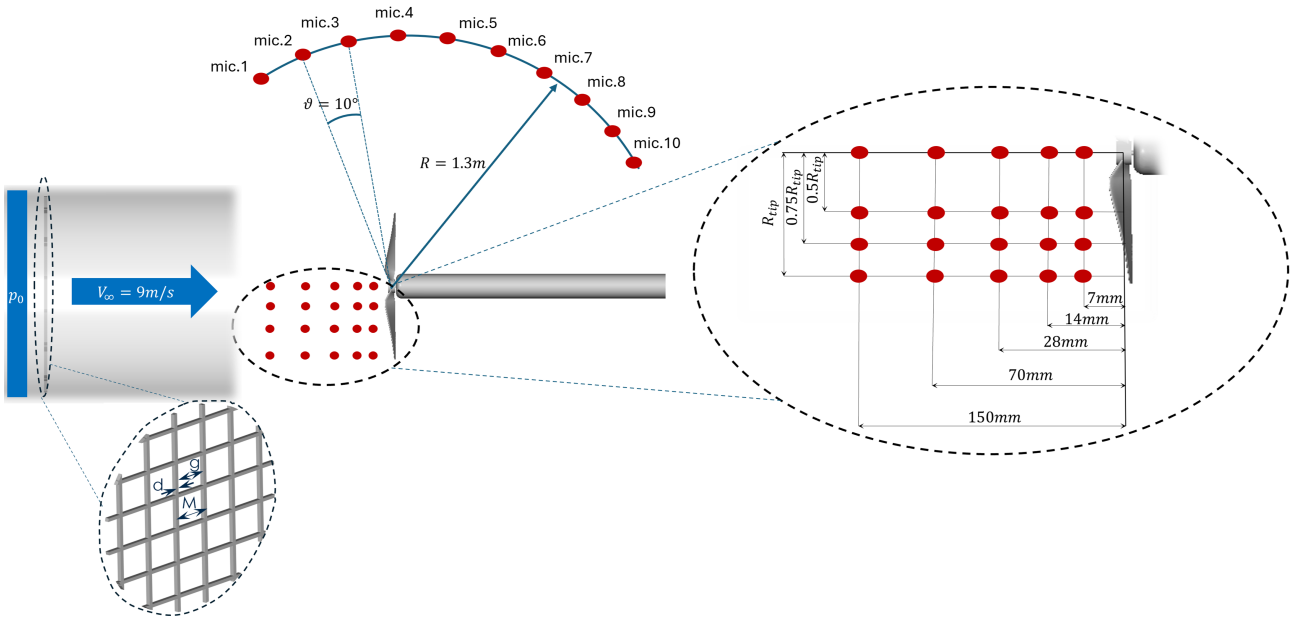

Figure 1: Numerical setup and turbulence grid - $g = 9cm$, $d = 1cm$, $M = 10cm$

is enclosed into the pipe $0.6m$ upstream from the exit and at $1m$ from the propeller plane. The propeller is the same as previous works [2, 5, 15]; the diameter is $0.3m$ and the airfoil profile is the NACA-4412. The rotational speed is $\Omega = 6000RPM$.

The total pressure p_0 is prescribed as a boundary condition upstream of the grid to match the reference mean velocity value $V_\infty = 9m/s$. It is computed accounting for the local pressure losses introduced by the grid, Δp^0 as [16]:

$$\frac{\Delta p^0}{q} = A\left(\frac{1}{\beta^2} - 1\right)^B, \tag{1}$$

where q is the upstream dynamic pressure, β is the grid porosity, and A and B are functions of Reynolds number, Mach number, and grid geometry. For a square-mesh grid, porosity is given by:

$$\beta = \left(1 - \frac{d}{M}\right)^2 \tag{2}$$

Free-stream and ambient static pressure are imposed as boundary conditions at the borders of the computational domain to prevent flow recirculation.

20 probes are distributed upstream of the propeller plane to characterize the inflow (fig.1). After 3 initial settling revolutions, data are sampled for 10 revolutions with sampling frequency $f_s = 20kHz$. The signal is then divided into 4 Welch blocks with 50% overlap, resulting in a resolution frequency $\Delta f = 20Hz$. Surface pressure is sampled at $f_s = 367kHz$ with a spatial averaging of $0.4mm$ over the propeller and nacelle surfaces to feed the FWH analogy and obtain acoustic spectra.

The setup for the clean case is obtained by removing the turbulence grid and resetting the total pressure. In addition, VR 11, previously used to resolve incoming turbulence, is reduced to an offset of the propeller to keep the same resolution at the propeller while reducing the computational cost.

2.3 Validation

Grid convergence is assessed for all tested cases and the results are validated against data from the reference experiment [12]. Two meshes (coarse and medium) are analyzed. The results of the fine resolution will be presented in the future. The characteristic length M (fig.1) is discretized with 80 and 120 voxels for the coarse and medium grid, respectively.

Since the load cell was not used in the experiment, the numerical thrust and torque coefficients, C_T and C_Q, are compared in tab.1 with the ones available in the literature [2], obtained through a BEMT approach. A good match

is observed for all the meshes, with the C_T from the LBM being slightly lower than BEMT prediction.

Table 1: Convergence of C_T and C_Q

	Coarse	Medium	BEMT ([2])
C_T	0.087	0.088	0.09
C_Q	0.008	0.0081	0.008

Table 2 compares the mean velocity V_m, the turbulence intensity TI, and the turbulence integral time scale T_{uu} obtained from the numerical simulations and the experiments at $x/R_{tip} = 1$, $r/R_{tip} = 0.5$ without and with the propeller. The integral time scale T_{uu} is used in the table because the mean velocity gradients introduced by the propeller invalidate Taylor's hypothesis for the computation of the integral length scale $\Lambda_{uu,x}$.

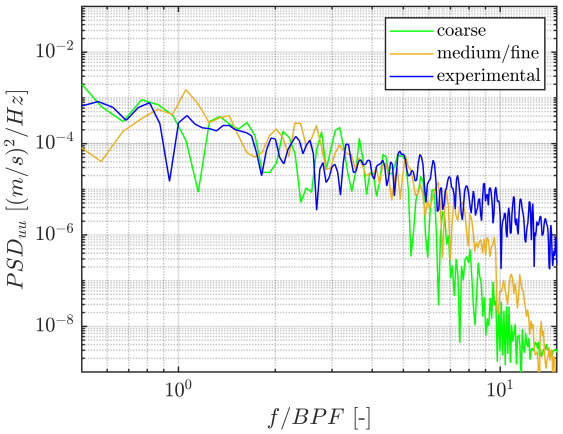
Table 2: Flow quantities at $x/R_{tip} = 1$, $\frac{r}{R_{tip}} = 0.5$

	$V_m[m/s]$		$TI[\%]$		$T_{uu}[s]$	
	Num.	Exp.	Num.	Exp.	Num.	Exp.
wo prop.	9.55	9	6.98	7.13	0.17	0.25
with prop.	10.3	9.68	6.3	6.4	0.16	0.2

Mean velocity and velocity fluctuations are computed considering the velocity measured by the hot wire as described by Zamponi et al. [17].

The integral time scale T_{uu} is obtained as the integral of the autocorrelation function in the interval from its maximum to the point where it decreases to $1/e^2$ [17]. For the case with turbulent inflow, the phase-locked average is subtracted from the instantaneous signal to remove the periodicity introduced by the blade passage. Numerical and experimental results show good agreement, with the numerical V_m being up to $0.6m/s$ higher than the experimental one.

Similarly, the comparison of the turbulence spectra (fig. 2) shows a good agreement on the frequency range considered. The drop in the spectra at the 5^{th} and 8^{th} harmonics of the Blade Passing Frequency (BPF) in the coarse and medium/fine cases, respectively, is due to the filtering effect of the mesh. The numerical scheme requires at least 10 voxels per wavelength to resolve the wave. An increase in the overall resolution will solve the turbulence up to the 10^{th} BPF harmonic, but the computational cost will be prohibitive. However, as proved later, the far-field noise is well captured making the increase of computational cost not needed for the scope of this paper.



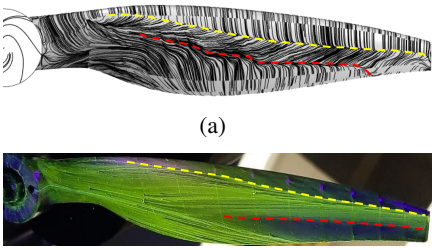


Figure 2: Turbulence spectrum at $x = 1R$, $r/R = 0.5$ without propeller

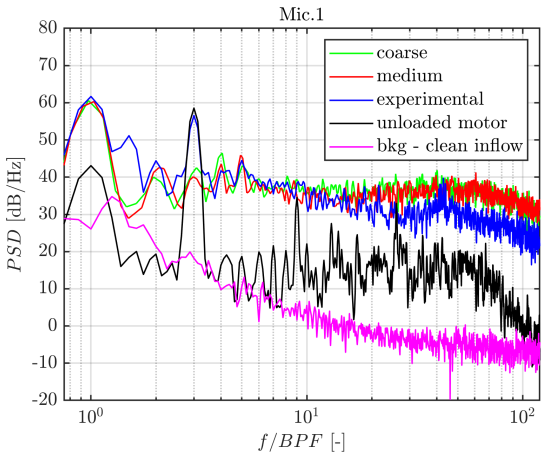
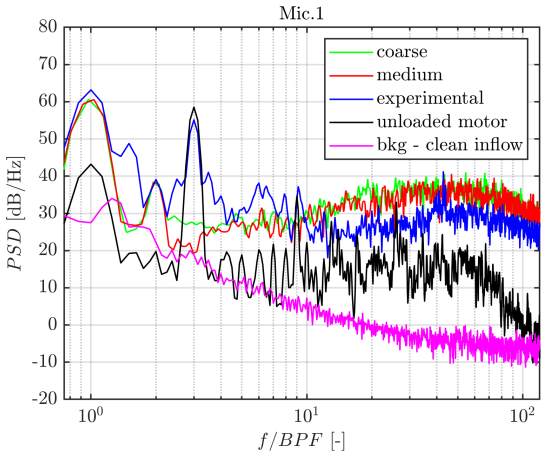
(a)



(b)

Figure 3: Time-averaged surface streamlines 3(a) and oil flow visualization 3(b)



To further support the validation of the numerical database, the time-averaged surface streamlines are compared with oil flow visualization in fig. 3 only for the turbulent case, for conciseness. Separation and reattachment lines, indicated by yellow and red dotted lines, respectively, are slightly delayed with respect to the experimental result. This can be due to the still high y^+, the adopted wall model, and the slightly higher mean velocity in the numerical simulations. Improvement in fine resolution is expected. The effect of different wall models on the LSB prediction will be the objective of future studies.

Acoustic spectrum at mic.1 (fig. 1) is shown for both the turbulent (fig.4(a)) and clean (fig.4(b)) inflows. The slight underprediction (less than $2dB$) at the 1^{st} harmonic, mostly influenced by steady loading and thickness noise, is likely due to the higher numerical mean velocity, which

reduces the steady loading, consequently under-predicting C_T. The experimental result at the third harmonic is dominated by motor noise, while the tones at half of the BPF harmonic originate from the motor shaft frequency. For the clean inflow case, the difference between numerical and experimental results from the 3^{th} to the 8^{th} BPF harmonic is likely due to the loaded motor noise, not present in the simulations. The over-prediction at frequencies higher than the 20^{th} harmonic is ascribed to inaccuracies in reattachment point prediction. The mesh refinement from coarse to medium does not affect the acoustics.

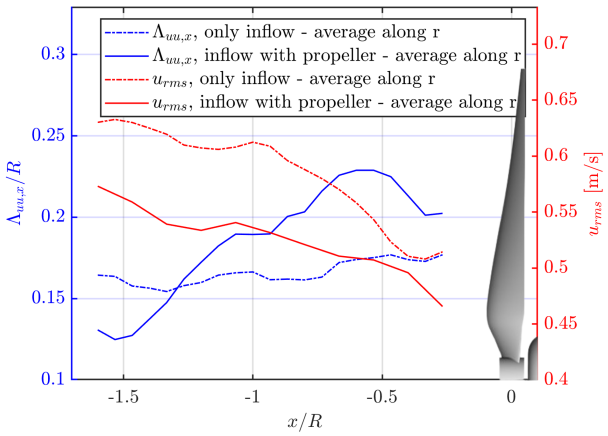
3. RESULTS AND DISCUSSION

3.1 Characterization of turbulence

3.1.1 Absolute frame of reference



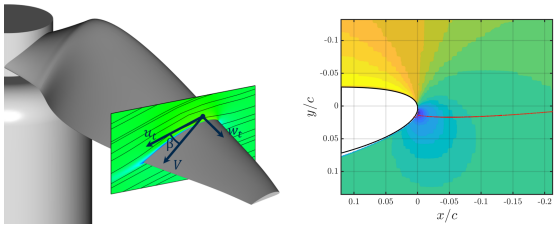


Figure 5: $\Lambda_{uu,x}(x)$ and $u_{rms}(x)$, radially averaged, with and without the propeller

Figure 5 shows the evolution of the integral length scale $\Lambda_{uu,x}(x)$ and root mean square $u_{rms}(x)$, with and without the propeller. The quantities have been radially averaged to highlight the general trend, although inhomogeneity remains present along the span. It can be observed that, without the propeller, $\Lambda_{uu,x}$ is almost constant, with $\Lambda_{uu,x} \approx 2.4cm$. In the presence of the propeller, the integral length scale grows faster approaching the propeller plane, as a result of the stream tube contraction. $u_{rms}(x)$ presents lower values and a faster decay in the presence of the propeller because of the stream tube contraction that, while elongating the eddies in the streamwise direction, reduces the fluctuation of the axial component.

3.1.2 Relative frame of reference

The analysis presented in this section refers to a plane at $r/R_{tip} = 60\%$ in the rotating frame of reference, normal to the spanwise direction (fig. 6(a)). The in-plane components, u, and v are projected along the mean local direction to obtain u_t and v_t, the tangential and normal components, respectively, relative to the mean streamline (fig. 6(b)), while w_t is the out-of-plane component.

Figure 7 presents the root mean square of the three velocity components along the mean stagnation line. Approaching the propeller plane, u_t decelerates and $u_{t,rms}$ decreases, while $v_{t,rms}$ increases, and w_t shows a weaker

(a) (b)

Figure 6: (a) Visualization of the rotating frame of reference and (b) mean stagnation line s at $r/R = 60\%$

increase. This observation suggests a momentum transfer from u_t to v_t, aligning with the physical description of the Rapid Distortion Theory (RDT) [18] showed with the dashed line in the figures.

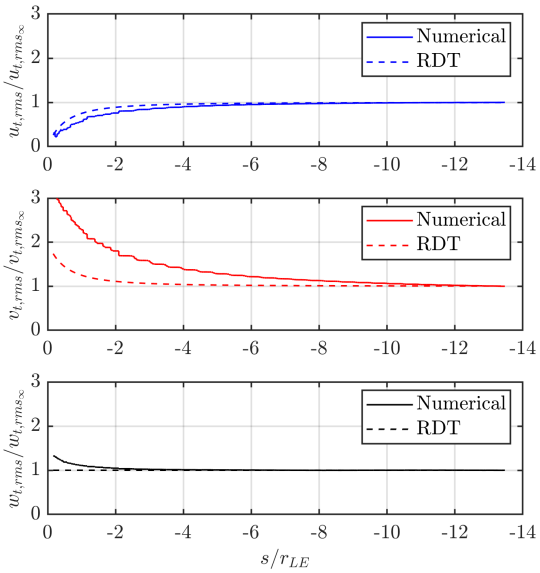

Figure 7: $u'_{t,rms}$, $v'_{t,rms}$ and $w'_{t,rms}$ along the mean stagnation line

More specifically, $u_{t,rms}$ obtained from the numerical simulations follows the RDT prediction well up to $-4r_{LE}$, then approaching the stagnation point it decreases a bit faster than predicted; $v_{t,rms}$ diverges from the RDT prediction already at $s = -10r_{LE}$, reaching values up to 3 times the undisturbed level. The early increase in $v_{t,rms}$, occurring before the decrease in $u_{t,rms}$, suggests the existence of an additional mechanism - beyond the momentum transfer from the streamwise component - that enhances $v_{t,rms}$. In this case, a possible explanation can lie in the curvature of the mean streamline, which is not accounted for in RDT: streamwise velocity fluctuations induce oscillations in the centrifugal force acting on fluid particles, leading to fluctuations in the radial pressure gradient. These fluctuations influence the normal velocity component. To validate this hypothesis, a comparison with a 2D simulation of a wing section will be conducted in future studies.

Figure 8 shows the spatial distribution of the integral length scales $\Lambda_{u_t u_t,s}(s)$ and $\Lambda_{v_t v_t,span}(s)$ along the mean stagnation line. These quantities are normalized with respect to their value at $s/r_{LE} = -6$. Approaching the leading edge, $\Lambda_{u_t u_t,s}(s)$ decreases, while $\Lambda_{v_t v_t,span}(s)$ increases. This indicates that vortices are compressed against the leading edge and elongated in the spanwise direction, enhancing the spanwise coherence of normal velocity fluctuations.

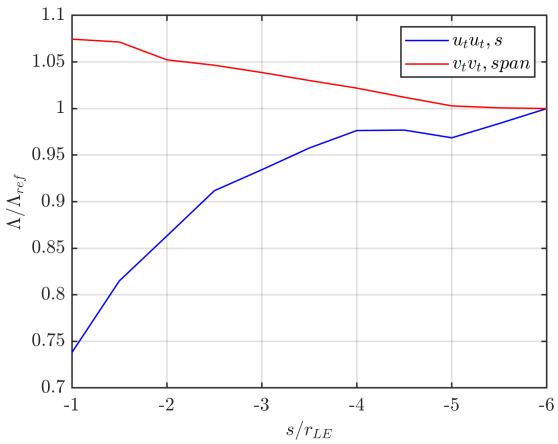

Figure 8: Spatial distribution of the integral length scales $\Lambda_{u_t u_t,s}(s)$ and $\Lambda_{v_t v_t,span}(s)$ along the mean stagnation line

3.2 Laminar separation bubble

The time-averaged surface streamlines, superimposed to the standard deviation of the surface pressure fluctuations coefficient c_{p_σ}, are shown in fig. 9 for both turbulent and clean inflows. No significant difference is observed in the mean flow features of the LSB, visualized through

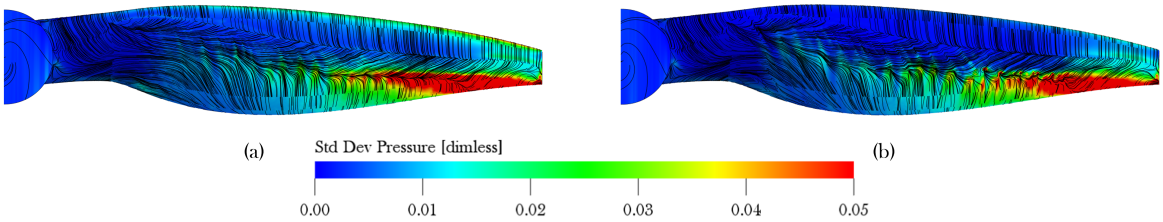

Figure 9: Time-averaged surface streamlines, superimposed to the standard deviation of the surface pressure fluctuations coefficient c_{p_σ} over the blade surface for turbulent (a) and clean (b) inflow

the surface streamlines. The impact of turbulence on noise sources becomes evident by looking at c_{p_σ}. Incoming turbulence increases the amplitude of the surface pressure fluctuations at the leading edge, along the separation line, and inside the bubble itself. This suggests that incoming turbulence enhances the unsteadiness of the LSB.

3.3 Far-field noise

Figure 10 shows the far-field noise spectrum at mic.1 for the turbulent and clean inflows, while the noise sources are described in fig. 11.

Ingested turbulence increases broadband noise up to the 30^{th} harmonic and introduces tones at the harmonics higher than the 2^{nd}. The first harmonic is dominated by the steady loading and therefore is not affected by the presence of free-stream turbulence. At $f > 30BPF$, where trailing-edge noise is the dominant source, all the spectra collapse meaning that the surface pressure fluctuations at the trailing edge are weakly affected by the inflow turbulence .

Figure 11 shows the constructive (CP) and destructive (DP) contribution maps, expressed in dB, to the far-field noise at mic.1 in the frequency $1.3kHz < f < 1.5kHz$, where the difference between the turbulent and clean acoustic spectra is $5dB$. CP and DP are computed from the coherence between the acoustic pressure radiated from the surface element and the total acoustic pressure at the same location ([3]). The CP map shows noise sources, that constructively interfere, due to inflow turbulence at the leading edge and on the suction side up to the laminar separation bubble. The DP map shows that the leading edge, in clean inflow, generates destructive contribution in this frequency range, which is canceled in the turbulent case. After reattachment, the sources are influenced by the mean LSB characteristics and therefore they are not affected by the ingested turbulence.

4. CONCLUSIONS

This paper investigated the interaction of a low Reynolds propeller with incoming turbulence, both in terms of turbulence distortion and the impact of turbulence on the generated far-field noise. Streamtube contraction induces elongation of the largest eddies in the streamwise direction, reducing the intensity of u_{rms}, while the leading

edge distortion increases the intensity and spanwise coherence of normal fluctuations. These results will be exploited in a future work to evaluate the performances of Amiet's model when turbulence distortion is taken into account. In addition, incoming turbulence was shown to have an impact on the unsteady behavior of the laminar separation bubble, increasing the unsteady loading on the blade. In this configuration, trailing edge noise is not affected by ingested turbulence.

A STUDY OF URBAN AIR MOBILITY ROTOR NOISE AT MODERATE REYNOLDS NUMBERS WITH COLLECTIVE PITCH CONTROL.

Charles E. Tinney[1†] **John Valdez**[1] **Yingjun Zhao-Dubuc**[1]
[1] Applied Research Laboratories, The University of Texas at Austin, Austin, Texas, USA
https://www.arlut.utexas.edu/gdl

ABSTRACT

Measurements of hover performance and acoustics of a Mach-tip scaled notional rotor for urban air mobility is presented. The blade shape is a 35% geometrically scaled replica of an earlier generation Joby rotor blade first studied by Tinney and Valdez [1] and is evaluated for changes to blade tip Mach number (between 0.28 and 0.40), rotor collective pitch angle, as well as rotor solidity (number of blades). The findings demonstrate that, in general, sound levels decay with increasing collective pitch angle, while they increase with increasing blade count. A delay in the collective pitch angle, where decreasing noise transitions to increasing noise with increasing collective, is also observed. When using thrust coefficient as the performance metric for comparing different rotor operating conditions, the transition point from decreasing noise to increasing noise is delayed to higher collective pitch angles as blade count increases. This tends to occur for the same range of rotor figures of merit between 0.65 and 0.70; peak hover efficiency is found for a figure of merit of 0.75. The findings provide a first principals understanding of the tradespace between hover performance and acoustics using a UAM relevant blade shape at Reynolds numbers of practical importance.

1. BACKGROUND

A low noise rotor capable of efficient take-off, landing and hovering operations is a prerequisite to the successful integration of urban air mobility (UAM) vehicles into the transportation network. This is an ambitious undertaking as the features of the blade that enhance propulsive efficiency in either hover or forward flight are different from the ones that are needed for low noise operations. To develop a blade shape that can satisfy all of these targets requires a contemporaneous understanding (either measured or simulated) of both rotor performance and its sound field, and at scales that are large enough to overcome Reynolds number effects. The last of these is problematic for most indoor test facilities and has averted the refinement of some rotor noise prediction methods, especially lower-fidelity approaches that lean on experimental validation for confidence. A second issue is concerned with identifying a metric that can capture community annoyance. One of the most commonly adopted metrics for static rotor noise tests is overall sound pressure level (OASPL). Corrections for human perception effects using well established weighting functions are easily incorporated into the OASPL metric and can improve insight into the effect of rotor operating conditions on community annoyance. Though these traditional metrics may not be the best indicators of annoyance, and one might consider other metrics that are designed to be sensitive to impulsive and distorted features in the acoustic waveform [2].

In this study, we present measurements from a test campaign performed in 2022 at The University of Texas at Austin to characterize the hover performance and acoustics of a notional UAM (or eVTOL) rotor blade. A description of this database was first presented by Tinney and Valdez [1] and focused mostly on reporting experi-

mental uncertainties and characterizing facility enclosure effects. Unlike a number of the laboratory-scale rotor tests being reported in the open literature using fixed pitch drone scale rotors, the rotor geometry studied here is a Mach tip scale rotor with collective pitch control, and with chord and twist distributions that are representative of the ones found on nearly all UAM platforms. An analysis of the trade-space between hover performance and perceived noise using this notional UAM rotor blade is presented for different blade number combinations and collective pitch settings of the rotor. The results are part of a larger effort by this group to characterize the performance and acoustic trade space of these unique UAM rotors and are complementary to the experimental and numerical studies reported by Brentner et al. [3], Baskaran et al. [4], and Pascioni et al. [5].

2. HARDWARE AND SETUP

Hover performance and acoustic measurements of a 35% scale UAM rotor were acquired in the Gas Dynamics Laboratory (GDL) of the Applied Research Laboratories, The University of Texas at Austin (ARL-UT). The GDL is a fully enclosed and acoustically treated laboratory encompassing $\dot{V} = 30,100$ ft^3 of climate controlled open air space over 1,500 ft^2 of floor space with an average ceiling height of 21 ft. ARL-UT is located in Austin, Texas near sea-level conditions ($p_\infty = 14.7$ psia (103,325 Pa), $T_\infty = 529$ R (294 K), $\gamma = 1.4$, $\rho = 2.33 \times 10^{-3}$ slug/ft^3) with a sound speed of air being estimated at $a_\infty = 1128$ ft/s. The blade is fabricated from 6061 aluminum using CNC machining and is a geometrically scaled replica of the blade shape flown on an earlier generation Joby Aviation prototype vehicle in 2017 and described recently by Stoll and Bevirt [6]. The 35% scale blade has a diameter of $D = 39.96$ in. (0.665 m) and has non-uniform chord and twist distributions, as shown in Fig. 1a where $cmax = 3.2976$ in. while the blade twist at the root is $\beta_0 = 26.15$ deg. Changes to rotor solidity were evaluated by changing the blade count from $N_b = 2$ to 5, thereby resulting in changes to the blade area from $A_b = 110$ in^2 to 276 in^2, respectively. Additional details concerning the GDL at ARL:UT, as well as the rotor and test stand are provided by Tinney and Valdez [1].

During testing, a magnetic rotary encoder tracks and records the angular speed and phase to within 0.0879 deg over the full duration of testing while a triad of hi-torque servos control collective pitch angles over the range $0 \leq \alpha \leq 18$ in $\delta\alpha = 3$ deg. increments. Blade pitch angles are routinely measured using a 0.1 deg accurate inclinometer while rotor collectives are referenced to a blade pitch angle of zero at $r = 0.75R$. An image of the 5-bladed rotor during testing is shown in Fig. 2. A test matrix of available databases that have been generated for this rotor is provided in Table 1. Symbols identified by (●) pertain to databases encompassing hover performance measurements only, whereas (▶) identify measurements comprising both performance and acoustics. Only a subset of this database will be used in the current discussion. The peak Reynolds numbers ($\mathrm{Re}_c = u(r)c(r)/\nu$) for these three rotor speeds occur at $r/R = 0.82$ and are valued at $Re_c = [3.7, 4.3, 4.9] \times 10^5$ with blade tip Mach numbers $M_t = \Omega R/a_\infty$ valued at 0.28, and 0.32, and 0.37, respectively.

3. HOVER SLIPSTREAM

Visualizations of the rotor slipstream were realized using a laser with sheet forming optics and a high-speed digital camera synchronized to the 1/rev magnetic encoded. The flow is seeded using a combination of atomized olive oil and glyceron fog with particle sizes ranging between 1-10μm; this is the same kind of setup used for Particle Image Velocimetry [7, 8]. The laser sheet is 2-3mm thick and is aligned with the quarter-chord of the blade to capture the tip-vortices, slipstream and blade wake generated by the different rotor configurations in hover. This is shown for the 3-bladed rotor in Fig. 3 at $\alpha = 12$ deg pitch and $M_t = 0.28$ (grid lines have increments of $0.1R$). The image is a pseudo-instantaneous snapshot made up of several images that are combine using Adobe Photoshop v.24. The process involves substitution (not addition or averaging) and works well for this kind of flow. Vortex centers are identified by hand (no vortex centering technique) and are labeled in degrees according to their wake age, ψ_v. The image is rich with information that is expected of this kind of flow. That is, the large radial displacement of the tip vortex up until the first blade pass is observed, followed by an abrupt change in its trajectory towards large axial displacements and increased vortex wander. Between the first and second blade passes, the blade wake passes from the roll-up of the first tip vortex, down to the second. The downwash reveals strong radial dependence at this rotor collective setting with the largest values residing at approximately 30% of the rotor radius. At higher rotor collectives (not shown) the downwash is relatively uniform across the slipstream. A broad range of turbulence scales are observed in the blade wake, while streamlines corresponding to the slipstream between subsequent blade wakes are smooth. This suggest that the rotor inflow is relatively free of turbulence.

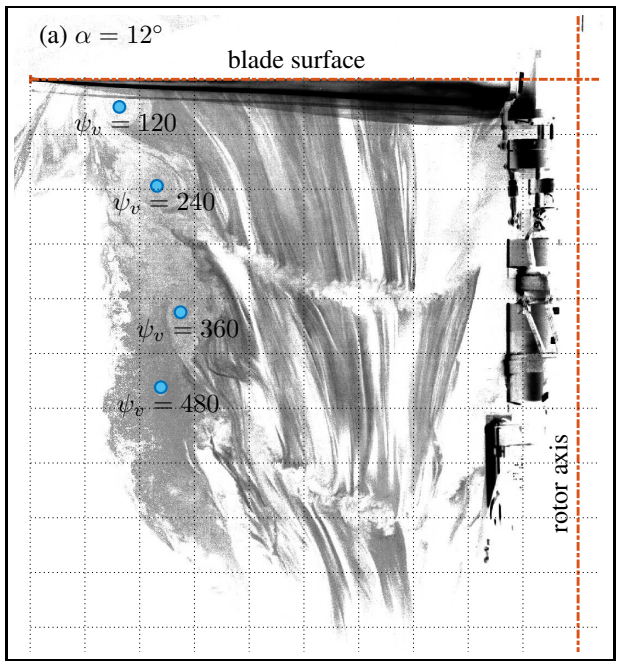

Figure 3. Visualization of the rotor wake generated by the 3-blade rotor at $\alpha = 12$ deg pitch and $M_t = 0.28$.

4. HOVER PERFORMANCE

Rotor torque and thrust were measured using an Interface Model 1216 bi-axial load cell with a 1000-lbf axial force T range (± 0.4 lbf) and a 500 lbf-in. torque Q range (± 0.35 lbf-in.). For each rotor condition, a minimum of three tests were conducted with each test encompassing 32.77 s of interrupted recordings. Measurements were recorded after the wake had stabilized and with the rotor disk elevated three rotor diameters above the facility floor [9]. Thrust coefficient $C_T = F_z/(\rho A(\Omega R)^2)$, power coefficient $C_P = \tau\Omega/(\rho A(\Omega R)^3)$ and rotor figure of merit $FM = C_T^{3/2}/(\sqrt{2}C_P)$ were calculated where $A = \pi D^2/4$ is the disk area, $\Omega = 2\pi\omega$ is the motor rotation speed in rad/s, and $P = Q\Omega$. Large changes in the facility time-scale ($t_v = \dot{V}/Av_i$ where $v_i = \lambda_i \Omega R$ is the rotor inflow and $\lambda_i = \sqrt{C_T/2}$), were observe and found to range from 351 s (for low collective settings of the 2-bladed rotor) to 96 s for the 5-bladed rotor at $\alpha = 15$ deg. collective. Blade loading coefficients (C_P/σ and C_T/σ) are shown in Fig. 4a for different blade number combinations and increasing collective pitch control. Hover efficiency is then reported in Fig. 4b for the same conditions

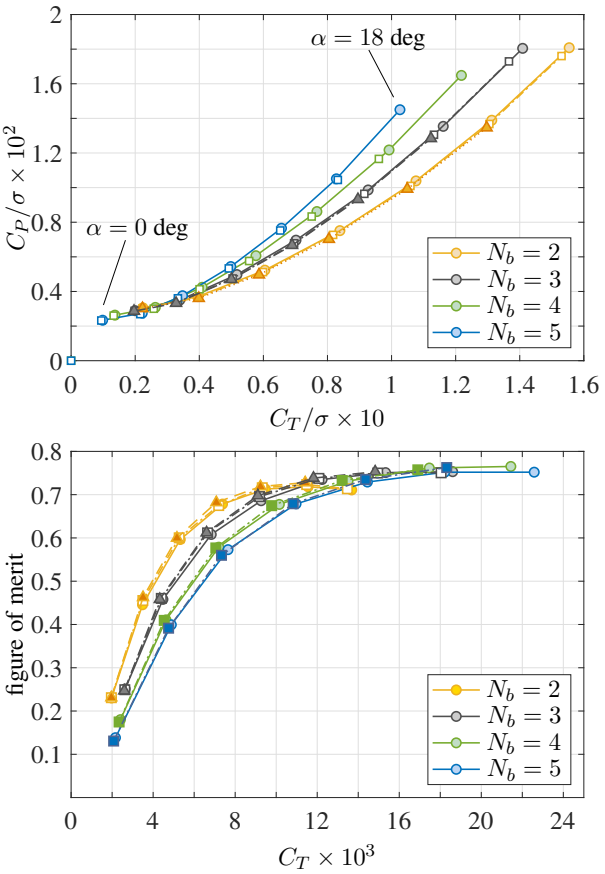

Figure 4. a) Blade loading coefficient and b) figure of merit for $M_t = 0.28$.

where colors are used to distinguish between blade numbers while symbols identify different rotor speeds. Low thrust coefficient and low figure of merit corresponds to low collective, while high thrust coefficient identifies the largest collective setting of the rotors. Peak figure of merit is valued at 0.75 and is achieved by the 4-bladed and 5-bladed rotors. The thrust coefficient where peak hover efficiency is achieved increases with blade count. For a given blade number count, increases to rotor speed have negligible effect on hover performance, thereby demonstrating that the performance of this scale rotor appears to be independent of Reynolds number effects.

5. HOVER ACOUSTICS

The sound field generated by this rotor was captured using a line array of 12 G.R.A.S. IEPE-type free-field microphones (combination of quarter-inch and half-inch capsules). Data was recorded uninterrupted for 20.48 s at 50 kHz sample rate using two NI-PXI-4472 boards (24-bit A/D converters with Butterworth filters). The microphone array was positioned so that the forth sensor was located at the rotor disk plane with remaining sensors being biased towards observers located below the rotor. The array was then traversed radially to create a 2D grid of measurements between $1.0 \leq r/D \leq 3.5$ in increments of $\delta r/D = 0.5$. Ensemble averaged sound pressure spectrum levels (SPSL, re: 20μPa) are computed using a hanning window with 75% overlap and a spectral resolution of $f_s/N = \delta f = 2.0345$ Hz. Microphone corrections (diffraction effects) are implemented following manufacturer guidelines [10]. In Fig. 5, a comparison between facility noise, motor noise and noise from the rotor are shown for an observer located below the rotor disk plane. Motor noise penetrates the rotor noise spectra at the fifth bpf harmonic, but is otherwise too low to contaminate the rotor noise measurement.

