MITIGATION STRATEGIES FOR ACOUSTIC REFLECTIONS GENERATED BY AN AXISYMMETRIC WIND TUNNEL NOZZLE

Luca Nicola Quaroni [1*] **Roberto Merino-Martínez** [1]

[1] Faculty of Aerospace Engineering, Delft University of Technology, the Netherlands

ABSTRACT

The issue of acoustic reflections caused by an axisymmetric nozzle is addressed both numerically and experimentally. The contraction (with an exit diameter of 420 mm and a contraction ratio of 2) is representative of typical open-jet wind tunnel exits. Such a category of wind tunnels are extensively used in aeroacoustic studies due to the possibility of acoustic treatment of the test chamber (plenum) walls and the placement of acoustic sensors outside of the flow. The distance between the wind tunnel's nozzle exit and the model being tested is usually limited to around one hydraulic diameter in order for the model to be fully contained within the exit jet's core. Partly for this reason, the wind tunnel nozzle normally protrudes inside the anechoic plenum to distance the tested model from the (acoustically-treated) walls. This effectively creates a cavity, which is in communication with the test section. Acoustic simulations through a commercial finite-element code (COMSOL Multiphysics) show that the presence of the nozzle leads to interference patterns within the test section and a substantial modification of a source's measured directivity pattern. Experimental measurements in a fully anechoic chamber confirm these results. Melamine foam inserts on both the exit flange and part of the inner walls of the contraction are shown to mitigate the issue partly.

1. INTRODUCTION

Awareness of the adverse health effects of noise exposure from the aviation sector has been steadily increasing over the past few decades as the volume of flights has increased globally [1]. Furthermore, in an effort to increase propulsive efficiency, novel architectures (i.e. distributed propellers, boundary layer ingestion, etc.) have been introduced, potentially contributing to and altering the noise generation [2]. Improvements in control technologies and the lowering of production costs have then led to the widespread use of small Unmanned Aerial Vehicles (UAVs) for both professional and entertainment purposes, further exacerbating the issue [3]. Research for mitigation strategies has therefore followed suit, with experimental testing usually involving anechoic chambers and/or open-jet wind tunnels. While offering anechoic conditions (i.e. free-field sound propagation) over a large frequency range, anechoic chambers lack the possibility of adding any inflow, restricting their use to hovering UAVs [4]. Open-jet wind tunnels, on the other hand, allow for the presence of low-turbulence subsonic inflows in an anechoic environment, making them the perfect candidates for aeroacoustic studies. Common designs present a turbulence-reducing contracting nozzle protruding into an anechoic plenum, matched by a collector on the opposite side for the creation of a semi-closed air circuit [5]. Recent contributions involving anechoic open-jet wind tunnels focused on isolated propellers [6, 7], propeller installation effects [8], and turbulence-airfoil interaction [9,10].

Because of the widespread use of open-jet anechoic wind tunnels in aeroacoustic investigations, a clear understanding of the effects related to their specific testing environment is essential for a correct interpretation of

the results obtained. The present paper focuses on the issue of acoustic reflections caused by an axisymmetric contracting nozzle designed for an open-jet wind tunnel facility. It summarizes the results of a numerical and experimental investigation of the acoustic interference patterns generated by a simple point sound source located outside of the nozzle's exit, representative of the typical location of test models. The effectiveness of acoustically absorbing panels at mitigating the issue is also discussed.

2. PROBLEM OVERVIEW

2.1 Contraction geometry

An axisymmetric contraction was designed as part of a broader investigation [7] of turbulence-ingestion noise generation by an isolated propeller at the anechoic wind tunnel facility (A-Tunnel) of Delft University of Technology [11]. The nozzle is intended to both improve the isotropy of grid-generated turbulence and reduce the grids' self-noise, following suggestions by Bowen et al. [12]. The contraction follows the fifth-order polynomial wall profile indicated by Bell & Mehta [13]:

$$\mathrm{D(z)} = \mathrm{D_{wt}} + (\mathrm{D_{wt}} - \mathrm{D_{ext}}) \left[-10 \left(\frac{z}{\mathrm{L_c}} \right)^3 + \right.$$
$$\left. + 15 \left(\frac{z}{\mathrm{L_c}} \right)^4 - 6 \left(\frac{z}{\mathrm{L_c}} \right)^5 \right], \quad (1)$$

where all the geometrical parameters and their values are shown in Fig. 1. The additional cylindrical section after the contracting profile, of length $\mathrm{L_a} = \mathrm{R_{wt}}/2 = 150$ mm, was inserted to improve the flow's homogeneity at the nozzle's exit. Two flanges with a thickness of 15 mm and six aluminum struts (see top view in Fig. 2) were included for both structural and practical reasons and for compatibility with existing nozzles designed for the same wind tunnel, e.g. [11, 14]. A hot-wire anemometry campaign showed that the contraction produces streamwise turbulence intensity levels u'/U_∞ lower than 0.1% with good flow homogeneity within the first diameter $\mathrm{D_{ext}}$ from the nozzle exit [7].

2.2 Example: interference patterns in turbulence-interaction noise investigation

Fig. 3 shows the experimental setup used for the aforementioned investigation of turbulence-interaction noise by

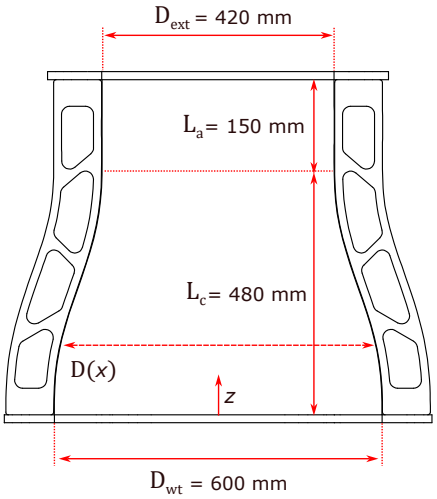

Figure 1. Sectional view of the axisymmetric contraction. The flow is in the positive z direction.

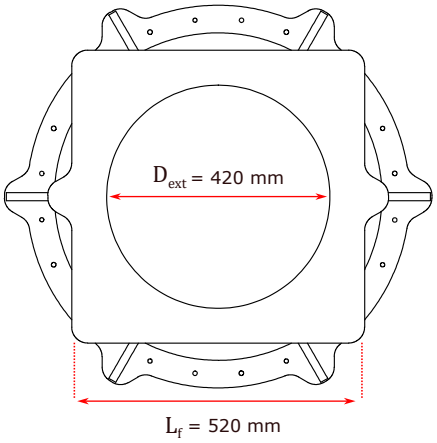

Figure 2. Top view of the axisymmetric contraction.

an isolated propeller. A turbulence-generating grid was inserted between the main wind tunnel's exit on the floor and the inlet of the additional contraction, allowing for the generation of turbulence intensity levels in the streamwise direction z of approximately 3% at the location of the propeller's disk ($z = 0.4\,\mathrm{D_{ext}}$, with $z = 0$ m at the nozzle exit plane). For further details, the reader is referred to Quaroni et al. [7]. The self-noise produced by the supporting structure and the propeller's nacelle was obtained by substituting the propeller with a dummy spinner and installing or removing the turbulence-producing grid at the base of the additional contraction. The self-noise of the system

composed of the nozzle and grid only was also tested by removing the propeller's setup altogether.

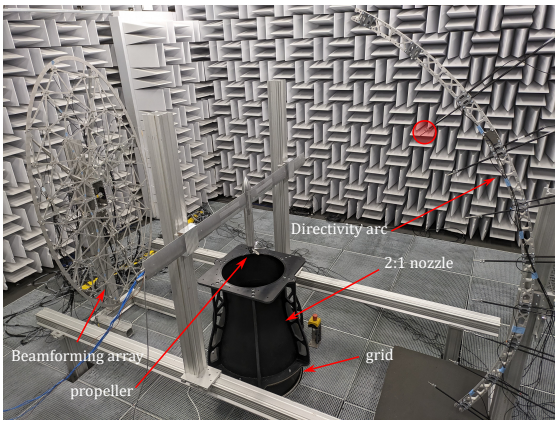

Figure 3. Overview of the setup for the study of turbulence-interaction noise by an isolated propeller, from [7]. Microphone at $\vartheta = 50°$ highlighted.

Fig. 4 reports the power spectral density (PSD) of the acoustic pressures measured at a distance $r = 1.3$ m from the center of the propeller's disk and at emission angle $\theta = 50°$ downstream of the propeller's disk for the self-noise cases and the condition with an operational propeller spinning at 180.57 Hz; a common inflow velocity of $V_\infty = 30$ m/s was set. Characteristic undulations in the broadband spectra are clearly visible in all cases. Oscillation 'amplitudes' increase while their 'wavelengths' remain constant when going from the case of clean inflow to the support structure to the case of turbulent inflow and installed propeller. This observation seems to indicate that the behavior might be related to the acoustic response of the overall wind tunnel system rather than to a particular sound generation mechanism (e.g. turbulence-ingestion noise). For the cases of 'grid on' and 'propeller setup on-off', the spectral oscillations almost perfectly overlap for frequencies higher than $\approx$ 2000 Hz, indicating that the acoustic scattering due to the support structure has a limited effect. Finally, a previous characterization of the wind tunnel facility showed that the anechoic plenum has a cut-off frequency of 200 Hz [11]. This leads to the conclusion that the newly designed axisymmetric nozzle might be responsible for the introduction of spurious acoustic reflections, leading to complex interference patterns within the anechoic plenum of the wind tunnel. The following sections explore this possibility through a numerical and experimental investigation of the acoustic properties of the contraction.

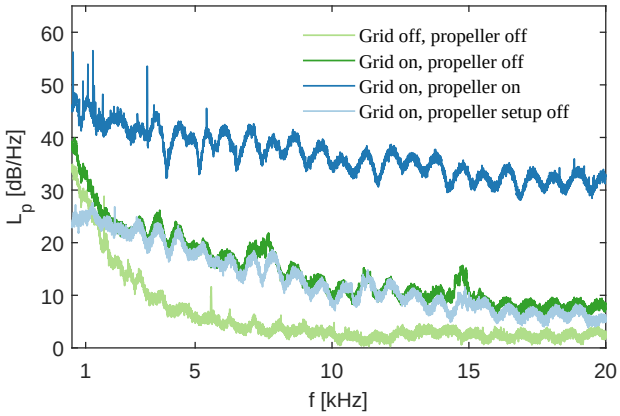

Figure 4. Power spectral density (L_p, $\Delta f = 1$ Hz) of acoustic pressure at $r = 1.3$ m and $\theta = 50°$ downstream of propeller's disk for the case of: no grid and dummy spinner, grid and dummy spinner, grid and propeller, grid on and propeller setup off ($V_\infty = 30$ m/s).

3. NUMERICAL INVESTIGATION

The commercial software COMSOL Multiphysics 6.2 was used to gain insight into the acoustic scattering effects caused by the introduction of the axisymmetric nozzle to the wind tunnel's anechoic plenum.

3.1 Numerical model

A simplified geometry of the nozzle was considered in order to reduce the problem to a 2D axisymmetric one. Both the bottom flange and the side struts were removed, while the shape of the top flange was converted from a square with rounded edges to an infinitely thin circular plate. This allowed for a considerable reduction in computational costs while maintaining the main parameters of interest to the problem. Fig 5 reports a sketch of the numerical domain. An acoustic point source of strength Q_s was placed at $z_s = \mathrm{L}_c + \mathrm{h}_s$, with $\mathrm{h}_s = 0.4\,\mathrm{D}_{\mathrm{ext}} = 164$ mm being the distance of the source from the nozzle exit (same as the distance to the propeller disk in the example before). The value of Q_s was computed from the formula for monopole sources [15]:

$$p_{rms}^2 = \frac{Q_s^2 k^2 (\rho_0 c^2)}{16\pi^2 r^2 (1 + k^2 a^2)} \tag{2}$$

where $k = 2\pi f_s/c = \omega_s/c$ is the wave number and a is the source radius. Letting $a \to 0$ and imposing p_{rms} such that the sound pressure level $L_p = 45$ dB/Hz at a distance $r = 1.3$ m, a value of for Q_s could be computed for each simulated source frequency f_s. Such distance was set equal to the inner radius of the directivity arc shown in Fig. 4 (and used in the experimental analysis discussed in Section 4).

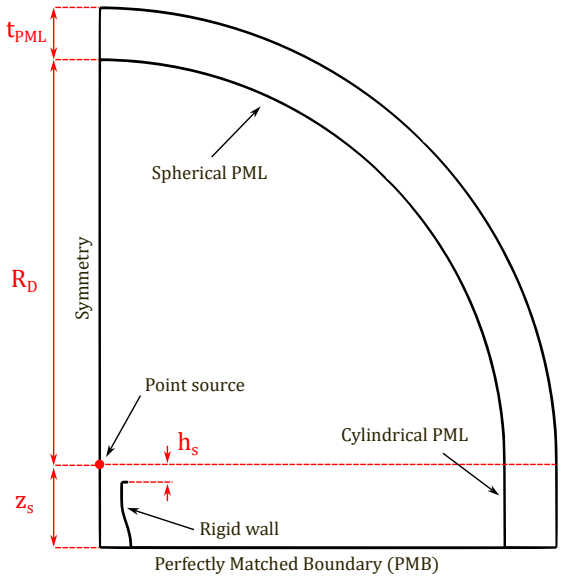

Figure 5. Sketch of the numerical domain including source position and boundary conditions.

To reproduce acoustic free-field propagation conditions, Perfectly Matched Layers (PML) and a Perfectly Matched Boundary (PMB) were added to the numerical domain's boundaries. A spherical and a cylindrical PML enclosed the top and right boundaries while a PMB represents the floor of the anechoic chamber. At least 5 cells per acoustic wavelength λ are recommended for a correct discretization of an acoustic field [16]. In the present case, the maximum cell size in the domain was set to $h_{max} = \lambda/8$. Preliminary simulations without the inclusion of the rigid-walled contraction showed that free-field conditions were obtained when imposing a radius of the numerical domain $\mathrm{R}_D = 4$ m $\approx 20\mathrm{D}_{ext}$ and a PML thickness $t_{PML} = 0.5$ m. This last value is related to the ability of the PML to absorb incoming waves and should be in the order of the largest wavelength to absorb. The application of acoustically absorbing panels to mitigate the interference caused by the nozzle was also numerically explored. Melamine foam was selected over other materials (e.g. glass wool, polyurethane foam) due to its better acoustic performance when grazing flows are involved [17]. Foam inserts were applied on both the upper flange and on the internal walls of the end (cylindrical) section of the nozzle (Fig. 6). This was done to minimize the possible influence of the foam layers on the flow quality (homogeneity and turbulence intensity) of the nozzle. The Johnson-Champoux-Allard (JCA) model was used to model the acoustic absorption by the melamine foam inserts, with the required physical properties listed in Table 1.

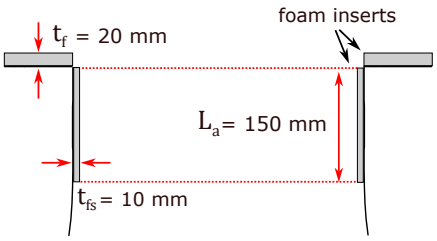

Figure 6. Diagram of melamine foam inserts on the upper end of the simplified contraction geometry.

Table 1. Melamine foam properties, from [18].

Quantity	Symbol	Value
Porosity	ε_p	0.95
Flow resistivity	R_f	10500 Pa · s/m^2
Drained density	ρ_d	11 kg/m^3
Viscous length (coeff.)	s	0.49
Thermal length	L_{th}	470 μm

3.2 Results

The sound pressure level distribution over the numerical domain for the untreated contraction and a source frequency $f_s = 4000$ Hz is reported in Fig. 7. Such frequency corresponds to a Helmholtz number $He = 2\pi L/\lambda \approx 31$, where $L = D_{ext}$, which is within the typical frequency range of interest for aeroacoustic testing. A complex pattern of alternating lobes is present due to constructive and destructive interference. This clearly shows the deviation in terms of directivity with respect to the

spherical propagation expected for a point sound source and typically assumed in acoustic beamforming [11].

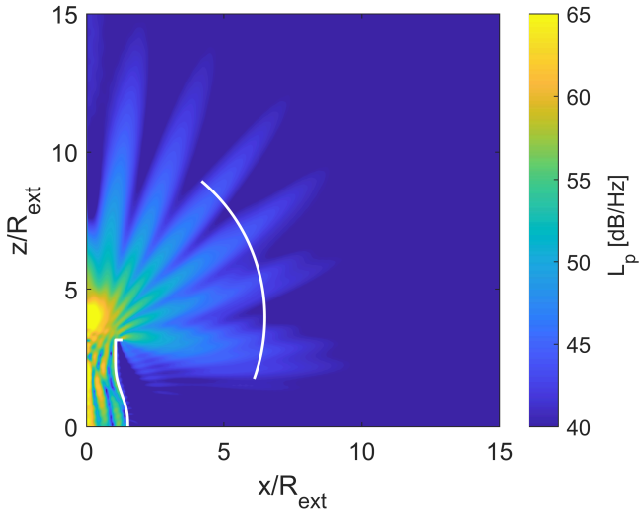

Figure 7. Simulated sound pressure level (L_p) distribution for the case of the untreated (simplified) nozzle geometry and an acoustic point source with frequency $f_s = 4000$ Hz at a distance $h_s = 0.4\mathrm{D}_{ext}$ from the nozzle exit. The directivity arc and nozzle outline are highlighted in white.

Figs. 8-10 depict the directivity patterns of L_p at $r = 1.3$ m and polar angles $\vartheta = [-20°, 50°]$ (with $\vartheta = 0°$ corresponding to the nozzle exit plane and ϑ positive anti-clockwise) for three different source frequencies $f_s = 1000$ Hz, 4000 Hz and 6300 Hz. Both cases of untreated and acoustically treated nozzle are reported. The range for ϑ is chosen to be consistent with the angle covered by the directivity arc shown in Fig. 3 and used in the experimental investigation (Sec. 4). The source frequencies f_s correspond to a selection of typical 1/12-octave band center frequencies of interest during aeroacoustic investigations. Large differences in L_p along the arc length are visible at all source frequencies, with the number of lobes increasing with increasing f_s. The addition of melamine foam helps to some extent in reducing the amplitude of the lobes and its effectiveness increases with increasing f_s. This last consideration had to be expected since the foam inserts' small thickness limits the dampening of longer wavelengths (i.e. lower frequencies).

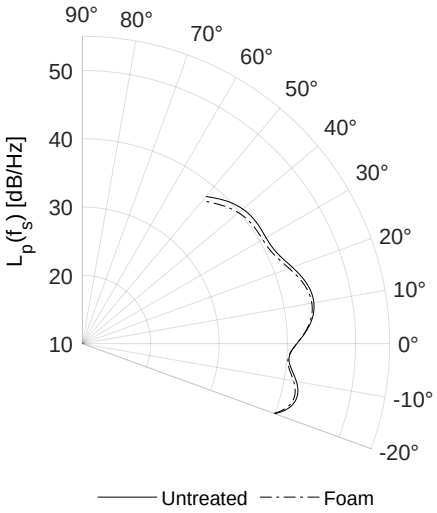

Figure 8. Simulated sound pressure level L_p directivity at $r = 1.3$ m ($r/R_{ext} \approx 6$) for a single source frequency of $f_s = 1000$ Hz.

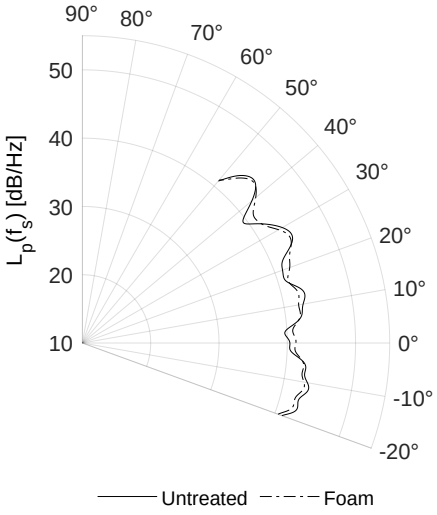

Figure 9. Simulated sound pressure level L_p directivity at $r = 1.3$ m ($r/R_{ext} \approx 6$) for a single source frequency of $f_s = 4000$ Hz.

4. EXPERIMENTAL INVESTIGATION

An experimental campaign was conducted to confirm the effectiveness of the melamine foam treatment in mitigating the issue of acoustic reflections by the presence of the nozzle.

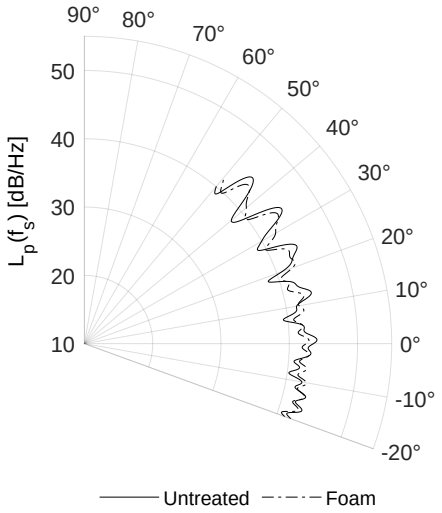

Figure 10. Simulated sound pressure level L_p directivity at $r = 1.3$ m ($r/R_{ext} \approx 6$) for a single source frequency of $f_s = 6300$ Hz.

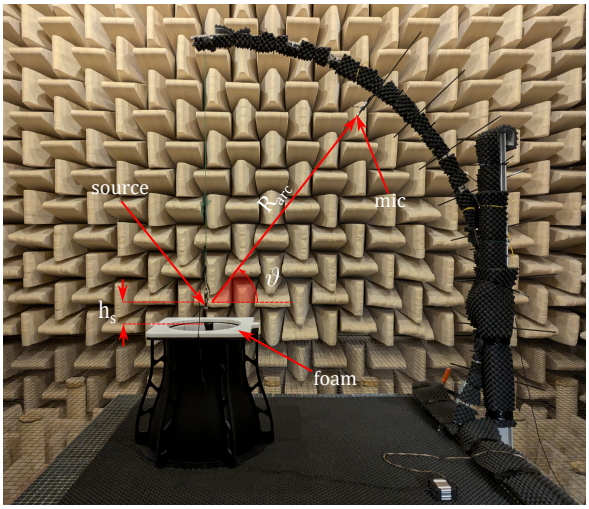

Figure 11. Experimental setup at the anechoic chamber of Delft University of Technology.

4.1 Experimental setup

The experiment was conducted at the 8 m × 8 m × 8 m anechoic chamber of the Applied Sciences faculty of Delft University of Technology (Fig. 11). A miniature sound source (Qsources, type QindW) was positioned at a distance $h_s = 0.4\mathrm{D_{ext}}$ above the center of the contraction's exit ($r = 0$). The source presents good omnidirectionality properties over the frequency range from 500 Hz to 7000 Hz and an accompanying amplifier allows for the production of white noise in this range [19]. The same directivity arc shown in Fig. 3 was employed to sample the acoustic pressure field at a distance $r = R_{arc} = 1.3$ m over the polar angle range $\vartheta = [-20°, +50°]$ with a step $\Delta\vartheta = 10°$. A prepolarized 1/2-inch free-field microphone (Brüel & Kjær, Type 4189) was sequentially moved along the directivity arc and its signal was acquired for 45 s and sampled at 40 kHz through a hand-held analyzer (Brüel & Kjær, Type 2250).

4.2 Results

Figure 12 presents the power spectral density at $\vartheta = 50°$ for the untreated and the acoustically treated nozzle. Oscillations in the spectra are visible in both cases. However, the addition of the melamine foam layer effectively reduces their amplitude over the considered frequency range. Figs. 13-15 report the 1/12-octave band sound pressure level $L_{p_{1/12}}$ directivity plots for the center frequencies of $f_c = 1000$ Hz, 4000 Hz, and 6300 Hz. The $L_{p_{1/12}}$ is computed as:

$$L_{p_{1/12}}(f_c) = 10\log_{10}\left(\sum_{n=1}^{N}\frac{S_{pp}(f_i)\Delta f}{p_{ref}^2}\right), \qquad (3)$$

where $f_1 = f_L$ and $f_N = f_U$ are the lower and upper bounds of the 1/12-octave band with center frequency f_c, S_{pp} is the acoustic power spectral density, Δf is its frequency interval, and $p_{ref} = 20$ μPa is the reference acoustic pressure. At the lowest frequency, the pattern is highly non-omnidirectional but foam addition seems to nonetheless mitigate the issue by reducing the $L_{p_{1/12}}$ difference between points along the arc. For the larger center frequencies, the increase in frequency bandwidth considered in the computation of the $L_{p_{1/12}}$ makes the overall directivity closer to the omnidirectional one. However, it is also evident that adding foam has the effect of improving the source omni-directionality, especially at larger polar angles ϑ.

5. CONCLUSIONS

The present paper has dealt with the issue of acoustic interference by an axisymmetric contraction in an open-jet wind tunnel exit. It was shown through both numerical

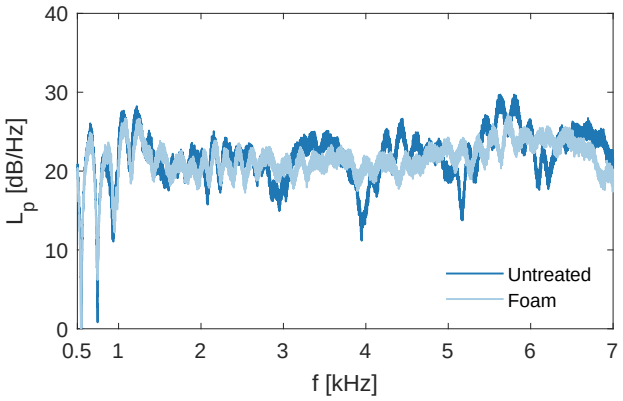

Figure 12. Power spectral density of microphone signal at $\vartheta = 50°$ for both acoustically treated and untreated nozzle ($\Delta f = 1$ Hz).

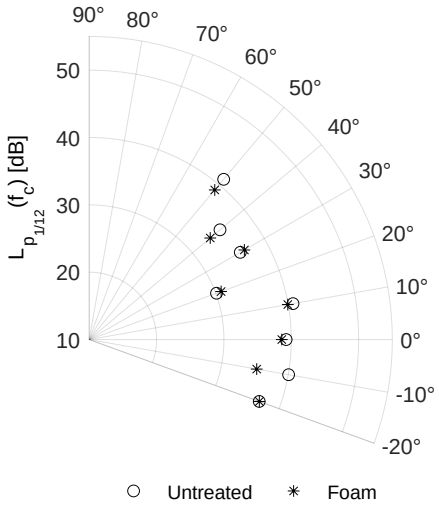

Figure 13. Directivity of 1/12-octave band sound pressure level $L_{p_{1/12}}$ at center frequency $f_c = 1000$ Hz and $r = 1.3$ m ($r/R_{ext} \approx 6$) for both acoustically treated and untreated nozzle.

and experimental analyses that the introduction of the nozzle to an anechoic environment caused substantial modifications in the directivity pattern of a simple point source placed at a typical position of aeroacoustic sources in wind tunnel testing. Adding melamine foam inserts on the upper flange and along the end section of the internal wall of the contraction helped mitigate the issue to some extent.

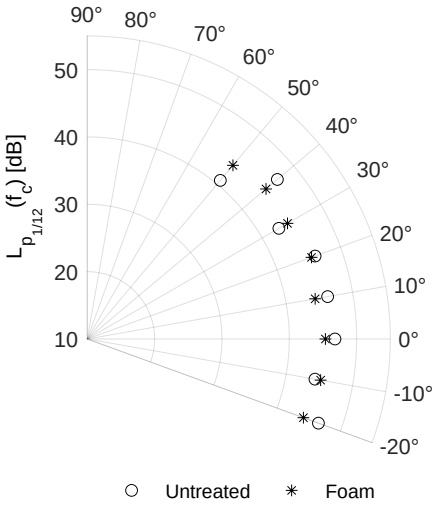

Figure 14. Directivity of 1/12-octave band sound pressure level $L_{p_{1/12}}$ at center frequency $f_c = 4000$ Hz and $r = 1.3$ m ($r/R_{ext} \approx 6$) for both acoustically treated and untreated nozzle.

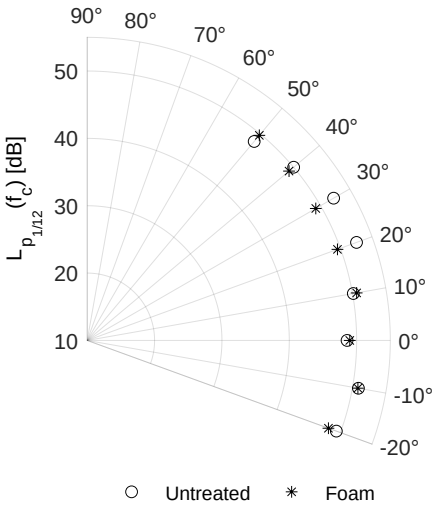

Figure 15. Directivity of 1/12-octave band sound pressure level $L_{p_{1/12}}$ at center frequency $f_c = 6300$ Hz and $r = 1.3$ m ($r/R_{ext} \approx 6$) for both acoustically treated and untreated nozzle.

SUPPRESSION OF AN AEROACOUSTIC FEEDBACK MECHANISM IN A COMPLEX PIPELINE

Erika Quaranta[1*] **Malcolm Smith**[1]
[1]ISVR Consulting, University of Southampton, UK

ABSTRACT

This paper describes a study aimed at understanding and controlling an unsteady flow induced resonance in the metering system of a gas production platform, which had constrained the platform's operating conditions for many years. The resulting high-level vibrations posed a risk of fatigue failures in the attached pipework.
Various numerical flow and aeroacoustic modelling techniques were used to simulate the flow through the different parts of the system to identify the main physical excitation mechanism. This was found to be analogous to a so-called Rossiter tone, commonly occurring in grazing flows over cavities. In this case, vortex shedding at bifurcations in different parts of the pipeline were identified as sources of flow instability, associated with an aeroacoustic feedback mechanism from features further downstream. The numerical analysis also enabled an understanding of the persistence and varying strength of this mechanism along the entire pipeline, also depending on the flow regime at which the pipeline was operated.
The in-depth understanding provided by this analysis enabled recommendations for an efficient redesign of the entire system to control the problem at source.

Keywords: ***Aeroacoustics, resonance, numerical modelling, computational fluid dynamics.***

1. INTRODUCTION

A comprehensive review on resonance due to flow-induced pulsation in pipelines with various configurations of closed branches was presented in 2011 [1]. The review primarily focused on the aeroacoustic feedback mechanism, where boundary layer-excited vorticity couples with acoustic modes in the cavity. Many studies have investigated the aeroacoustics of cavities in pipelines, using both experimental and numerical approaches, with some of the most recent being [2-4]. Additionally, other aeroacoustic sources in a pipeline are T junctions, where vortex shedding from the junction can couple with an acoustic resonant mode of a nearby portion of the piping system [5-6].
The present study addresses a real-world problem, where for decades gas production on a platform has been disrupted by flow-induced vibrations in the gas metering ductwork, depending on flow regimes and velocity. At higher flow velocities, instabilities within the 30-35 Hz range triggered structural response in a mode of vibration at 34 Hz, causing significant issues.
The pipeline design includes an inlet duct where flow bifurcates into a header, then redirects into the metering system, and finally into the outlet duct (Fig. 1). Previous studies suggested various possible causes of instability, but our 2023 study [7] combined CFD and acoustic FEM analysis to confirm that vortex shedding and flow instability in the inlet header create an aeroacoustic feedback mechanism coupling with the pipeline's acoustic modes.
A follow-on study [8] extended the analysis to the outlet manifold, indicating a strong possibility of resonance in the outlet header, analogous to that previously identified in the inlet.
Based on our findings, the platform management company proposed a complete redesign of the entire pipeline aim to eliminate these issues at source.
After summarizing the aeroacoustic results and our proposed interpretation of the feedback mechanisms at the two different flow regimes in the current pipeline, this paper aims to present the equivalent results obtained for the redesigned pipeline and so demonstrate the improvements achieved by implementing the proposed modifications.

2. AEROACOUSTIC MODELLING

In this study we utilised compressible Unsteady Reynolds-Averaged Navier-Stokes (URANS) simulations with the k-ω SST turbulence model to analyse turbulent and acoustic pressure fluctuations in the pipeline. Despite the average Mach number being characteristic of incompressible flow, compressible analysis was necessary to capture the relevant aeroacoustic phenomena.

We used the open-source software OpenFOAM [9], because it was the most efficient and cost-effective solution, in conjunction with High-Performance Computing (HPC).

Key Aeroacoustic Insights:

- The focus was on low-frequency interactions between vortex shedding and acoustic waves, which are crucial for understanding flow physics and providing design modification recommendations.
- Standard CFD tools face challenges such as dissipative numerical schemes that damp acoustic wave propagation and boundary conditions that reflect acoustic waves. Accurate modelling required careful treatment of these factors.
- Fully structured meshes were used to minimise numerical dissipation, allowing sound wave propagation without compromising stability. Non-reflective boundary conditions and progressively increasing aspect ratio meshes were employed to reduce wave reflection at inlets and outlets.

The pipeline system operates in single and dual stream regimes, with the inlet manifold feeding two metering trains. This study's findings aimed to mitigate flow-induced vibrations by addressing aeroacoustic feedback mechanisms in both regimes.

From test data measured on the platform, it was identified that the critical inlet velocity of 20 m/s triggered high vibration levels. In the dual stream case, this results in 10 m/s flow at each metering duct inlet, while in the single stream case, it remains 20 m/s at the single inlet. In the headers, due to expansion into a wider duct, the flow decelerates to 6 m/s in the dual stream case and 12 m/s in the single stream case.

The pipeline carries a mixture of natural gases, with a static outlet pressure of 11.3 MPa, and constant temperature and density of 330 K and 80 kg/m³, respectively. The speed of sound in the duct was 430 m/s.

3. ANALYSIS OF THE CURRENT PIPELINE

As reported in the previous studies [7] and [8], CFD analysis has been performed to identify the aeroacoustic feedback mechanism responsible for the resonance in the two different flow regimes.

We have employed wavenumber analysis to examine the spatial-frequency distribution of unsteady pressure perturbations. This powerful tool is used to plot the power spectral density of a wave over frequency f and wavenumber k, enabling the identification of standing and traveling waves and their propagation velocities. This method helps determine whether perturbations are turbulence, propagating at the speed of the flow, or acoustic waves, propagating at the speed of sound. More details on the application of this methodology were explained in our previous paper [7].

Using this method, we analysed both the inlet and outlet separately and surprisingly found both similarly problematic, despite the differences in flow patterns.

This is a summary of our findings and interpretations.

3.1 Dual Stream Case

The CFD model of the pipeline in this flow regime is shown in Fig. 2. The flow bifurcates at the inlet manifold, which feeds two metering ducts, and then rejoin in the outlet manifold.

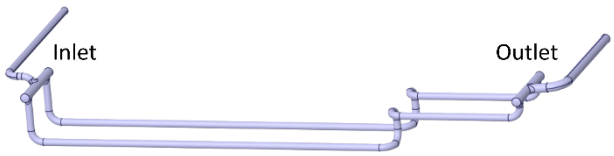

Figure 2: The current pipeline model in the dual stream flow regime.

Wavenumber analysis on the headers and metering ducts are shown in Figs. 3, 4, 5 and 6. In the headers dominant tones result from a combination of turbulence and acoustics. However, in the metering ducts the same tones are propagating as purely acoustic waves. Even if mechanisms differ significantly between the inlet and outlet manifold.

These are indications of vortex instability in the header triggering acoustic waves travelling in the metering duct.
In the case of flow over a cavity, discrete acoustic frequencies arise from the interaction between vortices formed over the cavity and the cavity's acoustic modes. This phenomenon is known as Rossiter tone feedback mechanism [10]. It is generally associated with shear layer vorticity generating acoustic waves when impinging on the downstream edge of the cavity, then travelling upstream through the cavity. The pressure disturbances are converted back into vorticity waves in the shear layer, completing the feedback loop, which is strongly dependent on the flow velocity. This mechanism is particularly critical when the pressure disturbances couple with the acoustic modes of the cavity.
The Rossiter formula calculates the Strouhal number (non-dimensional frequency) at which resonance occurs, as

$$St = \frac{fD}{U} = \frac{n-\alpha}{1/k + M}, n = 1,2,3 \ldots \quad (1)$$

where:

- D is the cavity opening,
- U is the mean flow velocity,
- M is the Mach number,
- α is the phase delay (approximately 0),
- k is the ratio between the convection speed and the mean speed (experimentally 0.6).

In the current case, the flow is within the cavity rather than over it, but the vorticity generated by the flow instability can trigger the same aeroacoustic feedback mechanism.
Using Eq. 1, we can evaluate the critical frequencies. Given that both the headers have similar geometry, using D = 1.1 m (distance between the T-junction and the bifurcation), U = 6 m/s (mean speed in the header), and M = 0.014, the Rossiter frequencies are approximately multiple of 3.2 Hz. The wavenumber analysis of the inlet header (Fig. 3) shows dominant tones at 18 and 36 Hz, while the outlet header (Fig. 5) shows dominant tones at 12, 32, and 48 Hz. There appears to be an approximate 6 Hz factor, which can lock in with the header cavity modes. Specifically, 36 Hz corresponds to a quarter wavelength of the entire header, and the distance between the T-junctions of 2.3 m is a quarter wavelength at 48 Hz.

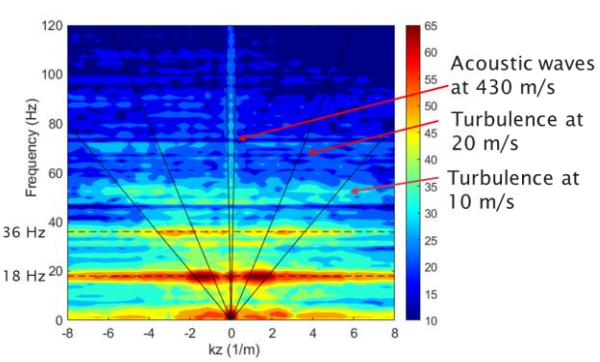

Figure 3: Wavenumber analysis in the inlet header.

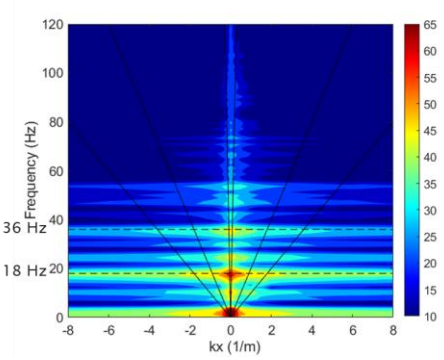

Figure 4: Wavenumber analysis in the metering duct, when only the inlet header is modelled.

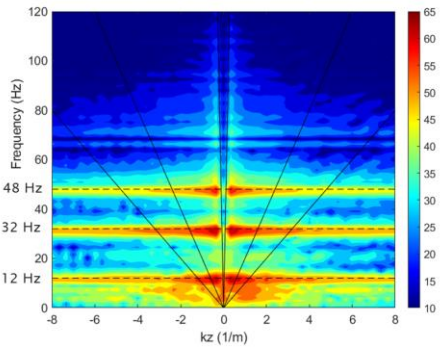

Figure 5: Wavenumber analysis in the outlet header.

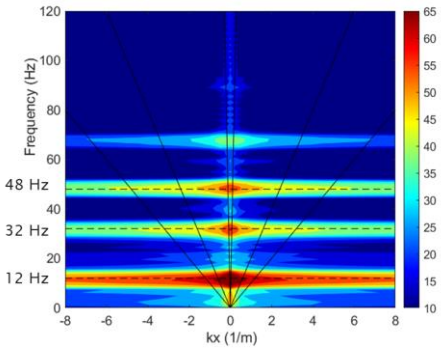

Figure 6: Wavenumber analysis in the metering duct, when only the outlet header is modelled.

3.2 Single Stream Case

The CFD model of the pipeline in this flow regime is shown in Fig. 7. With only one metering duct open, branches are present on the closed line.
For brevity, only the wavenumber analysis on the headers are shown in Figs. 8 and 9. The instability is even more pronounced in both the inlet and outlet headers, as the mean velocity is effectively doubled in this case. There is also evidence of the same Rossiter feedback mechanism, with a similar 6 Hz factor, which is further amplified by the presence of the closed branches. In fact, the two dominant tones 12 and 20 Hz are the same in both headers, as the two branches have similar lengths, approximately a quarter wavelength at 20 Hz.

Figure 7: The current pipeline model in the single stream flow regime.

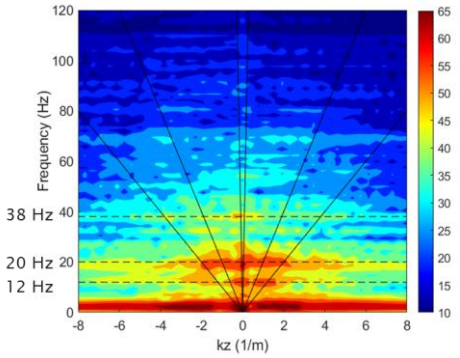

Figure 8: Wavenumber analysis in the inlet header.

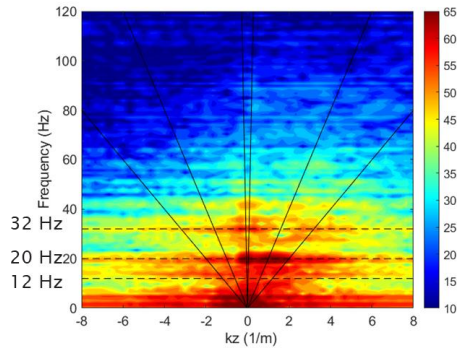

Figure 9: Wavenumber analysis in the outlet header.

4. REDESIGN OF THE PIPELINE

Our study has identified that the main cause of flow instability leading to aeroacoustic resonance is the flow bifurcation and convergence occurring in the header, coupled with the expansion of the flow from a narrower to a wider duct.
Therefore, we have recommended eliminating the headers and finding alternative, smooth solutions to redesign the pipeline avoiding sharp edges, which are strong sources of turbulence. Figures 10 and 11 illustrate the proposed design for the new inlet and outlet, which primarily utilise T-junctions only, as T-junctions itself have not shown potential to be a source of vortex shedding, when using smooth rounded joints.
Further analysis of the proposed design has demonstrated significant improvements in both the flow stability and acoustics of the pipeline.

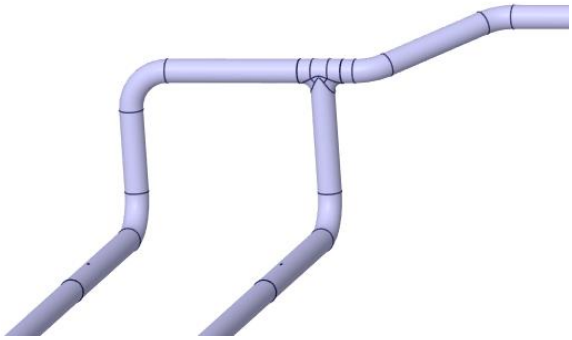

Figure 10: New design of the inlet header.

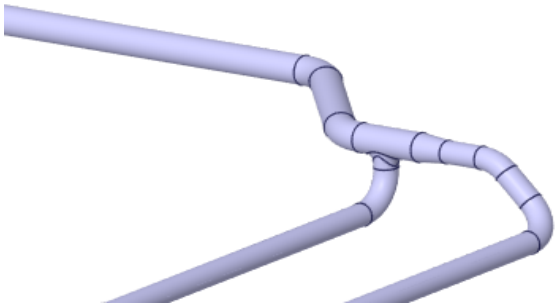

Figure 11: New design of the outlet header.

4.1 Dual Stream Case

The wavenumber analysis shown in Figs. 12 and 13 reveal a complete absence of strong tonal components. There is no evidence of a potential aeroacoustic problem.

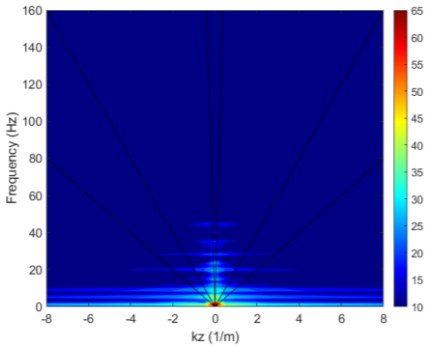

Figure 12: Wavenumber analysis in the inlet header.

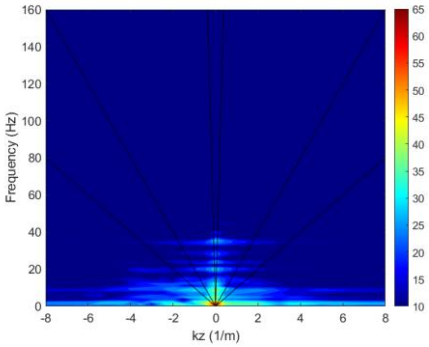

Figure 13: Wavenumber analysis in the outlet header.

4.2 Single Stream Case

Despite showing an overall improvement on the tonal content, the wavenumber analysis (Figs. 14 and 15) in this case still reveals some evident tonal components.
Flow analysis (Fig. 16) indicates that flow instability arises from the expansion occurring upstream of the T junction. This expansion is necessary as the outlet duct is wider than the metering ducts, but we have argued that moving the expansion downstream of the T junction would be beneficial to stabilise the flow.

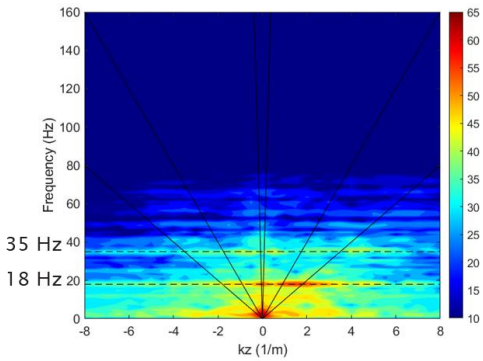

Figure 14: Wavenumber analysis in the outlet header.

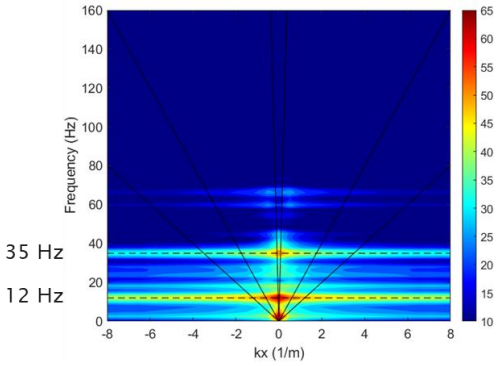

Figure 15: Wavenumber analysis in the outlet header.

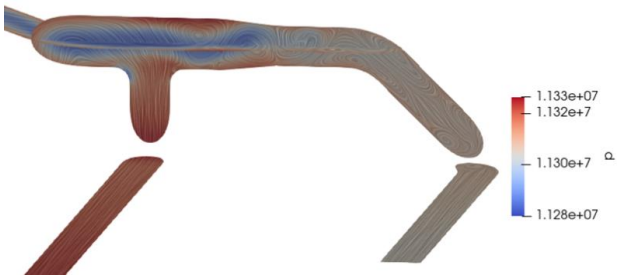

Figure 16: Pressure instability arising at the flow expansion.

5. REDESIGN OF THE OUTLET EXPANSION

To prove our hypothesis with the minimum effort, instead of redoing the full CFD analysis on a redesigned outlet, which would have required issuing an updated CAD and remeshing it, we modified the inlet model by adding an expansion duct to transition from the metering duct to the outlet duct size.

This model is shown in Fig. 17 and was used as an outlet with flow only inlet into the metering duct connected by the T junction to demonstrate the beneficial effect of the smooth transition downstream of the T junction.

Wavenumber analysis in the header of this fictitious outlet (Fig. 18) confirms our assumption, by showing a lack of tonal component.

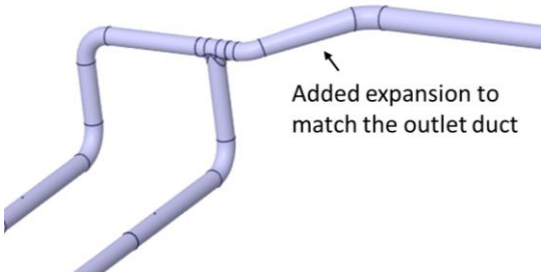

Figure 17: Using the inlet header to prove the effect of moving the expansion downstream the T junction.

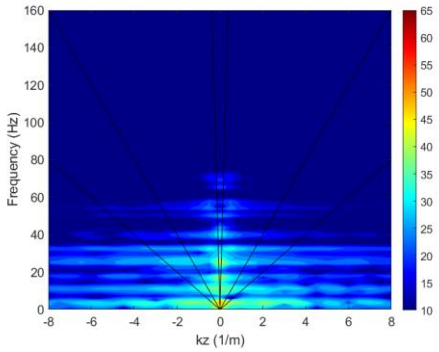

Figure 18: Wavenumber analysis in the header.

6. CONCLUSIONS

The CFD analysis successfully identified the aeroacoustic feedback mechanisms responsible for resonance in two distinct flow regimes. By employing wavenumber analysis, we examined the spatial frequency distribution of unsteady perturbations and revealed that both the inlet and outlet headers exhibited similar problematic behaviour despite differences in flow patterns.

The wavenumber analysis indicated dominant tones resulting from a combination of turbulence and acoustics, with evidence of vortex instability triggering acoustic waves. The single stream case showed even more pronounced instability, amplified by the acoustic modes of closed branches.

To address these issues, we recommended eliminating the headers and redesigning the pipeline using only T-junctions, which have not shown potential to be a source of instability. Further analysis of the proposed design demonstrated significant improvements in both flow stability and acoustics.

However, in the single stream case, despite overall improvement, some evident tonal components remained. Further analysis confirmed that moving the expansion downstream of the T-junction removed the strong tonal components.
This numerical modelling approach provided powerful insights to identify the physical mechanisms involved in this complex engineering problem and has the potential to be applied to a wide range of other aeroacoustic problems.

7. ACKNOWLEDGMENTS

We want to acknowledge the use of the HPC facility Iridis 5 and 6 at the University of Southampton for running all the CFD cases.
We also want to thank the offshore engineering and petrochemical industry participants in this project for their permission to publish this paper.

IMPACT OF RESONANCE LOADING ON THE SOUND GENERATION FROM IN-DUCT POINT SOURCES

Maximilian Behn* **Ulf Tapken**
German Aerospace Center, Institute of Propulsion Technology, Engine Acoustics Department
Berlin, Germany

ABSTRACT

Analytical models of the sound generation from ducted turbomachinery stages often apply spatially distributed point sources such as monopoles and dipoles, which can be derived from the in-duct Green's function. Another important application of point source models is the localisation of sound source distributions, which is done inside ducts so far mainly for fan stages. One difficulty with current point source models is the unconstrained excitation of resonant modes at their cut-on frequencies leading to unrealistically high sound power levels. Simultaneously, the resonant modes manifest an immense loading on the point sources according to Newton's third law. To achieve more realistic predictions, an extension of the point source models is developed that accounts for the impact of resonance loading by including an internal source impedance. The resulting sound power distribution over the range of cut-on modes is derived for relevant source configurations and compared with reference models and experimental data from a fan test rig.

Keywords: acoustic point source model, mode excitation, sound power, flow ducts

1. INTRODUCTION

The design and further improvement of turbomachinery stages with low noise excitation relies on accurate prediction tools to support the design process during the pre-design phase. These tools are often semi-analytical, and model the sound generation from the rotor and stator by application of equivalent, spatially distributed point sources [1, 2]. Depending on the sound generating mechanism, the point sources can have monopole, dipole and quadrupole characteristics. Another important application of in-duct point source models is the localisation of source distributions from microphone array measurements [3, 4]. In both fields of application, the reliability of existing tools and methods is impeded at the mode cut-on frequencies, where single modes are resonant, and an infinite mode amplitude and sound power is predicted, which overestimates the resonant mode excitation in comparison with experimental observations. Different approaches have been proposed in the past, ranging from sound power correction terms for the sound power radiated into the far field, as proposed by Moreau [2], to a complete disregard of the resonant mode behaviour, as proposed by Dougherty [5] for the localisation of in-duct noise sources.

In order to provide a physics-based source model that achieves more realistic predictions of the resonant mode excitation, the in-duct point source model of Goldstein [1] is extended by including an internal source impedance. Doak stated that acoustic sources in turbomachinery stages are constrained by an internal source impedance, but did not provide an explicit expression of the form of the source model [6]. So far, the concept of internal source impedance has been applied in ducted systems only for frequencies below the cut-on frequency of the first higher-order modes (e.g. [7–9]). This article describes an extended in-duct point source model for the prediction of the excitation of higher-order, acoustic modes in resonant and off-resonant conditions. The impact of the model extension is evaluated by example of monopole and dipole source distributions and by comparison with experimental results from a fan test rig.

2. POINT SOURCES IN FLOW DUCTS

The sound radiation from a monopole source at position $(\check{x}, \check{r}, \check{\phi})$ in a cylindrical flow duct of radius R is described as a superposition of acoustic modes and can be derived from the in-duct Green's function (see e.g. [1]):

$$p^{\pm}_{\text{monopole}}\left(x, r, \phi|\check{x}, \check{r}, \check{\phi}\right) = q\frac{\rho c}{4\pi R^2}\cdot \sum_{m=-\infty}^{\infty}\sum_{n=0}^{\infty}\frac{f_{mn}(r)f_{mn}(\check{r})}{\alpha_{mn}}e^{im(\phi-\check{\phi})}e^{ik^{\pm}_{mn}(x-\check{x})} \tag{1}$$

with volume flow q as source strength, density ρ and speed of sound c. Each mode is described in terms of the azimuthal order m, radial order n, axial wave number $k^{\pm}_{mn}$ and radial mode shape factor $f_{mn}(r)$, which in combination yield the mode transfer function $f_{mn}(r)e^{i\left(m\phi+k^{\pm}_{mn}x\right)}$ [10]. The generated mode amplitude $A^{\pm}_{mn}$ is proportional to $q\frac{\rho_0 c}{4\pi R^2}\frac{1}{\alpha_{mn}}$, where α_{mn} denotes the mode propagation factor, which ranges between 0 and 1 above the mode cut-on frequency and is imaginary for cut-off modes. As a consequence, the mode amplitude reaches infinite sound pressure at the mode cut-on frequency. In terms of sound power, which is given for cut-on modes by the following expression

$$P^{\pm}_{mn} = \frac{\pi R^2}{\rho c}\frac{\alpha_{mn}(1-M_x^2)^2}{(1\mp\alpha_{mn}M_x)^2}|A^{\pm}_{mn}|^2, \tag{2}$$

The $1/\alpha_{mn}$-term in the expression of the mode amplitude cancels the α_{mn}-term in Eq. (1) resulting in an infinite sound power of resonant modes with $\alpha_{mn} = 0$ excited by a monopole source. Therefore, similarly to the mode amplitude, the mode sound power $P^{\pm}_{mn}$ is proportional to $\frac{1}{\alpha_{mn}}$.

At subsonic operating conditions, the dominant acoustic sources in turbomachinery stages have dipole characteristics [1]. The generated sound pressure from a dipole source is obtained from the directional derivative of the monopole Green's function in Eq. (1) with respect to the dipole axis given by vector $\mathbf{n} = [\cos\alpha_{\text{dipole}};\ 0;\ \sin\alpha_{\text{dipole}}]^T$ [11] [1]:

$$\begin{aligned} p^{\pm}_{\text{dipole}}\left(x, r, \phi|\check{x}, \check{r}, \check{\phi}\right) &= \partial_{\mathbf{n}} p^{\pm}_{\text{monopole}}\left(x, r, \phi|\check{x}, \check{r}, \check{\phi}\right) \\ &= \nabla p^{\pm}_{\text{monopole}}\cdot\mathbf{n} \\ &= q_d\frac{\rho c}{4\pi R^2}\cdot \end{aligned} \tag{3}$$

$$\sum_{m=-\infty}^{\infty}\sum_{n=0}^{\infty} -i\left(k^{\pm}_{mn}\cos\alpha_{\text{dipole}} + \frac{m}{\check{r}}\sin\alpha_{\text{dipole}}\right)\cdot \frac{f_{mn}(r)f_{mn}(\check{r})}{\alpha_{mn}}e^{im(\phi-\check{\phi})}e^{ik^{\pm}_{mn}(x-\check{x})} \tag{4}$$

with dipole moment q_d. Note, that the gradient ∇ is evaluated with respect to the source position $(\check{x}, \check{r}, \check{\phi})$. Equation (4) shows that the mode amplitude and, hence, the mode sound power have generally the same proportionality with $\frac{1}{\alpha_{mn}}$ as for the monopole source. Only for $M_x = 0$, the $\frac{1}{\alpha_{mn}}$-term is lifted for modes with azimuthal mode order $m = 0$.