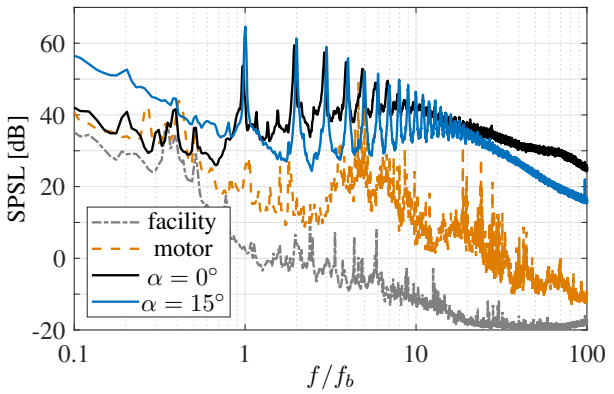

Figure 5. Sound pressure spectrum level [dB, re: 20μPa] of the facility background noise, motor noise and rotor noise at $M_t = 0.28$ for two pitch angles of the 5-bladed rotor as seen by a ground observer.

For the same observer and rotor operating conditions, the effect of blade pitch on the SPSL is shown in Fig. 6 with subsequent spectra being shifted by 20 dB to reduce clutter. An increase in rotor collective from $\alpha = 0$ deg to 6 deg is shown to shift rotor broadband noise to higher frequencies and is attributed to a reduction in blade vortex interaction noise. For $\alpha \geq 6$ deg, and higher, the characteristic frequency of the broadband noise hump is unaffected by changes in rotor collective, or the changes are too small to quantify.

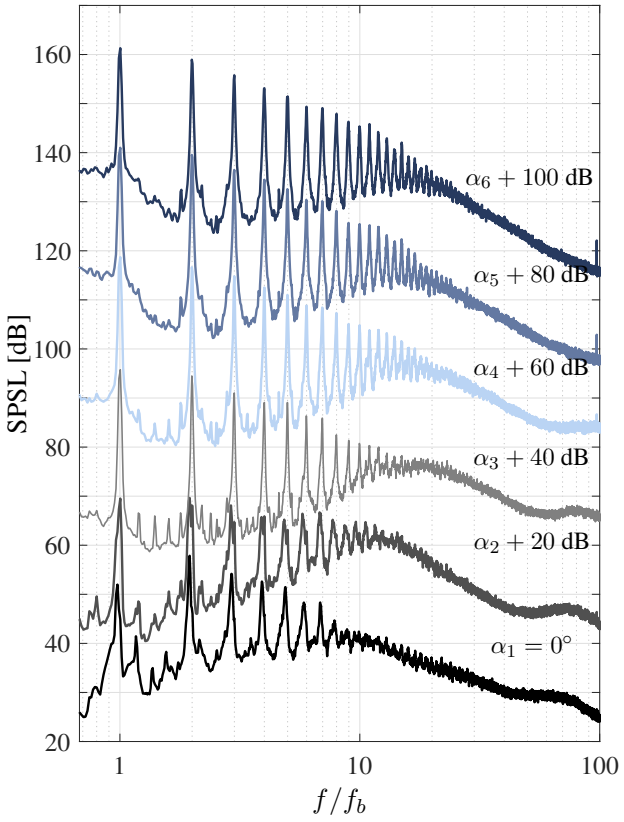

Figure 6. Effect of blade pitch angle on SPSL [dB] for an observer located at $r/D = 2.5$ at the a) rotor disk plane, and b) below ($\theta = -38$ deg). This is for the 5-bladed rotor at $M_t = 0.28$.

6. SCALING AND PERCEPTION

Rotor noise measurements are scaled to full scale conditions and then weighted using the A-weighting noise standard. Scaling is achieved by matching the product of Strouhol number with Mach number which produces Helmholtz number $H_m = fD/(\Omega R) \cdot M_{tip}$. Since blade tip Mach numbers are matched, the scaling reduces to changes in the source frequency using $f^* = \xi f$, where ξ is the geometrical scale factor between the laboratory and full-scale blades and is valued at 0.35. A demonstration of this is shown in Fig. 7 where both unweighted (dB) and weighted (dBA) SPSL are shown for an observer located below the rotor disk plane for the 5-bladed rotor at 30 rps and 15 deg blade pitch. As expected, the effect of A-weighting is a significant reduction in rotor harmonic noise, while rotor broadband noise remains unaffected and is now the dominant noise source. The high frequency peaks are electrical noise and are not related to the rotor or test stand.

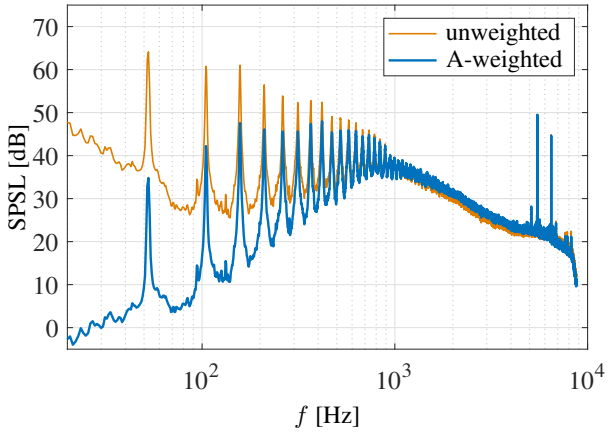

Figure 7. Scaled SPSL [dB] for the microphone observer located at $r/D = 3.05$ and $\theta = -35$ deg for the 5-bladed rotor operating at $M_t = 0.28$ and $\alpha = 15$ deg blade pitch.

The broader impacts of scaling and weighting the SPSL is demonstrated using contours of overall sound pressure level (OASPL) in Fig. 8 for the full 2D grid array. This is first demonstrated using the 3-bladed and 5-bladed configuration at $M_t = 0.28$ and $\alpha = 15$ deg pitch angle. Alongside these unweighted contours are contours of the scaled and weighted values. Comparing the two reveals the significant reductions in noise over all observer locations when human perception effects are included. As most of the low-frequencies associated with thickness and loading noise have been removed, self-noise from boundary layer turbulence on the pressure and suctions sides of the blade are shown to generate a sound field that is directive above and below the rotor. While these patterns signify dipole behavior, it is known that self-noise source mechanisms are quadrupoles and that their directivity is governed by the turbulence in the boundary layer whose spatial wavenumbers convect at speeds that allow them to become acoustically matched with the surrounding gas. The dipole shape is due to individual contributions of self-noise from the suction and high-pressure sides of the rotor. Fig. 8 shows this to be the case for both the 3-bladed and 5-bladed rotors.

Scaled and weighted SPSL are then evaluated in

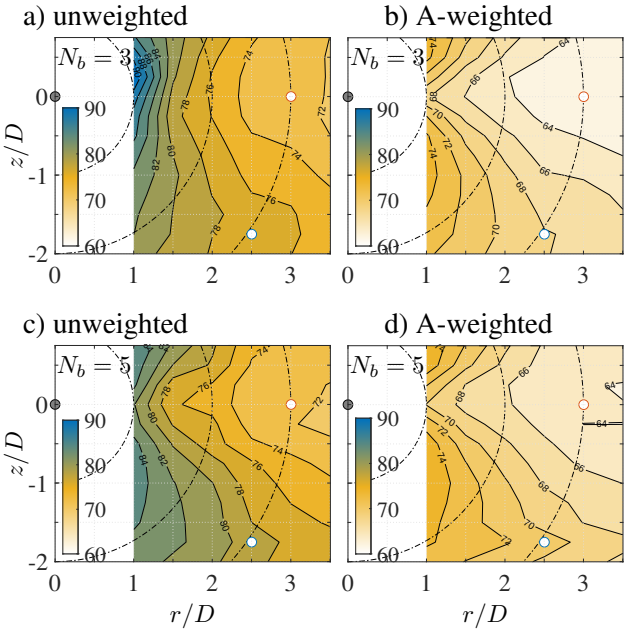

Figure 8. a,c) Unweighted and b,d) weighted OASPL at $M_t = 0.28$ and $\alpha = 15$ deg blade pitch for the a,b) 3-bladed and c,d) 5-bladed rotor.

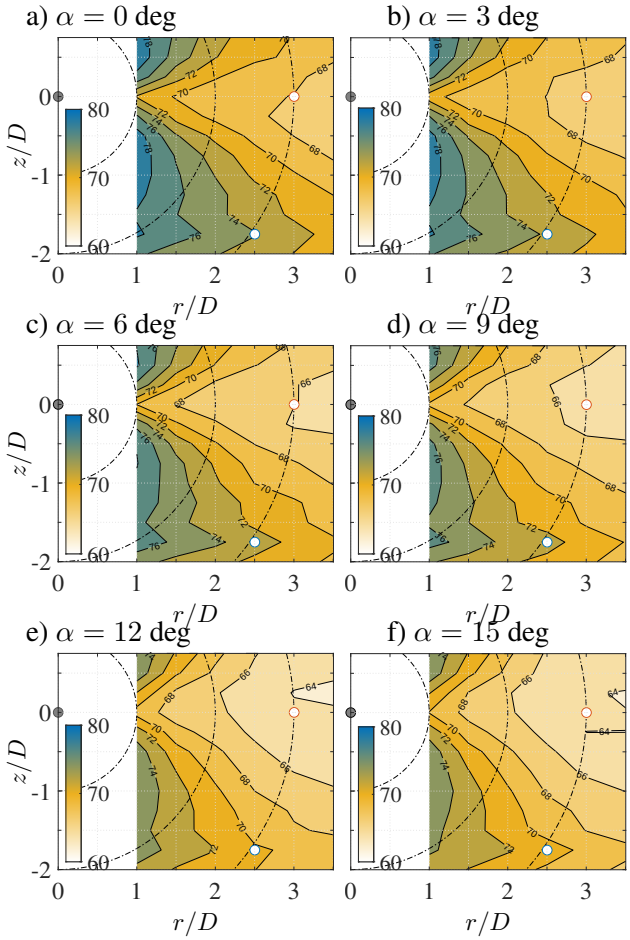

Figure 9. A-weighted OASPL at $M_t = 0.28$ for the 5-bladed rotor and all blade collective pitch angles.

Fig. 9 for all blade collectives to see the effect of rotor inflow on the self-noise. This is demonstrated using the 5-bladed rotor at $M_t = 0.28$. The contour decrements have been enhanced to accommodate the new A-weighted range of sound levels with each illustration comprising the same color scale so that direct comparisons can be made. The findings demonstrate negligible changes in contour shapes and sound directivity pattern on account of changes to rotor collective. Furthermore, OASPL levels are mostly unaffected by increasing rotor collective. In fact, at the highest collective pitch setting of $\alpha = 15$ deg, rotor noise amplitudes are shown to decrease over the entire observer space.

Scaled and weighted OASPL are now used to evaluate the trade-space between perceived noise and hover performance for all blade numbers and collective pitch settings. A presentation of findings from this can be overwhelming so the analysis is isolated to a single ground observer identified by blue circles in Figs 8 and 9; this is the same ground observer used to generate the SPSL in Fig. 7. The results are first reported in Figs. 10a and 10b without and with the effect of A-weighting, respectively, and with thrust coefficient as the performance metric. Starting with the 2-bladed and 3-bladed rotors, minimum perceived noise is achieved at moderate rotor collectives. As blade count advances to the 4-bladed and 5-bladed rotors, minimum perceived noise levels migrate towards higher rotor collectives thereby demonstrating that higher blade count rotors have increased inflow and subsequently generate more downwash which reduces the ingestion of turbulence from the wakes generated by preceding blades. For the 5-bladed configuration, the A-weighted noise decreases with increasing thrust, and complements the observations made concerning the contours in Fig. 9.

The same rotor conditions are then evaluated in Fig. 11 to reveal the trade-space between figure of merit and weighted/unweighted OASPL. For all blade number counts and at low hover efficiency conditions, as rotor collective increase, and consequently hover efficiency in-

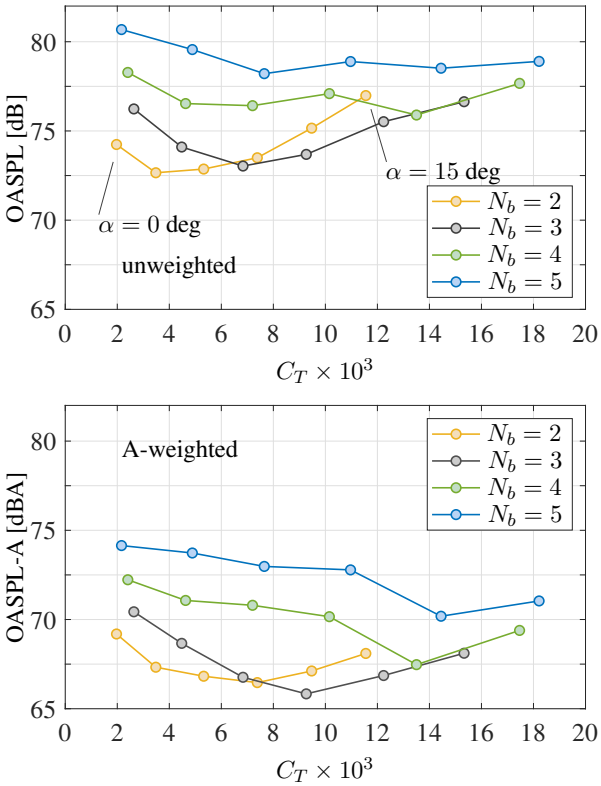

Figure 10. a) unweighted and b) weighted OASPL [dB] for the microphone observer located at $r/D = 3.05$ and $\theta = -35$ deg at $M_t = 0.28$.

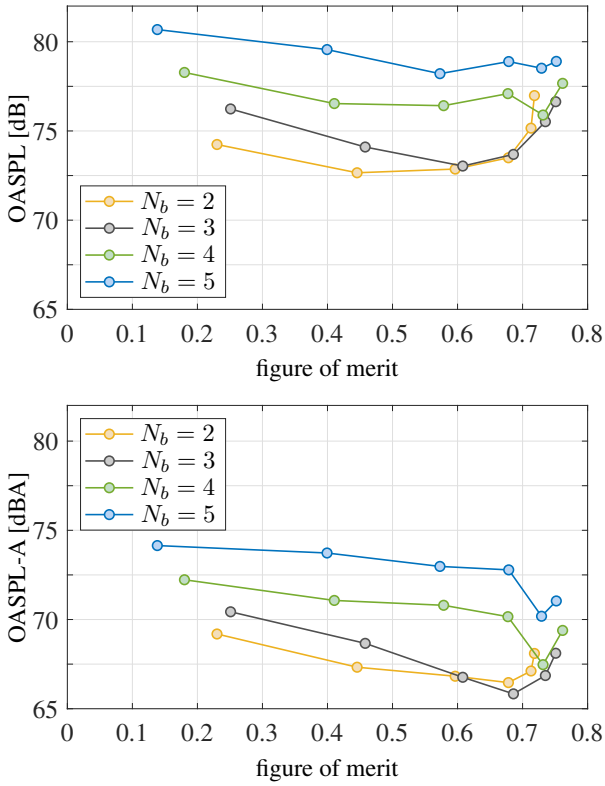

Figure 11. a) unweighted and b) weighted OASPL [dB] for the microphone observer located at $r/D = 3.05$ and $\theta = -35$ deg at 30 rps.

creases, perceived noise decreases. Eventually as the rate of change in hover efficiency begins to roll off, overall perceived noise levels begin to rise. This change is nearly consistent for all blade number combinations and occurs around a figure of merit between 0.65 and 0.7. The change is attributed to thickening of the boundary layers on the suction sides of the blades which promotes turbulence production. Regions of the blade close to the hub may be incipiently separated or stalled. Flow measurements / visualizations (like the one shown in Fig. 3) with the interrogation region being perpendicular to the rotor radius (complementary to the smoke visualizations of Yarusevych et al. [11]) are needed to address this question, and are currently underway. As hover efficiency approaches peak values of 0.75 for the different blade number counts, noise levels generated by all blade number combinations are within 3 dB for both the unweighted and A-weighted values.

7. SUMMARY

An analysis of hover performance and acoustics of a 35% scale UAM blade shape was presented using the experimental database described by Tinney and Valdez [1]. Performance measurements were acquired using a bi-axial load cell so that traditional metrics like thrust coefficient, power coefficient and rotor figure of merit were evaluated. The acoustic field was captured along a two-dimensional grid covering observer locations both above and below the rotor and between 1.0 and 3.5 rotor diameters from the hub; pressure measurements in this region are shown to transition from hydrodynamic to acoustic waveforms. Both hover performance and acoustics are evaluated for changes to the rotor collective pitch angle and for different blade number counts as well as increasing rotor speed (tip Mach numbers ranging between 0.28 and 0.37). At this scale, rotor performance was shown to be independent of Reynolds numbers while the thrust coefficient where peak

hover efficiency resided increased with increasing blade count. Contour maps of unweighted and A-weighted overall sound pressure levels were then evaluated for different collective pitch settings of the 3-bladed and 5-bladed rotor and by scaling the rotors to match full-scale conditions. As expected, a significant increase in loading noise and self-noise (rotor broadband noise) was observed while thickness noise, which is predominantly monopole-like, was suppressed. When the blade count advanced from a 4-bladed rotor to a 5-bladed rotor, minimum perceived noise levels were shown to migrate towards higher rotor collectives thereby demonstrating that higher blade count rotors have increased inflow and subsequently generate more downwash. The additional downwash reduces the ingestion of turbulence from the wakes generated by preceding blades.

ABSTRACT

Acoustic liners, passive devices to mitigate engine noise, operate under high-speed grazing flow and grazing acoustic waves. To investigate the complex physics governing this interaction, high-fidelity numerical simulations of a spatially evolving turbulent boundary layer grazing a multi-orifice acoustic liner at a bulk Mach number of 0.32 are performed. The simulations replicate conditions from a reference experiment. Grazing tonal plane acoustic waves with amplitudes of 130 dB and 145 dB and propagating in the same direction and the direction opposite to the mean flow are analyzed. The results show that the boundary layer displacement thickness doubles in the presence of the liner and its growth rate is affected by the amplitude and propagation direction of the acoustic wave. The acoustic liner also promotes the formation of an outer hump in both the logarithmic region of the streamwise and wall-normal velocity variance, with these effects becoming more pronounced under acoustic forcing. Furthermore, impedance estimation, using Dean's method, reveals that near-wall flow modifications, quantified through the displacement thickness, influence the local value of the computed impedance.

1. INTRODUCTION

Acoustic liners are essential components to reduce noise in aircraft engines. They are typically installed in the intake and core jet sections of aircraft engines. The advent of ultra-high bypass ratio engines, characterized by larger fan diameters, has significantly increased the contribution of fan noise, comprising a tonal component at the Blade-Passing Frequency (BPF) and broadband noise due to rotor-stator turbulence interaction [1–3].

Acoustic liners vary in complexity and absorption properties. Conventional Single Degree-Of-Freedom (SDOF) liners consist of a perforated face sheet, a backing cavity, and a rigid backplate, operating as Helmholtz resonators tuned to the fan's BPF or harmonics [4]. A widely used approach to characterize the acoustic liner is to measure its acoustic impedance, a quantity defined in the frequency domain as:

$$\hat{Z}(\omega) = \frac{\hat{p}}{\hat{v} \cdot \mathbf{n}} = \theta + i\chi, \tag{1}$$

where p is the acoustic pressure, u_n the acoustic particle velocity normal to the face sheet, θ the resistance, and χ the reactance. Although impedance is an intrinsic property of the liner surface, studies have shown that it is highly sensitive to the eduction technique used for its calculation [5]. Furthermore, impedance is strongly influenced by the presence of grazing flow, with research highlighting its dependence on boundary layer parameters, particularly the displacement thickness δ^* [6].

The presence of a grazing flow adds complexity to impedance eduction, requiring an appropriate boundary condition. The most widely adopted boundary condition is the Ingard-Myers one [7], which assumes an in-

finitely thin vortex sheet along the liner surface. To improve accuracy, several studies have incorporated boundary layer profiles with finite thickness in impedance modeling [8–10]. To characterize the flow near the wall, fully three-dimensional numerical simulations of sound interacting with laminar and turbulent boundary layers were performed by Zhang and Bodony [11]. Although this computational study provided valuable information on flow-acoustic interactions within a single orifice, it remained limited to single-resonator configurations and did not account for boundary layer modifications induced by multiple cavities.

A step forward was taken by Shahzad et al. [12], who performed pore-resolved compressible direct numerical simulations of a turbulent flow that grazes a multi-cavity acoustic liner. Their findings show that the turbulent flow over an acoustic liner behaves similarly to flow over a porous surface. However, their study did not consider the presence of acoustic waves.

A comprehensive analysis of the acoustic and aerodynamic fields over multi-cavity liners, particularly the boundary layer evolution and its effect on impedance, remains lacking. This study employs high-fidelity numerical simulations using the Lattice-Boltzmann Very-Large-Eddy-Simulation (LB/VLES) approach to model a turbulent boundary layer grazing an acoustic liner in the presence of grazing acoustic waves. The simulated geometry corresponds to the one experimentally investigated by Bonomo et al. [6].

The paper is structured as follows: section 2 details the methodology and the computational setup. Section 3 presents and discusses the numerical results. Section 4 summarizes the main findings.

2. METHODOLOGY

2.1 Solver

The commercial software 3DS Simulia PowerFLOW version 6 is adopted. It is based on an extended LB method. A VLES approach is used, which resolves only the large turbulent scales. It accounts for sub-grid effects using a turbulence model based on two-equation renormalization group theory k-ϵ. This approach differs from the computation of an equivalent eddy viscosity. It dynamically adjusts the Boltzmann model to match the characteristic time scales of turbulent flow. Reynolds stresses are not explicitly added to the governing equations; they arise implicitly from the chaotic exchange of momentum in turbulent flow, where characteristic times are shorter than the slowly varying turbulent flow.

To reduce the computational approach, a wall-model based on the extended law-of-the-wall is adopted [13]. This solver has been widely used to study fluid dynamic and aeroacoustic fields over acoustic liners [14–16].

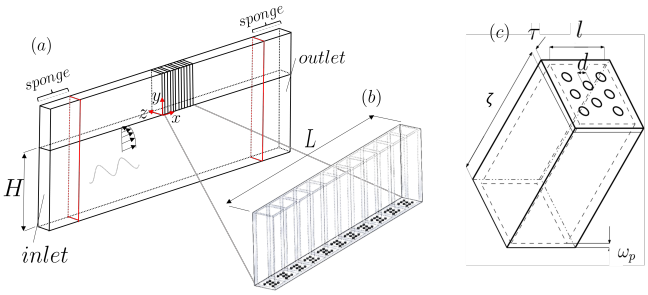

Figure 1: Overview of the computational domain: (a) schematic of the simulation setup, (b) detailed view of the acoustic liner, and (c) magnified depiction of a single cavity.

2.2 Numerical set-up

The computational domain, shown in Fig. 1, replicates the UFSC grazing flow test facility [17]. The liner is positioned on the top wall of a channel with rectangular cross section. The channel height is $H = 2h = 40$ mm. Each cavity, with a square cross-section $l = 8.46d$ and depth $\zeta = 32.56d$ ($d = 1.17$ mm is the orifice diameter), has eight orifices, partition walls with thickness $w_p = 2.17d$, and a face sheet $\tau = 0.46d$ thick. This configuration results in a cavity porosity of 5.63%. The simulated liner consisted of a row of eleven cavities, yielding a total streamwise length of $L = 116.23d$. A zig-zag trip with a height of $0.21d$ and length of $1.71d$ is placed upstream at $x = -1367d$ to match the experimental velocity profile [17].

The simulation is initialized with the flow at rest. A inflow velocity boundary condition is applied at the inlet, allowing the flow to develop spatially within the channel until statistical convergence is reached. For the acoustic simulations, an instantaneous flow field is saved and modified by superimposing a plane acoustic wave with a specified frequency and amplitude using the *OptydB* toolkit. This modified flow field serves as the initial condition for the simulations that include the acoustic excitation.

A total of five cases are tested, as summarized in Table 1. The first case is the smooth wall one; it serves as the baseline reference. The second case has a lined wall subjected to the same turbulent boundary layer. In the remaining cases, acoustic excitation is added at a fixed frequency of 1400 Hz, with SPLs equal to 130 dB and 145 dB. For both SPLs, cases with upstream and downstream acoustic wave propagation are tested. However, since the 130 dB cases exhibited trends similar to those at 145 dB, only the latter are presented for brevity.

2.3 In-situ technique

In this work, impedance is computed using the in-situ technique proposed by Dean [18]. It involves measuring unsteady pressure at the face sheet and the bottom of the cavity. This method provides a local measurement of impedance. It is based on the following key assumptions: the wavelength of the incident acoustic wave is significantly larger than the cavity width; the walls of the cavity are considered to be sufficiently thick, resulting in the liner being locally reactive; any wave entering the cavity is assumed to be completely reflected at the backplate. Consequently, the acoustic pressure of the standing wave within the cavity is the sum of the incident and reflected waves. Using the linearized momentum equation, it is possible to calculate the acoustic-induced velocity and, subsequently, the impedance as:

$$Z_f = \frac{Z}{Z_0} = -i\tilde{H}_{fb}\frac{1}{\sin(k\lambda)}; \qquad (2)$$

where Z_0 is the characteristic impedance of air, $\tilde{H}_{fb}$ is the transfer function defined as the ratio between the pressure measured at the face sheet $\tilde{p}_f$ and at the backplate $\tilde{p}_b$, and $k = \omega/c_0$ is the free-field wavenumber, with ω being the acoustic wave angular frequency. This technique has been widely used for calculating the impedance of acoustic liners in the presence of grazing flow [11, 19]. Unlike impedance eduction techniques [17], a model of the acoustic field is not required for the in-situ technique, so boundary conditions to model the presence effects of the boundary layer are unnecessary. However, studies have underlined the sensitivity of this technique on the sampling position [20, 21].

Mach	Case	SPL (dB)	Freq. kHz	ac. pos.
0.32	Smooth	-	-	-
0.32	Lined	-	-	-
0.32	Lined	130	1.4	up
0.32	Lined	145	1.4	up
0.32	Lined	145	1.4	down.

Table 1: List of simulations carried out.

3. RESULTS

3.1 Mean flow velocity profiles

Figure 2 presents streamwise velocity profiles sampled at three locations along the liner: $x/L = 0$, $x/L = 0.5$ and $x/L = 1$. The velocity profiles are expressed in outer coordinates, where U_∞ denotes the centerline streamwise velocity, and h is the half height of the channel.

Figure 2a compares the mean velocity profiles with and without the liner and in the absence of grazing acoustic wave. It can be observed that introducing a liner causes a velocity shift. Figure 2b compares the velocity profiles at $x/L = 0$ and $x/L = 0.5$ in the absence of acoustic excitation. The presence of cavities affects the near-wall flow, with a further velocity shift of $\Delta U = -14\%$ in the range $0.01 < y/h < 0.04$ at $x/L = 0.5$ compared to $x/L = 0$. Conversely, comparing the velocity profiles at $x/L = 1$ with the one at $x/L = 0.5$ (Figure 2c) it can be observed that the velocity shift is reduced to $\Delta U = -3\%$.

The effect of the presence of the acoustic wave is visible already upstream of the lined section. As a matter of fact, a slight downward shift in velocity compared to the no-acoustic case, $\Delta U = -4\%$, is found in the region $0.01 < y/h < 0.04$ for the upstream propagating wave with SPL equal to 145dB. At $x/L = 0.5$, the influence of acoustic waves is more pronounced than in the upstream region. As shown in Figure 2e, a higher SPL increases the velocity deficit. As a matter of fact, for the cases with SPL = 130 dB the differences with respect to the no-acoustic cases are smaller ($\Delta U = -4\%$) than for the cases with higher SPL ($\Delta U = -8\%$). At the end of the liner ($x/L = 1$, Figure 2f) the differences between acoustically excited cases and the no-acoustic case are within 3%.

The comparison of the velocity profiles between upstream and downstream propagating wave shows that the largest difference appears at $x/L = 0.5$ (Figure 2h); the downstream case exhibits a velocity profile closer to the no-acoustic case, with deviations remaining below -4%. Furthermore, downstream of the liner, the combined effect of the cavities and grazing acoustic waves diminishes.

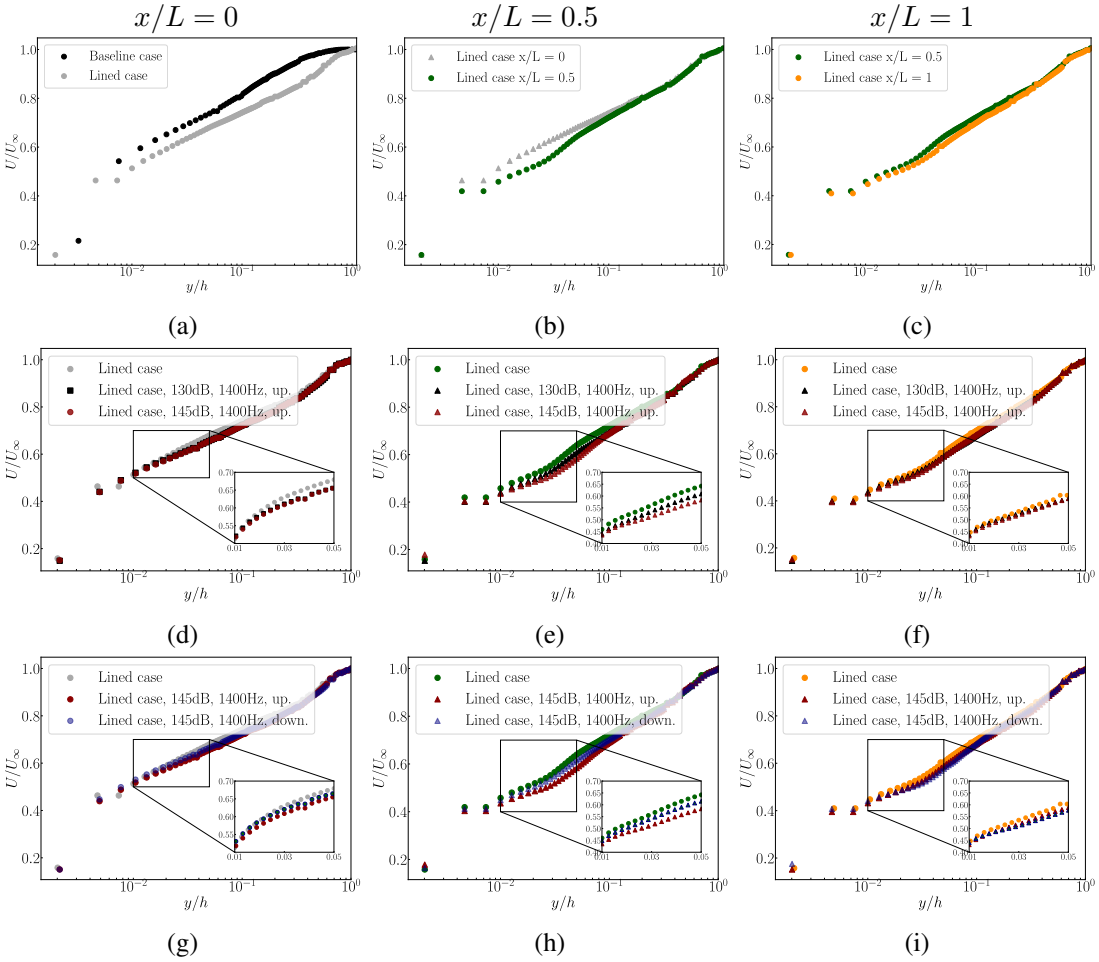

Figure 2: Streamwise velocity profiles in outer coordinates at three different locations along the liner: (left column) $x/L = 0$, (center column) $x/L = 0.5$, and (right column) $x/L = 1$. Velocity profiles are normalized by the centerline velocity U_∞ and channel half-height.

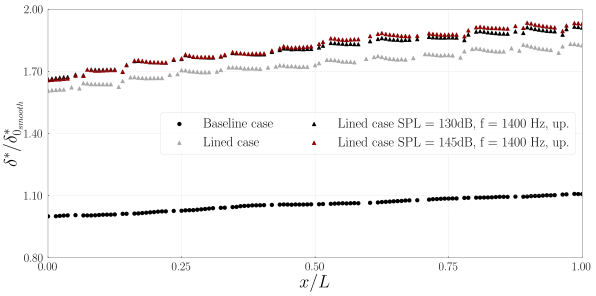
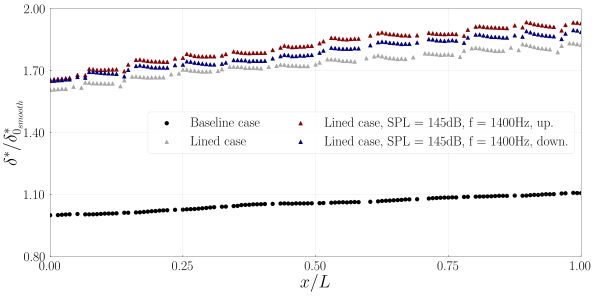
3.2 Integral boundary layer parameter streamwise evolution



Although these parameters are not commonly used for turbulent channel flows, some, such as δ^*, are present in the semi-empirical model for predicting impedance .

In this context, the boundary layer displacement thickness δ^* is defined as:



$$\delta^* = \int_0^h \left(1 - \frac{U(y)}{U_\infty}\right) dy \tag{3}$$

Figure 3 shows that, in the presence of the liner, δ^* increases by approximately 50% with respect to the smooth wall case. δ^* shows localized humps after each orifice, followed by a slight decrease until the next pair of orifices is encountered. This periodic variation results in an overall displacement thickness increase of 13% at the end of the liner.

The streamwise development of δ^* is also dependent on the presence of the acoustic wave, its amplitude and direction of propagation. As shown in Figure 3a, the presence of the acoustic wave increases the δ^*; starting from $x/L = 0.5$ the impact of the SPL also is visible even if it is not very strong. On the other hand, differences become more relevant when assessing the impact of the direction of propagation of the acoustic wave: the case

(a)

(b)

Figure 3: Streamwise evolution of δ^* over the liner: (a) effect of different sound pressure levels at a fixed frequency of 1400 Hz, (b) effect of acoustic wave propagation direction at SPL = 145 dB.

with a downstream-propagating wave exhibits a slightly lower increase in δ^* compared to the upstream propagating case. Nonetheless, differences in boundary layer displacement thickness remain below 5% relative to the no-acoustic case, whereas the most significant effect is the 50% increase in δ^* caused by the presence of the liner and the oscillatory variations over the cavities. These findings highlight that the presence of the lined surface is the most important factor that affects the boundary layer development.

3.3 Variance of the velocity fluctuations

The variance of streamwise and wall-normal velocity fluctuations normalized by the centerline velocity are reported in Figure 4. The variance profiles are sampled at three different streamwise locations: $x/L = 0$, $x/L = 0.5$ and $x/L = 1$.