3. MODEL EXTENSION BY SOURCE IMPEDANCE

The infinite sound power output from in-duct point sources at the mode cut-on frequencies stands in contradiction to two experimental observations of the excited sound field from turbomachinery stages. Firstly, an increased sound pressure is indeed measured at the mode cut-on frequencies, typically at low frequencies, but it does not reach infinite amplitudes. Therefore, according to Eq. (4) with $\alpha_{mn} = 0$ the resulting, measured mode sound power is zero in contrast to the analytical model, which predicts an infinite sound power. Secondly, towards higher frequencies the density of mode cut-on frequencies increases exponentially, which leads to a high number of resonance peaks in the analytically modelled spectra, but measured sound pressure spectra do not show any resonance effects in this frequency range.

In comparison, the sound power output from a point source in free field conditions increases monotonously with [12]

$$P = \frac{k^2\rho c}{8\pi}q^2 \tag{5}$$

for a monopole source, respectively

$$P = \frac{k^4\rho c}{12\pi}q_d^2 \tag{6}$$

[1] The assumption that the dipole axis lies in the x-ϕ-plane is valid for blades with sufficiently small lean.

for a dipole source. It appears plausible that a point source in a duct at high characteristic frequencies kR should generate a sound power output at a similar level to that in free field conditions. Albeit, the point source model in Eq. (1) predicts much higher sound power levels, in particular for modes near their cut-on frequencies. In the following, the in-duct point source model of a monopole source is extended in order to achieve a more realistic characteristics of the sound power output. The transfer to dipole sources is easily made using Eq. (3).

The mode impedance $Z^{\pm}_{mn} = A^{\pm}_{mn}/q$ is chosen as the starting point for the model extension. More precisely, it is given by the following expression:

$$Z^{\pm}_{mn}\left(\check{x},\check{r},\check{\phi}\right) = \frac{\rho c}{4\pi R^2}\frac{f_{mn}(\check{r})}{\alpha_{mn}} e^{-im\check{\phi}} e^{-ik^{\pm}_{mn}\check{x}}. \quad (7)$$

The mode impedance describes the ratio of the excited mode amplitude to the source volume flow. However, it can also be interpreted as the pressure on the source as a back reaction of the mode relative to the source strength [6]. At the mode cut-on frequencies the pressure of the resonant modes becomes infinite. In the idealised point source models in Eq. (1) and (4) the back reaction of the modes on the source is not considered, so that the source effectively acts as a constant volume flow source. Morfey [13] investigated the behaviour of this source type as well as constant pressure sources and showed that in the latter case no resonance phenomena occur. A more realistic source model, whose behaviour lies somewhere between these two extremes, is obtained by including an internal source impedance for each cut-on mode. An illustration of the extended model is given in Fig. 1.

The model is based on an electroacoustic analogy, which considers the volume flow q as current and pressure resp. mode amplitude as voltage. It is assumed that the loading due to each mode does not depend on the source position. Therefore, the factors of the mode impedance in Eq. (7) that are independent from the source position are separated from the position-dependent terms, i.e. $\hat{Z}^{\pm}_{mn} = \frac{\rho c}{4\pi R^2}\frac{1}{\alpha_{mn}}$. The model's network structure allows a straightforward analysis employing Kirchhoff's loop and node laws. For each mode, the mode impedance is connected in parallel with the internal source impedance resulting in the effective mode impedance of the internal source impedance (ISI-)model given by:

$$\hat{Z}^{\pm}_{mn,\mathrm{ISI}} = \frac{Z_S \cdot \hat{Z}^{\pm}_{mn}}{Z_S + \hat{Z}^{\pm}_{mn}}. \quad (8)$$

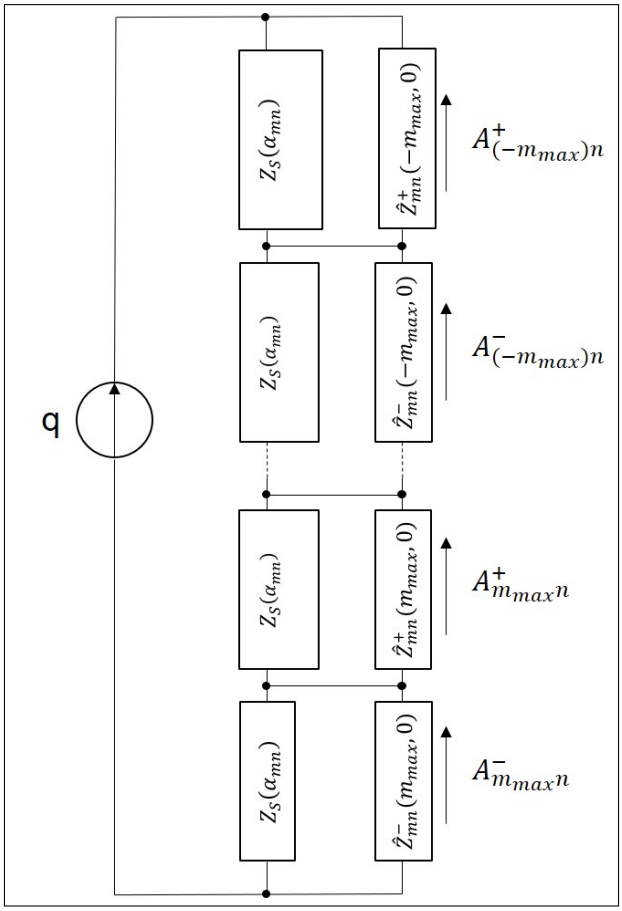

Figure 1. Illustration of the extended source model with internal source impedance Z_S and radiation impedances $Z^{\pm}_{mn}$.

In combination with the source position-dependent terms, the excited mode amplitude according to the ISI-model is expressed as:

$$Z^{\pm}_{mn,\mathrm{ISI}} = \frac{A^{\pm}_{mn}}{q} = \hat{Z}^{\pm}_{mn,\mathrm{ISI}} f_{mn}(\check{r}) e^{-im\check{\phi}} e^{-ik^{\pm}_{mn}\check{x}}. \quad (9)$$

At the mode cut-on frequencies, the loading due to $Z^{\pm}_{mn}$ is very high, so that the effective mode impedance of the ISI-model yields:

$$Z^{\pm}_{mn,\mathrm{ISI}}\left(\alpha_{mn}=0\right) \approx Z_S. \quad (10)$$

Thus, modes are not excited with infinite pressure at their cut-on frequencies, but instead the mode amplitude yields $A^{\pm}_{mn}\Big|_{\alpha_{mn}=0} = Z_S q$.

Additional fundamental assumptions are:

1. each mode is an additional load for the source,
2. the source impedance relates the in-duct source output to the free field case, and
3. the influence of the source impedance is maximal for resonant modes and diminishes for $\alpha_{mn} \to 1$.

A natural choice for the internal source impedance of an in-duct monopole source is the radiation impedance of a monopole source in free field conditions, which is given by [12]:

$$Z_{FF} = \frac{p_{FF}}{q} = \frac{\rho c}{4\pi R^2} (kR)^2 . \tag{11}$$

However, Z_{FF} shows a low sound pressure excitation at low frequencies. In order to achieve a realistic resonance behaviour at low frequencies, an additional term $\chi(kR)$ is included that increases the mode excitation at low frequencies. Finally, the first and last assumptions lead to the following expression of the internal source impedance:

$$\begin{aligned} Z_S(\alpha_{mn}) =& \frac{Z_{FF} + \chi(kR)}{N_M \cdot (1 - \alpha_{mn})} \\ =& \frac{\rho c}{4\pi R^2} \frac{(kR)^2 + \frac{25}{kR}}{N_M \cdot (1 - \alpha_{mn})}. \end{aligned} \tag{12}$$

with the number of cut-on modes N_M. The expression of the additional term $\chi(kR)$ is hypothetical and primarily included to demonstrate the behaviour of the proposed model extension. The low-frequency characteristics of the internal source impedance requires further investigation.

The internal source impedance in Eq. (12) distributes the sound generation potential according to the free field radiation impedance over all cut-on modes by division by the number of cut-on modes N_M. The additional term $1/(1 - \alpha_{mn})$ corresponds to the third fundamental assumption. This choice increases the impact of resonance loading on the excitation of modes, which are close to their cut-on frequencies, while modes with a high propagation factor, i.e. $\alpha_{mn} \to 1$, are not affected by resonance loading. As a result, the internal source impedance Z_S approaches infinity for modes with a high propagation factor, which means that for these modes the ISI point source model acts a constant volume flow source.

The effective mode impedance in Eq. (9) yields after some rearrangement:

$$Z^{\pm}_{mn,\mathrm{ISI}} = \frac{Z^{\pm}_{mn}\left(\check{x}, \check{r}, \check{\phi}\right)}{1 + \frac{N_M}{(kR)^2 + \frac{25}{kR}} \frac{1 - \alpha_{mn}}{\alpha_{mn}}}. \tag{13}$$

4. EVALUATION OF SOURCE DISTRIBUTIONS USING THE EXTENDED SOURCE MODEL

The extended source model is evaluated for dense distributions of two different source types:

- incoherent monopoles and
- incoherent dipoles with $\alpha_{\mathrm{dipole}} = -\frac{\pi}{4}$,

which are distributed equally over the duct cross-section.

As an example, the duct geometry and flow conditions of DLR's fan test rig CRAFT (Co-/Counter-Rotating Acoustic Fan Test Rig) are considered. The duct diameter is 453.6 mm. The flow Mach number in the inlet is $M_x = 0.11$ at the fan design point. Further information is provided in [14].

Figure 2 shows the development of the internal source impedance as a function of the non-dimensional frequency kR for $\alpha_{mn} = 0$. The internal source impedance approaches an asymptotic limit of approximately 2 already at relatively low frequencies. Between $kR = 5$ and 25, the normalised internal source impedance is almost constant and predominantly determined by Z_{FF}/N_M. The results show that the additional term $\chi(kR)$ has an impact only at low frequencies $kR < 5$.

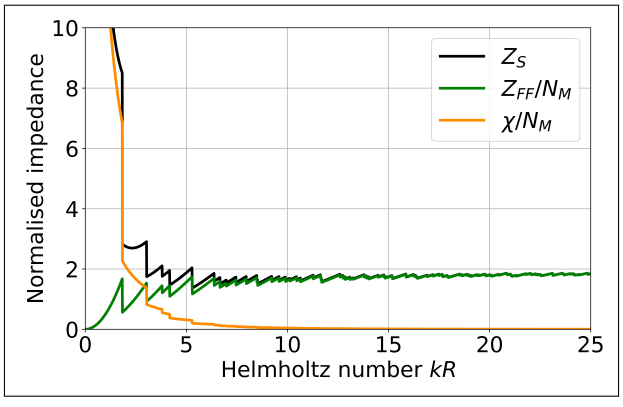

Figure 2. Internal source impedance Z_S and its components as a function of non-dimensional frequency. Values are normalised by $\frac{\rho c}{4\pi R^2}$.

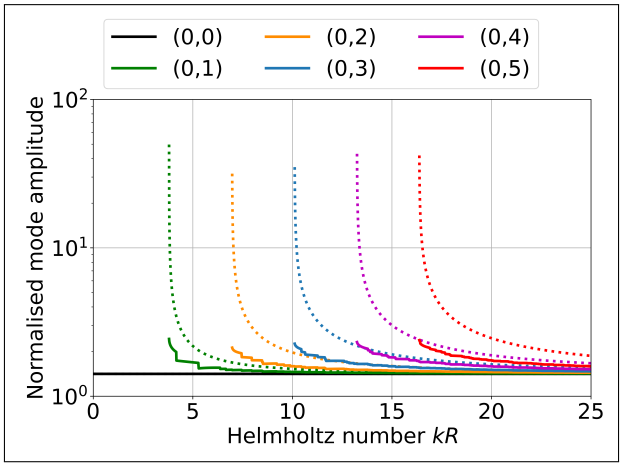

Figure 3. Mode amplitudes for azimuthal mode order $m = 0$ excited by a dense distribution of incoherent monopole sources. Values are normalised by $\frac{\rho c}{4\pi R^2}$. Solid lines show results for the ISI-model and dashed lines for the Goldstein point source model.

The mode amplitudes with azimuthal mode order $m = 0$ that are excited by the distribution of monopole sources, are displayed in Fig. 3. The plane wave mode $(0, 0)$ has a propagation factor $\alpha_{00} = 1$ and therefore, is not affected by resonance loading. All higher radial mode orders exhibit significantly lower amplitudes close to the cut-on frequencies in comparison to the reference point source model by Goldstein (cp. Eq. (1)). The mode amplitude of mode $(0, 1)$ is characterised by two larger discontinuities, which occur due to a discrete increase of N_M at neighbouring mode cut-on frequencies. With increasing frequency, the cut-on of additional mode orders has a small impact on the mode amplitude curves, because the number of cut-on modes N_M is growing exponentially. Furthermore, both point source models converge asymptotically towards high frequencies. However, whereas for mode $(0, 1)$ the predicted mode amplitudes are almost equal within $\Delta kR = 5$ to 6 from the mode cut-on frequency, the convergence of the predicted mode amplitudes extends over a much larger frequency range for higher radial mode orders. For example, for mode $(0, 4)$ convergence is observed for approximately $\Delta kR = 10$. Thus, the impact of resonance loading is stronger towards high frequencies.

The most important characteristics of the newly proposed ISI-model is observed from the development

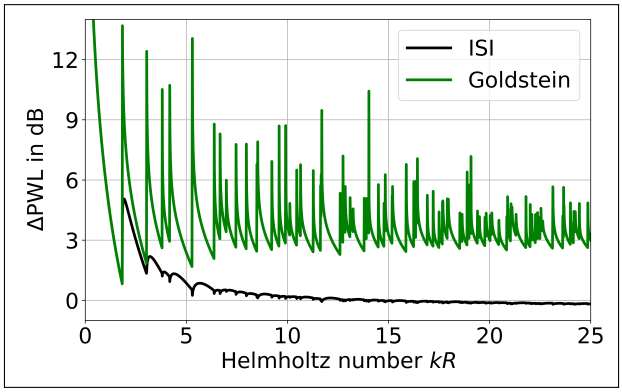

Figure 4. Total sound power generated by a dense distribution of incoherent monopole sources relative to the sound power output of a monopole source in free field conditions (cp. Eq. (5)).

of the total sound power, which is depicted in Fig. 4. At low frequencies, both source models show significantly increasing sound power levels at the mode cut-on frequencies, but the levels of the ISI-model are limited with e.g. an increase of 4 dB at the cut-on frequency of the modes $(\pm 1, 0)$ compared to more than 11 dB for the Goldstein point source model. Towards high frequencies, the ISI-model approaches the sound power level of the free field source asymptotically, while the results of the Goldstein model exhibit strongly fluctuating sound power levels and an average offset of approximately 2.5 dB.

The second source distribution consists of dipole sources, whose dipole axes are oriented at -45 degrees with respect to the duct axis. The excited mode amplitudes of azimuthal mode order $m = 0$ are presented in Fig. 5 and the total sound power in Fig. 6.

The trend of the mode amplitude curves for the distribution of dipole sources is almost inverted to those for the monopole distribution. The results for the reference model indicate a very narrow notch of the mode amplitude curves near to the cut-on frequencies and an asymptotic increase towards high frequencies. The impact of the ISI-model is twofold. Firstly, the maximum mode amplitude at the cut-on frequency is strongly reduced. And secondly, the rate of increase is reduced, which is particularly pronounced with increasing radial mode order. Both characteristics of the ISI-model can also be identified in Fig. 6. Due to the limitation of the

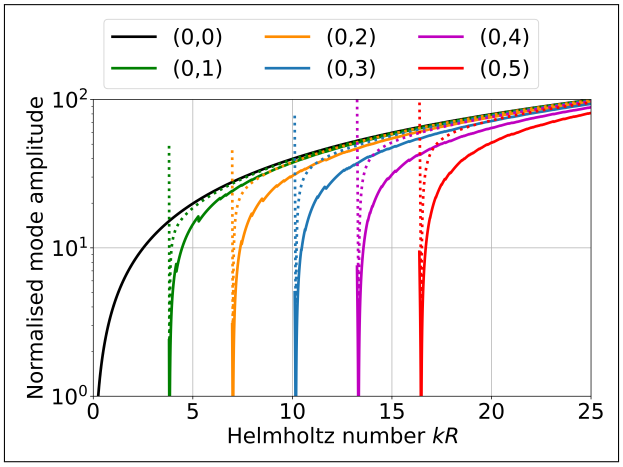

Figure 5. Mode amplitudes for azimuthal mode order $m = 0$ excited by a dense distribution of incoherent dipole sources. Values are normalised by $\frac{\rho c}{4\pi R^2}$. Solid lines show results for the ISI-model and dashed lines for the Goldstein point source model.

maximum mode amplitude at the cut-on frequencies, the total sound power exhibits a smooth development with respect to frequency above $kR = 5$ in contrast to the results of the Goldstein point source model. Furthermore, the general rate of increase of the sound power predicted by each model is similar to that of the free field dipole source. An offset of approximately 2.5 dB for both source models is reached at $kR = 25$, which is similar to the monopole case. Note, however, that the difference between the ISI-model and the free field dipole does not indicate a less accurate prediction, because, unlike in the free field, the sound power output of the ducted dipole sources is influenced by the dipole angle with respect to the duct axis.

5. COMPARISON WITH EXPERIMENTAL RESULTS

In this section, the sound power distributions obtained with the Goldstein and the ISI point source models are compared with experimentally determined mode sound powers using radial mode analysis. The details of the measurements on the CRAFT test rig and the analysis of the measurement data are given in [15].

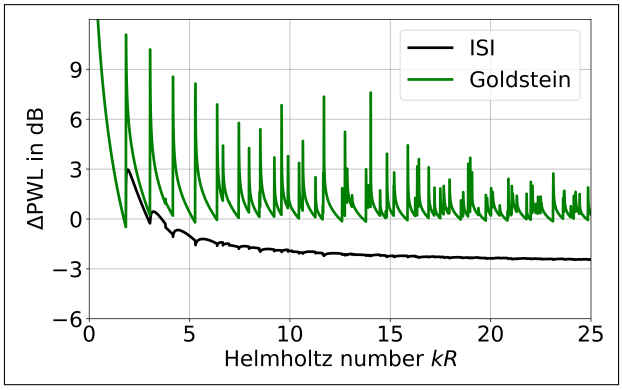

Figure 6. Total sound power generated by a dense distribution of incoherent dipole sources relative to the sound power output of a dipole source in free field conditions (cp. Eq. (6)).

Figures 7 and 8 show the mode sound power distribution of the rotor-incoherent, broadband sound field component at $kR \approx 20$, which were measured in the inlet and outlet of the CRAFT at the aerodynamic design point of the fan stage. In the inlet, only upstream propagating and rotor co-rotating modes are considered for the comparison, because the rotor shielding effect has an additional effect on the sound power distribution that is not included in the modelling discussed here. In contrast, in the outlet only downstream propagating, rotor counter-rotating modes considered. Additionally, modelled mode sound power distributions according to distributions of dipole sources with $\alpha_{\text{dipole}} = -\frac{\pi}{4}$ using the Goldstein and the ISI point source models as well as two mode energy distribution models: "'equal mode energy"' (EME) and "'equal mode energy density"' (EDEM), which are matched to the total measured sound power.

The modelling results show two different trends. On the one hand, the "'equal mode energy"' distribution corresponds to a constant sound power level independent of the mode propagation factor. Interestingly, the results of the Goldstein point source model show a trend that is similar to the EME distribution. On the other hand, the "'equal mode energy density"' predicts an increasing sound power level for high values of the mode propagation factor. A very similar trend is observed for the ISI point source model.

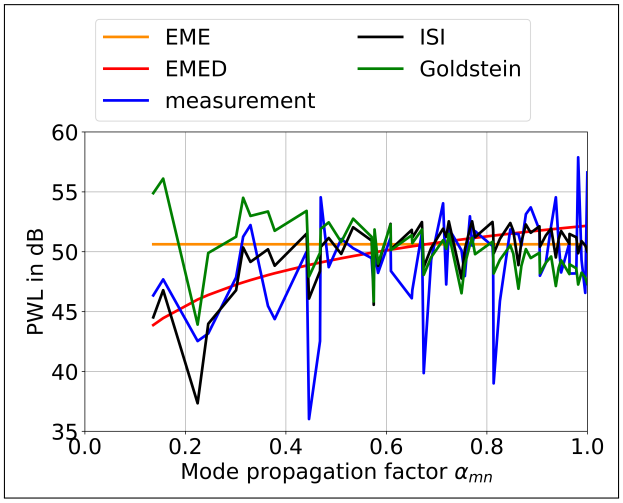

Figure 7. Comparison of measured mode sound power in the inlet of the CRAFT test rig and matched distributions from different source and mode energy distribution models at $kR \approx 20$.

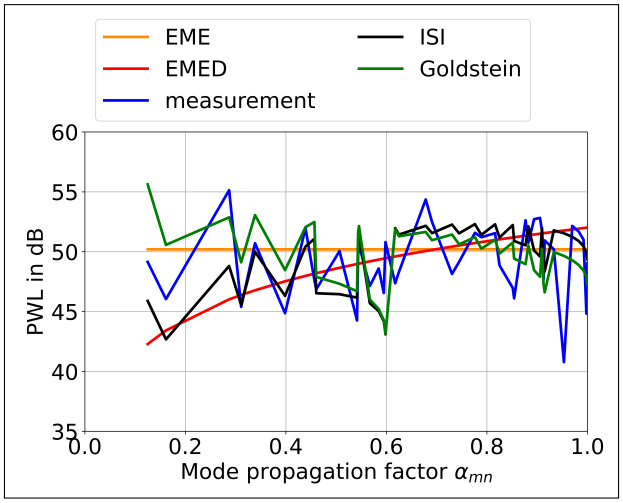

Figure 8. Comparison of measured mode sound power in the outlet of the CRAFT test rig and matched distributions from different source and mode energy distribution models at $kR \approx 20$.

In comparison with the measured sound power distribution, the EMED distribution and the prediction using the ISI-model achieve a very good agreement in the inlet regarding the overall trend. In case of the ISI-model, the distribution of dipole sources at a single axial plane is insufficient in order to predict dips in the mode sound power distribution like the ones at $\alpha \approx 0.45$, 0.67 and 0.81, which correspond to the modes $(-1, 3)$, $(-1, 4)$ and $(-1, 5)$.

In the outlet, the results of the ISI-model are in good agreement with the measured sound power levels above $\alpha = 0.3$. For modes that are closer to their cut-on frequencies, the measured sound power levels are elevated, which is caused by resonant excitation of the modes, but also by stronger reflections at the rotor of the corresponding modes $(18, 0)$, $(13, 1)$ and $(9, 2)$.

6. CONCLUSION

The widely used point source models by Goldstein are extended by incorporation of an internal source impedance (ISI) with the aim to achieve a more realistic excitation of acoustic modes in resonant conditions. For the internal source impedance, the radiation impedance of a monopole point source in free field conditions is taken in combination with an additional term, that boosts the mode excitation at low frequencies. The evaluation of monopole and dipole distributions demonstrates the effective reduction of overestimated mode sound powers at the cut-on frequencies leading to a continuous total sound power spectrum above $kR = 10$. A good agreement of the predicted sound power distribution using the ISI-model is found in comparison with experimental data from DLR's CRAFT fan test rig. Furthermore, the trend of the sound power distribution from the ISI-model resembles the "'equal mode energy density"' (EMED) distribution in contrast to the original Goldstein model, which shows a stronger resemblance to the "'equal mode energy"' model (EME). The demonstrated characteristics of the ISI-point source model are particularly beneficial for the robustness of noise prediction tools and source localisation techniques for turbomachinery stages, especially, at high frequencies, where the modal density increases exponentially.

ABSTRACT

Hydrodynamic noise is an important component of the overall noise radiated by a ship, particularly at low frequencies where propeller noise could be dominant especially at high speed. This study proposes a simplified analytical solution of the phenomenon of spectral humps of propeller noise due to the interaction between a rotating propeller and an incident turbulent flow. The acoustic radiation is described by the Ffowcs-Williams and Hawkings analogy in the compact approximation. The inflow turbulence field is assumed to be homogeneous and isotropic and is modeled using a von Kármán spectrum. Experimental validation and comparison with more costly analytical solutions demonstrate the ability of the developed model to correctly capture the characteristics of the humps related to turbulence ingestion. From the results obtained, a parametric analysis enables us to define a criterion for the emergence and shape of turbulence ingestion humps according to the propeller advance ratio, improving the criterion proposed by Ffowcs-Williams and Hawkings in 1969.

1. INTRODUCTION

In the context of propeller hydroacoustics, turbulence ingestion noise is due to the interaction between the rotating blades and the turbulent wake of a submarine or a surface vessel. The development of predictive models to better understand the physical origins of turbulence ingestion noise and estimating its levels is critical to enhance ship discretion. Understanding fundamental noise generation mechanisms allows architects to propose solutions like optimized blade and hull geometries or operational adjustments. Integrated early in design, it can reduce detectability by passive sonar in defense contexts and mitigate environmental impacts on marine life (Fig. 1).

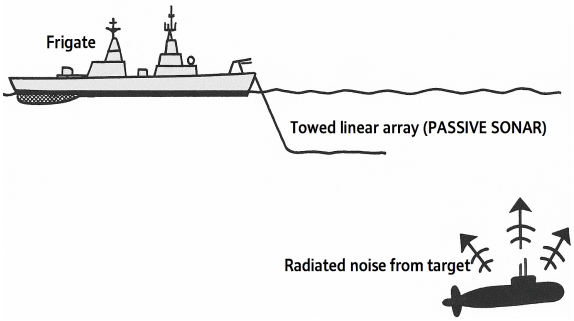

Figure 1. Detection of a submarine by passive SONAR in anti-submarine warfare.

This study targets low-frequency noise, specifically turbulence ingestion humps. When a turbulent flow is ingested by a rotating propeller, the incoming eddies are periodically chopped by the propeller. This interaction can potentially lead to a correlation (depending on the config-

uration) between the broadband turbulence spectrum and the periodic passage of the blades. This correlation creates a series of humps centered at blade passage frequency (BPF) harmonics on the resulting spectrum. The objective is to study the influence of propeller's parameters on the spectral humps and to define a criterion for the appearance of these humps, building on prior research to fully resolve turbulence-blade interactions while keeping computational costs industrially feasible.

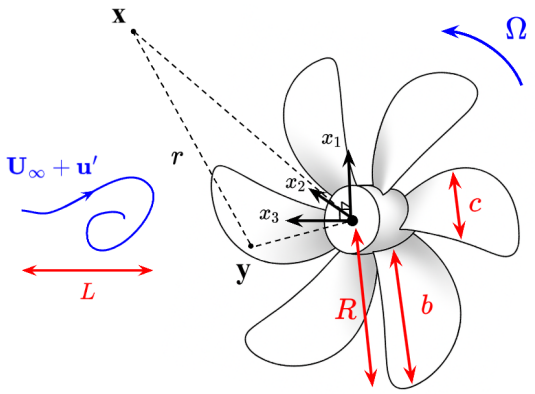

Figure 2. Fixed reference frame, with origin at the center of the propeller. $\boldsymbol{x}$ corresponds to the receiver's coordinate, and $\boldsymbol{y}$ to the coordinate within the volume containing the sources near the propeller (Ffowcs-Williams and Hawkings analogy).

2. NOISE RADIATION MODELING

To predict turbulence ingestion noise, this study employs a simplified version of the Ffowcs-Williams formulation for moving surfaces under the compact source approximation : $K_0 c < 1$, $K_0 R < 1$, where $K_0 = \omega/c_\infty$ is the acoustic wavenumber, c is the blade chord and R the propeller radius (see Fig. 2). For a propeller with N blades rotating at angular velocity Ω, the far-field ($|\boldsymbol{x}| \gg R$) acoustic pressure spectrum is thus expressed as in [1] section 6.6.2:

$$\widehat{p}(\boldsymbol{x},\omega) \simeq \frac{iK_j}{8\pi^2|\boldsymbol{x}|} e^{i\boldsymbol{K}\cdot\boldsymbol{x}} \widehat{F_j}(\omega), \tag{1}$$

with the acoustic wave vector in a convected medium:

$$\boldsymbol{K} = \frac{\omega}{c_\infty}\left(\frac{\boldsymbol{x}}{|\boldsymbol{x}|} - \boldsymbol{M}_\infty\right), \quad \boldsymbol{M}_\infty = (0,0,M_\infty), \tag{2}$$

$\widehat{F_j}(\omega)$ represents the force fluctuation spectrum and is expressed as [2],

$$\widehat{F_j}(\omega) = \sum_{n=0}^{N-1} \int_{-\infty}^{+\infty} \int_{S(\tau)} f_j(\boldsymbol{y}^{(n)},\tau) dS(\boldsymbol{y}^{(n)}) e^{i\omega\tau} d\tau, \tag{3}$$

with f_j is the surface force fluctuation, N the number of blades and S the surface of each blade. The radiated pressure spectral density in the far-field, is then derived as:

$$S_{pp}(\boldsymbol{x},\omega) \simeq \frac{K_i K_j}{64\pi^4|\boldsymbol{x}|^2} S_{F_iF_j}(\omega), \tag{4}$$

where the force spectral density $S_{F_iF_j}(\omega)$ is computed using a rotating reference frame and Taylor's frozen turbulence hypothesis. For propellers with low twist angle, $S_{F_iF_j}(\omega)$ can be approximated only by it's axial contribution $S_{F_3F_3}(\omega)$, that can be expressed as an integral over the blade radius r and the chordwise wavenumber k_2 (see [1] section 6.6.2) for waves propagating from the leading edge to the trailing edge ($k_2 \geq 0$):

$$S_{F_3F_3}(\omega) = \int_{R-b}^{R} \int_0^\infty A(r)|H(k_2)|^2 \cdot B(k_2,r)\psi_{33}(\omega,k_2,r)\, dk_2\, dr. \tag{5}$$

Here, A accounts for the axial force amplitude,

$$A(r) = \frac{1}{U_\infty}(2\pi^2\rho_\infty c(r)U(r))^2, \tag{6}$$

where $U(r)$ is the total effective speed perceived by the blades:

$$U(r) = \sqrt{U_\infty^2 + (r\Omega)^2}. \tag{7}$$

B captures inter-blade correlations,

$$B(k_2,r) = \frac{\sin^2(\pi k_2 r)}{\sin^2(\pi k_2 r/N)}. \tag{8}$$

H is the blade response function, given in the low frequency regime by the Sears function [3] of modulus approximated by [4] equations 6.4.3 and 6.4.4:

$$|H(k_2)|^2 \simeq \frac{1}{1+\pi c(r)k_2}, \quad k_2 \geq 0. \tag{9}$$

Finally, ψ_{33} is the turbulence spectrum in the rotating frame in the axial direction and will be given in the next section. This framework provides the foundation for the parametric analysis detailed later.

3. TURBULENCE MODELING

The incident turbulence is modeled as homogeneous and isotropic using the von Kármán spectrum [5] section 9.1:

$$\phi_{ij}(\boldsymbol{k}) = \frac{E(\boldsymbol{k})}{4\pi|\boldsymbol{k}|^2}\left(\delta_{ij} - \frac{k_i k_j}{|\boldsymbol{k}|^2}\right), \tag{10}$$

$$E(\boldsymbol{k}) = A_\phi \frac{|\boldsymbol{k}|^4/k_e^4}{(1+|\boldsymbol{k}|^2/k_e^2)^{17/6}}, \tag{11}$$

where $\boldsymbol{k} = (k_1, k_2, k_3)$ and the constants are defined by:

$$A_\phi = \frac{55}{9\sqrt{\pi}}\frac{\Gamma(5/6)}{\Gamma(1/3)}\frac{\overline{u^2}}{k_e}, \tag{12}$$

$$k_e = \frac{\Gamma(5/6)}{\Gamma(1/3)}\frac{\sqrt{\pi}}{L}, \quad \overline{u^2} = I_t U_\infty.$$

where I_t is the turbulent intensity. In the rotating frame, the turbulence spectrum is given by

$$\psi_{33}(\omega, k_2, r) = \phi_{33}\left(0, k_2, \frac{\omega - k_2 r\Omega}{U_\infty}\right), \tag{13}$$

providing the turbulence inputs for the the equations (5) and (4) of the noise model.

4. MODEL VALIDATION

The model is validated against Blake's analytical results [1] associated with Wojno experimental data [6] reproducing a similar configuration of the famous Sevik's study [7] with a ten-blades rotor. The parameters used for this configuration are listed in Tab. 1. The comparison, shown in Fig. 3, demonstrates good agreement, despite differences arise because Blake uses the frozen turbulence hypothesis on the chordwise wavenumber $k_2 = \omega/U(r)$ while we use the frozen turbulence hypothesis on the upstream axial wavenumber $k_3 = \omega/U_\infty$. Moreover, an offset of $10\log_{10}(U_\infty)$ has been removed from Blake's data due to the absence of normalization by U_∞ in Blake's model. This normalization is necessary when making the frozen turbulence hypothesis.

The compact source approximation leads to good predictions when the observer is located near the rotor rotational axis, where the sound level is maximum. It is underpredicted when the observer is positioned far from the axis of rotation. This underestimation is illustrated in Fig. 4, where the compact model is compared to the non-compact

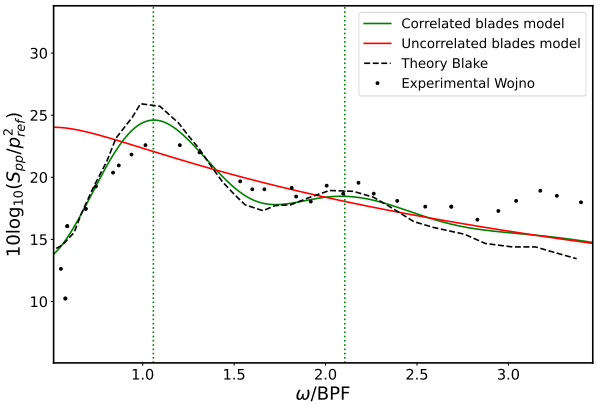

Figure 3. Comparison of radiated pressure spectrum with Blake's model and Wojno's measurements. The green solid line corresponds to the model (4) used with data from Tab. 1 and the red solid line corresponds to the same but with $B = 1$ in (5) (uncorrelated blades noise).

model of Raposo and Azarpeyvand [8] for an observer located at 90 degrees from the axis of rotation. Used parameters values correspond to the wind turbine case from Table 1 in [8].

Despite this, it is observed in Fig. 3 and Fig. 4, that the

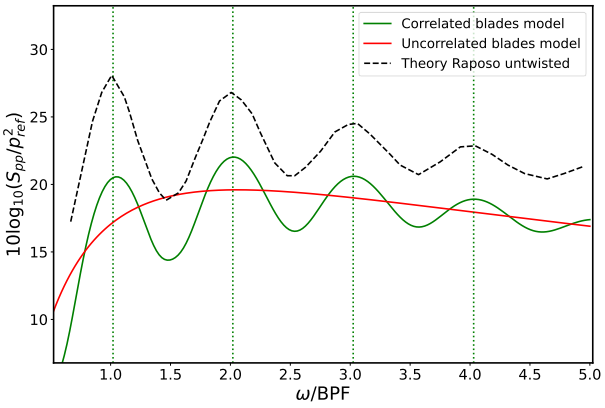

Figure 4. Comparison of radiated pressure spectrum with Raposo and Azarpeyvand's untwisted model. The green solid line corresponds to the model (4) used with data from Table 1 in [8] data and the red solid line corresponds to the same but with $B = 1$ in (5) (uncorrelated blades noise).

shape of the turbulence ingestion humps is correctly reproduced. Moreover, it is precisely this criterion (humps shape) that will be important later in the analytical definition of the emergence of these humps.

5. PARAMETRIC ANALYSIS

This section leverages the noise radiation model, specifically equation (5), to conduct a detailed parametric study of the spectral humps generated by turbulence ingestion. The analysis focuses on hump positions, their bandwidths, and the critical conditions under which these humps emerge or disappear, providing insights into noise characteristics and design implications.

5.1 Positions of the spectral humps

The positions of the spectral humps are determined by analyzing the peaks in the radiated pressure spectrum. The peak frequencies of the force spectrum (5) are derived by finding the maximum of the turbulence spectrum $\psi_{33}(\omega, k_2, r)$ with respect to ω. Setting the partial derivative $\partial\psi_{33}/\partial\omega = 0$, the resulting frequencies are:

$$\omega_{T,n} = r\Omega k_2 = nN\Omega. \tag{14}$$

These frequencies correspond to the blade-passing frequency ($BPF = N\Omega$) harmonics of harmonic number n reflecting the periodic chopping of turbulent eddies by the blades. In (14), the condition $k_2 = nN/r$ has been used indicating that the inter-blade interference term B reaches its maximum, as illustrated in the force spectrum construction process (Fig. 5).

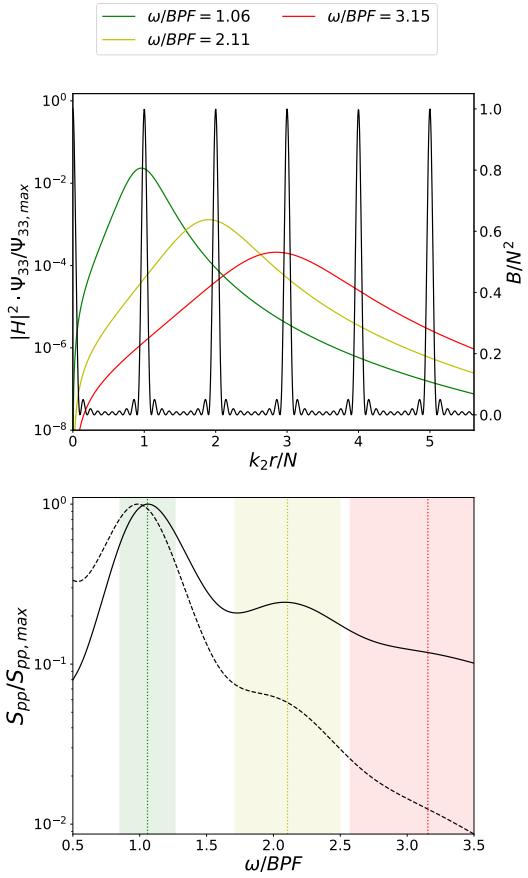

Figure 5. Normalized construction of the pressure spectrum S_{pp} (solid line lower figure) and force spectrum $S_{F_3F_3}$ (dotted line) from the integration over the chordwise wavenumber of the diffracted turbulence $|H|^2\psi_{33}$ (wide curves upper figure) times the inter-blade interference function B (narrow curve).

5.2 Bandwidths of the spectral humps

The bandwidths of the spectral humps, defined as the frequency range at half-height of their peaks, quantify their

spread and influence their distinguishability in the spectrum. For turbulence humps, the bandwidth at half-height is calculated by solving $\psi_{33}(k_2,\omega) = \frac{1}{2}\psi_{33}(k_2,\omega_T)$, yielding:

$$\Delta\omega_{T,n} \simeq U_\infty \sqrt{\frac{n^2N^2}{R^2} + k_e^2}. \tag{15}$$

This expression shows that the bandwidth increases with the inflow velocity U_∞, the harmonic number n, and the number of blades N, while being moderated by the radial position r and the turbulence integral scale $L \propto 1/k_e$. In Fig. 5, shaded zones correspond to the bandwidth predicted by (15). The relative bandwidth, normalized by the peak frequency, is:

$$\frac{\Delta\omega_{T,n}}{\omega_{T,n}} = \sqrt{\frac{J_\Omega^2}{\pi^2} + \frac{9}{16n^2N_h^2}}, \tag{16}$$

where $J_\Omega = \pi U_\infty / R\Omega$ is the propeller tip advance ratio and $N_h = N\Omega L/U_\infty$ is the chopping number introduced by Ffowcs-Williams and Hawkings in their humps prediction criterion [9] eq. 8, predicting $\Delta\omega_{T,n}/\omega_{T,n} \propto 1/N_h$ implying narrow humps when $N_h \gg 1$. This criterion is used in several studies such as Homicz and George [10], Martinez [11], Glegg et al. [12], Glegg and Devenport [4], Raposo and Azarpeyvand [8]. Unlike Ffowcs-Williams and Hawkings prediction, the present criterion (16) indicates a stronger dependence on the advance ratio J_Ω, meaning that a large N_h does not necessarily imply narrow humps. Note that this new formulation is equivalent to that of Ffowcs-Williams and Hawkings when $J_\Omega \to 0$.

5.3 Hump emergence criteria

The emergence of spectral humps is a pivotal concept in this study, as it directly informs strategies for noise control in propeller design. Turbulence humps are distinguishable in the spectrum when their bandwidths do not exceed the frequency spacing between consecutive humps, given by $N\Omega$. If the bandwidth $\Delta\omega_{T,n}$ surpasses this threshold, the humps overlap and the spectrum flattens into a broadband signature. Mathematically, this condition is expressed as:

$$\frac{\Delta\omega_{T,n}}{N\Omega} > 1. \tag{17}$$

Substituting the bandwidth from Equation (15), this inequality becomes:

$$J_\Omega > \frac{\pi}{\sqrt{n^2 + \frac{r^2k_e^2}{N^2}}}, \tag{18}$$

meaning that the n-th turbulence hump vanishes if J_Ω is superior to a critical advance ratio, as their bandwidth exceeds the BPF spacing. This critical advance ratio is defined by:

$$J_{\Omega,c}(n) = \frac{\pi}{\sqrt{n^2 + \frac{r^2k_e^2}{N^2}}}. \tag{19}$$

The most restrictive case occurs at the first harmonic ($n = 1$), where overlap eliminates all subsequent humps if exceeded. Fig. 6 illustrates this effect, showing how increasing J_Ω beyond the critical value leads to a loss of distinct humps. A trend consistent with experimental observations where humps disappear at higher inflow velocities relative to rotation speed even with the number N_h being fixed (see [8] section 4.2). Given the expression (19), we can reformulate the relative bandwidth (15) only in terms of the advance ratio :

$$\frac{\Delta\omega_{T,n}}{\omega_{T,n}} = \frac{J_\Omega}{nJ_{\Omega,c}(n)}. \tag{20}$$

Physically, a high J_Ω implies a faster axial inflow U_∞ compared to the rotational speed $R\Omega$, increasing the frequency at which eddies are chopped and thus broadening the spectral humps to the shape of the turbulence spectrum. For the Blake's parameters in Tab. 1, $J_{\Omega,c}(1) \simeq 2.92$, $J_{\Omega,c}(2) \simeq 1.54$ and $J_{\Omega,c}(3) \simeq 1.04$. Thus the experimental $J_\Omega = 1.14$ suggests overlap after the second humps, which is what we observe in Fig. 3. This criteria for hump emergence offer actionable insights for propeller design. Optimizing parameters like blade count N, turbulence integral scale L, and rotor's radius R can suppress humps, by diminishing the critical advance ratio $J_{\Omega,c}$ an thus reducing ship's detectability.

5.4 Spectral humps perceived by the observer

The spectrum perceived by the observer is that radiated by the pressure fluctuations (4) resulting from the propagation and deformation of the force spectrum from the blades such that $S_{pp} \propto \omega^2 S_{F_3F_3}$. The frequency of the perceived humps $\omega_{p,n}$ (peaks of S_{pp}) is therefore different from that of the turbulent humps (peaks of $S_{F_3F_3}$). The link between the perceived humps and turbulence's humps is established by expressing the peaks of S_{pp} in function of the peaks of $S_{F_3F_3}$ using (4) and (2):

$$\omega_{p,n} \simeq \frac{\omega_{T,n}}{2} + \frac{1}{2}\sqrt{\omega_{T,n}^2 + \frac{\Delta\omega_{T,n}^2}{\ln(2)}}. \tag{21}$$

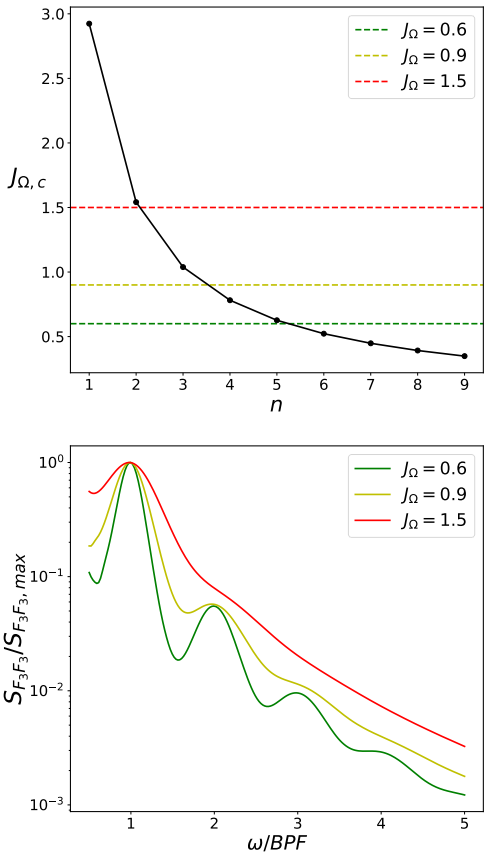

Figure 6. Impact of critical advance ratio on turbulence hump visibility, showing $J_{\Omega,c}$ versus harmonic number (upper figure) and normalized force spectrum flattening (lower figure). Parameters values are from Tab. 1.

It is therefore noted that the position of the humps perceived by the observer is slightly shifted to the right (higher frequencies) as the humps bandwidths increases, consequence of the propagation from the propeller to the observer. This phenomenon is illustrated in Fig. 5. Recently, this 'blue shifting' phenomenon has been qualitatively described by Huang [13] and numerically studied by Qin et al. [14]. Moreover, Martinez [15] made a theory for large N, predicting the first hump's 'blue shifting' of the force spectrum $S_{F_3F_3}$ (i.e. on the shift of $\omega_{T,n} > nN\Omega$ which is not seen here) but not for the pressure spectrum S_{pp} (i.e. not for $\omega_{p,n}$). By injecting the expression (15) obtained for the bandwidths into (21), we derive the explicit expression of $\omega_{p,n}$ as a function of the problem's parameters:

$$\omega_{p,n} = \frac{\omega_{T,n}}{2}\left(1 + \sqrt{1 + \frac{1}{n^2 \ln(2)}\frac{J_\Omega^2}{J_{\Omega,c}^2}}\right). \qquad (22)$$

with $\omega_{T,n} = nN\Omega$. It is interesting to note that there exists a maximum shift, dependent only on n, when $J_\Omega = J_{\Omega,c}$, since the n-th peak overlaps for higher advance ratio (when $J_\Omega > J_{\Omega,c}$). The first peak satisfies $\max(\omega_{p,1}) \simeq 1.28\omega_{T,1}$, corresponding to a maximum shift of 28%. The maximum shift then rapidly decreases with n, such that $\max(\omega_{p,2}) \simeq 1.08\omega_{T,2}$ and $\max(\omega_{p,3}) \simeq 1.04\omega_{T,3}$, corresponding to 8% and 4%, respectively. For the parameters of Tab. 1, we obtain a shift of $\omega_{p,1} \simeq 1.06\omega_{T,1} = 1.06BPF$, which is a better prediction of the experimental shift observed in Fig. 3 (dotted vertical lines).

6. SPECIFIC CASES

In this last section, an analysis of special cases of the previous model is presented to demonstrate its equivalence with theories in the literature dealing with limit cases.

6.1 Static propeller

When the propeller is static ($\Omega = 0$) and has only one blade ($N = 1$), the model reduces to leading edge diffraction noise as in section 14.3 of [4]:

$$S_{F_2F_2}(\omega) = 4\pi^4 \rho_\infty^2 c^2 U_\infty b \left|H\left(\frac{\omega}{U_\infty}\right)\right|^2 \Phi_{22}\left(0, \frac{\omega}{U_\infty}\right),$$

$$S_{pp}(\boldsymbol{x}, \omega) = \left(\frac{\omega x_2}{8\pi^2 c_\infty |\boldsymbol{x}|^2}\right)^2 S_{F_2F_2}(\omega). \qquad (23)$$

with $\Phi_{22}(k_1, k_3) = \int_{-\infty}^{+\infty} \phi_{22}(k_1, k_2, k_3) dk_2$ the two-dimensional turbulence spectrum in the blade plane. This model thus reproduces the result of Glegg and Devenport [4], for a fixed wing in turbulent flow, modulo a factor 2π, given that the normalization of the Fourier transform used is not the same as here (see appendix).

6.2 Uncorrelated blades

The cross-correlation function between the blades B is responsible for the periodic reproduction of the turbulence spectrum (and thus the production of the humps) in (5).

Setting $B = 1$ amounts to neglecting the interaction between the incident turbulent field and the periodicity of the blade passage, which thus eliminates the humps while still preserving the average trend of the spectrum (red mean line without humps in Fig. 3 and 4) given by the diffraction of the turbulence corresponding to $|H|^2 \cdot \psi_{33}$ in (5). This uncorrelated approach has already been theorized by Sevik during his experiment in 1971 [7].

7. CONCLUSION

This study has successfully developed a simplified analytical model to predict turbulence ingestion noise for marine propellers, focusing on the characterization of spectral humps. The key steps undertaken include: (1) the adaptation of the Ffowcs-Williams and Hawkings formulation to model acoustic radiation from moving surfaces, incorporating a homogeneous and isotropic von Kármán turbulence spectrum; (2) validation of the model against Blake's and Raposo's analytical and experimental results, confirming its ability to reproduce hump shapes despite some underpredictions in non-compact scenarios; (3) a detailed parametric analysis to determine hump positions, bandwidths, and emergence criteria, introducing a refined critical advance ratio $J_{\Omega,c}(n)$ that improves upon the original Ffowcs-Williams and Hawkings criterion; and (4) an exploration of special cases, such as static propellers and uncorrelated blades, demonstrating equivalence with established theories. Future works will focus on implementing realistic propeller geometry (with twist, sweep and skew angles, etc.) into the models and relaxing compacity hypothesis to study the potential influence on humps positions, and bandwidths.

8. APPENDIX

8.1 Fourier transform conventions

For the Fourier transforms in time and space, the following conventions and notations are used:

$$\widehat{f}(\omega) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} f(t) e^{i\omega t} dt,$$

$$f(t) = \int_{-\infty}^{+\infty} \widehat{f}(\omega) e^{-i\omega t} d\omega$$

ABSTRACT

In this paper, we present a modification of Amiet's model for rotating systems aimed at enhancing the assessment of inflow-conditions effects on turbulence-interaction noise generation and prediction. This involves replacing the original three-dimensional turbulence input, which is particularly challenging to measure both experimentally and numerically, with a one-dimensional term, enabling probe measurements to be directly used as input. The proposed modification also allows for the extension to rotating systems of turbulence-distortion models developed for rectilinear motion to account for realistic geometry effects in sound prediction. The approach is validated against experimental acoustic data obtained for a low-Reynolds two-bladed propeller interacting with grid-generated turbulence.

Keywords: *Rotating Systems, Turbulence Modeling, Turbulence-Ingestion Noise, Low-Fidelity Noise Prediction.*

1. INTRODUCTION

Aeroacoustic optimization of urban aerial vehicles is essential for the successful implementation of urban air mobility. Such a necessity arises from strict urban regulations and the complex, heterogeneous flow conditions that characterize urban environments. This highlights the importance of analyzing turbulence-ingestion noise (TIN), which results from the interaction between the incoming turbulence structures and the rotor. The complexity is further increased by the growing diversity of rotor geometries and configurations, making flow-structure interactions even more challenging to predict and control.

The interaction of turbulence with a rotating system can be divided into three distinct phases. In the first phase, the streamtube contraction induced by the rotating system elongates the turbulence structures in the streamwise direction [1]. Consequently, even if the incoming turbulence is homogeneous and isotropic far upstream, the rotor encounters anisotropic flow conditions [1, 2]. In the second phase, these elongated structures are chopped by the rotor blades, generating coherent unsteady surface pressure across different blades. This blade-to-blade correlation introduces narrow-band quasi-tonal peaks to the mainly broadband features of the TIN spectra. Finally, in the third phase, the elongated and chopped structures undergo distortion as they interact with the blade leading edge, accelerating along its surface. Although the impact of this mechanism on noise generation has been extensively studied in the context of rectilinear motion [3, 4], its potential effects on rotating systems remain largely unexplored.

Since the identification of this flow-induced noise source by Sharland in the 1960s [5], several low-fidelity models — mainly used for the optimization phase — have been developed, with Amiet's model [6] standing out for its robustness and simplicity. Despite its numerous simplifying assumptions, this model has proven capable of providing accurate predictions across a wide range of conditions [7]. It also accounts for blade-to-blade correlation and partially incorporates rotor geometry by discretizing the blade into narrow strips using a strip-theory approach [8]. However, its implementation depends on precise modeling or extensive characterization of inflow conditions, which poses a significant limitation for many

cutting-edge configurations currently under development.

The purpose of this study is hence to propose a modification to Amiet's model that enables the use of direct, simple flow measurements as input. This modification is especially useful for complex configurations where low-fidelity noise prediction is needed but a detailed description or reliable model of the inflow is unavailable, allowing the use of hot-wire anemometry measurements to assess the acoustic performances. The modified model has been validated against experimental measurements from a simple turbulence-rotor configuration.

The outline of the paper is the following. The experimental setup is presented in Sec. 2, while the modification and the results are reported in Sec. 3. The conclusions are then drawn in Sec. 4.

2. METHODOLOGY

The experimental campaign has been carried out in the anechoic open-jet wind tunnel (A-Tunnel) at the Low-Speed Laboratory of TU Delft, shown in Fig. 1a and extensively described by Merino-Martinez *et al.* [9]. A turbulence-generating grid (with rectangular rods $0.01\,\mathrm{m}$ wide separated by $0.10\,\mathrm{m}$) has been placed at the exit of the tunnel, followed by a $0.60\,\mathrm{m}$ long circular nozzle with a diameter of $0.60\,\mathrm{m}$. This configuration was chosen to prevent microphone measurements from being contaminated with grid noise.

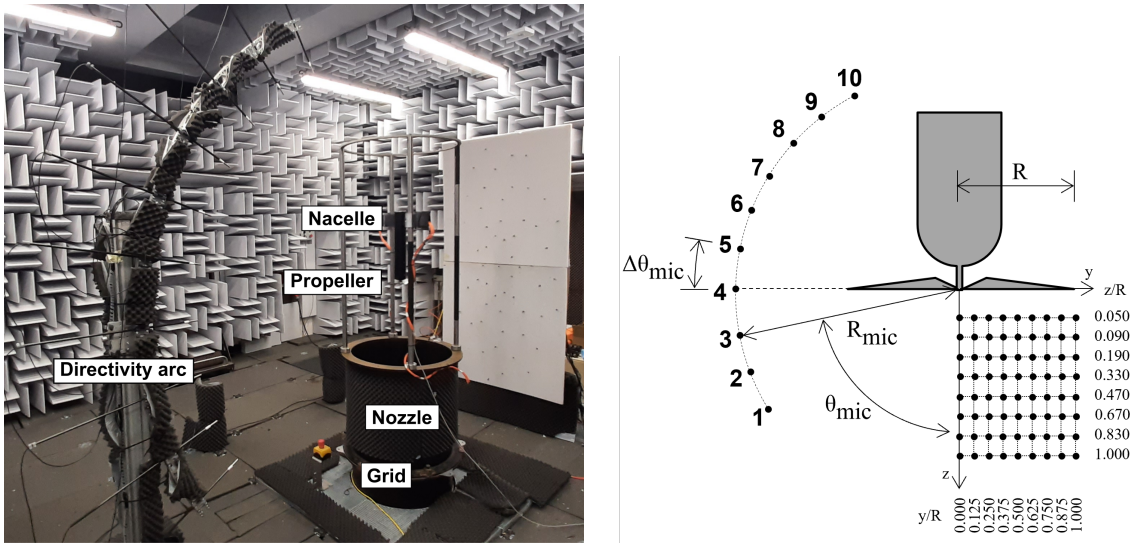
The propeller is an APC 9×6 rescaled to have a diameter of $0.30\,\mathrm{m}$ and modified to feature a NACA 4412 as blade section. Positioned $0.40\,\mathrm{m}$ from the nozzle exit, the propeller is powered by a Lehner Motors LMT 2280/34 brushless inrunner. Further information about the propeller manufacturing and the support nacelle is provided by Grande *et al.* [10]. A single rotational speed of $6000\,\mathrm{RPM}$ has been considered, resulting in an advance ratio $J = W_\infty/nD$, with n being the rotational speed in Hz, of 0.30.