Upstream of the liner, profiles of both the streamwise and wall-normal velocity variance collapse, closely resembling the one obtained for the smooth wall. At $x/L = 0.5$, an outer hump emerges in the variance of the streamwise velocity component for the no-acoustic case. This indicates that the lined surface alters the distribution and amplitude of the velocity fluctuations within the boundary layer. A clear secondary peak in streamwise velocity turbulent fluctuations appears at $y/h \approx 0.1$. At the same location, also the fluctuations of the wall-normal velocity component show an increase. These findings align with previous results on porous material [22, 23] and are likely related to a development of secondary flow structures, due to the injection of momentum near the wall [24]. The intensity of both peaks increases at downstream locations (i.e., $x/L = 1$), with the vertical velocity component showing a larger increase than the wall-parallel one.

It is interesting to note that the introduction of acoustic excitation modifies the turbulence statistics. The outer hump is more pronounced as the SPL increases. This is demonstrated by comparing Figure 4 (b) and (c). At the most downstream location $x/L = 1$, the amplitude of the acoustic source is higher for the downstream acoustic source because the acoustic amplitude is higher. Furthermore, it is also possible to notice that the development of the flow has also an impact on the wall-normal profile of the variance of the streamwise velocity fluctuations. At the most downstream location, a higher amplitude of the acoustic wave shows a more uniform high-intensity fluctuations region with a less evident difference between the inner and outer peaks. Conversely, the wall-normal velocity fluctuations show less dependence on the intensity of the acoustic source with the peak at $x/L = 1$ being very similar.

3.4 Impedance streamwise analysis

Using the in-situ technique on a numerical database, it is possible to analyze the distribution of impedance on the entire liner surface, thus providing insights into how individual orifices affect locally the impedance value.

Figures 5 show the distribution of resistance and reactance values computed on all the streamwise points at $z/l = 0.5$. A periodic pattern emerges in the distribution of resistance for all cases, with values doubling along each cavity peaking after the orifices and tending to decrease near the end of the cavity. This pattern follows the one discussed for δ^* (Figure 3). This is observed regardless of SPL value and the acoustic wave propagation direction; however, the downstream case shows higher variation of resistance compared to the upstream one. Considering the

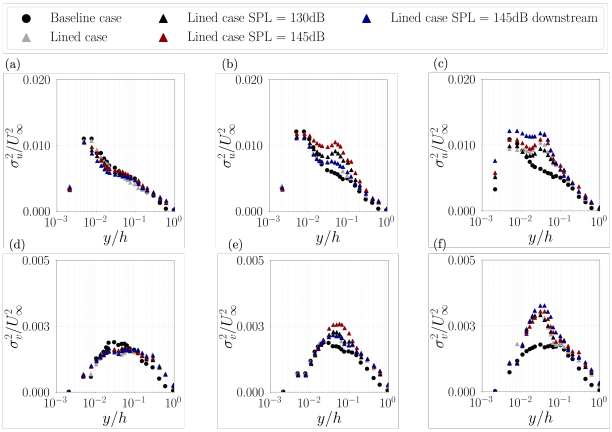


Figure 4: Streamwise (top row) and wall-normal (bottom row) velocity variance at three streamwise locations: $x/L = 0$ (a-d), $x/L = 0.5$ (b-e), and $x/L = 1$ (c-f).

variation of resistance along each cavity, this is enhanced for the downstream propagating case.

Considering the mean resistance value, small differences are found between the cases analyzed. The upstream acoustic source case yields $\theta = 0.78$ for SPL = 130 dB and $\theta = 0.80$ for SPL = 145 dB, while for the downstream case at SPL = 145 dB $\theta = 0.82$.

Reactance exhibits spatial variations across each cavity, following a trend that depends on the propagation direction of the acoustic wave. This is consistent with the established relationship between reactance and the phase of the acoustic wave. In the downstream acoustic source case, reactance variation is reduced compared to the upstream case. However, as for the resistance, the differences in the mean values are not large. Specifically, for SPL = 130 dB the mean reactance is $\chi = -0.52$, while, for SPL = 145 dB, the upstream acoustic source case yields $\chi = -0.46$ and the downstream case $\chi = -0.47$. Previous studies employing in-situ measurement techniques [16] have reported similar spatial dependencies in resistance and reactance within a single cavity.

These findings indicate that the wake generated by each orifice has a relevant impact on the impedance computed with the Dean's method.

To evaluate the impact of the local boundary layer profiles, Figure 5 compares the computed components of impedance with the one predicted by a semi-empirical model [25]. This model requires as input the value of δ^*. In this case, the prediction obtained using the δ^* from the smooth-wall simulation upstream of the liner, as it is typically done, and the prediction obtained using the δ^* obtained at each streamwise location in the presence of the liner. Results obtained with the latter agree better with the simulation results, regardless of the acoustic wave propagation direction. When the smooth-wall displacement thickness is used in the semi-empirical model, the discrepancy in impedance estimation is 17%, whereas incorporating the local boundary layer displacement thickness it reduces to 3%. Similar results are found for the reactance.

4. CONCLUSION

This study investigates the interaction between grazing acoustic waves and a turbulent boundary layer over an acoustic liner using high-fidelity numerical simulations. The study revealed that the presence of the liner leads to a 50% increase in displacement thickness (δ^*) compared to a smooth wall, with an additional 13% streamwise growth. The downstream-propagating wave results in a slightly lower δ^* growth compared to the upstream case. Overall, the impact of acoustic waves remains secondary to that of the cavities. This confirms that the liner geometry plays a dominant role in modifying the boundary layer, with the impact of acoustic forcing diminishing towards the liner's downstream end. The lined surface alters second-order flow statistics, promoting the formation of an outer hump in the streamwise and wall-normal velocity variance. This effect is amplified by acoustic forcing, particularly at higher SPLs, causing an increased inner-outer interaction within the boundary layer. The modifications in the grazing flow streamwise evolution have been linked to impedance through in-situ eduction technique. The impedance eduction analysis reveals significant spatial variations in resistance and reactance. The periodic pattern in resistance, peaking just after each orifice and decreasing within the cavity, closely follows the displacement thickness evolution. The study highlights that assuming a uniform boundary layer profile different from the local one leads to inaccuracies in impedance predictions, particularly when using semi-empirical models. The direction of acoustic wave propagation affects both flow statistics and impedance characteristics. However, differences in mean resistance and reactance values remain minimal, reinforcing the idea that local variations play a more significant role than acoustic propagation direction.

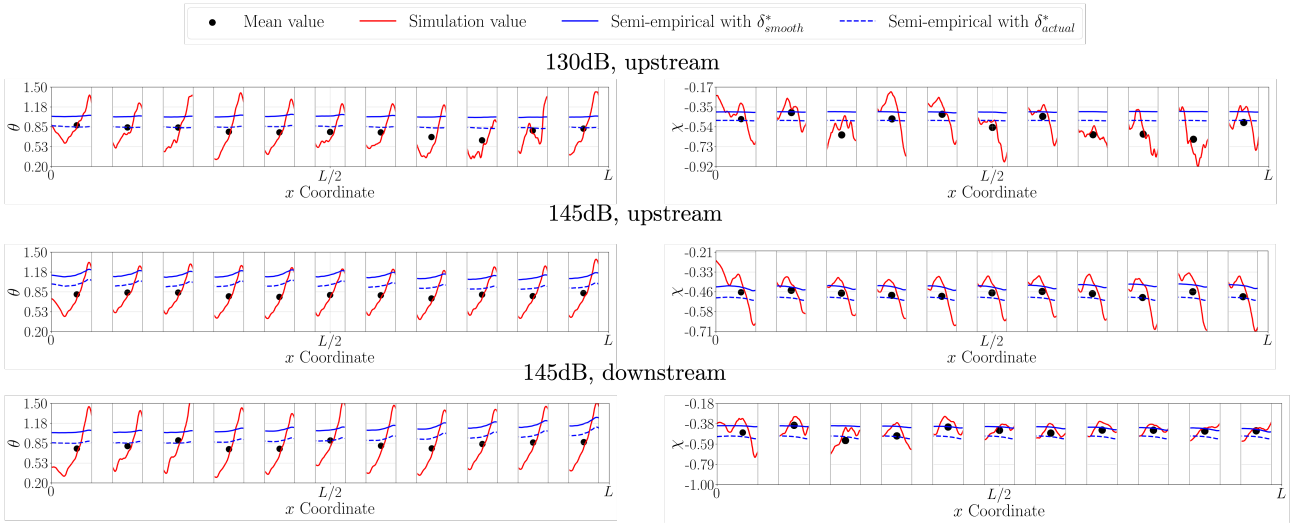

Figure 5: Streamwise distribution of (left) resistance, and (right) reactance along the liner surface for different acoustic wave's SPLs and direction of propagation at fixed $f = 1400$ Hz.

RELEVANCE OF RADIATOR INSTALLATION ON THE EFFICACY OF NOISE REDUCTION STRATEGIES IN AN INDUSTRIAL ENGINE COOLING FAN

Francesco Bellelli* **Renzo Arina** **Francesco Avallone**
Department of Mechanical and Aerospace Engineering, Politecnico di Torino, Torino, Italy

ABSTRACT

Engine cooling fans must be efficient and quieter, as their acoustic contribution is today more noticeable considering the reduced noise from electric motors. Therefore, more effective noise reduction technologies must be designed. This paper investigates how noise reduction technologies, designed for an isolated fan, are impacted by the presence of a radiator pulling upstream. Two modifications to the baseline fan geometry are studied: (i) one with a ring shape that mitigates the backflow-rotor interaction and (ii) one with stator vane azimuthal spacing optimized to reduce rotor-stator interaction tonal noise. They are assessed with high-fidelity simulations performed both on an isolated fan and a full cooling module including the radiator, which is simulated using an equivalent porous medium. Results reveal that the modified ring shape effectively prevents backflow-rotor interaction on the isolated fan, reducing broadband noise by radially redirecting the backflow. However, its performance is less effective when a radiator is present due to the presence of the casing. Conversely, stator vane optimized spacing shows robust noise reduction in both configurations, because the effect of distributing tonal energy across several modes is not altered by the presence of the radiator.

1. INTRODUCTION

With the transition to electric motors, reducing car component noise emissions has become a critical focus. This shift has led the scientific community to investigate several conventional [1] and bio-inspired [2] noise reduction strategies.

One of the main noise contribution for low-speed fans is tip-clearance noise, generated by coherent vortex structures present in the tip-gap region [3]. Tip-clearance noise is usually mitigated by introducing a rotating ring [4] to prevent the formation and growth of coherent structures responsible for sub-harmonic humps. However, a rotating ring may generate unwanted flow patterns if the fan is subjected to a pressure rise, causing backflow end increasing unsteady loading noise. It has been demonstrated that rotor-backflow interaction is a major source of unsteady loading noise even at design conditions [5, 6]. Strategies such as tailored short ducts [7], porous leading edges [8], or serrated bio-inspired designs [9] have been conceived to mitigate this noise source, albeit they increase high-frequency broadband noise.

Rotor-stator interaction is another significant noise source [10] for fans. If the rotor-stator axial clearance is short, aerodynamic potential effect dominates over wake impingement [11]. Geometrical azimuthal inhomogeneities might increase noise [12] and give rise to additional azimuthal pressure modes. Unevenly spacing the vanes with specific modulations, as done by Duncan [13] and Mellin-Sovran [14], is a typical solution. However, these approaches act only in a discrete fashion on the vanes spacing, eventually discarding optimal solutions, as repoted in Ref. [15].

A comprehensive understanding of how these strategies influence backflow-rotor interactions still deserves

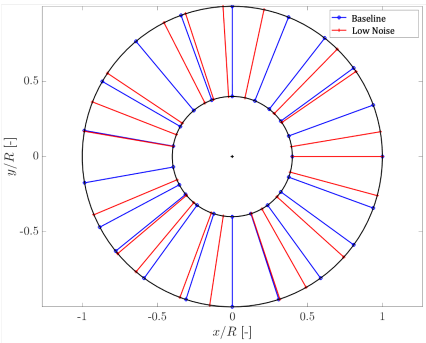

Figure 3: Baseline and low-noise stator-vane azimuthal distributions.

further studies. Deterministic unsteady loading contributions such as non-viscous rotor-stator interaction are rarely addressed, and optimization procedures to mitigate these effects are almost absent. Finally, most noise reduction techniques are evaluated on isolated fans rather than on the real installed configuration. This must be considered when the same casing, for the fan and the radiator, is used to test different configurations [16]. This aspect is expected to impact the efficacy of noise reduction techniques when applied to a baseline fan.

This paper examines numerically the influence of shape modifications of the rotating ring to mitigate the backflow-rotor interaction noise and explores the effects of stator-vane uneven spacing to minimize rotor-stator interaction tonal noise. Furthermore, the paper considers how the radiator installation impacts the performance of noise reduction strategies in typical operations.

2. FAN AND RADIATOR GEOMETRY

The fan consists of a 465 mm diameter (D) rotor with $B = 11$ unevenly spaced blades connected to a ring, a hub, a driving electrical motor, $N_v = 20$ unevenly spaced stator-vane, and a shroud, as shown in Fig. 1. The fan tip-clearance is equal to $0.009D$. The radiator consists of a heat exchanger of $1.44D \times 1.48D$ placed $0.02D$ upstream of the fan hub and of a square casing that joins it to the fan, as shown in Fig. 2.

A first modification to the ring geometry was performed with the scope of preventing the backflow to interact with the blades. The ring shape was modified to further redirect the backflow from the blades. The axial spacing between the ring and stator-vane was reduced by 30% to mitigate adverse flow in the tip-clearance. The shroud was shifted forward in the x direction of the top structure to keep constant the axial spacing with respect to the ring.

A second modification concerned the stator vane azimuthal distribution. The spacing was designed following the random spacing approach as described in Ref. [15]. This allows to redistribute more efficiently the acoustic energy of the rotor-stator interaction tones. In Fig. 3 the baseline and low-noise stator-vane azimuthal distributions are represented.

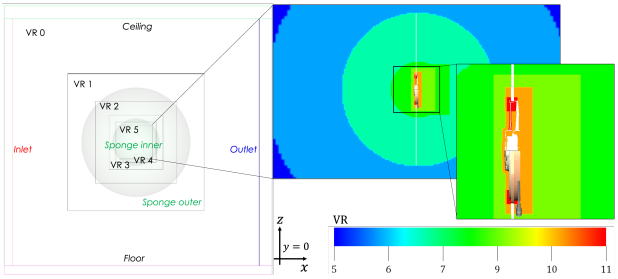

Figure 4: Sketch of the computational domain in the plane at $y/D = 0$.

3. NUMERICAL SETUP

Simulations have been performed with the commercial software 3DS PowerFLOW version 6, based on the lattice-Boltzmann method (LBM) [17].

The computational domain used to simulate all the configurations is shown in Fig. 4. A large fluid domain of $135D \times 135D \times 135D$ was built to simulate a free-field environment that encloses the fan. The ceiling and the floor of the simulation domain were modelled as a solid reflecting wall, while both inlet and outlet had a static ambient pressure boundary condition. A discretization strategy based on 11 Variable Resolution (VR) regions was adopted. The regions with maximum resolutions were set around the rotating blades and near the tip gap region, where there are 11 voxels in the tip-clearance. The resolution in the tip gap region was similar to the one adopted by Avallone et al. [18]. The voxel size between one VR region and the adjacent one was doubled. In the VR3 region, a sponge region was defined by an artificial change of viscosity of a factor of 100, with an exponential function between the inner and outer region, as outlined in Fig. 4. Both the increase in voxel size and the sponge region were used to mitigate reflections of acoustics waves at the domain boundaries.

In the isolated fan configuration, an anechoic wall separating the two environments was introduced so that a pressure rise Δp across the fan could be imposed [6]. The fan maximum efficiency point was simulated, corresponding to a load coefficient of $\psi = \frac{\Delta p}{\frac{1}{2}\rho v_{tip}^2} = 0.14$, where ρ is the ambient density and v_{tip} is the tip velocity, and a flow coefficient of $\varphi = \frac{\dot{V}}{\pi(R_{tip}^2 - R_{hub}^2)v_{tip}} = 0.10$, where $\dot{V}$ is the volume flow rate through the fan. R_{tip} and R_{hub} are respectively the tip and hub radii. In the full cooling module configuration, the heat exchanger was modelled as an equivalent porous medium [19]. No pressure difference was imposed in this configuration, as the equivalent porous medium provided the fan with a pressure loss which corresponded roughly to the maximum efficiency point of the complete cooling module system.

A physical time of 20 revolutions was simulated at a resolution of 1200 voxel per diameter (vox/D) in the finest VR region. A grid resolution study was performed on this setup in a previous work [6]. Data was saved only during the last 10 revolutions. Two planes parallel to the fan were sampled at $x/D = -0.14$ and $x/D = -0.06$ to compute averaged flow fields. The locations correspond respectively to the rotating ring upstream boundary and the rotor-stator interstage. Pressure on all the solid surfaces of the cooling module was sampled at a frequency of $48,000\,Hz$ and the volume flow rate was sampled, at the same frequency, on a plane at $x = 0/D$. Finally, a fully circular array of 12 equally spaced far-field probes, located in the plane $z/D = 0$ at a radius $r/D = 2.15$ far from the fan centre, was used to sample directly the acoustic field from the simulations. The spectral content of the signals was computed through the Welch averaging algorithm [20] with 8 Hamming windows and 50% of overlap, resulting in a frequency resolution of $11.8\,Hz$.

+2.0	+6.4	+10.9	-6.0

Table 1: Aerodynamic performance variation between the baseline and low-noise geometries in the isolated fan configurations.

First, the effects of the proposed noise reduction strategies on the aerodynamic performance is discussed. In Tab. 1 the variations of axial thrust force (T), volume flow rate through the fan ($\dot{V}$), aerodynamic torque (Q), and aerodynamic efficienc of the low-noise geometry with respect to the baseline geometry are reported. The efficiency is calculated as

$$\eta = \frac{\frac{T}{\pi(R_{tip}^2 - R_{hub}^2)}\dot{V}}{Q\Omega}, \tag{1}$$

where Ω is the fan rotational speed in rad/s. The low-noise configuration displays an increase of both thrust and

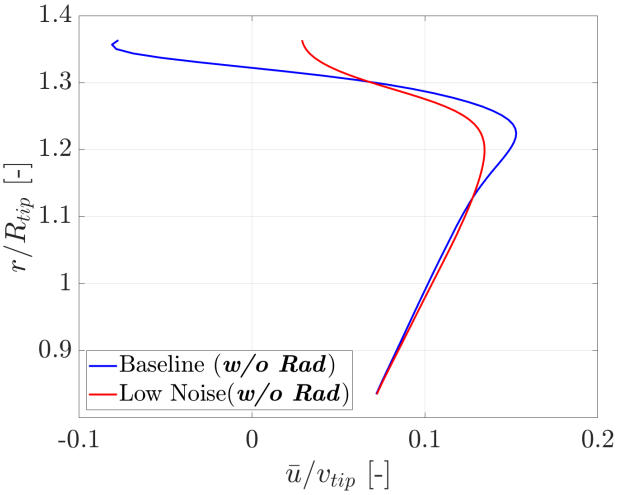

Figure 5: Mean axial velocity in the near-tip region ($0.8 \leq r/R_{tip} \leq 1.1$), at $x/D = -0.14$, azimuthally averaged.

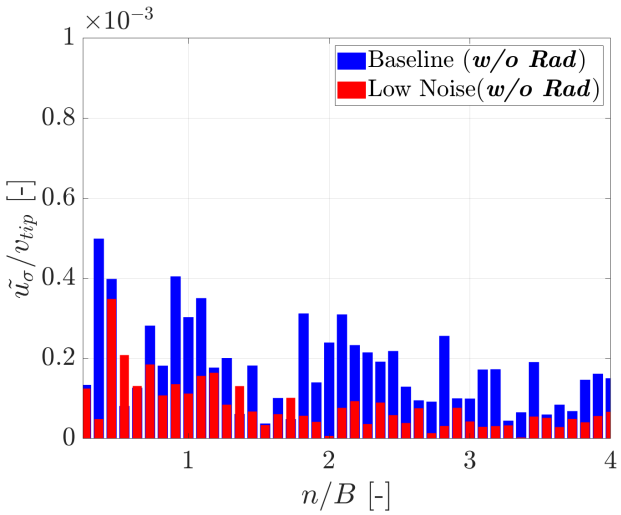

Figure 6: Azimuthal mode decomposition of the axial velocity root mean square (rms) sampled on a fully circular line at $r/R_{tip} = 0.9$ in a plane located at $x/D = -0.14$. n is the mode order and B is the number of rotor blades.

torque due to the increase of aerodynamic surface, as well as an increase of volume flow rate through the fan that can be explained with a decrease in backflow. However, both the increase in thrust and flow rate cannot compensate the increase in torque, leading to an aerodynamic efficiency reduction.

The impact of the ring shape on the upstream flow is analyzed. In Fig. 5 the time and azimuthally averaged axial velocity sampled on a plane at $x/D = -0.14$ is shown. The velocity is made dimensionless with the tip velocity. It is observed that the low-noise configuration reduces the velocity gradient in the region $1.1 \leq r/R_{tip} \leq 1.4$; $\bar{u}/v_{tip}$ does not attain negative values on the low-noise configuration, proving absence of the backflow.

The azimuthal mode decomposition of the axial velocity root mean square is shown in Fig. 6. The quantity is sampled on a plane at $x/D = -0.14$ and along a circular line at $r/R_{tip} = 0.9$. Results confirm previous observations, as the low-noise configuration is characterized by a considerable decrease in the axial velocity modal content among all the frequencies of interest. This is associated with the redirection of the backflow achieved by the modified ring geometry, reducing blade-backflow interaction.

The relevance of stator-vane azimuthal distribution is now discussed by looking at the azimuthal mode decomposition of the mean axial velocity in Fig. 7. The velocity is sampled on a plane at $x/D = -0.06$, which cor-

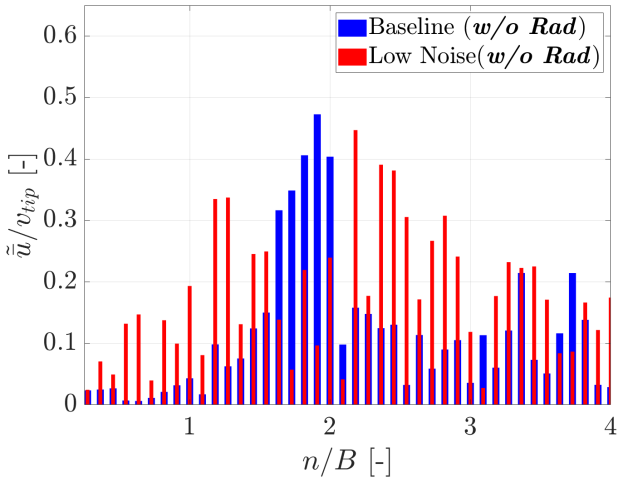

Figure 7: Azimuthal mode decomposition of the mean axial velocity sampled on a fully circular line at $r/R_{tip} = 0.7$ in a plane located at $x/D = -0.06$.

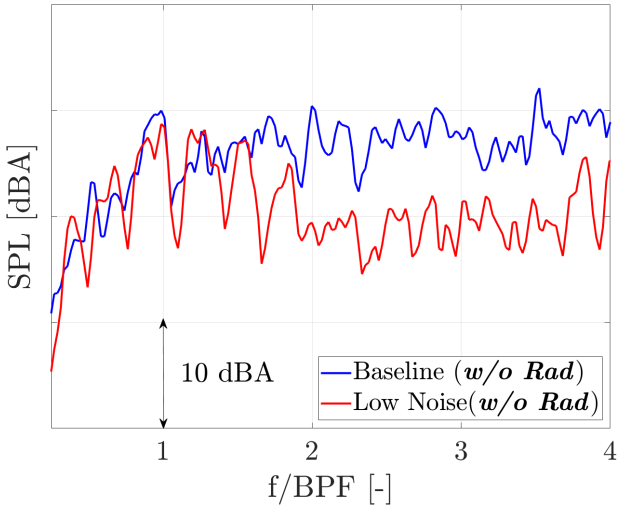

Figure 8: Pressure fluctuations at $x/D = -2.15$, $y/D = 0$, and $z/D = 0$.

responds to the rotor-stator interstage, and on a circular line located at $r/R_{tip} = 0.7$. The low-noise configuration positively contributes to the redistribution of energy among several other modes n. In particular, the low-noise configuration can substantially reduce the modal content in the range $1.5 \leq n/B \leq 2$, which has been previously shown by the authors [6] to be critically dominated by aerodynamic potential rotor-stator interaction on this fan configuration.

Finally, the efficacy of the proposed noise reduction strategies is discussed in Fig. 8, where the spectra of sound pressure fluctuations sampled at $x/D = -2.15$, $y/D = 0$, and $z/D = 0$ are shown in terms of Sound Pressure Level (SPL). The probe lies on the fan rotational axis, at a distance of $2.15D$ upstream of the fan. The frequency axis is made dimensionless with the blade passing frequency ($BPF = \omega B$, where ω is the fan rotational frequency in Hz). The spectrum clearly shows that the low-noise configuration is characterized by a considerable decrease in broadband content for $f/BPF \geq 1.5$. This improvement is attributed to the absence of backflow-rotor interaction in the low-noise configuration, achieved through the modified ring shape that redirects the backflow far from the blades. Moreover, it should be noted that also the tonal content of the low-noise configuration is reduced, especially in the range $1.5 \leq f/BPF \leq 2$, as a result of the optimized vane distribution. Both noise reduction strategies led to a decrease in Overall Sound Pressure Level (OASPL) of about $4.9\,dBA$.

ΔT [%]	$\Delta \dot{V}$ [%]	ΔQ [%]	$\Delta \eta$ [%]
-0.4	-2.6	+2.9	-5.7

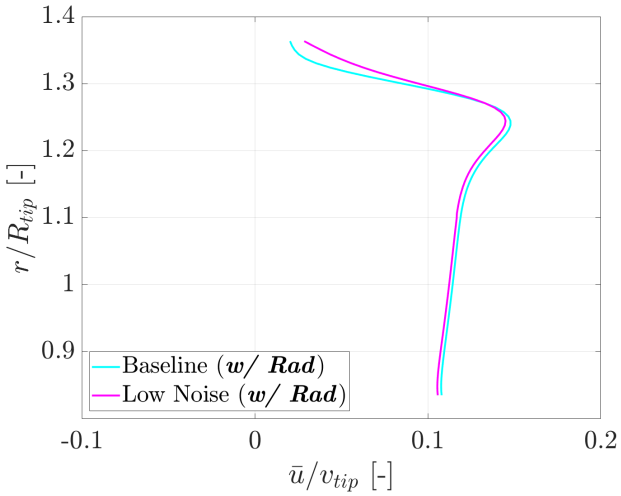

Figure 9: Mean axial velocity in the near-tip region ($0.8 \leq r/R_{tip} \leq 1.1$), at $x/D = -0.14$, azimuthally averaged.

4.2 Full cooling module

The variations in aerodynamic performance for the full cooling module baseline and low-noise configurations is assessed in Tab. 2. Overall, the low-noise geometry results in smaller variations of almost every investigated quantity. The thrust is mainly unaltered and the torque is only slightly increased. However, the volume flow rate through the fan is decreased, unlike the isolated fan configurations. This is due to a different flow physics associated with the backflow when considering the radiator installation. These differences in aerodynamic quantities lead to an aerodynamic efficiency decrease less important than the one for the isolated fan configurations (Tab. 1).

In Fig. 9 the time and azimuthally averaged axial velocity sampled on a plane at $x/D = -0.14$ is shown for the full cooling module configurations. The baseline and low-noise configurations have an almost identical spanwise trend of mean axial velocity near the tip, with a sub-

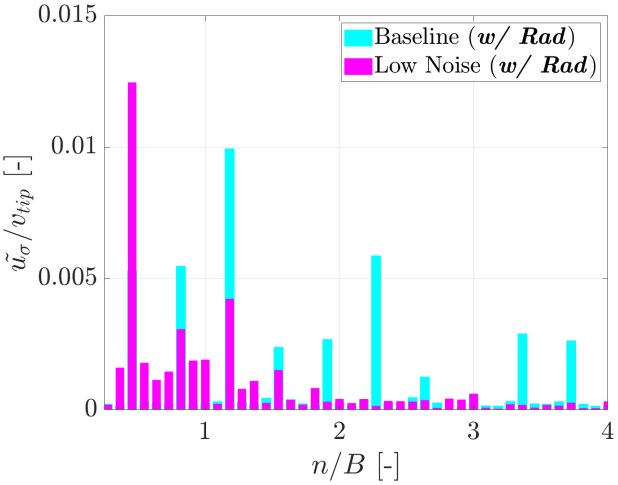

Figure 10: Azimuthal mode decomposition of the axial velocity root mean square (rms) sampled on a fully circular line at $r/R_{tip} = 0.9$ in a plane located at $x/D = -0.14$.

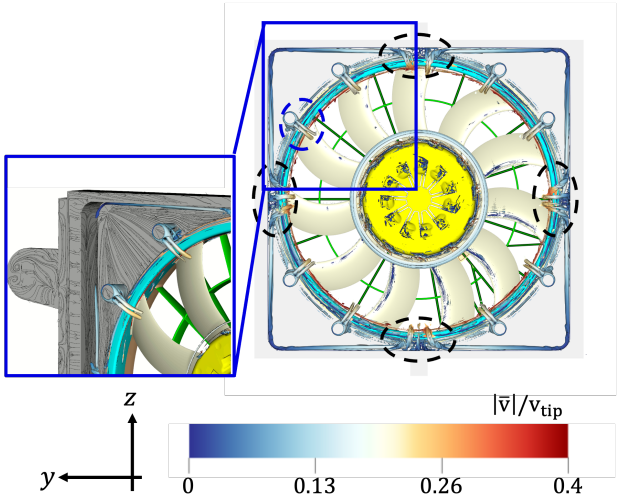

Figure 11: Mean $\Lambda_2 = -2.5 \cdot 10^5 1/s$ iso-surfaces coloured with velocity magnitude in the upstream casing for the baseline configurations.

stantial reduction of the mean axial velocity gradient with respect to the isolated fan, as seen in Fig. 5. This is associated with the presence of the equivalent porous medium, that has been previously shown by the authors [21] to locate the pressure losses on the fan disk up to $r/R_{tip} \leq 0.9$.

The azimuthal mode decomposition of the axial velocity root mean square at $x/D = -0.14$ and $r/R_{tip} = 0.9$ is shown in Fig. 10. It is observed an increase in the low frequency modal content up to $n/B \leq 2$ which is associated with the highly limited space in the radial extent due to the presence of the casing. This prevents the backflow to be radially redirected. Conversely, a stronger recirculation takes place in the casing upstream of the fan and is expected to negatively influence the acoustic performance of the system. The highly tonal content observed in both the baseline and low-noise configurations is instead associated with periodic recirculation spot in the casing that are due to the flow distortion induced by the square-to-round shape transition from the casing to the fan and by the presence of several cylindrical screw holders that are present in the casing. These features in the flow field are outlined for the baseline configuration only in Fig. 11, where $\Lambda_2 = -2.5 \cdot 10^5 1/s$ iso-surfaces are shown, colored by velocity magnitude.

In Fig. 12 the azimuthal mode decomposition of the mean axial velocity at $x/D = -0.06$ and r/R_{tip} shows that the stator-vane distribution is consistently able

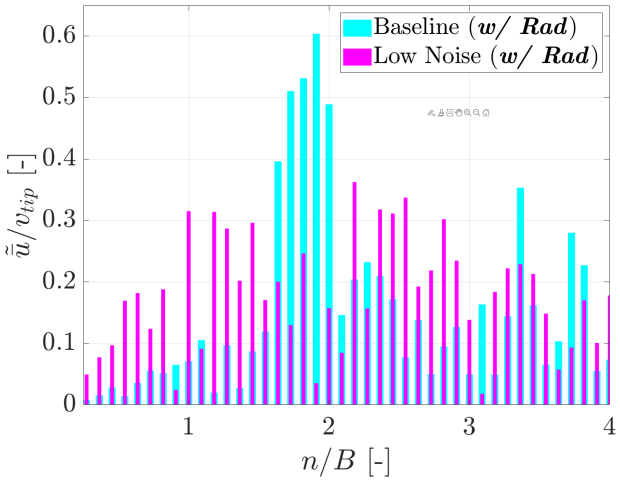

Figure 12: Azimuthal mode decomposition of the mean axial velocity sampled on a fully circular line at $r/R_{tip} = 0.7$ in a plane located at $x/D = -0.06$.

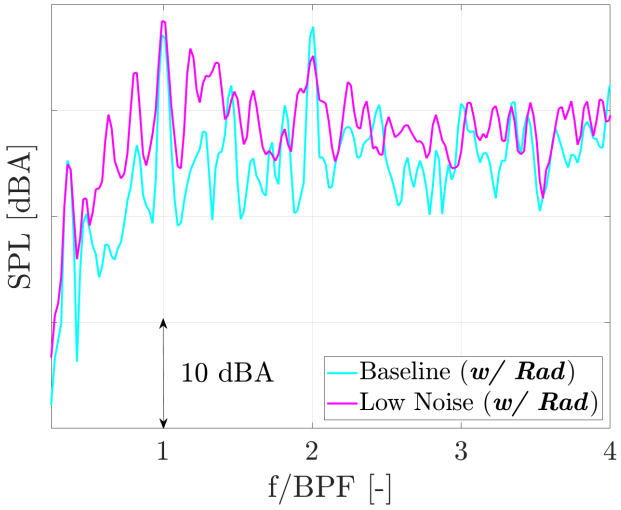

Figure 13: Pressure fluctuations at $x/D = -2.15$, $y/D = 0$, and $z/D = 0$.

to reduce the prominence of single modes n by heterogeneously distribute the energy, as seen also in Fig. 7 for the isolated fan configurations. As a matter of fact, the radiator installation does not influence the flow physics in the interstage between rotor and stator, leading to considerably similar results between the isolated fan and the full cooling module configurations.

In Fig. 13 the spectra of sound pressure fluctuations sampled at $x/D = -2.15$, $y/D = 0$, and $z/D = 0$ are shown. The probe location is upstream of both the fan and the radiator. The low frequency ($0.5 \leq f/BPF \leq 2$) broadband content of the low-noise configuration is higher than the baseline configuration, meaning that the modification on the ring shape is not consistently able to reduce the backflow-rotor interaction noise contribution. This results in a higher noise contribution in the low frequency range. From $f/BPF \geq 2$ the broadband content is similar to the baseline configuration. Nevertheless, the tonal content of the low-noise configuration is consistently lower than the baseline configuration, as a result of the stator-vane redistribution. It has been shown in Fig. 12 that the vanes are not influenced by the presence of the upstream radiator. The OASPL is increased by $2.5\,dBA$ because of the broadband content increase.

5. CONCLUSIONS

Two modifications to the baseline geometry of an engine cooling fan are studied: one with a ring shape that mitigates the backflow-rotor interaction and one with stator vane's spacing optimized to reduce rotor-stator interaction tonal noise. They are investigated on an isolated fan and a full module where the radiator is simulated as an equivalent porous medium. Results revealed that the proposed noise reduction strategies slightly reduced the aerodynamic performance, mainly because of the increased aerodynamic surface of the modified ring shape that led to a drastic increase in torque. The low-noise ring prevented backflow-rotor interaction on the isolated fan, but showed poor performance when the radiator is present because of its casing. On the other hand, stator vane spacing showed robust noise reduction in both configurations since the effect of distributing tonal energy across several modes is not altered by the presence of the radiator upstream. Results shown in this paper highlight the importance of considering the radiator installation when designing possible noise reduction strategies, especially when the flow physics exploited to reduce noise can be substantially altered by the presence of the radiator.

ROTOR NOISE CONTROL USING COAXIAL CO-ROTATING ROTORS.

Charles E. Tinney[1†] **Yingjun Zhao-Dubuc**[1] **John Valdez**[1]
[1] Applied Research Laboratories, University of Texas at Austin, Austin, Texas, USA

ABSTRACT

The development of a low-noise rotor blade has received considerable attention in recent years due to emerging interests in electric vertical take-off and landing (eVTOL) vehicles. One of the most impact-full methods for reducing the acoustic footprint from multirotor platforms is by augmenting the angular phase between neighboring rotors so that sound waves interfere either constructively or destructively for an observer in the far-field. For stacked, co-rotating rotors operating in hover, this form of noise control has been shown to augment rotor performance, thereby providing a trade-space between changes in noise, versus changes in performance. Here we evaluate the same trade-space using a combination of low-order analysis methods capable of filtering out the most energetic waveforms that make up the sound field of this rotor. This combines the conventional form of the proper orthogonal decomposition (POD) with vold-kalman filters (VKF) to filter structures in both space and time, respectively. The findings show that for an observer located below the rotor disk plane, sound pressure levels corresponding to the first few blade pass frequency harmonics can be reduced by as much as 4 dB with only moderate losses in hover efficiency.

1. BACKGROUND

Most studies concerned with the acoustics of multirotor platforms focus on side-by-side configurations with or without synchrophase control. The coaxial (stacked), co-rotating rotor is another multirotor configuration that, unlike the traditional side-by-side setup, ha an acute sensitivity to both performance and acoustics on account of changes to rotor operating conditions. As such, the co-rotating offers a much more promising approach for controlling rotor noise through the constructive and destructive interference (CDI) of sound waves generated by neighboring rotors. These sources of noise are the result of thickness noise and blade loading noise, which are impulsive (unlike rotor broadband noise), and are the key drivers of community annoyance. In 2018, a number of initiates began at the Applied Research Laboratories, The University of Texas at Austin (ARL:UT) to study this trade-space with key findings being published in a number of conference papers [1, 2] and journal articles [2–4]. This paper serves to review the highlights of these findings, while providing new results for the interested reader. Other efforts to characterize the hover performance and acoustics of stacked rotors can be found in the literature [5, 6].

2. HARDWARE AND SETUP

Measurements were performed in the Gas Dynamics Laboratory (GDL) at ARL:UT near standard sea level conditions ($p_\infty = 14.7$ psia (103,325 Pa), $T_\infty = 526$ R (292 K), $\rho = 2.34 \times 10^{-}3$ slug/ft^3 and $a_\infty = 1.126 \times 10^3$ ft/s). A description of the GDL can be found here: `https://www.arlut.utexas.edu/gdl/` and is a 24 ft tall acoustically treated facility enclosing $\dot{V} = 30,100$ ft^3 of open air space over 1,500 ft^2 of floor space. The performance and acoustics of various rotor platforms covering

Table 1. Definitions for rotor index angle ϕ [deg] and rotor lead/lag φ [deg].

j	1	2	3	4	5	6
ϕ_j [deg]	12	30	48	66	84	102
φ_j [deg]	12	30	48	66	84	-78
k	7	8	9	10	11	
ϕ_j [deg]	120	138	156	174	192	
φ_j [deg]	-60	-42	-24	-6	12	

a range of scales have been tested over the years at the GDL, [7,8]. For now, we will concentrate on a stacked co-rotating configuration using model 18×5.5 MR-P blades ($D = 18$ in.) manufactured by APC Propellers. These blade shapes are highly twisted and are inverted with the rotor disk plane elevated 105 inches from the laboratory floor so that the thrust vector points down. This equates to a distance of sixteen rotor diameters between the rotor disk plane and the virtual floor (ceiling) to reduce ground effects.

The upper blade assembly was designed so that changes to both rotor index angle (angle between upper and lower rotors ranging between $\phi_1 = 12$ deg and $\phi_{11} = 192$ deg with $\delta\phi = 18$ deg increments) and stacking distances between rotors could be tightly controlled. Table 1 lists the notation used to identify the differences between index angle (ϕ_j) and lead/lag angle (φ_j) where φ is positive when the upper rotor is leading the lower rotor in the direction of rotation. The third variable of interest is rotor rotation speed, which varied from $\omega = 50$ rotations per second (RPS) to 90 rps, in 10 rps increments. Only the $\omega = 90$ rps and $\delta z/D = 0.061$ condition will be evaluated here and corresponds to a blade chord Reynolds number at $r = 0.75R$ of $\mathrm{Re}_{c75} = 1.9 \times 10^5$ and a blade tip Mach number valued at 0.38. An illustration of the upper assembly with rotor blades is shown in Fig. 1a.

3. ROTOR PERFORMANCE

Several instruments were used to understand the mechanisms governing the trade-space between hover performance and acoustics, and the effect of synchrophasing on rotor noise control. The first of these was a Futek model MBA500 bi-axial load cell for measuring axial thrust and torque with reported errors of 0.125 lbf and 0.125 in-lbf, respectively. Thrust coefficient $C_T = F_z/(\rho A \Omega^2 R^2)$, torque coefficient $C_\tau = \tau/\rho A_d (\Omega R)^2 R$, and rotor figure

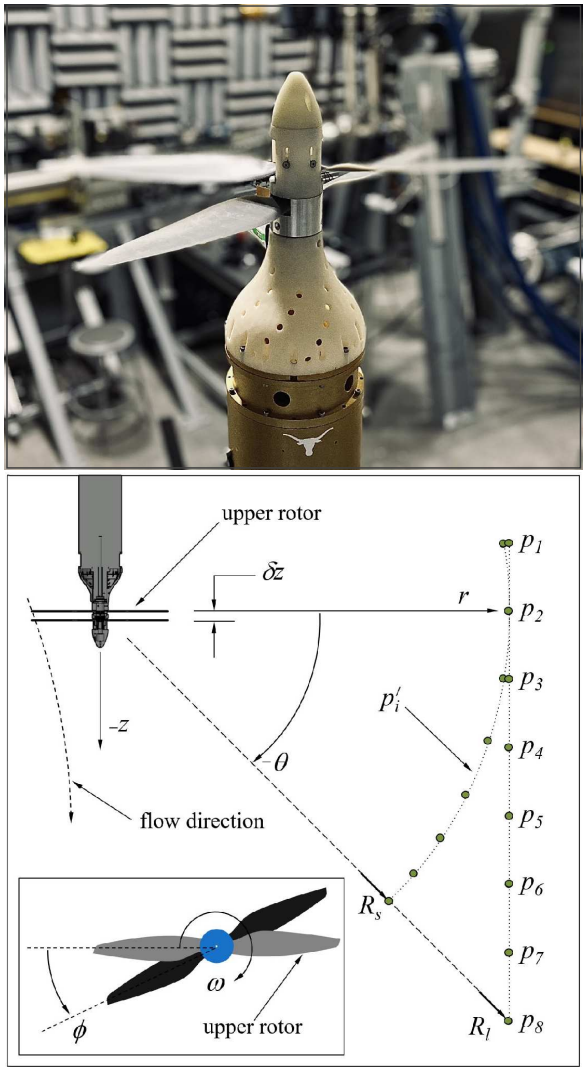

Figure 1. a) The coaxial, co-rotating rotor used by Tinney and Valdez [1] with APC propeller models 18×5.5 MR(P) b) Orientation of rotor test stand with coordinate system.

of merit $FM = C_T^{3/2}/\sqrt{2}/C_\tau$, were calculated for each test case where $R = D/2$ is rotor radius, $A = \pi D^2/4$ is rotor disk area and Ω is motor rotation speed in rad/s ($\Omega = 2\pi\omega$). In Fig. 2a, thrust coefficient and torque coefficient are reported for the 90 rps rotor speed and with systematic changes to rotor index angle. Rotor efficiency is reported in Fig.2b and is typical of rotors of this scale [7]. The findings demonstrate the key features of the stacked, co-rotating rotor. The first is that changes in rotor index

angle have a profound impact on hover performance and that the optimum hover performance is achieved when the upper rotor lags the lower rotor. This occurs for this rotor configuration around $\varphi = -30$ deg.

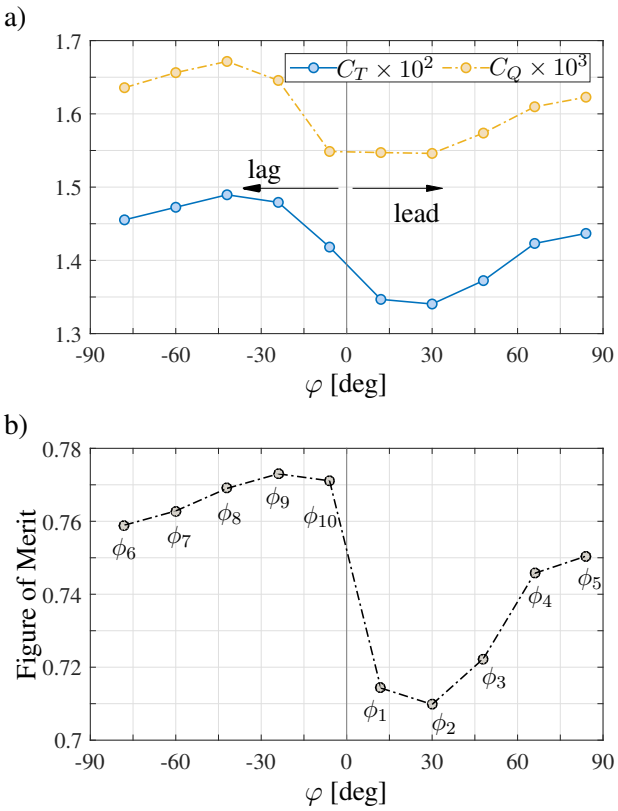

Figure 2. a) Thrust coefficient, torque coefficient, and b) rotor figure of merit at 90 rps rotor speed.

4. ROTOR WAKE AND SLIPSTREAM

A single camera PIV system mounted to a two-stage linear traverse was then used to measure the wake and slipstream boundaries generated by the stacked rotor [3]. The measurement window was oriented to capture vortices from both the upper and lower blades including provisions for wander. The principal components of the PIV system comprised a Nd-YAG laser, a single 2M pixel CCD camera operating at sample rate of 7 Hz (double frame mode), as well as a PIVTEC 14 Laskin nozzle seeder for generating 0.1 to 1.0μm size olive oil particles. A total of 250 statistically independent image pairs were captured for each of the 37 wake ages ($0° \leq \psi \leq 360°$ deg in increments of $\Delta\psi = 10$ deg) and all eleven index angles thereby resulting in a total of 101,750 image pairs that were converted to vector maps using DaVis v.10.1. The location of the slipstream boundary was identified using the Γ_1-method to correct for vortex jitter. Numerous reviews on both integral-based and divergence-based schemes for characterizing vortex jitter are provided by Mula et al. [9] and the references therein.

A sample result from the PIV system is shown in Fig. 3 for the stacked rotor operating at 90 rps with $\delta z/D = 0.061$ and $\phi_1 = 12$ deg. At each wake age, small grey symbols identify the instantaneous locations of jittering vortices from all snapshots, followed by the average value (large color symbols). Lines are drawn connecting the trajectory of vortices generated by the upper and lower rotors with increasing wake age. The full PIV database is then compiled to identify the flow mechanisms responsible for effecting changes to hover performance. This is accomplished by evaluating the miss distance between the upper rotor vortices with the lower rotor blade, which is plotted in Fig. 4. Here, the solid symbols are from direct measurements while open symbols are extrapolated from trajectories of the vortex using the last known measurements from that index angle. The findings demonstrate that for a given rotor speed, index angle and stacking distance of the co-rotating rotor, thrust is maximum when the tip vortex generated by the upper rotor grazes the low pressure side of the lower rotor.

5. ROTOR ACOUSTICS

The last of the instruments used for this study was a line array of eight 1/2-inch free-field microphones (G.R.A.S. model 46AE with matching preamplifiers) positioned three rotor diameters from the hub with equal spacings of $z_i/D = 0.5$, and with the second microphone aligned with the rotor disk plane as shown in Fig. 1b. Remaining sensors were then biased towards locations below the rotor resulting in an acoustic corridor between $\theta_1 = 9.5°$ (above the rotor) and $\theta_8 = -45°$ (below the rotor). Microphone signals were sampled uninterrupted for 20.48 seconds at a rate of $f_s = 40$ kHz using 24 bit accurate A/D converters. Acoustic waveforms were then propagated using $p \propto 1/r$ decay to a virtual arc array located three rotor diameters from the hub and identified by p' in Fig. 1b. Ensemble averaged sound pressure spectrum levels (SPSL, Re: 20μPa) are computed using a Hanning window with 75% overlap and a spectral resolution of $f_s/N = \delta f = 2.0345$ Hz. No corrections for atmospheric absorption or human ear effects are employed. Albeit, precautions should be taken when conducting acous-

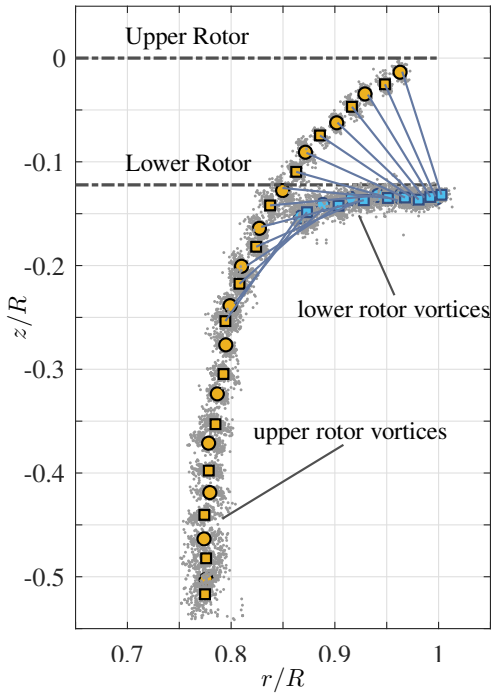

Figure 3. Average vortex locations from the upper and lower rotors of the stacked rotor operating at 90 rps with $\delta z/D = 0.061$ and $\phi_1 = 12$ deg.

tic and performance measurements in enclosed facilities which warrant some discussion.

5.1 Gauging Facility Enclosure Effects

Determining whether facility effects are corrupting one's measurements continues to be a contentious topic of discussion at conferences and workshops. While there is no unified framework for gauging these effects, some simple exercises can be performed during testing and are listed as follows:

i ***Facility time-scale:*** The first of these seeks to estimate the time required for the rotor to fully digest the volume of air enclosed by the facility. This was proposed by [8] and was motivated by concerns over recirculation effects [10]. This facility time-scale is determined by $t_v = \dot{V}/(Av_i)$ and uses rotor inflow $v_i = \lambda\Omega R$ and inflow ratio $\lambda_i = \sqrt{C_T/2}$ as inputs. For the highest thrust generating condition of this stacked rotor, the facility time scale is valued at $t_v = 465$ [s] and is sufficiently large for enclosure effects to be considered negligible.

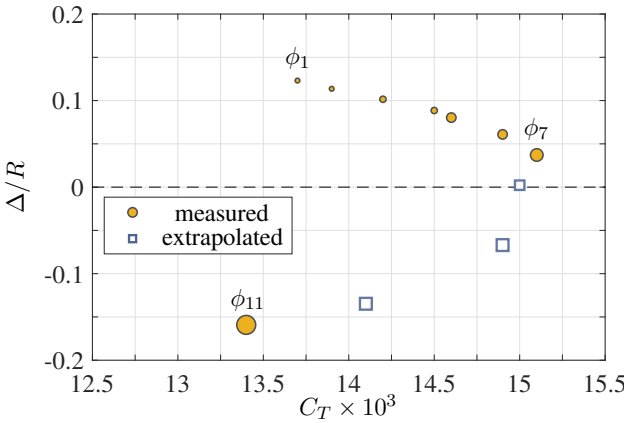

Figure 4. Miss-distance (Δ) between the upper rotor tip vortex and the lower rotor centerline versus thrust coefficient for ω_5 and δz_1. Symbol size increases with increasing index angle ϕ_k.

ii ***Spherical decay:*** If measurements are in the acoustic field and the source is compact, then pressure amplitudes should follow the $p \propto 1/r$ decay law. A simple check for this was performed using the isolated rotor spinning at $\omega = 90$ rps and by traversing a single microphone radially along the rotor disk plane between $1.0 \leq r/D \leq 8.0$. The findings are shown in Fig. 5 where the onset of spherical decay appears around $r/D \sim 2.5$ from the hub. Errors, relative to the spherical decay law, are 1.17 dB for $r/D \geq 2.5$, that then reduce to 1.03 dB for $r/D \geq 3.0$.

iii ***Isolating motor noise:*** Most drone scale rotor measurements are powered using outrunner type brushless DC motors, which are notoriously loud. The source of motor noise is well known and is caused by the first few structural modes of the motor casing [11]. Most motor noise falls into the same frequency bands where rotor broadband noise is prevalent. As such, SPSL provides an easy metric for gauging whether facility or motor noise tones are leaking into the rotor noise measurements. This is evaluated using the isolated rotor operating at 90 rps and is shown in Fig. 6 where $f_b = N_b \cdot \omega$ is the blade-pass frequency. Noise from the motor appears in some of the higher frequency tones (above $10 f_b$). The shapes and amplitudes are what one might expect for rotors of this scale.

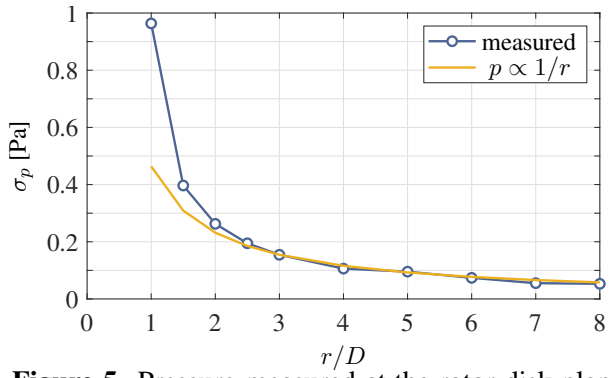

Figure 5. Pressure measured at the rotor disk plane compared with the $1/r$ decay for the isolated rotor at 90 rps.

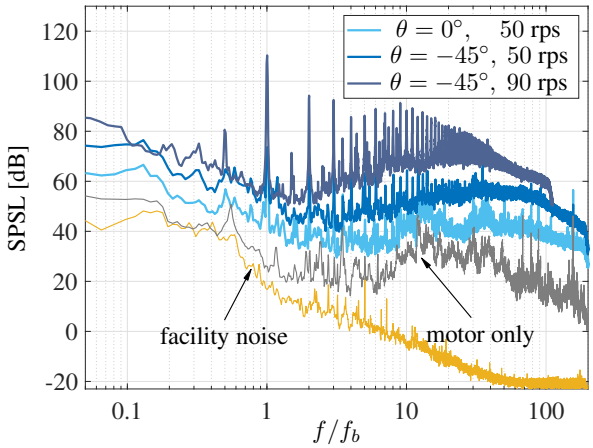

Figure 6. Background noise relative to the isolated two-blade rotor. Subsequent spectra are shifted upwards by 10 dB.

5.2 Constructive and Destructive Interference

A known feature of synchrophased rotors is the constructive and destructive interference of sound waves generated by neighboring blades and their effect on the far-field noise. This is not limited to co-rotating stacked rotors and is a common discussion point for studies involving multi-rotor platforms operating numerous motors independently without phase-synchronized control. That is, tones appear intermittently, due to nonlinear coupling between neighboring rotors and was shown early on using wavelet spectra of Tinney and Sirohi [12]. A simple demonstration of this is shown in Fig. 7 using two acoustic pressure time series from an isolated rotor (some filtering of the data has been performed to improve clarity). The pressure waveforms are identical and are used to generate a new waveform $\hat{p}(\tau) = p(t) + p(t+\tau)$ by retarding the same measured waveform using $\tau = \phi_k/\omega \cdot 360$ as the retarded time. Calculating this effect over all rotor index angles ϕ_k demonstrates the change from constructive interference to destructive interference.

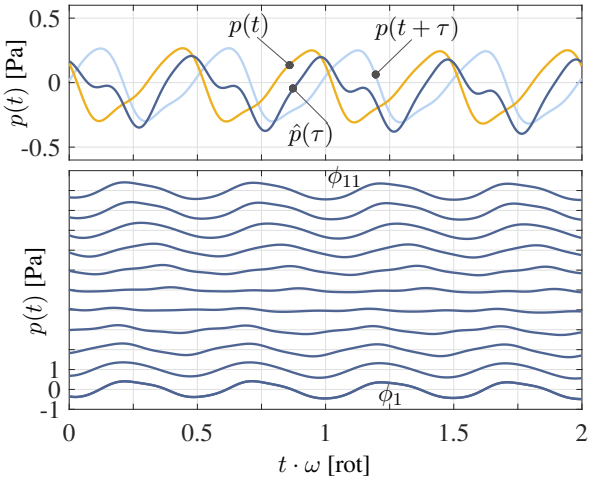

Figure 7. Top: Linear superposition of an acoustic pressure time series with its retarded time. Bottom: Comparison between estimates and measurements of acoustic pressure time series for ω_5 and δz_1. Adapted from Tinney and Valdez [1].

5.3 Analysis methods.

Data reduction techniques play a pivotal role in separating out features responsible for governing the bulk physics of a system. To this end, a number of techniques have been proposed that combine various forms of the POD (conventional, spectral, gappy) with Vold Kalman filters, to distill structure from unsteady stationary signals. In what follows, the outline of one such approach is described and is leveraged to flush out the mechanisms responsible for generating the abundance of noise generated by synchrophased stacked rotors. The process first decomposes spatially evolving acoustic waveforms using the conventional form of the POD, followed by filtering of the first few rotor harmonics using Vold Kalman filters.

5.3.1 *Conventional POD*

The simplest form of Lumley's POD is one where the kernel comprises a covariance matrix that forms from the inner product of one of two variables that make up the vector

space. In this case, the two variables stretch over space (θ) and time (t), so that

$$R(\theta,\theta') = \sum_t p(\theta,t)p^*(\theta',t) \tag{1}$$

which is self-adjoint: $\det([R_{\theta\theta'}]^{-1}) = 0$. An eigenvalue problem then forms: $R(\theta,\theta')\Phi(\theta',n) = \Lambda(n)\Phi(\theta,n)$ whose solution generates a discrete set of eigenvalues $\Lambda(n)$ with corresponding eigenvectors $\Phi(\theta,n)$ where n is an integer corresponding to the mode number ($n \in m$). Since eigenvectors are properties of the kernel, they can be used to reconstruct the variable space in two simple steps

$$a(t,n) = \sum_\theta p(\theta,t)\Phi(\theta,n) \tag{2}$$

$$\hat{p}^{(m)}(\theta,t) = \sum_n^m a(t,n)\Phi(\theta,n) \tag{3}$$

The reconstruction process is what allows certain signals to be retained while others are discarded (or filtered out). If ever a bias is introduced by the user, it occurs in the reconstruction process. If $m = \text{rank}(R_{\theta\theta'})$, then $\hat{p}^{(m)}(\theta,t) = p(\theta,t)$, and no filtering has been performed.

While POD can be used to decompose both variables, we will resort to Vold-Kalman filters (VKF) to decompose the other variables as this has the option of being performed in real time. In this case, a second generation Vold-Kalman multi-order tracking method is proposed.

5.3.2 *Vold-Kalman Multi-Order Tracking Filter*

Like POD, the VKF separates structure $P(\theta,t)$ from noise $\eta(\theta,t)$ using a two step reconstruction process as follows

$$s_k^\theta(t) = [H_{ttk}]^{-1}\Theta_k(t)^* p(\theta,t) \tag{4}$$

$$P(\theta,t) = \sum_k s_k^\theta(t)\Theta_k(t) \tag{5}$$

where $p(\theta,t) = P(\theta,t) + \eta(\theta,t)$ is the full signal, $s_k^\theta(t)$ is a low-frequency complex envelop, $\Theta_k(t)^*$ is a complex phasor, and the order of the filter k is denumerable. In practice, k defines the number of waveforms to be extracted. Similar to the role of the eigenvectors in the POD, the phasor serves to extract waveforms that make up the structured components of $p(\theta,t)$. The extraction is achieved by minimizing the error between the phasor and the raw signal and is performed using backward finite differencing. The crux of the problem is the formation of a multi-order difference matrix

$$[H_{ttk}]^{-1} = \begin{cases} r^2[A]^T[A] + [I], & \text{for} \quad k = l \\ \Theta_k(t)^*\Theta_l(t), & \text{for} \quad k \neq l \end{cases} \tag{6}$$

where r is a weighting parameter that depends on the number of poles in the filter, $[A]$ is a triangular array of coefficients and $[I]$ is an identity matrix. For a 2-pole filter, the weighting function is approximated numerically while the coefficients are based on Pascal's triangle and is written as

$$\begin{aligned} \nabla^2 s_k(t_i) &= s_k(t_{i+2}) - 2s_k(t_{i+1}) + s_k(t_i) \\ &= \epsilon(t_i) \end{aligned} \tag{7}$$

For a multi-order approach of order k, Eq. (7) resorts to an inverse problem of the form $[A][s_k^\theta(t)] = [\varepsilon_k(t)]$.

5.3.3 *Combining Methods*

There are several ways in which the POD and VKF techniques can be combined to dissect the different variables that make up the signal, thus making them complementary techniques. For the conventional POD, two options are proposed. The first uses VKF to filter the time variable by substituting $p(\theta,t)$ with its structured component $P(\theta,t)$ followed by a calculation of the POD coefficients. That is, Eqs. (4) and (5) are repeated for all of θ followed by the substitution of $P(\theta,t)$ into Eqs. (2) and (3) so that,

$$a_k(t,n) = \sum_\theta P(\theta,t)\Phi(\theta,n) \tag{8}$$

$$\hat{p}^{(mk)}(\theta,t) = \sum_n^m a_k(t,n)\Phi(\theta,n) \tag{9}$$

A potentially less costly alternative is to use the VKF to filter the POD coefficients $a(t,n)$ in place of the physical variable $p(\theta,t)$ since the opposing variable θ is suppressed during the summation process. In this case, the VKF is applied to individual POD expansion coefficients.

5.3.4 *Results*

In Fig. 8, normalized eigenvalues are shown for changes in rotor index angle where the denominator comprises the total resolved signal: $E = \sum_\theta \sum_t p(\theta,t)^2 = \sum_n \Lambda(n)$. The decay in convergence is less rapid as rotor index angle increases and advances from being dominated by two blade passes per rotation, to four blade-passes per rotation. As such, the sound field should be less structured and is an indicator of CDI rotor noise control.

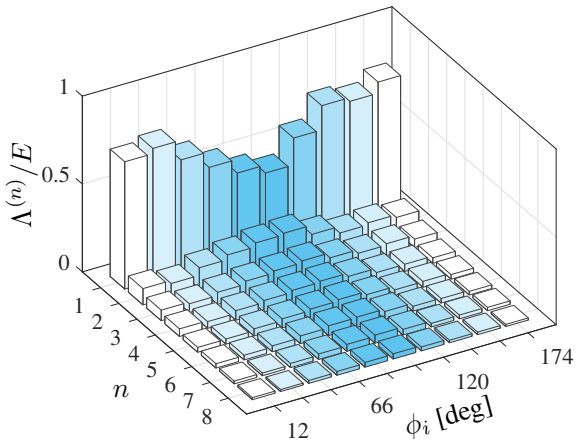

Figure 8. a) Normalized eigenvalue convergence and b) cumulative sum.

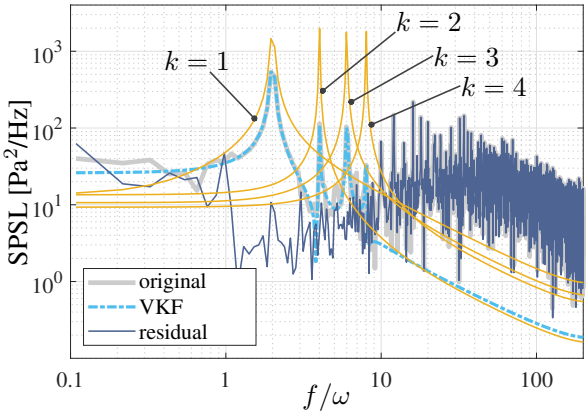

Figure 9. a) Sample acoustic time series with and without filtering, and b) its corresponding spectra superimposed the first four VKF phasors, the structural and residual components of the signal.

As for the VKF method, the instantaneous spectra of the raw acoustic pressure time series are shown in Fig. 9 superposed the structured component and its residual. Filtering is performed using $k = 4$ phasors corresponding to the first four blade pass frequency harmonics. Several reconstructions of the filtered sound field are then shown in Fig. 10 for changes to the rotor index angle and using the same combination of POD modes and VKF orders. When the upper and lower rotors are aligned and the sound field is a manifestation of constructive interference, sound waves are shown to extend over all observer positions. Eventually destructive interference takes over as the rotor index angle advances to a four blade configuration as seen in Figs. 10c and 10d.

5.4 Performance trade-space

An evaluation of the trade-space between rotor noise and hover performance is evaluated using Sound Pressure Levels (SPL) of the filtered waveforms at two observer locations in the far-field. The first is located at the rotor disk plane ($\theta = 0$ deg) while the second is where a ground observer would reside ($-\theta = 45$ deg). Symbol sizes increase with increasing index angle (ϕ). As seen in Fig. 11, rotor hover efficiency ranges from a maximum of 0.77 at $\varphi = -6$ deg, and then drops to 0.72 at $\varphi = 30$ deg. This change generates a 8% increase in hover performance with only a 0.40 dB and 0.03 dB increase in SPL for the rotor disk plane and ground observers, respectively. When implementing noise control measures through changes in rotor index angle, SPL levels drop by as much as 6 dB and 4 dB for the rotor disk plane and ground observers, respectively, while the rotor advances from $\varphi = -78$ deg to $\varphi = -6$ deg. This equates to a moderate loss in hover efficiency by -2%.

FURTHER INVESTIGATION OF THE SIMPLIFIED SEPTA ACOUSTIC LINER CONCEPT

Brian M. Howerton[1*] **Jordan R. Kreitzman**[1]
[1] Applied Acoustics Branch, NASA Langley Research Center, USA

ABSTRACT

Additional refinements of an acoustic liner design incorporating single-hole perforate septa were evaluated by the NASA Langley Liner Physics Team. The design, termed the 'Simplified Septa' concept, incorporates embedded septa as found in traditional, multidegree-of-freedom liners. Typically, such septa are either multihole perforates or porous mesh, whereas the Simplified Septa uses only one hole per cell. An optimization scheme was employed to determine the liner geometry based on a target absorption cost function. These optimized designs incorporating one and two septa were tested in the NASA Langley Normal Incidence Tube (NIT) to determine impedance and absorption spectra for swept tonal excitation at 120 and 140 dB. Experimental results were compared to predictions from a liner model based on the Zwikker-Kosten Transmission Line (ZKTL) code and showed good agreement for no-flow conditions. Absorption performance was found to be good over a wide portion of the frequency range tested. The single-septum design geometry was applied to a larger sample suitable for evaluation in the NASA Langley Grazing Flow Impedance Tube (GFIT). The sample was subjected to grazing flow speeds up to Mach 0.5 and swept tonal excitation at 120 and 140 dB to determine its impedance under these conditions. The results gave confidence that the concept could be used successfully in a grazing flow environment.

1. INTRODUCTION

Certification requirements limit the noise levels commercial aircraft can produce during operations. Aircraft engines are typically the primary contributor to the overall noise spectrum with the engine fan being a significant contributor [1]. The application of acoustic liners to the walls of the inlet and aft bypass ducts of turbofan engines has been highly effective in reducing total engine noise [2–4]. Engine design trends have led to reduced tonal levels relative to the broadband components of the total noise spectrum [5]. Thus, liner concepts with wider absorption bandwidth are of interest for future applications.

Examples of liners typically used in aircraft engines are shown in Figure 1. Single-degree-of-freedom (SDOF) liners provide excellent absorption for a narrow range of frequencies (approximately one octave) controlled through the choice of cavity depth and facesheet geometry. Widening this frequency range can be achieved by embedding a porous septum within the liner core to create a two-degree-of-freedom (2DOF) liner. The additional resonant frequencies extend the effective absorption range to two octaves. Using additional septa can widen this further but with additional complexity and cost.

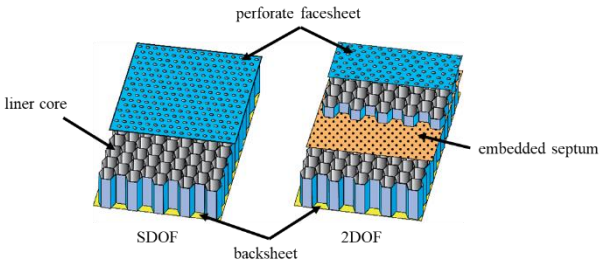

Figure 1. Conventional liner construction.

A previous paper detailed the development of the Simplified Septa (SS) liner concept whereby embedded septa employing a single perforation were used. Results showed good broadband performance for optimized 2- and 3-septa configurations [6]. The current work continues the development of the concept through testing a new set of 1- and 2-septa designs optimized for absorption from 600-3000 Hz at 140 dB tonal excitation. Samples were manufactured using stereolithography and evaluated in the NASA Langley Normal Incidence Tube (NIT) at source sound pressure levels (SPLs) of 120 and 140 dB to determine their acoustic performance. One configuration was also evaluated using the NASA Langley Grazing Flow Impedance Tube (GFIT) for the same frequencies and SPLs at Mach numbers up to 0.5 to determine if the concept performs adequately when exposed to flow.

2. BACKGROUND

2.1 Simplified Septa Concept

The SS concept is an alternative embodiment of the typical 2DOF liner that may be attractive for certain applications. The use of a single-hole septum perforate can simplify manufacturing of the liner core. The required perforations could be punched, drilled or lasered (depending on diameter) either before or after septum placement. Additive manufacturing (AM) could be readily applied as the perforations are large enough to be within the limits of such methods. The use of a single hole generates dissipation through the creation of vortical structures separating from the hole edges, especially at high SPLs. The resultant liner is, therefore, nonlinear with increasing acoustic levels.

2.2 Septa Optimization

Determination of the liner facesheet properties along with septa placement, hole diameter and liner depth were done via an optimization process. The liner was modeled using a version of the NASA Zwikker and Kosten Transmission Line (ZKTL) impedance prediction code [7–10]. The impedance modeling approach was implemented in a set of Python scripts and coupled with a nonlinear optimization routine, NLopt [11]. Specifically, the BOBYQA [12] algorithm was implemented, which is a derivative free bound constrained local minimum solver.

Constraints were imposed upon the various geometric parameters of the liner as shown in Table 1. The bounds were chosen to ensure resulting designs could be manufactured with available methods but provides latitude for parameter values outside of those found in production liners. Note that septa placement was done as a percentage of the available height and bounded to prevent placement either too close to the facesheet, backplate or other septa. Figure 2 provides a diagram of a liner unit cell with pertinent dimension labels. Note that the number of septa used was a fixed parameter, not a variable in the optimization.