Figure 1b shows a schematic of the experimental setup. The reference frame is centered on the rotor hub, with the z axis aligned along the axial (streamwise) direction, pointing upstream. The x and y axes lie within the rotor plane, forming a right-handed coordinate system. The corresponding velocity components are denoted as w, u, and v.

The sketch also illustrates the placement of ten G.R.A.S. 40PH microphones along the directivity arc at a radius of $R_{\text{mic}} = 1.3\,\mathrm{m}$, positioned between $\theta_{\text{mic}} = 60°$ and $\theta_{\text{mic}} = 150°$ in increments of $10°$, with θ_{mic} measured relative to the z axis. The microphones have a frequency range of 10 to $20\,\mathrm{kHz}$ and a maximum sound pressure level of $135\,\mathrm{dB}$.

Aerodynamic measurements were conducted using hot-wire anemometry (HWA). Axial velocity fluctuations were recorded at the grid points shown in Fig. 1b. The probe used is a platinum-plated tungsten Dantec Dynamics P11, with a width of $5\,\mu\mathrm{m}$ and a length of $1.25\,\mathrm{mm}$. HWA data were used to characterize the flow at the nozzle exit, where the free-stream velocity is $W_\infty = 9.5\,\mathrm{m\,s^{-1}}$, the turbulence intensity $\sqrt{\overline{w'^2}}$ is $6\,\%$, and the integral length scale L^z_{ww} is $0.018\,\mathrm{m}$.

Acoustic and aerodynamic data were collected for $60\,\mathrm{sec}$ at a sampling rate of $51.2\,\mathrm{kHz}$. The power spectral densities (PSDs) were computed using Welch's method with a Hanning window and a $50\,\%$ overlap, achieving a frequency resolution of $1\,\mathrm{Hz}$.



3. RESULTS

Amiet's model for turbulence-ingestion noise prediction [6] is based on the analytical approach developed in the two-dimensional regime [11]. This is used to calculate the instantaneous sound emission of the blade at each azimuthal position γ, which is hence modeled as if the blade were moving in rectilinear motion. This assumption holds as long as the considered noise frequencies are much higher than the rotational frequency of the propeller.

From a modeling perspective, the implementation of the rectilinear motion model requires three key considerations. First, an average must be taken over the azimuth. Second, the relative motion of the source with respect to the listener's position must be taken into account, which means that the listener's position $\mathbf{x}_\mathrm{B} = (x_\mathrm{B}, y_\mathrm{B}, z_\mathrm{B})$ should be calculated in the reference frame moving with the blade (from which the subscript $_\mathrm{B}$). Third, the Doppler effect must be incorporated into the calculation. The following equation is then finally retrieved for the far-field acoustic pressure $S_{pp}\left(\mathbf{x}_\mathrm{B}, \omega_0\right)$

$$S_{pp}\left(\mathbf{x}_\mathrm{B}, \omega_0\right) = \frac{1}{2\pi}\int_0^{2\pi}\left(\frac{\omega_\mathrm{B}}{\omega_0}\right)^2 S_{pp}\left(\mathbf{x}_\mathrm{B}, \omega_\mathrm{B}, \gamma\right)\mathrm{d}\gamma, \tag{1}$$

with $\omega_\mathrm{B}/\omega_0$ indicating the Doppler's effect as the ratio between ω_B, i.e., the "de-Dopplerized" frequency in the rotating reference frame, and ω_0, i.e., the "Dopplerized" sound frequency as heard by the observer in the fixed reference frame.

(a) (b)

Figure 1: (a) Picture and (b) sketch of the experimental setup at the TU Delft A-tunnel facility.

In the formulation incorporating blade-to-blade correlation, the instantaneous noise emission generated by the blade in the rotating reference system $S_{pp}\left(\mathbf{x}_\mathrm{B}, \omega_\mathrm{B}, \gamma\right)$ is expressed as

$$S_{pp}\left(\mathbf{x}_\mathrm{B}, \omega_\mathrm{B}, \gamma\right) = \left(\frac{\omega_\mathrm{B} z_\mathrm{B} \rho_0 c}{2 c_0 \sigma^2}\right)^2 \pi U_\mathrm{x} \left(\frac{L}{2}\right) \times \overline{w'^2} \left(\frac{c}{2}\right)^2 \left|\mathcal{L}\left(K_x, K_y, M_x\right)\right|^2 \times \sum_{n=-\infty}^{\infty} \Phi_{ww}\left(K_x, K_y, K_z^{(n)}\right) \frac{2\pi}{\left(\frac{c}{2}\right)^2 \overline{w'^2} Z}, \quad (2)$$

with ρ_0 being the flow density, c_0 is the speed of sound, c the chord and L the span, while $\sigma_0 = \sqrt{x_\mathrm{B}^2 + \beta_x^2 \left(y_\mathrm{B}^2 + z_\mathrm{B}^2\right)}$, with $\beta_x = \sqrt{1 - M_x^2}$, considers convection effects. U_x, with the respective Mach number M_x, indicates the flow velocity along the blade chord that accounts for the local pitch angle, as in the approach of Sinayoko *et al.* [12]. $\mathcal{L}\left(K_x, K_y, M_x\right)$ is the aeroacoustic transfer function, for which the original formulation of Amiet [13] has been implemented, and $\Phi_{ww}\left(K_x, K_y, K_z^{(n)}\right)$ is the three-dimensional turbulence spectrum. The wavenumbers are obtained as $K_x = \frac{\omega_\mathrm{B}}{U_\mathrm{x}}$, $K_y = \frac{\omega_\mathrm{B} y_\mathrm{B}}{c_0 \sigma}$, and $K_z^{(n)} = \frac{2\pi n + \omega_0 T_2}{Z}$. The expression for $K_z^{(n)}$ is obtained in the framework of the blade-to-blade correlation: T_2 is the time between the eddie chops as heard by the listener, Z can be defined as the distance between the blade paths in fluid, and n is an index representing the correlation between the 0-th and the n-th blade. As a detailed overview of the model falls outside the scope of the present manuscript, the reader is referred to Amiet [6, 13] for the derivation and expressions of all the parameters.

The present implementation considers the inverse strip theory approach proposed by Christope *et al.* [8] to calculate the blade noise emission. With this methodology, the blade is divided into M narrow-span strips of width L/M, whose emitted sound is calculated as the difference between a wing of span L_1 and a wing of span $L_2 = L_1 - L/M$, with $L_1, L_2 >> 1$. Referring to Eq. 2, this hence leads for $S_{pp}\left(\mathbf{x}_\mathrm{B}, \omega_\mathrm{B}, \gamma\right)$ for the m-th strip to

$$S_{pp}\left(\mathbf{x}_\mathrm{B}, \omega_0, \gamma\right)\Big|_m = \Big(S_{pp}\left(\mathbf{x}_\mathrm{B}, \omega_0, \gamma\right)\Big|_{L_1} + - S_{pp}\left(\mathbf{x}_\mathrm{B}, \omega_0, \gamma\right)\Big|_{L_2}\Big)\Big|_m. \quad (3)$$

Finally, Eq. 1 must be applied for all the M strips and the B blades, yielding

$$S_{pp}\left(\mathbf{x}_\mathrm{B}, \omega_0\right) = B \sum_{m=1}^{M} S_{pp}\left(\mathbf{x}_\mathrm{B}, \omega_0\right)\Big|_m. \quad (4)$$

The present study proposes the substitu-

tion of the three-dimensional turbulence spectrum $\Phi_{ww}\left(K_x, K_y, K_z^{(n)}\right)$ in Eq. 2 with a one-dimensional one $\Theta_{ww}\left(K_x\right)$ to allow the use of direct probe measurements. This is carried out using the analytical results of Wilson [14] on the multi-dimensional correlation and wavenumber spectra of homogeneous isotropic turbulence. The findings indeed show that it is possible to write

$$\Phi_{ww}\left(K_x, K_y, K_z^{(n)}\right) = \Psi_{ww}\left(K_x, K_y\right) \times \tilde{A}\left(K_x, K_y, K_z^{(n)}\right), \quad (5)$$

with $\tilde{A}\left(K_x, K_y, K_z^{(n)}\right)$ indicating an auxiliary function and $\Psi_{ww}\left(K_x, K_y\right)$ being the two-dimensional wavenumber spectrum. $\tilde{A}\left(K_x, K_y, K_z^{(n)}\right)$ can be calculated by performing the ratio of the von Kármán analytical expression of $\Phi_{ww}\left(K_x, K_y, K_z^{(n)}\right)$ and $\Psi_{ww}\left(K_x, K_y\right)$ [15], obtaining

$$\tilde{A}\left(K_x, K_y, K_z^{(n)}\right) = \left(\frac{55}{16}\frac{L_{ww}^z}{\pi}\right) \times \frac{\left(1+\left(\frac{K_x}{k_e}\right)^2+\left(\frac{K_y}{k_e}\right)^2\right)^{\frac{7}{3}}}{\left(1+\left(\frac{K_x}{k_e}\right)^2+\left(\frac{K_y}{k_e}\right)^2+\left(\frac{K_z^{(n)}}{k_e}\right)^2\right)^{\frac{17}{6}}}, \quad (6)$$

with $k_e = \pi/L_{ww}^z \Gamma\left(5/6\right)/\Gamma\left(1/3\right)$.

The two-dimensional wavenumber spectrum is then converted into a one-dimensional spectrum following the formulation of Amiet [11]

$$\Psi_{ww}\left(K_x, K_y\right) = \frac{1}{\pi}\Theta_{ww}\left(K_x\right) l_y\left(K_x\right), \quad (7)$$

with l_y being the spanwise coherence length of the upwash velocity component, for which the following expression is derived:

$$l_y\left(K_x\right) = \frac{8L_{ww}^z}{3}\left[\frac{\Gamma\left(1/3\right)}{\Gamma\left(5/6\right)}\right]^2 \times \frac{\left(\frac{K_x}{k_e}\right)^2}{\left(3+8\left(\frac{K_x}{k_e}\right)^2\right)\sqrt{1+\left(\frac{K_x}{k_e}\right)^2}}. \quad (8)$$

The introduction of the two auxiliary functions $\tilde{A}\left(K_x, K_y, K_z^{(n)}\right)$ and $l_y\left(K_x\right)$ thus allows the turbulence term in Eq. 2 to be expressed in terms of the one-dimensional spectrum, finally leading to

$$S_{pp}\left(\mathbf{x}_\mathrm{B}, \omega_\mathrm{B}, \gamma\right) = \left(\frac{\omega_\mathrm{B} z_\mathrm{B} \rho_0 c}{2c_0\sigma^2}\right)^2 \pi U_\mathrm{x}\left(\frac{L}{2}\right) \times \overline{w'^2}\left(\frac{c}{2}\right)^2 \left|\mathcal{L}\left(K_x, K_y, M\right)\right|^2 \left(\frac{1}{\pi}\Theta_{ww}\left(K_x\right) l_y\left(K_x\right)\right) \times \sum_{n=-\infty}^{\infty} \tilde{A}\left(K_x, K_y, K_z^{(n)}\right) \frac{2\pi}{\left(\frac{c}{2}\right)^2 \overline{w'^2} Z}. \quad (9)$$

The inclusion of a one-dimensional turbulence term enables the application of the altered spectra provided by turbulence-distortion models [3, 16]. Originally developed for bidimensional regime, these approaches effectively characterize the impact of thick airfoil geometries on noise generation.

Alternatively, the one-dimensional spectrum can be obtained using a direct probe measurement in the frequency domain as input, such as the frequency spectra of axial velocity - corresponding to the upwash component with respect to the propeller - obtained by means of HWA in the rotor inflow. These are shown in Fig. 2, which compares the measurements taken far upstream at $z/\mathrm{R} = 1.000$, at an intermediate distance $z/\mathrm{R} = 0.470$, and in the vicinity of the propeller at $z/\mathrm{R} = 0.050$ for 4 radial positions ($y/\mathrm{R} = 0.125$, $y/\mathrm{R} = 0.375$, $y/\mathrm{R} = 0.625$, and $y/\mathrm{R} = 0.875$). A decrease in velocity fluctuations in the low-frequency range, up to $f/\mathrm{BPF} \simeq 0.7$, can be observed as the frequency spectrum of the axial velocity is sampled closer to the rotor plane, especially for the mid-radial positions. This results from the alteration of turbulent structures as they are elongated in the streamtube contraction induced by the propeller, as in the case of the converging section of a wind tunnel [17, 18].

Such a mechanism also impacts sound production, as can be inferred by applying Amiet's model with the HWA spectra as input using Eq. 9. A filtering operation was applied to the velocity spectra sampled at intermediate distances and very close to the rotor plane to remove the tones caused by the blade passage. The resulting noise prediction is shown in Fig. 3, which shows the sound pressure level (SPL) at microphone positions 1 and 8. A clear variation in noise levels is observed in the low-frequency range when the sampling position of the velocity spectrum

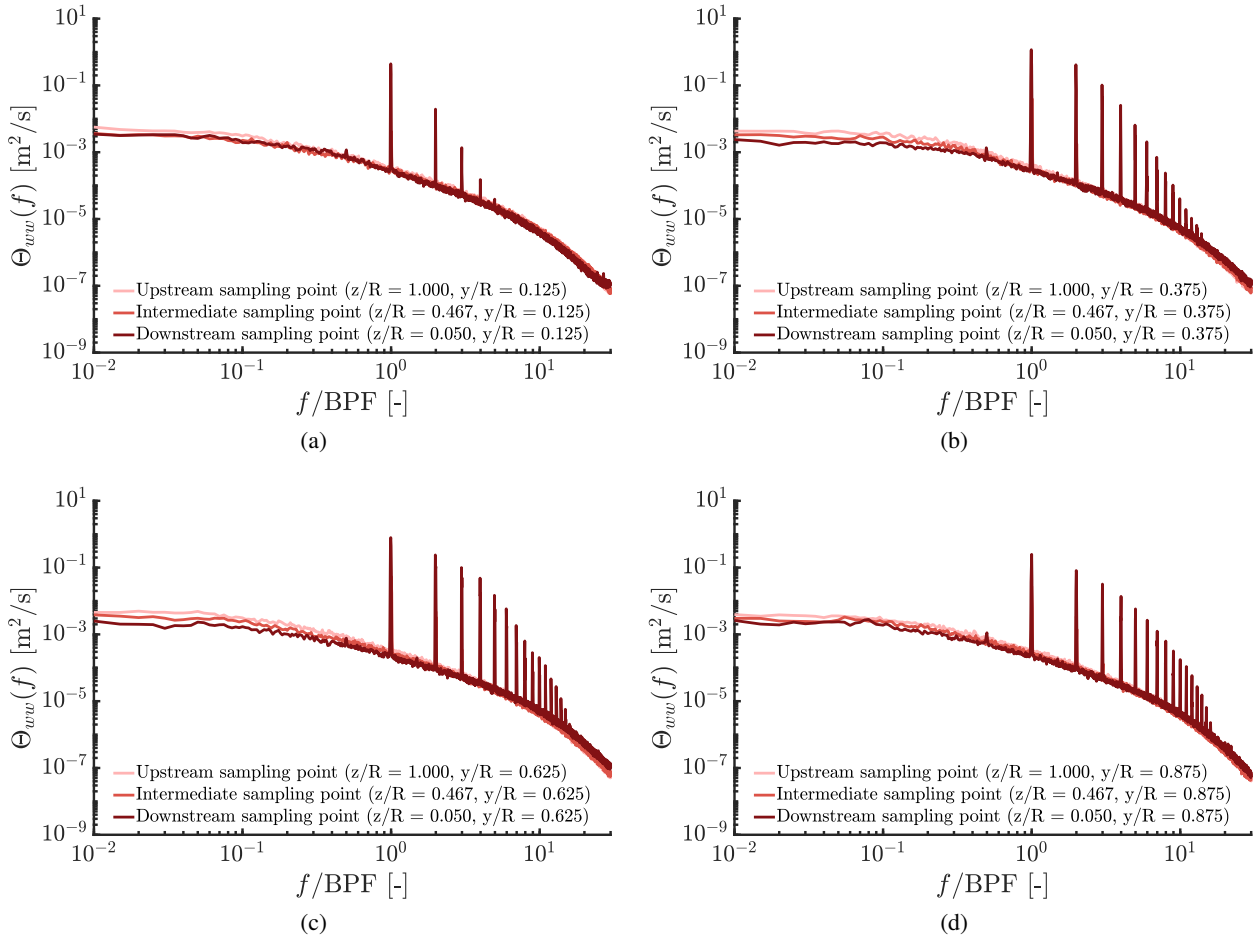


Figure 2: Frequency spectra of the axial velocity at radial positions (a) $y/\mathrm{R} = 0.125$, (b) $y/\mathrm{R} = 0.375$, (c) $y/\mathrm{R} = 0.625$, and (d) $y/\mathrm{R} = 0.875$. The spectra sampled far upstream at $z/\mathrm{R} = 1.000$, at intermediate distance $z/\mathrm{R} = 0.470$, and in the vicinity of the propeller at $z/\mathrm{R} = 0.050$ are compared.

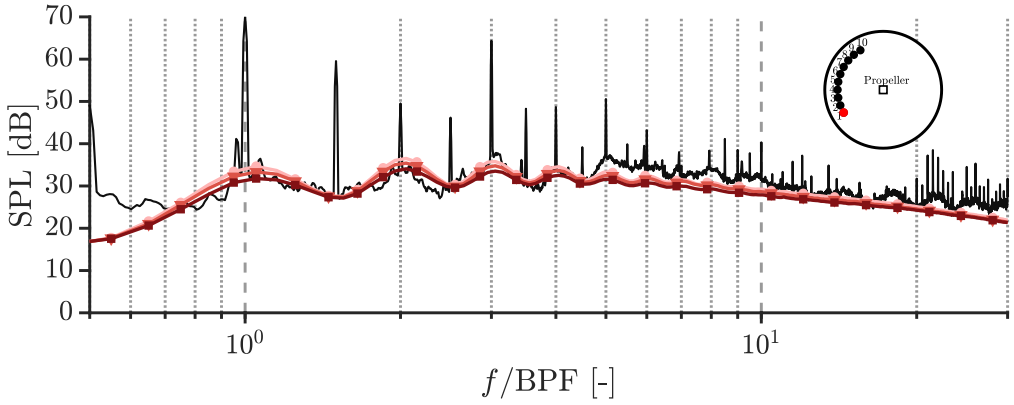
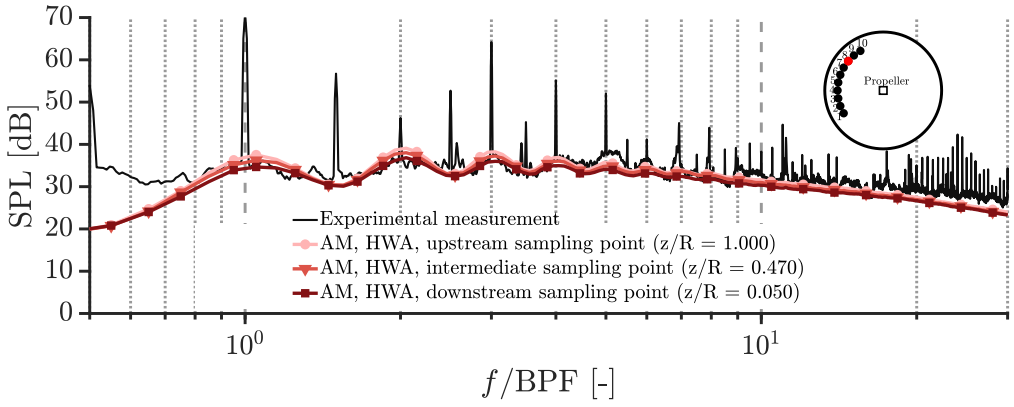


is changed, with higher accuracy achieved by sampling closer to the rotor plane.

4. CONCLUSIONS



An implementation of Amiet's model for turbulence-ingestion noise in rotating systems has been proposed to allow direct flow measurements obtained through hot-wire anemometry to be used as input. This modification was validated using experimental data from a two-bladed propeller interacting with grid-generated turbulence. It was found that the variation in the inflow characteristics as the rotor plane is approached significantly affects the noise generation and prediction. This effect was evaluated by changing the position at which the HWA velocity spectrum, used as input for the model, is sampled. The results confirm that this modification of Amiet's model can effectively assess the impact of inflow conditions and play a crucial role in providing low-fidelity predictions of acoustic performance for configurations with limited availability of flow measurements and modeling.

VIBRO-ACOUSTIC CALIBRATION FOR THE FEM SIMULATION OF A THIN-WALLED DUCT SYSTEM AND FAN HOUSING

Patrick Heidegger[1*] **Felix Czwielong**[2] **Stefan Schoder**[1]
Stefan Becker[2] **Manfred Kaltenbacher**[1]

ABSTRACT

Evaluating the acoustic behavior of a ducted ventilation system poses multiple challenges, e.g., possibly changing cross-sections, a lack of symmetry due to a non-straight layout, or a thin-walled structure acting as a bypass for sound waves traveling to the exterior. These aspects can be tackled via numerical simulation methods, like the finite element method, but uncertainties remain. Examples are the necessity to omit geometrical details for obtaining a computable model, the unknown and often non-ideal behavior of parts like the suspension or connecting joints, and unknown material properties. This proceeding discusses the calibration process for the vibroacoustic simulation of a thin-walled aluminum duct and a centrifugal-fan housing belonging to a high-precision aeroacoustic test rig.

Keywords: *centrifugal fan, finite element method, duct acoustics, model calibration*

1. INTRODUCTION

Centrifugal fans transport air and gases for industrial and civilian applications, e.g., in building ventilation systems. In ducted ventilation systems, the noise produced by the operating fan may propagate over wide distances within the ducts. The noise approaches the exterior field either via duct openings or by transmission through the duct walls (acoustic breakout) [1] and may constitute a source disturbance for potential listeners.

Acoustic breakout may contribute significantly to the total sound emission of the ducted ventilation system, depending on various parameters such as the construction material, the wall thickness, and the duct cross-section [2]. Understanding the vibroacoustic behavior of the duct can thus be essential for classifying the sound emission of a ducted ventilation system.

Numerical simulation methods are widely employed to gain such insights, but obtaining a valid computational model that reflects the actual real-world system poses multiple challenges. Examples are non-symmetric duct layouts, the necessity to omit geometrical details in the meshing process, the unknown and usually non-ideal behavior of mountings or connecting joints, and unknown material properties. For investigating the complex fluid-structure-acoustic interactions occurring in ducted centrifugal fans, a benchmark case for an academic centrifugal fan is being established in a research project. The benchmark case is an extension to the test rig proposed in [3] and covers simulations of the fluid mechanical, structural mechanical, and acoustic fields, accompanied by extensive measurements of all three physical domains.

This work in progress describes the vibroacoustic finite-element (FE) model of the fan housing, the duct walls, and the surrounding air of the benchmark case. Further, two approaches for tuning the simulation models to reference measurements are discussed. One refers to laser-vibrometry scans on parts of the mechanical structure excited by an impact hammer (method 1). The other refers to exterior microphone signals, excited via a voice-coil loudspeaker attached to the duct end (method 2).

2. EXPERIMENTAL SETUP

The housing of the test fan consists of an 8 mm aluminum sheet connected by flanges. The duct system is mainly made of a 2 mm aluminum sheet, connected by flanges or welded joints. It consists of a narrowing transition piece (close duct) mounted on the downstream side of the fan housing and an extension part with a constant cross-section (extended duct). The two duct parts are connected by a flexible connector (canvas sleeve) made of truck tarpaulin, which has the purpose of mitigating the coupling of mechanical vibrations between the parts. The test rig is located in an acoustically treated chamber to reduce the room-acoustic impact on the sound radiation of the structure. A photograph of the setup is depicted in Fig. 1.

A system identification was performed using two types of measurements. Method 1: an impact hammer was used to excite the structure on the front flange of the fan housing in the surface-normal direction. The vibration response was scanned on the front, upper, and lower surfaces of the fan housing and the closed duct by 3D laser-vibrometry. The back-side surfaces could not be scanned due to the limited space. Method 2: An enclosed voice-coil loudspeaker was installed on the end of the extended duct to excite the system, and the sound radiation was recorded in twelve different positions.

3. SIMULATION MODELS

The measured data should be reproduced by numerical simulations. For this purpose, FE models for the interior acoustic field and the mechanical field, as well as the exterior sound field, were set up. Two types of models are required. One high-fidelity model is backed by grid-refinement studies, and one low-fidelity model is used in the procedure of tuning the model parameters to satisfy the reference data. The solutions are computed for the time-harmonic case. The frequency band of interest is 20 Hz - 3000 Hz.

3.1 Method 1

Here, only the mechanical FE system should be calibrated, where the acoustic domain and the extended duct part are omitted. A unit normal force is applied to the same position as the hammer impact of the measurement. The time-harmonic structural vibration can be described by the Fourier-transformed linearized Navier's equation. Finite-element discretization and including a damping model leads to a system of equations of the form

$$\left(\underline{\boldsymbol{K}} - \mathrm{j}\omega\underline{\boldsymbol{C}} + \omega^2\underline{\boldsymbol{M}}\right)\underline{\boldsymbol{u}} = \underline{\boldsymbol{f}}, \tag{1}$$

where $\underline{\boldsymbol{K}}$, $\underline{\boldsymbol{C}}$, and $\underline{\boldsymbol{M}}$ are the stiffness, damping, and mass matrices, respectively. Furthermore, $\underline{\boldsymbol{u}}$ is the solution vector holding the mechanical displacements, $\underline{\boldsymbol{f}}$ the right-hand-side excitation vector, ω the angular frequency, and j the imaginary unit. The boundary conditions for Eqn. (1) are defined on the one hand by the natural (traction) boundary conditions arising due to the finite-element procedure. On the other hand, zero-displacement boundary conditions are set on all mounting positions of the construction and on the connecting surfaces to the omitted duct parts, respecting the direction of the opposing force.

In addition to the boundary conditions, the solution of Eqn. (1) depends on several material properties. Coefficients in the mass matrix are proportional to the material density ρ, while the stiffness-matrix coefficients are related to the elasticity modulus E_m and the Poisson ratio ν_P [4]. For the coefficients of the damping matrix, the most common approach is to exploit a linear combination of the stiffness and mass matrices (Rayleigh damping),

$$\underline{\boldsymbol{C}} = \alpha_R\underline{\boldsymbol{M}} + \beta_R\underline{\boldsymbol{K}}, \tag{2}$$

with the mass- and stiffness-proportional coefficients α_R and β_R, respectively. This leads to five parameters needed

to be specified for an entirely unknown isotropic material: ρ, E_m, ν_P, α_R, and β_R.

The material properties are given to a sufficient extent in the datasheet of the main construction material, aluminum "AlMgSi1-3.2315". However, the exact material properties of the canvas sleeve and the plastic flanges of the sleeve connector are not known. Additionally, all flanges contain screws and are sealed by a thin rubber tape in between, features that are not included in the finite-element mesh. Also, the welding seams connecting the edges of the aluminum plates and the suspension behavior of the mountings might influence the solution.

The model validity at a single frequency can be indicated by considering the normalized root-mean-squared error (RMSE) of the transfer functions over all positions i on the measured surfaces,

$$\mathrm{RMSE}_\omega = \sqrt{\frac{\sum_i (H_{ref,i} - H_{sim,i})^2}{\sum_i H_{ref,i}^2}}, \tag{3}$$

where the transfer function is calculated from the surface-normal velocities divided by the normal excitation force,

$$H_i(\omega) = \frac{\boldsymbol{n}_i \cdot \boldsymbol{v}_i(\omega)}{f_{n,i}(\omega)}. \tag{4}$$

For calculating Eqn. (3) the transfer functions need to be determined on the same positions. Hence, the measured and simulated data needs to be interpolated to the cell centroids of the finite-element grid's outer surfaces and projected into the surface-normal direction beforehand. A k-nearest-neighbor interpolation with inverse-distance weighting was employed for this purpose, using the Python package pyCFS-data [5].

An initial simulation run of the high-fidelity model, where the canvas sleeve material was roughly estimated based on online available data sheets and the rest of the structure set to the properties of aluminum "AlMgSi1-3.2315" revealed an unsatisfactorily high RMSE over the investigated frequency range.

3.2 Method 2

The second validation method is complementary to method 1. Here, the mechanical FE model should produce sufficiently valid results already. The aim of method 2 is to include the left-out duct parts and the air domain to the calibration procedure. Here, the whole vibroacoustic FE model is solved, which leads to significantly higher computational cost. The loudspeaker is modeled as an acoustic normal-velocity boundary condition on the corresponding surface.

The direct-coupled vibroacoustic finite element simulation solves for Eqn. (1) and the system for the acoustic wave equation simultaneously. The system for the homogeneous acoustic wave equation in the time-harmonic case is of the form

$$\left(\underline{\boldsymbol{K}}_a + \omega^2 \underline{\boldsymbol{M}}_a\right) \boldsymbol{p} = \boldsymbol{0}, \tag{5}$$

where $\boldsymbol{p}$ holds the acoustic pressures. The systems are coupled by applying the correct interface conditions to the corresponding domain boundaries in the weak form [4]. Here, for a homogeneous fluid, the terms of the mass matrix are inversely proportional to the squared speed of sound, which can be specified via the mean fluid density ρ_0 and the compression modulus K, so that

$$c_0^2 = \frac{K}{\rho_0}. \tag{6}$$

Similarly to method 1, the model validity can be evaluated via the RMSE between measured and simulated results, Eqn. (3). Here, however, the excitation signal cannot be recorded from the loudspeaker. Hence, the frequency response of the loudspeaker mounted in a large baffle was determined in a separate laser-vibrometry measurement. As there is an expected deviation between the baffled and the duct-mounted frequency response, this topic is part of ongoing investigations.

4. OPTIMIZATION WORKFLOW

The model calibration should be done in three steps. First, evaluate the most relevant material parameters and boundary/interface conditions to vary in the mechanical model. Second, an optimized mechanical model can be determined via method 1. Third, calibration method 2 is used to optimize what is left: the acoustic material parameters and the extended duct.

For determining the most significant regions and material parameters to vary in the mechanical model, their effect should be tested with respect to the RMSE in method 1. For this purpose, the model is separated into multiple regions of different (effective) materials, which are sampled using Latin hypercube sampling and scaled to subjectively estimated bounds, considering available material catalogs and data sheets. For the boundary conditions modeling the suspension behavior of the mountings, spring elements can be applied and varied instead of using fixed boundary conditions.

Due to the initial high dimension of the parameter space and the high computation time required to solve for the mechanical FE model, the method for the significance ranking should be chosen carefully. The Spearman rank coefficient has been employed to evaluate correlations when the feature space is sparse. It is a non-parametric measure that assesses the strength and direction between two ranked variables [6]. Additionally, a Least Absolute Shrinkage and Selection Operator (LASSO) regression could be employed. This method is a form of regression that allows coefficients to shrink to zero. Thus, it is especially useful for variable selection and sparsely sampled data [7]. As a third method, the feature-importance values of a trained random forest (RF) regression model can be used to rank the feature significance. RF regressors are robust to overfitting and inherently handle nonlinear relationships and interactions between variables [8]. Combining these three methods is expected to provide a robust significance estimation, even when applied to sparsely sampled data.

After reducing the feature space to sufficiently few features, optimization can be performed by using the trained RF regressor as a surrogate model and determining the optimized parameter set for a minimum RMSE. The optimization can be done, e.g., by exploiting a stochastic optimization algorithm.

5. CHALLENGES FOR THE METHOD

The major challenge of the optimization is the exceedingly high computational cost of evaluating the FE simulations. Hence, it is not feasible to evaluate the eigenfrequencies of the system via an eigenvalue analysis or to compute the full frequency band of interest in a sufficient resolution. Additionally, the low-fidelity model, which is required to save computation time, deviates significantly from the high-fidelity model for higher frequencies. Further, the measured transfer functions yield insufficiently high noise rates at frequencies below 60 Hz. For the calibration method 2, the unknown excitation of the loudspeaker might impact the result. Finally, the high initial RMSE of the mechanical simulation complicates the determination of significant variables and optimized solutions.

A first attempt to optimize the mechanical FE model was already conducted. Here, only seven frequencies in non-integer ratios ranging between 70 Hz and 780 Hz were simulated. Only material parameters, but no boundary conditions, varied. The procedure was conducted in three rounds of 650 simulation evaluations. The first two rounds were used to reduce the feature space from initially 65 to 13 features. The third round was then used to determine optimized parameters. This first attempt did not lead to satisfactory results.

6. CONCLUSIONS AND OUTLOOK

This proceeding discusses the workflow to calibrate the vibroacoustic system for a thin-walled duct system and the housing of a centrifugal fan. It documents the current state of a work in progress and outlines methods and difficulties for achieving the goal of a calibrated simulation model.

ABSTRACT

Acoustic liners are comprised of small holes in the walls of gas turbine combustors. The flow through them both cools the combustion chamber and absorbs acoustic energy, such that their aeroacoustic, aerodynamic, and heat transfer performance are all important. Their circular holes typically have straight edges, whose length (compared to the radius) plays a significant role in their acoustic behaviour. In the case of "short" holes, where the flow through the hole separates without reattaching within it, there can be an amplification of acoustic energy at certain frequencies, leading to a phenomenon known as "whistling". Previous analyses suggests that heat transfer can either exacerbate or mitigate this undesirable occurrence. Furthermore, altering the inlet or outlet geometry of the holes can eliminate the whistling effect, shifting the acoustic behaviour toward damping. Such geometry changes will also affect the holes' aerodynamic and heat transfer performance. This research numerically investigates optimisation of the hole geometry, considering aeroacoustic, aerodynamic performance and heat transfer performance. Simulations integrate the energy equation into a linearised Navier-Stokes solver and employ Bayesian optimisation to refine the orifice shape based on a cost function that combines acoustic absorption, aerodynamic and heat transfer measures. The results indicate that heat transfer through the orifice surface significantly impacts acoustic performance. To enhance the acoustic absorption, a large downstream chamfer is optimal, while for aerodynamics, a moderate upstream chamfer is best. For optimal heat transfer, or to achieve a combined multi-objective target, a large upstream chamfer is identified as the most effective geometry.

1. INTRODUCTION

Thermoacoustic instability occurs when acoustic waves interact with unsteady heat release during combustion. This phenomenon can lead to significant pressure fluctuations within combustors, negatively impacting operational performance and potentially damaging components [1]. The challenge of thermoacoustic instability is especially pertinent when using decarbonised fuels such as hydrogen, with hydrogen flames being especially sensitive to acoustic disturbances due to their high flame speed. Acoustic dampers, like liners and Helmholtz resonators, are often installed in engines to mitigate these issues. These devices absorb acoustic perturbations and help suppress thermoacoustic instability in various industrial applications, including gas turbines and rocket engines.

Acoustic liners consist of multiple circular holes through which a bias flow passes. When the flow travels through these holes, it can significantly enhance the acoustic absorption and effective bandwidth of a perforated liner. Additionally, its tunable properties can be adjusted by varying the mean flow velocity [2]. The mechanism underpinning the acoustic damping is recognised as the conversion of acoustic energy into vortical energy,

which is then dissipated as heat [3, 4]. Furthermore, the bias flow from the orifice also provides an impingement jet for cooling the combustor surface [5]. Thus, the effect of heat transfer within the hole must be taken into account.

Howe's model [6] has been widely used to predict the acoustic absorption of holes. It assumes that the hole is infinitely thin and that there is a straight vortex-shedding path from the hole downstream. It predicts that an orifice can absorb sound energy, but cannot generate it. Subsequent research [7] indicates that the dimensions of the orifice significantly impact its acoustic behaviour, and the thickness of the orifice must also be taken into account.

A "short" hole, defined as having a length-to-diameter ratio of less than one but not close to infinitesimal, exhibits flow characteristics that can amplify acoustic energy at certain frequencies, a phenomenon referred to as "whistling" [8–10]. This occurs due to the two-way interaction between acoustic waves and vortical disturbances. It presents challenges in engineering design, as it can decrease the acoustic absorption capability and may even amplify acoustic perturbations, potentially leading to structural failures. The above works considered isothermal hole flows: recent research on heat transferring flows suggests that a temperature gradient can alter the acoustic behaviour of a flow, either increasing or decreasing its acoustic absorption ability [11].

For isothermal hole flows, recent theoretical and numerical studies have shown that the acoustic characteristics of short holes are highly sensitive to their geometry [12,13]. Even minor changes in shape can significantly alter the acoustic response, causing a hole's behaviour to shift from amplification to damping [13, 14]. The present study numerically investigates the optimal performance of short holes, considering aeroacoustic, aerodynamic and heat transfer performance.

2. PROBLEM FORMULATION

2.1 Simulation configuration

To evaluate the aeroacoustic performance, a two-step simulation method is employed [15, 16]. In the first step, the mean flow field is obtained using a Reynolds-Averaged Navier-Stokes (RANS) k-ω-SST turbulence model. Next, acoustic perturbations are added to the mean flow field, which is then solved using a linearised Navier-Stokes Equation (LNSE) solver in the frequency domain. This method has been validated against experimental data and direct simulation techniques, demonstrating greater computational efficiency compared to more intensive methods like Large Eddy Simulation (LES) [13]. Additionally, Bayesian optimisation is utilised as a powerful approach for black-box problems with costly evaluations [17, 18]. The high resource cost associated with each evaluation during the optimisation process limits the number of sampling operations.

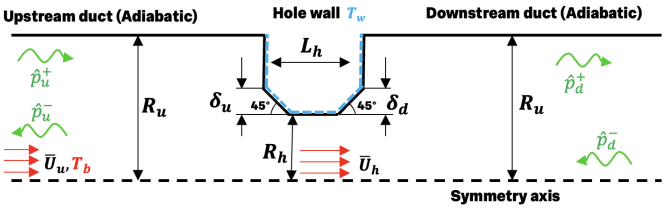

Figure 1. Schematic of the hole configuration, with heat transfer through the wall of the hole.

The configuration studied is a single axisymmetric hole, whose wall is subject to heat transfer. A turbulent mean flow passes through the hole, as illustrated in Figure 1. The radii of the upstream and downstream ducts are R_u, while the radius of the concentric circular hole is R_h. The ratio of the duct radius to the hole radius is $R_u/R_h = 2$. The length of the hole is set to $L_h = 0.66R_h$, which is typical for a short hole. To account for a heat transfer effect, the mean flow is considered to have a temperature of $T_b = 500$ K, while the orifice wall is considered to be at a cooler fixed temperature of $T_w = 300$ K, with the upstream and downstream duct walls considered adiabatic.

A subsonic mean flow with an inlet velocity $\bar{U}_u$ is defined at the inlet boundary as a fully developed turbulent profile. The mean flow is characterised by two dimensionless parameters: the Reynolds number and the Mach number. At the orifice, the Reynolds number is defined as:

$$Re = \frac{R_h \bar{U}_h}{\nu} = 20,000 \tag{1}$$

where $\bar{U}_h$ represents the average flow velocity at the orifice, and ν denotes the kinematic viscosity of the average flow. The Mach number is defined as:

$$M = \frac{\bar{U}_h}{\bar{c}_u} = 0.104 \tag{2}$$

where $\bar{c}_u$ represents the mean speed of sound in the flow. Previous simulations and experimental results [8, 10] suggest a potential for whistling under these flow conditions with a straight hole geometry in adiabatic conditions.

To optimize the geometry, two chamfers are added to the hole edges at both the upstream and downstream sides of the hole. Each edge features a fixed chamfer angle of 45 degrees with variable length, denoted as δ_u for the upstream edge and δ_d for the downstream edge.

The Strouhal number, denoted St, is a dimensionless quantity used to describe normalised frequencies of sound waves. It is defined as:

$$St = fL_h/\bar{U}_h = \frac{\omega}{2\pi} L_h/\bar{U}_h \tag{3}$$

where f is the frequency of the acoustic wave, ω is the angular velocity of the wave and $\bar{U}_h$ represents the mean flow velocity passing through the orifice. In this research, our focus is on Strouhal numbers ranging from 0 to 0.5, as this range is linked to the first whistling mode of the geometry under investigation.

The absorption coefficient, represented as Δ [14, 19, 20], is used as a measure of the aeroacoustic performance of the hole. It is defined as:

$$\Delta = 1 - \frac{|W_u^-| + |W_d^+|}{|W_u^+| + |W_d^-|} \tag{4}$$

where $W_j^{\pm}$ $(j = u, d)$ represents the averaged acoustic energy flux of a plane wave propagating in the positive (+) or negative (-) directions, at the upstream (u) or downstream (d) locations, respectively. It represents the ratio of acoustic energy moving away from the orifice to that entering it. A value of $\Delta = 1$ indicates full absorption, meaning that all incoming energy is absorbed and no acoustic energy escapes the hole. Conversely, $\Delta = 0$ signifies that the acoustic energy remains unchanged by interaction with the hole. If $\Delta < 0$, the acoustic energy is amplified by the presence of the hole, a phenomenon commonly referred to as "whistling".

The aerodynamic characteristics of the orifice are represented by the discharge coefficient, C_d. This is defined as the ratio of the actual discharge to the theoretical discharge from an orifice, expressed as:

$$C_d = \frac{Q_{\text{real}}}{Q_{\text{ideal}}} = \frac{\dot{m}}{A\sqrt{2\rho\Delta P}} \tag{5}$$

where, $\dot{m}$ is the mass flow rate through the hole, A is the cross-sectional area of the hole, ρ is the fluid density, and ΔP is the pressure difference across the hole. Knowing the value of C_d is essential for designing the air distribution system within gas turbine engines [21].

To characterise the heat transfer performance of the hole, we define a normalised power coefficient, denoted P^*, given by:

$$P^* = \frac{P_{wall}}{\rho \bar{U}_h^3 L_{wet}^2} \tag{6}$$

where, P_{wall} represents the power transferred from the orifice wall to the flow. The sign of P_{wall} indicates the direction of heat transfer: a positive value means that the wall loses heat to the flow, while a negative value indicates that the wall absorbs heat from the flow. The denominator, $\rho \bar{U}_h^3 L_{wet}^2$, represents the kinetic power of the flow and has units of Watts. ρ is the mean flow density, $\bar{U}_h$ is the mean flow velocity, and L_{wet} refers to the total length of the orifice wall, which includes the hole length, chamfer length, and radial length in cross-section. The coefficient P^* quantifies the ratio between the energy transferred into the flow and the flow kinetic energy through the hole.

2.2 Numerical Implementation

To evaluate all of the aerodynamic, heat transfer and aeroacoustic performance, a two-step simulation method was employed [15, 16] which decomposed the fluid variables into mean and perturbation terms. The first step involved obtaining the mean turbulent flow field using a compressible Reynolds-Averaged Navier-Stokes (RANS) simulation with the open-source solver OpenFoam (version 11). A steady-state simulation solution was achieved using the SIMPLE algorithm along with the K-Omega SST turbulence model. A fully developed turbulent flow profile was imposed at the inlet boundary, where the inlet pressure was defined as a zero gradient, and the outlet pressure was set to zero gauge pressure. The temperature of the flow inlet is assigned $T = 500$ K. The upstream and downstream walls are set to adiabatic and the hole wall is set to a fixed temperature T_{wall} = 300 K. The upstream, downstream, and wall surfaces were assigned a no-slip condition.

The second step then involved solving for the linearised flow perturbations using a compressible linearised Navier-Stokes Equation (LNSE) solver. This was performed in the frequency domain using a finite element method within the open-source computing framework FEniCS [22], with more detail provided in [23]. Non-reflecting boundary conditions were implemented at both the inlet and outlet boundaries, and acoustic waves of different frequencies were forced from the inlet boundary into the downstream flow. The acoustic response was evaluated using the two-microphone method at the inlet and outlet boundaries to distinguish between the acoustic waves. For the acoustic perturbations, the walls of the hole

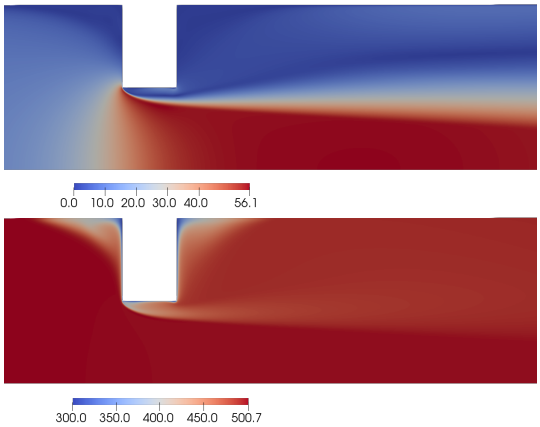

Figure 2. Magnitude of the mean flow velocity field (upper) and temperature field (lower) for the original, unmodified hole geometry with a wall temperature $T_{wall} = 300K$.

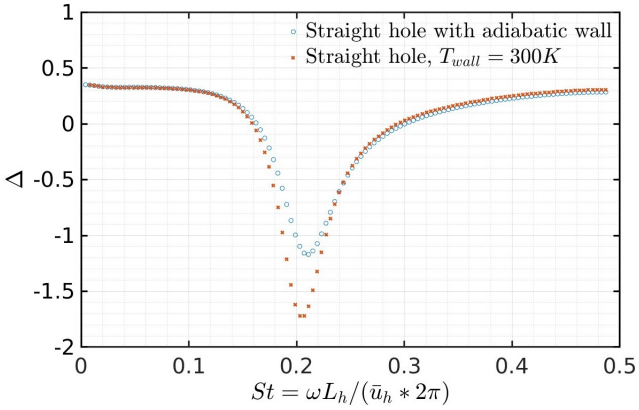

Figure 3. Absorption coefficient Δ of original geometry with an adiabatic wall and with a cooler wall. Negative Δ indicates the acoustic amplifying phenomenon known as "whistling".

were defined as non-slip boundaries with $\hat{\mathbf{u}} = 0$. The upstream and downstream walls were assigned slip boundary conditions $\hat{\mathbf{u}} \cdot \mathbf{n} = 0$ to reduce the computational costs that would be associated with acoustic boundary layers along the upstream and downstream duct walls.

For isothermal flows, the two-step method was validated for straight holes against experimental data and direct simulation techniques, demonstrating accuracy and computational efficiency [13]. For the present work, validation was for the isothermal straight hole geometry, with the $u_d, u_u = 0$, condition validated by comparison to experimental data and numerical simulations [23]. The mean velocity and temperature fields of the straight hole (δ_u, δ_d = 0) with $T_{wall} = 300K$ are shown in Figure 2. This mean flow field is subsequently used in the perturbation solver to determine the acoustic response to an input acoustic wave. The absorption coefficient Δ as a function of frequency St is shown in Figure 3.

2.3 Optimisation configuration

The geometry of a straight hole serves as the baseline for optimizing the aeroacoustic, aerodynamic, and heat transfer performance. With the acoustic performance known to be sensitive to geometry [13], two 45-degree chamfers of variable length were added to the upstream (inlet) and downstream (outlet) edges of the hole to modify the energy amplification. The optimisation algorithm controls the depths of the two chamfers, δ_u,δ_d, while keeping the total length of the hole constant ($\delta_u + \delta_d < L_h$).

For the optimisation procedure, Bayesian optimisation was chosen, this being a powerful approach for black-box problems with costly evaluations [17, 18]. For the present numerical problem, computing the mean flow solution and perturbations at a single frequency takes approximately 500 CPU hours, primarily due to the mean flow simulation. Bayesian optimisation is performed using a modified version of the scikit-optimize library that includes a constraint function [24] [25]. The acquisition function is set to the probability of improvement (EI), and the acquisition optimizer function is configured as "lbfgs." The optimisation problem is formulated as follows:

$$\arg\max_{\delta_u, \delta_d} f(\delta_u, \delta_d) \tag{7}$$

subject to $\delta_u \in [0, L_h]$, $\delta_d \in [0, L_h]$ and $\delta_u + \delta_d \leq L_h$ to maintain the geometry's topology. 45 initial sampling points, selected using the grid method, were computed in advance to initiate the optimisation. The optimisation was performed for 5 steps to provide a fast indication of the potential optimal geometry.

The acoustic absorption coefficient, Δ, of a straight hole with and without heat transfer is shown in Figure 3. Δ shows acoustic energy amplification in the frequency range $0.16 < St < 0.30$, with the most pronounced whistling effect occurring at $St = 0.20$, for which Δ reaches its minimum value of -1.72. The presence of a hot bias flow and heat transfer increased the maximum nega-

tive value of Δ; this is consistent with recent research [11] suggesting that heat transfer out of a flow can increase Δ and vice versa.

In this study, the acoustic absorption coefficient at frequency $St = 0.20$, denoted $\Delta_{st=0.20}$, is identified as the aeroacoustic parameter that needs optimisation. The aerodynamic performance is represented by the discharge coefficient, C_d, and the heat transfer performance by the normalised heat transfer power, $P*$, both of which depend only on the mean flow solution. The values of these three performance parameters for the straight (unmodified) hole are summarised in Table 1.

Table 1. Aeroacoustic, aerodynamic and heat transfer performance of unmodified straight hole geometry.

Geometry	$\Delta_{st=0.20}$	C_d	$\lvert P^* \rvert$
$\delta_u, \delta_d = 0$	-1.72	0.66	0.77

In order to perform an optimisation which accounts for aeroacoustic, aerodynamic and heat transfer performance, an objective function f is defined which combines all three using weighting factors α, β and γ:

$$f = \alpha\,\Delta_{st=0.20} + \beta\,C_d + \gamma|P^*| \tag{8}$$

By altering these weight factors such that they sum to unity, optimal geometries can be obtained which differently prioritise the three performances.

3. RESULTS

3.1 Optimisation of only the acoustic absorption coefficient $\Delta_{st=0.20}$

When optimisation is performed for solely the aeroacoustic performance (i.e. $\alpha = 1$, $\beta = 0$, $\gamma = 0$), the results in Figure 4 show that an orifice with a large downstream chamfer would provide the best aeroacoustic absorption performance. The mechanism of the improved performance is likely to be associated with the downstream edge being moved further from the vortex shedding path, weakening the generation of acoustic waves at the hole opening.

3.2 Optimisation of only the aerodynamic performance, C_d

When optimisation is performed for solely the aerodynamic performance (i.e. $\alpha = 0$, $\beta = 1$, $\gamma = 0$),

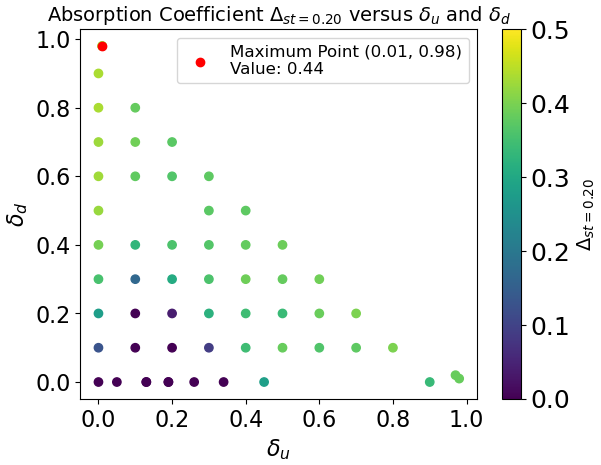

Figure 4. Acoustic absorption coefficient $\Delta_{st=0.20}$ versus δ_u and δ_d. An optimised value of $\Delta_{st=0.20} = 0.44$ was found for which $\delta_u = 0.01L_h$ and $\delta_d = 0.98L_h$.

the optimisation results in Figure 5 show that a moderate upstream chamfer of size $\delta_u = 0.19L_h$ and no downstream chamfer($\delta_d = 0$) is best. The presence of an upstream chamfer reduces flow separation at the upstream edge, which ultimately helps to alleviate the pressure drop across the hole.

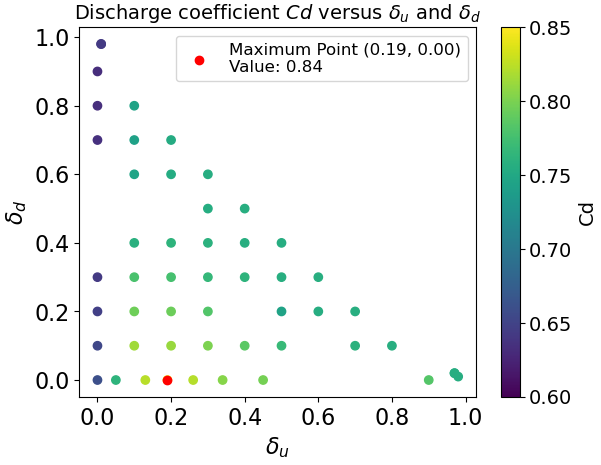

Figure 5. Discharge coefficient C_d versus δ_u and δ_d. An optimised value of $C_d = 0.84$, was found for which $\delta_u = 0.19L_h$ and $\delta_d = 0.0$.

3.3 Optimisation of only the heat transfer performance, $|P*|$

When optimisation is performed for solely the heat transfer performance (i.e. $\alpha = 0$, $\beta = 0$, $\gamma = 1$), the optimisation results in Figure 6 show that a large upstream chamfer provides the highest heat transfer. This outcome can be attributed to the larger contact area created with the flow upstream, which enhances heat transfer.

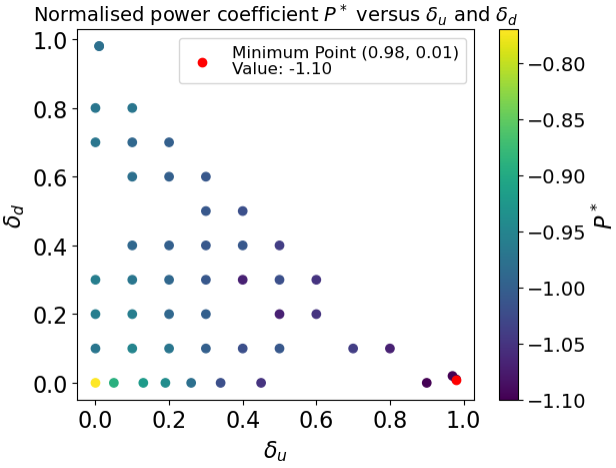

Figure 6. Normalised power coefficient P^* versus δ_u and δ_d, with the highest heat transfer performance obtained for $\delta_u = 0.98L_h, \delta_d = 0.01L_h$

3.4 Optimisation for combined objective function

For the multi-objective optimisation, the combined objective function in Equation 8, is applied using weight factors of $\alpha = 0.33$, $\beta = 0.33$, and $\gamma = 0.33$. With this combination of weight factors, the optimisation process returns an optimal geometry characterised by a large upstream chamfer, consistent with the results of P^*. This results in a high heat transfer power transfer coefficient while causing only minor reductions (compared to the best achievable) in $\Delta_{st=0.20}$ and C_d. A summary of these geometries is presented in Table 2. The aeroacoustic performance of the optimized geometry is illustrated in Figure 3, while the mean flow fields are depicted in Figure 2.