Table 1. Simplified Septa liner optimization constraints.

	Description	Lower Bound	Upper Bound
Facesheet	hole dia. (d_n)	0.51 mm	1.52 mm
	thickness (t_n)	0.51 mm	2.54 mm
	POA	4 %	16 %
Septa	hole dia. (d_n)	0.51 mm	3.81 mm
	thickness (t_n)	0.51 mm	1.52 mm
Cavities	total length (L)	7.62 mm	43.18 mm
	L_n (% of available height)	10	90

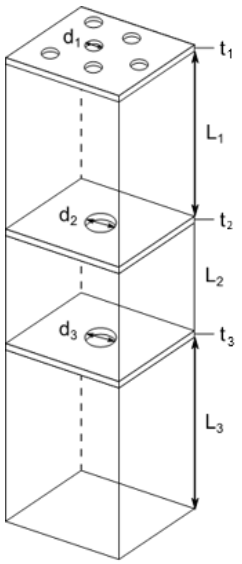

Figure 2. AM liner core unit cell diagram.

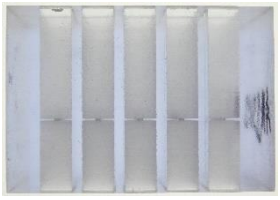
An objective function based on maximizing the computed absorption coefficient over a desired frequency range was used. If X is a vector of the liner design variables, then the

average absorption coefficient over a given frequency range can be expressed as:

$$\bar{\alpha} = \frac{1}{f_2 - f_1}\int_{f_1}^{f_2} \alpha(X)df \quad (1)$$

where f_1 and f_2 are the lowest and highest frequencies of interest. For the current study, these frequencies were set to 600 and 3000 Hz to reflect the majority of the testing range. A source SPL of 140dB was chosen for the optimization to more closely match the expected SPLs of a practical engine application.

3. EXPERIMENT



Liner samples were constructed using AM and consist of the liner core and a separable facesheet fabricated via a stereolithography process whereby liquid plastic resin is photopolymerized to build the part. The experimental investigation involves two phases of testing. The first evaluated two configurations in the NASA Langley NIT to determine their impedance and absorption spectra. These results were used to downselect a configuration for Phase 2 testing in the grazing flow environment of the GFIT test rig.

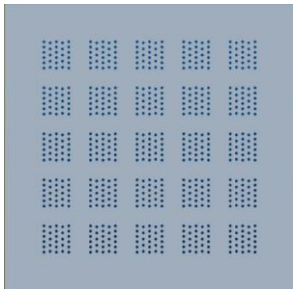
3.1 Liner Core Construction

The AM liners for the NIT testing employed a 5x5 grid of 7.62 mm square unit cells separated by 2.54 mm partitions forming a total sample area of 2581 mm^2. This sample area matches the cross-section area of the NIT waveguide. Table 2 lists dimensions for the two Phase 1 core samples, the first with one embedded septum per cell (AM1S) and the second with two embedded septa per cell (AM2S). Images of the core samples are provided in Fig. 3 showing the embedded septa in each cell.

Table 2. Liner core unit cell dimensions.

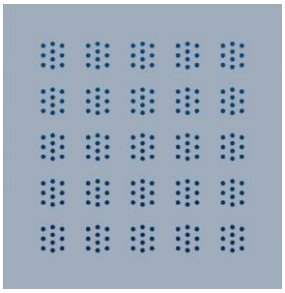
Dimension (mm)	1 Septa (AM1S)	2 Septa (AM2S)
t_1	1.32	1.35
d_1	0.56	0.99
L_1	26.49	24.08
t_2	0.30	0.30
d_2	1.19	1.42
L_2	16.76	12.19
t_3	N/A	0.30
d_3	N/A	0.79
L_3	N/A	7.7
Total Length	29.85	

a) AM1S



b) AM2S

Figure 3. Side view of AM liner core samples.



An additional core sample, based on the AM1S unit cell geometry, was constructed for Phase 2 testing in the GFIT. The sample was an extended replication of the NIT liner geometry, creating a 5x40 cell grid with dimensions of 50.8 x 254 mm (width x length).

3.2 Liner Facesheet Construction

Each core was paired with a printed facesheet with unique porosity, hole geometry, spacing and thickness. The AM1S sheet (Fig. 4a) is 1.32 mm thick and has a percent open area (POA) of 13.3 using 28 0.56 mm diameter circular holes per cell distributed in a staggered pattern. The facesheet for AM2S (Fig. 4b) is 1.35 mm thick with a POA of 11.8 and ten 0.99 mm diameter holes per cell (again in a uniform, staggered pattern). The facesheet for the GFIT sample is based on the AM1S geometry from Table 2, but rather than being a separate part, was integrally constructed with the core.

b) AM2S

Figure 4. Top view of AM liner facesheets.

3.3 Experimental Test Rigs

3.3.1 Normal Incidence Tube (Phase 1)

The NIT consists of a group of six electromagnetic acoustic drivers coupled radially into a cylindrical tube that transitions to the 50.8 mm x 50.8 mm square cross-section waveguide. Samples are placed at the exit of the tube to be exposed to the generated sound field. Individual digital-to-

analog converters for each speaker allow for the creation of arbitrary waveforms to energize each driver. Typically, tonal or broadband signals are employed for impedance eduction. Impedance spectra for each sample are obtained in the NIT via the switching Two-Microphone Method (TMM) [13] and the Multipoint Method of Jones and Stiede [14]. Figure 5 is a diagram of the acquisition system while Figure 6 is a rendering of the NIT showing the pertinent features. Further details on the experimental setup can be found in Ref. 6.

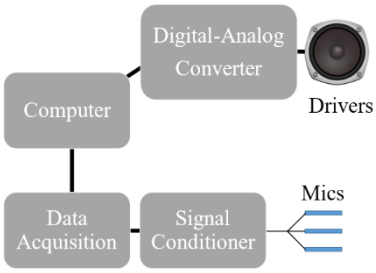

Figure 5. Normal Incidence Tube acquisition system diagram.

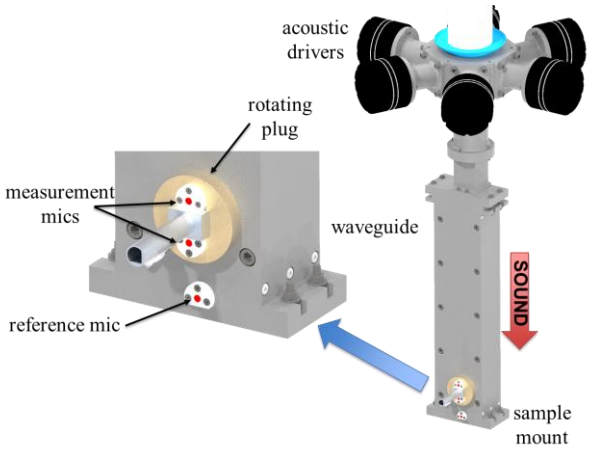

Figure 6. NASA Langley Normal Incidence Tube (NIT) general arrangement.

3.3.2 Grazing Flow Impedance Tube (Phase 2)

Grazing flow tests are performed on the liner samples using the GFIT. A schematic diagram of the setup is shown in Fig. 7. The GFIT is an acoustic wind tunnel with a 50.8 mm x 63.5 mm cross-section at the test section capable of centerline flow Mach numbers up to 0.6. Either of the two speaker arrays can be energized to achieve SPLs up to 150 dB depending on the desired orientation. For this investigation, the upstream array was employed to simulate conditions in the aft duct of a turbofan engine. An array of 95 pressure-field condenser microphones positioned along the length of the duct were used to measure the acoustic pressure profile. SPL and phase readings from each microphone were used to educe the liner acoustic impedance using the Straightforward Method of Watson and Jones [15].

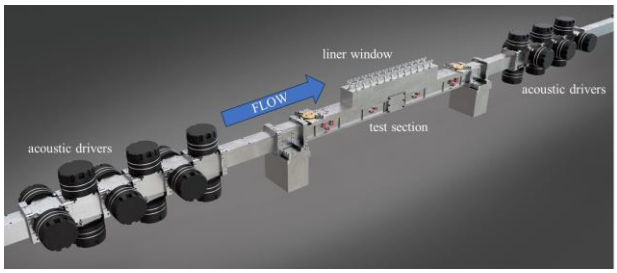

Figure 7. NASA Langley Grazing Flow Impedance Tube (GFIT) general arrangement.

3.3.3 Measurement Process

For both phases of testing, the Swept-Sine Method (SSM) [16] was used to obtain the complex acoustic cross spectra between the measurement microphones and the source signal supplied to the acoustic drivers. The acoustic source signal increases linearly in frequency from 400 to 3000 Hz during the measurement process and was amplitude modulated such that the total SPL at the sample surface was constant. A Vold-Kalman order tracking filter was employed to extract complex acoustic pressures at each microphone for the frequencies of interest. These pressures provided input for the various impedance eduction methods employed.
In the GFIT, grazing flow speed was set to duct centerline Mach numbers of 0.0, 0.3, and 0.5. At each Mach number, the acoustic source generates sine sweeps at SPLs of 120 dB and 140 dB for the same frequency range as used in the Phase 1 NIT testing.

4. RESULTS

4.1 Phase 1 - NIT

The impedance spectra for sample AM1S are shown in Figs. 8–9 at the two SPLs along with matching predictions. For both sound pressure levels, the model predicts the impedance behavior well with some deviation around antiresonance (~1800 Hz). Such deviations can be expected between model and experiment at 140 dB because the

model does not account for nonlinearities that create a reactance loss associated with perforates at high SPLs. There is work planned to incorporate a correction. Note that the frequency variation in both resistance and reactance decreases for the higher SPL which is a desired characteristic in a broadband absorber.

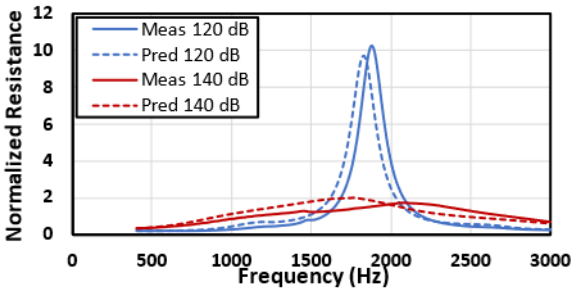

Figure 8. Comparison of measured AM1S acoustic resistance spectra to model predictions.

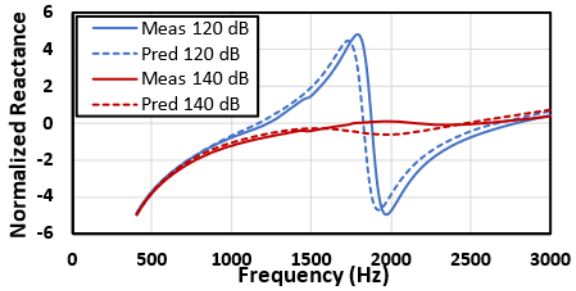

Figure 9. Comparison of measured AM1S acoustic reactance spectra to model predictions.

Figure 10 shows the computed and predicted absorption coefficient spectra for this configuration. As with impedance, the predictions are well matched to experimental results. Liners with normal incidence absorption coefficients above 0.4 have, historically, provided significant attenuation when evaluated in a grazing incidence environment such as the GFIT. Thus, one could expect reasonable broadband performance for this configuration above approximately 800 Hz and especially for higher sound pressure levels.

The addition of a second septum to the AM2S sample altered the characteristics of the impedance spectra as evident in Figs. 11–12. One can see in the 120 dB resistance spectra the appearance of a second antiresonance peak in the upper frequency range. The magnitudes of the peaks, however, are lessened compared to AM1S. Similar behavior is noted in the reactance, where the antiresonant spikes are not as sharp as AM1S.

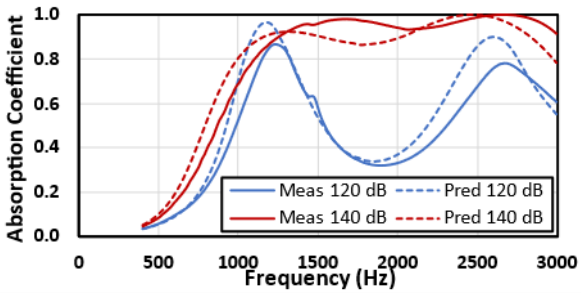

Figure 10. Comparison of measured AM1S absorption spectra to model predictions.

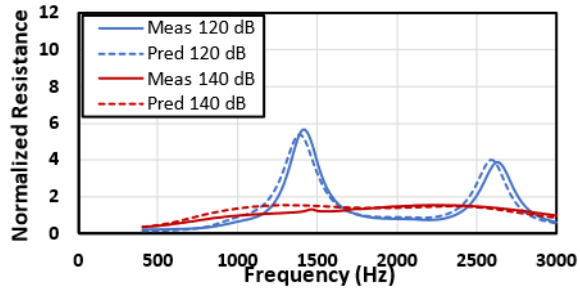

Figure 11. Comparison of measured AM2S acoustic resistance spectra to model predictions.

At 140 dB, there is little difference between the impedance spectra for both configurations. Interestingly, the agreement between experiment and modeling improved slightly for this configuration especially at the antiresonance frequencies. Enhanced absorption characteristics in the midfrequency range are observed for the 120 dB SPL case (Fig. 13), but performance at the design point of 140 dB was relatively unchanged compared to the simpler AM1S design.

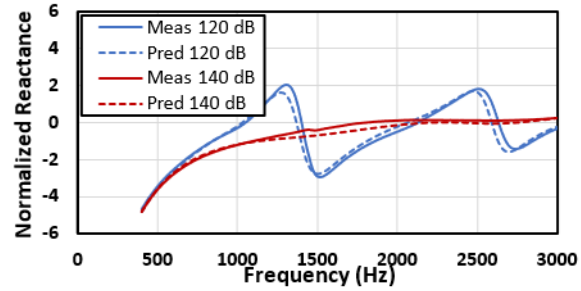

Figure 12. Comparison of measured AM2S acoustic reactance spectra to model predictions.

Based on these results, a decision was made to downselect the AM1S configuration for Phase 2 testing in the grazing flow environment of the GFIT. The addition of the second septum for AM2S does not appear to offer a significant acoustic benefit to justify the complexity and cost of production for flightworthy engine applications.

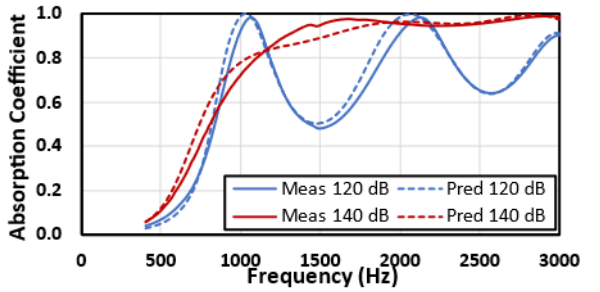

Figure 13. Comparison of measured AM2S absorption spectra to model predictions.

4.2 Phase 2 - GFIT

The intent of this investigation phase is to determine if the broadband absorption performance of the Simplified Septa concept observed in Phase 1 would carry over to a grazing flow environment. Ideally, one would see similar impedance characteristics for the design between the two test rigs, but it should be noted that the liner geometry was not optimized for the GFIT and grazing flow.

For the AM1S liner geometry, educed resistance and reactance spectra for an SPL of 120 dB are provided in Fig. 14 and 15, respectively, at the three test Mach numbers. At M=0.0, resistance and reactance are very similar to that seen in Phase 1 (Figs. 8–9) testing. Increasing flow speed shifts antiresonance to slightly higher frequencies with reduced peak values for both impedance quantities.

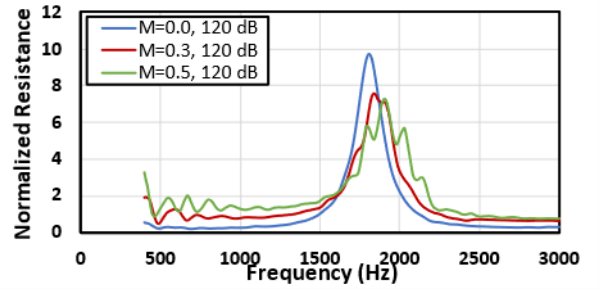

Figure 14. Educed AM1S acoustic resistance spectra for various flow Mach numbers, 120 dB SPL.

Resistance away from the peak increases as expected while reactance seems to flatten slightly for frequencies below antiresonance.

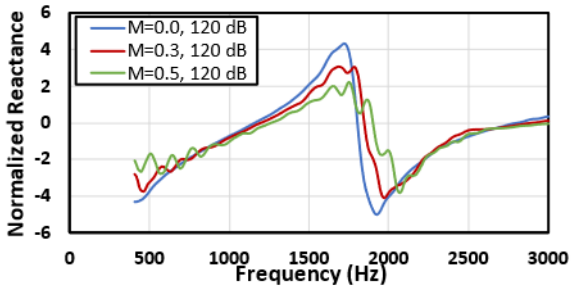

Figure 15. Educed AM1S acoustic reactance spectra for various flow Mach numbers, 120 dB SPL.

Increasing the acoustic excitation levels to 140 dB reduces the frequency variation in the impedance spectra for all Mach numbers, but variation is greater than observed in Phase 1 (Fig. 16–17). Resistance follows similar trends as the 120 dB data while reactance is only marginally affected by increasing the flow Mach number. The relative

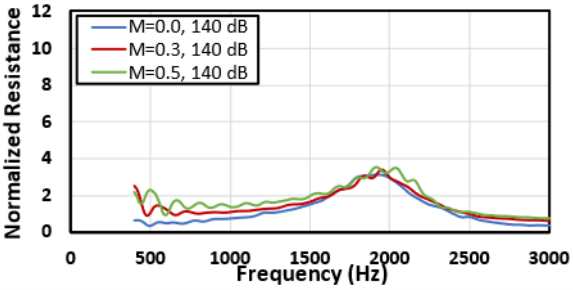

Figure 16. Educed AM1S acoustic resistance spectra for various flow Mach numbers, 140 dB SPL.

insensitivity to Mach number is somewhat expected given the POA of the facesheet as it is on the higher end of values used in engine liners. Such behavior could be desired in achieving predictable acoustic performance in practical applications.

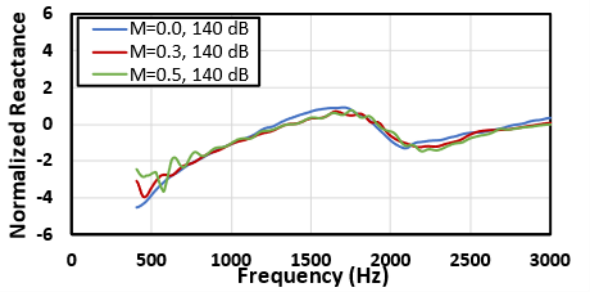

Figure 17. Educed AM1S acoustic reactance spectra for various flow Mach numbers, 140 dB SPL.

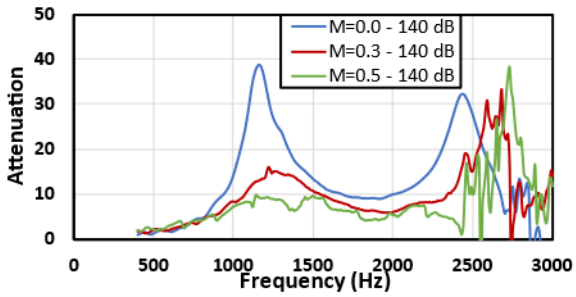

Figure 18. Calculated AM1S attenuation spectra for various flow Mach numbers, 140 dB SPL.

For both source SPLs, the educed impedance spectra exhibit an interesting characteristic with grazing flow. Some 'waviness' is observed in the impedance spectra, especially at lower frequencies and around antiresonance and becomes more pronounced at the higher Mach numbers. As the effect appears at both source levels, it is likely not acoustically induced but driven by some flow phenomenon. An initial hypothesis centers around possible compliance of the septum as its thickness (0.3 mm) is less than half of a typical facesheet. Further study is warranted to determine the cause, but the effect does not change the overall character of the spectra or the conclusions from this investigation.

Combining microphone SPL, relative phase and location data, one can compute the incident and reflected levels upstream and downstream of the liner sample. By subtracting pressure levels of the waves travelling with the flow, a simple measurement of liner attenuation can be computed. Data for both SPLs showed similar trends as the flow Mach number increased. As the higher source SPL is more relevant to most applications of this concept, only those results are presented. Figure 18 provides frequency spectra of this attenuation calculation for the AM1S sample at the three flow conditions for an SPL of 140 dB.

In keeping with the results from Phase 1 where the calculated absorption coefficient was above 0.4 for frequencies above 800 Hz, attenuation levels are generally greater than 5 dB up to the point the first higher-order mode is cut on (~2700 Hz @ M=0.0, ~2400 Hz @ M=0.5). Such levels have been shown previously to be sufficient for accurate impedance eduction [17]. The peaks in attenuation seen for the no-flow case are significantly reduced as Mach number increases. This is expected as the propagating wave has less time to interact with the liner due to flow convection.

Improved performance could be realized by altering the optimization objective function to target an impedance spectrum that produces greater attenuation in the GFIT. In developing SS liners for practical applications, this would be the likely approach.

5. CONCLUSIONS

Liner samples based on the Simplified Septa concept were constructed via AM and tested to determine their acoustic performance. Data from NIT were used to calculate impedance and absorption coefficient spectra for optimized single- and two-septa liners at two SPLs for frequencies between 400 and 3000 Hz. Comparisons of experimental results to predictions from a liner model based on ZKTL showed very good agreement. Both designs provided good absorption over a wide frequency range. The single-septa configuration was employed to create a larger liner for use in the GFIT to explore the effect of grazing flow. Acoustic data over the same frequency range, at 120 and 140 dB SPL and for Mach numbers up to 0.5 was used to educe impedance spectra and calculate the resulting attenuation levels. This phase of testing confirmed the introduction of grazing flow did not markedly alter the impedance characteristics of the liner. Thus, there is confidence the concept can be successfully employed in such noise control applications.

6. ACKNOWLEDGMENTS

The authors would like to thank Robert Andrews of the NASA Langley Additive Manufacturing Center for his efforts to construct the test samples. Appreciation also goes to NASA Langley Liner Physics Team members Christopher Shoemaker for processing the GFIT test data and Alonzo 'Max' Reid for acquiring the NIT data.

TURBULENCE EFFECT ON THE ACOUSTIC BOUNDARY LAYER OF PERFORATED ACOUSTIC LINERS

Anita Schulz[1*] **Dirk Ronneberger**[2]
[1] University of Applied Sciences (HTW) Berlin, 12459 Berlin, Germany
[2] retired, formerly Drittes Physikalisches Institut, 37077 Göttingen, Germany

ABSTRACT

In this work the shear stress effect on the acoustic boundary condition of liners with grazing turbulent mean flow is investigated. The lined wall is supposed to be rigid and homogeneously permeable. We have derived two semi-analytical models supplemented by DNS data which provide insight in the qualitative dependencies and the governing parameters of the turbulence effect. We found a critical frequency $\omega_c^+ = 10^{-2}$, which separates two regimes: For high frequencies the sound-synchronous shear stress does not reach beyond the viscous sublayer and the turbulence has no impact on the acoustic boundary condition. However, for low frequencies the shear wave penetrates into the turbulent flow layer and deforms the turbulent vorticity field. This causes an increased magnitude of sound-coherent wall shear stress as well as a significant change of the wall shear stress impedance and of the effective acoustic boundary condition. It was found that the latter depends particularly strongly on the dynamic processes which take place in the near-wall region of the turbulent wall boundary layer. In order to get more insight into the course of these processes impulse response functions of the sound-coherent shear stress have been calculated from existing DNS data. The results confirm a previous hypothesis that a shear wave propagates from the wall into the viscous sublayer, triggers a reaction of the turbulent shear stress in the turbulent region of the boundary layer, which in turn generates a viscous shear stress field that extends to the wall. This latter reaction manifests itself in a distinct 'turbulent portion' of the sound-coherent wall shear stress. It was found also that this dynamic process takes a characteristic time of $t^+ \approx 160$.

1. INTRODUCTION

Passive acoustic linings are widely used to reduce noise emission for instance in the inlet or bypass duct of aircraft engines or in the duct walls of gas turbines. In most of these applications, the liner is naturally exposed to a highly turbulent grazing flow. It is well known from experiments that the acoustic properties of liners, especially the impedance and the sound absorption, can change significantly due to the grazing mean flow. The mean grazing flow is to be expected to interact with the acoustic particle velocity through the perforations of the rigid face-sheet of the liner. This induces a sound-coherent ('acoustic') shear stress at the wall which can exceed the well-known shear stress of the no-flow case by orders of magnitude. This shear stress plays an essential role in the acoustic boundary condition and its correct consideration is crucial for the design of liners if precise predictions of the sound attenuation of the liner should be achieved. The propagation of shear stress in the so-called acoustic boundary layer is strongly affected by the Reynolds stresses of the turbulence, which in turn depends on the sound-induced temporal change of the acoustic boundary condition. However, little is known about the involved physical effects and its governing parameters and in most models, the acoustic shear stress and the turbulence effect are ignored completely.

This report presents the current status of an ongoing study on the turbulent shear stress effect. The long-term goal from an engineering point of view is to derive an 'effective' acoustic boundary condition which includes the

distribution of shear stress caused by turbulence together with the effect of the wall impedance. However, for this purpose we must first investigate how sound-coherent shear stress is generated and propagates in the turbulent boundary layer, how the Reynolds stress and other turbulence characteristics react spatially and dynamically to the acoustic perturbation of the mean flow, and what the governing parameters of these processes are.
It has to be noted that in the course of the study and as a first step we have limited ourselves to a particular and somewhat artificial type of liner wall: the rigid homogeneously permeable wall with infinitesimally small pores. For this wall, the acoustic effects due to the macroscopic openings of realistic liners (e.g. propagation and scattering of sound waves and hydrodynamic waves, local production of shear stress, shear layer instabilities) can be neglected and the no-slip condition applies. [1, 2] This is beneficial since it allows a simplified theoretical description and precisely defines the generation of a shear wave and the wall-normal gradient of acoustic shear stress at the wall. Moreover, we assume that the solutions for the homogeneously permeable wall will be at least part of the solution of the full problem (when the effects of the macroscopic openings are included).

2. INFLUENCE OF THE TURBULENCE ON THE EFFECTIVE BOUNDARY CONDITION

In our previous work [2, 3], the influence of turbulence on the effect of the acoustic boundary condition of a rigid, but homogeneously permeable liner has already been qualitatively investigated and some of the governing factors have been determined. These findings are summarized here briefly in order to build on this with further conclusions and analysis on the generation of sound-coherent shear stress:

1. The distribution of sound-coherent shear stress in the acoustic boundary layer is modified by two individual effects or properties of the turbulence:

   - Shear deformation of the turbulent vorticity field: The turbulence in the acoustic boundary layer is sheared and deformed by the shear wave which is exited at the wall. This results in a modulated or sound-synchronous part of the Reynolds shear stress which must be modeled somehow. In the few available models [4–8] the classic Boussinesq hypothesis associated with a fictive 'eddy viscosity' was used, which is a well-established concept for mean flow turbulence. However, the transfer of this concept to the acoustic case is questionable and the results of a direct numerical simulation (DNS) [9] have supported this concern.

   - Relaxation due to wall-normal displacement of the turbulent vorticity field: In a flow in equilibrium, also the statistical characteristics of the turbulent tangle of vortex filaments is in a state of equilibrium depending on the distance from the wall. If the vortex filaments are displaced due to the acoustical flow through the wall, turbulent relaxation processes will set in which seek to restore the previous state of equilibrium. This turbulent relaxation has never been investigated before in case of turbulent flow with an acoustical displacement at the boundary.

2. We have developed two semi-analytical models to include the above mentioned turbulence effects. Both models are based on extremely different physical assumptions:

   - The first model ('Model 1') follows the traditional concept of an eddy viscosity, i.e. it assumes a strictly local relationship between turbulent shear stress and strain rate. The parameter of the eddy viscosity was estimated by DNS data of Hartmann [9].

   - The second model ('Model 2') is based on the rather speculative hypothesis, suggested by the results of the DNS, that the sound-synchronous Reynolds stress, at least near the wall, is controlled solely by the acoustic wall shear stress and is independent of any local properties of the flow field. The wall shear stress parameter in this model was also estimated by DNS data.

It has to be emphasized that both models present two very hypothetical and simplified physical concepts and, in fact, we have no idea which approach is closer to reality. Moreover, the models represent two extreme cases for the interaction between the turbulent shear stress and the flow field: Model 1 assumes a strictly local interaction, whereas Model 2 is based on an extreme remote effect. The models can be used to show how strong the influence of the previously neglected effects can be in general and what the qualitative dependencies and the governing parameters of the turbulence effect are.

3. A representative result for the two models is

shown in Fig. 1 for the wall shear stress impedance

$$z_\tau^+ = \frac{1}{\rho_0 u_\tau} \frac{\widetilde{\tau}_w}{\widetilde{u}_0}. \tag{1}$$

We consider z_τ^+ [9, 10] as an appropriate quantity to discuss the turbulence effect since, in first instance, it can be regarded as measure for the acoustic wall shear stress $\widetilde{\tau}_w$ reacting to the streamwise acoustic velocity $\widetilde{u}_0$ at the wall. Also, it has been found that z_τ^+ determines directly the effective admittance of the liner if the Doppler-shift of the frequency is disregarded (not shown here). Note that we use the common normalization by turbulent boundary layer quantities, i.e. the kinematic viscosity $\nu = \mu/\rho$ and the friction velocity u_τ in Eq. 1. Figure 1 depicts the magnitude and phase of the wall shear stress impedance as a function of the normalized frequency $\omega^+ = \omega\nu/u_\tau^2$. The colors of the curves mark the solutions for the two extreme cases of turbulent relaxation: non-relaxed flow (red) or fully-relaxed flow (black). By 'non-relaxed flow' we refer to the initial state of flow before relaxation processes set in after a sudden wall-normal displacement $\widetilde{\xi}$ of the fluid at the boundary. In this case, the displacement would lead to an immediate shift of the flow profile, the turbulent vortex filaments, and their inherent velocity correlations as a whole to a new distance from the wall. This is because the time scales of the acoustic displacement are small compared to the time scales of the turbulent boundary layer. The subsequent start of turbulent relaxation rebalances the flow, i.e. eventually adapt the flow profile and the velocity correlations to the new wall distance. We refer to this second state of flow as the 'fully-relaxed' flow. Note that the solution for a real relaxing flow, which relaxes with a finite relaxation time, is supposed to be somewhere between the solutions of the two relaxation limits. Previous models [4–8, 11, 12] have only considered implicitly the limit of a fully-relaxed flow which implies that the turbulence always adjusts without the slightest delay to the wall-normal displacement.

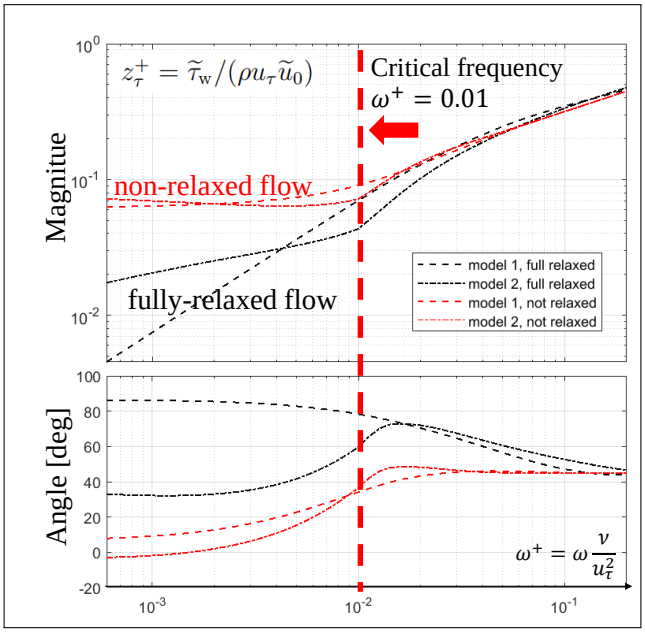

Figure 1. Results for the wall shear stress impedance $z_\tau^+ = \frac{1}{\rho_0 u_\tau} \frac{\widetilde{\tau}_w}{\widetilde{u}_0}$ normalized with wall parameters as a function of the normalized angular frequency.

The results, which are shown in Fig. 1 among others, can be interpreted as follows.

- We found a **'critical frequency'** $\omega_c^+ \approx 10^{-2}$, which separates two regimes of impact of turbulent shear stress on the acoustic boundary condition. This frequency is highlighted in Fig. 1. For 'high' frequencies $\omega > \omega_c$ the results become more and more independent of the applied turbulence model and of the state of relaxation effect. This is because at high frequencies the sound-synchronous shear stress decays close to the wall due to the short wavelength of the according diffusion wave and does not reach beyond the viscous sublayer. Thus, in this regime the turbulence has no impact on the effective boundary condition and can be ignored in practical situations.

- However, for 'low' frequencies $\omega < \omega_c$ the acoustic shear stress wave penetrates into the turbulent flow (at least into the buffer layer) which causes a great change in the spatial distribution of sound-coherent shear stress. This is more pronounced and covers a larger distance from the wall the lower the frequency is. On the one hand, this results in a strongly increased magnitude of acoustic wall shear stress and accordingly on a change of the wall shear stress impedance z_τ^+. On the other hand, it leads to a major change of the effective impedance relative to the liner impedance (not shown here, see [3]) which can reach orders of magnitude depending on the Mach number and the streamwise wavenumber of the sound wave. Also, completely different trends have been found for wave propagation in or against the flow direction. Even nega-

tive real parts of the effective impedance have been found for cases of wave propagation against the flow and it is still unclear if this indicates production of sound or just an energy transport in the opposite direction.

- Unfortunately, in the low-frequency regime not only the deviation between the solutions for the two limiting flow states, non-relaxed and fully-relaxed flow, are increasing, but also the discrepancies between the solutions of the two models. Fig. 1 gives us a rough estimate of the range of possible solutions, but the uncertainty between the models is considerably increased at low frequencies.
- It is noteworthy, that the low frequency regime is actually achieved in practical liner applications, so the effect cannot simply be neglected. To give a practical example: For a Mach number of 0.17 the critical frequency would be at $f = 1$ kHz. For $M = 0.4$, however, the affected frequency range would be already stretched up to 5 kHz. Moreover, the effect is supposed to be even more pronounced at realistic liner surfaces where the wall is usually not hydraulically smooth but somewhat rough. At a rough wall the viscous sublayer is thinner compared to a smooth wall. Hence, a shear wave that has decayed in the viscous sublayer for a smooth wall would interact with the turbulence (i.e. the turbulent buffer layer) at a rough wall. Thus, the critical frequency is shifted towards higher frequencies and the turbulence effect applies at a wider frequency range.