4. CONCLUSION

The present work has presented a two-step simulation method for simultaneously characterising the aeroacous-

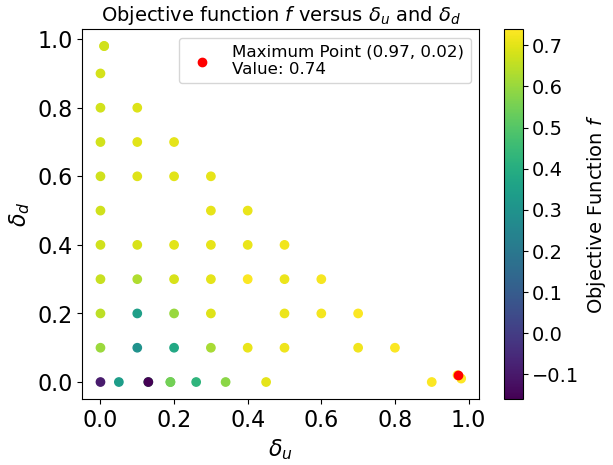

Figure 7. The combined cost function f, which accounts for aeroacoustic, aerodynamic, and heat transfer performance, δ_u and δ_d.

Table 2. Summary of the performance of the original and optimised geometries.

Geometry(δ_u, δ_d)	$\Delta_{st=0.20}$	C_d	$\lvert P^* \rvert$	f
Straight(0,0)	-1.72	0.66	0.77	-0.09
$(0.01L_h, 0.98L_h)$	0.43	0.64	0.98	0.68
$(0.19L_h, 0)$	-0.17	0.86	0.97	0.55
$(0.98L_h, 0.01L_h)$	0.38	0 .76	1.10	0.74

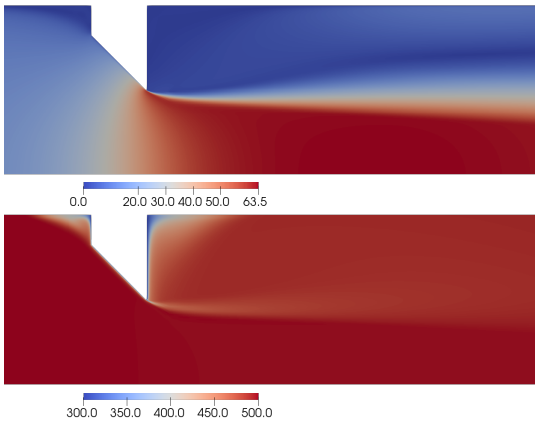

Figure 9. Magnitude of the mean flow velocity field (upper) and temperature field (lower) for the optimised hole.

tic, aerodynamic and heat transfer performance of a hole flow with heat transfer. Heat transfer through the wall of the hole is seen to accentuate the acoustic whistling effect in the absence of hole geometry changes. A Bayesian optimisation technique for optimising the chamfer lengths of 45 degree chamfers at both the hole inlet and hole outlet was then employed.

The optimisation can target the individual aeroacoustic, aerodynamic, and heat transfer performances resulting in three distinct optimal geometries. It was also shown that it is possible to apply a combined objective function which incorporates different combinations of the above three performance measures. The optimal geometry then obtained involves a large upstream chamfer which ensures good heat transfer, aerodynamic and aeroacoustic performance.

This work thus represents a step in being able to design the shapes of orifices according to acoustic, aerodynamic and heat transfer priorities, with finer geometry control being possible through additive manufacturing.

ABSTRACT

The acoustic source we study is a vortex whistle composed of three parts of geometry and dimension similar to that of a bottle. The device consists of a cylindrical cavity with a circular base, a single fluid inlet tangential to the base of the cylinder and a cylindrical fluid outlet downstream which is a cylinder with a radius smaller than that of the cavity. The fluid (here air) entering the cavity generates a circular motion in the cavity and in the downstream cylinder. This device produces a sound with a dominant frequency. The frequency of the sound is controlled by the fluid flow rate. The characterization of the fluid vortex is performed in air by stereo-PIV (Particle Image Velocimetry), a laser optical diagnostics, resolved temporally and spatially, combined with acoustic measurements by microphone. In the exit section of the whistle, the center of the vortex circulates with a precession motion. From a decomposition into eigenmodes of the velocity field, the contributions to this motion are specified. The directivity diagram is established by calculating the Rayleigh integral based on the measured velocity fluctuations. The coupling between the acoustic field and the flow dynamics is thus highlighted and analyzed.

1. INTRODUCTION

The Vortex Whistle (Vonnegut, 1954 [1]) is a device generating sound by rotating a vortex within a cylindrical section with a tangential inlet. Vonnegut was the first to explain that the sound frequency generated at the outlet of the device is proportional to the fluid flow rate. At the outlet of the device, the fluid movement becomes unstable and generates a vortex agitated by a precessional movement. This instability is the cause of the sound emitted and an empirical formula in which the sound frequency varies according to the inlet-outlet pressure gradient and the dimensions of the device was proposed. His experiments showed that the Vortex Whistle works equally well in air and water. In 1963, Chanaud [2] sought to demonstrate the relationship between the vortex generated by instability and the sound frequency. His experimental work allowed him to explain that the sound frequency is the same as the frequency of the vortex's precessional motion at the device's outlet. Both Vonnegut and Chanaud mentioned the importance of considering friction losses in order to establish a right relation between frequency and flow rate, this being taken into account through a fitting empirical parameter in the law proposed by Vonnegut.
In the 2000s, applications for the Vortex Whistle emerged. For example, in 2013, Di et al. [3] suggested using it as a flow meter, given that frequency varies linearly with flow rate. In 2016, the device began to be used as a spirometer for medical applications [4].
In 2020, Kristiansen et al. [5] proposed a model based on the conservation of angular momentum, including friction losses. This model predicts the frequency as a function of the flow rate and device dimensions. The agreement was obtained with experiments in air and water for two different Vortex Whistles, respectively. The vortex precession at the outlet section of the Whistle was quantified by velocity

measurements by PIV ($2D-2C$) associated to acoustics measurements by microphone in air. A technique of phase averaging was performed in order to reconstruct the temporal dynamic of the vortex since the PIV was performed at 10 Hz whereas the characteristic flow frequency is in the range $200-1500Hz$. Their experiments allow them to characterize the acoustic radiation of the source, which they find similar to that of a dipole, confirming the previous result of Chanaud [2].
The objective of the present study is to identify the main contribution of the flow dynamics to sound generation. The detailed characterization of the vortex at the Vortex Whistle outlet is performed in air by fast stereo-PIV (Particle Image Velocimetry, $2D-3C$), a laser optical diagnostic, resolved temporally and spatially, combined with acoustic measurements by microphone. The experimental setup is described in Section 2. The velocity and acoustics results are analyzed in Section 3. By considering the helicoidal movement in the two cylinders constituting the Vortex Whistle, some improvements of the model initially developed in [5] are proposed. A Proper Orthogonal Decomposition is performed on the velocity field in order to highlight the cyclic movement associated to the dominant frequency for a given flow rate (Section 4).

2. EXPERIMENTAL SETUP

The geometry of the Vortex Whistle is presented in (Fig. 1). The main core of the Vortex Whistle with air tangential inlet is in aluminum, it is quite long compared to those studied by [2] and [5] with a length-to-diameter ratio of $L_c/D_c = 3.5$ (Tab. 1). For the nozzle, designed in plexiglass, this ratio is $L_o/D_o = 3.0$. The sudden reduction between these two parts is characterized by a diameter ratio $D_c/D_o = 2.5$. The surface of the internal wall is considered smooth.

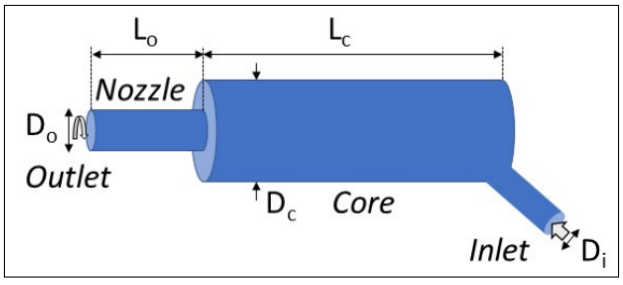

Figure 1. Geometry of the Vortex Whistle.

Table 1. Dimensions of the Vortex Whistle.

Geometry	Dimension
Inlet diameter, $D_i = 2R_i$	$14mm$
Outlet diameter, $D_o = 2R_o$	$20mm$
Oulet pipe length , L_o	$60mm$
Core diameter, $D_c = 2R_c$	$50mm$
Core length, L_c	$175mm$

Stereo-PIV images are acquired by a Dantec Dynamics system (RapiDO) that includes two T4040 SpeedSense Phantom high-speed cameras (2560×1664 $pixels$, 12 bits), and a double pulsed laser (Fig. 2). The pulsed laser is a Photonics laser (527nm, $2 \times 30mJ$ at a nominal 1kHz repetition rate). The DynamicStudio software controls synchronization of image acquisition. A laser sheet generator constituted of several suited lenses is installed at the end of the optical arm so that a flow field of $75.5 \times 49mm^2$ is illuminated. Stereo-PIV needs a depth calibration in order to correctly measure the U_z velocity component. This is performed with five calibration images of a motorized target positioned at $Z = 200\mu m$, $100\mu m$ and $0\mu m$, the laser sheet center. PIV images are acquired at a $4kHz$ rate and the time delay between two associated pulses is $5\mu s$. The flow is seeded by olive oil droplets of $2-3\mu m$ diameter introduced in the air circuit upstream the inlet of the Vortex Whistle.

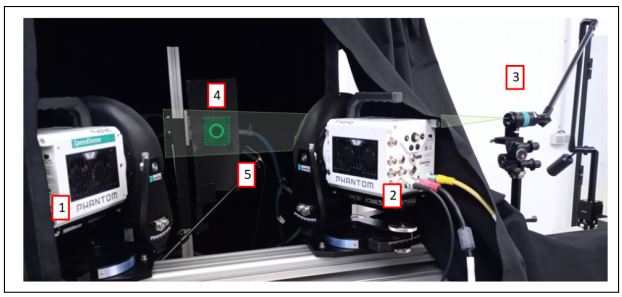

Figure 2. Set up of the nozzle outlet (4) flow investigation by high-speed stereo-PIV including two cameras (1 and 2), a laser sheet generator (3) and a microphone (5).

The spatial resolution is $\delta_x = \delta_y = 472\mu m$. The (O, X, Y, Z) coordinate system is centered on the exit cross-section on the nozzle where the investigation is fo-

cused. The three instantaneous components ($3C$) of velocity (U_x, U_y, U_z) are measured on the plane ($2D$) $Z = 0$ specified in (Fig. 2) by a green dotted line square. The velocity components in polar coordinates are (U_r, U_θ, U_z). 4000 instantaneous velocity fields are acquired for each flow conditions during $1s$. In the same time of PIV measurements, the acoustic pressure is measured by a microphone (1/4", GRAS) located at $(83mm, -63mm, 60mm)$ during $10s$ at a $25.6kHz$ sample frequency. Statistics and other post-processing on velocity fields and acoustic signals are performed by homemade codes developed in Matlab.

3. FLOW CHARACTERIZATION

The whistling is clearly detected by spectral analysis of acoustic pressure measured by microphone in the range $135 - 1200Hz$. Five flow conditions with velocity-pressure measurements are performed for the whistling frequencies $F_w = 135$, 410, 520, 620, 720 Hz. The flow rates q associated to these frequencies F_w are deduced from integration of the U_z velocity component over the exit cross-section of the nozzle. A summary of the flow conditions is given in Tab. 2.

Table 2. Flow conditions. $\tilde{U} = q/(\pi R_o^2)$, $\omega_o = 2\pi F_w$, $\overline{U}_z^* = \overline{U}_{z,max}/\tilde{U}$, $\overline{U}_\theta^* = \overline{U}_{\theta,max}/(\omega_o R_o)$, $S_w = \overline{U}_{\theta,max}/\overline{U}_{z,max}$.

F_w	$\tilde{U}$	$\omega_o R_o$	$\overline{U}_z^*$	$\overline{U}_\theta^*$	S_w
(Hz)	(m/s)	(m/s)			
135	2.15	3.92	1.48	0.474	0.583
410	12.5	25.8	1.58	0.523	0.682
520	15.3	32.8	1.59	0.500	0.674
620	18.0	39.0	1.57	0.500	0.689
720	19.8	45.2	1.58	0.473	0.684

Fig. 3 presents the mean velocity field at the section $Z = 0$. The rotating movement is in agreement with a tangential inlet located in the quarter ($X > 0, Y < 0$). In the outer region, for radius $R > 10mm$, the velocity vectors orientations highlight the external flow entrainment. This external part of the flow is not considered for the flow rate calculation.

The $\overline{U}_\theta$ (shown in Fig.4) and $\overline{U}_z$ mean velocity components are not maximum in the same regions of the flow,

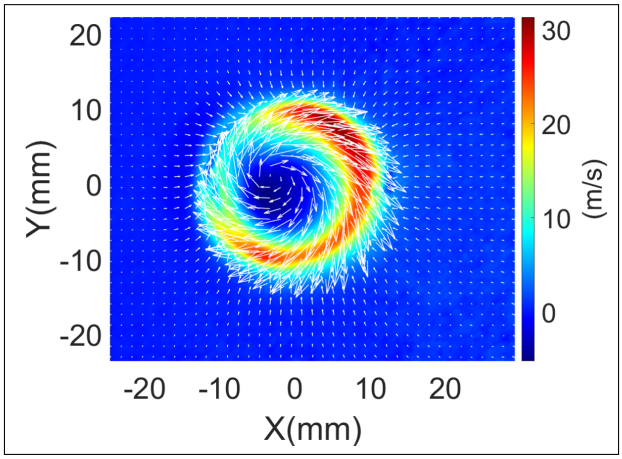

Figure 3. Mean velocity for $F_w = 720Hz$: ($\overline{U}_r$, $\overline{U}_{theta}$) vectors and $\overline{U}_z$ contours (see colorbar).

their maximum occur on rings centered on a radius of $8.3mm$ and $9.5mm$, respectively and independently of the flow conditions investigated here by PIV. In the quarter ($X < 0$, $Y > 0$) where $\overline{U}_z$ presents a minimum on its ring, it corresponds to a local maximum $\overline{U}_{\theta,max}$ of $\overline{U}_\theta$. The local maximum of $\overline{U}_z$ is named $\overline{U}_{z,max}$. Thus, the averaged velocity field is not axisymmetric. The similar non-dimensionalized values of $\overline{U}_\theta^*$ and $\overline{U}_z^*$ and of the swirl number S_w gathered in Tab. 2 for different F_w suggest a regime in similarity in the range $410 - 720Hz$.

Negative values of $\overline{U}_z$ in the center of this ring are significative of a flow reverse inside the nozzle due to the high level of swirl. The mean vortex center observed in Fig. 3 is in the region of negative $\overline{U}_z$. However, this mean position must be considered carefully, since actually, the instantaneous vortex follows a precession movement so that it is never at this position as shown in Fig. 5. The mean trajectory of the vortex center is shifted from the nozzle cross-section center and is located in the quarter ($X < 0, Y > 0$).

Thanks to the high speed PIV system, the instantaneous three velocity components are acquired at a sufficient high frequency in order to allow a right spectral analysis. Fig. 6 highlights the presence of the same predominant frequency in the velocity component signals extracted at the position ($X = 5mm$, $Y = 5mm$, $Z = 0mm$) than in the acoustic pressure signal measured by microphone according to the frequency resolution of 3.91 Hz for velocity and 1.56 Hz for acoustics. This

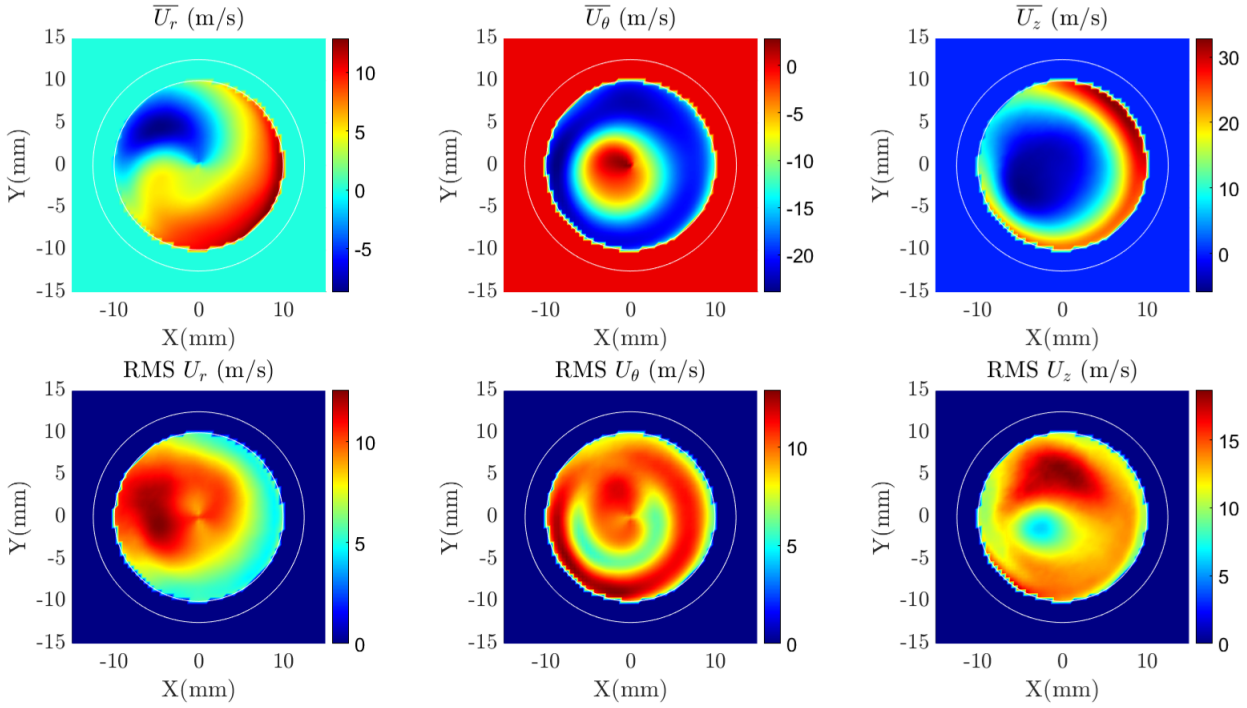

Figure 4. Velocity statistics in the exit cross-section of the nozzle from stereo-PIV measurements. Mean velocity components $\overline{(.)}$ (up) and velocity root mean square (RMS, down) for $F_w = 720Hz$.

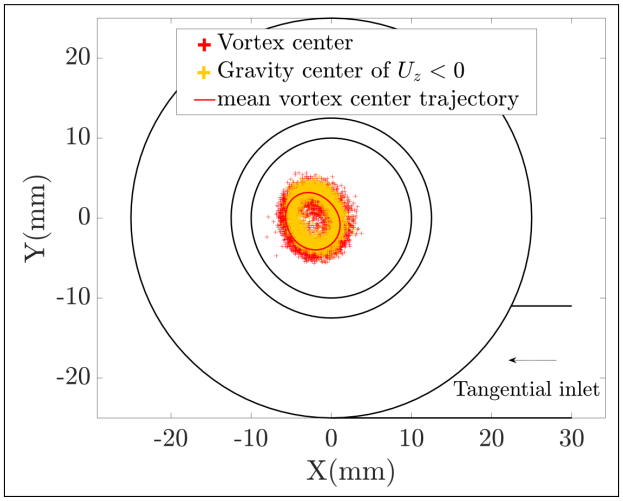

Figure 5. Instantaneous vortex and negative U_z region center positions detected from the 4000 PIV fields for $F_w = 720Hz$.

concordance is true in the whole velocity field and for all investigated flow rates.

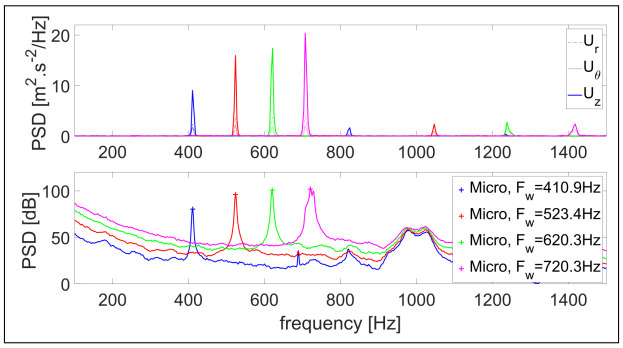

Figure 6. Spectral analyses of velocity components extracted at ($X_e = 5mm$, $Y_e = 5mm$, $Z_e = 0mm$) and pressure for different flow rates.

The linear dependency between flow rate q and whistling frequency F_w is confirmed as usually observed

for Vortex Whistle ([1, 2, 5]) as shown in Fig. 7. The model proposed by Kristiansen et al. [5] is compared with the present experimental results. Their relation between the whistling frequency F_w and the volume flow rate q was deduced from the balance of the kinetic momentum. The expression obtained without wall friction was :

$$F_w = \frac{q}{(\pi R_i R_o)^2}\,(R_c - R_i) \tag{1}$$

When considering the wall friction along the L_c and L_o lengths of the core and the nozzle respectively, the expression becomes:

$$F_w = q\frac{\sqrt{1 + 16\dfrac{(C_{F_c}L_c + C_{F_o}L_o)\,(R_c - R_i)}{R_i^2}} - 1}{8\pi^2\,(C_{F_c}L_c + C_{F_o}L_o)\,R_o^2} \tag{2}$$

where C_{F_c} and C_{F_o} are the friction coefficients in the core and the nozzle.

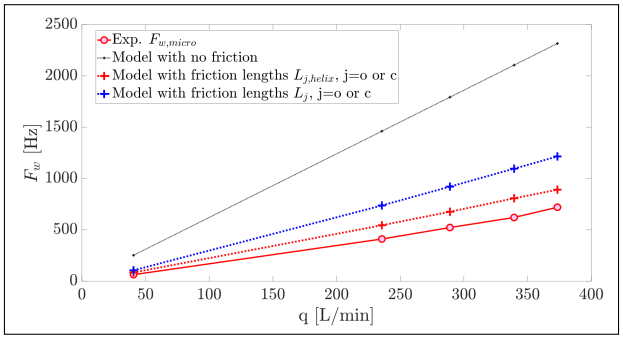

Figure 7. Whistling frequency vs flow rate. Adjustment of the model [5] by considering an elongation of friction length due to the helical movement inside the core and the nozzle.

While the model was in a good agreement with the results obtained by Kristiansen et al. [5] for Vortex Whistle with $L_c/D_c = 1.76$ and 1.94, the agreement is not so good with the present experimental results because the present frequencies are lower than those expected by the original model. The decrease of whistling frequencies for similar flow rate but with larger ratio length/diameter was also observed by Chanaud when varying L_o/D_o while keeping the same L_c/D_c. In the present experiment, the ratio $L_o/D_o = 3$ is smaller than those of the vortex whistles of Kristiansen et al. [5] where $L_o/D_o = 3.42$ and 3.85 while the D_i/D_c ratio are quite similar: respectively 0.28 here, and 0.30 and 0.26 for [5]. Thus, the lower experimental frequencies is not due to the variation of the parameter L_o/D_o, but probably to the larger ratio L_c/D_c = 3.5 for the present experiment. It means that friction is probably not sufficiently taken into account in the model. A proposed improvment of the model is to consider that a fluid particle will follow a helical trajectory both in the core and the nozzle, so that the friction length L_j ($j = o$ or c) to be considered in the model will become the length of the helix in each part of the Vortex Whistle by considering the translation velocity $q/\pi R_j^2$ and the rotation velocity $\omega_j R_j$:

$$L_{j,helix} = \frac{\pi R_j^2 L_j \sqrt{(\frac{q}{\pi R_j^2})^2 + \omega_j^2 R_j^2}}{q} \tag{3}$$

Results presented in Fig. 7 show a better agreement with this proposed model, but some differences remain, that can not be fully solved with this simple model.

4. FLOW FOOTPRINT ON ACOUSTICS

4.1 POD of the velocity field

In order to typify the effect of flow fluctuations on acoustics, the coherent structures that contribute to the dynamics are sought. The POD (Proper Orthogonal Decomposition) [6] is a right tool for the analysis of the fluctuating part of the velocity field. The POD principle is based on the decomposition on a basis of eigen modes sorted by their energetic contribution to the quantity of interest, here the velocity components. The decomposition is performed on 4000 uncorrelated snapshots of the three velocity components (U_r, U_θ, U_z), which determines a number of modes equal to the number of realizations. The interest is here focused on the ten first energetic modes.

Fig. 8 illustrates the cumulative energy for modes 1 to n when non-dimensionalized by the cumulative energy for mode 1 up to mode 10. When considering the cumulative energy of the two first modes (condition named POD [1 2] in Fig. 9 for e.g.), almost 50% of the cumulative energy of the 10 first modes (POD [1 ... 10]) is reached.

A spectral analysis made on the U_z signal extracted at the position ($X_e = 5mm$, $Y_e = 5mm$, $Z_e = 0mm$) from the PIV field measured for $F_w = 720Hz$ is presented in Fig. 9. The power spectral density (PSD) is compared with different POD reconstructed signals

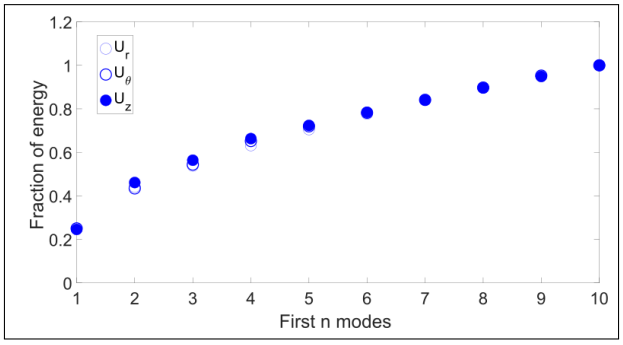

Figure 8. Fraction of energy captured by POD according to the ($n \leq 10$) considered modes for $F_w = 720Hz$.

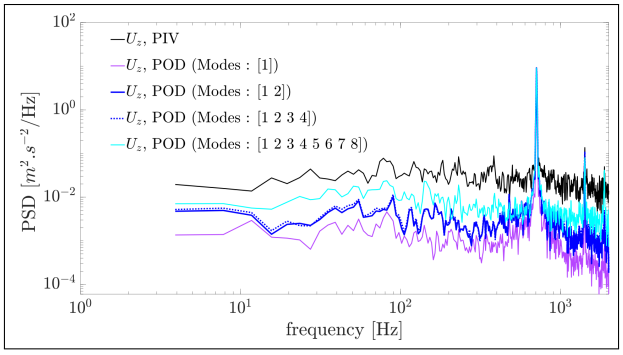

Figure 9. Spectral analysis of PIV and POD velocity signals at the position ($X_e = 5mm$, $Y_e = 5mm$, $Z_e = 0mm$) for $F_w = 720Hz$.

of U_z including only the first mode (POD [1]) up to eight modes ([POD [1...8]). For all the reconstructed POD signals, the predominant frequency F_w is preserved while the noise energy level is reduced. The energy related to the predominant peak is also respected since $PSD = 9.29m^2/s^2/Hz$ for the PIV and 9.16 and $9.11m^2/s^2/Hz$ for POD [1 2] and POD [1 2 3 4], respectively. Note that for POD [1] the PSD is only $3.88m^2/s^2/Hz$. Since no great difference in energy level is observed between the POD reconstructed PSD for POD [1 2] and POD [1 2 3 4], the rest of the following POD analyses will be based on the two first modes.

An example of velocity time series reconstitution by POD [1 2] at the position (X_e, Y_e, Z_e) is given in Fig. 10 (right) for the three velocity components (U_r, U_θ, U_z). The harmonic behaviour of the velocity signals is highlighted by POD while the phase is respected. In the left part of the figure is presented an instantaneous velocity field for (U_r, U_θ) where only one vector out of three is plotted for the sake of readability. The vector field obtained from POD is obviously smoothed and the instantaneous position of the vortex center is clearly detected.

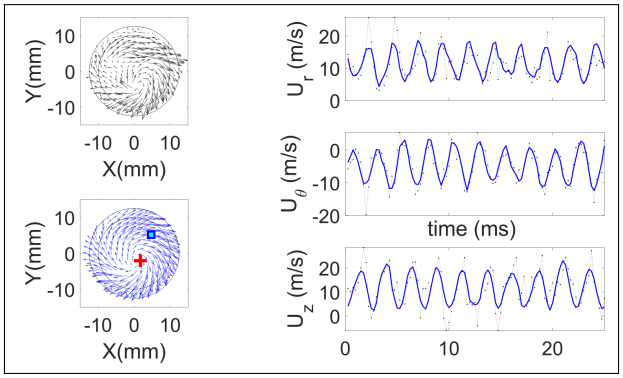

Figure 10. Comparison between PIV (black) measurements and POD analysis (blue) with the two first modes [1 2] for $F_w = 410Hz$. Instantaneous velocity vector (U_r,U_θ) at the exit cross-section of the nozzle (left). Extracted velocity signals (U_r, U_θ, U_z) at the position ($X_e = 5mm$, $Y_e = 5mm$, $Z_e = 0mm$) located by a blue square on the left figure (right). The red cross indicates the vortex center.

4.2 Directivity diagram

Since the signal $U_z(X, Y, Z, t = time)$ is available in the whole exit cross-section of the nozzle, the next step is to check if it is possible to estimate the acoustic pressure level and the directivity diagram from the POD [1 2] reconstruction. This estimation is performed by Rayleigh integral applied in the time domain, that can be written:

$$P(M,t) = \rho \iint_{\Sigma} \frac{1}{2\pi r_{MS}} \frac{dv_n(S, t - \frac{r_{MS}}{c})}{dt} dS \qquad (4)$$

where c is the sound speed, Σ is the source area and $v_n = U_z$ is the fluctuating velocity component normal to the exit cross-section of the nozzle. M is an observation point situated at a radius R_M from the center O of the nozzle exit section and at the angle ϕ where the contribution to the directivity diagram will be calculated. Fig. 11 illustrates the geometry for this pressure model. The red

radius is the location of the observation points M. dS (white square) is a surface element centered on the source point S located on the exit cross-section of the nozzle colored in blue in Fig. 11. The Rayleigh integral is calculated for $R_M = 0.5m$ using POD [1 2] reconstruction of U_z for $F_w = 410Hz$ and $720Hz$.

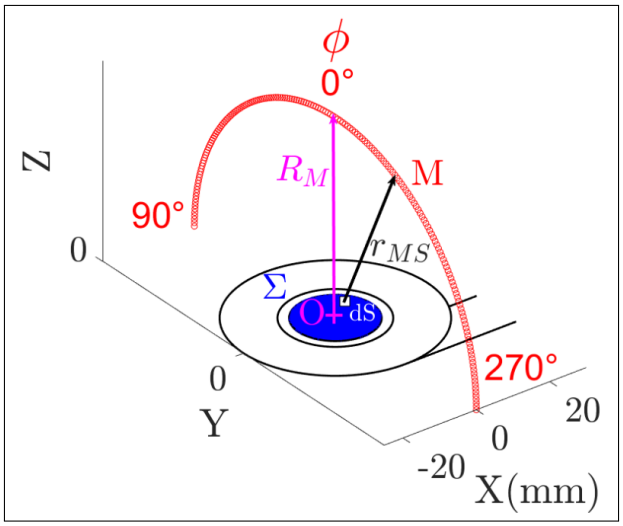

Figure 11. Angular positions of microphone (in red) for diagram directivity measurements.

The results are compared to measurements made at the same distance R_M with the microphone previously described (See Section 2) for three whistling frequencies $F_w = 606, 700$ and $725Hz$. For this experiment, the Vortex Whistle exit cross-section was installed flush with a rigid panel of large dimensions $1.5m \times 2.5m$. The results are presented as a directivity diagram in Fig. 12. The values of sound pressure level are overestimated by Rayleigh integral calculated with POD modes comparatively to experiments and no minimum is obtained at ϕ=0°. Contrariwise, such minimum of radiation at 0° angle, the main outlet flow direction, and larger values towards 90° and 270° are observed with experimental data, it could be associated to a dipole radiation as previously suggested by [2] and [5]. However the radiation is not symmetric against angles, a larger radiation is detected for the three experimental frequencies F_w in the angle range $300 - 330$, this is probably to be associated to the asymmetry of the real flow. Another proposed approach is to modeled the $U_z(R, \theta, z, t)$ by a sinus whose amplitude $A(R)$ is the radial profile of the experimental U_z root mean square deduced from PIV statistics post-process (See Fig.4), multiplied by $\sqrt{2}$. The proposed formulation is :

$$U_z(R, \theta, z, t) = A(R)\ sin(\omega_o\, t + \theta) \qquad (5)$$

The Rayleigh integral is calculated with this sinus model for $F_w = 720Hz$. A comparison between dU_z/dt calculated from POD modes or this sinus model is presented in Fig. 12 Due the symmetry of the sinus model, the typical radiation of a dipole is obviously obtained, but it is interesting to note that the maximum sound pressure levels are in good agreement with the experimental results as seen in the angle range 30-180°.

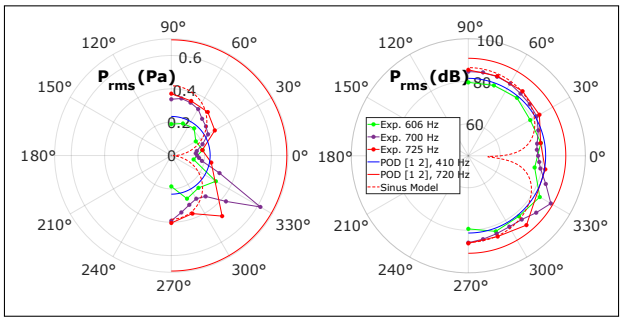

Figure 12. Directivity diagram in Pa (left) and in dB (right). The angle ϕ=0° corresponds to measurements on the axis on the outflow side.

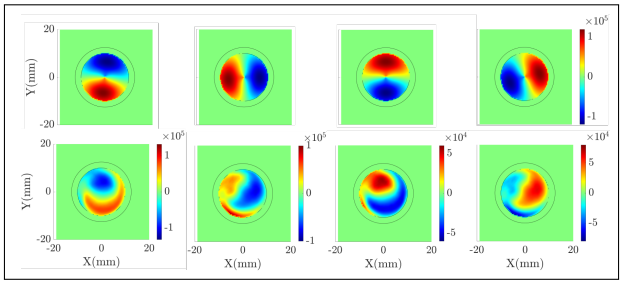

Figure 13. dU_z/dt with U_z estimated by sinus model (up) and POD (modes [1 2]) (down) for $F_w = 720Hz$ at four typical instants.

In order to check if acoustic radiation of the present experimental source embraces other characteristics of a dipole, one analyses the SPL level according to the whistling frequency. By considering that the sound power level Lw at distance R_S from the sound source, located in free field positioned over a rigid plane, can approximately

related to sound pressure level (SPL) by the relation:

$$Lw = SPL + 10log10(\frac{2\pi R_M^2}{S_0}) \quad (6)$$

where $S_0 = 1m^2$ and R_M is the radius of a large hemisphere enclosing the source, a study of the SPL will give some information on Lw. Fig. 14 illustrates the increase of SPL with the whistling frequency F_w for the acoustic pressure measured by microphone at the angle ϕ=30°. Comparisons are made with SPL calculated for the microphone signal filtered with a narrow pass-band filter around F_w and also with the SPL deduced from the Rayleigh integral on POD [1 2]. The typical slope 6 of a sound power level for a dipole is rather in a good agreement with the present results.

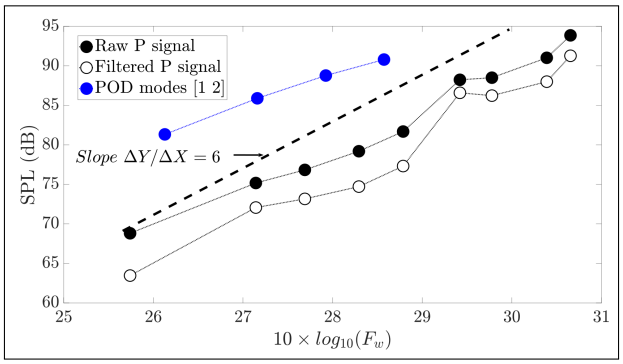

Figure 14. Sound pressure level *vs.* whistling frequency.

5. CONCLUSION

The flow dynamics in the exit section of a Vortex whistle was characterized by high-speed stereo-PIV velocity measurements combined with acoustic pressure measurements by microphone. Using POD, the spatio-temporal organization of the flow was highlighted. The main characteristics of Vortex Whistles previously studied in the literature were found, the dynamics of the velocity field and the acoustic pressure being interdependent. However, it seems that the length of the main cylinder influences the characteristics of the acoustic source that the Vortex Whistle simulates. If the acoustic levels and their radial distribution remain close to that typical of an acoustic dipole, the decentering of the precession movement seems to induce an additional complexity that a simple radiation model does not fully describe.

6. ACKNOWLEDGMENTS

ABSTRACT

An experimental investigation is performed on a small-scale axial flow fan in a ducted configuration to observe rotor shielding effects. The study focuses on spinning azimuthal modes incident on a rotor-stator layout in the presence of flow. The sources considered are a ring of loudspeakers generating a particular spinning mode. Along with the reflection and modified transmission, several phenomena like mode scattering and mode trapping are expected. An array of 64 microphones is employed in the interstage, i.e. between the rotor and stator rows. The microphones are arranged in two rings and two spirals on the duct surface using a remote probe configuration and its axial extent is 40mm. The interstage array helps in providing a detailed understanding of the noise propagation between the rotor-stator rows. The modal decomposition is based on a Bayesian inversion method. Both the frequency dependence and the spin direction are examined at various engine operating points.

1. INTRODUCTION

Despite considerable advancement in the recent years to reduce noise emission by aircraft, fan noise remains to be one of the major contributors of noise generated by aircraft engines during all phases of operation. Several studies have been conducted to model the sound generation mechanisms in an engine and the free-field propagation [1, 2]. However, the study of noise transmission inside turbofan engines poses some specific challenges owing to the presence of complex geometries and heterogenous flow, and in turn, multiple noise generation and propagation mechanisms. One of the main noise source mechanisms is the rotor-wake and stator interaction noise, that generates Tyler and Sofrin modes [3]. The noise radiates in both upstream and downstream directions. A deeper understanding of the noise transmission through the rotor blades is therefore crucial for enabling more accurate assessments of noise.

One of the first analytical models to study noise transmission through static rotor blades was proposed by Kaji and Okazaki [4, 5] known as 'Cascade theory'. The blades are modelled as a cascade of finite chord length and infinitesimal blade thickness. The angle of incidence of the propagating waves has been shown to influence the reflection and transmission coefficients across the blades. The theory was further developed by using mode-matching technique to model sound generation and propagation in outlet guide vanes [6, 7]. A comparative study of different 2D and 3D analytical approaches has been performed to estimate sound transmission across stator blades [8]. Three phenomena are described based on the direction of prop-

agation of incident waves: Venetian blind, Modal condition and Blocking condition. Experimental studies have also been performed to estimate modal amplitudes generated at the inlet of a ducted fan by inverting the modal directivity matrices [9] and also using compressed sensing based mode analysis [10]. The flow between the rotor and stator blades are characterised by swirl effects, which can alter modal behaviour. A qualitative analytical model to explain transmission of BPF tones in the swirl region and through the rotor blades have been proposed [11].
In the present study, spinning azimuthal modes are generated using a ring of loudspeakers. The propagation of these modes across rotor and stator blades are observed using microphone arrays and an iterative Bayesian Inverse Approach. The experimental setup and analysis methodology are presented in the following sections. The results and comparison of transmission loss across fan stages for different modes are presented in Sec. 3, followed by a brief conclusion.

2. METHODOLOGY AND EXPERIMENTAL SETUP

Assuming linear acoustics behavior and a stationary sound field, the complex acoustic pressure inside a hard-wall cylindrical duct with a circular or annular cross-section and in the presence of a flow, can be expressed as a weighted sum of modes as shown in Eqn. 1 [12]:

$$p(r,\theta,z,t) = \sum_{m=-\infty}^{\infty}\sum_{n=0}^{\infty}[A^{+}_{mn}e^{ik^{+}_{z,mn}z} + A^{-}_{mn}e^{ik^{-}_{z,mn}z}]f_{mn}(r)e^{im\theta}e^{i\omega t} \quad (1)$$

where A^{+}_{mn} and A^{-}_{mn} are complex-valued mode amplitudes propagating downstream and upstream respectively. The subscripts m and n are the azimuthal and radial mode orders. $f_{mn}(r)$ is a normalised modal shape factor depending on the duct's cross section (circular or annular) and hard-wall boundary conditions. The axial wavenumbers $k^{\pm}_{z,mn}$ of a particular mode (m,n) in both downstream $(^{+})$ and upstream $(^{-})$ directions in the presence of a flow of Mach number M are given by

$$k^{\pm}_{z,mn} = \frac{\mp Mk_0 + \sqrt{k_0^2 - (1-M^2)k^2_{r,mn}}}{1-M^2} \quad (2)$$

where, $k_{r,mn}$ is the radial wave number of mode (m,n) obtained from the solutions of Bessel functions constituting modal shape factor $f_{mn}(r)$. The purpose of the study is to generate particular modes inside a duct and observe the behavior across different blade rows of a fan.

2.1 Experimental setup

The experimental setup consists of a circular duct with a radius of 0.085 m. A low-speed electrical HVAC (Heating, ventilation and air-conditioning) fan, henceforth known as LP3, manufactured by Safran Ventilation Systems is installed inside the duct. Modular rings are present between the rotor and the stator blades in order to increase or decrease the gap among them. A Turbulent Control Screen (TCS) upstream of the fan at the inlet minimizes inflow distortions. A vane at the end of the duct can be opened or closed as required to control the mass flow inside the duct. Pressure probes and thermo-couples are fitted before and after LP3 and venturi to measure the physical parameters in the duct during operation. The parameters of LP3 are listed below:

Rotor blades number	B	17
Stator vanes number	V	23
Diameter	ϕ	17 cm
Hub to tip ratio	R_H/R_T	0.55
Tip Mach number	M_{tip}	0.3
Maximum rotational speed	Ω_{max}	$\sim$ 10000 rpm
Maximum mass flow rate	Qm	$\sim 1\ kg\ s^{-1}$
Maximum mean axial flow velocity	U_0	$\sim 40\ m\ s^{-1}$

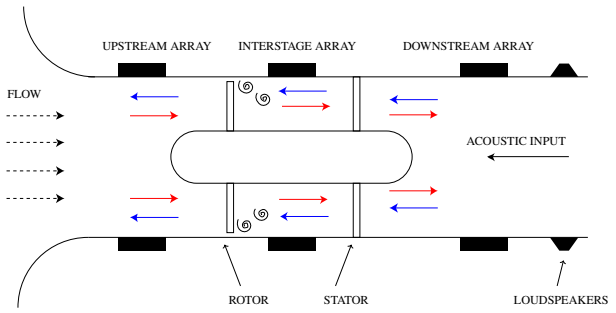

Figure 1: Schematic diagram of the experimental setup showing the positions of microphone antenna and direction of acoustic wave propagation, blue arrows depict the incident direction of modes *i.e.* the same direction as that of acoustic input and the red arrows depict the reflected direction of mode propagation

A ring of 13 loudspeakers downstream of LP3 generate a particular azimuthal mode inside the duct based on relative phase difference as explained in the methodology. The acquisition system consists of 25 nos. 1/4" microphones upstream and 25 nos. 1/4" microphones downstream with respect to the fan mounted in pin-hole configuration, and 64 nos. 1/4" microphones in the interstage mounted remotely. Fig. 1 gives a pictorial representation of the experimental setup. The fan is operated at three rotational speed and mass flow rate combinations. The performance map of the fan at these operating points are shown in Fig. 2. One of these points (9800 rpm and 30 mm vane opening) is chosen as the baseline configuration (marked with an 'o' symbol) and the corresponding results are present in the following section. The number of loudspeakers used for mode generation limits the maximum mode number that can be excited without aliasing, which is determined as half of the number of loudspeakers. Thus, for the experimental campaign modes -6 to +6 are chosen. The generation are pure tones excited individually at 30 frequencies between 500 Hz and 10000 Hz for each azimuthal mode.

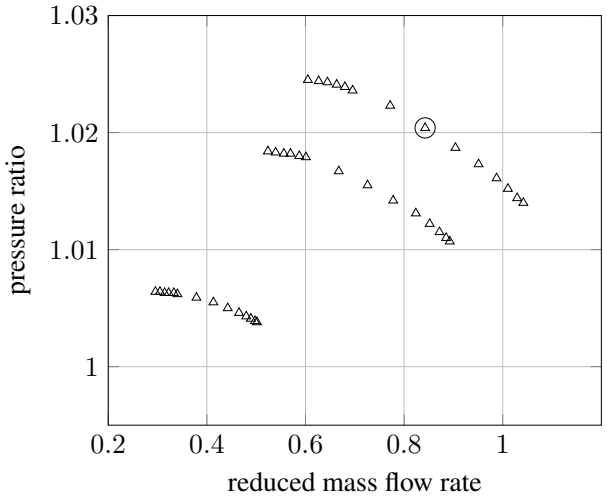

Figure 2: Performance map of the LP3 fan used in the experimentation with considered operating point marked in 'o'

2.2 Calibration of microphone arrays

The installation of the microphones on the duct is an important aspect of the experimental setup. A common method is to mount them flushed to the duct inner surface, with or without the protection grid. However, such a configuration is prone to measurement of pressure fluctuations due to turbulent boundary layer at the duct surface, along with the acoustic pressure. Furthermore, the distance between the rotor-stator rows in the long configuration is 40mm, not sufficient for flush-mounting the necessary number of microphones required for the study. Using a remote sensor installation, known as pin-hole system provides flexibility in designing a more efficient microphone array [13]. The pin-hole system creates a small cavity in front of the microphone, which acts as a Helmholtz resonator and modifies the frequency response of the microphone. Two methods of calibration are employed- individual and global calibration [14]. For individual calibration of microphones, a calibrating device consisting of a flush-mounted reference microphone and an already calibrated microphone are used. The transfer function between the target microphone and the reference microphone is measured. This is followed by the measurement of the transfer function between the reference microphone and the already calibrated microphone placed on a controlled surface. The ratio of the two transfer functions provide the calibration factor of the target microphone. The method is time-consuming and very sensitive to the position of the reference microphone in front of the pin-hole, thus difficult to reproduce. Moreover, once the setup is installed, the downstream and interstage microphones arrays are inaccessible. Therefore, individual calibration is performed for all the arrays, once before mounting the setup. Then global calibration is performed regularly during the experimental campaign. Fig. 3 gives an example of the calibration curves of microphone arrays obtained upon performing the abovementioned procedure. The curves are then used during post-processing to account for the frequency amplification and signal attenuation due to remote installation.

2.3 Mode generation

A particular spinning mode can be generated inside a duct using a combination of phased loudspeakers ([15,16]). To generate a spinning wave of azimuthal mode 'm' using 'K' monopole sources, the phase of the 'j^{th}' source is given by:

$$\phi_j = \frac{2\pi m}{K}(j-1) \tag{3}$$

The 13 loudspeakers are connected to the duct using waveguides of diameter 14 mm, resulting in a cut-off fre-

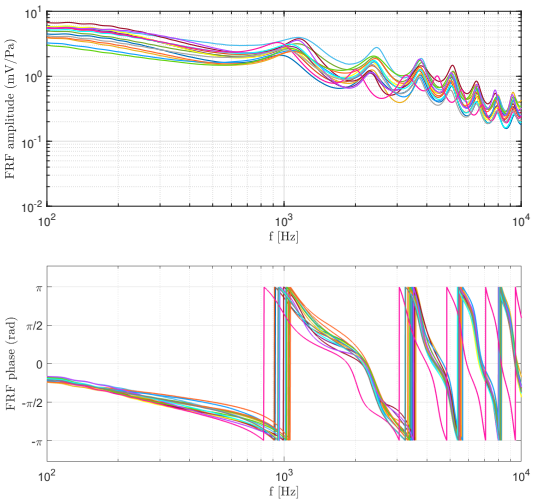

Figure 3: Sensitivity curves (amplitude and phase) for a group of microphones in the interstage array

quency of 14240.4 Hz. This ensures that the loudspeakers can be modelled as monopole sources for the range of frequencies considered in the study. The generation of radial modes cannot be controlled owing to the fact that the loudspeakers are positioned along a unique axial and radial position. The generation is performed considering a cylindrical duct, which is applicable at the position of the loudspeakers. However, at the location of the fan, notably at the Interstage array, the geometry transitions to an annular duct. It has to be noted that certain modes might become propagative, *i.e.* cut-on, as the sound propagates due to the aforementioned transition.

2.4 Analysis methodology

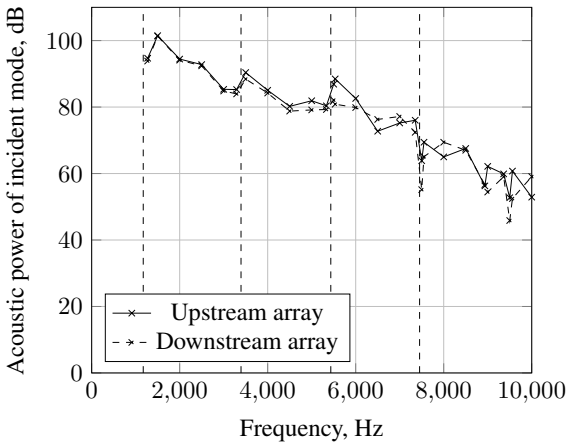
The iterative Bayesian Inverse Approach (iBIA) has been implemented to perform the modal analysis [17]. Eqn. 1 can be represented in a matrix notation.

$$\mathbf{p} = \mathbf{\Phi c} + \mathbf{n} \tag{4}$$

where, $\mathbf{p} \in \mathbb{C}^K$ is a vector of complex pressure coefficients (result of a Fourier transform) from measurements at a given frequency ω, $\mathbf{n} \in \mathbb{C}^K$ accounts for additive noise, $\mathbf{c} \in \mathbb{C}^L$ is a vector containing the unknown complex coefficients ($A^{\pm}_{mn}$) and $\mathbf{\Phi} \in \mathbb{C}^{K\times L}$ depends on the problem being solved ($\mathbf{\Phi} = e^{ik^{\pm}_{z,mn}z} f_{m,n}(r) e^{im\phi}$ in this case). The unknowns $\mathbf{c}$ and observations $\mathbf{p}$ are considered as random variables which are modelled through probability density functions and an algorithm based on the majorisation–minimisation (MM) principle is employed to solve the problem. Since, recorded sound pressure includes effects of the fan itself, notably when the excitation frequency is close to the blade passing frequency (BPF) or its harmonics, it is important to filter out the recorded data from these effects. To achieve that, a frequency band of 200 Hz is chosen around the excitation frequency and analysis is performed only within this range.

3. RESULTS

Upon post-processing the recorded microphone signals using the methodology explained above, the amplitudes of all cut-on modes present inside the duct are obtained. The mode amplitudes correspond to respective array locations and frequencies put to the test during the experiment. The results are presented in terms of acoustic power of the excited modes. Experiments have been conducted at specific test points. Continuous lines joining these points in the figures are for better visualisation.



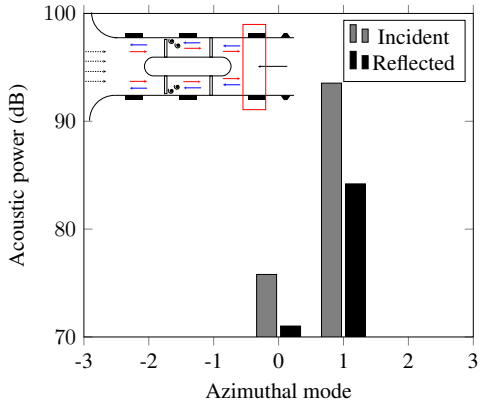


Figure 4: Acoustic power of azimuthal mode -1 (summed for all cut-on radial modes) along incident direction for upstream and downstream arrays in the case of an empty circular duct (dashed vertical lines represent the cut-off frequencies of subsequent radial modes)

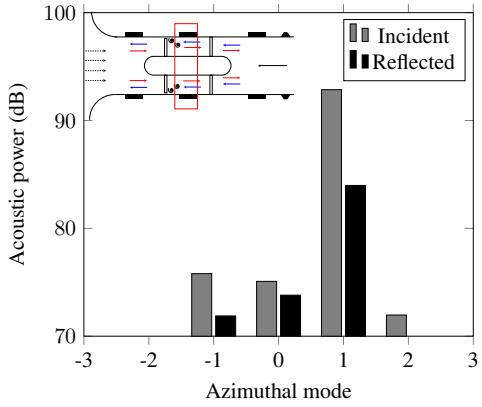
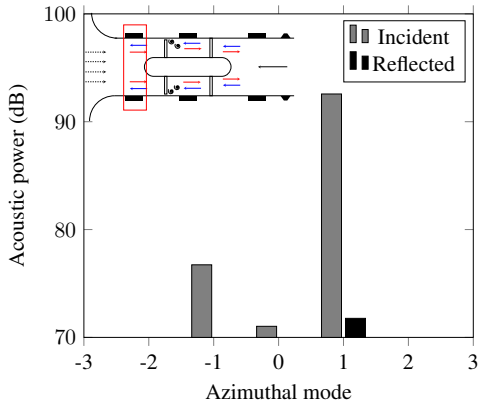


For the first part of the analysis, simpler configurations have been investigated: an empty circular duct

and the duct with LP3 but without rotation of blades or flow. These analyses demonstrate the performance of the methodology in conditions where the behaviour is theoretically predictable. Further, such an analysis enables the separation of the shielding due to the setup geometry from that generated due to the blades rotation and the effect of the flow. Fig. 4 presents the acoustic power of azimuthal mode -1 along the incident direction recorded by microphones of the upstream and downstream arrays. As theoretically expected, the acoustic power is conserved across the microphone arrays, specially at low frequencies where very few radial modes are cut-on. At higher frequencies, the acoustic power decrease in general and their values at upstream and downstream arrays diverge from each other. This is due to the presence of several radial modes and also spurious azimuthal modes which are excited by the loudspeakers. The method struggles to differentiate the modes, when several modes are present with comparable energy. Jumps in the power values are also observed near the cut-off frequencies of radial modes. Near the cut-off frequencies, evanescent modes with longer axial wavelength are present and recorded by the microphones. These modes have not been taken into account during the analysis. The analysis has been limited to low frequencies and test points near cut-off frequencies have been removed to ensure that observations are made within the limits of the method. Similar observations have been made for the other azimuthal modes. The results are comparable and reinforce the confidence on the generation and post-processing methodology.



The next step is to analyse the effect of the rotor rotation on the noise transmission. Fig. 5 presents an example of the results obtained when mode 1 is excited at 2000 Hz with LP3 at 9800 rpm and vane opening of 30 mm. It is the operating point marked with 'o' in Fig. 2. 'Incident' and 'reflected' represent the direction of mode propagation with respect to the acoustic input. It can be seen that the difference in amplitude of incident $m = 1$ across different antenna is negligible ($\sim$ 0.6 dB). However, the amplitude of reflected mode is considerably high at the interstage array compared to upstream array, indicating that the rotor blades are the major contributors towards reflecting $m = 1$. It can also be observed that other cut-on modes like $m = 0, -1$ are excited, however their amplitudes are negligible compared to those of $m = 1$. The overall decrease in transmission can be obtained by taking the difference of incident mode power at upstream array from that at downstream array. Fig. 6 shows the transmission loss of mode -1 with frequency for different con-

(a) Downstream array

(b) Interstage array

(c) Upstream array

Figure 5: Acoustic power of cut-on modes (along incident and reflected direction of propagation with respect to acoustic input) present at different microphone array locations upon excitation of azimuthal mode 1 at 2000 Hz with LP3 rotating at 9800 rpm and vane opening of 30 mm (operating point marked with 'o' in Fig. 2)

figurations. Higher difference in mode power (y-values) means lower transmission across blades. The presence of LP3 slightly decreases the transmission of mode -1. However, higher transmission loss is detected when LP3 rotates at 9800 rpm with 30 mm vane opening. The rotation of rotor blades and presence of flow are possible causes for this transmission loss. Transmission loss across each blade rows of the fan can be obtained by using the microphone measurements of interstage array. The difference in incident power of excited azimuthal mode across the downstream and interstage arrays (depicting transmission loss across stator blades) and that across the interstage and upstream arrays (depicting transmission loss across stator blades) are calculated and shown in Fig. 7 for modes $m = -1$ and $m = 1$. For the present study, $m = 1$ represents a co-rotating mode and $m = -1$ a counter-rotating mode with respect to the rotor rotation. For $m = 1$, the transmission loss across stator blades are slightly higher at low frequencies compared to rotors but above 2000 Hz, transmission loss across rotors dominate. The trend is consistent for $m = -1$, in which case, the transmission loss across rotor blades dominate throughout. The stators are slightly more efficient in blocking $m = 1$ compared to $m = -1$ but the differences are quite small and maybe accounted from the uncertainties of measurement or post-processing. However, the rotor blades are more efficient in blocking $m = -1$ upto 3 dB at 2500 Hz.

Fig. 8 shows the transmission loss across LP3 at 9800 rpm and vane opening of 30 mm for various modes. The values are obtained by taking the difference in acoustic power along incident direction of upstream array from downstream array. The lower order modes follow the trend as explained above at frequencies below 4000 Hz. With increase in frequency, transmission loss across the fan increases. However, at higher frequencies and for higher order modes, no conclusion can be drawn. It is to be noted that, along with the mode required to be excited, aliased modes are also being generated. These aliased modes are related to the number of loudspeakers present in the generation system and are given by Eq. 5.

$$m_{\text{aliased}} = m_{\text{desired}} \pm \text{Nos. of loudspeakers} \qquad (5)$$

These modes are cut-on for higher order modes and thus are generated by the loudspeakers. One example of this phenomenon can be observed in Fig. 9 where mode -7 is excited along with the intended mode 6 at downstream array inside a circular duct even without LP3. The acoustic power of both these modes are comparable with a difference of ~ 1 dB. Since, both the desired and aliased modes

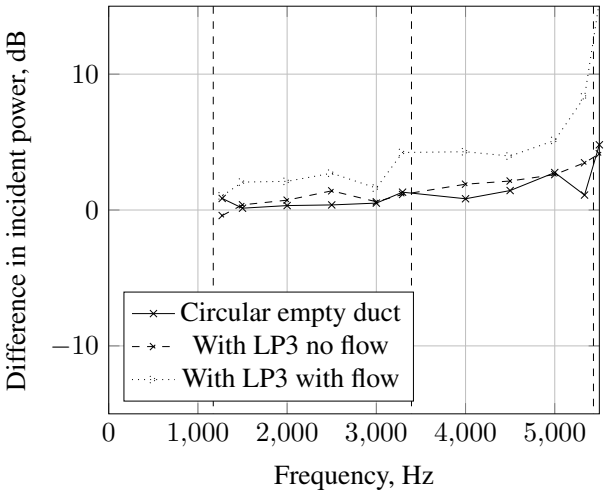


Figure 6: Difference in acoustic power along incident direction of upstream array from downstream array of azimuthal mode -1 (summed for all cut-on radial modes) for three different configurations (dashed vertical lines represent the cut-off frequencies of subsequent radial modes)

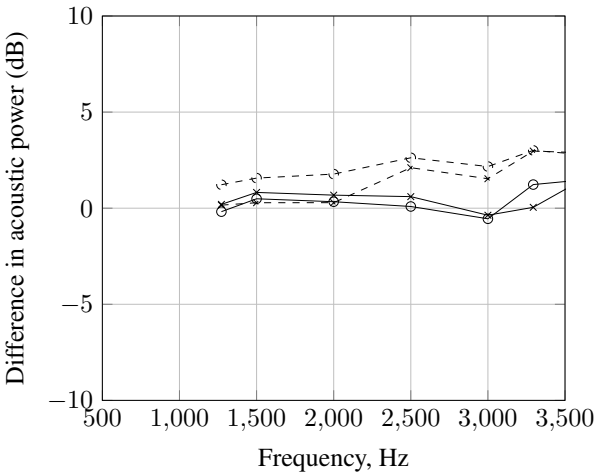

Figure 7: Difference in acoustic power of incident azimuthal mode $m = 1$ (x) and $m = -1$ (o) across stator (solid) and rotor (dashed) blades with LP3 rotating at 9800 rpm and vane opening of 30 mm

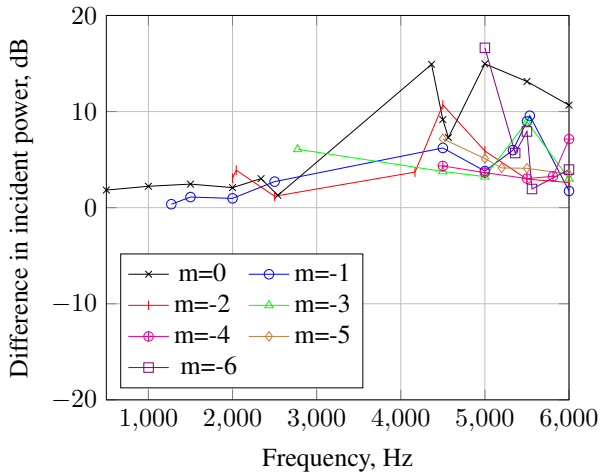

Figure 8: Difference in acoustic power along incident direction of upstream array from downstream array for different azimuthal modes (summed for all cut-on radial modes) with LP3 rotating at 9800 rpm and vane opening of 30 mm

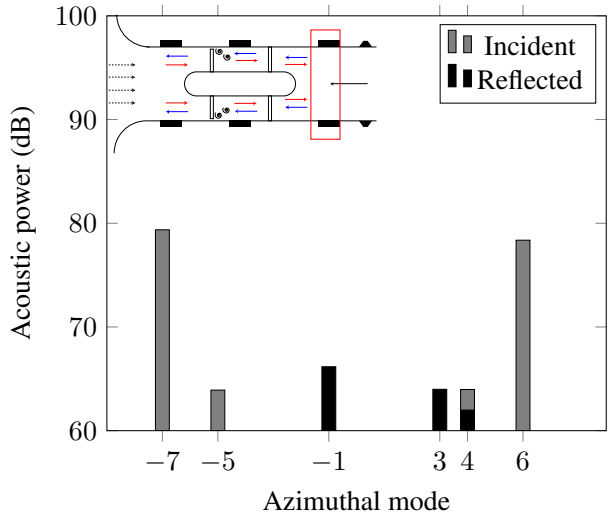

Figure 9: Acoustic power of cut-on modes (along incident and reflected direction of propagation with respect to acoustic input) present at downstream array location upon excitation of azimuthal mode 6 at 6500 Hz inside a circular duct without LP3

are generated by the same sources, they are correlated and create interference patterns inside the duct. It is possible that the energy of the aliased modes are transferred to the desired modes and vice-versa during the application of the inverse method.

4. CONCLUSION AND DISCUSSIONS

Rotor shielding across an axial fan comprising of rotor and stator blades has been studied experimentally. The analysis of lower order modes provides some information regarding rotor-shielding effects. The rotation of blades and the presence of flow increase rotor shielding effects across a fan. Stator blades are relatively transparent to the modes owing to their low stagger angles. The counter-rotating modes are shielded more efficiently by the rotor blades than the co-rotating modes. However, the analysis of higher order modes and high frequency excitation pose several challenges. It has been observed that other cut-on modes are also excited along with the desired azimuthal modes. In most cases, the mode amplitudes are considerably lower to those of the excited mode but can be comparable at certain frequencies. Due to the use of a single ring of loudspeakers, the generation of radial modes cannot be controlled. Thus, at higher frequencies and higher modes, the analysis becomes more complex and uncertain. Near the cut-off frequencies, evanescent modes are present and recorded by the microphones. Mainly at the interstage array, these modes and also the evanescent modes generated at rotor and stator edges are recorded. The evanescent modes have been ignored in the analytical formulation and thus in the modal basis of analysis. Further, the flow between the rotor and stator features swirl. For the present study, the swirl has been approximated to an equivalent axial velocity. Including the swirl effects and adding evanescent modes in the modal basis will lead to better estimation of the mode amplitudes at the interstage array. Moreover, several phenomena occur inside the experimental setup like transition from circular to annular duct, multiple reflections between rotor and stator rows and coupled effect of transmission and reflection at both the blade rows. These effects cannot be decoupled by merely investigating the mode amplitudes at microphone arrays. A numerical study is presently being conducted to simulate the experimental setup and estimate the propagation of modes across the fan. The numerical study would enable understanding of each individual phenomenon. The information will then be used to deepen the experimental analysis.

STOCHASTIC APPROACH FOR ESTIMATING THE SOUND POWER OF TONAL MODE COMPONENTS IN FLOW DUCTS BASED ON AZIMUTHAL MODE ANALYSIS

Maximilian Behn* **Ulf Tapken**
German Aerospace Center, Institute of Propulsion Technology, Engine Acoustics Department
Berlin, Germany

ABSTRACT

The accurate experimental determination of the sound power in the ducts of aircraft engines, engine demonstrators and turbomachinery test rigs is challenging due to limited installation space for sensor arrays. Particularly in the inlet, a high number of propagating modes requires sensor arrays with multiple axial positions in order to decompose the measured sound field into its radial mode constituents. As an alternative, a sensor ring array requires a minimum of axial installation space and provides insight into the mode distribution using an azimuthal mode analysis (AMA). In this case, it is necessary to use radial mode distribution models, such as "equal mode energy" in order to estimate the sound power. However, the difficulty with tonal components, e.g. those generated by rotor-stator interaction, is that the radial modes are mutually coherent. This leads to a complex relation between the azimuthal mode amplitudes and the underlying mode distribution, which varies with the individual case, e.g. operating parameters of the rotor-stator configuration. To account for this variability, a stochastic approach is proposed in which, in particular, the phase relationships of the modes are varied and a distribution of sound power is determined. Its validity is evaluated by comparison with the results of a radial mode analysis obtained at a fan test rig.

1. INTRODUCTION

The next generation of UHBR aircraft engines will be equipped with shorter nacelles in order to reduce the overall engine weight. This development has an impact on the fan inflow and the resulting fan noise excitation, which needs to be assessed experimentally under realistic conditions. Engine demonstrators, just like the real aircraft engines, provide a very limited installation space for microphone arrays, particularly in the inlet. Therefore, microphone ring arrays are applied in many cases enabling the decomposition of the measured sound field into azimuthal modes. In contrast to radial modes, which are determined by radial mode analysis, azimuthal modes do not allow a direct computation of the propagating sound power. Based on the original work of Joseph et al. [1], a sound power estimation technique had been developed on the basis of azimuthal mode spectra and radial mode distribution models and applied to experimental data from small and large-scale test rigs [2–4]. One of the fundamental assumptions of this estimation technique is mutual incoherence of all radial mode constituents, which is an appropriate assumption for broadband sound field components. Regarding tonal mode components, this approach neglects the fact, that all radial modes are fully coherent resulting in interference of the modes and strongly fluctuating sound pressure levels depending on the axial position of the microphone ring array. Despite the inappropriateness of the assumption of mutual mode incoherence, the approach for the broadband case was applied to the analysis of tonal mode components on a LPT rig [2] and on a radial compressor rig [5].

This article explores a stochastic approach that allows to take coherent modes into account and to evaluate the

impact of varying phase relations between the modes. Just like in the broadband case, the magnitudes of the radial mode amplitudes are prescribed according to radial mode distribution models. Additionally, the individual radial modes are assigned with randomly selected phases so that the resulting interference can be evaluated stochastically in a Monte Carlo study. The result of this approach is a distribution of sound power, of which the spread and the usefulness of the median value as a possible sound power estimation value are evaluated using measured data from a fan test rig and compared with reference results from radial mode analysis.

2. SOUND POWER ESTIMATION BASED ON AZIMUTHAL MODE ANALYSIS

Sound fields in cylindrical and annular flow ducts with a uniform background flow with Mach number M_x can be decomposed into radial modes of the form

$$p\left(x,r,\phi\right) = \sum_{m=-\infty}^{\infty}\sum_{n=0}^{\infty}\left(A_{mn}^{+}e^{ik_{mn}^{+}x} + A_{mn}^{-}e^{ik_{mn}^{-}x}\right)\cdot e^{im\phi}f_{mn}(r) \tag{1}$$

with azimuthal mode order m, radial mode order n, mode amplitudes $A_{mn}^{\pm}$, axial wave number $k_{mn}^{\pm}$, and radial mode shape function $f_{mn}(r)$ [6]. On the basis of the mode amplitude, the mode sound power is calculated as:

$$P_{mn}^{\pm} = \frac{\pi R^2}{\rho c}\frac{\alpha_{mn}(1-M_x^2)^2}{\left(1\mp\alpha_{mn}M_x\right)^2}|A_{mn}^{\pm}|^2, \tag{2}$$

with the outer duct radius R, static density ρ and speed of sound c. The term α_{mn} is called the mode propagation factor and plays a particular role in the estimation of the mode sound power. It is defined as:

$$\alpha_{mn} = \sqrt{1-\left(1-M_x^2\right)\frac{\sigma_{mn}^2}{\left(kR\right)^2}}, \tag{3}$$

where σ_{mn} is the radial-transversal eigenvalue. For propagating modes, α_{mn} ranges between 0 at the mode cut-on frequency and 1. It is imaginary for cut-off modes and determines the rate of decay in axial direction through its relation to the axial wave number $k_{mn}^{\pm} = \frac{k}{1-M_x^2}\left(-M_x \pm \alpha_{mn}\right)$.

The determination of the radial mode amplitudes in Eq. (1) via Radial Mode Analysis (RMA) requires a considerable effort in equipment (microphones, traversing devices) and measurement duration. The microphone arrays, that are typically installed at the duct walls, extend over an axial installation space, which increases depending on the highest frequency of interest and is usually limited due to spatial constraints of the test environment [6]. An alternative analysis technique is the azimuthal mode analysis (AMA) (see e.g. [7]), which requires a ring array of wall-flush mounted microphones and can be realised in spatially limited test environments such as the inlets of aero engines or engine demonstrators. Mathematically, AMA corresponds to the discrete form of the spatial Fourier transform of the in-duct sound field in circumferential direction conducted e.g. with microphones installed flush at the outer duct wall:

$$A_m(x) = \frac{1}{N_{\text{mic}}}\sum_{j=1}^{N_{\text{mic}}} p(x, r=R, \phi_j)\cdot e^{-im\phi_j}. \tag{4}$$

The relation of the azimuthal mode amplitude A_m and the amplitudes of the underlying radial modes is obtained from eq. (4):

$$A_m(x) = \sum_{n=0}^{n_{\max}}\left(A_{mn}^{+}e^{ik_{mn}^{+}x} + A_{mn}^{-}e^{ik_{mn}^{-}x}\right)\cdot f_{mn}(R) \tag{5}$$

as a summation over all cut-on radial mode orders. In contrast to the radial mode amplitudes, the azimuthal mode amplitude can vary strongly depending on the axial position of the ring array. In order to estimate the mode sound power from azimuthal mode amplitudes, Eqs. (2) and (5) need to be combined. Since the axial wave numbers are determined from the known duct geometry, frequency and flow conditions, the main difficulty in estimating the mode sound power from azimuthal mode amplitudes lies in the estimation of the unknown amplitudes and phases of the radial modes. In previous studies, the mode sound power in broadband sound fields was estimated using mode distribution models such as "'equal mode energy"' or "'equal mode energy density"' to relate the magnitude of the radial mode amplitudes to single parameters of the corresponding mode distribution model [1,3,4] with the assumption of mutual incoherence of the radial modes, which makes it possible to neglect the mode phases and the axial propagation terms $e^{ik_{mn}^{-}x}$. In combination with

the assumption that only modes propagating in a single direction, e.g. upstream, are present, the square of Eq. (5) yields for the broadband case:

$$|A_m|^2 = \sum_n |A_{mn}^-|^2 f_{mn}^2(R). \tag{6}$$

Equation (6) can be solved for the radial mode amplitudes $|A_{mn}^-|^2$ using a mode distribution model.

Tonal sound field components comprise coherent modes whose phase relations have to be considered. Because the mode phases are unknown and can not be retrieved via AMA, a stochastic approach is sought. The initial equation, which relates A_m to A_{mn}^-, then yields:

$$A_m = \sum_n |A_{mn}^-| f_{mn}(R) e^{i2\pi\mathcal{U}(1,0)}. \tag{7}$$

In Equation (7), the mode phases are randomly selected from a uniform distribution with unit standard deviation and zero mean. As a consequence, the radial mode amplitudes and the resulting mode sound powers are random variables. An efficient evaluation of these random variables can be realised by Monte Carlo simulations.

3. MODE SOUND POWER DISTRIBUTION MODELS

Currently, generalised mode distribution models are lacking for the tonal mode components from turbomachinery stages. Therefore, two mode distribution models (see [1]), "'equal mode energy"' (EME) and "'equal mode energy density"' (EMED), that are widely applied for the analysis of fan broadband noise, and the sound power distribution according to point source models are introduced in the following to demonstrate the stochastic approach for mode sound power estimation. However, the expressions can easily be adapted to other mode distribution models in the future.

3.1 "'Equal mode energy"' model

The EME model assumes that all propagating modes with the same azimuthal mode order have the same sound energy and as a result, the same mode sound power, i.e. $P'_m := P^-_{mn}$. Now P'_m is inserted in Eq. (2), which is then solved for $|A_{mn}^-|^2$. From Eq. (7) the following expression for the azimuthal mode amplitude is obtained:

$$|A_m|^2 = \frac{\rho c}{\pi R^2} \frac{1}{\left(1 - M_x^2\right)^2} P'_m \cdot \left| \sum_n \frac{1 + \alpha_{mn} M_x}{\sqrt{\alpha_{mn}}} f_{mn}(R) e^{i2\pi\mathcal{U}(1,0)} \right|^2. \tag{8}$$

Then, the summed sound power $P_m^{\text{EME,-}} = N_n \cdot P'_m$ yields:

$$P_m^{\text{EME,-}} = N_n \frac{\pi R^2}{\rho c} \left(1 - M_x^2\right)^2 |A_m|^2 \cdot \left| \sum_n \frac{1 + \alpha_{mn} M_x}{\sqrt{\alpha_{mn}}} f_{mn}(R) e^{i2\pi\mathcal{U}(1,0)} \right|^{-2}. \tag{9}$$

The EME model is sensitive to modes that are close to their cut-on frequencies and whose propagation factor α_{mn} is close to 0. In this case, the summation over all radial mode orders is dominated by the contribution of the highest cut-on radial mode order, which effectively is closest to its cut-on frequency. Because the $1/\sqrt{\alpha_{mn}}$-term is unbounded at the cut-on frequency, the estimated sound power is zero directly at this frequency. Hence, the EME model is prone to underestimate the sound power.

3.2 "'Equal mode energy density"' model

For the EMED model, the sound power is expressed in terms of the energy density $\Pi_{mn}^{\pm}$ [1]:

$$P_{mn}^{\pm} = \Pi_{mn}^{\pm} S c_{\text{g,mn}} = \Pi_{mn}^{\pm} S c \frac{\alpha_{mn}\left(1 - M_x^2\right)}{1 \mp \alpha_{mn} M_x}, \tag{10}$$

with the duct cross-section S and the mode group velocity $c_{\text{g,mn}}$. It is assumed that all upstream propagating modes with the same azimuthal mode order have the same energy density, i.e. $\Pi'_m := \Pi^-_{mn}$. Modes propagating downstream are neglected at this point. Setting Eq. (10) equal to Eq. (2) and solving for $|A_{mn}^-|^2$ yields:

$$|A_{mn}^-|^2 = S \frac{\rho c^2}{\pi R^2} \frac{1 + \alpha_{mn} M_x}{1 - M_x^2} \Pi'_m. \tag{11}$$

From Eq. (7) the relation between azimuthal mode amplitude and mode energy density reads:

$$|A_m|^2 = S \frac{\rho c^2}{\pi R^2} \frac{1}{1 - M_x^2} \Pi'_m \cdot \left| \sum_n \sqrt{1 + \alpha_{mn} M_x} f_{mn}(R) e^{i2\pi\mathcal{U}(1,0)} \right|^2. \tag{12}$$

The summed sound power is computed as follows:

$$P_m^{\text{EMED,-}} = Sc\left(1-M_x^2\right)\Pi_m' \sum_n \frac{\alpha_{mn}}{1+\alpha_{mn}M_x}. \quad (13)$$

Combining Eqs. (12) and (13) provides the estimation equation for the EMED model:

$$P_m^{\text{EMED,-}} = \frac{\pi R^2}{\rho c}\left(1-M_x^2\right)^2 |A_m|^2 \cdot \frac{\sum_n \frac{\alpha_{mn}}{1+\alpha_{mn}M_x}}{\left|\sum_n \sqrt{1+\alpha_{mn}M_x} f_{mn}(R) e^{i2\pi\mathcal{U}(1,0)}\right|^2}. \quad (14)$$

In comparison to the EME model, the EMED model is less sensitive to low values of the mode propagation factor α_{mn}.

3.3 ISI point source model

Point source models such as monopoles and dipoles are suitable to model the sound generation from different interaction mechanisms in turbomachinery stages [8]. For high accuracy of the determined sound power, the blade geometries and aerodynamic properties need to be modelled in detail to calculate the source strengths. Instead, a dense distribution of point sources is assumed across the duct cross-section as a substitute model, which ensures that each mode order can be excited effectively. A distribution of a high number of densely positioned point sources is equivalent to a continuous source distribution as described in [1]. The integration of the contribution of each point source over the duct cross-section yields the total radiated mode field, which depends on mode-specific parameters like the mode propagation factor α_{mn}, but is independent of the radial and azimuthal mode shape. Furthermore, the stochastic sound power estimation approach based on the azimuthal mode analysis is chosen, in which only the distribution of mode amplitudes is predicted by the point source models and the mode phases is selected randomly from a random distribution.

The absolute values of the radial mode amplitudes are predicted on the basis of the mode impedance $\hat{Z}_{mn}^{\pm}$ and the source strength q, which are described for different source types in more detail e.g. in [9]. In this reference, the ISI point source model is introduced, which is characterised by a more realistic excitation of modes close to their cut-on frequencies by virtue of an internal source impedance and applied in the following investigation:

$$|A_{mn}^{\pm}| = |\hat{Z}_{\text{mn,ISI}}^{\pm} q|. \quad (15)$$

The mode impedance of the source distribution with an assumed dipole characteristic is approximated as:

$$\hat{Z}_{\text{mn,ISI}}^{\pm} = -i\frac{\rho c}{4\pi R^2}\frac{1/\alpha_{mn}}{1+\frac{N_M}{(kR)^2+\frac{25}{kR}}\cdot\frac{1-\alpha_{mn}}{\alpha_{mn}}} \cdot \left(k_{mn}^{\pm}\cos\alpha_{\text{dipole}} + \frac{\sigma_{mn}}{R}\sin\alpha_{\text{dipole}}\right) \quad (16)$$

with the total number of cut-on modes N_M and the dipole angle α_{dipole}.

From Eq. (7) the azimuthal mode amplitude can be expressed as:

$$A_m = |q|\sum_n |\hat{Z}_{\text{mn,ISI}}^{-}| f_{mn}(R) e^{i2\pi\mathcal{U}(1,0)}. \quad (17)$$

Likewise, the summed mode sound power is directly computed by inserting Eq. (15) in Eq. (2):

$$P_m^{\text{ISI,-}} = \sum_n \frac{\pi R^2}{\rho c}\frac{\alpha_{mn}(1-M_x^2)^2}{(1+\alpha_{mn}M_x)^2}|\hat{Z}_{\text{mn,ISI}}^{-} q|^2 \quad (18)$$

$$= \frac{\pi R^2}{\rho c}|A_m|^2 \sum_n \frac{\alpha_{mn}(1-M_x^2)^2}{(1+\alpha_{mn}M_x)^2} \cdot \frac{|\hat{Z}_{\text{mn,ISI}}^{-}|^2}{|\sum_{\tilde{n}=0}^{n_{\max}}|\hat{Z}_{\text{m}\tilde{n},\text{ISI}}^{-}| f_{m\tilde{n}}(R) e^{i2\pi\mathcal{U}(1,0)}|^2}. \quad (19)$$

4. APPLICATION TO FAN TEST RIG DATA

The stochastic approach for sound power estimation based on azimuthal mode amplitudes is demonstrated on both, synthesized and experimental data from DLR's fan test rig CRAFT (Co-/Counter-Rotating Acoustic Fan Test Rig). It is equipped with a fan stage whose rotor has 18 blades and stator has 21 vanes. The duct diameter at the inlet test section is 453.6 mm. At the fan design point, the flow Mach number in the inlet is $M_x = 0.11$. Typically, the upstream radiated sound power of the tonal mode components is determined by radial mode analysis on the basis of traverse measurements with an axial microphone array, which is depicted in Fig. 1. The RMA results serve as reference data for the comparison with the estimated sound powers using the measured data from the ring array in combination with the stochastic estimation approaches.

For further information on the CRAFT test rig itself as well as on the measurements and data analysis of the data used here, the interested reader is referred to Ref. [10] and Ref. [11].

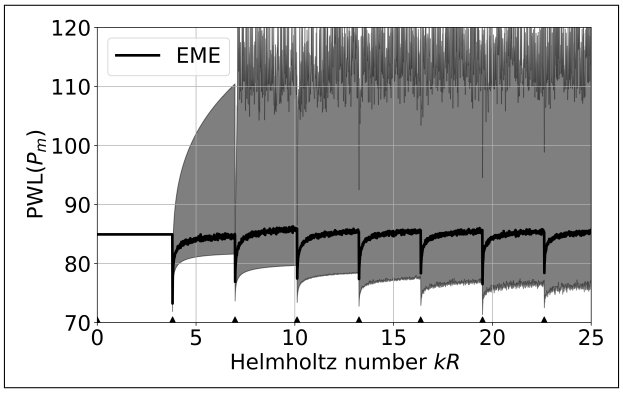

Figure 2. Sound power estimation results for constant azimuthal mode amplitude $A_0 = 1$ assuming "'equal mode energy"'.

First, the stochastic sound power estimation procedure is demonstrated for a synthetic case with constant azimuthal mode amplitude $A_0 = 1$. The results in Figs. 2, 3, and 4 show the estimation results for $m = 0$ using the mode distribution models EME and EMED and the ISI point source model. For the Monte Carlo study, a total of 1000 iterations were performed. The shaded areas indicate the complete dynamic range from the minimum to the maximum of the distribution of

estimated sound powers. The median value of the sound power distribution is shown by the darker lines. Below $kR \approx 4.5$, only the radial mode order $n = 0$ is cut-on, which leads to the same sound power estimation for all models. Furthermore, in this case the sound power distribution is concentrated at a constant value, despite the variation of the mode phase terms. Hence, the stochastic variation, which is introduced in Eq. (7), only has an impact if several radial mode orders are cut-on for the same azimuthal mode order. Also, although no particular sound power distribution is assigned in the comparison of the different models, that is supposed to be reconstructed, it seems plausible that if the azimuthal mode amplitude is constant, the sound power lies in a rather narrow dynamic

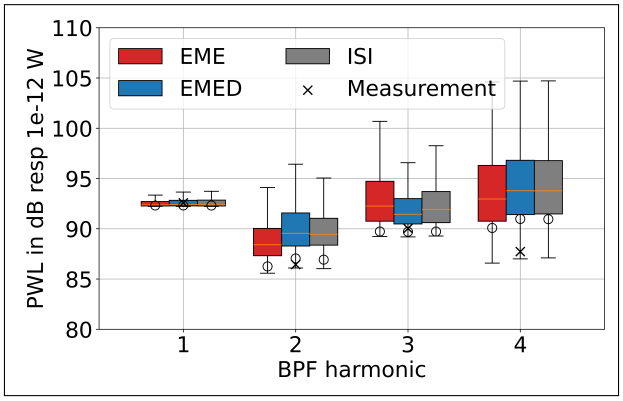

Figure 5. Total estimated sound power for the tonal mode components at 1BPF to 4BPF in comparison to reference measurement data (indicated by crosses) and estimation results assuming mutual mode incoherence (cp. (6), indicated by circles).

range.

Above the cut-on frequency of $n = 1$, which is indicated by a small triangle at $kR \approx 4.5$ at the bottom of the figure, the dynamic range of the sound power distribution increases rapidly and asymmetrically. The results for the EMED model exhibit the steepest increase reaching a maximum dynamic range of more than 40 dB just below the cut-on frequency of the next higher radial mode order $n = 2$. For the EME model, the estimated sound power drops directly at the mode cut-on frequencies and then increases monotonically up to a dynamic range of about 30 dB, at least up to the cut-on frequency of $n = 2$. The sound power distribution for the ISI model extends over a smaller dynamic range of about 15 dB below the cut-on frequency of $n = 2$. However, above approximately $kR = 7.5$ the dynamic range of the sound power distributions fluctuates between 30 and 45 dB independent of the underlying model.

The median proves to be a robust descriptor for the estimated sound power. For the EME model, the median sound power drops at each mode cut-on frequency and then increases approaching a sound power level of approximately 85 dB. In contrast, the median sound power for the EMED model is almost constant, except for small drop at the cut-on frequency of the mode order $n = 1$. The ISI model leads to results that combine the characteristics of the EME and the EMED model. At relatively low frequencies, the median curve is similar to the one of the EME model, particularly at the cut-on frequency of mode order $n = 1$. With increasing frequency, the median curve of the ISI model becomes more similar to the median curve of the EMED model with very small fluctuations close to the mode cut-on frequencies.

In the following, the stochastic approach is applied to measured data from the inlet of the CRAFT fan test rig in order to estimate the sound power of the tonal components radiated upstream at the blade passing frequency (BPF) and its harmonics. Figure 5 shows the distributions of the estimated total sound power for the three different models in comparison with the reference results, which were obtained by RMA. Additionally, the estimation results under the assumption of mutual mode incoherence, which is a common assumption for the analysis of broadband sound fields, are indicated with circles. Except for 1BPF, the median of the estimated distributions overestimates the radiated sound power in comparison with the RMA results by 2 to 3 dB at the second and third harmonic, and approximately 9 to 10 dB at 4BPF. The results show that none of the three applied models leads to a significantly better agreement with the experimental data than the others.

In Fig. 6, the sound power levels are shown only for

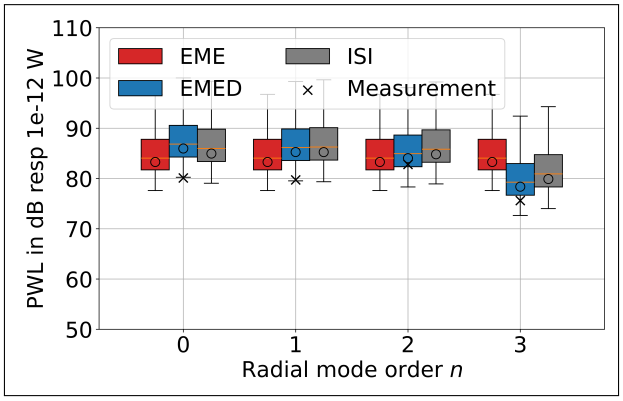

Figure 7. Estimated sound power of the rotor-stator interaction mode with mode order $m = -9$ at 4BPF in comparison to reference measurement data (indicated by crosses) and estimation results assuming mutual mode incoherence (indicated by circles).

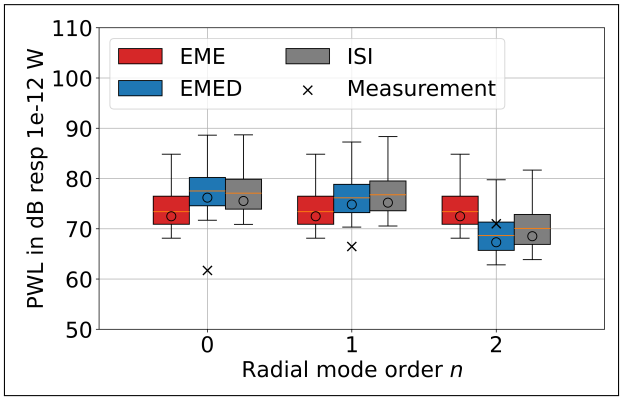

Figure 8. Estimated sound power of the rotor-stator interaction mode with mode order $m = 12$ at 4BPF in comparison to reference measurement data (indicated by crosses) and estimation results assuming mutual mode incoherence (indicated by circles).

the rotor-stator interaction modes, which are obtained from the Tyler-Sofrin rule [12]. For 1BPF and 2BPF, only radial mode order $n = 0$ is cut-on for the respective azimuthal mode orders, so that all models yield the same result for the tonal and broadband analysis. The corresponding sound power estimation results are in very good agreement with the reference results. At 3BPF, the median values of the three estimated distributions are nearly equal and lie within 1 dB of the measurement result. Similar to the results of the total sound power, for 4BPF the median values of all three distributions overestimate the radiated sound power by 9 to 10 dB in comparison with the reference results, which is further investigated next.

The first rotor-stator interaction mode at 4BPF has the azimuthal mode order $m = -9$. Figure 7 shows the sound power levels and distributions for each propagating radial mode order. It is evident, that the relative distribution of sound power over the radial mode orders matches relatively well with the EMED and ISI model. However, for the low radial mode orders both models overestimate the sound power stronger than the EME model.

The mismatch between the actual sound power levels of the propagating radial mode orders and the mode distribution models is even more pronounced for the second rotor-stator interaction mode at 4BPF with the azimuthal mode order $m = 12$. As shown in Fig. 8, the sound power levels of the reference results increase from low to higher radial mode order, which is in contrast to the mode distribution models. This mismatch leads to a strong overestimation of 10 to 12 dB for mode order $n = 0$ and 4 to 6 dB for mode order $n = 1$. This example illustrates an important deficiency of the available mode distribution models: their inability to represent the complex source distribution of turbomachine blade tones, which vary significantly with the rotor-stator stage geometry and the operating-point-dependent rotor wake characteristics (see e.g. [8]). These complex relations are not considered in any of the available mode distribution models.

5. CONCLUSION

A stochastic approach for sound power estimation based on azimuthal mode analysis is proposed, which takes into account the mutual coherence of tonal mode components radiated from turbomachinery stages. The approach combines prescribed magnitudes of the radial modes according to mode distribution models and randomly selected mode phases. Evaluating the sound power estimation in a Monte Carlo study yields a sound power distribution. It is shown that the spread of the distribution depends strongly on the number of propagating radial mode orders, whereas the median value of the distribution is a robust indicator of the estimated sound power. Besides two commonly used mode distribution models, "'equal mode

energy"' and "'equal mode energy density"', a third distribution model is developed based on a dense distribution of point sources, which is equivalent to constant source distribution over the duct cross-section. Here, the internal source impedance model for dipole sources from [9] is applied. However, the results for the estimated sound power from the three distribution models do not show a clear superiority of any distribution model. In the investigated test case from a fan test rig, the estimated sound power is in good agreement with the reference results obtained by radial mode analysis for the first three BPF harmonics. At 4BPF, the sound power is overestimated by 9 to 10 dB, which is likely to be linked to an insufficient match between the mode distribution models and the actual mode sound power distribution with respect to the radial mode order. Due to complex relations between the geometric and aerodynamic design of the rotor-stator configuration and the generated distribution of the radiated mode sound power, it is difficult to determine a generally valid mode distribution model for tonal fan noise. Therefore, the sound power estimation for tonal components based on azimuthal mode analysis is challenging, but it can be useful to determine trends of the radiated sound power in test environments with limited installation space.

ABSTRACT

This paper presents the study of a multi-criteria approach for the instrumentation and measurement validation of an experimental testrig. The study case is an aircraft engine liner characterization bench (named CANNELLE) which is a 3m-long circular duct, based on higher-order modal generation and detection principles. This approach has been initiated for rigs with a large number of sensors, being in this case two arrays of a hundred flush mounted microphones, distributed in an optimized pseudo-random arrangement. Heavy experimental campaigns with associated large test matrices lead to huge datasets, which need to be rapidly validated after the recording, and before moving forward to the next testpoint. Therefore, the proposed validation is based on a multiple criteria approach, and aims at comparing them with target values and associated confidence intervals. Thus, the final objective is to identify potential anomalies in each measurement run among the three following categories: a priori validated data, with nominal criteria; the "should be ok" data, with barely nominal criteria, and little investigation to perform; and the data with severe defaults, which require further analysis. The proposed paper presents the outcomes of this study, exploring criteria on the temporal, frequency, and modal domains when applied to a fully rigid bench without aerodynamic excitation flow.

1. INTRODUCTION

In the civil aircraft industry, the turbofan engines are the standard today for most of the mid- to long-range commercial flights. As the overall traffic is increasing and will continue to grow, the aircraft and engine manufacturers are more and more preparing their next products with a sustainable approach. Meanwhile, the latest international regulations, the ICAO chapter 14 [1] and the FAA stage 5 [2], are reinforcing the emission targets. For instance, they are imposing for the external noise a cumulative reduction of 7 EPNdB versus the previous version chapter 4 / stage 4, and further restrictions are expected for the next generation of aircraft. Therefore, it is of paramount importance to design and validate model of acoustic liner with efficiency and reliability. For that, testing is a key feature, especially when disruptive design are proposed, for which precise modeling and simulations are not mature or fast enough.

Research on liners is very abundant and diversified [3–12], as being at the crossroad of several disciplines, including for instance pure acoustics, aerodynamics, thermic coupling, or icing. Higher-order (also called transverse) acoustic modal content is a specific research field. Indeed, it is not that easy to set-up and measure, requiring several sources and microphones which quantities can be quite large, especially for turbofan engine experiments, whose number of blades is high, so that is the modal order. At the origin of the present paper, there are two

testrigs developed at the acoustic testing laboratory of Airbus Commercial Aircraft (Toulouse, France), which are heavily instrumented, with more than 150 sensors: a rectangular cross-section bench and a circular one. The testcampaigns performed with these benches are often parametric, to have a deep understanding of the physics, which leads to large temporal datasets. During the testcampaign, it is mandatory to validate the running testpoint before moving to the next one, in order to ensure the quality of the data, as the testmatrix sequences are optimized depending on priorities and added value.

To do so, data validation must be specific to guide the experimenter towards the potential issues and facilitate their root cause analysis. The proposed strategy is to work both on the microphone temporal data, their frequency transforms, and finally the modal calculations, by computing criteria on these three datasets. To be more specific, each criterion is compared to a target value, and several thresholds are defined, allowing to classify the criterion into three categories: a priori validated data; the "should be ok" data; and the data with severe defaults. The criteria have been chosen to explore three domains: the instrumentation, the measurement and the experiment quality. This approach has been developed for the above-mentioned rectangular cross-section bench called ModSquare [13, 14] at the Airbus acoustic lab, and its extension to the circular one named CANNELLE is proposed in this study.

The paper as proposed by the authors is organized in two main parts. The first one introduces some of the key features of the CANNELLE bench, including an overview of the test rig, its instrumentation, and post-processing. A focus is made on the bench specificities, based on modal generation and detection principles, with multiple sources arranged azimuthally, generating higher-order transverse modes in the duct. The second part presents the validation methodology of the generation, acquisition and test quality, based on experimental results, using temporal, frequency and modal data. Then, the chosen criteria are explained in detail. The proposed analysis is based on the canonical case of a purely rigid duct, without any aerodynamic excitation. Indeed, this configuration is used as a reference, and has been characterized several times during each campaign, for validation, repeatability and reproducibility purposes since the bench entry into service. Finally, the criteria results are discussed, as well as the thresholds and global outcomes of this analysis.

2. TESTRIG PRESENTATION

The following section presents the bench chosen for this paper, named CANNELLE. The main features of the testrig are presented, as well as its experimental set-up and operations.

2.1 Bench overview

The testrig chosen for this study is called CANNELLE, which stands in French for *Caractérisation des traitements Acoutiques Nacelle en eNvironnement et EcouLement réaListEsEs*. It has been developed in between the late 2000s and early to mid 2010s at the Airbus acoustic testing laboratory in Toulouse, with the motivation to validate modeling and numerical simulations with experimental data for impedance eduction, mainly applied to the liners of the engine's nacelles. It is a straight duct of about 3m-length, with a circular cross section of 350 mm diameter, whose walls are made of thick aluminum. The bench is based on higher-order modal generation and detection principles. The in-duct acoustic modal theory is not reminded in this paper, as already well documented in many publications and books [15, 16]. Fig. 1 proposes a picture of the CANNELLE bench when installed in "pure acoustic" configuration, meaning that there is no aerodynamic flow in the duct. The rig can be decomposed into several

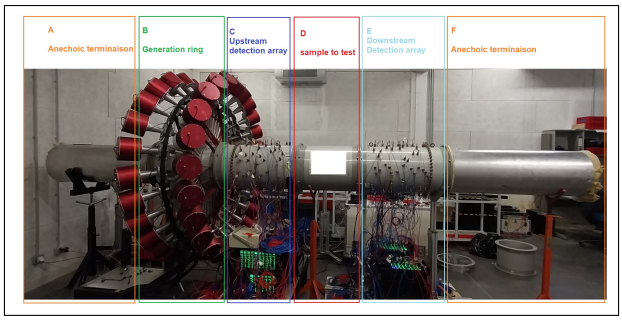

Figure 1. Picture of the CANNELLE bench in the Airbus acoustic laboratory, Toulouse (France).

sub-parts such as follow:

- the part [A], a first ending of about 1m, filled with glasswool;
- the part [B], the generation ring composed of 50 loudspeakers, used for modal excitation;
- the part [C], a first modal detection ring, consisting of an azimuthal array of 50 microphones equally

spaced, and an optimized pseudo-random array of 100 microphones;
- the part [D], the location for the sample to test;
- the part [E], the second modal detection ring, with the same arrangement than the part [C], except that sensor positions are symmetrical regarding the sample;
- the part [F], the second ending, as part [A].

The parts [A] and [F] are considered anechoic at the frequency and levels of interest, based on preliminary studies performed during the bench development phase. All parts are aligned with pins, ensuring a fair flushness into the bench. This aspect is very important because the bench can also be used in wind tunnels, in order to combine the aerodynamic flow to the acoustic excitation. In such a case, the parts [A] and [F] are removed, and the wind tunnel is connected on one side (let's say instead of part[A]), whereas a sonic throat of the Mach number of interest is plugged at the other end (instead of part [F]). There are three sonic throats built to this day, designed for Mach numbers 0.3, 0.45 and 0.6. The specificity of the CANNELLE bench is that the acoustic excitation could be-mounted both for parallel or counter flows. Indeed, by moving the generation ring (part B) after the downstream detection array (part [E]), the acoustic excitation is traveling against the aerodynamic flow. If acoustic liners of an engine nacelle are tested in the bench, and the generation ring (part [B]) is simulating a fan, counter flow is representing the inlet configuration, whereas parallel flow aims for bypass or exhaust.

2.2 Instrumentation and operations

During the bench design and development phases, a compromise has been made between the maximal modal order, the maximal frequency and the generation (the number of loudspeakers) and instrumentation size (the number of microphones), leading to approximately 40 cut-on modes at 5000 Hz, linked to the duct diameter. The generation signal is a sinusoidal pure tone, sent to all loudspeakers with the appropriate phase delays, in order to directly generate the desired azimuthal mode shape. As loudspeakers only control the pressure on the duct wall, selecting a specific radial mode is not possible. Thus, all cut-on radial modes are excited simultaneously. The gain is adjusted to reach the expected level based on the acoustic pressure level, once averaged over all the microphones of the upstream acoustic array (part [B] in Fig. 1). The MaxMSP software is used to master the generation. A digital signal is sent encoded into MADI (Multichannel Audio Digital Interface) format towards two chained digital-to-analog RME M-32 DA converters, which output are the 50 analog lines sent to the 25 double channel QSC Audio RMX 2450 amplifiers. Finally, the amplified signals are sent to the 50 BMS 4599 compression drivers.

When used in the Airbus acoustic lab, the bench is in a "pure acoustic" configuration, meaning there is no aerodynamic flow. A temperature sensor (PT100) is installed flush mounted at the end of the bench, and recorded simultaneously with the microphones. The atmospheric pressure is manually entered in the testcampaign log, allowing to compute the sound wave celerity combined with the temperature. Only the 100 optimized pseudo-random microphones of each detection array (parts [C] and [E]) are used. These 200 sensors are 1/4 inch pressure field microphones with front-vented cartridges, mounted flush without their protection grids. To record, Brüel and Kjær 6-channel Lan-xi acquisition systems are used, powered and mounted on rack frames. The clock synchronization is managed by a B&K layer using PTP (Precision Time Protocol), with a classical master-slave architecture. A local network is connecting all the rack frames, the generation and acquisition computers using a network switch.

A record for one given frequency and modal configuration lasts 5 seconds, using a 7 seconds generation that includes a fade-in and a fade-out. A trigger signal sent from the MaxMSP patch is used to synchronize the acquisition. There is no feedback control loop or enslavement: indeed, the gain adjustment is done separately, at the beginning of the campaign. As already mentioned, the target is to reach a level on the average of the upstream detection array, when the bench is fully rigid, meaning that there is no liner installed. The usual target is around 120 or 130 dB for linear regime, and between 140 and 150 dB to reach non linearity. Parallel to the record, a "perfo" file is created, logging data such as the absolute and unique number of the run, the generation frequency, the targeted mode, and the atmospheric pressure for instance. All the frequency data (auto and inter-spectra, transfer function and coherence) are computed from the temporal raw data file, using B&K Connect version v26.0.0.241. Finally, the modal amplitudes and intensities are computed from the frequency data using an in-house code called MoDe, which has been validated on canonical cases with Actran FEM simulations in 2013 [17]. The transmission loss can be calculated by computing the modal difference between the two detection arrays, providing a direct evaluation of the acoustic sample efficiency.

3. CRITERIA METHODOLOGY AND APPLICATION

This chapter presents the validation methodology developed from the experimental results, and based on temporal, frequency and modal data. The chosen criteria are detailed, with their expected targeted values based on experience from the past campaigns, and on engineering judgment. They are applied to the purely rigid duct measurements in the CANNELLE bench without aerodynamic flow, which is considered as a reference measurement. To ease the presentation, a given testpoint, called α chosen randomly, is used in this chapter. A testpoint is the triplet combination of a target frequency, its associated level, and the azimuthal order of the mode to generate.

3.1 Validation based on criterion in the time domain

It is firstly proposed to simply compute the overall sound pressure level (OASPL) as a function of time, and to verify that it is somehow constant / stable during the acquisition. To save some computation time, it has been chosen to compute it on one microphone only. Indeed, the purpose here is to verify that the generation is stable, not the microphones during a record, so that it is assumed here that the acquisition chain is behaving as expected (this aspect is detailed later in this paper). The first microphone of the upstream detection array (part [C] in Fig. 1) has been chosen, as also being used for the cross-spectral computation as the reference for this detection barrel. The criterion C1 is the OASPL computed with a time integration step of 0.25s, and compared the the target level during the 5 second of record. The chosen thresholds are summarized in Table 1, and the data are considered such as validated if the OASPL lies within a range of +/- 1dB around the target level.

Table 1. Criterion C1: OASPL VS time.

C1 $\in$ target +/- 1dB	Validated data
C1 $\ni$ target +/- 1dB	Defaults

This criterion is not intended to evaluate in detail the issues that could appear at different steps, such as:

- problems in the generation chain itself (from the generation computer, the digital to analog conversion, or from the amplification);
- issues due to the loudspeakers distortion;
- unknown effects during the propagation of the acoustic waves inside the duct;
- noise pollution linked to the acoustic background noise of the lab;
- issues in the acquisition chain (electrical noise, grounding issues, etc.).

Several of these points are addressed in the next section.

3.2 Validation based on criteria in the frequency domain

As described in section 2.1, there are two microphone arrays in the bench, one upstream and one downstream of the sample, with 100 pseudo-randomly distributed microphones each. It is proposed to compute the "mean auto-spectrum" for each array, which corresponds to the mean of all the microphone auto-spectra over the 5-second record. This quantity gives an overview of the sensors and signals behaviors in each array. The next six criteria are all based on this mean auto-spectrum for the upstream microphone array, the one between the source and the sample, as the example of Fig. 2.

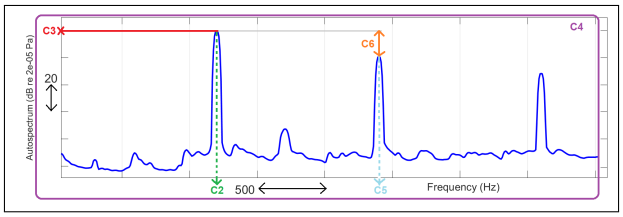

Figure 2. Mean auto-spectrum and schematic criteria representation for the testpoint α.

First, in order to ensure that the generated frequency is indeed the targeted one, the maximum peak frequency is detected in the mean auto-spectrum, and the difference with targeted frequency is computed, sketched as the criterion C2 in Fig 2. Any deviation would discard the testpoint, and a root cause analysis must follow.

Table 2. Criterion C2: max frequency identification.

C2 $= 0$	Validated data
C2 $\neq 0$	Severe defaults

The chosen thresholds are summarized in Table 2, and the data are considered as validated if there is no difference between the maximal frequency of the mean auto-spectrum, and the target frequency. This of course assumes that the generation frequency is piloted in accordance with the frequency step of the delta f used in the spectrum computations.

Directly after, the level of this maximum peak, identified as criterion C3, is compared to the generation target, ensuring proper correspondence. As above mentioned, all the generation gains are adjusted in the campaign preparation phase, and there is no enslavement or feedback control loop during a record. Any discrepancy in the productive tests has to be identified and investigated. A threshold value of 2dB is proposed, as presented in Table 3.

Table 3. Criterion C3: max level identification.

C3 $\in$ target +/- 2dB	Validated data
C3 $\ni$ target +/- 2dB	Defaults

It has to be noted that the gains are derived for the fully rigid sample, and applied then for all samples to be tested. Due to their impedance, or the quality of the mechanical flushness of the tested sample, the reflected energy will change, and can affect then the levels on the upstream array.

In a third step, the next criterion compares the target level at the targeted frequency with the global OASPL, in order to detect any significant perturbations. Indeed, most of the energy should be carried by the targeted frequency in a laboratory environment such as the CANNELLE one. The C4 criterion is the absolute value of the difference between the max SPL at the targeted frequency with the OASPL averaged of the 100 microphones of the mean auto-spectrum, both on the upstream array. Based on the past experiences, and expectations of such a set-up, it has been decided to build two thresholds values, leading to the three categories mentioned in Table 4.

Considering the high levels injected in the bench, the harmonics of targeted frequency are often generated by the compression drivers. If harmonic distortion occurs, the second highest level of the mean auto-spectrum might probably be a peak, and the first harmonic of the targeted frequency. For that, the second highest level is detected, and the ratio between the first and second max level frequencies is computed, to validate if it is indeed a harmonic. For the search of the second maximum, it is proposed to explore all the rest of the spectrum. However, a certain distance to the first peak has been set. Working with a delta f of 4 Hz, several values have been tested, and the selected distance is further than 20Hz (so 5 spectral lines) on each side of the first maximum. As summarized in Table 5, this is an all-or-nothing criterion. When it is different of two, so not an harmonic, it could have several root causes, like the generation chain (digital to analog conversion, the amplification), the loudspeakers distortion, the lab acoustic background noise, or the acquisition chain (electrical noise, grounding issues, etc.).

Table 4. Criterion C4: max level and OASPL difference

C4 ≤ 0.1	Validated data
$0.1 >$ C4 ≤ 0.5	Should be ok data
C4 > 0.5	Severe defaults

Table 5. Criterion C5: 2^{nd} and 1^{st} max level frequencies ratio.

C5 $= 2$	Validated data
C5 $\neq 2$	Defaults

Immediately after, if the second peak is indeed the first harmonic, it is proposed to compare it to the first maximum. The difference of the two is computed, leading to criterion C6. This is mainly providing information on the compression drivers health. The threshold of this criterion are difficult to set, mainly because it is directly linked to the targeted level. Indeed, if for instance, 130 dB is expected, the distortion is reasonable, and the C6 can be up to 20 dB when there is no default on the generation. However, if the target is 140 or 150 dB, then C6 criterion can easily be 5 dB or less, even when the compression drivers are working properly. Table 6 summarizes the threshold values for the C6 criterion.

The last criterion in the frequency domain is based on

Table 6. Criterion C6: difference between 1^{st} and 2^{nd} max levels.

C6 $>$ 20dB	Validated data
C6 $\in$ [10 ; 20] dB	Should be ok data
C6 $<$ 10dB	Defaults

coherence. It is quite straightforward in order to detect any issue linked to one or several microphones. Fo that, the coherence is computed for all microphones of both upstream and downstream arrays, with the reference sensor being the first microphone of each array. The criterion C7 is computed by extracting the coherence values at the generated frequency, as shown in Fig 3.

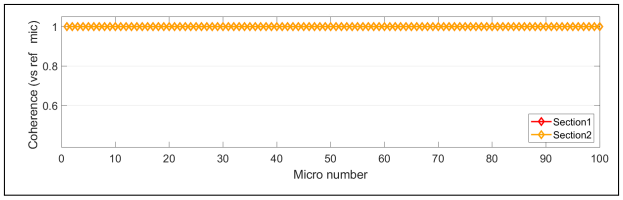

Figure 3. Coherences at the excitation frequency of all microphones of the two detection arrays for the testpoint α.

Table 7 summarizes the thresholds values for this criterion.

Table 7. Criterion C7: coherence values at the target frequency.

C7 $>$ 0.99	Validated data
C7 $\in$ [0.9 ; 0.99] dB	Should be ok data
C7 $<$ 0.9	Defaults

As the CANNELLE set-up is in a lab environment, the coherence is expected to be very close to 1, considering that there is no flow, and that all the microphones are in the same waveguide. A lower coherence might indicate a defect on the SPL at targeted frequency, a mic issue, or the presence of parasitic noise, either acoustic background or electrical noise. A value lower than 0.99 illustrates a significant difference. Furthermore, a value lower than 0.9 directly shows a severe default on the concerned microphone.

3.3 Validation based on criteria in the modal domains

As the purpose of the bench is the modal generation, it is important to verify that the test has reached its objectives.

First, only the upstream detection array is considered. Figure 4 represents the intensities of the incident and reflected propagative modes of the testpoint α. The maximum modal intensity is identified, and its associated azimuthal order is compared to the target, and the criterion C8 is their difference. Any deviation would discard the testpoint, and a root cause analysis follows, as summarized in Table 8.

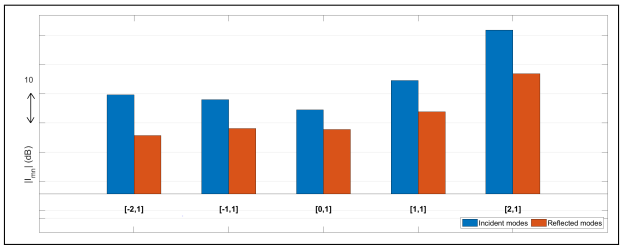

Figure 4. Intensities of the incident (blue) and reflected (orange) propagative modes in the upstream detection array for the testpoint α.

Table 8. Criterion C8: dominant mode identification.

C8 $= 0$	Validated data
C8 $\neq 0$	Severe defaults

Then, the second maximum modal intensity is identified and analyzed. First, its modal intensity is compared to the maximum one, leading to Table 9 threshold values for this C9 criterion.

The way this criterion is computed has to be adapted when at least one second-order radial mode is cut-on. Indeed, the modal energy of the same azimuthal order will be spread over all radial cut-on modes.

Moreover, it is interesting to analyze which mode is the one with the second largest modal intensity. It could be the same mode but its reflected part, meaning the acoustic waves traveling backwards. It could also be another

Table 9. Criterion C9: difference between 1^{st} and 2^{nd} max modal intensities.

C9 $>$ 20dB	Validated data
C9 $\in$ [10 ; 20] dB	Should be ok data
C9 $<$ 10dB	Defaults

mode: the closest one in terms of azimuthal content, or the mode with the cut-on frequency being the nearest to the generation frequency for instance. There is no criterion on this aspect because it has to be analyzed case by case. Then, this C9 criterion can be computed for the downstream detection array as well, and the results have to be put into perspective regarding what has been found on the upstream detection array.

Finally, the last criterion is the transmission loss (TL) on the generated mode. With the bench in a "pure acoustic" configuration, it is assumed that it is equal to 0 when the rigid section is installed (if the viscous dissipation on the duct wall is not taken into account). Even if the approach followed in this study does not aim at assessing the experiment uncertainty, this final criterion provides a fair idea of the full method reliability and robustness, because it includes the impact of the bench mounting, the generation, the acquisition and the full data post-processing chain. A confidence interval of +/-1dB is proposed, as presented in Table 10.