3. DYNAMIC REACTION OF THE TURBULENT FLOW TO THE ACOUSTIC DISTURBANCE AT THE WALL

3.1 Frequency response and impulse response function of z_τ^+

To overcome the great uncertainty in choosing the right turbulence model ('model 1/2'? or something else?) at low frequencies $\omega < \omega_c$, it is crucial to obtain more insight in the mechanisms of generation and propagation of sound-coherent shear stress in the boundary layer. This includes the question of how the system of the turbulent flow (with its inherent Reynolds shear stresses) reacts dynamically to the sound-induced temporal variation of the boundary condition and how this ultimately results in a certain distribution of the total sound-coherent shear stress in the acoustic boundary layer. To this end an understanding of the temporal sequence of the (local or global) physical mechanisms involved would be beneficial.

A useful base for this could be provided by the impulse response function (IRF) of the sound-coherent shear stress. We have started this investigation by evaluating the impulse response function of the shear stress impedance z_τ^+ (Eq. 1). This corresponds to the temporal response of the wall shear stress to a dirac pulse of the streamwise velocity at the wall (which would be observed at the wall without the no-slip condition). Note that the latter velocity can be also regarded as the difference between the streamwise velocities of the bulk flow and the fluid which sticks to the wall. The impulse response function is obtained by an inverse Fourier transformation (ifft) of the frequency response of z_τ^+. The latter was evaluated from the DNS data of Hartmann [9] and from corresponding measurements [10]. Note that the original frequency response was multiplied with a Gaussian function first since the ifft cannot be applied to a monotonically increasing function (as $z_\tau^+ \propto \sqrt{i\omega^+}$). The real and imaginary part of the frequency response for the DNS data (multiplied with the

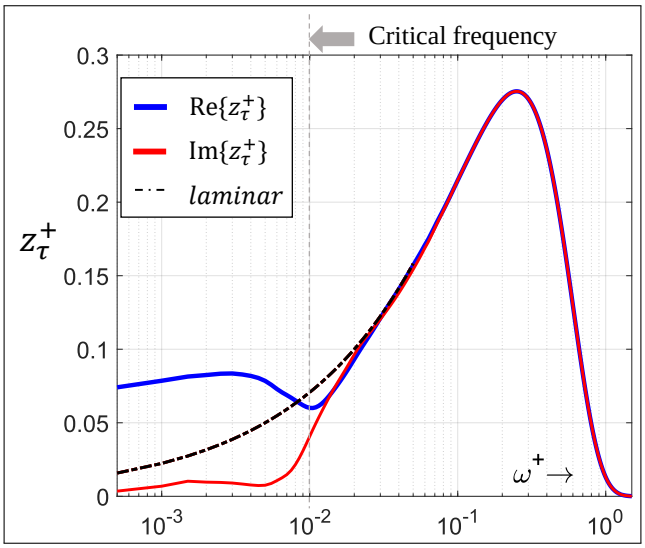

Figure 2. Real and imaginary part of the frequency response (multiplied with a Gaussian function) of the wall shear stress impedance z_τ^+ which was evaluated from the DNS data [9]. The normalization is the same as in Fig. 1. The black dash-dotted curve shows both the real part and the imaginary part of z_τ^+ in a laminar flow.

Gaussian function) is shown in Fig. 2 together with the solution for a laminar flow (black dash-dotted line), i.e. the shear stress is governed only by the molecular viscosity and the shear rate.
Note that the calculation of the impulse response was prone to considerable uncertainties since the frequency response is given only for a certain number of frequencies in both data sets. Thus, some effort has been put in an appropriate data processing which conditions the shear stress impedance by a cost function first (details not shown here).

3.2 Results

Fig. 3 shows the results for the evaluated impulse response function as a black, solid line. Note that the impulse response is causal (there are no contributions at negative times except of a small portion due to the convolution with the Gauss function) which confirms that the streamwise change in the position of the wall relative to the bulk flow can indeed been considered to be the cause of the shear stress. Fig. 3 a) shows that mainly a high, somewhat deformed peak is obtained at $t^+ = 0$, which - physically speaking - reflects the infinitely high wall shear stress at the infinitely high wall velocity during the delta pulse. The deformation of the peak is caused by the dynamics of the radiated viscous shear wave. The corresponding impulse response, which accounts for the purely laminar flow case, is shown as a red dashed line. Since it can hardly be distinguished from the actual impulse response in Fig. 3 b) the same information is shown with an enlarged scaling of the ordinate and a broader time scale. The difference between the total and the laminar impulse response is caused by the reaction of the turbulent shear stress on the wall shear stress. This difference (total solution minus laminar solution) is specifically shown in Fig. 3 c) and compared between the DNS data and the experimental data.

4. CONCLUSIONS AND OUTLOOK

The turbulent portion of the impulse response in Fig. 3 c) clearly reveals a distinct peak after a time $t^+ \approx 160$ (note that t is made dimensionless by ν/u_τ^2). This fits into our previously expected view of the physical processes: Since the wall is smooth, it is directly exposed to the viscous sublayer of the turbulent boundary layer which means that the sound-coherent shear stress at the wall has to be generated exclusively by viscous forces (viscosity times shear rate). Thus, the information of the turbulent shear stress (which originates from e.g. the buffer layer of the turbulent boundary) cannot pass directly to the wall, but is instead (indirectly) transmitted by shear waves. These shear waves propagate from the wall through the viscous sublayer, then trigger a reaction of the turbulent shear stress in the turbulent region of the boundary layer, which in turn generates a viscous shear stress field that extends back to the wall. The result of this latter portion manifests itself in a distinct sound-coherent wall shear stress in Fig. 3 c). This idea is further confirmed by the position of the maximum of the impulse response at a characteristic time $t^+ \approx 160$, which interestingly corresponds to the reciprocal of the characteristic frequency $\omega_c^+ \approx 10^{-2}$. It is assumed that this time span contains the sum of the shear wave transit times and the time required by the turbulence to respond to the shear rate.
Recent results indicate that the impulse responses of the turbulent shear stress and the shear rate as a function of wall distance provide further insight into these processes. In fact, the acoustic boundary condition of the homogeneously-permeable wall with grazing turbulent mean flow depends particularly strongly on the processes that take place in the near-wall region of the turbulent wall boundary layer. The estimation of the impulse responses thus proves to be a meaningful addition to the frequency responses that have been considered almost exclusively up to now. However, due to the difficulty of data preparation in obtaining the impulse response from the frequency response, it would be beneficial in the future to obtain the data directly from a numerical or real experiment, which provides the impulse response of the shear stress to a pulse of the streamwise velocity.

ABSTRACT

This computational study investigates the impact of manufacturing inaccuracies of face sheet orifice geometries on acoustic liners' impedance and flow dynamics. Normal Impedance Tube (NIT) lattice-Boltzmann very-large eddy simulations at 130 and 145 dB and 800, 1400, and 2000 Hz reveal that sharp-edged geometries present increased acoustic resistance and absorption than geometries with smoother edges. Rounded and double-chamfered edge shapes, mimicking real-world imperfections, reduce the resistance component of impedance by up to 28%, thus reducing the absorption coefficient. The inspection of the velocity field shows the flow features that cause these differences. Results demonstrate that minor edge imperfections, potentially due to manufacturing, may alter liner performance. This underscores the need to account for geometric imperfections in industrial design and quality control.

Keywords: *acoustic liners, orifice geometry, impedance, computational fluid dynamics, manufacturing imperfections*

1. INTRODUCTION

Reducing fan noise in turbofan engines is a critical area of research; acoustic liners are one of the most effective noise mitigation strategies [1]. Acoustic liners generally consist of a perforated face sheet, a honeycomb core, and a rigid backing, forming a structure that enhances sound attenuation [2]. The perforated face sheet facilitates acoustic dissipation through viscous and thermal losses at the orifice walls, whereas the backing structure enables reactive interference, effectively reducing noise levels. This configuration is particularly efficient in attenuating noise within a narrow frequency range, typically centered around the fundamental blade passing frequency (BPF) during take-off and landing conditions [3].

The shape of the perforations of the face sheet represents a key geometrical parameter in the design and optimization of acoustic liners. Recent advancements in liner performance have focused on modifying the geometry of these perforations or orifices to enhance their effectiveness [4]. Modifications to traditional Helmholtz resonator (HR) liners, particularly through additive manufacturing techniques, have led to the development of novel liner configurations. Examples include HRs with extended necks [5], inserted necks [6], spiral necks [7], and tapered necks [8]. These modifications allow for a reduction in the overall absorber thickness without compromising sound absorption performance, highlighting the critical role of perforation shape in acoustic liner efficiency. However, given the small size of these perforations and their significant influence on liner performance, achieving precise manufacturing tolerances remains a major challenge.

In an ongoing experimental study conducted by the present research group on the effect of grazing flow on acoustic liner performance, it was observed that the manufacturing finish of perforation edges plays a crucial role [9]. Specifically, when liners are 3D-printed, the edges tend to be filleted, whereas in metal-machined liners, the perforation edges are chamfered. With more advanced machining techniques, sharper edges can be maintained. These variations in edge geometry have been found to

have a pronounced impact on liner performance.

Motivated by these observations, the present study aims to numerically investigate and quantify the effect of small modifications of perforation edge shape on acoustic liner performance. The analysis is conducted using computational fluid dynamics (CFD) simulations under normal sound plane wave excitation, without a grazing flow, to isolate the effect of perforation edge shape. Simulations are performed at different sound pressure levels (130 dB and 145 dB) and frequencies (800 Hz, 1400 Hz, and 2000 Hz) to evaluate the impact of the orifices edge geometry on the liner performance.

2. COMPUTATIONAL SETUP AND TEST CASES

The liner geometry investigated in this study consists of 33 cells, each featuring a face sheet with eight orifices positioned over a rectangular cavity, as illustrated in Figure 1. The parametric analysis was carried out on four different face sheet orifice geometries, as shown in Figure 2. These geometries were derived by modifying a reference experimental geometry, named scanned. This was obtained through the 3D scanning of the geometry experimentally available. In addition to the scanned geometry, three alternative configurations were considered: sharp, chamfer double, and chamfer top. The corresponding geometrical parameters are provided in Table 1. The height of the cavity h is 38.1 mm and the side of the square cavity l is 9.89 mm

The four liner geometries were tested numerically using the commercial software PowerFLOW. A Normal Impedance Tube (NIT) setup was automatically constructed using $OptydB - Kundt$. The NIT setup consists of a tube, positioned above the simulated acoustic liner, whose length varies based on the minimum frequency of interest. For the present case, the duct has a length of 2.28 m and a diameter of 0.08 m.

Tonal acoustic plane waves with amplitudes of 130 dB and 145 dB and frequencies of 800, 1400, and 2000 Hz were tested. An example of the spectral content of the input acoustic waves for the two investigated amplitudes at a tonal frequency of 1400 Hz is shown in Figure 3. The theoretical resonance frequency of the current acoustic liner geometry is 1170 Hz [10], making 1400 Hz the closest tested frequency to resonance. Therefore, this frequency is selected as the representative case, particularly at the high sound pressure level of 145 dB, for which flow details will be further analyzed and discussed in the results section.

The computational domain was discretized using nine variable-resolution regions, with a minimum voxel size of 20 vx/τ (0.0274 mm). The grid resolution was highest near the face-sheet orifice and decreased further away. It was ensured that the resolution remained above 15 vx per wavelength for the shortest wavelength of interest. In the present setup, the minimum and maximum frequencies of interest were set to 50 Hz and 2500 Hz, respectively, leading to a total simulation time of 0.02 s.

Data were sampled at a frequency of 50 kHz at both the backplate and face sheet to compute the surface impedance distribution using Dean's method [11]. Additionally, ten virtual probes were placed along the cen-

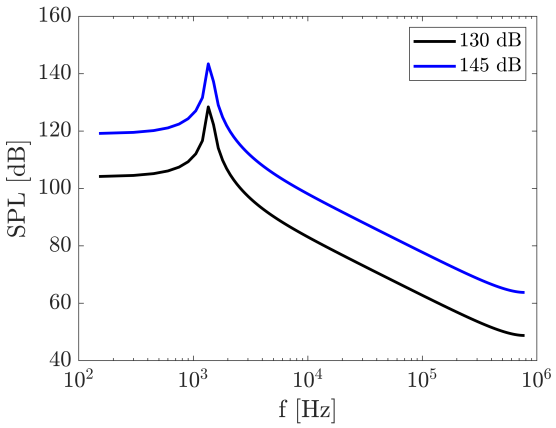

Figure 3. Sound pressure level spectra given as input to the normal impedance tube simulations.

terline of the duct, evenly spaced between 0.228 m and 1.144 m above the liner. These probes were used to compute impedance, following the same methodology as in the experiments. In the subsequent analysis, data from the ten probes were averaged, and error bars indicate the minimum and maximum values of the computed impedance and absorption coefficients.

Before conducting simulations for all geometries of interest and plane acoustic waves, a grid resolution study was performed using three different resolutions: 10 vx/τ, 20 vx/τ, and 40 vx/τ. The face sheet thickness τ was chosen as the reference length scale since it is smaller than the orifice diameter [12]. The geometry selected for this study was the scanned configuration, owing to the availability of experimental results obtained using the normal impedance tube at the Federal University of Santa Catarina (UFSC), Brazil. The grid resolution study was conducted for a single condition: a tonal acoustic plane wave with an amplitude of 145 dB and a frequency of 1400 Hz due to significant nonlinear effects.

Results from the grid resolution study are presented in Figures 4 and 5, alongside experimental data for comparison. Two experimental datasets are reported: the black curve corresponds to results obtained using broadband noise excitation with an overall sound pressure level of 145 dB; the blue curve represents results from tonal acoustic wave excitation at 145 dB. The error bars indicate the minimum and maximum values obtained by performing experiments on four parts of the liner sample. As observed, the experimental NIT results with tonal acoustic excitation exhibit large fluctuations and trends that do not fully align with theoretical expectations. Consequently, the broadband source excitation case is considered as the reference.

The comparison between experimental and numerical results indicates that the simulations slightly overpredict the experimental resistance θ, while reactance χ values are in closer agreement. This discrepancy may arise from minor differences between the orifice geometries in the numerical simulations and those in the experiments, and differences in the acoustic excitation. The computational results demonstrate a converging trend with increasing grid resolution. A resolution of 20 vx/τ was selected as a suitable compromise between computational accuracy and cost.

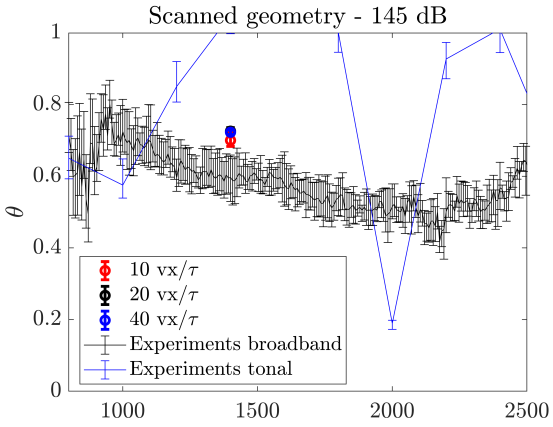

Figure 4. Resistance comparison between experiments and simulations carried out with three gird resolutions.

3. RESULTS

Acoustic results are presented in Figures 6, 7, and 8, where resistance and reactance components of impedance and the absorption coefficient are shown. The error bars indicate the maximum and minimum values computed using different virtual probes.

The analysis highlights the influence of the face sheet orifice geometry on the computed impedance and absorption coefficients. It is observed that resistance and reactance, as well as the absorption coefficient, vary with the orifice geometry. Specifically, the scanned and double chamfer geometries exhibit the lowest resistance, re-

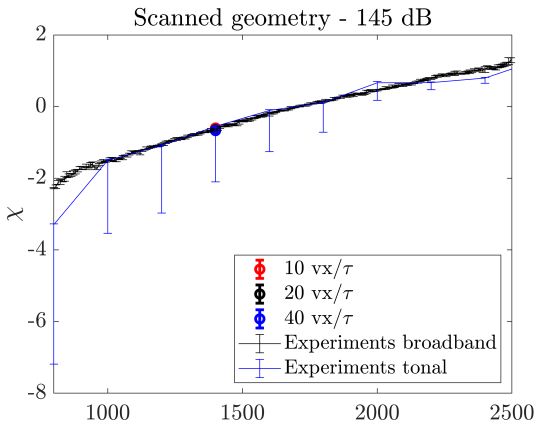

Figure 5. Reactance comparison between experiments and simulations carried out with three gird resolutions.

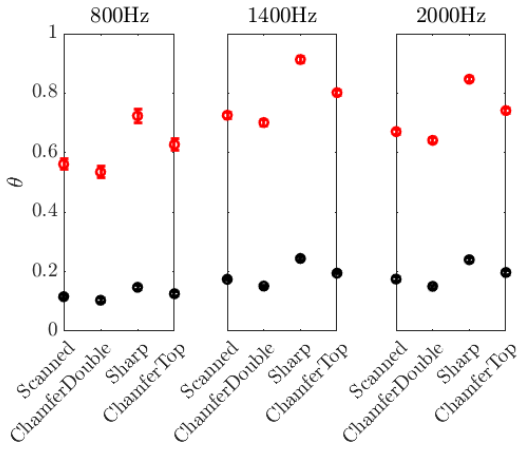

Figure 6. Resistance component comparison between geometries. Simulations were performed with acoustic plane waves with different frequencies and amplitudes equal to 130 dB (black) and 145 dB (red).

actance, and absorption, with minimal difference. When one edge is sharpened, as in the chamfer top geometry, resistance, reactance, and absorption increase, and they reach their highest values when both sides are sharpened in the sharp geometry for all the frequencies and SPLs.

The maximum mass flow rate across the orifices, obtained during the inflow and outflow phases, are presented in Figure 9 for all the test cases. It is observed that the trend of the in- and out-mass flow rate is the opposite of that seen in the acoustic impedance and absorption results. Specifically, the scanned and double chamfer geometries exhibit the highest mass flow rates, with minimal differences. When one edge is sharpened, as in the chamfer top geometry, the mass flow rate decreases, reaching its lowest values for the sharp geometry across all frequencies and SPLs.

Figure 10 presents the quality factor Q, computed by optimizing the fit between the theoretical and simulated vertical velocity across the analyzed frequencies (800, 1400, and 2000 Hz). The results indicate that, for most cases, Q follows a similar trend to the impedance, increasing as the orifice edges become sharper. This behavior is consistent with the theoretical relationship between Q and acoustic resistance, where a higher resistance leads to lower damping and thus a higher Q factor [13]. The scanned and double chamfer geometries exhibit the lowest Q values suggesting greater energy dissipation. Conversely, the chamfer top and sharp geometries yield the highest Q, indicating reduced dissipation. This trend is influenced by the vena-contracta effect, which alters the effective orifice area and modifies the in-orifice velocity dynamics [13], which will be discussed in the following.

The vertical velocity profiles, perpendicular to the face sheet, nondimensionalized by the speed of sound in air (a_∞), within the orifice at the midplane of the face sheet during the inflow and outflow phases are shown in Figure 11 for all SPL and frequency values. Each subfigure presents the velocity profiles for the four geometries, extracted in the middle of the face sheet thickness. The spanwise location corresponds to the plane crossing two orifices in the streamwise direction (refer to Figure 1). Notably, at 1400 Hz, the vertical velocities during both inflow and outflow phases exhibit the highest values. For SPL=130 dB, the peak velocity is significantly lower, approximately five times smaller than that at SPL=145 dB.

Comparing the different geometries, the sharp-edged orifice consistently exhibits the highest inflow velocities across nearly all SPL and frequency combinations. Conversely, the scanned and double chamfer geometries display similar velocity profiles, both during the inflow and outflow phases due to their comparable edge designs. The chamfer top geometry typically shows intermediate inflow velocities; however, during the outflow phase, it occasionally surpasses the sharp geometry in velocity magnitude. This velocity profile trend aligns with impedance and mass flow results (Figures 6–9). Sharp geometries, with the highest acoustic resistance and absorption, gener-

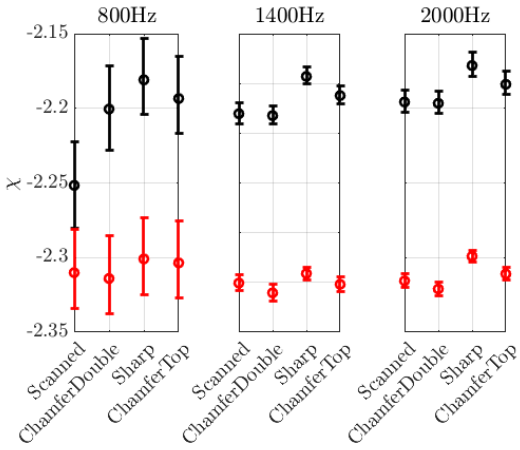

Figure 7. Reactance component comparison between geometries. Simulations were performed with acoustic plane waves with different frequencies and amplitudes equal to 130 dB (black) and 145 dB (red).

ate intense localized inflow velocities, due to the vena contracta effect, also visible in the vertical velocity contours in Figure 12 (1st and 2nd rows). These contours highlight the pronounced flow contraction at the sharp inflow edge, which restricts the effective cross-sectional flow area, resulting in the lowest net mass flow. Scanned and double-chamfered geometries reduce flow contraction through symmetric edge treatments, lowering resistance and enabling higher mass flow despite diminished peak velocities. The chamfer top geometry balances these effects: its chamfered inflow edge mitigates separation, reducing resistance compared to the sharp case, while the sharp outflow edge increases expulsion resistance. This asymmetry explains why the chamfer top geometry achieves intermediate absorption (Figure 8) and occasionally exceeds the sharp geometry in outflow velocity acceleration. However, its overall mass flow remains lower than the scanned and double-chamfered cases due to residual outflow losses. These mechanisms scale consistently with SPL, reflecting acoustic forcing intensity.

It is interesting to notice, that the velocity profiles, for all the cases, are not symmetric within the orifice, thus suggesting that there is a fluid dynamic interaction between the orifices, even at the lowest SPL analyzed.

The horizontal velocity contours (Figure 12, 3rd & 4th rows) further clarify these dynamics. During the inflow (3rd row), sharp geometries exhibit larger recirculation zones that restrict mass flow. During the outflow (4th row), the sharp geometry's horizontal velocity field reveals a narrow, high-speed jet, whereas the scanned and double-chamfered geometries produce broader, slower jets. Chamfer top's outflow (4th row) combines features of both: its sharp bottom edge generates a jet, while the chamfered top edge from the inflow phase minimally perturbs the expelled flow, explaining its intermediate mass flow and occasional velocity exceedance.

Figure 13 illustrates the root-mean-square (RMS) contours of vertical velocity fluctuations during the inflow and outflow phases at 145 dB and 1400 Hz. During the inflow (1st row), the sharp-edged orifice exhibits the highest RMS values near the orifice walls, consistent with intense turbulent shear layers generated by abrupt flow contraction and vena contracta effects. The chamfer top geometry shows moderately high RMS levels at the orifice walls but the highest fluctuations inside the cavity, likely due to asymmetric vorticity generation from its chamfered inflow edge interacting with the sharp outflow edge. In contrast, scanned and double-chamfered geometries display minimal RMS amplitude at the walls and low fluctuations within the cavity, reflecting their smoother inflow patterns and reduced flow separation. During the outflow (2nd row), the sharp geometry produces the strongest RMS fluctuations outside the orifice, indicative of turbulent jet expulsion, while the chamfer top shows elevated wall-adjacent fluctuations. Scanned and double-chamfered cases maintain low RMS values at both loca-

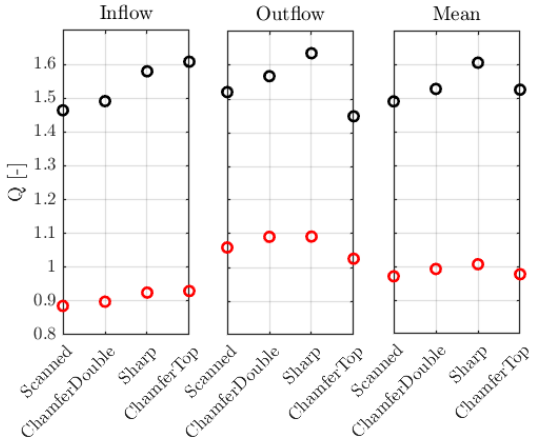

Figure 10. Quality factor comparison between geometries. (130 dB (black) and 145 dB (red))

tions. Asymmetry in the RMS contours across all geometries emphasizes the three-dimensional nature of vortex shedding and turbulence.

4. CONCLUSIONS

This work systematically evaluates the influence of orifice edge geometry on the performance of acoustic liners through high-fidelity CFD simulations. By analyzing four configurations under varying SPLs and frequencies, key insights into the interplay between edge geometry, acoustic impedance, and flow dynamics are established. The sharp-edged orifice maximizes acoustic resistance and absorption. In contrast, unsharpened edges (scanned and double-chamfered geometries) reduce acoustic absorption and facilitate higher mass flow rates within the orifices.

RMS velocity fluctuations highlight the role of edge geometry in vortex generation, with the sharp edges producing intense shear layers. These findings emphasize that manufacturing imperfections—often dismissed in idealized models—critically influence liner performance. For industries relying on perforated liners, this study underscores the importance of stringent quality control to minimize geometric deviations and calibrate predictive tools to account for real-world imperfections.

ABSTRACT

This paper presents an experimental study on suppressing propeller noise in a short duct configuration by installing Over-Tip-Rotor (OTR) liners on the wall casing. Far-field noise measurements are reported alongside in-duct pressure measurements at the wall obtained using an axial and azimuthal microphone array installed upstream of the propeller plane. In-duct measurements reveal that the OTR liner is effective in reducing broadband noise, achieving up to 4 dB of noise reduction over 1-5 BPFs. The axial decay of tonal components was compared with an analytical solution based on the Green's function of an axial dipole source, requiring a large number of cut-off modes to match the experimental observations. The findings emphasise the importance of evanescent modes in compact duct acoustics, with direct implications for source modification, scattering effects, and far-field radiation.

Keywords: *OTR liners, propeller noise, noise suppression, ducted rotors*

1. INTRODUCTION

Compact ducted propellers, also known as shrouded propellers, have regained attention in the development of Unmanned Aerial Vehicles (UAVs) and Urban Air Mobility (UAM) solutions due to their potential advantages in thrust augmentation, noise reduction, and operational safety. Several studies have shown that incorporating a duct can lead to a significant increase in thrust compared to an open propeller configuration [1, 2]. The integration of a duct enhances safety by providing a protective barrier or blade containment. This feature is particularly advantageous in densely populated areas where UAVs and UAM vehicles are expected to operate.

Recent studies have investigated the effect of a short duct on propeller noise. Overall noise reductions can be achieved in some conditions, but the effect of the duct on noise radiation can vary significantly between hover and in-flight conditions. Malgoezar et al. [3] conducted experiments on both isolated and shrouded propellers in hover and in-flight conditions. In hover, the use of the duct reduced the Blade Passing Frequency (BPF) tone while increased broadband noise by up to 20 dB. In contrast, the increase in broadband noise was significantly lower in-flight conditions. Cuppoletti and Riley [4] also found an increase in tonal noise at all BPFs and in broadband noise when including a shroud in their experimental investigation of ducted and unducted propellers at hover and at constant RPM. More recently, Go et al. [5] studied a 12-inch propeller experimentally and numerically with and without a shroud, finding that the shroud reduced propeller loading by generating additional thrust. This led to lower tonal noise from the blades in comparison to an isolated propeller. However, while the shroud decreased tonal noise downstream, it increased it upstream compared to an isolated propeller.

Ducted propellers can accommodate the installation of acoustic treatments to further mitigate propeller noise. Acoustic liners are widely used in aero engines, and maximising the treatment area is desirable for noise reduction. The treatment of the area directly above the fan

casing, i.e., Over-Tip-Rotor/Over-The-Rotor (OTR) liners, has been investigated experimentally by NASA over the last two decades [6] and has shown the potential of this technology to increase the treated area and enhance the suppression of fan noise.

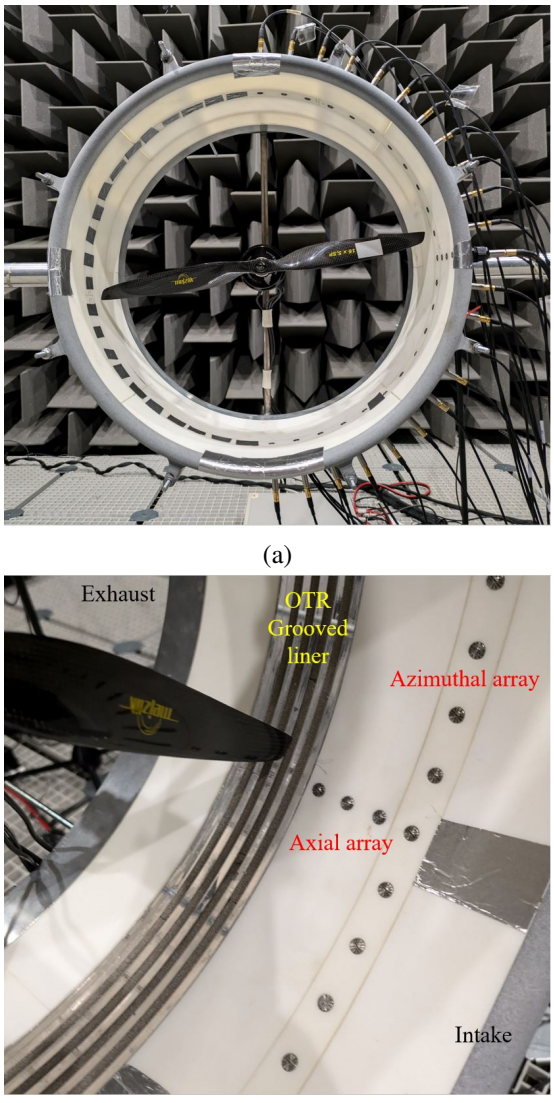
The mechanisms of noise reduction of OTR liners have been investigated analytically [7–9], numerically [10, 11] and experimentally [6, 12] in recent years. The noise reductions are mainly attributed to a combination of: (1) conventional noise attenuation by the liner, which can be enhanced by a larger fluid particle oscillation through the acoustically treated wall due to the close proximity to the fan [8], and (2) source modification effects, which include both acoustic back-reaction effects changing the power output of the source [7, 11], and hydrodynamic changes affecting the unsteady blade loading [8, 10, 12].

Despite OTR liners were originally developed for aero-engine applications, recent work has been carried out to investigate their application for smaller, more compact, ducted propellers for UAV and UAM vehicles. The technology is particularly suitable for such applications due to the much lower area available for acoustic treatments. Some of these works include an experimental investigation by Zhong et al. [13] with OTR side-branch tubes to reduce tonal noise and the numerical work of Zhao et al. [10] showing the influence of the liner on the tip leakage flow.

The current paper is an extension of a previous study by the authors investigating the reduction of shrouded propeller noise with OTR liners [14]. Far-field noise results were presented in [14] for two types of liners - a Single Degree of Freedom (SDOF) liner and a grooved metal foam liner - placed in an OTR position, upstream and downstream of the propeller. The modular shroud used in the experiment featured either a bellmouth intake or an unflanged intake. The geometry of the intake was found to have a major influence on the flow characteristics upstream of the propeller plane and the sources of propeller noise. The study found that OTR liners can reduce overall sound pressure levels by up to 5 dB near the propeller axis, with peak noise reductions in the PWL spectra reaching 6 dB in both tonal and broadband noise. The current study extends this previous investigation by instrumenting the propeller duct with an axial and azimuthal array to gain understanding of the source near-field and how it is impacted by the OTR liner.

2. EXPERIMENTAL SET-UP

2.1 Shrouded propeller rig



The experiments were carried out on a modular ducted rotor rig with a single propeller, described in [14]. The propeller, motor, and loadcell are held on the shroud axis by a pair of vertical rods. The duct consists of a series of modular sections that allow for varying the length of the shroud, instrumenting the duct with in-duct microphones, installing acoustic treatments in the casing, and modifying the intake geometry. The current investigation was performed with a simple rounded intake and for two configurations: (a) hard wall baseline, and (b) an acoustic liner installed over the propeller tip. The picture of the rig for each configuration is shown in Fig. 1. In both cases, the length of the duct is $L = 260$ mm and the diameter is $D = 410$ mm, resulting in a compact ducted propeller configuration with $L/D \approx 0.6$. The propeller is at an axial distance $z_{prop} = 105$ mm from the duct exhaust.

The rotor was powered by a U7-V2.0 KV420 Brushless T-motor mounted on a MINI45 ATI 6-axis loadcell. The electronic speed controller used in conjunction with the motor was a Master Mezon 135 opto unit. An ICP Laser Tachometer sensor was used to measure the propeller rotational speed (Rotations Per Minute, RPM). A 2-bladed MEJZLIK propeller with a diameter of 16 inches was used in this investigation. All the results in this article were acquired with a constant thrust of the propeller of $T = 10$ N with a corresponding RPM of approximately $N = 4600$. The thrust provided by the shroud has not been considered in this investigation.

2.2 Microphone instrumentation

The experiments were carried out at the Institute of Sound and Vibration Research's anechoic chamber of dimensions 6.7 m $\times$ 6.7 m $\times$ 4.9 m. The walls are acoustically treated with open-cell polyurethane wedges whose cut-off frequency is 70 Hz. Far-field noise measurements were obtained by using 3 1/4" GRAS 40PL-10 CCP microphones located in the forward arc (upstream of the propeller). The microphones were located at a distance of 2.5 m centred on the propeller rig and at polar angles of $\phi = 0°$, 45°, and 90°, where 0° is on the propeller axis. In-duct pressure measurements were performed by using an axial and azimuthal array in a cross-configuration, as shown in Fig. 1b. A total of 25 quarter-inch GRAS 40PL-10 CCP microphones were flush mounted on the intake casing, 3 (+1) on the axial array ($z_{axial} = 32 - 85$ mm

upstream of the propeller plane), and 22 in the azimuthal array ($z_{azm} = 85$ mm upstream of the propeller plane), equally spaced between $\theta = 0°$ and 180°. The data were acquired for a duration of 10 s at a sampling frequency of 40 kHz.

(a)

(b)

Figure 1: Ducted propeller rig; photograph of the rig with for the (a) hard wall baseline (front view), and (b) OTR liner configuration (detailed view of instrumentation).

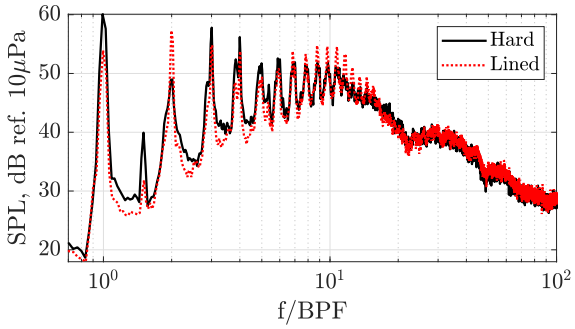
2.3 Acoustic liner properties

The acoustic liner considered in this investigation is a grooved liner in which the annular grooves are filled with a nickel chromium alloy metal foam flush with the inner wall of the duct. This is a semi-locally reacting liner that is locally reacting in the axial direction and non-locally reacting in the azimuthal direction, as described in [15, 16]. The liner has a Percentage Open Area POA$= 44\%$ [1], a cavity depth $d = 17.5$ mm and a porosity of the metal foam $\sigma = 90\%$. The total length of the liner module on the tip of the propeller is $l = 50$ mm long, as for the hard-wall baseline configuration.