Table 10. Criterion C10: transmission loss.

C10 $\in$ [-1 ; 1] dB	Validated data
C10 $\ni$ [-1 ; 1] dB	Defaults

4. DISCUSSION AND CONCLUSION

This study presents a methodology for the validation of experimental data, applied to a circular testrig that works on the principle of higher-order modal generation and detection. The approach is based on the computation of criteria in the temporal, frequency and modal domains, and to compare them with the target values and their associated thresholds.

The bench considered is CANNELLE, a circular waveguide built on modal generation and detection principles, generally used for acoustic liner characterization in pure acoustic or in aero-acoustic configurations, mounted in this study with a rigid part considered as a reference set-up. Several criteria are computed from the microphone temporal raw data: 1 in the temporal domain, 6 in the frequency domain, and 3 in the modal domain. One or several thresholds are proposed, in order to establish if the criterion is considered: as nominal and lies within the expected target, so that the data are a priori validated; as barely nominal , with little investigation to perform, so that data "should be ok"; or as a default (more or less severe), which are requiring further analysis.

Several conclusions are drawn from this study. First, the criteria provide information for different validation aspects: at the instrumentation level, the measurement and the experiment itself. For the instrumentation, it can reflect if the acquisition has properly worked (no electrical perturbations or large faulty contact, microphones capturing the signal, etc.). About the measurement, it helps to identify if the generation is working as expected, or if the generated signal is emerging from the background noise, or if there are any other perturbations in the record, electrical or acoustical. Concerning the experiment, it helps to understand if the experiment has worked, meaning that the targeted mode is the dominant one, and that other cut-on modes, either created by error in the generation or by some modal re-distribution during propagation for instance are not perturbing the test. One of the key features of the criteria analysis is that these indicators clearly prepare the testpoint validation, and allows to put the focus towards particular results that might need further investigations to understand the abnormal behavior.

However, it clearly appears that the target values and their associated thresholds need to be refined. Although the values proposed in this study are based on the past experiences and testcampaign observations, with engineering judgment, a previous study on another testbench [14] has shown that a statistical analysis of a representative dataset could help to fine tune the values. Moreover, it is obvious that some thresholds should be adapted to the target level. Indeed, the compression drivers do not have the same behavior when excited to reach 130dB or 150dB. For instance, the harmonic distortion is strongly dependent on the voltage of the excitation. A consequence could be directly observed on the C6 criterion, the difference between the first and the second maximum levels of the mean-spectrum. Following the same reasoning, the thresholds should also be adapted to the frequency: the responses of

the compression drivers differ a lot between 300 Hz and 5000 Hz. This might be considered in the next improvement phase of the methodology, to have frequency and level dependent thresholds for some specific criteria.

In order to continue the development of such a methodology, it will be interesting to apply this approach to other reference samples, which are measured several times during each testcampaign, mainly for reproducibility purposes.

Then, the step after could be to evaluate the limit of the criteria and associated target values, with for instance their application to *a priori* unknown liner sample. In addition, this method is planned to be extended to the bench when used in wind tunnel testing for aero-acoustic liner tests. The target values and the thresholds might be adapted, as well as some criteria (e.g. C5). Indeed, it sometimes happens that wind tunnel aerodynamic flow carries some tonal component, linked to the fan of the facility. In addition, the frequency computations might also be modified to use synchronous averaging as in [12].

NUMERICAL ASSESSMENT OF A MODE DETECTION ARRAY FOR AZIMUTHAL DECOMPOSITION

Hugo Vincent* **Antonio Pereira** **Marc C. Jacob**

Ecole Centrale de Lyon, CNRS, Universite Claude Bernard Lyon 1, INSA Lyon, LMFA, UMR5509, 69130, Ecully, France

ABSTRACT

The efficiency of a mode detection array for azimuthal mode decomposition in turbofan nacelle experiments is numerically investigated by analyzing acoustic solutions computed using the commercial finite-element code ACTRANTM. First, irrotational inviscid mean flow fields are computed for sideline conditions, with and without an external flow at a Mach number of 0.2. Then, the upstream propagation of duct modes representing fan noise components is performed for three frequencies by solving the Möhring equation in the frequency domain using ACTRANTM. The acoustic solutions are interpolated to the microphone locations of the mode detection array. In all cases, the azimuthal structure of the interpolated data is obtained using Fourier transforms. It is compared to a reference one, determined by a duct mode decomposition of the full acoustic solution. The results provide guidelines for the analysis of ongoing experiments. They indicate that the detection antenna will be able to efficiently capture the azimuthal mode distributions, but not the radial structure. The procedure can be applied to design improved microphone arrays by defining judicious axial and radial positions for azimuthal and radial mode decompositions. Moreover, the approach can determine the optimum discretization for azimuthal mode decomposition.

1. INTRODUCTION

Aircraft produce noise that affects the health of people living near airports. Acoustic radiation originates mainly from the engine and, in particular, from the jet and the fan stage. With the development of Ultra-High Bypass Ratio (UHBR) engines, the noise produced in the fan stage has become the main noise contributor, as described in the recent review by Moreau [1]. The noise generated in the fan stage is characterized by tonal and broadband components. The tonal noise is produced at the Blade Passing Frequency (BPF) and its harmonics [2]. It is reduced by the use of acoustic liners [3], the optimization of which requires an in-depth knowledge of the acoustic field properties.

During their propagation in a turbofan intake, the acoustic waves reflect on the nacelle walls, leading to constructive and destructive interference at specific radial and azimuthal locations. As a result, the acoustic field can be decomposed into azimuthal and radial duct modes [4, 5]. The duct modes satisfy specific dispersion relations whose properties are used to determine key features of the acoustic field from in-duct experimental measurements [6–8].

The measurements are generally performed with wall-flush mounted microphones. The azimuthal structure of the acoustic field can easily be estimated from pressure measurements obtained on a microphone ring using Fourier transforms in the azimuthal direction. Computing the radial-mode amplitudes is more challenging since it is not possible to put microphones in the radial direction in a turbofan without significantly disturbing the flow. To the best of the authors' knowledge, Moore [6] was the first to describe a method for performing radial decomposition.

This method consists in projecting the acoustic field onto Bessel functions. Using this method, Moore [6] was able to decompose a synthetic field into azimuthal and radial modes. He also successfully applied the method to circumferential and radial measurements for a ventilation fan. Considering only measurements obtained in the azimuthal and axial directions, with rings and lines of microphones, and using the properties of the solutions of the convective wave equation, Enghardt *et al.* [7] were able to carry out an azimuthal and radial mode decomposition of the pressure fields measured in an axial-flow fan, using a method similar to the one introduced by Moore [6].

From measurements in the radial, azimuthal, and axial directions, it is possible to separate the upstream and downstream waves and to determine the amplitudes of the duct modes by applying procedures described by Rienstra [9]. However, in practice, such a full-mode decomposition cannot usually be performed because it requires microphones in the radial direction.

In the framework of the COMPANION (COMmon Platform and Advanced iNstrumentration readIness for ultra efficient propulsiON) project, pressure measurements obtained on a mode detection antenna will be analyzed to characterize the propagation of fan noise in a new-generation nacelle intake. The antenna is represented in figure 1. It is made of two rings and 4 axial lines linked to the azimuthal angles $\theta = 0, \pi/2, \pi$ and $3\pi/2$. All microphones are uniformly spaced and flush-mounted in the wall. A part of the nacelle intake is also depicted in figure 1. The geometry is non-axisymmetric and has a plane of symmetry.

The objective of the present work is to assess the capacity of the detection antenna to perform an azimuthal and radial decomposition. The study is conducted by analyzing pressure fields associated with fan noise propagating upstream through the nacelle intake. These pressure fields are simulated using the commercial finite element code ACTRANTM. Two flow configurations for sideline conditions and three frequencies are considered.

The remainder of this paper is organized as follows. Mean flow computations are documented in section 2. The numerical methods used for acoustic propagation calculations, as well as the pressure fields obtained, are described in section 3. A full mode breakdown is described in section 4. The capability of the antenna to perform azimuthal and radial decompositions is assessed in section 5. Concluding remarks are provided in section 6.

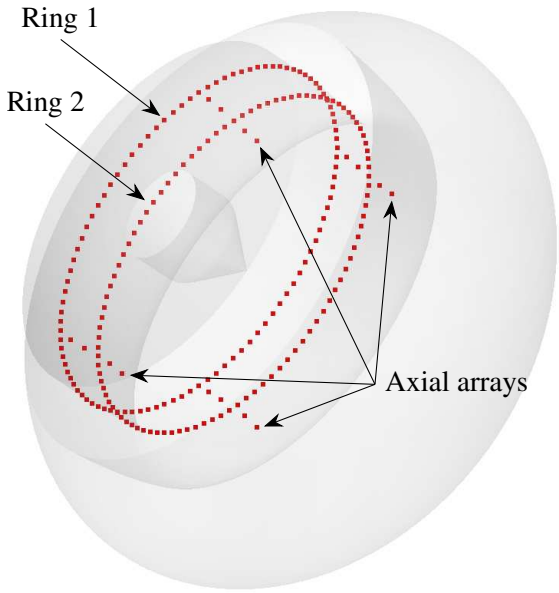

Figure 1. Representation of the inlet acoustic antenna composed of 2 rings and 4 axial lines; A part of the nacelle intake is displayed with transparency.

2. MEAN FLOW COMPUTATIONS

Two flow configurations associated with sideline conditions with and without an external flow at a Mach number of 0.2 are considered. Compressible irrotational inviscid mean flow fields are calculated using a potential flow solver implemented in ACTRAN. For that, an almost cylindrical computational domain is defined using the open-source software GMSH [10]. It is closed by an outlet surface normal to the flow direction located slightly downstream of the intersection between the rotor blades and the spinner. The rotor blades are not considered.

Mean pressure, density, and velocity fields are obtained by solving a generalised Laplace equation for the scalar potential using the finite element method. This equation is solved for an unstructured mesh composed of 9.4 million first-order triangles and tetrahedra generated using GMSH [10]. The element sizes were determined by a mesh sensitivity study, not described in this paper for the sake of brevity. The calculations required 28 GB of memory and less than one CPU hour. The mean flow fields were stored in all the mesh elements. They were used by ACTRANTM to solve the convected wave equation.

Cross-sections of the mean velocity fields obtained for $\mathrm{M_{ext}} = 0$ and $\mathrm{M_{ext}} = 0.2$ are represented in figures 2(a,b). For both cases, outside the nacelle, the levels are close to the exterior velocity associated with $\mathrm{M_{ext}} = 0$, as expected. Inside the geometry, they are higher and the mean velocity fields are nearly uniform, with velocity values around $165\,\mathrm{m/s}$. The strongest levels are found inside the geometry near the inlet lips. They are around $250\,\mathrm{m/s}$ for $\mathrm{M_{ext}} = 0$ and $200\,\mathrm{m/s}$ for $\mathrm{M_{ext}} = 0.2$. The flow near the inlet lips is thus more accelerated for $\mathrm{M_{ext}} = 0$ than for $\mathrm{M_{ext}} = 0.2$. These results are consistent with those reported by Doherty & Namgoong [11] and Xiong *et al.* [12].

3. ACOUSTIC PROPAGATION COMPUTATIONS

The acoustic propagation computations are carried out using ACTRANTM by solving a frequency domain formulation of the Möhring's equation [13], i.e. the convected wave equation for a non-uniform irrotational flow. Acoustic modes are injected slightly downstream of the intersection between the rotor blades and the spinner. Three arbitrarily chosen frequencies $f = 1000\,\mathrm{Hz}$, $3000\,\mathrm{Hz}$ and $5000\,\mathrm{Hz}$ are considered. They are associated with the Helmholtz numbers $\mathrm{He} = 2\pi f R/c_0 = 6, 18, 30$, where R is the outer duct radius and c_0 is the speed of sound in ambient medium. For each frequency, the propagation of all acoustic modes with a cut-off frequency below $3000\,\mathrm{Hz}$ is computed. The amplitude of the modes is set to $1\,\mathrm{Pa}$ at the injection plane. Thus, 16 modes are considered for $f = 1000\,\mathrm{Hz}$, whereas 126 modes are taken into account for $3000\,\mathrm{Hz}$ and $5000\,\mathrm{Hz}$.

The numerical methods used for the simulations are very similar to those recommended by Van Antwerpen *et al.* [14]. The computational domains are semi-elliptical and their size varies with frequency. Exploiting the planar symmetry of the nacelle intake, half-domain computations are performed using a fully automated strategy for decomposing the acoustic solutions into symmetric and anti-symmetric parts implemented in ACTRANTM. Acoustic meshes are generated using GMSH [10]. They are made of quadratic triangles and tetrahedra, and are refined so that each acoustic wavelength is discretized by at least four elements. The Perfectly matched layers (PMLs) described by Hu [15] are used at the boundaries considering non-uniform mean flow fields. Their thickness varies with frequency and is equal to $\lambda = c_0/f$. Six different meshes are thus considered. They contain between 710 000 and 7 200 000 nodes.

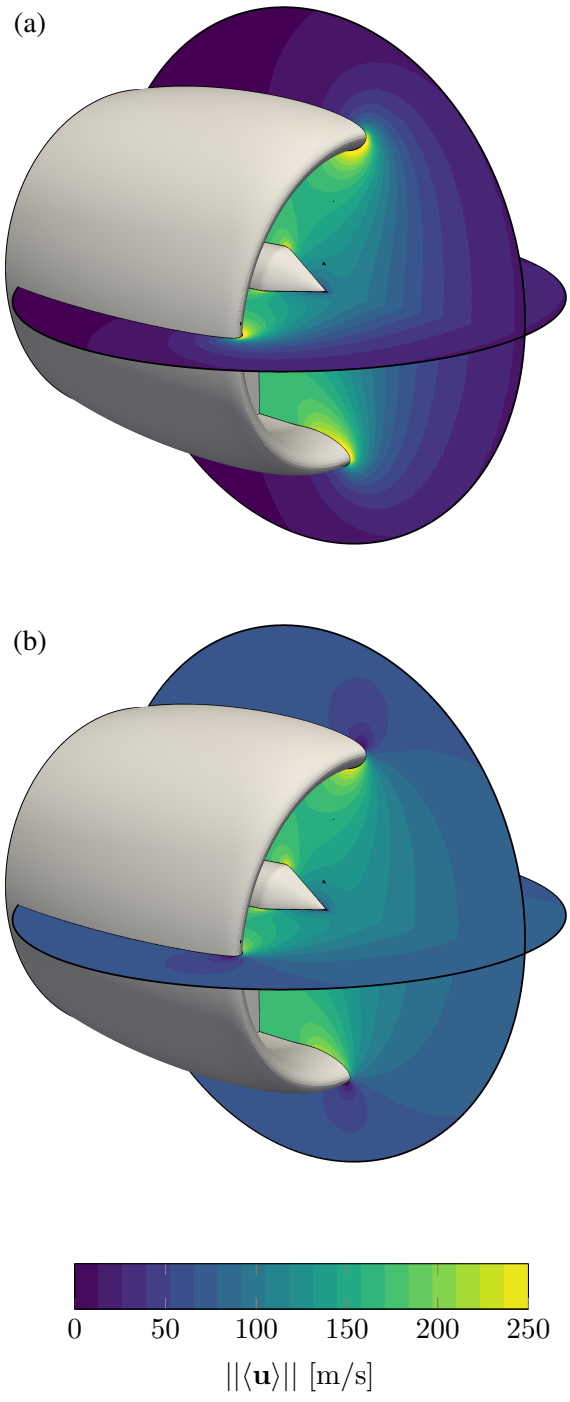

Figure 2. Magnitude of mean velocity vector on two longitudinal slices for sideline conditions and an external flow at (a) $\mathrm{M_{ext}} = 0$ and (b) $\mathrm{M_{ext}} = 0.2$.

For $f = 1000\,\text{Hz}$, the computations require around 8 GB of memory and less than one hour of CPU time. For $f = 5000\,\text{Hz}$, the simulations need approximately 200 GB of memory and 10 CPU hours. For each frequency and mode, the solutions have been stored on a full 3D mesh associated with the computational domain without the PML, on the microphone locations of the detection antenna, and on a cylindrical structured grid. The solutions for more than 500 modes were thus stored, constituting a database of approximately 700 GB.

The pressure fields obtained for the three frequencies 1000 Hz, 3000 Hz and 5000 Hz, for the two flow conditions with $\text{M}_{\text{ext}} = 0$ and $\text{M}_{\text{ext}} = 0.2$, for the plane mode, are represented in figures 3(a-f). In all cases, the propagation of acoustic waves through the inlet geometry and in the near field can be seen. The wavelengths are shorter for higher frequencies, and near the high velocity regions, as expected. For $f \geq 3000\,\text{Hz}$ in figures 3(b,c) and 3(e,f), the footprints of modes with radial orders $n \geq 0$ can be observed on the upstream boundaries of the domains.

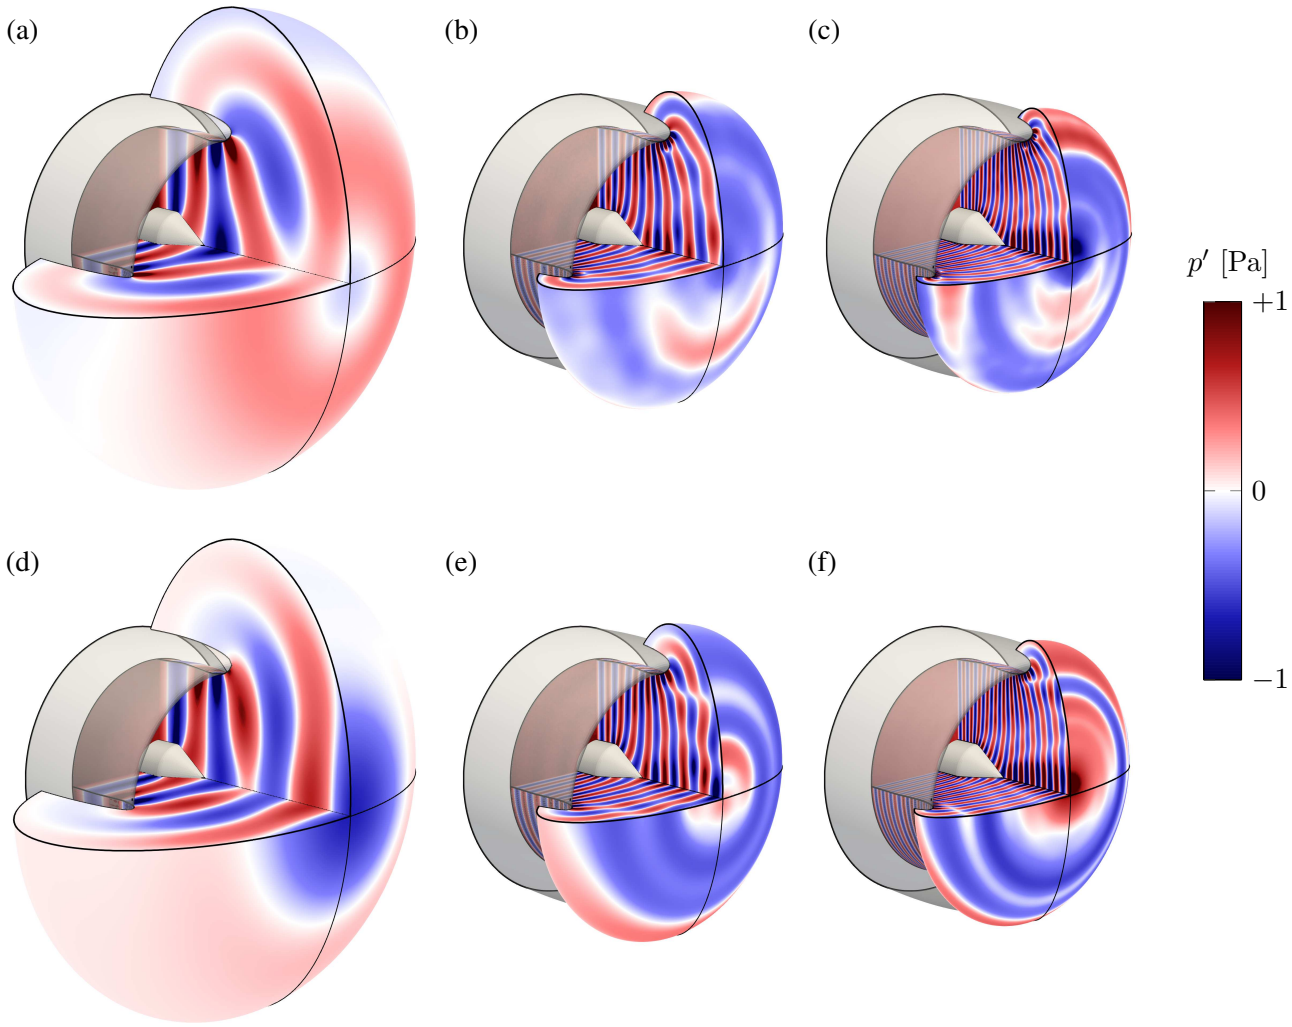

Figure 3. Representations of the real part of the pressure fields obtained for (a-c) $\text{M}_{\text{ext}} = 0$ and (d-f) $\text{M}_{\text{ext}} = 0.2$, and (a,d) $f = 1000\,\text{Hz}$, (b,e) $f = 3000\,\text{Hz}$ and (c,f) $f = 5000\,\text{Hz}$; three quarters of the computational domains without the PMLs are shown, and the geometry is displayed in gray with transparency.

4. DUCT-MODE DECOMPOSITION

The acoustic solutions are decomposed into upstream and downstream propagating azimuthal and radial modes by applying a procedure described by Rienstra [9]. The pressure fields satisfy equation (1), where $A_{m,n}$ and $B_{m,n}$ are respectively the amplitudes of the upstream and downstream propagating modes associated with the eigenfunctions for annular and circular duct sections $f_{m,n}$, and $k^+_{z_{m,n}}$ and $k^-_{z_{m,n}}$ are the associated axial wavenumbers, m and n are the azimuthal and radial orders, and i is the imaginary unit. The decomposition is performed for the duct-modes with azimuthal and radial orders between $m = 0$ and 4 and $n = 0$ and 4, using the complex pressure and axial velocity obtained on the structured grid previously mentioned. This grid is uniform and contains $N_r = 50$, $N_\theta = 64$, and $N_z = 60$ points in the radial, azimuthal, and axial directions. It extends radially from $r = 0$ up to the outer radius, and axially from $z = 0$ up to the end of the duct at $z \simeq 0.92R$. For each axial position, the amplitudes of the upstream and downstream propagating azimuthal and radial duct modes are estimated.

The contributions of the first five azimuthal modes to the sound pressure levels (SPL) of the upstream propagating fluctuations, obtained from the decomposition for the plane mode for $f = 3000\,\text{Hz}$, for $\text{M}_{\text{ext}} = 0$ and $\text{M}_{\text{ext}} = 0.2$ are represented as functions of the axial distance in figures 4(a,c). The axial positions of the two rings of the detection antenna are also depicted. In both cases, the dominant mode is axisymmetric, as expected for the plane mode. Upstream of the first ring for $z \gtrsim 0.25R$, strong levels are found for higher azimuthal orders $m = 1{-}4$, indicating that a proportion of the plane mode energy is redistributed on higher azimuthal modes during the propagation through the inlet. This was also the case in other studies [11, 12], and is certainly due to the non-axisymmetric geometry of the intake. The SPL of the axisymmetric mode for the first five radial modes in the flow conditions with $\text{M}_{\text{ext}} = 0$ and $\text{M}_{\text{ext}} = 0.2$, are displayed in figures 4(b,d). The plane mode is initially the mode with the highest energy content. This is not the case at the end of the duct, for $z \gtrsim 0.7r_0$, where the contributions of the radial modes with $n = 1 - 4$ are predominant, in agreement with the pressure fields in figures 3(b,e).

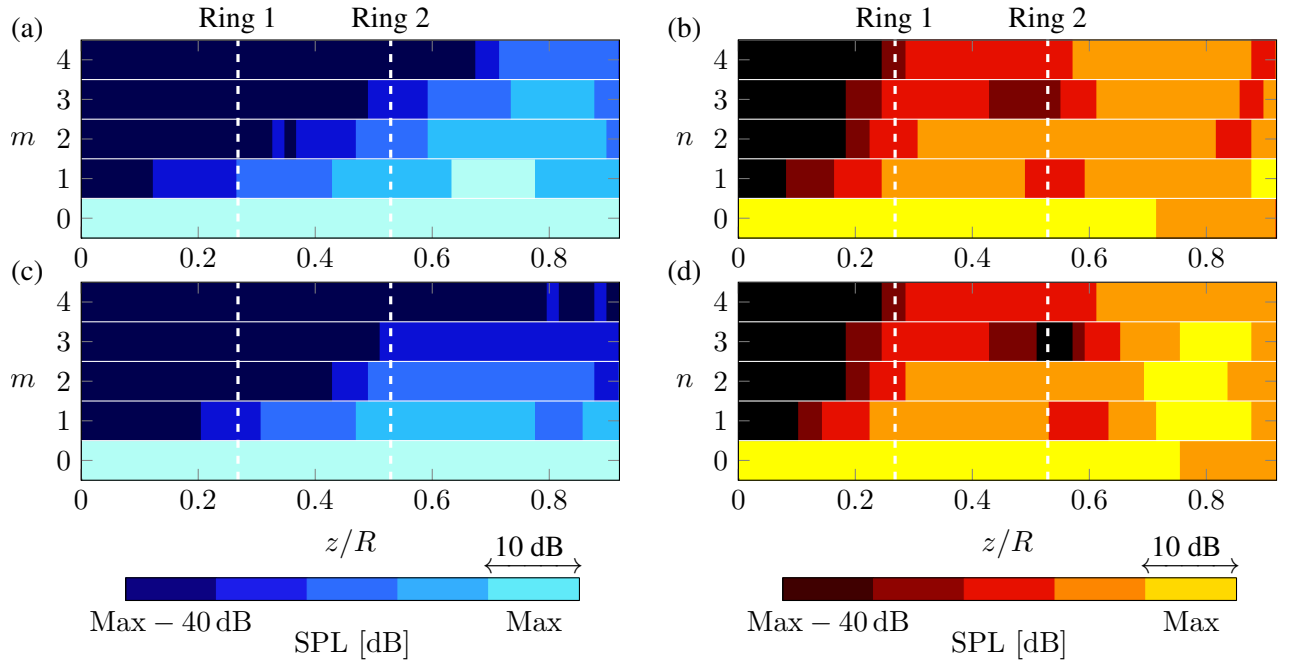

Figure 4. Sound pressure levels for the plane mode for $f = 3000\,\text{Hz}$ for (a,b) $\text{M}_{\text{ext}} = 0$ and (c,d) $\text{M}_{\text{ext}} = 0.2$, for upstream propagating (a,c) azimuthal modes and (b,d) axisymmetric radial modes ($m = 0$).

$$p\left(r,\theta,z\right)=\sum_{m=-\infty}^{\infty}\sum_{n=0}^{\infty}\left(A_{m,n}e^{ik_{z_{m,n}}^{+}z}+B_{m,n}e^{ik_{z_{m,n}}^{-}z}\right)f_{m,n}\left(r\right)e^{im\theta} \tag{1}$$

5. ASSESSMENT OF THE ANTENNA

To assess the capability of the antenna, only the complex pressure values obtained at the microphones of the detection antenna are analyzed in what follows. First, an azimuthal decomposition is performed by applying Fourier transforms to the pressure determined at the microphones of the two rings. The SPL obtained for the plane mode are represented as a function of the azimuthal order for the three frequencies for $\mathrm{M_{ext}} = 0$ in figures 5(a-c). They are displayed in red for Ring 1 and in blue for Ring 2. For both rings, the levels for the helical modes are stronger for higher frequencies, indicating that the redistribution of the plane mode energy on higher azimuthal modes is more important for these frequencies. Moreover, for $f = 5000\,\mathrm{Hz}$ in figure 5(c), the SPL associated with the first helical mode is approximately $15\,\mathrm{dB}$ higher than for the axisymmetric mode.

For all frequencies, the contributions of azimuthal modes with $m \geq 1$ are higher for Ring 2 than for Ring 1. They are therefore consistent with those determined along the duct axis, shown in figure 4(a). This indicates that the mode detection antenna can be useful for performing an azimuthal decomposition. Similar results, omitted here for clarity, are obtained for the other flow configuration with $\mathrm{M_{ext}} = 0.2$.

To investigate the ability of the mode detection antenna to perform a radial decomposition, the complex pressures obtained on the two rings and on the four axial lines are first arranged in a matrix $\mathbf{\Phi} \in \mathbb{C}^{K\times L}$, where L is the number of modes computed at a given frequency and K the total number of microphones in the antenna. Then, the modal coherence matrix [8, 16]

$$\mathbf{\Gamma} = \max_{1\leq i<j\leq L} \frac{|\langle \mathbf{\Phi}_i, \mathbf{\Phi}_j\rangle|}{\|\mathbf{\Phi}_i\|_2 \|\mathbf{\Phi}_j\|_2}, \tag{2}$$

where $\mathbf{\Phi}_i$ is the ith column of $\mathbf{\Phi}$, is computed for all cases. It quantifies the linear interdependence between two modes [17] and is therefore linked to the ability of the detection antenna to dissociate two modes.

The modal coherence values obtained for the first six cut-on axisymmetric modes for $f = 3000\,\mathrm{Hz}$ and $5000\,\mathrm{Hz}$ for $\mathrm{M_{ext}} = 0$ are presented in figures 6(a,b). In both cases, the values are equal to 1 along the diagonal since they are associated with the coherence of a mode with itself. They are also equal to 1 for the radial modes with $n \leq 3$, indicating that the footprints of these modes on the detection antenna are similar. This suggests that the antenna will not be able to separate these different radial modes. Overall, the coherence levels for $f = 5000\,\mathrm{Hz}$ in figure 6(a) are higher than those for $f = 3000\,\mathrm{Hz}$ in figure 6(b). This indicates that the capability of the

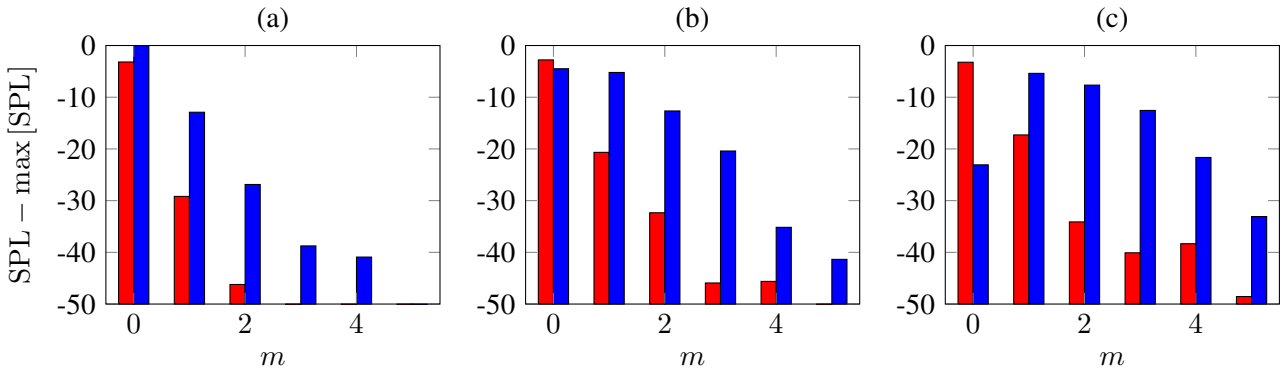

Figure 5. SPL for the plane mode as a function of the azimuthal order for (a) $f = 1000\,\mathrm{Hz}$, (b) $f = 3000\,\mathrm{Hz}$, (c) $f = 5000\,\mathrm{Hz}$ for $\mathrm{M_{ext}} = 0$, for the pressure obtained at the microphones of Ring 1 and Ring 2. The common SPL reference for the three plots is arbitrary.

antenna to distinguish two modes with the same azimuthal structure is reduced for a higher frequency.

The modal coherence levels obtained for 5000 Hz for $M_{ext} = 0.2$ are represented in figure 6(c). They are similar to those for $M_{ext} = 0$ in figure 6(a), suggesting that the ability of the antenna to separate two modes does not depend on the external flow Mach number.

A Tyler & Sofrin [2] mode linked to rotor-stator interaction is now considered. Its azimuthal order is $m = -4$. The coherence values obtained for the first five cut-on modes with $m = -4$ are displayed in figures 6(d-f). They exceed 0.5, suggesting that the detection antenna is not suitable for separating the radial modes of the Tyler & Sofrin mode under consideration. Moreover, the coherence levels for $m = -4$ are slightly lower than those for the plane mode in figures 6(a-c). The antenna therefore seems slightly better suited to separate modes with relatively high azimuthal modes.

6. CONCLUSIONS

The ability of a mode detection array for duct-mode decomposition in turbofan nacelle experiments is numerically investigated by analyzing acoustic solutions computed using the commercial code ACTRANTM. A full-mode breakdown is performed to obtain reference amplitudes for the upstream and downstream propagating azimuthal and radial modes. The detection antenna effectively captures azimuthal mode distributions. However, its capability to distinguish between modes with the same azimuthal structure remains limited. This provides guidelines for the analysis of future experimental measurements. In future work, it will be interesting to compare the results with solutions obtained using analytical models [18] or a Green's function discretization technique [19]. It could also be interesting to apply an inverse method [20] to determine the modal amplitudes.

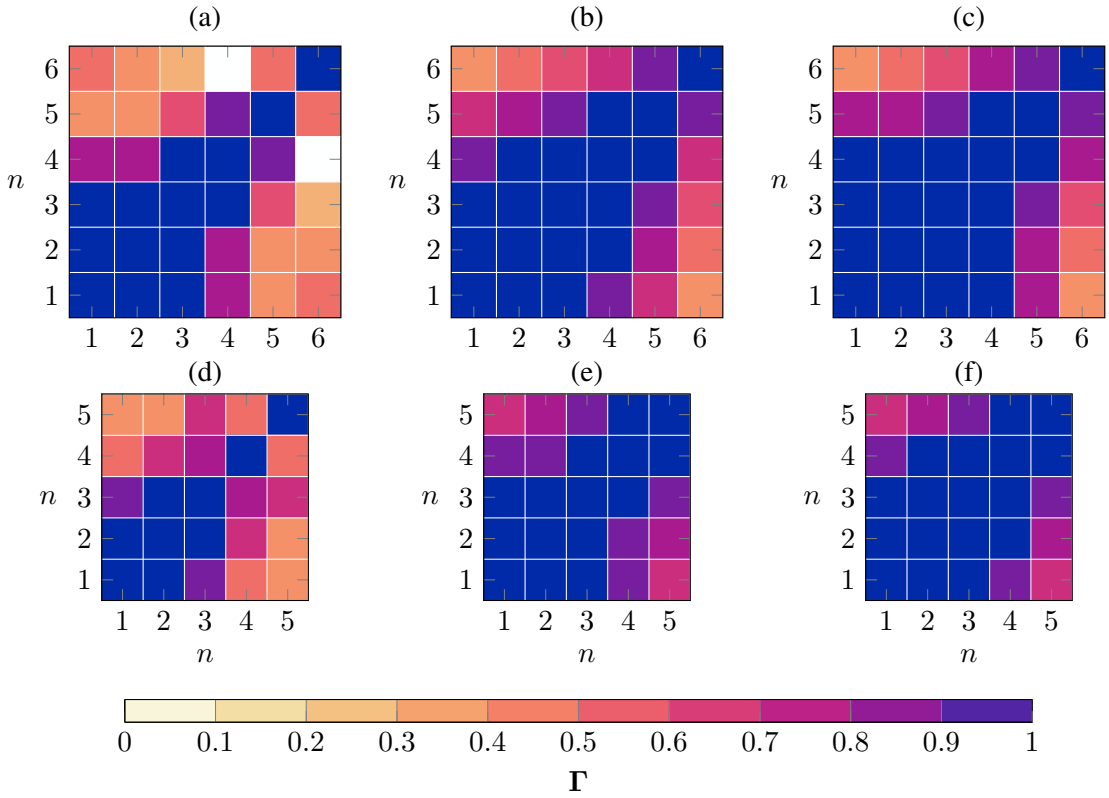

Figure 6. Modal coherence for (a,d) $f = 3000$ Hz and (b,e) $f = 5000$ Hz for $M_{ext} = 0$, and (c,f) $f = 5000$ Hz for $M_{ext} = 0.2$, for (a-c) the first six axisymmetric modes ($m = 0$) and (d-f) the first five modes with $m = -4$, which is the azimuthal order of a Tyler & Sofrin mode.

APPLICATION OF ATMOSPHERIC WIND FILTER ARRAYS FOR ACOUSTIC MONITORING UAVS

Ramesh Raja Subramanyam[1*] **Criostoir Gerasch**[1] **Stefan Jacob**[1]

ABSTRACT

The application of Uncrewed Aerial Vehicles (UAVs) in low frequency acoustic measurements is, among other factors, limited by the disturbances induced by atmospheric wind noise. The infrasound sensor networks used in the seismic activity monitoring consists of a wind filter array that filter the acoustic disturbances caused by the atmospheric turbulence. These arrays function as spatial filters, eliminating the incoherent noises generated by the wind. In this study we design and test wind filter arrays for their application in a UAV based measurement platform. Different configurations of the wind filters such as the Rosette filter, porous circular pipes and several other derived configurations were studied. The frequency response function of the filters indicated a significant distortion from the acoustic resonance in the filter tube for some designs. Acoustic plane wave theory is used to tune these wind filter arrays for shifting these resonances beyond the frequency range of the measurement. In addition, an investigation is made by coupling arrays of varying dimensions to increase the effective frequency range of the filter.

Keywords: *infrasound measurement, wind noise filter, atmospheric turbulence, sensor array, uav measurement*

1. INTRODUCTION

The increasing growth of renewable energy converters, e.g. Wind turbines, has raised a low frequency noise concern in the nearby residential areas [1], [2]. The blade passing frequency of wind turbines and rotor blade interaction with wind generates an infrasound noise that are measured several kilometres in the downwind direction [3]. Sound power characterisation of wind turbines involves ground based measurements based on the standard guidelines in IEC 61400 – 11 [4]. Microphones equipped with spherical windscreens are used to measure the Sound Pressure Level (SPL) in a linear array of points to estimate the sound power of the wind turbines. Application of this technique for infrasound frequencies is infeasible because longer wavelengths require measurements with network arrays. Moreover, the acoustic signal in the low frequencies is masked by atmospheric wind noise making it difficult to measure infrasound noise.

Infrasound Monitoring Stations (IMS) developed as a part of the Comprehensive Nuclear Test Ban Treaty Organisation (CTBTO) employ wind filter arrays to reduce the disturbance caused by atmospheric wind [5], [6]. These filter arrays are constructed with a series of pipes and their working principle is that the atmospheric wind induced turbulence is incoherent with a shorter wavelength in comparison to the infrasound signal which is filtered with a sensor array larger than the turbulent scale. The most common design is the rosette filter, consisting of multiple pressure sensing inlets distributed in a geometric pattern in a larger perimeter. As stated in the reference text, for filtering the wind noise in the frequencies below 5 Hz, a filter diameter of at least 18 m is required. The rosette filter design is limited by the acoustical resonance effect which is addressed with another form of wind filter design using porous pipe in a circular loop [7], [8]. It differs from the rosette filter design in that a single tube with porous inlets is used rather than a series of tubes. The circular filter, however, undergoes degradation due to defects arising over time. Furthermore, the remote location of IMS permits the

construction of these large infrasound filter arrays which are otherwise difficult to build near a residential area. For the measurement of infrasound noise in areas with limited spaces, spherical porous domes or large windscreens are used to shield the microphone from turbulence effects producing a maximum of 7 dB noise reduction [9], [10].

In recent times, the application of UAVs for remote sensing and environmental condition monitoring has gained traction for its improved accessibility to remote terrains [11]. The limiting factor in the use of UAVs for acoustic monitoring is the inherent noise they generate, which has been studied extensively [12], [13]. In our previous experimental study [14], we measured the low frequency noise signature of UAVs and concluded that in the low frequencies, the self-noise of the drone is minimal. Hydrodynamic fluctuations caused by the rotor thrust masked the acoustic signal in low frequencies, but it was limited to the downstream direction of the rotors. Having figured out the sweet spot for sensor location, in this study, we construct a wind filter array for measuring the infrasound noise using UAVs. We equip the UAV with the rosette filter, porous hose filter, and circular filter configuration and measure the filter response in the vicinity of the reference infrasound source of known sound power output [15].

While the porous wind filter domes are effective in infrasound range [10], their application in UAV measurements is prevented by the payload limitations of the drone. Except for the dimensional differences, both windscreens and wind domes average out the turbulence effects in the wind by integrating the sound pressure over a larger surface area. In addition, the porosity of the windscreen creates viscous and inertial losses which further reduces the atmospheric turbulence effects [16]. Measurements performed with various windscreens in a wind tunnel showed a significant noise reduction performance in low frequencies [17]. So, we constructed a circular microphone array using the microphones equipped with windscreens. Further, to filter the incoherent turbulences in the atmosphere, the spatial filter technique from the rosette pipe design was adopted. The construction of the array and the filters are explained in section. Results for each of the filter configurations tested are summarised in section 3. Finally, discussions and conclusions from the present study are provided in section 4 along with the future research plan.

2. METHODOLOGY

2.1 Measurement setup

2.1.1 UAV assembly

Measurements in this study are performed with PM X6 Pro Hexacopter drone with a payload capacity of 5 kg. We equipped the drone with 3D - printed attachments to carry the measurement hardware. Measurement data is acquired remotely using National Instruments NI 9181 DAQ. The sound pressure signal was recorded with a half - inch infrasound condenser microphone GRAS 47 AC powered by GRAS 12 AL CCP power module. The measured data is then relayed to a PC through a Wi-Fi router. For extending the Wi-Fi range while flying, a Wi-Fi bridge is mounted on the drone along with the power backup. The assembly of the measurement system on the drone is shown in Fig 1 (a).

2.1.2 Rosette filter design

Flexible PET pressure hose of 4 mm inner diameter and 1 mm wall thickness were used in constructing the filter. Filter was designed using the parametric relations given in the electroacoustic model developed by B. Alcoverro [6]. The inlet pipes of the filter are supported by the carbon tubes attached to the arms of the drone. Pneumatic connectors were used in connecting the inlet pipes to the secondary pipes. The secondary pipe is interfaced to the infrasound microphone through a 3D printed manifold of 30 mm × 30 mm × 5 mm volume. The constructed filter has a diameter span of 2.32 m and consists of six pressure inlets. The assembly of the rosette filter is shown in Fig 1 (b).

2.1.3 Porous hose design

For the porous filter design, holes of 2 mm diameter were drilled in the inlet pipes of the rosette filter. Holes were made for 300 mm length from the open end with an interval of 50 mm resulting in 36 pressure inlets in total. Porosity length was limited to avoid hydrodynamic fluctuations of the rotor. The rest of the assembly of the filter is similar to the rosette filter design described above.

2.1.4 Circular filter design

For the circular filter, 7.5 m pressure hose is made porous with 1 mm diameter hole with 100 mm interval. There were a total of 69 pressure inlets and the filter was looped around the ends of the carbon tubes at 2.32 m diameter. While one end of the filter was closed the other end was connected to the manifold. The filter construction is shown in Fig 1 (c).

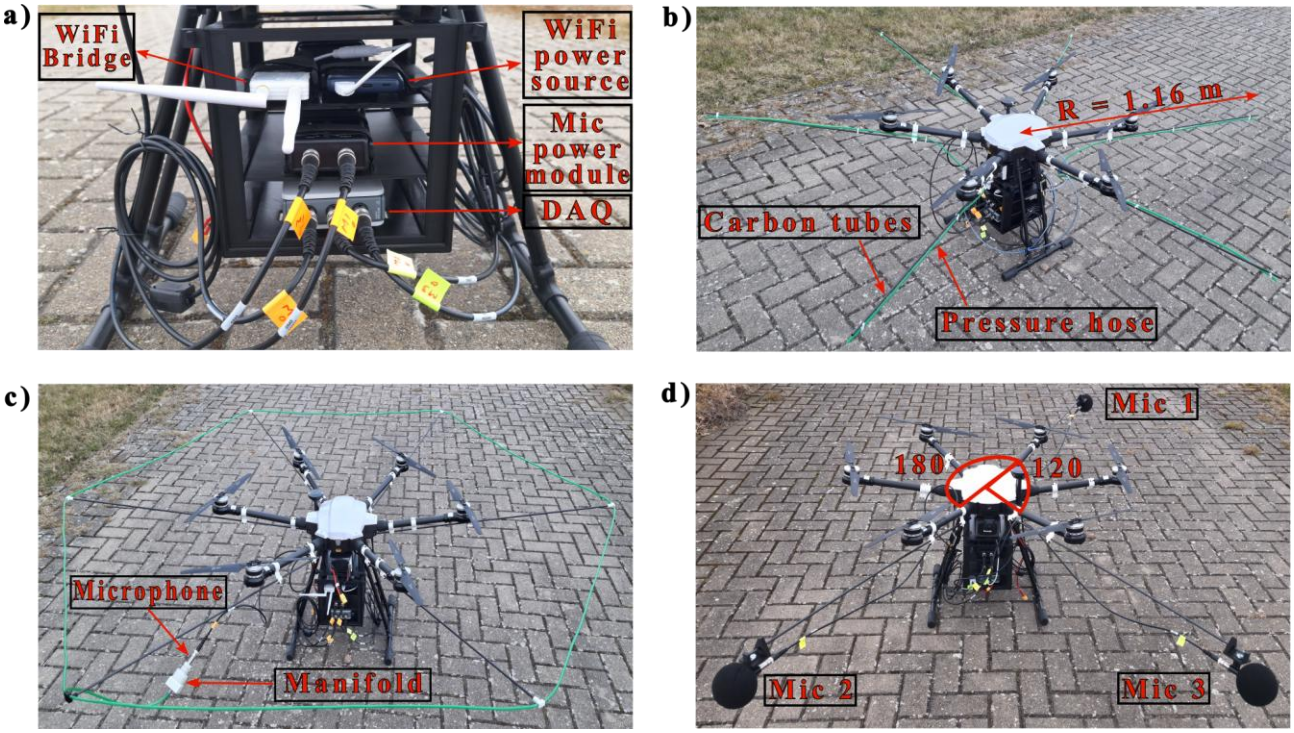

Figure 1. Picture showing the measurement setup in the UAV. a) DAQ hardware assembly, b) Rosette filter assembly, c) Circular filter assembly, d) Three microphone array assembly.

2.1.5 Three microphone array

A circular microphone array was built with three infrasound microphones (GRAS 47 AC). At the end of the carbon tubes, the microphones were mounted with a 3D printed support and GRAS 90 mm windscreens were attached to the microphones. The microphone filter array has a diameter span of 2.37 m. Two microphones were mounted 180 degrees apart and the third microphone was mounted at 120 degrees from the first mic to have a different separation distance as shown in Fig 1 (d).

2.2 Data acquisition

Measurements were performed at PTB's open field on a slightly windy day with an average wind speed of 10 kmph (forecasted value). The reference infrasound source [15] was used to radiate a 10 Hz tonal noise. Sound pressure was measured at ground level at 10 m from the source with the drone turned off and at an altitude of 10 m above the reference source with the drone in hover mode. The time signal was acquired for 300 seconds. Using Welch's algorithm [18] in Python, the measured time signal is converted to the frequency domain with 1 Hz resolution and 300 averages. Further, the background wind noise is measured without the infrasound source for comparative study. In addition, sound pressure is measured using a reference microphone stationed at the geometric centre of the filters tested.

3. RESULTS

The measurement results are plotted in terms of SPL spectra for a frequency bandwidth of 1 – 100 Hz. While the Power Spectral Density (PSD) is used for calculating the filter array SPL, Cross Spectral Density (CSD) is used for three microphone array results. The window correction factor, bandwidth correction factor, and microphone sensitivity are applied in estimating the exact SPL values in each case.

Fig 2 shows the comparison of SPL spectra measured with the three filter configurations (Rosette filter, Porous hose filter, and Circular filter) along with SPL spectra measured with the reference microphone. The

background noise measured at the ground level in Fig 2 a) indicates that the designed filter is less effective in reducing the wind induced noise compared to the single microphone with windscreen attached. Comparing the spectra of the three filter configurations, the rosette filter provides a better noise reduction for most of the bandwidth. Particularly in the infrasound range, the rosette filter response was 10 dB lower than the other two filter configurations. From the electroacoustic model [19], the high frequency cut off for the rosette filter with the given dimensions and 10 kmph wind speed was calculated to be 70 Hz (approx.) which agrees with the measurement result. As pointed out in the literature, the rosette filter response was affected by the internal resonances of the pipes around 40 Hz frequency.

The porous hose filter response resembles the rosette filter response except for the higher amplitude level. The increase in the SPL can be an effect of an increased number of pressure inlets. Likewise, for the circular filter, the SPL level is identical to that of the porous hose filter, but the resonance effects were shifted towards higher frequencies. Despite the absence of resonance in the frequency range of interest, the circular filter was least effective in filtering the wind noise.

However, the comparison of background noise at 10 m altitude in Fig 2 b) indicates a better performance with the circular filter. This is mainly due to the resonance effects in the rosette and porous hose filter amplifying the background noise. Also, the porous hose filter provides a better noise reduction in frequencies below 8 Hz, unlike the background noise measured at ground level. At higher altitudes, tonal noise corresponding to the shaft frequency of the drone rotors is generated around 70 Hz which is measured in all filters. Because of the variation in the rotational frequency of the rotor in each arm of the drone, the peak appears broader. However, the overall noise level measured with the filter has increased further by 10 to 15 dB at higher altitudes in comparison to the spectra measured at the ground.

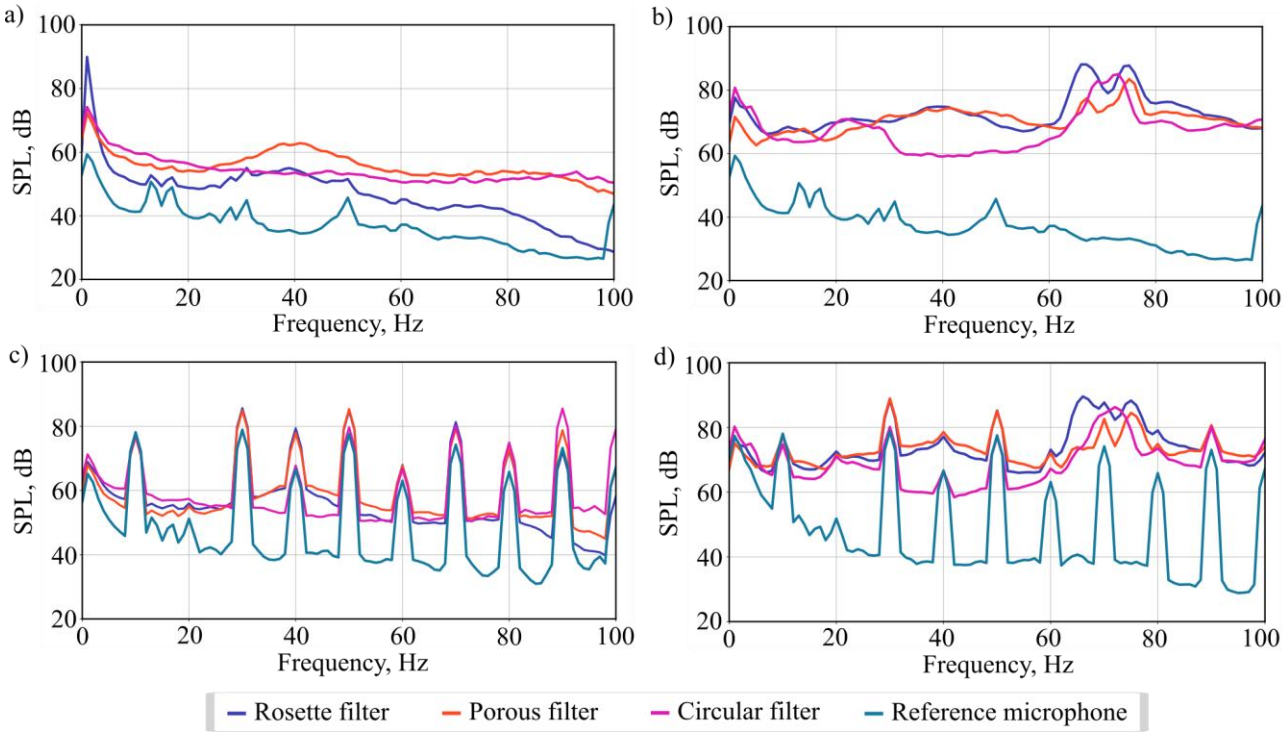

Figure 2. Comparison of SPL spectra measured with the filters and the reference microphone. a) Background noise at ground, b) Background noise at 10 m height, c) Infrasound source noise measured at ground, d) Infrasound noise measured at 10 m height.

To quantify the filter effects on the measured amplitude levels, an investigation using the infrasound noise source is performed. The source noise measured at the ground level is plotted in Fig 2 c). All filter configurations measured the same amplitude level of the 10 Hz tone as the reference microphone. The amplitude levels of the overtones between 30 Hz to 50 Hz were higher with rosette and porous hose filter due to the internal resonances. Beyond 70 Hz, the porous hose filter and circular filter gives a higher amplitude level, which could be the result of amplification caused by the increased number of inlets.

The source noise measured at 10 m altitude plotted in Fig 2 d) shows little difference in the frequency response of the filters. The 10 Hz amplitude peak remained identical among the filter spectra while the overtone peaks were amplified due to resonance and shaft noise of the rotor. Nevertheless, it is evident from Figure 2 that the spatial filter configurations tested had a minimal effect on the wind noise reduction in comparison to the spherical windscreens. Therefore, the three-microphone array was investigated as an alternative solution.

The advantage of using two or more microphones over a single microphone for filtering the atmospheric wind noise is showcased through the comparison of the CSD of the microphones with the auto spectra of a single microphone in Figure 3. Note, in the figure only the CSD spectra of Mic 1 and Mic 2 is plotted. The background noise comparison at ground level is shown in Fig 3 a). As seen from the plot, the frequency response with the microphone array overlaps the single microphone response in higher frequencies. But, in infrasound frequencies below 15 Hz, noise reduction of at least 10 dB is achieved. Similarly, the background noise measured at 10 m height is plotted in Fig 3 b) and it shows that the microphone array gives a noise reduction of at least 7 dB across the bandwidth. Furthermore, the source noise measured with the microphone array at 10 m height is shown in Fig 3 c) and it indicates negligible difference in the amplitude levels.

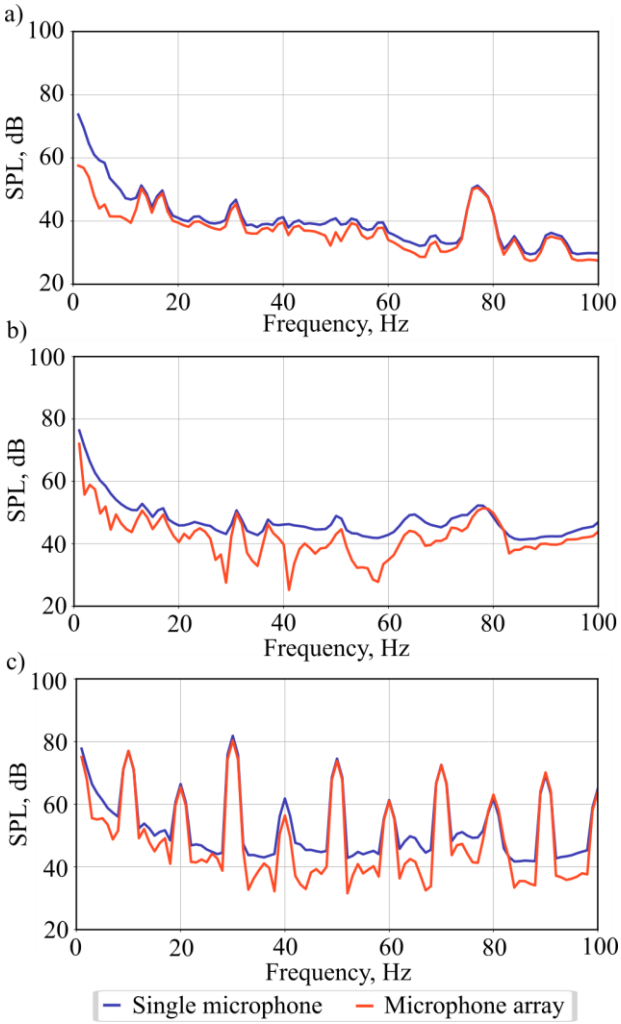

Figure 3. SPL spectra of microphone array compared to a single microphone spectra a) Background noise at ground level, b) Background noise at 10 m altitude, c) Infrasound source noise at 10 m altitude.

4. DISCUSSIONS AND CONCLUSION

The lack of effectiveness of the wind filter arrays in comparison to a microphone with windscreens is a result of the design complications involved in the filter construction. Only the rosette filter with solid pipes gave a better noise reduction efficiency in the comparative study with various filter configurations. However, one of the primary limitations in the rosette filter design is the resonance effects that reduce the effective bandwidth of the measurement. By combining arrays of different sizes, the measurement range can be extended like in the study performed by Hedlin [5] and Alcoverro [6], where 18 m and 70 m rosette filters were used to measure two different frequency ranges. Nevertheless, implementing those designs on UAV based measurement platform is difficult as we end up in the downwash region of the rotor that masks the actual acoustic signal. Further, the resonance effects arising due to the impedance mismatch in the filter design were found to introduce phase delays in the measured signal [20]. Capillary plugs matching the characteristic impedance of the tube were used to break the internal resonances in the

tube. However, the design complications of the capillary plugs further result in a complex filter design. Also, the efficiency of the rosette filter was found to be dependent on the grazing angle of the waves at the inlet [6], [21]. This might introduce some decay in the frequency response and geometric symmetry of the filter must be ensured to eliminate these effects [21]. Since the filter is subjected to vibration during the flight, geometrical symmetry becomes questionable at higher altitudes with UAVs.

The porous hose filter was tested with the assumption that multiple inlets of varying distances increase the bandwidth of the measurement. Rather these inlets only increased the averaging effect which was confirmed in a previous empirical study as well [22]. While the filter was partially effective in frequencies below 10 Hz, they were found to amplify the signals in higher frequencies making their application obsolete. The circular filter configuration, which is an extension of a porous filter, suffered from a similar issue, though the resonance issues in the low frequency were eliminated.

Considering the aforementioned reasons, the application of a microphone with a windscreen for low frequency measurement in UAVs seems beneficial. A comparative measurement was performed on a windy day (15 kmph forecasted value) between the microphone with and without windscreen attached and noise reduction of at least 10 dB was achieved in the infrasound range. Also, previous experimental studies revealed that larger windscreens (> 60 mm diameter) effectiveness in low frequencies [17] which explains the better performance achieved in our case with 90 mm windscreens.

However, the efficiency of windscreens in high turbulence conditions is reduced [23]. The analytical model [24] and numerical simulation model [25] can be used in estimating the turbulence induced noise in the measurement. But these methods are complicated in that the turbulence parameters such as stability and roughness, and the stagnation pressure are to be estimated. Also, the application of the models is limited by the estimation accuracy of these parameters. In comparison, by using the CSD of two or more microphones that are spatially separated, the incoherent atmospheric turbulence effects are straightaway averaged out resulting in a simpler measurement protocol. Hence, the noise reduction mechanism of a windscreen is combined with the mechanism of a spatial filter array improving the noise reduction further. But the wind noise reduction achieved with the microphones separated by 60 degree angle (Mic 2 and Mic 3) was less than the noise reduction attained with 180 degree separation (Mic 1 and Mic 2). This implies that a longer separation distance between the sound pressure inlets provides a better averaging of the turbulence effects.

For further validation of this experimentation method, a comparison study with the analytical and numerical models discussed before would be beneficial. Also, measurement campaigns on varying wind profile conditions are required to quantify the efficiency and applicability of the microphone array for low frequency noise measurements with UAVs. Moreover, studies targeting design variations of the array and improving the data processing techniques are necessary for increasing the number of sensors thereby, to have better averaging of atmospheric turbulence.

A STUDY ON THE TRANSFER CHARACTERISTICS OF IN-WHEEL MOTOR SYSTEM BASED ON EV PLATFORM

Park, Sangwon[1*] **Lee, Jongwha**[1] **Lee, Minsung**[1] **Woo, Jongmun**[1]

ABSTRACT

The In-Wheel motor system is mounted directly on the inside of the tire where the road load comes in and increases the unsprung mass, which has a critical effect on the NVH performance of the vehicle. Although the evaluation of the In-Wheel motor at the component and vehicle level is performed respectively, performance at the system level is difficult to predict due to the absence of a test system. In this study, two types of test system are developed to verify the integrated platform performance at the level of the drive unit + suspension system in order to predict the characteristics of vehicles assembled with the in-wheel motor system. So, the dynamic performance difference is analyzed by the load transfer ratio between the suspension system in which the EV motor and the in-wheel motor are assembled.

1. INTRODUCTION

Recently, according to the global interest in eco-friendliness, electrification is being carried out at a rapid pace in the automobile industry. Representatively, the strengthening of CO_2 regulations and tax benefits for eco-friendly cars require automobile manufacturers to develop low-emission and high-energy-efficient vehicles.[1] Following this trend, various types of motors are being developed for the purpose of driving automobiles. This study deals with the contents of the direct drive type In-Wheel system. In the direct drive type In-Wheel system, the motor and brake system are mounted directly inside the wheel of the vehicle and directly drive the wheel without a drive shaft. Compared to existing vehicles, it has the advantage of a simple path and structure for transmitting power.[2] Since the motor support structure is designed in a small space inside the wheel and the motor is directly coupled to the suspension system, there is a disadvantage in that the excitation force of the motor is directly transmitted to the vehicle body.[3][4]. And the road load also comes in directly and increases the unsprung mass, which has a critical effect on the NVH performance of the vehicle. In order to predict this problem in advance, it is necessary to study not only the component and vehicle level, but also the system level as the intermediate stage. [5] In this study, an integrated platform evaluation system for drive unit + suspension system + tire level was developed to analyze the NVH characteristics in order to analyze the NVH characteristics of the suspension system applied to the in-wheel system.

2. TEST SYSTEM I : ROLLER BENCH

In order to simulate the driving conditions of an actual vehicle, a roller bench test device was built as an integrated platform consisting of a drive unit + suspension system + tire, and the system was configured as shown in Fig. 1. The load transfer characteristics of the suspension system level were verified by utilizing the input load from the roller-tire patch surface, which implements the same surface friction coefficient as the asphalt road, and the output load of the vehicle body mountings. In addition, the roller base height was adjusted to generate a pre-load of the actual vehicle. The input force can be measured from the wheel force transducer (WFT) mounted on the tire and the output force

can be measured from the force sensor mounted on the vehicle body jig mount to obtain the load transfer ratio at the ratio of the two loads. This load transfer ratio can be defined as a characteristic of the system.

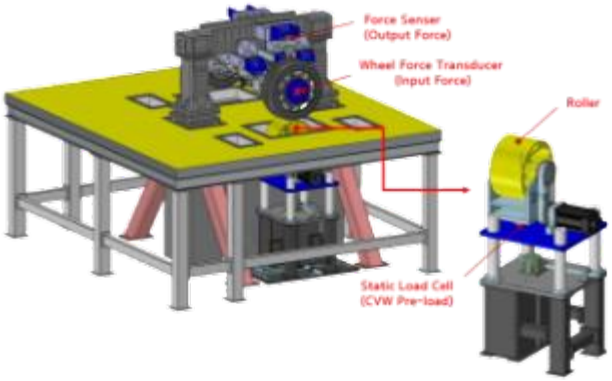

Figure . Roller Bench Test System.

2.1 Input Force

In this study, the roll bench system was operated by a test mode that simulated run-up 0 to 100 kph based on the actual vehicle drive mode. Analyzing the characteristics of the input load shown in Fig. 2, the 1st and harmonics are generated under system conditions, which does not occur in In-Wheel single-component dynamo evaluation, due to unbalance of tire deformation caused by pre-load. In addition, the tire resonance mode moves from 190 Hz to 200 Hz according to the sweep speed, and In-Wheel motor (64 pole 60 slots) mounted directly inside the tire generates 32nd/60th/64th order and sideband components by electromagnetic force of motor.

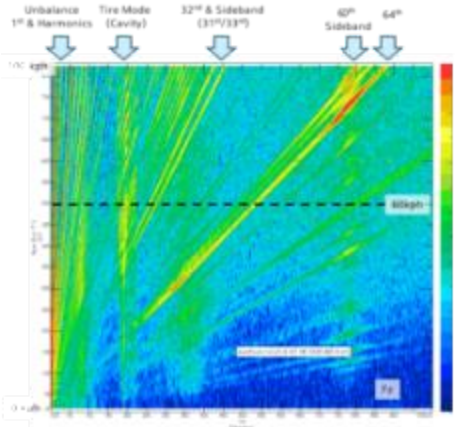

Figure 2. Input Force of Tire Wheel Center in In-Wheel Motor System

2.2 Output Force

In order to obtain the output force of the suspension system, the dynamic force sensor was directly mounted on four body mounts (Shock Absorber, Spring, Member FR/RR Mount). Finally, the Z-direction load, which is the most dominant force according to the mounting direction, was selected as the representative value.

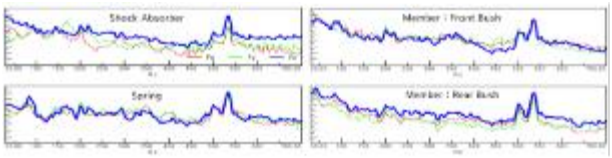

Figure 3. Output Force of Tire Wheel Center in In-Wheel Motor System

2.3 Load Transfer Ratio

It is possible to define the load transfer ratio of the system by the measured input/output force. Using this quantitative value, the contribution of transfer path of the suspension system the vehicle body transfer path can be analyzed on target frequency band.

Hyundai Mobis Restricted

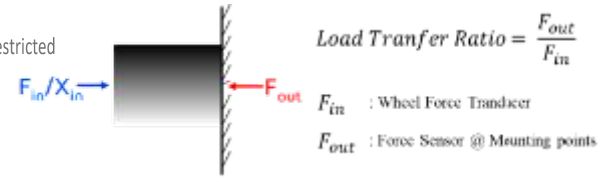

Figure 4. Definition for the Load Transfer Ratio

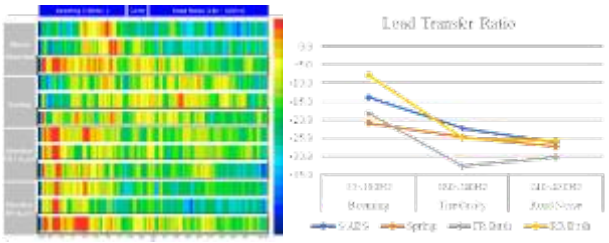

Figure 5. Load Transfer Ratio on Mounting Points at Roller Bench Test.

To define the load transfer characteristics of the frequency band, it is classified and analyzed into three bands according to the noise pattern: booming noise below 180 Hz, tire cavity between 180 and 240 Hz, and road noise band up to 500 Hz based on frequency range.

First, in the booming noise band (180 Hz ↓), the transmission is large in the order of rear bush > shock absorber > front bush > spring.
Second, the contribution can be found in the order of shock absorber > rear bush ≒ spring > front bush in the tire cavity band (180 Hz ~ 240 Hz).
Lastly, in the road noise band (240 Hz to 500 Hz), it can be seen that a large amount of load is transmitted in the order of rear bush ≒ shock absorber ≒ spring > front bush.
Comprehensively looking at contributions across all frequency bands, the suspension system can determine that the transfer paths to the member rear bush and shock absorber are dominant.

2.4 Analysis of Dynamic Characteristics for Suspension System

In addition to the load, the vibration transfer phenomenon of each system component was verified. As shown in Fig. 6, the vibration is amplified in the suspension arms compared to the input part equipped with the in-wheel motor. In addition, when the vibration is transmitted to the member after the suspension bushes, the vibration is reduced again.
A mode map of dynamic characteristics of the suspension system was constructed to analyze the contribution of load transfer by components in more detail. As shown in Fig. 7, it can be seen that the resonance mode of each component element occurs at frequencies where the load transfer ratio peaks. Particularly, the global mode of the suspension system is the main cause in a band of 100 Hz or less, and that the load transfer ratio is deteriorated by the individual modes of the members/arms and the mode coupling between parts more than 100 Hz. This mode map is meaningful in that it has established a process of selecting an improvement target by checking the cause parts of the problem frequency in the future.

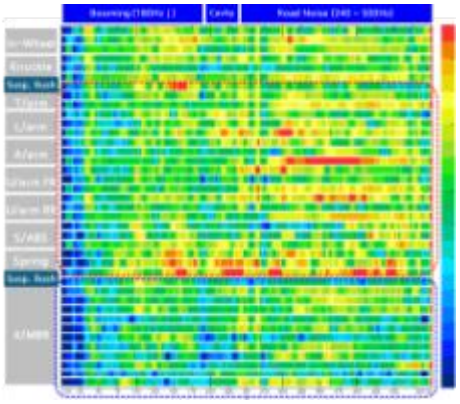

Figure 6. Vibration Transfer characteristics of components

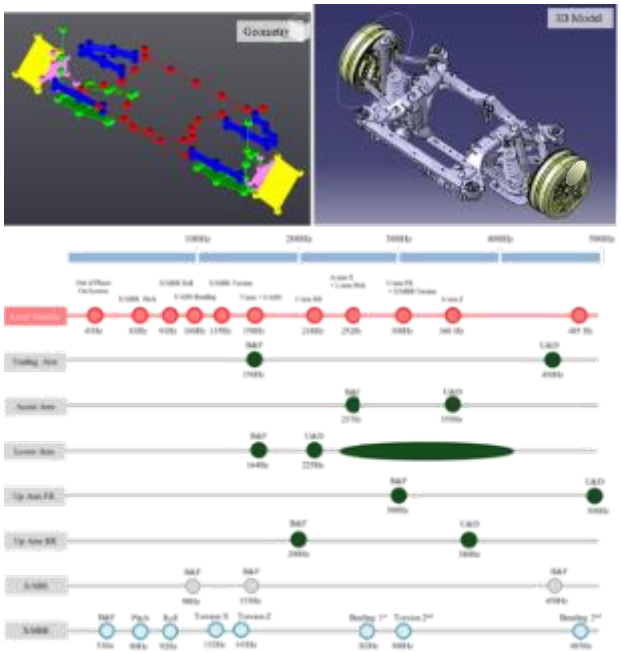

Figure 7. Geometry and Mode Map for the In-Wheel System

Hyundai Mobis Restricted

2.5 Comparison between In-Wheel and EDU System

The test results were analyzed to compare In-Wheel type and the EDU system, which are currently mass-produced electric vehicles. In-wheel shows different characteristics in input load and load transfer ratio because there is a structural difference in which the motor is rigidly fastened directly to the inside of the tire and the EDU type is fastened to the member by mount bushes. Due to these structural differences, it was verified that tire components (180 to 220 Hz) and unbalanced components due to pre-load are equally generated at the input load, but motor/gear order components are not generated in the EDU type at 500 Hz or less, as shown in Fig. 7.
As shown in Fig. 8, by quantitatively comparing the load transfer ratio of the two systems, it can be seen that the In-Wheel motor system has a superior load transfer ratio compared to the EDU system in all frequency range and transfer paths. In other words, it can be predicted through system level evaluation that In-wheel system's road noise is better than EDU system in real vehicles.

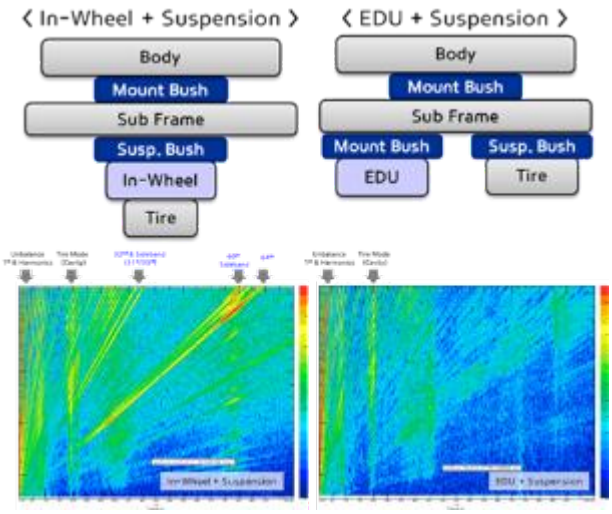

Figure 8. Comparison between In-Wheel and EDU System

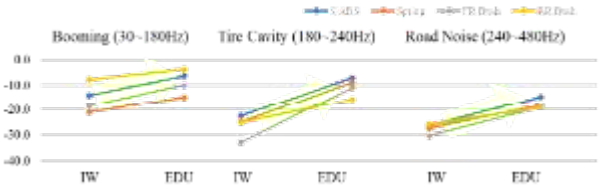

Figure 9. Result of Load Transfer Ratio between In-Wheel and EDU System at Roller Bench Tester

3. TEST SYSTEM II : LINEAR ACTUATOR

The second evaluation system developed is a linear actuator type as shown in Fig. 10. In this test system, a large-capacity excitation motor of 1 ton was newly developed and applied to control the static pre-load and the dynamic force at the same time. Compared to the roller bench type, it is evaluated as a system that combines only the drive unit + suspension system excluding the tire, so the difference is that it reflects the original characteristics of the suspension.
In the linear excitation test, sweep the LH/RH vertical axis to the 30 to 300 Hz in both the in-phase and out-of-phase to obtain the load transfer ratio. Based on this linear actuator system, the load transfer ratio can be compared for two drivetrain types, In-Wheel and EDU, and the results are shown in Fig. 11.

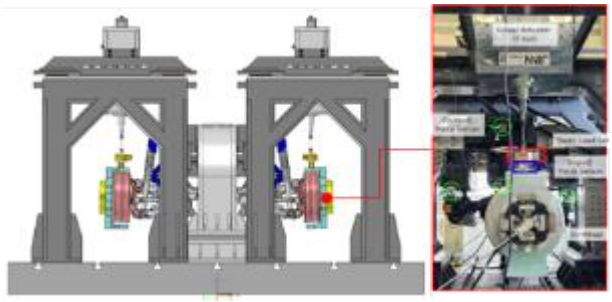

Figure 10. Linear Actuator Test System

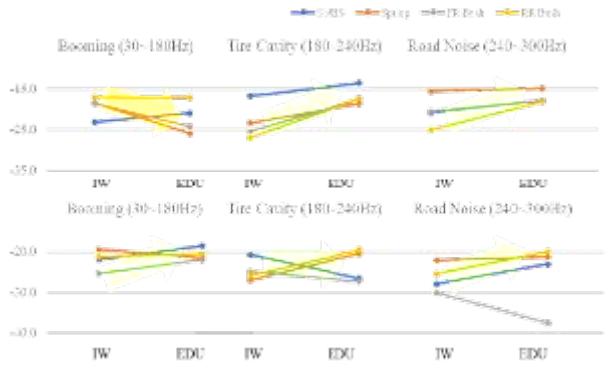

Figure 11. Result of Load Transfer Ratio between In-Wheel and EDU System at Linear Actuator Tester

Hyundai Mobis Restricted

Overall, the In-Wheel system has a superior load transfer ratio than the EDU system, just like the previous roller bench test. However, when the linear actuator tester is in-phase excited, the result is opposite to the roller bench test in which the In-Wheel type is inferior only in the booming noise band (30 ~ 180 Hz). When the test results are compared in detail in the frequency domain, the load transfer ratio in the 140 ~ 180 Hz band is amplified in the In-Wheel type, which can be judged as the effect of the boundary conditions of the two excitation systems. Although there are differences in boundary conditions such as whether tires are mounted or not, or excitation conditions such as roller/linear exciters, it can be seen that each test has independent characteristics at the same time.

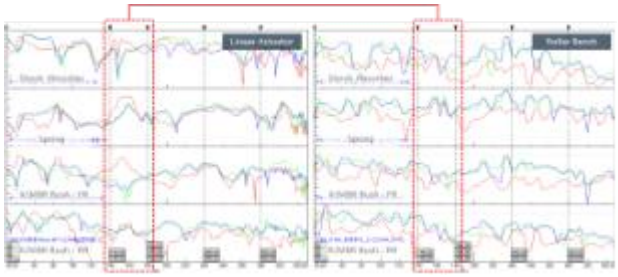

Figure 12. Comparison between Linear Actuator and Roller Bench Test System

4. CONCLUSION

So far, we have introduced the development of an evaluation system for verifying system-level NVH performance for the In-Wheel motor. In addition, the NVH performance of the system level due to the difference in the drive unit (In-Wheel vs EDU) was extracted and compared with a quantitative value called the load transfer ratio. And a mode map was constructed to analyze the causative component for selecting the target component when improving performance. Using this study, we laid the foundation for verifying the performance of the integrated platform level including the drive unit and suspension system.

RELATIONSHIP AMONG NOISE, CAVITATION STRUCTURE AND EROSION RISK IN INDUSTRIAL CENTRIFUGAL PUMPS WITH A FAN-TYPE INDUCER

Shimpei Narimatsu[1*] **Haruto Utsumi**[1] **Shinichiro Ejiri**[2] **Masahiro Miyabe**[1]
[1]Osaka Institute of Technology, Osaka, Japan
[2]Nikkiso Co., Ltd. , Tokyo, Japan

ABSTRACT

There is a strong demand for pump manufacturers to prevent problems such as noise, vibration and erosion due to cavitation before delivering products to the site. This study aims to establish a practical technique for predicting the occurrence, structure, and erosion risk of cavitation by noise measurements. A centrifugal pump with a fan-type inducer was operated to measure noise both outside and inside of pipes at various suction conditions and flow rates. Visualization experiments around the inducer were also conducted to identify the cavitation structure. In addition, the paint erosion test was conducted to estimate the cavitation erosion risk at the blades of the inducer. From these experiment results, the relationship between noise, cavitation structure and erosion risk were discussed. The overall sound pressure level measured by air-borne noise measurements was found to be characterized as the increase with the enlarged peeling area obtained from the paint erosion test. Furthermore, the overall sound pressure level measured by the liquid-borne noise measurements was also confirmed to be related with the vibration due to cavitation instability phenomena.

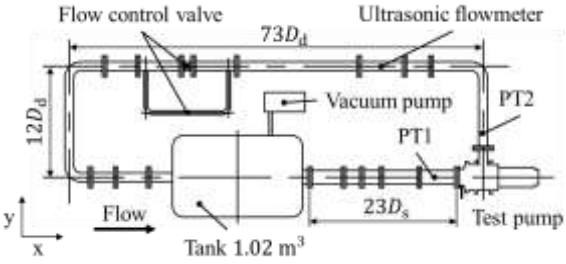
1. INTRODUCTION



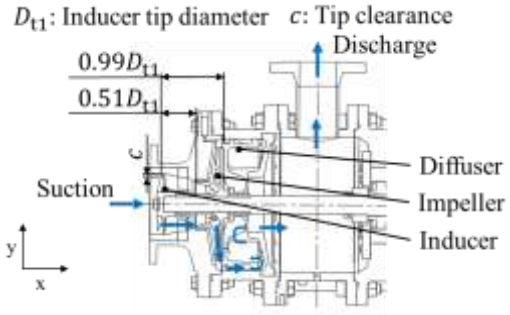
Cavitation in turbopumps is a serious problem due to the vibration, noise, and damage it causes in comparison to the stability of the pump[1]. Therefore, pump manufacturers are required to identify problems caused by cavitation before delivering products to the site. Predictions have been made by experimental methods and numerical fluid analysis, but users and designers may determine the existence of cavitation from noise. Dong[2] et al. attempted to visualize the occurrence of cavitation in centrifugal pumps and to measure liquid-borne noise with the hydrophone. The results indicate the feasibility of detecting the presence of cavitation from the over-all value of the liquid-borne noise. In terms of Air-borne noise, Chudina[3] measured audible external noise for a centrifugal pump impeller. As a result, there is a large change in the 1/2BPF (Blade Passing Frequency) before and after the occurrence of cavitation, and it is thought that the change in this frequency band may be used to detect cavitation. Černetič[4] et al. made the similar measurement and confirmed that besides discrete frequencies, there are also large changes in a wide frequency range of 20 Hz to 20 kHz, indicating that it can be used for detection. In addition, Iga[5] et al. used a centrifugal pump with the visualization system to measure the unsteady flow and external noise using the microphone during cavitation instability phenomena. As a result, it was confirmed that the external noise had a predominant swirling frequency component during the occurrence of the rotating cavitation, and the possibility of inferring the occurrence of the cavitation was reported. As described above, liquid-borne and air-borne noise measurements have shown positive results in detecting the occurrence of cavitation. However, since noise measurement is greatly affected by component materials, pump geometry, and measurement environment, various research results are

needed for further practical application. Furthermore, the prediction of cavitation erosion has been studied by numerical fluid dynamics analysis[6-7], but experimental prediction is also important due to its sophistication, as it must consider the collapse and growth of individual bubbles. In this study, a fan-type inducer, with cavitation instability phenomenon[8] confirmed at low flow rates, will be experimentally investigated and analyzed to establish a practical method for noise by investigating the occurrence and development of cavitation, its morphology, and the risk of erosion. The effects of varying the blade leading edge geometry on the cavitation collapse area and the noise are investigated.

2. EXPERIMENTAL FACILITY

2.1 Test Facility

Figure 1 indicates the experimental apparatus mainly consists of suction pipes D_s (JIS (Japan Industrial Standards) 125A), discharge pipes D_d (JIS 80A), a control valve, an ultrasonic flow meter, a vacuum pump, and a tank. A pump is placed in the test section and motor is electronically controlled to maintain the rotational speed constant at any set value. The working fluid is fresh water. The pump performance is evaluated from shaft rotational speed, torque, flow rate, and the difference of static pressure between section A and B. The flow rate is adjusted to any set value with a control valve and is measured by an ultrasonic flowmeter. The pressure of the liquid level in the tank is adjusted by a vacuum pump to change the pressure of the entire piping system. The centrifugal pump used in the present study is a vertical pump that is mainly used for transporting Liquified Natural Gas. The discharge port was modified by turning sideways to apply to Osaka Institute of



Technology test facility.

Figure 1. Test Facility

2.2 Test Pump

Figure 2 shows the cross sectional view of the test pump. The test pump has a 4-blade fan-type inducer, a 9-blade closed impeller, and an 8-vane axial diffuser with vane slit[9].

D_{t1} represents the inducer diameter. The impeller inlet is $0.51D_{t1}$ axially away from the trailing edge of the inducer and the diffuser inlet is $0.99D_{t1}$. The type number of this pump is 156 (specific speed :138 m^3/min,m,min^{-1}).

Figure 2. Cross-sectional view of the test pump

2.3 The fan-type Inducer

Figure 3 shows the external view of the fan-type inducer (Base type). Table 1 shows the primary geometrical properties of the fan-type inducer[10]. It summarizes the parameters that relate to the cavitation performance. The design parameter that represents the most significant feature of this inducer is solidity which is defined as equation (1). This type of inducer is suitable for high flow rate and low head specifications and is used in industrial applications, but few studies have been conducted. Inlet flow rate / inlet tip blade tip angle ratio, m_1 satisfies recommended value, m_1>0.4 defined as equation (2). In comparison with the design guideline of the turbopump for a rocket[11]. It indicates that flow instabilities due to backflow such as cavitation surge are unlikely to occur at the design flow rate for this inducer. In addition, inlet tip blade angle, β_{t1} meets within recommended value which should be less than 20 deg. However, the outlet tip bade angle is larger and the backflow is likely to occur at low flow rate. On the other hand, the hub / tip ratio, ν_1 is larger than the recommended value 0.25 to 0.35[11] and it suppresses to occur backflow at low flow rate because average flow velocity is relativity large at the inducer inlet. The diameter of the inducer hub is determined by that of the shaft and pump performance is well balanced by those two parameters, β_{t1} and ν_1. However, cavitation is relativity easy to occur. Furthermore, the tip

clearance ratio, c is smaller than recommended value 0.009 to 0.011 to achieve high efficiency.

Table 1. Design parameters of fan-type inducer

Number of blades [-] : n_1	4
Tip diameter [mm] : D_{t1}	125.3
Hub diameter [mm] : D_{h1}	51.0
Hub height [mm] : h_1	40.0
Solidity at tip [-] : S_t	0.77
Solidity at hub [-] : S_h	0.83
Inlet flow rate/Inlet blade tip angle ratio [-] : m_1	0.47
Inlet blade tip angle [deg.] : β_{t1}	10.5
Hub/Tip ratio [-] : ν_1	0.41
Tip clearance [mm] : c	0.65

3. EXPERIMENTAL METHODS

3.1 NPSH test

NPSH test is conducted to measure pump cavitation performance. The pressure of the inlet is decreased by the vacuum pump, the pump total head at each cavitation number is recorded. Experiment is conducted until the condition where pump head drop is confirmed by 3 % (NPSH3). The rotational speed is 3000 min^{-1}.

3.2 Noise measurement test

Air-borne and liquid-borne noise were measured to clarify the effectiveness of noise measurements in detecting cavitation and the characteristics of the collapse sound. The locations of the air-borne and liquid-borne noise measurements are shown in Fig. 4. For the air-borne noise measurements, a microphone (BOYA, PVM1000) was placed 5 mm away from the outside wall of the casing. These measurements were based on previous studies by Saito[12]. The measured sound pressure was passed through an amplifier and frequency analyzed using an FFT (Fast Fourier Transform) analyzer(ONOSOKKI, CF-5210). The frequency range was recorded from 25 Hz to 20 kHz, which is the audible range, and from 25 Hz to 5 kHz to observe the BPF in detail. The frequency-weighted A-weighted characteristics were evaluated in consideration of human hearing. For the liquid-borne noise measurements, a hydrophone (Brüel & Kjær, Type 8103) was installed inside the pipe upstream of the inducer. The tip of the hydrophone was placed at the same position as the inner wall of the pipe. Liquid-borne sound pressure data acquired by a data logger (KEYENCE, NR-X100, CA04) was subjected to FFT analysis using a data evaluation code written in Python 3.13.2. The frequency range is 25 Hz to 5 kHz.
In this study, an anechoic chamber was not used, assuming a factory environment where industrial pumps are operated.

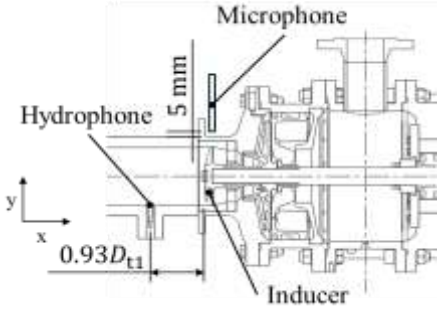

Figure 4. Positions of a microphone and a hydrophone

3.3 Visualization test

Visualization experiments were conducted to observe and identify cavitation foam. Figure 5 shows a schematic view. The inducer casing is made of acrylic, and a high-speed camera (Photron, FASTCAM Mini AX100) was used to capture images at a speed of 6,000 fps. The brightness of the images was adjusted by using a 500 W halogen light source (EARTH MAN, WLT-260).

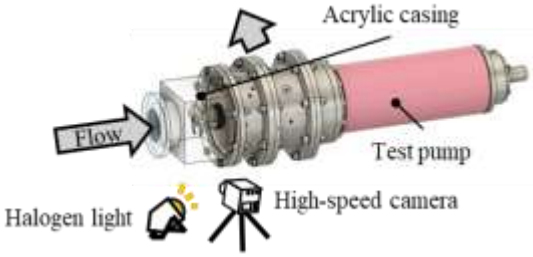

Figure 5. Schematic view of visualization test rig

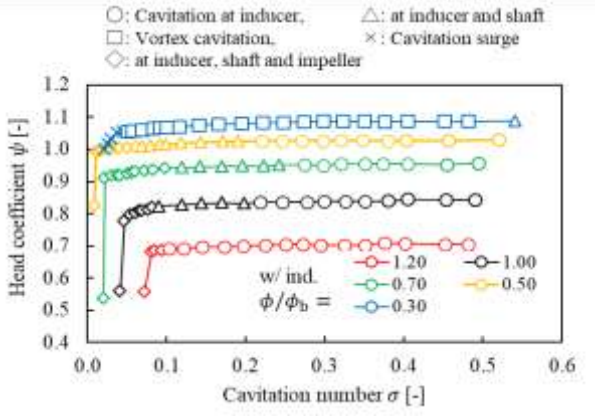
3.4 Paint erosion test

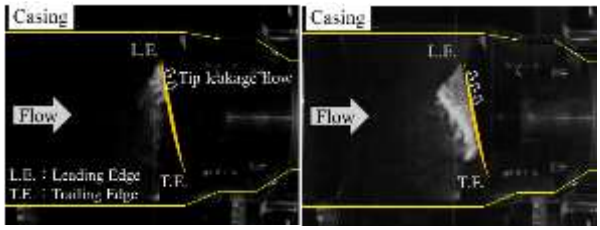
Paint erosion test is conducted to observe paint removal area due to cavitation on the blade surface of a fan type inducer. Blue varnish (JIP 101) is painted on the inducer blade surface with reference to Fukaya[6]. After 30 minutes of operation with constant flow rate and cavitation number, the inducer is removed from the test stand and the condition of the blade surface is observed.

4. EXPERIMENTAL RESULTS AND DISCUSSION

4.1 Results of NPSH tests and visualization tests

Figure 6 shows the suction performance curve of the test pump and the development and form of cavitation under each operating condition. For ϕ/ϕ_d =0.50, 0.70, 1.00, and 1.20, ψ dropped sharply after maintaining a constant value with the decrease in σ. The visualization experiments revealed that cavitation occurred at the inducer (○ in the figure) and then developed into the shaft and impeller (△ and ◇ in the figure), which may be due to the blockage of the flow channel by the cavities. Focusing on ϕ/ϕ_d =0.30, vortex cavitation in reverse flow occurred in the range of σ =0.057 to 0.541 (□ in the figure). Furthermore, below σ = 0.051, a cavitation surge was observed, with intermittent cavitation expansion and contraction. Under conditions where cavitation surges occurred, the pump system vibration increased, so measurements could not be taken until the head dropped (x in the figure).





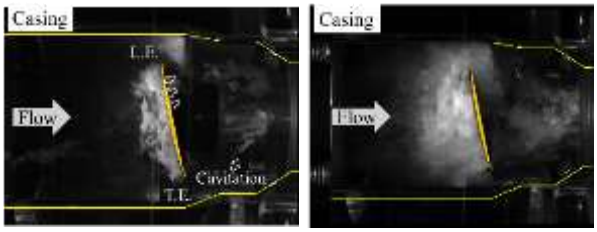


Figure 6. Suction performance curve of test pump and cavitation patterns

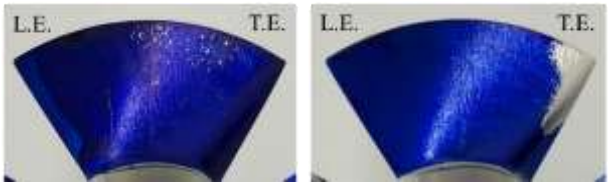
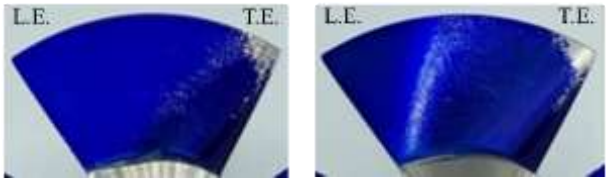
Next, we show the development form of cavitation based on the results of the visualization experiment. Figure 7(a) shows the cavitation morphology at the rated flow rate of the pump. σ = 0.453, cavitation occurred with the same shape on the negative pressure surface of all inducer blades. Cavitation originated at the leading edge of the blade and fluctuated at the trailing edge due to the gap leakage from the casing, confirming the release of a group of bubbles. These cavitation patterns are a mixture of sheet cavitation, crevice cavitation, and bubble cavitation[13]. Figure 7(b) shows a visualization image of the same flow rate with lower pump suction pressure. As σ decreases, the cavities expand to the trailing edges of the blades, and the leakage cavitation expands at the same time. Cavitation was also observed around the shaft and continued to the impeller inlet with a swirling element. Cavitation was also observed at the impeller inlet in Fig. 7(c), the point of 3% drop in pump head. Since the flow path between the inducer blades is not completely blocked by cavitation, the drop in pump head is considered due to channel blockage caused by cavitation in the impeller. The same cavitation development process was also observed for ϕ/ϕ_d =0.50, 0.70, and 1.20. Figure 7(d) shows the vortex cavitation in reverse flow with ϕ/ϕ_d =0.30 and σ =0.324, exhibiting a cluster of fine bubbles around the inducer blade. The cavitation form was not changed with a decline in suction pressure, and intermittent expansion and contraction of a cluster of fine bubbles were observed during the cavitation surge. Visualization experiments confirmed the cavitation occurred at the leading edge of the blades and developed in the direction of the trailing edge.



(a) ϕ/ϕ_d =1.00, σ =0.453, (b) ϕ/ϕ_d =1.00, σ =0.170



(a) ϕ/ϕ_d =1.00, σ = 0.453, (b) ϕ/ϕ_d =1.00, σ =0.170

Figure 7. Cavitation development around inducer

The following sections compare the paint removal on the suction side of the inducer blade in the paint erosion test. As shown in Fig. 8(a), a small detachment was observed from the center of the blade edge to the trailing edge at ϕ/ϕ_d =1.00 and σ =0.197. Decreasing the pump suction pressure, σ =0.052 in Fig. 8(b), shows the change to a plane delamination extending to the trailing edge of the airfoil. Figure 8(c) and (d) with ϕ/ϕ_d =1.20 also resulted in a plane delamination. For other ϕ/ϕ_d conditions, sparse and areal detachment was not observed at the point of head reduction. Cavitation collapse was stronger on the trailing edge of the inducer blade, suggesting a high risk of erosion near the trailing edge for ϕ/ϕ_d =1.00 and 1.20.

(a) ϕ/ϕ_d =1.00, σ =0.197 (b) ϕ/ϕ_d =1.00, σ =0.052

(c) ϕ/ϕ_d =1.20, σ =0.094 (b) ϕ/ϕ_d =1.20, σ =0.058

Figure 8. Paint peeling area at suction surface

4.2 Relationship between cavitation erosion area and noise characteristics

This section compares the relationship between paint erosion test results and noise measurement results. Figure 9 shows the relationship between the overall noise level and each of the operational conditions, and as in Fig. 6, markers are used to classify the development and form of cavitation in the visualization experiment. The markers are filled in the conditions with surface delamination confirmed by the paint erosion test. The air-borne noise in Fig. 9(a) shows a similar trend with decreasing σ for ϕ/ϕ_d =0.50, 0.70, 1.00, and 1.20, and different trend for σ <0.250. At ϕ/ϕ_d =1.00 and 1.20, there is an increase in noise at higher σ than the operating conditions in both cases with areal exfoliation observed. This range is the transition from sparse exfoliation to areal exfoliation and is considered to capture the collapse of cavitation. Paint erosion tests help to predict in advance the conditions under high risk of erosion. Also, at ϕ/ϕ_d =0.50 and 0.70, the overall value increased rapidly at the 3% drop point of the pump head. The trend was consistent with the results of Dong et al[3], considering the fluid force due to cavitation blockage was converted to acoustic energy. Comparing the suction condition of vortex cavitation in reverse flow at ϕ/ϕ_d =0.30 with other ϕ/ϕ_d conditions, the overall value was decreased. Since the visualization test showed fine bubble clusters and the paint erosion test showed no areal detachment, it is assumed the bubble clusters always weakened the sound propagation without collapsing it. Therefore, predicting cavitation instability phenomena from external noise is difficult with current measurement methods. In addition, the characteristic noise change during the cavitation surge was not observed. The liquid-borne noise in Fig. 10 exhibited similar trends for all ϕ/ϕ_d conditions. Characteristic changes in the noise measurements were not observed for the operating conditions with a high risk of erosion. A previous study[3] showed a positive relationship between the development of cavitation and an increase in noise. The difference in the liquid-borne noise trend indicates the position of the hydrophone. In this study, the hydrophone was installed upstream of the inducer, resulting in the inability to measure localized changes in sound pressure due to cavity collapse. On the other hand, cavitation surge with ϕ/ϕ_d =0.30 indicates significant increase in noise and good response to reverse flow and fluctuations in the internal flow.

FFT analysis was performed on the air-borne noise measurements for each ϕ/ϕ_d condition to confirm the validity for the prediction of erosion risk. Figure 11 shows the results for each ϕ/ϕ_d condition at σ =0.143. The horizontal axis indicates the dimensionless frequency divided by the revolution frequency, and the vertical axis is the sound pressure value [dB] measured at the pressure [Pa] and converted by the equation (4). The BPF of the inducer and impeller and its higher-order components appear in the low frequency range of 25 to 800 Hz. Therefore, discrete specific frequencies due to geometry and flow are affected in the low-frequency range. At high risk of erosion ϕ/ϕ_d =1.00,1.20, the increase was observed in a wide band of high frequencies above 1 kHz. In particular, the increase was significantly larger at 3kHz to 4kHz, and the peak was found to increase around 3.5kHz. These results are similar to the experimental results of Matsumoto et al[14] in their liquid injection method, concluding this phenomenon is the frequency of intermittent release of bubbles from the tail of the cavity. Figure 12 shows the liquid-borne noise at the onset of the cavitation surge; σ =0.051 has a prominent peak below 20 Hz, which is consistent with the frequency

response measured in a previous study[8]. Therefore, it is considered that the air-borne noise was strongly affected by the flow control valve and BPF and could not be captured under the occurrence of cavitation surges.

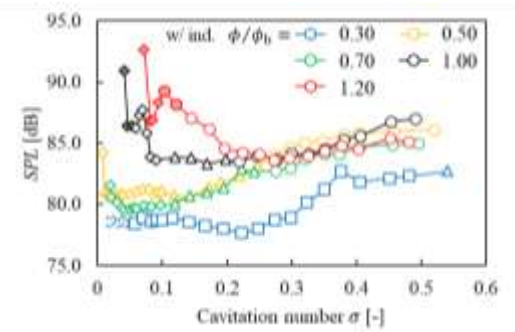


Figure 9. Relationship between cavitation number and air-borne noise

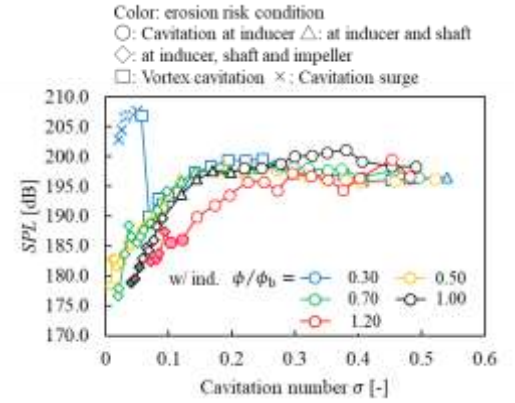

Figure 10. Relationship between cavitation number and liquid-borne noise

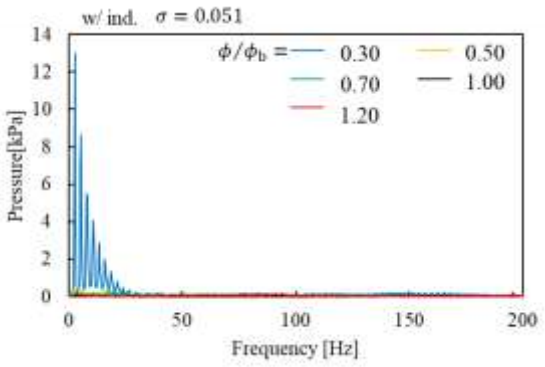

Figure 11. Comparison of air-borne noise spectrum with different flow rate

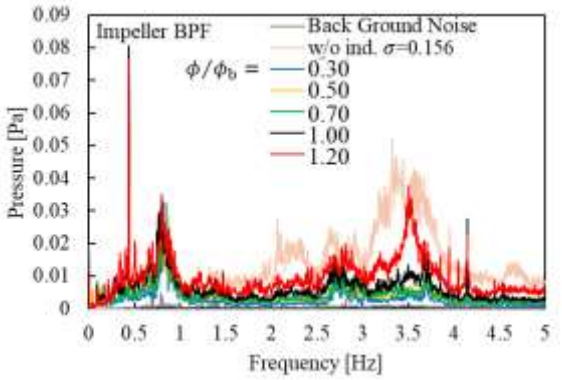

Figure 12. Overall value of high-pass filtered air-borne noise (evaluated range is from 25Hz to 20kHz)

Based on the above results, the measurement in the high-frequency band above 3.0 kHz is considered to be effective for noise evaluation of the risk of erosion. Figure 11 shows the results of applying a high-pass filter above 3.0 kHz in the human audible range of 25 Hz to 20 kHz. It is possible to determine the risk of erosion based on differences in air-borne noise tendency and improve the prediction reliability of erosion risk by using a high-frequency bandwidth.

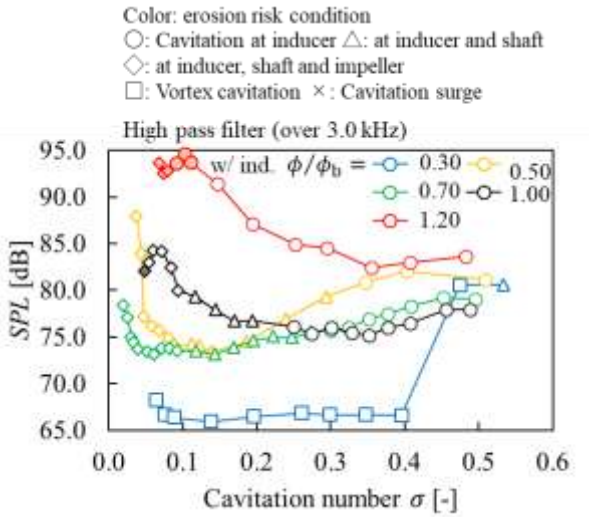

Figure 12. Overall value with 3.0 kHz high pass filter of air-borne noise; 25 Hz to 20 kHz

4.3 Suppression of cavitation erosion by modifying the blades' geometry

Paint erosion experiments showed the area of high erosion risk to be the trailing edge of the inducer blades. Therefore, the geometry of the leading edge of the blade tip was modified to lower the risk of erosion. The effects of applying a borehole or a sweep angle were also investigated. The inducer with the forward sweep angle that had the most significant effect on cavitation instability and noise reduction is shown below. Figure 13 shows the view of the inducer with forward sweep; the leading and trailing edges of the blade tip are swept upstream. In this study, the inlet and outlet angles are the same as the base geometry without the sweep angle. The comparison of the overall values of air-borne noise with and without sweep angle is shown in Fig. 14. Applying the leading edge sweep angle, the noise reduction was confirmed even under the σ condition at ϕ/ϕ_d =1.00, with a high risk of erosion.

The visualization test in Fig. 15 shows the forward sweep is effective in suppressing the development of cavitation generated at the leading edge to the blade tip direction. Furthermore, the paint erosion experiment in Fig. 15 shows the lower risk of erosion, since no areal detachment was observed. These results suggest the cavitation collapse at the inducer blade tip leads to higher risk of erosion with more noise increase. The addition of a forward sweep angle is expected to lower the noise level and decrease the risk of erosion. On the other hand, the sound pressure level did not increase significantly at ϕ/ϕ_d =1.20, although it remained consistently higher than for the other ϕ/ϕ_d conditions. Therefore, employing the forward sweep enables to lower both the noise and the risk of erosion, but further investigation of the blade geometry is required to determine the cause of the noise gain in the high flow region.

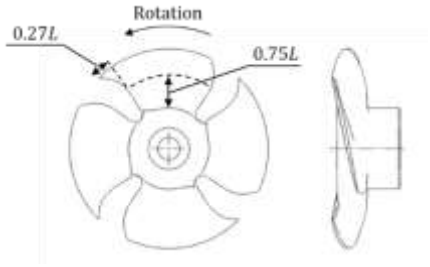

Figure 13. Fan-type inducer with forward sweep

(a) Visualization; σ =0.291 (b) paint erosion; σ= 0.052

Figure 15. Inducer with forward sweep at ϕ/ϕ_d=1.00

5. CONCLUSIONS

- It is possible to predict erosion risk by the tendency of air-borne noise.
- It is also possible to make the prediction accuracy higher using high pass filter over 3.0kHz.
- The cavitation surge can be detected by liquid-borne noise.
- The erosion risk and noise are reduced by adopting the forward sweep geometry.
- The cavitation development near the inducer tip is suppressed by the forward sweep geometry.

6. EQUATIONS

The equations used in this study are shown below.

$$s_t = l_t / t_t \quad (1)$$

$$m_1 = \varphi_{1t} / \tan\beta_{1t} \quad (2)$$

$$\psi = \frac{p_{out} - p_{in}}{\rho u^2} \quad (2)$$

$$\varphi = \frac{Q}{Au^2} \quad (3)$$

$$\sigma = \frac{p_{in} - p_v}{\frac{1}{2}\rho u 2} \quad (4)$$

$$SPL = 10\log_{10}\frac{p^2}{p_0^2} = 20\log_{10}\frac{p}{p_0} \quad (5)$$

$$OA = 10\log_{10}\left(\sum_{i=1}^{n} 10^{\frac{SPL}{10}}\right) \quad (6)$$

ABSTRACT

The noise spectrum generated by a gearbox depends on multiple factors, such as gear design parameters, casing geometry, rotational speed of the shafts and the presence of imperfections. This numerical study analyses the influence of the helix angle and gear width on the noise radiated by a gearbox through parametric studies. The numerical investigation combines a time-domain analysis on a multibody model of the gearbox with a frequency-domain analysis on a boundary element model of the air to evaluate noise radiation in an open space in free-field conditions. The simulations assume a constant workload and a constant rotational speed of the shafts. The results indicate that increasing the helix angle and gear width leads to a smoother noise spectrum and modifies its shape. Compared to spur gears, helical gears generate lower sound power levels due to a reduced variation in the meshing stiffness.

Keywords: *gearbox, noise radiation, helical gears, numerical prediction.*

1. INTRODUCTION

Gearboxes, essential components of mechanical transmission systems, typically consist of one or more pairs of gears enclosed in a casing. They are widely employed in applications such as compressors, pumps and fans to regulate motion and torque. Acoustically, gearboxes are often part of complex noise generation systems, in which multiple noise sources interact, making it difficult to isolate and identify individual contributions. As a result, experimentally evaluating the noise generated by gears meshing and radiated in the surrounding fluid by the casing in real operating conditions is typically challenging.

The noise spectrum radiated by a gearbox depends on various factors, including gear geometry, rotational speed, axis misalignment, and surface imperfections [1,2]. In a previous study, the effect of the workload was assessed for a pair of spur gears [3]. These gears exhibit a distinct harmonic component at the meshing frequency, which is associated with significant variations in the meshing stiffness throughout the meshing cycle. This study employed a coupled numerical approach to evaluate the radiated noise: a time-domain multibody analysis on a finite element (FE) model of the gearbox to determine the dynamic response of the casing and a frequency-domain acoustic analysis on a boundary element (BE) model of the semi-infinite fluid domain to determine noise radiation in free-field conditions [4].

This paper investigates the influence of the helix angle and gear width on the noise radiated by a gearbox employing the same numerical method. Section 2 describes the numerical model used for the study and outlines the parametric analysis conducted to assess the effects of helix angle and gear width. Section 3 presents the results of this parametric analysis. First, the influence of these two parameters on the meshing stiffness function is analyzed. Then, their effects on the sound power spectrum and overall sound power level are examined. Finally, Section 4 discusses the key findings of this study and the potential follow-up for future research.

2. METHODOLOGY

The parametric analysis to assess the influence of the helix angle and gear width is structured into three main stages. The first stage evaluates the meshing stiffness of helical gears. For this purpose, a helical gear of width L is assumed to be composed of a series of spur gears with an infinitesimal width dz, each rotated by a small angle determined by the helix angle β. Specifically, the meshing stiffness $K_{G,H}$ of the helical gears as a function of the rotational angle θ is determined as:

$$K_{G,H}(\theta) = \int_0^L K_{G,S}\left(\theta + \frac{z}{R}\tan\beta\right)\frac{dz}{L_0}, \quad (1)$$

where R represents the pinion pitch radius and $K_{G,S}(\theta)$ is the meshing stiffness of the spur gears with the same cross-section as the helical gears. This function is computed from a multibody simulation in which the spur gears of width L_0 are treated as elastic bodies in contact: the pinion rotates of a certain angle θ, while the wheel rotates of the same angle plus an additional twist $\theta + \mathrm{d}\theta$.

Once the meshing stiffness $K_{G,H}(\theta)$ is determined, the second stage consists of a time-domain analysis on the multibody model shown in Fig. 1. This model consists of two helical gear pairs, treated as rigid bodies with geometrical characteristics detailed in Tab. 1. The helix angle β and the gear width L are varied as part of the parametric study. The elasticity of these elements is incorporated into the meshing stiffness function $K_{G,H}(\theta)$ previously determined. The steel casing measures 250 mm x 150 mm x 120 mm, with a thickness of 3 mm and is modelled through isotropic linear elastic 3D elements, with an elastic modulus $E = 200$ GPa, Poisson's ratio $\nu = 0.3$, damping factor $\eta = 5\%$ and density $\rho = 7850\ \mathrm{kg/m^3}$. The casing is assumed to be fixed to the ground at four localized points, while the two shafts are supported by the walls perpendicular to the y-axis through two pairs of hinges, which allow rotation around their respective axes. The analysis considers a pinion rotational frequency of $f_p = 100$ Hz and a resisting torque of $T = 100$ Nm applied to the wheel. The duration and the time step imposed in the time-domain simulations are set to 0.021 s and $3.5 \cdot 10^{-5}$ s respectively.

In the final stage, the normal acceleration computed on the casing, which is responsible for the noise radiation in the free field, is transformed into the frequency domain using a Fourier transform. The resulting acceleration field is mapped onto a BE model representing the infinite acoustic domain, which, in this study, is bounded by the source boundaries, corresponding to the external surface of the casing. The acoustic model is discretized with a maximum element size equal to one-fifth of the shortest wavelength, which, in this study, is associated with the highest analyzed frequency of 5000 Hz. The radiated sound power is determined by integrating the sound intensity field over the upper hemisphere of a sphere with a radius of 2 m, enclosing the noise source.

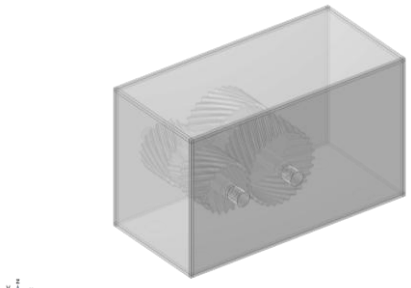

Figure 1. Geometry of the gearbox employed in numerical simulations.

	Pinion	Wheel
Teeth Number	20	30
Pitch Diameter	50 mm	75 mm
Pressure Angle	25°	25°
Shaft Diameter	15 mm	15 mm
Teeth Height	4.5 mm	4.5 mm

3. RESULTS

3.1 Meshing stiffness analysis

In the first stage, the meshing stiffness was evaluated for helix angles ranging from 0° (spur gears) to 40° and for gear widths varying between 10 mm and 50 mm. Fig. 2 shows the meshing stiffness function over the meshing cycle for different helix angles. The increase of the helix angle reduces the oscillation of this function. Similar conclusions can be deduced for the increase of the gear width. Fig. 3 illustrates the normalized amplitude difference Δ_n for different helix angles and gear widths, defined as:

$$\Delta_n = \frac{K_{G,H,max} - K_{G,H,min}}{K_{G,H,avg}} \cdot 100, \quad (2)$$

where the $K_{G,H,max}$, $K_{G,H,min}$ and $K_{G,H,avg}$ represent the maximum, minimum and average value of the meshing

stiffness over the meshing cycle, respectively. For spur gears, the gear width acts as an identical scaling factor for all three values (maximum, minimum and average). Thus, the normalized amplitude difference Δ_n does not depend on the gear width. In contrast, for helical gears, the effect of helix angle and gear width are combined. As both parameters increase, the normalized amplitude difference Δ_n progressively decreases. This trend can be attributed to the fact that, compared to spur gears, helical gears have more teeth simultaneously engaged in meshing at any given instant, leading to a smoother and more continuous load distribution.