3. FAR-FIELD NOISE REDUCTION

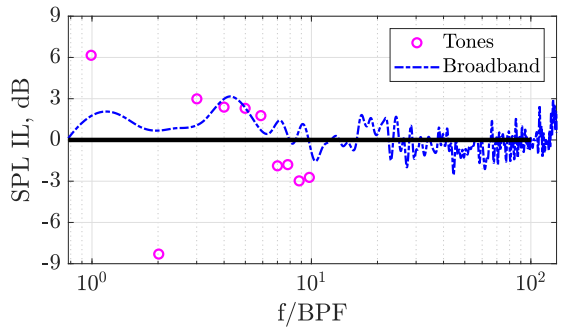
The aim of this section is to present the far-field noise spectra for the hard wall baseline and the acoustically treated configuration. Results are only presented for the microphone on-axis ($\theta = 0°$) for brevity. The far-field PWL noise spectra integrated in the forward arc and the directivity of these two configurations were presented in the preceding investigation [14].

The Sound Pressure Level (SPL) spectra for the hard wall baseline and lined configurations are shown in Fig. 2a. Measurements of the flow characteristics upstream of the propeller for the 'lip' intake, used in the current investigation, identified a region of flow separation at the lip centred around 90% of the radius [14]. This was related to significantly higher levels of tonal and broadband noise than with a streamlined bellmouth intake that prevents such separation from occurring. The current configuration with the 'lip' intake, therefore, presents stronger tones than the bellmouth, likely caused by the periodic chopping of eddies in the incoming separated flow (tonal) and turbulence leading edge interaction noise (broadband). This discussion is recalled here to explain the strong broadband component of the SPL spectra in Fig. 2a, which becomes dominant over tonal noise from about $10 \times$ BPF.



The noise sources outlined above are arguably independent of whether a hard or lined configuration is considered, other than possible hydrodynamic modifications on the source caused by the OTR liner, which shall be discussed in further detail later in the paper. The results in Fig. 2a show that the OTR liner yields modest reductions

[1] This POA only accounts for the grooved area relative to the total liner area and not the open area of the metal foam within the grooves.



in broadband noise of 1-3 dB at frequencies between BPF and 10 × BPF. The first BPF tone is reduced by 6 dB, but the reductions are smaller at other harmonics, and the higher harmonics in the liner configuration can even be larger than for the hard wall baseline. The same results are shown in Fig. 2b in the form of SPL Insertion Loss (IL), that is,

$$\mathrm{IL} = \mathrm{SPL_H} - \mathrm{SPL_L} \quad , \quad \mathrm{dB}, \tag{1}$$

where $\mathrm{SPL_H}$ and $\mathrm{SPL_L}$ are the SPLs for the hard and lined configurations, respectively. The SPL IL in Fig. 2b is separated into the tonal and broadband contributions. Tonal SPL IL is only plotted up to 10 × BPF since broadband noise becomes dominant at higher frequencies. The observations from Fig. 2a are now clearer, and it also becomes evident that a strong noise increase is caused by the liner at the 2 × BPF tone, with some increase of tonal noise also at 6-10 × BPF. The broadband noise at frequencies above 10 × BPF is not significantly affected by the liner at this measurement location on the propeller axis.

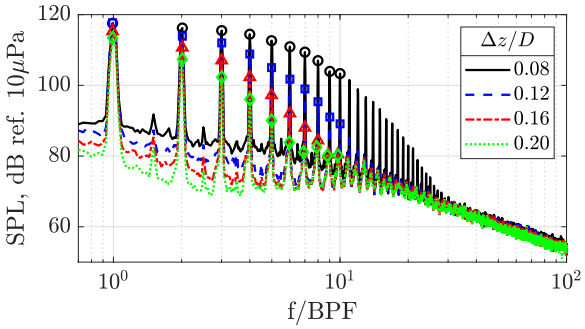
(b) Insertion Loss (IL)

Figure 2: Far-field SPL and IL spectra at $\theta = 0°$.

4. IN-DUCT PRESSURE MEASUREMENTS

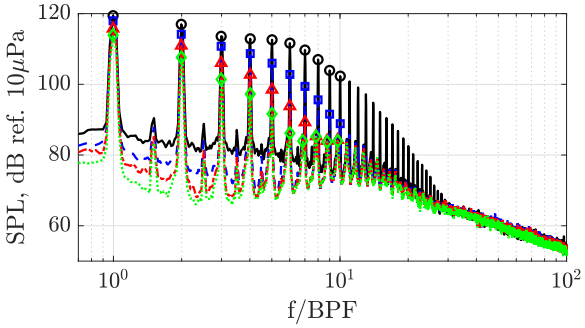
This section aims to present the pressure characteristics on the duct wall to understand the effect of the OTR liner on the near-field of the source and the propagation in the duct. To highlight the compactness of the problem, key length scales of the problem are compared to the wavelength at BFP ($\lambda \approx 2.2$ m) and harmonics in Table 1, namely duct diameter D, duct length L, and liner length l.

Table 1: Compactness of the problem at BPF and harmonics.



Frequency	D/λ	L/λ	l/λ
BPF	0.18	0.12	0.02
2 × BPF	0.37	0.23	0.05
3 × BPF	0.55	0.35	0.07
5 × BPF	0.92	0.59	0.11
10 × BPF	1.85	1.17	0.23

The compactness of the problem highlighted in Table 1 suggests that the role of evanescent or cut-off duct modes excited by the propeller and the struts can have a significant impact on the problem:



- Contributions to the far-field noise from evanescent modes scattered at the intake/exhaust [17].
- 'Trapped' modes in the short duct caused by evanescent modes reflected at the intake/exhaust.
- In the liner case, the effects of the acoustic back-reaction on the source can be significant at these low frequencies (low D/λ), which have been reported to be stronger for $e/\lambda < 0.5$ [7], were e is the distance between the source and the duct wall.
- Also in the case with the liner, scattering of evanescent modes acoustically close to the impedance discontinuity (low l/λ) can have a significant effect on the noise reduction performance [11].

The SPL spectra, measured along the axial array, are shown in Fig. 3a and Fig. 3b for the hard wall and lined configurations. Also shown are the tonal amplitudes of the first 10 BPFs. The distances Δz shown in the legend are relative to the propeller plane. The general trends in both configurations show a rapid decay of the tonal components when increasing the axial separation distance to

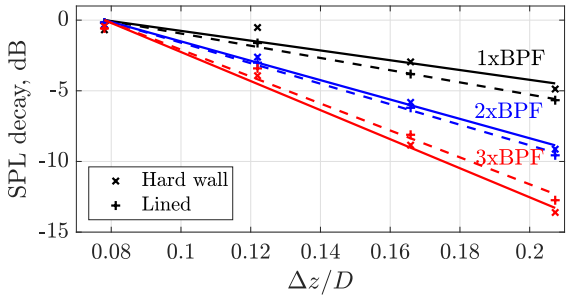
the source plane Δz. Furthermore, significant decay in broadband noise of up to 10 dB can also be observed in both cases for frequencies below 10 × BPF.

(a) Hard wall

(b) Lined

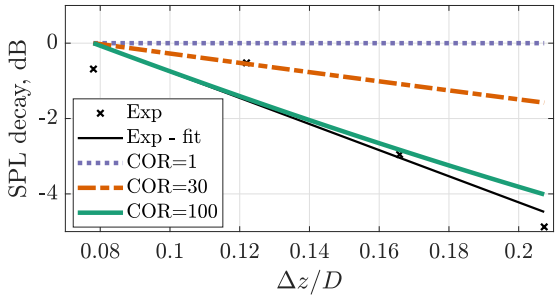
Figure 3: Axial variation of the wall SPL spectra for the hard wall and lined configurations.

The decay in tonal SPL at the harmonics of the BPF is found to be close to exponential. The SPL decay for the first 3 BPFs is shown in Fig. 4a for both the hard wall and lined configurations. Also shown is a linear fit of the tonal levels along the array. The decay rates in dB/m are summarised in Table 2. It can be observed that the decay is similar in both configurations, which is expected since these measurements are obtained at the hard wall section upstream of the propeller.



The measured decay of the BPF tone is compared with analytical predictions [7] in Fig. 4b. The predictions are obtained by evaluating the wall pressures at the wall of an infinite hard wall duct containing a point axial dipole located at 95% of the radius. The Green's function formulation used in this instance [7] is obtained from the monopole Green's function in Rienstra and Tester [18]. The number of modes included in the solution is controlled by the Cut-Off Ratio (COR). The definition used here for the COR for a mode with radial wavenumber α, at frequency ω and mean flow Mach number M is

Table 2: Tonal decay rates in dB/m for the lined and hard wall configurations.



BPF	Hard wall	Lined
1	-84.5	-105.4
2	-167.2	-177.1
3	-250.8	-223.3

$$\text{COR} = \frac{\alpha\sqrt{1-M^2}}{\omega} \quad . \tag{2}$$

For a given COR, all the modes with α smaller than $\omega\text{COR}/\sqrt{1-M^2}$ are therefore included in the solution.

(a) Measured decay of the BPF, 2xBPF and 3xBPF tones.

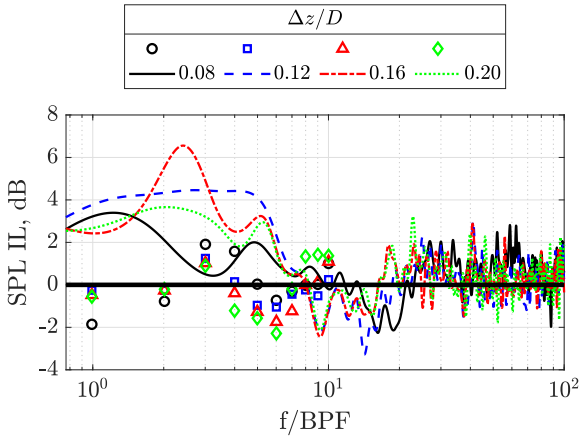
(b) Measured and predicted decay of the BPF tone.

Figure 4: Decay of tonal SPL along the axial array.

The analytical solutions shown in Fig. 4b are obtained with a COR of 1, 30 and 100. For the case with COR=1, only cut-on modes are included in the solution.

At the BPF frequency, only the plane wave is cut-on. The other two cases, COR=30 and COR=100, include a certain number of evanescent modes. At the BPF frequency, COR=30 corresponds to a total of 20 evanescent modes included in the solution and COR=100 corresponds to a total of 425. The comparison in Fig. 4b shows that a large number of evanescent modes are required in the analytical solution to obtain the rapid decay observed in the experiment. This result highlights the importance of the cut-off modes in the current problem and the need for further investigation to clarify its impact on the noise reduction characteristics of OTR liners and the noise radiation to the far-field.

The Insertion Loss spectra are presented in Fig. 5 to appreciate more clearly the effect of the OTR liner in the in-duct pressure field. It is observed that the liner only has a modest effect of ± 2 dB in the tonal noise, and that the variation across different axial locations is within 2 dB. In contrast, 4 dB of broadband noise reduction can be observed at most microphone locations for frequencies below 10 $\times$ BPF, with some variation across the array. In particular, weaker reductions are observed in the microphone closest to the propeller plane ($\Delta z = 0.08$).



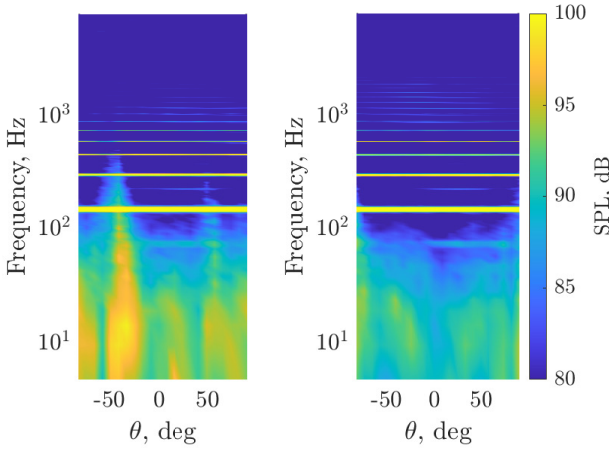


Figure 5: Axial variation of the Insertion Loss measured at the duct wall.

Very little variation in SPL IL would be expected between microphones in the axial array since they are all located in the hard wall section upstream of the liner. The differences observed in Fig. 5 may therefore be attributed to a different distribution of the modal amplitudes between the hard wall and lined case between the two configurations caused by (1) changes on the source caused by the OTR liner (source modification effects), and/or (2) modal scattering at the impedance discontinuity between the OTR liner and the hard wall section.

The azimuthal microphone array is now used to show the SPL spectra variation along the circumference over the 180° aperture of the array. This is presented in the form of contour plots in Fig. 6a and Fig. 6b for the hard wall and lined configurations, respectively. The wall pressure fluctuations around the duct present significant non-uniformity, especially at low frequencies below the first BPF, with up to 10 dB variations along the circumference. These results suggest significant non-uniformities in the flow field, potentially caused by the separation at the inlet lip, the development of the boundary layers, or non-uniformities in the impinging flow itself. Further investigation is needed to characterise the flow in the duct and provide insights into this discrepancy. However, the frequencies at which the liner has been found to be most effective in reducing noise in the far-field and in the in-duct axial array results are not affected by this contamination (the axial array is located at $\theta = 0°$).

(a) Hard wall (b) Lined

Figure 6: Azimuthal variation of the wall SPL spectra for the hard wall and lined configurations.

5. CONCLUSIONS

This paper has presented an experimental investigation on the reduction of propeller noise with Over-Tip-Rotor liners on a modular compact ducted propeller rig. In-duct wall pressure measurements indicate that OTR liners are effective in reducing broadband noise, yielding some 4 dB of noise reduction at frequencies between BPF and 5xBPF. This is in contrast to a modest effect of the liner of only ± 2 dB in tonal noise. Conversely, the far-field results (on axis) show up to 6 dB of noise reduction at the BPF tone and almost 9 dB of noise increase at the 2xBPF tone. The axial decay in the amplitude of the tones was compared to an analytical solution based on the Green's function of an axial dipole source. A large number of cut-off modes were required in the analytical solution to match the decay observed in the experiments. The main observation of this investigation is the importance of the evanescent modes in such compact ducts. This has direct implications for the source modification and scattering effects associated with OTR liners and in the radiation of these evanescent modes to the far-field. Future work is planned to understand the flow non-uniformities in the duct and the sources, as well as to investigate further the role of evanescent modes in hard and lined compact ducts.

IDENTIFICATION OF AN ACTUATION MANIFOLD FOR OPEN-LOOP CONTROL OF SUBSONIC JET NOISE WITH ACOUSTIC-BASED EXCITATION

Luca Franceschelli* **Marco Raiola** **Andrea Ianiro** **Stefano Discetti**

Department of Aerospace Engineering, Universidad Carlos III de Madrid,
Avda. Universidad 30, Leganés, 28911, Madrid, Spain

ABSTRACT

Subsonic jet noise remains a key contributor to aircraft noise, particularly during takeoff. While reducing jet velocity has helped, further mitigation requires controlling turbulent structures in the shear layer, which are primary sound sources. Active jet control offers a promising solution with minimal efficiency loss. This study investigates acoustic-based actuation in a turbulent subsonic jet. Experiments are conducted in the jet facility of the anechoic chamber at Universidad Carlos III de Madrid. Acoustic excitation is provided by counter-facing loudspeakers in the stagnation chamber, following an open-loop control strategy. The goal of this work is to explore the actuation manifold produced by the acoustic excitation using data-driven dimensionality-reduction techniques. Isometric Mapping (ISOMAP) and Proper Orthogonal Decomposition (POD) are applied to phase-averaged velocity fields measured via Particle Image Velocimetry, phase-locked with the actuation. The impact of actuation is further assessed using hydrodynamic pressure measurements in the shear layer and acoustic pressure in the far field. Results confirm the existence of an actuation manifold in the phase-averaged velocity fields. The influence of actuation on the jet is further supported by both shear-layer and far-field pressure measurements.

1. INTRODUCTION

Jet noise is a major contributor to aircraft noise pollution, particularly during takeoff and landing. Although advances in engine design and reductions in jet exhaust velocity have led to significant improvements, further noise reduction requires direct control of the turbulent structures in the jet shear layer, which are the primary sources of subsonic jet noise. Among emerging strategies, active flow control using acoustic excitation has shown promise in modifying the jet dynamics with minimal aerodynamic penalties [1].

Reduced-Order Modeling (ROM) has become central in the analysis and control of such complex flows. Classical techniques like Proper Orthogonal Decomposition (POD) offer a linear, energy-optimal decomposition of flow fields, providing compact representations useful for modeling and control [2, 3]. However, the inherently nonlinear behavior of turbulent and transitional jets often limits the effectiveness of such linear approaches in capturing the full extent of flow dynamics.

To overcome these limitations, nonlinear manifold learning methods aim to identify low-dimensional embeddings that reflect the true geometry of high-dimensional flow data. Isometric mapping (ISOMAP) [4], which preserves geodesic distances between flow snapshots, has recently shown promise in uncovering coherent structures in complex shear flows [5]. Compared to POD, ISOMAP has demonstrated better separation of flow regimes in experimental settings [6]. Furthemore, Marra et al. [7] have demonstrated that ISOMAP can be used to unveil "actuation manifolds", i.e., manifolds of flows under different types of actuations, with interpretable coordinates.

In this work, we apply ISOMAP to experimental data

from an acoustically-excited subsonic jet in a transitional regime, at $Re = 10,000$ (with the Reynolds number Re being based on the bulk jet velocity U_j and the nozzle diameter D). Open-loop actuation is applied via counter-facing loudspeakers mounted in the stagnation chamber, operating in phase. Measurements of the velocity field are acquired using Particle Image Velocimetry (PIV). Additionally, synchronized acoustic measurements using two sets of microphones are performed: four placed along the jet axis in the near field to track the evolution of pressure fluctuations, and two in the far field positioned at 30° and 90° relative to the jet axis. Synchronization with the actuation signal enables the computation of phase-averaged flow fields, capturing several phases of each periodic control actuation. The ability of ISOMAP to identify a low-dimensional actuation manifold in both turbulent and transitional regimes is assessed on phase-averaged flow fields. Results are compared with those obtained using POD, highlighting the advantages of nonlinear manifold learning in revealing coherent flow structures under periodic forcing. A similar analysis performed on the near- and far-field microphone temporal signals, however, failed in identifying a low-dimensional manifold, not providing a conclusive answer to whether a control manifold exists for the instantaneous noise measurements.

2. METHODOLOGY

The actuation manifold is identified using the ISOMAP algorithm, a nonlinear dimensionality-reduction technique that seeks to uncover a low-dimensional embedding that preserves geodesic distances between flow snapshots in a high-dimensional feature space. This section outlines the core steps of the methodology, which are further detailed in [7].

Let us consider a collection of M snapshots, each represented as a high-dimensional vector $\mathbf{u}_i \in \mathbb{R}^d$. The first pairwise distances between snapshots using the standard Euclidean norm are equal to:

$$\|\mathbf{u}_i - \mathbf{u}_j\| = \left(\sum_{m=1}^{d} \left| u_i^{(m)} - u_j^{(m)} \right|^2 \right)^{1/2}. \quad (1)$$

A neighborhood graph is constructed by connecting each snapshot to its k-nearest neighbors according to the Euclidean distance. The geodesic distances between all pairs of snapshots are then estimated as the shortest paths on this graph. The resulting geodesic distance matrix $\boldsymbol{D}_{\mathrm{G}} \in \mathbb{R}^{M \times M}$ approximates the manifold distances and serves as the basis for the embedding.

Classical multidimensional scaling (MDS) is then applied to compute the low-dimensional embedding $\Gamma = (\tilde{\gamma}_{ij})_{1 \le i \le M,\, 1 \le j \le n} \in \mathbb{R}^{M \times n}$. The optimal set of coordinates is obtained from the eigenvectors corresponding to the largest n eigenvalues of the double-centered squared distance matrix. Each snapshot $\mathbf{u}_i$ is mapped to $\boldsymbol{\gamma}_i \in \mathbb{R}^n$, preserving its geodesic relationships with other samples.

The quality of the embedding is evaluated using the *residual variance*, R_v, which measures how faithfully the embedding represents the geometry of the original dataset.

In this work, the ISOMAP algorithm is applied to a velocity field ensemble including 20 phase-averaged fields for each actuation at a distinct frequency, yielding a closed trajectory in the reduced-order manifold that captures the system's coherent response to forcing. ISOMAP has also been tested on portions of the time signal provided by the 2 sets of microphones. In this latter case no coherent trajectory has been identified in the reduced-order manifold, leaving open the question if a control manifold can be identified for the non-phase-averaged data.

3. EXPERIMENTAL SET-UP

The experiments are conducted in the jet facility located inside the anechoic chamber of Universidad Carlos III de Madrid [8]. The setup consists of an air jet issuing from a round nozzle with exit diameter $D = 10\,\mathrm{mm}$. The jet flow condition investigated correspond to a transitional jet at Reynolds number $Re = 10{,}000$, with natural transition inside the nozzle.

Open-loop acoustic forcing is applied in both cases using two counter-facing loudspeakers mounted in the stagnation chamber. A purely sinusoidal excitation is imposed through the loudspeakers at a set of discrete actuation frequencies f, selected to span a typical range of Strouhal numbers, defined as $St = fD/U_j$. The explored range covers $St \in [0.05, 1.2]$, with increments of 0.05. This corresponds to 24 actuation frequencies between 75 Hz and 1800 Hz. The acoustic signal is generated using two ND654 2 $\frac{1}{2}$" aluminum cone full-range drivers (4 Ω impedance), mounted in a counter-facing configuration. The input waveform is amplified using a Fosi Audio V1.0B stereo audio amplifier, and the output power supplied to the loudspeakers is fixed at 25 W. This configuration provides repeatable and robust acoustic excitation across the entire frequency range explored.

Two-component velocity fields are measured using

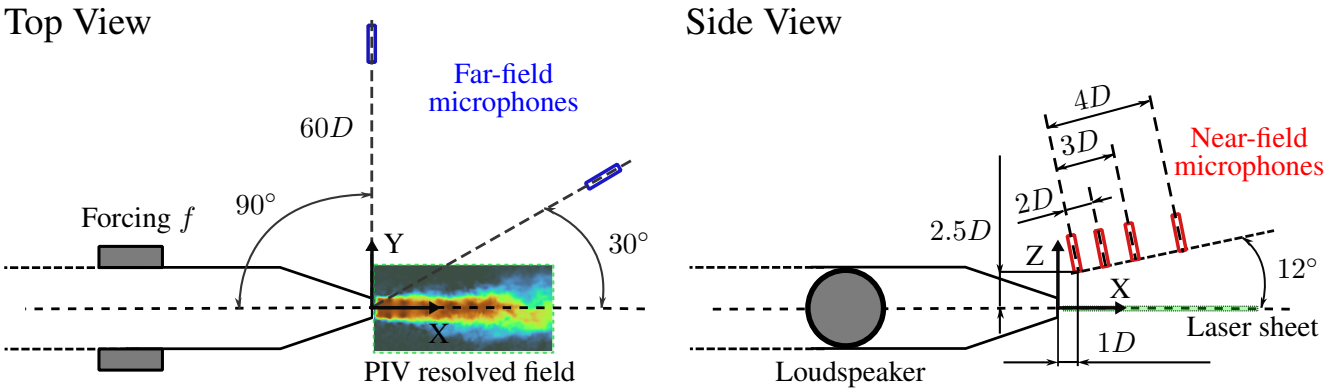

Figure 1: Sketch of the experimental setup. The top view (left) illustrates the positioning of the far-field microphones, while the side view (right) shows the placement of the near-field microphones.

PIV in the symmetry plane of the jet that intersects the axis of the two loudspeakers. The acquisition system consists of a 5.5 Mpx Andor Zyla sCMOS camera and a dual-cavity Nd:YAG laser operating up to 15 Hz with a pulse energy of 200 mJ. The flow is seeded with DEHS particles with a mean diameter of approximately 1 μm. The spatial resolution of the PIV setup is equal to 22.7 px/mm.

Image processing is performed using the PaIRS software developed at the University of Naples [9], with a final interrogation window of 32×32 px and 75% overlap. Optical reflections caused by the presence of four near-field microphones partially degrade the image quality. To mitigate this, a pre-processing step is applied to remove the background contribution. This is achieved using a POD-based technique, following the method described in [10], which enables efficient separation of the flow-induced particle signal from persistent light artifacts.

For each actuation frequency, phase-averaged velocity fields are obtained by synchronizing the non-temporally-resolved acquisition with the sinusoidal excitation signal. For each phase bin, 100 instantaneous velocity fields are recorded to ensure statistical convergence of the phase average. In total, 24 actuation frequencies are tested per flow condition, resulting in $M = 20 \times 24 = 480$ phase-averaged velocity fields for each case, which serve as the input for ISOMAP.

A rake of four Adafruit 1016 Electret Microphone Amplifier Boards (MAX4466) was installed in the near field, along with two GRAS 46AE microphones positioned in the far field. Microphone signals were acquired synchronously with both the actuation signal and the PIV system, at a sampling frequency of 200 kHz. A schematic of the experimental arrangement is shown in figure 1. The near-field microphones were arranged linearly along the jet development direction, inclined at 12° with respect to the jet axis. They were positioned at streamwise distances of 1, 3, 6, and 10 nozzle diameters D from the jet exit and mounted in a plane perpendicular to the PIV measurement plane. The far-field microphones were placed at a distance of $60D$ from the nozzle exit: one at an angle of 90° and the other at 30° relative to the jet axis.

4. RESULTS

To ensure consistent scaling across the dataset and enable meaningful comparison across different forcing conditions, the fluctuating phase-averaged velocity components u and v are normalized independently by their respective root-mean-square (rms) values, computed for each actuation case:

$$\bar{u} = \frac{u_{\text{PIV}}}{\text{rms}(u)}, \qquad \bar{v} = \frac{v_{\text{PIV}}}{\text{rms}(v)} \tag{2}$$

The ISOMAP and POD algorithms are then applied to the resulting normalized velocity field $\bar{\boldsymbol{u}} = [\bar{u}, \bar{v}]$, allowing for consistent low-dimensional analysis across the full range of forcing frequencies. This normalization prevents the dimensionality reduction methods from being biased toward actuation cases with inherently larger fluctuation amplitudes, ensuring that all cases contribute comparably to the extracted flow structures.

Before analyzing the embedding results in detail, we first assess the dimensionality reduction behavior of the two methods. Figure 2 compares the ISOMAP resid-

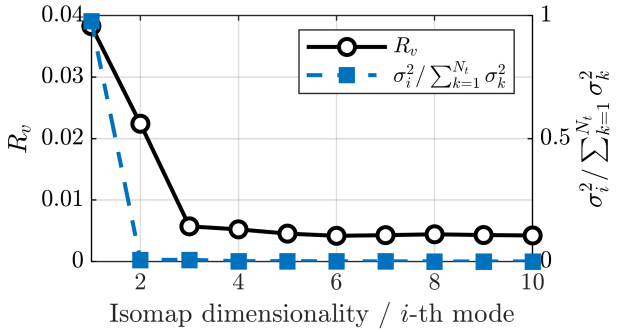

Figure 2: Comparison of dimensionality reduction: ISOMAP residual variance R_v (black) versus normalized POD eigenvalues $\sigma_i^2 / \sum \sigma_k^2$ (blue).

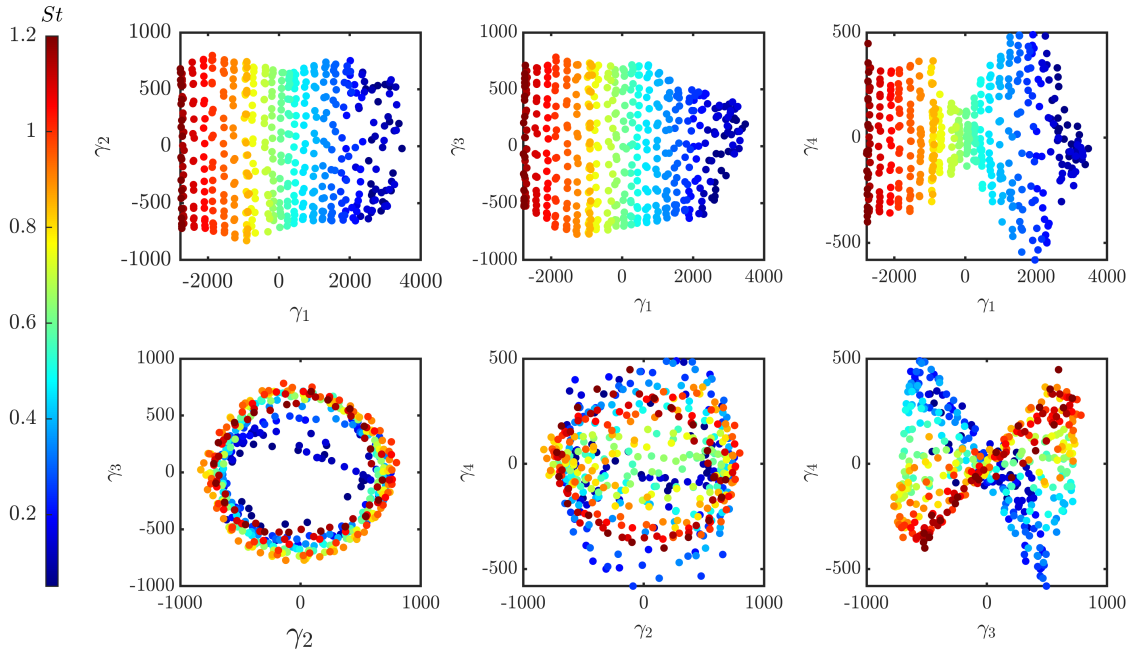
ual variance R_v and the normalized POD eigenvalues $\sigma_i^2 / \sum_k \sigma_k^2$ as functions of the mode index.

To further compare the effectiveness of the two methods, Figure 3 shows the pairwise projections of the first four low-dimensional coordinates obtained from ISOMAP (a) and POD (b), applied to the normalized fluctuating velocity fields. Each point corresponds to a phase-averaged snapshot and is color-coded by the Strouhal number St of the forcing. A neighborhood size of $k = 10$ is used for ISOMAP.

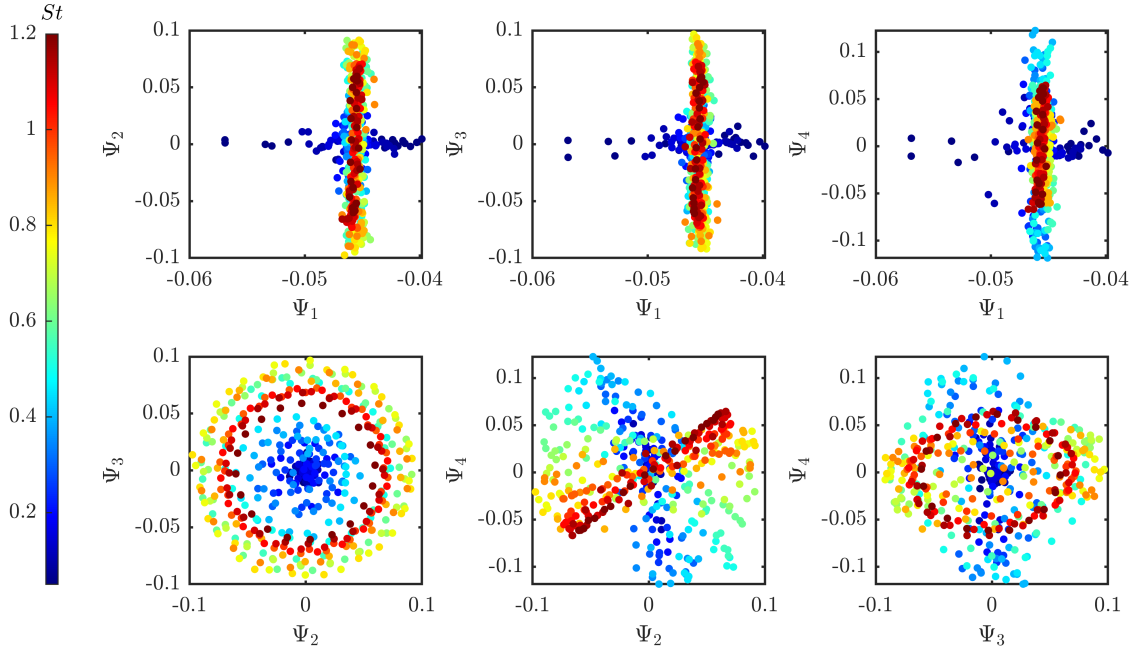
While POD succeeds in compressing the dataset energy into a few dominant modes, the resulting embedding fails to organize the snapshots coherently across the Strouhal number range. As shown in Figure 3b, the projections exhibit partial circular arrangements in the ψ_2-ψ_3 plane, which are reminiscent of phase-resolved dynamics for certain intermediate actuation frequencies. However, this structure fades significantly at low St, leading to a disordered and overlapping distribution of snapshots, where phase information is lost and actuation cases become indistinguishable.

In contrast, ISOMAP yields a more structured and physically interpretable embedding, as shown in Figure 3a. The pairwise projections of the first four coordinates reveal organized manifolds with clear geometric patterns—such as rings, spirals, and bifurcated surfaces—that consistently vary with the forcing frequency. Unlike POD, ISOMAP preserves the continuity of the phase trajectories even at low St, highlighting its ability to retain the intrinsic geometry of the flow dynamics and to represent both temporal evolution and actuation mechanisms in a unified low-dimensional space.



The contrast between actuation regimes is further explored by examining the flow structures associated with representative Strouhal numbers. Figure 4 shows the first spatial POD mode ϕ of the streamwise velocity fluctuations for three selected cases: $St = 0.15$, $St = 0.45$, and $St = 1$. The modes are normalized by $\sqrt{N_p}$, where N_p is the number of grid points. In the low-St case (top), the spatial mode reveals large-scale, nearly steady structures that extend over several jet diameters, reflecting a strong mean-flow pumping effect. At higher St, the modes become increasingly compact and periodic, with the $St = 1$ case (bottom) dominated by wave-like features consistent with Kelvin–Helmholtz vortices synchronized with the actuation.

To further investigate the flow response at different forcing frequencies, the phase-averaged voltage signals recorded from four near-field microphones are presented in Figure 5, for actuation cases $St = 0.15$, 0.45, and 1. The microphones are aligned along the jet centerline at axial distances of $1D$, $3D$, $6D$, and $10D$ from the nozzle exit (top to bottom).



At $St = 0.15$, the signals exhibit high-amplitude oscillations with a smooth and coherent phase shift across the microphones. The temporal behavior of the signals show a strong modulation, differing from the expected sinusoidal behavior typical of travelling waves. This pattern maintains its structure and shifts without significant deformation — likely driven by acoustic resonance within the facility. For $St = 0.45$ and $St = 1$, the voltage signals are significantly weaker but still exhibit low-amplitude oscillations. Interestingly, the waveform remains nearly unchanged across the four microphones, indicating limited spatial evolution and suggesting the presence of weak convective fluctuations rather than amplified coherent structures. In contrast, the $St = 0.15$ case shows strong spatial modulation of the waveform, with amplitude decreasing notably by $10D$, consistent with a resonance-driven wave confined to the near-nozzle region.

These findings reinforce the interpretation that the low-St regime excites a distinct, facility-driven mechanism with a strong near-field signature. This behavior differs fundamentally from the convective responses at higher frequencies, and explains why POD struggles to represent both within a common basis. ISOMAP, on the other hand, successfully embeds this physical variation into its low-dimensional manifold.

Finally, Figure 6 presents the power spectral density (PSD) of the far-field pressure signals acquired by the GRAS microphones placed at 30° (Mic1) and 90° (Mic2)

(a) ISOMAP

(b) POD

Figure 3: Pairwise projections of the first four low-dimensional coordinates obtained with ISOMAP **(a)** and POD **(b)**, applied to the normalized streamwise velocity fluctuations. Each point corresponds to a phase-averaged snapshot and is color-coded by the Strouhal number St. While POD compresses energy in a few modes, ISOMAP reveals a more structured and physically interpretable manifold.

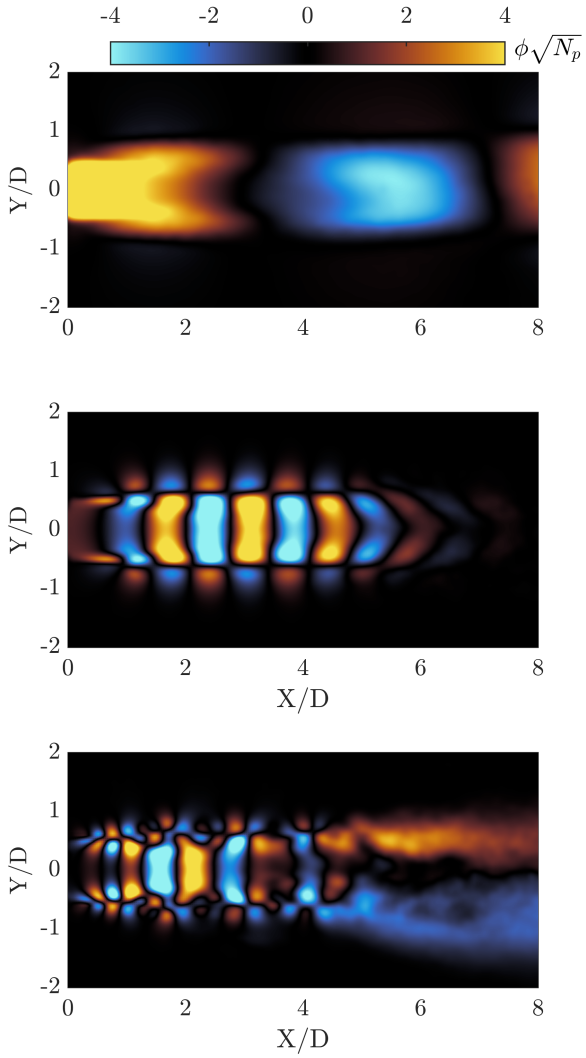


Figure 4: First spatial POD mode ϕ of the streamwise velocity fluctuations for the cases $St = 0.15$ (top), $St = 0.45$ (middle), and $St = 1$ (bottom). The modes are normalized by $\sqrt{N_p}$, where N_p is the number of grid points.

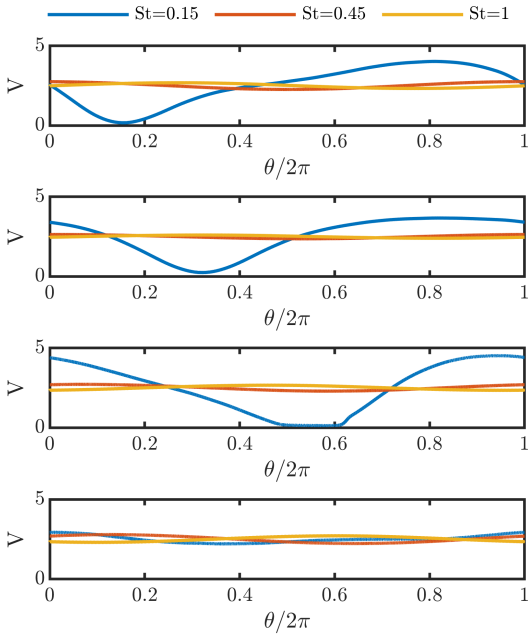

Figure 5: Phase-averaged voltage signals from four near-field microphones placed along the jet centerline at axial distances of $1D$, $3D$, $6D$, and $10D$ (top to bottom), for actuation cases $St = [0.15, 0.45, 1]$.

from the jet axis, comparing the uncontrolled and actuated cases at $St = 0.50$ and $St = 1.00$. The power spectra are plotted as Sound Pressure Levels (SPL), using a reference pressure of 20 μPa. The dominant peak observed in each actuated spectrum corresponds to the acoustic wave produced by the loudspeaker at the forcing frequency. However, the most informative effects of the actuation lie in the surrounding broadband spectral content. At 90° (Mic2), a substantial elevation of the high-frequency floor is observed in the actuated cases. This increase indicates enhanced radiation from small-scale turbulent structures, which typically dominate the side-radiated acoustic field [11]. In contrast, the spectra at 30° (Mic1) show more selective changes and are generally associated with sound generated by large-scale coherent structures aligned with the jet axis. These directional differences confirm that actuation not only injects tonal energy but also reorganizes the turbulence dynamics and their acoustic signatures in a frequency- and angle-dependent manner.

Overall, the results reveal that the acoustic impact of

actuation is far from trivial: while the forcing introduces energy at a specific tone, it also modifies the structure and distribution of broadband noise in ways that reflect deeper changes in the flow field. This complex interplay warrants further investigation to understand the link between actuation, turbulent structures, and jet noise generation mechanisms.

5. CONCLUSIONS AND FUTURE WORKS

The present work explores the existence of an actuation manifold for open-loop control of a subsonic transitional jet. The control action has been performed using acoustic excitation inside the stagnation chamber. Data-driven dimensionality reduction techniques have been applied to the phase-averaged velocity field measurements to identify the actuation manifold. Results shown the existence of a low-dimensional manifold for such data. The ISOMAP techniques, in particular, revealed to provide a more clear manifold than POD, being capable of coherently embedding different behaviors of the flow, i.e. "jet-pumping" mechanisms at low Strouhal numbers and Kelvin-Helmholtz vortices excitation at higher Strouhal numbers. The existence of a clear actuation manifold confirms the capability of the selected control action to affect the flow. This is further reinforced by the difference in behavior measured by both near-field microphones and the far-field microphones. Further work will focus in identifying a control manifold for non phase-averaged quantities.

NUMERICAL INVESTIGATION ON NOISE REDUCTION OF DISTRIBUTED PROPELLERS BY PHASE SYNCHRONIZATION

Zhe Yang[1*] **Matthias Meinke**[1] **Dominik Krug**[1] **Wolfgang Schröder**[1]

ABSTRACT

Distributed propulsion systems represent a promising solution for future Urban Air Mobility (UAM) aircraft, offering benefits such as noise reduction, improved efficiency, and enhanced maneuverability. Recent studies highlight propeller phase synchronization as an effective active control strategy for mitigating noise in distributed propellers with compact installation clearance.

To further explore the mechanisms underlying noise reduction through phase synchronization, large-eddy simulations with adaptive mesh refinement are conducted to investigate co- and counter-rotating propeller pairs with relative phase angles of 0° and 90°. The far-field noise signals are predicted from the LES flow field by a time-domain formulation of the Ffowcs-Williams and Hawkings analogy. The results exhibit good agreement with wind tunnel measurements in terms of noise spectra and directivity patterns.

The findings indicate that synchronized propellers with a 90° relative phase angle achieve noise reductions greater than 20 dB at the blade passing frequency across all directions. Additionally, the acoustic signals of two isolated propellers are superimposed and compared with dual-propeller configurations. The observed tonal noise reduction is attributed to two key mechanisms: (a) reduced aerodynamic interaction at the propeller tips, which mitigates unsteady loading noise that propagates in the streamwise direction; and (b) destructive acoustic interference between counter-phase neighboring propellers.

1. INTRODUCTION

As a key driver of the emerging low-altitude economy, Urban Air Mobility (UAM) [1] has attracted significant attention as an innovative transportation solution. By leveraging advanced flight control and electric propulsion technologies, UAM aims to meet the increasing demand for efficient point-to-point travel in congested metropolitan areas or regions with limited road infrastructure. Despite its potential, the widespread adoption of UAM faces significant challenges, with aircraft generated noise being a major regulatory societal concern.

Among the various technologies explored for UAM applications, distributed electric propulsion (DEP) has emerged as a leading solution [2]. Characterized by multiple electrically driven propellers distributed along the airframe, DEP enhances aerodynamic performance, increases safety redundancy, provides acoustic shielding, and reduces propeller loading, thereby lowering overall noise emissions. Nonetheless, the compact installation of propellers introduces engineering challenges related to inter-propeller interactions and propeller–airframe coupling [3]. These complexities underscore the need for in-depth investigations into the noise and performance characteristics of DEP systems.

The aerodynamic and acoustic interactions between closely installed propellers have been the focus of extensive research. When the tip-to-tip separation is below 0.5 times the propeller diameter, significant thrust fluctuations have been observed [4–6], leading to a measurable reduction in propulsive efficiency, typically in the range of 1% to 2% [4, 7]. The interaction of tip vortices between adjacent propellers results in the distortion of he-

lical vortical structures [5, 8, 9], elevating turbulence intensity in the wake [4]. From an acoustic perspective, studies have reported increased noise levels at the blade passing frequency (BPF) and overall sound pressure level (OASPL) [4, 5]. Variations in sound pressure levels of up to ±10 dB at specific observation points have been documented [7], highlighting the significance of inter-propeller interactions in shaping the acoustic footprint of DEP systems. Additionally, noise source localization studies have identified the primary noise source within the gap region between adjacent propeller disks, where noise intensity is approximately 5 dB higher than that of blade tip noise [10]. This phenomenon is attributed to intensified blade-turbulence interactions and unsteady blade loading effects.

To mitigate noise emissions in DEP configurations, active noise control strategies, such as propeller phase synchronization, have been proposed. By precisely controlling the relative phase angles between adjacent propellers, this technique has demonstrated the potential to achieve noise reductions by 15 to 46 dB at the BPF and up to 6 dB in OASPL [11, 12]. The primary mechanism responsible for this noise reduction is destructive acoustic interference between phase-locked propellers [4]. However, recent findings indicate that reduced aerodynamic interactions between adjacent propellers also contribute significantly to noise mitigation [7, 9]. A comparative analysis of noise spectra from two-propeller configurations and superimposed isolated propeller signals further supports the coexistence of these two mechanisms [13]. Notably, in configurations with minimal tip clearance, nonlinear aerodynamic interactions become increasingly dominant, influencing overall noise emissions.

Building upon prior research, this study aims to further elaborate on the underlying mechanisms of noise reduction through propeller phase synchronization in distributed propulsion systems using high-fidelity numerical simulations. The paper is structured as follows: Section 2 provides an overview of the flow solver and numerical methodologies. Section 3 details the computational setup, including the test geometry and simulation parameters. Section 4 presents the results and discusses the key findings of the study. Finally, Section 5 summarizes the conclusions and outlines potential directions for future research.

2. NUMERICAL METHODS

Large-eddy simulations (LES) are performed based on the flow solver multiphysics-Aerodynamics Institute Aachen (m-AIA) [14]. The simulation workflow is illustrated in Fig. 1. First, an unstructured hierarchical Cartesian mesh is automatically generated by a parallel grid generator according to predefined mesh parameters for the target geometry. To track the rotating geometry of the propeller blades, a level-set solver based on the kinematic motion level-set approach [15] is employed, providing information about the surface location for solution adaptive mesh refinement (AMR) during the simulation run. The Navier-Stokes equations are solved by a finite-volume (FV) solver [16] at second-order accuracy in time and space to perform wall-resolved LES of the turbulent flow field. A postprocessing module is integrated into the simulation workflow to conduct time averaging or time-series data sampling on the dynamically changing mesh. For the far-field noise, Farassat's time-domain formulation 1A [17] of the Ffowcs-Williams and Hawkings (FW-H) method is used to predict the pressure signals at far-field observer positions. Dynamic load balancing (DLB) [18] is used to alleviate workload imbalances among the parallel processes generated by AMR to improve the computational efficiency on high-performance computing systems.

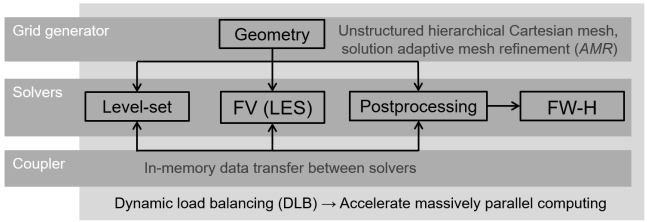

Figure 1. Overview of the m-AIA framework [14]

3. COMPUTATIONAL SETUP

3.1 Test geometry

Turhan et al. [12] have developed an experimental setup, shown in Fig. 2, to investigate the interaction noise of the closely arranged distributed propellers and evaluate the effectiveness of phase-synchronization for propeller noise reduction. The experiments were performed with two 2-bladed propellers manufactured by Mejzlik with a diameter of $D = 228.6\ mm$ (9 inch) and a pitch-to-

diameter ratio of $P/D = 1$. The center-to-center separation distance between adjacent propellers is $S/D = 1.05$. The two propellers were mounted 150 mm upstream of a supportive NACA0018 airfoil, with a chord length of $c_{wing} = 300$ mm, and a span of 940 mm.

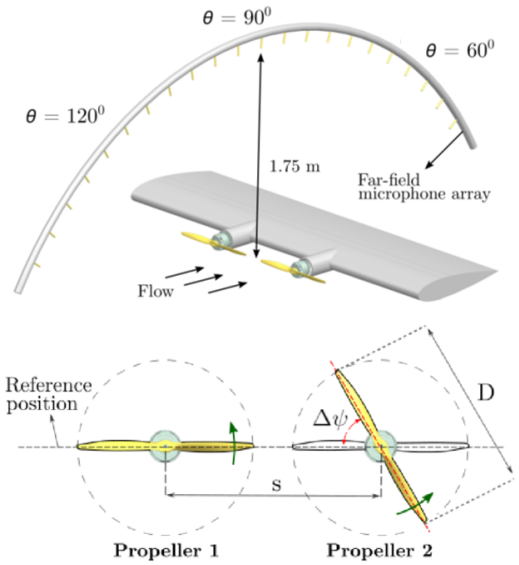

Figure 2. Experimental setup for propeller-propeller interaction noise [12].

The incoming freestream velocity is $U_\infty = 10$ m/s with a wing angle of attack $AoA = 0°$. The chord Reynolds number is approximately $Re_{wing} = 2 \cdot 10^5$. The two propellers rotate in the same direction at the speed of $n = 5000$ rpm, giving a blade tip tangential Mach number of about $M_{tip} = 0.17$, a blade passing frequency of $BPF = 166.7$ Hz and a propeller advance ratio of $J = U_\infty/(nD) = 0.53$. Two propeller blade relative phase angles, $\Delta\psi = 0°$ and $90°$ are tested.

3.2 Flow simulation setups

Based on the previous experimental/numerical observations by [19, 20] that the propeller-propeller interaction is a major noise source of the distributed propulsion system and has a much higher contribution to the far-field noise than the propeller-airfoil interaction, the flow field of only the two propellers are simulated and the supportive nacelle and airfoil are omitted to reduce the computational cost. The lengths $L_x = 1400$ mm, $L_y = 1200$ mm, and $L_z = 1000$ mm define the size of the computational domain. The no-slip boundary condition is imposed on all surfaces which are assumed to be adiabatic. Subsonic inlet and outlet conditions with an acoustic sponge layer are used for the far-field boundaries to absorb any spurious reflected pressure waves.

The computational mesh is shown in Fig. 3. To resolve the turbulent boundary layer near the solid surfaces, the minimum spatial step near solid surfaces is $4.3 \cdot 10^{-5}$ m. Approximately 300 cells are distributed along the propeller chord. Adaptive mesh refinement is applied to the fluid-solid interface with the minimum spatial resolution and coarsening towards the far field until a maximum spatial step of $1.4 \cdot 10^{-3}$ m is reached. Patch refinement boxes are implemented in the near field to better resolve the propeller slipstream. Overall, this leads to approximately $500 \cdot 10^6$ cells. The rotating propeller and the high-frequency turbulent scales are resolved by a time step of $1 \cdot 10^{-7}$ s, which is determined by the stability limit of the numerical method.

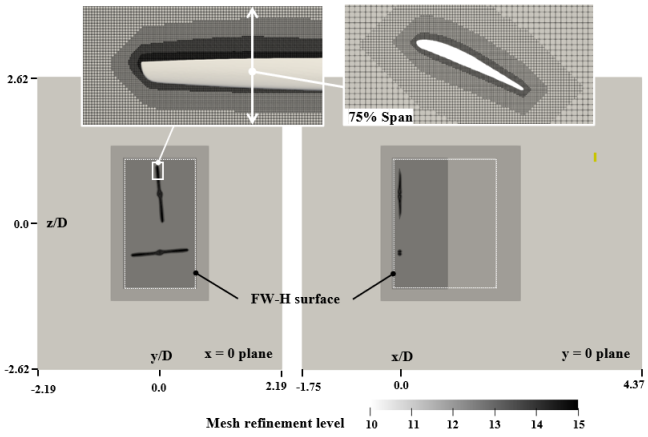

Figure 3. Illustration of the computational domain and mesh

3.3 Far-field noise prediction setups

A permeable FW-H surface around the vortex core of the propeller pairs is employed to record the near-field perturbations. The surface is a rectangular box, as defined by the white dashed lines in Fig. 3. The leeward side of the FW-H surface is left open to avoid spurious noise generated by hydrodynamic perturbations traveling over the sampling surface. The spatial resolution of the sampling surface is $2 \cdot 10^{-3}$ m. The sampling frequency is 65 kHz and data for 10 propeller revolutions are recorded.

4. RESULTS

4.1 Flow field

The generation and propagation of the instantaneous vortex structures of the co-rotating propeller pairs with relative phase angle $\Delta\psi = 0°$ are shown in Fig. 4.

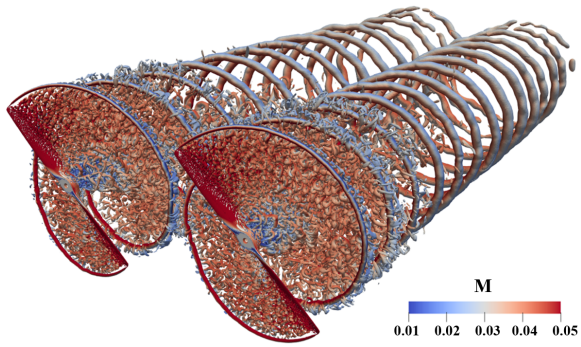

Figure 4. Vortex structures denoted by the Q-criterion [21] with an iso-surface value of $\tilde{Q} = 2$.

The time-averaged statistics of the thrust coefficient $C_T = F_T/(\rho_0 n^2 D^4)$ is provided in Tab. 1. The time histories of the thrust coefficient for propeller 1 at relative phase angles of $\Delta\psi = 0°$ and $90°$ are illustrated in Fig. 5, co-rotating propellers in Fig. 5 (a) and counter-rotating propellers in Fig. 5 (b). Both cases are compared against the isolated propeller.

The results indicate that closely installed propeller pairs exhibit an approximately 0.5% higher time-averaged thrust coefficient compared to an isolated propeller. Furthermore, the time-averaged thrust coefficient at a relative phase angle of $\Delta\psi = 0°$ is slightly higher than that at $\Delta\psi = 90°$.

The instantaneous thrust coefficients of installed propeller pairs show clear periodic fluctuations dominated by the blade passing frequency (BPF). The root-mean-square fluctuation of the thrust coefficient at a relative phase angle of $\Delta\psi = 0°$ is roughly 45% higher than that of an isolated propeller. For the $\Delta\psi = 90°$ phase angle, this increase reduces to about 24%. This demonstrates that adopting a relative phase angle of $\Delta\psi = 90°$ helps mitigate aerodynamic interference between adjacent propellers, and reduce periodic unsteady loading on the blades.

To further investigate the aerodynamic interactions between adjacent propellers, Fig. 6 presents the total pressure perturbation at the propeller tip gap located at

counter-r, $\Delta\psi = 0°$	0.083 74	0.000 89
counter-r, $\Delta\psi = 90°$	0.083 62	0.000 76

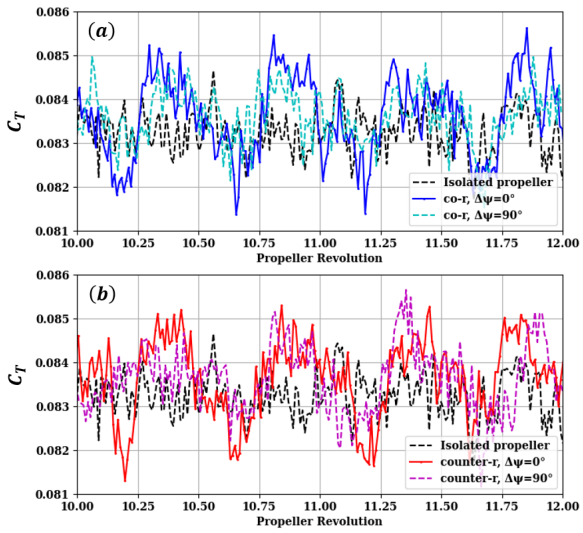

Figure 5. Time history of the propeller thrust coefficient of propeller 1; (a) co-rotating propellers, (b) counter-rotating propellers.

$(x, y, z) = (0, 0, 0)$. The nondimensional perturbed total pressure is defined as $\tilde{p_T'} = (p_T - \bar{p}_T)/(0.5\rho_\infty U_\infty^2)$. For an isolated propeller, the total pressure fluctuation at the blade tip exhibits periodicity corresponding to the blade passing frequency, with a clear pressure drop when each blade passes.

Considering the installed propeller pairs with a relative phase angle of $\Delta\psi = 0°$, the amplitude of the total pressure fluctuation approximately doubles due to simultaneous blade passages from both propellers through the tip gap. However, at a phase angle of $\Delta\psi = 90°$, the total pressure fluctuations are periodic at twice the rotor frequency, as blades from each propeller pass through the tip gap alternately. The fluctuation amplitude in this scenario is comparable to that of an isolated propeller. Moreover,

the rotation direction of the propellers has negligible influence on the total pressure fluctuations at the blade tip.

A comparison between Fig. 5 and Fig. 6 reveals that variations in total pressure fluctuations in the tip gap align closely with changes in propeller thrust. This correlation suggests that aerodynamic interference between adjacent propellers significantly contributes to unsteady aerodynamic loading on the rotor, which potentially increase noise generation.

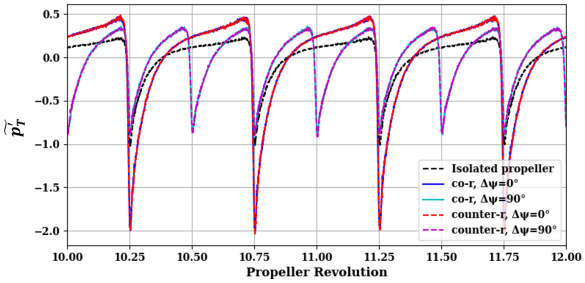

Figure 6. Total pressure perturbation in the tip gap.

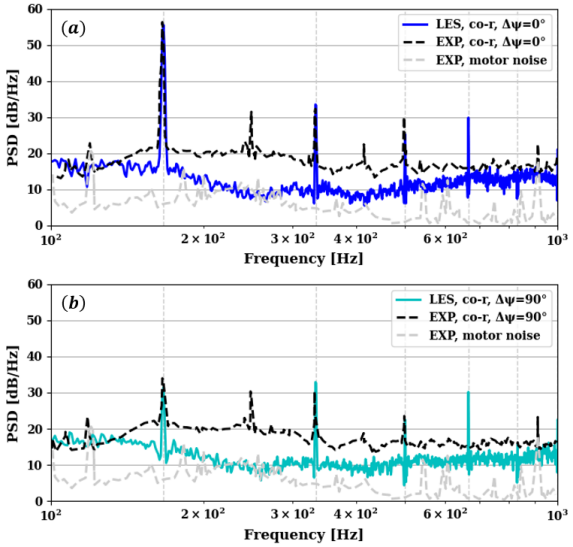

Figure 7. Predicted power spectral density of the co-rotating propeller pairs with relative phase angle (a) $\Delta\psi = 0°$, and (b) $\Delta\psi = 90°$.

4.2 Acoustic Field

The far-field noise of the synchronized propellers is determined by the permeable FW-H approach and compared with the wind tunnel measurements from [12]. The microphone is located 1.75 m off the propeller in the vertical plane with an angular position of $\theta = 90°$. The power spectral density (PSD) of the acoustic signal is calculated using Welch's method, 50% overlap, filtered by a Hanning window, with a frequency resolution of $\Delta f = 1.0\ Hz$, and the reference pressure is $2 \cdot 10^{-5}\ Pa$. The grey dashed lines in the plots represent the propeller blade passing frequency (BPF) and its harmonics.

Fig. 7 compares the predicted far-field noise spectra with the experimental reference data in the frequency range from 100 Hz to 1000 Hz. It can be seen that the propeller tonal noise at the first and second BPF frequencies is accurately predicted by the numerical method. The reference data showed a higher amplitude of broadband noise, which was mainly caused by the background motor noise in the wind tunnel experiment.

Next, the predicted noise spectra at the angular position of $\theta = 90°$ for cases with different rotation directions and relative phase angles are shown in Fig. 8. No significant difference in broadband noise was observed among the cases; variations mainly occurred in propeller tonal noise. A close look at the first two blade passing frequencies (BPF) reveals that the relative phase angle primarily affects the first BPF. At a relative phase angle of $\Delta\psi = 0°$, cases with different rotation directions exhibited similar far-field noise levels of approximately 55 dB at the first BPF. In contrast, at $\Delta\psi = 90°$, the first BPF noise level for the co-rotating case decreased by about 24 dB. Remarkably, in the counter-rotating case at $\Delta\psi = 90°$, the first BPF tonal noise was nearly eliminated, achieving a noise reduction exceeding 50 dB. This finding is consistent with experimental results reported by Shao et al. [11]. As a trade-off for the reduction in the first BPF, the second BPF tonal noise increases by approximately 1 dB for the cases with a $\Delta\psi = 90°$ relative phase angle. The above findings evidence that propeller phase synchronization effectively reduces the first BPF tonal noise, especially for counter-rotating propellers.

The directivity of the propeller far-field noise compared with experimental measurements is presented in Fig. 9. Fig. 9 (a) shows the sound pressure level (SPL) at the first BPF and Fig. 9 (b) illustrates the overall sound pressure level (OASPL) within the frequency range of 100 to 1000 Hz. As shown in Fig. 9 (a), the numerical predictions agree well with the experimental data upstream of the propeller but underestimate the SPL downstream. This

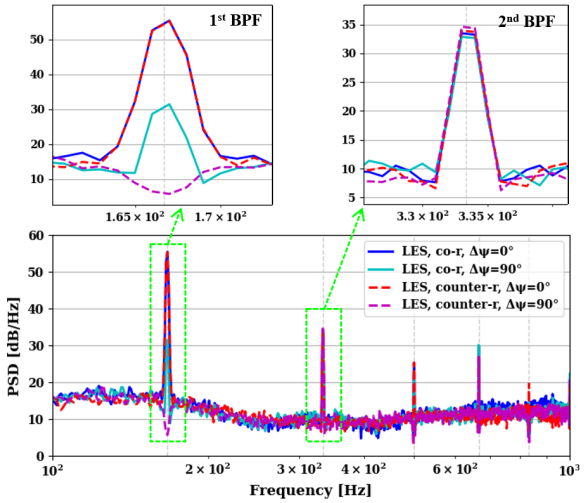

Figure 8. Comparison of predicted noise spectra for several test cases.

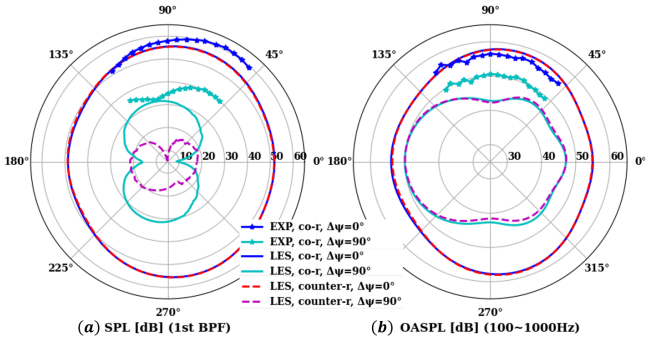

Figure 9. Directivity of the propeller noise.

discrepancy may arise from the scattering effect of the airfoil located downstream in the experiment, which alters the directivity of the sound field. A similar discrepancy was observed by Turhan et al. [22] in their mid-fidelity Vortex Lattice Method (VLM) simulations with the same test geometry. Consistent with Fig. 8, noise directivities for cases with a relative phase angle of $\Delta\psi = 0°$ are nearly identical. A relative phase angle of $\Delta\psi = 90°$ reduces far-field noise by over 20 dB at the first BPF in all directions. Compared to co-rotating propellers, counter-rotating propellers achieve an additional 10 dB noise reduction at $\theta = 90°$ and 270°, i.e. perpendicular above and below the propeller.

For the OASPL shown in Fig. 9 (b), numerical predictions at $\Delta\psi = 0°$ match very well with the experimental data, whereas at $\Delta\psi = 90°$, the numerical results exceed the experimental values on the top and bottom sides. The reduction of the OASPL ranges from 5 to 15 dB for different directions. The findings reveal that a staggered relative phase angle $\Delta\psi = 90°$ significantly reduces the overall noise levels in all directions, while the influence of different rotation directions on the OASPL is negligible.

4.3 Superposition of the isolated propeller noise

The principle of superposition [13] is employed to further understand noise-reduction mechanisms due to propeller phase synchronization. The far-field noise signal of a simulated isolated propeller is spatially and temporally shifted to construct a two-propeller system identical to the experimental setup but without aerodynamic interactions. The noise signals from these two isolated propellers are linearly superimposed to represent the dual-propeller noise, accounting only for acoustic interference. A comparison of the superimposed results with direct dual-propeller simulations in Fig. 10 shows the contributions from aerodynamic interactions and purely acoustic interference between adjacent propellers to far-field noise can be distinguished.

Figs. 10 (a) and (c) show the far-field noise for co-rotating and counter-rotating propeller pairs at a relative phase angle $\Delta\psi = 0°$. The isolated superimposed propellers exhibit a dipole-like directivity for the first BPF noise, with acoustic energy mainly concentrated on the top and bottom sides of the propellers, and relatively low noise levels upstream and downstream. In contrast, the dual-propeller simulation results show significantly increased noise upstream and downstream of the propellers. Specifically, tonal noise levels at $\theta = 0°$ and 180° increase by approximately 30 dB. This indicates that aerodynamic interactions between adjacent propellers generate strong additional noise sources, primarily propagating upstream and downstream.

Fig. 10 (b) presents the far-field noise of co-rotating propeller pairs at a relative phase angle of $\Delta\psi = 90°$. Due to the reduced aerodynamic interactions at the blade tips, the dual-propeller simulation results exhibit dipole patterns consistent with those predicted by linear superposition. Destructive wave interactions occur at the far-field microphone locations due to the phase difference between the two propellers, leading to a significant reduction in noise levels. The pure acoustic noise cancellation is most pronounced in the case of counter-rotating propellers with

$\Delta\psi = 90°$. As shown in Fig. 10 (d), the first BPF noise is nearly completely eliminated, such that the noise level is reduced to that of the background broadband noise.

In addition, we observed that in certain cases, such as at $\theta = 0°$ in Figs. 10 (a), (b), and (c), the noise level of the dual-propeller simulations are lower than the predicted value based on linear superposition. This indicates the presence of nonlinear effects in the dual-propeller case, which influence the directivity of propeller far-field noise.

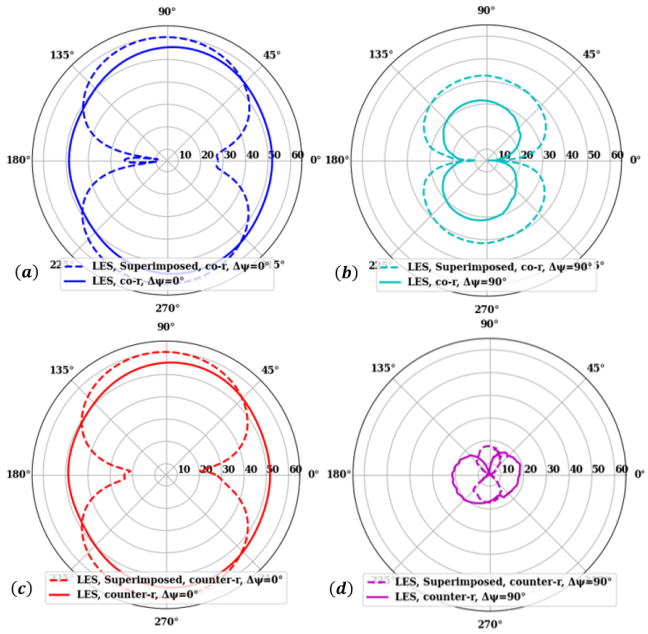

Figure 10. Comparison of first BPF noise directivity of the superimposed propellers and simulated propeller pairs.

5. CONCLUSIONS

The noise reduction mechanisms of distributed propeller systems through phase synchronization are investigated by a hybrid LES/FW-H approach. The numerical method accurately captures aerodynamic interactions and acoustic interference between adjacent propellers and is validated against wind tunnel measurements.

Results show that the relative phase angle of $\Delta\psi = 90°$ effectively reduces the tonal noise at the first blade passing frequency. Specifically, the co-rotating configuration achieves a noise reduction of approximately 24 dB, while the counter-rotating configuration yields an even greater reduction, with the first BPF tonal noise reduced by over 50 dB. Additionally, phase synchronization leads to an overall sound pressure level reduction of 5 to 15 dB, depending on the direction.

The observed noise reduction is primarily attributed to two mechanisms: (1) a reduction in aerodynamic interactions at the propeller tips, which mainly propagate upstream and downstream, and (2) destructive acoustic interference between counter-phase neighboring propellers which effectively cancels the first BPF noise component, particularly in counter-rotating configurations.

The present work offers practical insights into integrating phase synchronization in urban air mobility propulsion systems, emphasizing dual control of aerodynamic and acoustic sources. Future research could investigate additional propeller parameters, including tip clearance variations, transitional inflow conditions, elastic propeller blades, and multi-propeller configurations, to further refine noise mitigation strategies.

6. ACKNOWLEDGMENTS

The present work has received funding from the European Union's Horizon 2020 research and innovation program under the project ENODISE (Enabling optimized disruptive airframe-propulsion integration concepts) (`www.vki.ac.be/index.php/about-enodise`) grant agreement No. 860103. The authors would like to thank B. Turhan and M. Azarpeyvand from the University of Bristol (United Kingdom) for providing the test geometry and experimental data. The authors also gratefully acknowledge the Gauss Centre for Supercomputing e.V. (`www.gauss-centre.eu`) for funding this project by providing computing time on the GCS Supercomputer HAWK at Höchstleistungs-Rechenzentrum Stuttgart (`www.hlrs.de`).