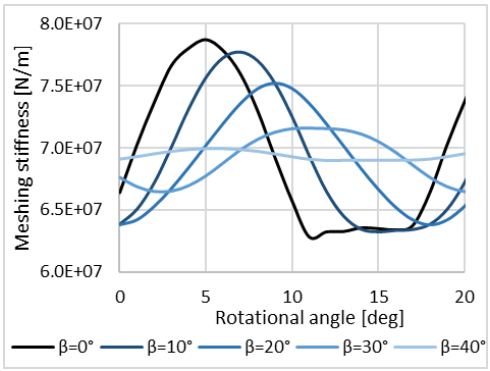

Figure 2. Meshing stiffness for different helix angles.

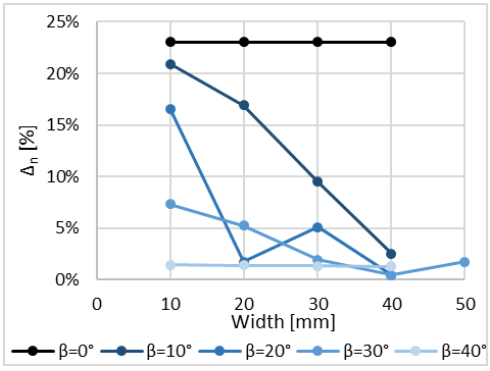

Figure 3. Normalized amplitude difference of meshing stiffness.

3.2 Effect of the parameters on the spectrum

Fig. 4 presents the sound power spectra for various helix angles, keeping the gear width constant at 30 mm. As the helix angle increases, the amplitude of the meshing frequency component decreases. This trend suggests that a larger helix angle results in smoother meshing between the gear teeth, reducing the impact of this tonal component. As a result, a significant reduction of the global level is observed, since the component associated with the meshing frequency represents the main contribution to the overall sound power level. On the other hand, there is a relevant increase in noise levels at lower frequencies, indicating a redistribution of energy across the spectrum. This shift may be due to changes in the dynamics of the gear meshing as the helix angle varies, affecting how vibrations are transmitted to the casing.

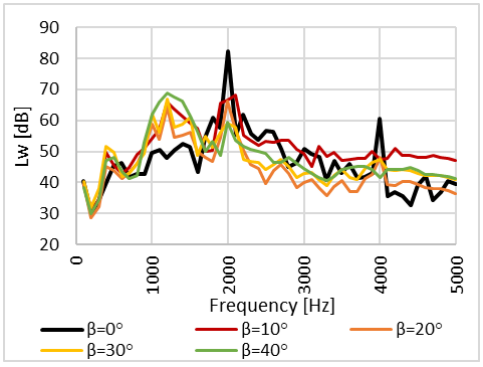

Figure 4. Sound power spectrum for different helix angles (width L = 30 mm).

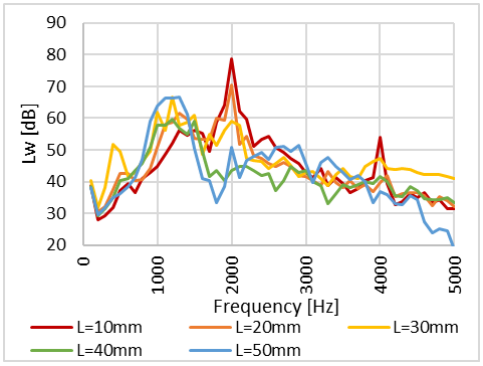

Figure 5. Sound power spectrum for different gear widths (helix angle $\beta = 30°$).

Fig. 5 shows the sound power spectra for different gear widths, while maintaining constant the helix angle value, $\beta = 30°$. Similar to the previous case, the increase in gear width provides a reduction in the amplitude of the meshing frequency component. This reduction can be attributed to a smaller amplitude difference in the meshing stiffness, leading to less pronounced fluctuations in the force

transmitted between the gear teeth. Additionally, there is a noticeable increase in noise levels below the meshing frequency, suggesting that as the gear width increases, more energy is distributed into lower frequencies, possibly due to changes in the contact mechanics and in the overall stiffness of the system.

3.3 Effect of the parameters on the overall level

The overall noise level as a function of the normalized amplitude difference Δ_n is shown in Fig. 6. This parameter accounts for the combined effects of both helix angle and gear width, providing a comprehensive measure to assess their influence on noise levels radiated by the gearbox. As shown in this figure, an increase in the normalized amplitude difference results in a higher sound power level radiated by the gearbox. Thus, larger variations in the meshing stiffness lead to an amplification of the generated noise. A non-uniform gear meshing, for which the helix angle and the gear width play an important role, will thus lead to higher vibration amplitude or more significant impacts during the meshing cycle.

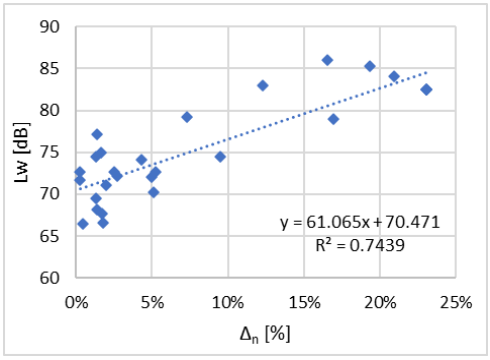

Figure 6. Correlation between the sound power level and the normalized amplitude difference of the meshing stiffness.

4. CONCLUSIONS

In this article, a numerical analysis is presented to investigate the influence of helix angle and gear width on noise radiated by a gearbox. In particular, the study focuses on how these two parameters influence the shape of the meshing stiffness function, which plays a crucial role in the acoustic behavior of the system. This function can be used as a control variable to assess and optimize the influence of helix angle and gear width on the overall noise level. A direct relationship between the sound power level and the normalized amplitude difference of the meshing stiffness was identified. This relationship shows that a larger variation in the amplitude of the meshing stiffness corresponds to a proportional increase in the overall sound power level. Since the meshing stiffness variation is significantly influenced by gear geometrical characteristics such as helix angle and gear width, an optimal design of these parameters can provide a reduction of noise radiated by the gearbox. Additionally, this study revealed that increasing either the gear width or the helix angle leads to a reduction in the amplitude of the meshing frequency component. However, this reduction also increases radiated noise at lower frequencies, suggesting a redistribution of the vibrational energy across the spectrum.
Through this analysis, a clear correlation between the key design parameters of the gears and the sound power level is established. Future research should aim at conducting experimental measurements to validate the trends observed in the numerical analysis. Furthermore, the effects of other geometrical factors and working parameters should be explored.

[2] Physikalisch-Technische Bundesanstalt, 38118 Braunschweig, Germany

ABSTRACT

Noise emissions from machinery are the main source of noise exposure for workers. To combat this risk at source, the European Machinery Directive requires the declaration of the main noise emission parameter, the sound power level. This quantity is determined according to 10 different EN ISO standards, requiring special laboratory environments or complex measurement techniques (reference sound sources, intensity probes, etc.). This high level of effort is considered to be a major reason why, despite legal requirements, noise data in instructions for 80% of machinery is unreliable or unavailable (NOMAD study). This project aims to reduce the measurement effort for machinery manufacturers, test houses and occupational health and safety personnel. To this end, existing methods, e.g., EN ISO 3744, that determine sound power from sound pressure measurements at discrete positions on the enveloping measurement surface around the machine shall be complemented by a new method based on manual sound pressure scans on the measurement surface. Ideally, these can be performed with a single microphone connected to a sound level meter. We present the results of first measurements on a model machine.

1. INTRODUCTION

Noise-induced hearing loss remains an important occupational safety issue. A significant contribution to reduce the noise hazard for workers can be made by purchasing "quiet machines", which, in addition to suitable characteristics, are also characterized by the lowest possible noise emissions, in line with the "Sell and Buy Quiet" concept [1]. In order for companies to be able to choose quieter machines ("Buy Quiet"), manufacturers must provide comparable and reliable noise emission data ("Sell Quiet").

However, a European market surveillance exercise, the so-called NOMAD (Noise Machinery Directive) survey revealed significant problems with the noise emission data provided in the instructions of machinery to be sold on the EU Single market [2]: 80 % of the noise emission declarations in more than 1500 investigated instructions did not meet the requirements of the EU Machinery Directive 2006/42/EC [3].

This rather poor compliance with legal requirements might – in part – be caused by the complicated basic noise emission standards that manufacturers have to apply to determine the noise emissions of their machines. Sec. 2 explains the application and as well the limitations of the existing standards in more detail, while Sec. 3 describes previous projects aimed at improving and simplifying the existing basic noise emission standards. Sec. 4 outlines the project LpScan, which aims to develop a new sound power standard, based on sound pressure scans instead of sound pressure level measurements at specified, fixed positions. Sec. 5 explains the methodology of this project, Sec. 6 presents the results of sound power measurements according to the existing ISO 3744 on a model machine and Sec. 7 concludes the paper with a summary and an outlook.

2. LIMITS OF EXISTING SOUND POWER STANDARDS

In accordance with the New Approach, many European Directives, such as the Machinery Directive [3], only define essential health and safety requirements, but not how they are to be achieved in detail/for each specific product. The EU-wide harmonization of product safety requirements is then achieved by means of harmonized standards, which are listed in the Official Journal of the European Union under the respective directive and the application of which is associated with a presumption of conformity (with regard to the requirements of the directive covered by the standard).

With regard to the noise emissions of machines, but also in general for other requirements of the Machinery Directive, a distinction is made between machine-specific standards, so-called C-standards, basic standards for specific hazards, etc. (B-standards) and basic standards (A-standards), defining principles, etc. (e.g. ISO 12100).

To determine the noise emission of a specific machine type, type-C standards define the applicable measurement methods by references to one or more B-standards, further measurement requirements, and the operating and mounting conditions.

There are many basic noise emission standards (B-standards) for determining the key noise emission quantity sound power level L_W. ISO 3740 [4] provides an overview of and information on when to use which B-standard/measurement method. The most important methods are the enveloping surface method (ISO 3744, ISO 3745 & ISO 3746), the reverberation room method (ISO 3741, ISO 3743-1, -2), the reference source method (ISO 3747) and the sound intensity method (ISO 9614, parts 1 to 3). The enveloping surface method, in particular the ISO 3744 and ISO 3746, makes relatively few demands on the measurement equipment, which is why the ISO 3744 method is the most widely used method. Most regulations, C-standards and product specifications refer to this accuracy grade 2 method.

However, ISO 3744 requires the determination of the environmental correction K_2 when used indoors outside of a hemi-anechoic test room and relies on fixed measurements positions. Both aspects may represent a challenge for machinery manufacturers, especially small- and medium-sized enterprises (SMEs), when determining the sound power level of their products on their own premises.

Measurements on larger machines and in particular on machines with a directed noise emission, e.g., from openings, vents, etc. require measurements on 21 or even more measurements positions (see Figure 7 showing the setup for model machine 1.)

This can increase the costs for the measurement equipment or when performed with a single sound level meter the measurement effort. Although sound intensity measurements according to ISO 9614-2 and ISO 9614-3 can be performed by intensity scans on the enveloping surface, using this method is no practical solution for SMEs. The measurement equipment is much more expensive than a sound level meter and the measurements require more expertise. Especially, since the current standards require the determination of partly unnecessary field indicators, which are not correlated to the accuracy of the determined L_W (see also Sec. 3) [5].

Thus, there is a need to develop an alternative method based on sound pressure level measurements that combines the low equipment costs of sound pressure level measurements and the reduction in measurement effort by scanning on the enveloping surface/measurement surface instead of measuring sound pressure on many fixed positions (see Sec. 4).

3. PREVIOUS PROJECTS AIMED AT IMPROVING BASIC NOISE EMISSION STANDARDS

In the course of its focus project “Practice-oriented simplification of noise emission measurement methods”, the Federal Institute for Occupational Safety and Health (BAuA) conducted several research projects aimed at a simplification of noise emission measurement of machines.

Project F 2438 “Simple approximate determination of the environmental correction” explored the feasibility of replacing expensive reference sound sources (RSS) with other small machines with sufficiently stable noise emission. The goal was to enable machinery manufacturers, in particular SMEs, to determine the environmental correction K_2 for the in-situ determination of the sound power level L_W themselves [6].

The local environmental correction K_3 for the in-situ determination of the emission pressure sound level requires even more effort. Project F 2495 “Determining the local environmental correction for the emission sound pressure level” investigated possibilities to simplify its determination and the effects of an amendment to ISO 11202:2010 [7].

Project F 2450 “Improving the practicability of the sound intensity method” was setup by BAuA and conducted by PTB in Braunschweig. It investigated potential simplifications to ISO 9614, parts 1 to 3 [5]. The project report contains drafts of a simplified ISO 9614, but these proposals have yet to be adopted in a revised version of the standard. Although the revision process has been started

already, it will still take a while until the revision will be completed.

4. CURRENT PROJECT: LPSCAN – DETERMINATION OF SOUND POWER LEVEL BY SOUND PRESSURE SCANNING (F 2571)

The project F 2571 “Determination of sound power level by sound pressure scanning (LpScan)” is a joint research project of BAuA and PTB, the national metrology institute of Germany, setup in the framework of the BAuA focus project “Practice-oriented simplification of noise emission measurement methods”. The aim of project “LpScan” is to develop a measurement method that determines the sound power level by scanning the sound pressure level around the machine [9]. Such a method has the advantage that the measurement can be carried out quickly using a single sound level meter. Compared to the sound intensity method (ISO 9614-2 and ISO 9614-3), which already works by scanning intensity on the enveloping surface, scanning with a single microphone connected to a sound level meter would offer great cost advantages (cost of measurement equipment). By moving the scans in the acoustic near-field of the machine, it might even be possible to perform the measurements without determining the background noise correction K_1 and the environmental correction K_2, making the method ideal for in-situ measurements on the premises of SMEs.
The project is planned for three years and the final result will be a draft for a standard to determine the sound power level of machines and other products from sound pressure scans on the enveloping surface, in openings of the encapsulation and in a few centimeters from the machine surface.

5. METHODOLOGY OF PROJECT LPSCAN

5.1 General

The research question is: Can the sound power of a machine be determined with sufficient accuracy and reproducibility by scanning the sound pressure level on an imaginary surface (called the measurement surface or enveloping surface) around the machine with a microphone, and is this a useful addition to existing standardized measurement methods?
Based on theoretically describable model radiators (e.g. monopole, dipole, etc.), the sound pressure scanning method is first analyzed at a typical measurement distance of 1 m. The deviations of the results obtained with this method from the known sound power of the model radiators are determined by varying the parameters such as enveloping surface shape, scanning speed, density of the scanning paths, shape of the paths, required stationarity of the sound field, level and distribution of the background noise level, orientation of the microphone or hand-held sound level meter. In addition to the results for sound pressure scanning, the results for discrete measurement point arrays are also used for comparison. The result of this work package is a basic understanding of the sound pressure scanning method at typical measurement distances and the most important parameters to be considered. At the same time, appropriate measurements will be performed to determine the sound power of model machines (see 5.3) using sound pressure scanning to verify the theoretical results.
Another application of sound pressure level scanning, which will be investigated in the project and developed into a measurement method, is the relocation of the scans in the near-field of the source. At distances of only a few centimeters to the surface of the machine, it may be possible to dispense with both the background noise correction K_1 and the correction for noise reflected in the measurement environment (environmental correction K_2).

5.2 Near-field scanning

In the case of near-field scanning, two methods can be distinguished:
In near-field full-surface scanning, the microphone is scanned over the entire surface of the machine to be tested at a distance of a few centimeters. It is also suitable for determining the sound power of individual components of linked systems.
Near-field partial surface scanning is based on the assumption that the sound power of the source is essentially radiated from certain spatially limited partial surfaces, so that the sound power can be determined only by scanning these areas. This method is also highly relevant in practice, since it can be used whenever machines are encapsulated for noise reduction, but openings in the encapsulation must be present for the machine to operate (e.g. in beverage filling machines).
In the context of near-field partial surface scanning, analytical calculations are conducted using synthetically generated sound pressure distributions that are strongly inhomogeneous on enveloping surfaces. These distributions are designed to model, for instance, openings in source enclosures. The study investigates the conditions under which it is feasible to determine the total sound power that passes through the enveloping surface by measuring solely at the most radiating partial surfaces. The validity of these

calculations is substantiated by measurements conducted on model machines.

5.3 Model machines

For this project, three model machines with variable "configurations" will be used to simulate measurements on real life machines under reproducible conditions. The machines are built from aluminum profiles and dampened aluminum sheets (see Figure 1 [7]).

Figure 1. Model machine 1 with a circular opening (Configuration I).

Three to four Brüel & Kjaer (Type 4204) aerodynamic reference sound sources (RSS) are placed in the model machines to ensure a sufficient, stable, reproducible and broadband noise emission. Each RSS has a sound power level $L_{WA} \approx 93$ dB. The configurations of openings in the model machines can be varied to allow the testing of different, but yet "challenging" configurations that have a directed, non-uniform noise emission in common.

5.3.1 Model machine 1

Model machine 1 has the following dimensions:
1,74 m×1,12 m×1,67 m (length × width × height).
The dimensions shall represent the dimensions of realistic machines, but yet have to be handled under laboratory conditions.

Figure 2 shows a sketch of the model machine 1 in the configuration with a circular opening that represents a small area dominating the noise emission on that side (configuration I).

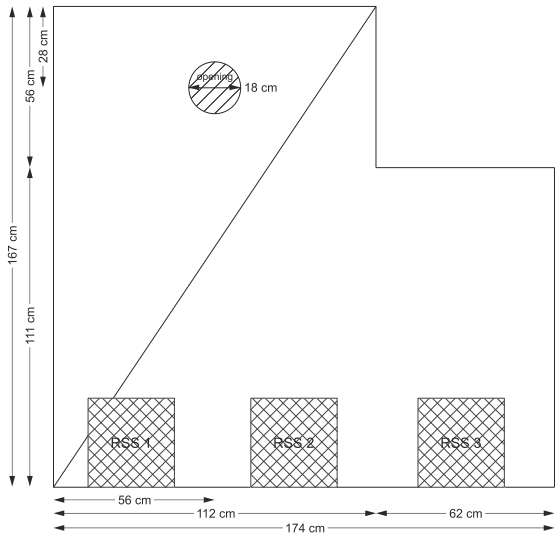

Figure 2. Sketch of model machine 1 with a circular opening (configuration I) [7].

The panel with the opening can be replaced with an open frame (configuration II (see Figure 3)) or a completely closed panel (configuration III).

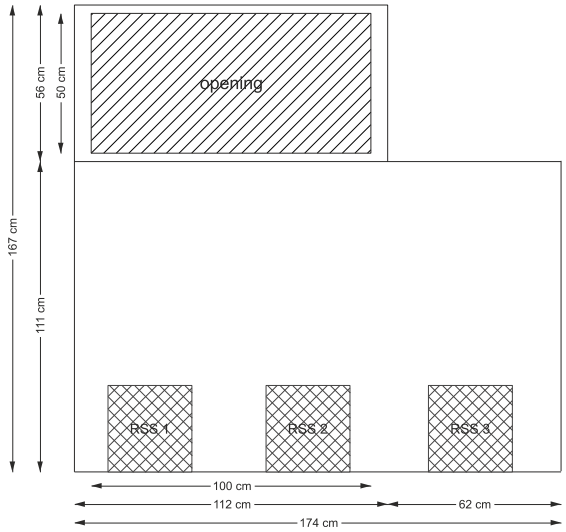

Figure 3. Sketch of model machine 1 with an open frame (configuration II) [7].

5.3.2 Model machine 2

Figure 4 shows a sketch of model machine 2 seen from the side. It has the following dimensions:
3,24 m×1,12 m×1,65 m (length × width × height).

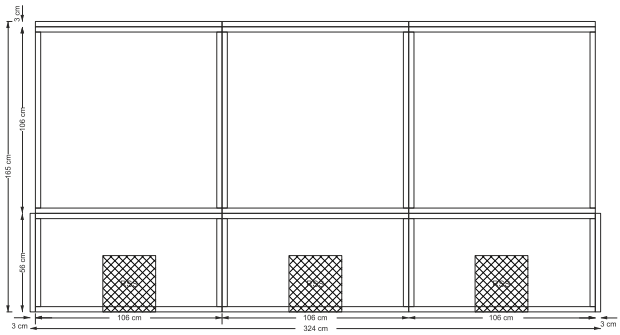

Figure 4. Sketch of model machine 2 (side view).

With openings at the ends, model machine II is designed to investigate partial-surface near-field scanning, where the goal is to determine the sound power level by scanning in these openings only.

5.3.3 Model machine 3

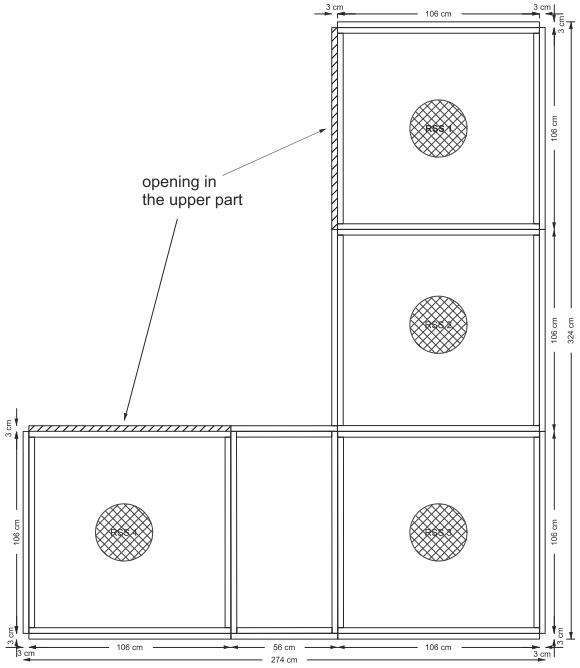

Figure 5. Sketch of model machine 3 (top view).

Figure 5 shows a sketch of the L-shaped model machine 3 seen from the top. Here, four RSS ensure a sufficiently high level of noise emission. The L-shape will be particularly demanding for full-surface near-field scanning, as noise emissions from the other opening might disturb the measurement, and maybe even when scanning at typical distances from the surface (d = 1 m).

5.4 Analysis of the results and comparative measurements

The findings from the calculations as well as the measurements on the model machines are then used to define a measurement method, which is subsequently tested through comparative measurements involving at least BAuA and PTB as participants. If feasible, additional cooperation partners should be sought to participate in these measurements, with the aim of determining the standard deviation of reproducibility of the measurement method.

5.5 Finalizing the report including a draft standard

The project will be concluded with a comprising report in English. As the key part of the report, the measurement method developed will be formalized as a draft standard. It is to be standardized as an EN ISO standard and will constitute a basic noise emission standard (B-standard) equivalent to ISO 3744. This basic standard for determining the sound power level by means of enveloping surface sound pressure scanning will also include criteria for the circumstances under which full-surface near-field scanning or partial-surface near-field scanning can be used while ensuring sufficient accuracy and reproducibility.

6. FIRST MEASUREMENTS ON MODEL MACHINE 1

We determine the sound power level of model machine 1 according to ISO 3744:2010 [10] using measurements at discrete positions on an enveloping surface/measurement surface. Due to the size and shape of model machine 1 a parallelepiped measurement surface with a distance d = 1 m from the reference box was chosen. According to ISO 3744, this meant that already 21 measurement positions were necessary (see Figure 6) – not taking account of possible non-uniform noise emission yet.
Figure 6 shows the setup for the sound power determination in the hemi-anechoic chamber. This test room is qualified from 63 Hz to 12,5 kHz according to ISO 3745.

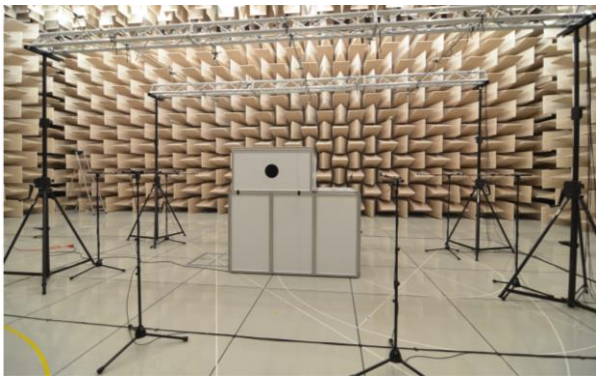

Figure 6. Model machine 1 and the setup according to ISO 3744 in the hemi-anechoic chamber at BAuA.

The measurements are conducted with 21 Brüel & Kjaer Type 4190 1/2-inch free-field microphones (IEC 61672 class 1) connected to a Brüel & Kjaer PULSE LAN-XI measurement system with 28 channels. This system is calibrated by an accredited external laboratory every two years. A system unavailable to most machinery manufacturers, especially SMEs.
However, even this high number of measurement positions is not sufficient to fully meet the requirements of ISO 3744 for configurations I and II of model machine 1, where sound pressure levels at the microphones near the circular opening and open frame, respectively, are higher. Here, 18 additional measurement positions are placed near the opening to ensure a proper sound power determination despite the directed emission of the source (see Figure 7).

Figure 7. Model machine 1 and 18 additional measurement positions according to ISO 3744 in the hemi-anechoic chamber at BAuA.

The sound power level L_W was calculated from the sound pressure level measurements at these 21 plus 18 measurement positions using the method described in Ref. [11]. Table 1 shows the sound power level for all three configurations of model machine 1. Note that the L_W of configuration III (closed) was determined from 21 measurement positions only.

Table 1. Sound power level of model machine 1 in different configurations, determined according to ISO 3744 [10].

	Conf. I Circ. open.	Conf. II Open. fr.	Conf. III Closed
L_W (dB)	88,8	93,0	87,4
L_{WA} (dB)	83,9	91,7	81,3

As expected, the sound power level of the configuration with the largest opening (configuration II, open frame) is the highest.

7. SUMMARY & OUTLOOK

We describe the details of Project LpScan. This project aims at developing a sound power standard based on (manual) sound pressure scanning. First results characterize the sound power level of model machine 1 using the existing enveloping surface method and demonstrate how much effort the established method according to ISO 3744 requires for such a machine (especially configurations I and II with a non-uniform noise emission).
As the main goal, the project will result in a new sound power standard (EN ISO) to be harmonized under the European Machinery Directive 2006/42/EC. This standard will support machinery manufacturers, in particular SMEs, to properly determine the sound power level of their products on their own premises with reduced effort. In turn, reliable noise emission data for machinery will improve market transparency regarding low noise machines. This enables employers to better protect their workers from noise by “Buying Quiet” when purchasing or hiring new machinery.

8. ACKNOWLEDGMENTS

We thank Anke Berger for carrying out the measurements on model machine 1 in the “Products and Work Systems Laboratory” at BAuA.

FORUM ACUSTICUM EURONOISE 2025

ANALYTICAL AND EXPERIMENTAL INVESTIGATION OF STATOR ASSEMBLY VIBRATIONS IN ELECTRIC MOTORS

Panagiotis Andreou[1] **Amal Z. Hajjaj**[1] **Mahdi Mohammadpour**[1]
Stephanos Theodossiades[1*]
[1] Loughborough University, School of Mechanical, Electrical and Manufacturing Engineering, Loughborough University, UK

ABSTRACT

This work presents a novel analytical model for the stator of an electric motor, modelled as a thick segmented cylindrical shell, to accurately capture its vibrational behaviour. The methodology employs the First-order Shear Deformation Stress Theory (FSDST) with considerations of mechanical property anisotropies and dimensional variations to represent the system's complex dynamics. An Experimental Modal Analysis (EMA) was performed using an impulse hammer, to identify the stator's modal characteristics. The analytical model demonstrated exceptional accuracy in capturing these features. The experimental results were used to enhance the Rayleigh damping approximation implemented in the model. The enhanced model was applied to predict the forced response of the system under impulse excitation. Comparisons between analytical predictions and experimental measurements revealed excellent agreement, validating the model's reliability in capturing the stator's dynamic response. This approach not only provides a comprehensive understanding of both the free and forced vibrational behaviour of electric motor stators but also establishes a dependable framework offering valuable insights for mitigating vibrations and improving the overall electric motor performance.

Keywords: *experimental modal analysis, e-motor stator assembly, analytical structural dynamics, forced response.*

1. INTRODUCTION

Electric motor noise, vibration, and harshness (NVH) are critical concerns in modern powertrain development, with stator vibrations being a dominant source of acoustic emissions [1]. Predicting accurately the natural frequencies and mode shapes of a stator assembly is essential for understanding its dynamic response under electromagnetic excitation and avoiding resonances that can lead to excessive noise and structural fatigue. While numerical methods provide detailed modal and dynamic predictions, their computational expense remains a major limitation, especially for high-frequency analyses requiring fine meshes and small time steps [2], [3]. Prior reduced-order and analytical approaches [4]-[6] have been proposed, however, they typically rely on simplifying assumptions, such as reducing the problem to two dimensions or neglecting critical structural and geometric complexities of the stator assembly, thereby limiting their applicability.

This paper proposes an analytical modelling framework for the modal and dynamic analysis of electric motor stator assemblies based on the First-order Shear Deformation Stress Theory (FSDST). The proposed methodology offers a highly accurate, computationally efficient alternative to numerical approaches. By axially segmenting the assembly and introducing continuous functions to characterise the material properties across its thickness, the model effectively captures the effects of anisotropic parameters as well as dimensional variations. The displacement field is formulated using orthogonal Jacobi polynomial functions and the natural frequencies and mode shapes are computed via the Lagrangian energy method. The Newmark-β integration technique is then employed for the evaluation of the forced response of the system under an impulse excitation. The methodology is outlined in Section 2, and results of the analytical model are presented and assessed against experimental data in Section 3.

2. METHODOLOGY

2.1 Mechanical Model and Material Characterisation

The stator assembly is modelled as a thick cylindrical shell of length L and radius R, divided into P segments, each with a thickness h_P and length L_P. This segmentation allows for the incorporation of dimensional variations within the cylindrical shell. To accurately represent the complex material properties of the assembly – including the stator windings, teeth, stator yoke, and cooling jacket or housing – carefully formulated continuous functions are introduced. These functions characterise the orthotropic nature of the stator lamination and the variation of material properties across the shell's thickness. More specifically, they comprehensively characterise the modulus of elasticity, shear modulus, Poisson's ratio, and density.

2.2 Displacement and Energy Equations

Through the assumptions that the shell displacements are small relatively to their thickness and that normal shear stresses are negligible, the displacement field can be expressed in accordance with first-order shear deformation shell theory (FSDST) as [7]:

$$\boldsymbol{u^p(x,\varphi,z,t) = u_0^p(x,\varphi,t) + z\beta_x^p(x,\varphi,t)} \quad (1)$$

$$\boldsymbol{v^p(x,\varphi,z,t) = v_0^p(x,\varphi,t) + z\beta_\varphi^p(x,\varphi,t)} \quad (2)$$

$$\boldsymbol{w^p(x,\varphi,z,t) = w_0^p(x,\varphi,t)} \quad (3)$$

where u, v, and w are the mid-surface displacements in the axial, circumferential and normal directions, and β_x and β_φ are the mid-surface rotations in the axial and circumferential directions, respectively. Once these functions are established, the FSDST is employed to express the kinetic energy T^P, potential energy U^P , and external work W^P associated with each segment, as follows:

$$U^p = \frac{R}{2}\int_0^{L_p}\int_{-h_p/2}^{h_p/2}\int_0^{2\pi}\left(\sigma_{xx}^p\varepsilon_x^p + \sigma_{\varphi\varphi}^p\varepsilon_\varphi^p + \tau_{x\varphi}^p\gamma_{x\varphi}^p + \tau_{xz}^p\gamma_{xz}^p + \tau_{\varphi z}^p\gamma_{\varphi z}^p\right)\left(1+\frac{z}{R}\right)d\varphi\,dz\,dx \quad (4)$$

$$T^p = \frac{R}{2}\int_0^{L_p}\int_{-h_p/2}^{h_p/2}\int_0^{2\pi}\rho_p\left(\dot{u}_p^2 + \dot{v}_p^2 + \dot{w}_p^2\right)\left(1+\frac{z}{R}\right)d\varphi\,dz\,dx \quad (5)$$

$$W^p = \frac{R}{2}\int_0^{L_p}\int_{-h_p/2}^{h_p/2}\int_0^{2\pi}\left(f_u^p u_0^p + f_v^p v_0^p + f_w^p w_0^p + f_{\beta_x}^p\beta_x^p + f_{\beta_\varphi}^p\beta_\varphi^p\right)\left(1+\frac{z}{R}\right)d\varphi\,dz\,dx \quad (6)$$

where σ, ε, τ and γ represent the normal stress, normal strain, shear stress and shear strain in each direction for the p-th segment, ρ is the density and f denotes the external force.

2.3 Boundary and Continuity Enforcement

To satisfy continuity between adjacent segments and ensure that transverse and shear displacements at the end of one segment match the start of the next segment, artificial massless springs are introduced. Similarly, artificial springs are incorporated at each end of the cylindrical shell, allowing for any possible boundary condition to be imposed, by varying the appropriate spring stiffnesses. The energy stored in the artificial continuity and boundary springs is calculated according to the penalty method [8], denoted as U_c and U_b, respectively.

2.4 Eigenvalue Analysis

Having established the energy formulations, the Lagrangian energy function $\mathcal{L}$, may be expressed as:

$$\mathcal{L} = \sum_{p=1}^{P}(T^p - U^p + W^p) - \sum_{p=1}^{P-1}U_c^{p,p+1} - U_b \quad (7)$$

Minimising the Lagrangian energy function with respect to each of the generalised coordinate variable yields:

$$\boldsymbol{M\ddot{q} + Kq = F} \quad (8)$$

where $\boldsymbol{q}$ is the global generalised coordinate vector, $\boldsymbol{M}$ and $\boldsymbol{K}$ are respectively the mass and stiffness matrices and $\boldsymbol{F}$ is the external load vector. For the eigenvalue analysis, external work is neglected, and the system is assumed to undergo free harmonic motion, i.e. $\boldsymbol{F = 0}$ and $\boldsymbol{q(t) = \bar{q}e^{i\omega t}}$. Substituting these into Equation 8 yields:

$$\boldsymbol{[-\omega_{nat}^2 M + K]\bar{q} = 0} \quad (9)$$

The solution of the above expression returns the natural frequencies of the system, ω_{nat} and their corresponding eigenvectors, $\bar{\boldsymbol{q}}$.

2.5 Forced Response

For the evaluation of the dynamic response of the system under impulse load, the Newmark-β integration method was utilised, due to its numerical stability, computational efficiency and versatility [9]. Having obtained the modal damping ratios from the Experimental Modal Analysis (EMA) performed on the actual system, the damping matrix was constructed following the Rayleigh damping method. The applied force in the analytical model, at location (x_0, θ_0, z_0), is expressed as:

$$f_w(x,\theta,t) = A(t)\delta(x-x_0)\delta(\theta-\theta_0)\delta(z-z_0) \quad (10)$$

where $A(t)$ denotes the time-dependent force amplitude obtained experimentally, and δ is the Dirac delta function, which allows for spatial localisation of the applied force.

3. RESULTS AND DISCUSSION

Having applied the methodology outlined above to a real stator assembly from an electric vehicle powertrain, this section presents and discusses some of the results obtained, with comparisons against experimental data. **Table 1** presents the results of the EMA compared against the analytical natural frequency predictions for the first five vibration modes of the system. The average error across the presented modes is -1.03% (maximum error 7.54%), thus within an acceptable range, confirming that the analytical method effectively captures the modal characteristics of the complex stator assembly, and that the assumptions utilised within the model are successful. The accuracy of the model is also shown in **Figure 1**, with the analytically derived cylindrical mode shapes being in very close conformity with the ones obtained from the EMA.

Table 1. Comparison of EMA results with analytical natural frequency predictions

Mode *(n,m)*	Exp. (Hz)	Damp. (%)	Ana. (Hz)	Error (%)
(2,0)	604	1.11	609	0.85
(3,0)	1692	0.99	1589	-6.07
(2,1)	2088	1.03	2172	4.00
(3,1)	2598	1.05	2692	3.61
(4,0)	2976	1.56	2751	-7.54

Finally, the experimental and analytical acceleration signals following the impulse excitation described in Section 2 are presented in the time-domain in **Figure 2**. It can be observed that both systems exhibit a sharp initial acceleration peak due to the applied impulse, followed by rapidly decaying oscillatory motion, as the stator assembly is allowed to come to rest. The peak acceleration values in both signals are similar, indicating that the application of the excitation in the analytical model is consistent with the experiment. There is however a slight discrepancy in the amplitude decay rate, which could be justified by the simplified damping representation implemented in the analytical model, as well as additional energy dissipation in the real system. This energy dissipation could be a result of friction at the interfaces between the assembly's layers or between the system and the elastic supports used to approximate free boundary conditions.

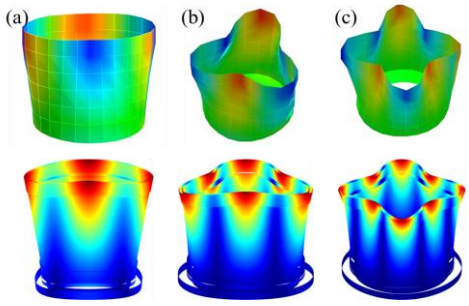

Figure 1. Comparison of experimentally obtained mode shapes (top) with analytically derived ones (bottom) for mode (a) (2,0), (b) (3,0) and (c) (4,0).

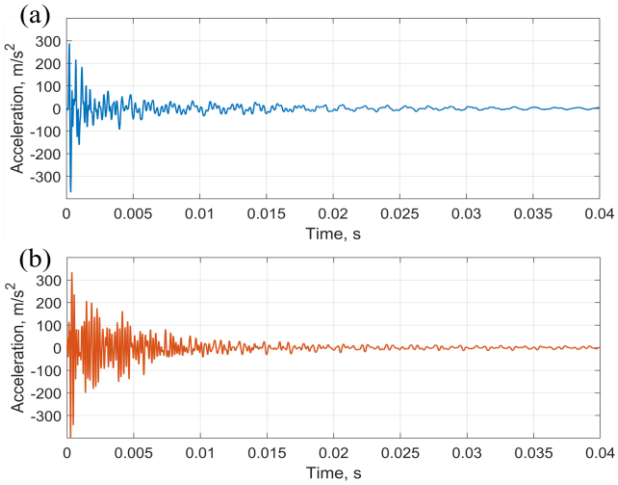

Figure 2. Experimentally obtained (a) and analytically predicted (b) acceleration response at a random location mode on the stator assembly following impulse excitation.

The Frequency Response Function (FRF) of the acceleration signals, shown in **Figure 3**, provides further insight into the accuracy of the analytical model in capturing the dynamic behaviour of the stator assembly. The dominant resonant peaks predicted analytically align well with those observed experimentally, confirming that the developed methodology accurately identifies the primary vibration modes of the structure. The discrepancies in the locations of the peaks are mostly explained by the errors in the calculation of the natural frequencies. Additionally, in the experimental signal there appear to be contributions in the range of 800-1350 Hz, as well as 1750-2000 Hz, which are caused by the degenerate mode pairs of vibration modes (2,0) and (3,0), but due to geometric asymmetries in the real system they have different frequencies. These asymmetries cannot be captured by the cylindrical analytical model hence there is no contribution

at those frequencies. Furthermore, minor discrepancies at higher frequencies may again be attributed to the assumptions introduced by the Rayleigh damping method and may be minimised through further damping refinement.

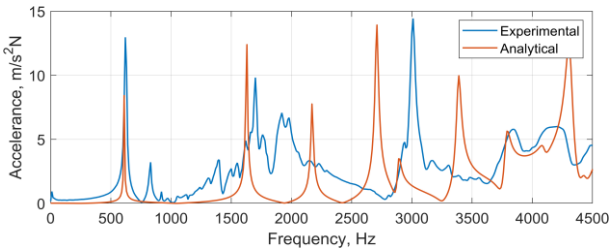

Figure 3. Acceleration Frequency Response Function (FRF) of the structure following impulse excitation.

4. CONCLUSIONS

This work introduces an accurate, yet highly computationally efficient framework for identification of the modal characteristics and the dynamic response analysis of electric motor stator assemblies. The overall agreement between analytical and experimental results demonstrates the effectiveness of the proposed methodology in predicting the dynamic behaviour of complex stator assemblies. The natural frequency and mode shape predictions of the analytical model are in excellent agreement with EMA results, with a maximum error of 7.54%. The dynamic response of the system to an impulse excitation is captured with great qualitative agreement, considering the differences in peak amplitudes can be attributed to damping simplifications, while the frequency deviations are a direct result of the deviations in natural frequency predictions. However, further refinement of damping parameter estimation could enhance the model's predictive capability. Incorporating additional experimental data to fine-tune damping coefficients or employing a more detailed dissipation model could further improve the accuracy of time-domain responses.

Despite these minor discrepancies, the developed analytical approach provides a computationally efficient and reliable tool for modal analysis of stator assemblies. Its ability to closely match experimental results highlights its potential for early-stage NVH assessment and optimization in electric powertrains.

PSYCHOACOUSTIC INVESTIGATION OF THE SOUND RADIATION OF ROTARY DRILLING RIGS

Jörg Riedel[1*] **Gabriel Beer**[1] **Franz Froschmeir**[2]

ABSTRACT

The acoustic emission of rotary drilling rigs consists of the partial sound sources of the diesel engine, the fans of the cooling system and the rotary drive. Usually, the machines are acoustically characterised according to the outdoor noise directive 2000/14/EC with a value for the averaged sound power. However, the subjective noise exposure for construction site employees can differ from the measured sound power level depending on their location on the construction site. In our test setup, we examine the acoustic emission of the device from the perspective of the construction site workers, once from the machine operator in the operator's cab and once from the site assistant giving instructions outside. Using artificial head measurements, we analyse the psychoacoustic parameters of loudness, sharpness, roughness and tonality at different operating points of the drilling rig. It turns out that, despite similar values for the sound power, the psychoacoustic parameters can characterise the sound radiation of the drilling rig in a more differentiated way at specific operating points.

Keywords: *psychoacoustics, construction site noise, rotary drilling rigs*

1. INTRODUCTION

According to a report by the German Federal Ministry of Labour and Social Affairs, noise-induced hearing loss is the second most common recognised work-related disease in Germany. In 2023, 18,076 new cases of occupational noise-induced hearing loss were reported to the relevant accident insurance companies. Of these, 7,889 new cases have already been confirmed and in 283 cases, noise-induced hearing loss was the reason for early retirement [1]. A significant proportion of these cases affect employees in the construction industry, with around 1,500 new cases of noise-induced hearing loss being recognised in this sector each year [2].

Particularly on major construction and civil engineering sites, construction workers and residents are exposed to high noise emissions due to the heavy construction machinery used. One machine type frequently employed in this context are rotary drilling rigs, which are used to drill piles, carry out soil mixing procedures or prepare the ground for following process steps [3]. An example of such a machine is shown in Fig 1.

Figure 1. Example for a rotary drilling rig.

2. PSYCHOACOUSTIC PARAMETERS

The application of psychoacoustic methods for product optimisation is nowadays well established in the mobility sector. Some examples in this context are the characterisation of automotive HVAC noise [4], sound design of warning signals for electric cars [5], or the characterisation of motors in pedelecs [6]. We apply the software ArtemiS SUITE 16.0 from HEAD acoustics to calculate the psychoacoustic parameters mentioned below.

2.1 A-weighted sound pressure/power level

For practical applications, the A-weighted sound power level is a commonly used metric to quantify the acoustic emission of a machine. The A-weighting takes into account the fact that the human ear is less sensitive to particularly low and high frequencies. However, strictly speaking, the A-weighting filter only corresponds to the curve of equally loud perceived tones at a volume between approximately 20 and 40 phon. Nevertheless, A-weighting is a very good approximation for the evaluation of tones, narrow-band noise and simple A-B comparisons, where A and B have the same sound characteristics. For broadband noise and when comparing noises that differ greatly in their underlying characteristics (e.g. additional tonal components), pure A-weighting however underestimates the volume compared to subjective volume perceptions from listening tests [7].

2.2 Loudness

When assessing the volume of a noise signal, loudness takes into account the physiological characteristics of human hearing. This includes, among other things, taking into account frequency-dependent masking effects and incorporating different rating curves depending on the maximum sound pressure level being present [7]. A 1 kHz sinusoidal tone with a sound pressure level of 40 dB is assigned the unit 1 *sone*. In our investigations, we use the calculation of loudness according to DIN 45631/A1, which is based on the frequency group method according to ZWICKER.

2.3 Sharpness

Speaking figuratively, sharpness describes the location of the centroid of the loudness-corrected spectrum of a sound. Noises with a focus in the high-frequency sound range are perceived as sharper [7]. A narrowband noise around the centre frequency of 1 kHz with the width of one critical band and a sound pressure level of 60 dB corresponds to 1 *acum*. In the present case, we use the calculation model according to AURES with an underlying loudness calculation according to DIN 45631/A1.

2.4 Roughness

The roughness indicates a parameter for characterising frequency- and amplitude-modulated sounds. A 1 kHz sine tone at 60 dB, which is amplitude-modulated with a frequency of 70 Hz and a modulation degree of 1, corresponds to a roughness of 1 *asper* [8]. We use the procedure according to DIN 38455 to calculate roughness.

2.5 Tonality

The tonality parameter is used to rate noise in terms of the annoyance of specific tonal components it contains. We use the tonality according to the SOTTEK hearing model, as shown in ECMA 418-2, in our analyses. A 1 kHz tone with a level of 40 dB receives the unit 1 tu_{HMS} (tonality units according to the hearing model of Sottek). Compared to other methods of calculating tonality, such as the tone-to-noise ratio or DIN 45681, the metric used here has the advantage that it uses psychoacoustic loudness as the basis for its calculations [9].

3. MEASUREMENT SET-UP

Construction equipment and machinery used outdoors are sound-characterised in Europe in accordance with the outdoor directive 2000/14/EG. This directive refers to EN ISO 3744 for determining the sound power of rotary drilling rigs. Accordingly, the sound power of rotary drilling rigs is determined using an enveloping surface method for a free sound field above one reflecting surface Fig. 2 shows the measurement set-up in this case. 12 microphone positions are defined around the device in a hemisphere with a radius of 16 m, in line with the standard. The microphones used for the sound power measurement are ½”- free-field microphones of the type MK 255 from MTG.

We use the KEMAR Head & Torso 45BB-10 with anthropometric ears as the artificial head. The artificial head is placed at a distance of 4 m from the outer contour of the machine, which is a typical working position for the drilling assistant (see Fig. 1). Data acquisition is carried out with an SQuadriga II from HEAD acoustics. During the measurements, the machine operator inside the device wears the Mobile Headset BHS II together with the mobile recorder SQobold from HEAD acoustics.

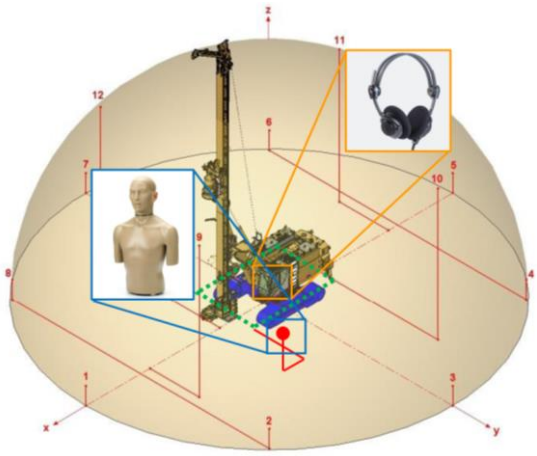

Figure 2. Set-up for determining the sound power of a rotary drilling rig according to EN ISO 3744. Also highlighted is the measurement equipment for the binaural recordings at the related positions

In our tests, we analyse a medium-powered rotary drilling rig with a 6-cylinder 4-stroke diesel engine. As already mentioned, the main sources of noise on such a machine are the diesel engine itself, the fans for cooling the engine, hydraulic circuit and charge air, and the operation of the power rotary head. In our measurement programme, we analyse the device in four different operating modes, which are summarised in Tab. 1. We examine time periods of 15 s for each operating point.

Table 1. Test plan of the considered operating points of the rotary drilling rig with corresponding sound power levels according to EN ISO 3744.

#	engine speed	fan speed	rotary drive	sound power level
M000	85 %	70 %	off	$L_{w,min}$
M100	100 %	70 %	off	$L_{w,min}$ +0,7dB(A)
M010	85 %	100 %	off	$L_{w,min}$ +7,5dB(A)
M011	85 %	100 %	on	$L_{w,min}$ +8,3dB(A)

In the first operating condition, M000, the engine is running at 85% of its nominal speed. All the fans are manually controlled at 70% of their maximum speed and the rotary drive is not in operation. In this setting, the lowest of all sound power levels, $L_{w,min}$, is measured and used as a reference for the other operating conditions. In the second operating state, M100, the speed of the diesel engine is then increased to nominal speed (100%). This results in a sound power increased by 0.7 dB(A) compared to the initial variant. In the third operating state, M010, the engine speed is reduced again to 85% of the nominal engine speed and the speed of the fans is increased to 100% instead; the rotary drive remains switched off. Compared to the initial variant M000, a sound power level increased by 7.5 dB(A) is now measured. In the last set-up, M011, the rotary drive is switched on, the motor engine speed remains at 85 % of its maximum and the speed of the fans are operated at 100 %. This results in an 8.3 dB(A) increase in sound power compared to the initial variant.

4. RESULTS

In Fig. 3, the results of the psychoacoustic analysis at the four different operating points are shown with the help of bar charts. Each row of the subplot represents a separate metric. Starting with level in dB(A) and moving on to loudness, sharpness, roughness and tonality. The results for the operator's position are shown in orange bars, and the results for the assistant are shown in blue.

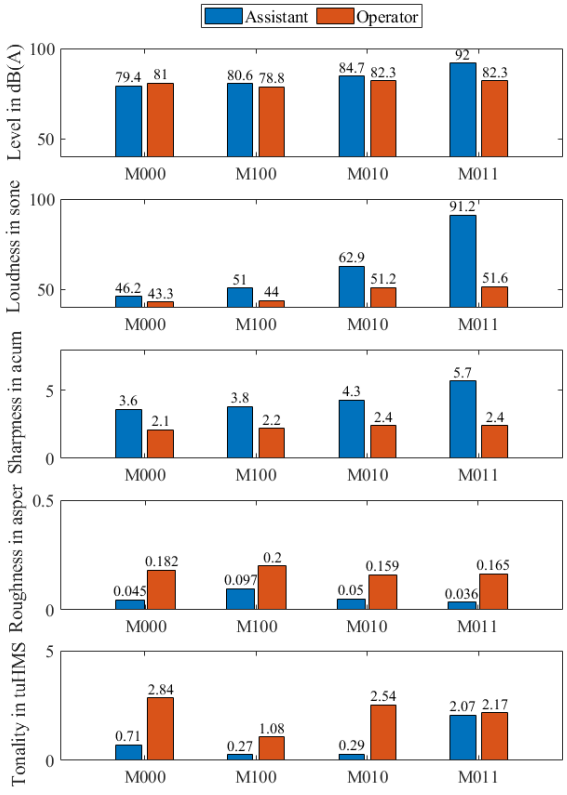

Figure 3. Single value results for the five different metrics of the psychoacoustic analysis.

4.1 Increased diesel engine speed

First, we investigate how an increase in engine speed (M000->M100) affects the sound perception for the operator and the assistant. According to Tab.1, this change results in a minimal increase in sound power of 0.7 dB(A). At the assistant's position, a slight increase in loudness of 4.8 sone is measured. While the pure A-weighted sound pressure level at the operator's position decreases by 2.2 dB(A) for this setting, the loudness increases by 0.7 sone. When listening to the sound recordings of the two operating points at the two positions, it becomes clear that the increase in engine speed is most clearly described by the parameters roughness and tonality. For both the operator and the assistant, the increase in engine speed results in a significant increase in the parameter roughness. At the same time, the parameter tonality decreases strongly at both observer positions.

4.2 Increased fan speed

Subsequently, we analyse how an increase in the fan speed (M000->M010) affects the sound perception of the construction site workers. With this particular modification, an increase of 7.5 dB(A) was observed for the sound power in Tab.1. In this case, an increase in loudness of 7.9 sone can be measured for the operator, and for the worker in front of the drilling rig, the increase is 16.7 sone. In addition to the volume, the sensation of sharpness changes when the fan speed is increased. The tonal components of the secondary aggregates are suppressed by the noise of the fan, which is expressed in the tonality parameter.

4.3 Switching on the rotary drive

Finally, we consider how an additional switch-on of the rotary drive (M010->M011) affects the noise perception of the construction site workers. The sound power level changes by only 0.8dB(A) at this setting. From the operator's position, it is almost impossible to detect the switching on of the rotary drive acoustically. However, the most significant differences for the assistant in the whole measurement campaign arise with this variation. The loudness increases in this case by 28.3 sone. The measured sharpness changes from 4.3 to 5.7 acum. And the tonality for the assistant increases by 1.78 tu_{HMS}.

5. CONCLUSION

In the present study, we examined how a change in characteristic machine parameters of a rotary drilling rig affects the subjective sound perception of construction site employees. Due to the fact that the machine emits a broadband noise spectrum with many different partial sound sources, the measured sound power level does not always adequately reflect the perceived noise exposure at the positions of the construction workers. Our research showed that the assistant perceives the various operating states of the machine in a much more differentiated way than the machine operator. This indicates that the machine's cab provides sound insulation and shields the operator. The work carried out shows that the psychoacoustic parameters are suitable for assessing the subjective noise exposure of construction workers.

ACOUSTIC MEASUREMENTS AND EMPLOYEE FEEDBACK: ADDRESSING NOISE IN INDUSTRIAL WORK ENVIRONMENTS – A CASE STUDY.

Pascal van Dort*
Rockfon (ROCKWOOL B.V.)
Industrieweg 15, 6045JG Roermond
Netherlands

ABSTRACT

(introduction) This study aims to evaluate the impact of high noise levels in an industrial hall on workers' health, wellbeing and productivity, with a focus on room acoustic measurements and employee feedback. (method) Various room acoustic measurements were conducted within the production hall to assess reverberation time and sound levels. Additionally, a survey was distributed to 83 workers to collect qualitative data on their experiences with noise exposure and its effects on their work environment. (results) The measurements indicated reverberant noise levels (L_{eq}) reaching up to 92 dB(A), and performed dosimeter readings among employees showed noise levels (L_{ex}) between 85 and 89 dB(A), highlighting a challenging indoor acoustic environment. Survey results revealed that a significant number of workers found their workplace to be excessively noisy, negatively affecting their stress levels, wellbeing, productivity, concentration and communication. (conclusions) The findings suggest that implementing sound-absorbing materials, such as suspended acoustic ceilings, could reduce noise levels by 5 to 6 dB(A), thereby improving working conditions. This study underscores the importance of addressing noise in industrial settings to enhance worker wellbeing and productivity, indicating that effective acoustic treatments can lead to a healthier and more happier workplace.

Keywords: *industry hall, noise exposure, health impact, wellbeing, employee feedback*

1. INTRODUCTION

Noise pollution in industrial work environments is a significant concern that can have far-reaching effects on employee health, wellbeing and productivity. In industrial settings, where machinery and equipment are primary noise sources, sound levels can easily exceed the World Health Organization's recommended level of sound exposure of 80 dB(A) for a maximum of 40 hours per week [1].

1.1 Noise exposure and its' impact on health and wellbeing

Short-term and long-term health effects have been associated with prolonged exposure to high levels of noise. Transient auditory fatigue and noise annoyance are short-term health effects of high noise levels (88 – 92 dB(A)) in factories, leading to substantial discomfort among workers [2]. Moreover, >85 dB(A) sound exposure during a working day dramatically raises the levels of the stress marker cortisol, and consequently fatigue and irritability [3]. Chronic noise exposure is associated with psychological symptoms such as anxiety and sleep disturbances. Workers in automotive industries reported increased stress and fatigue due to prolonged noise exposure [4-5]. Long-term health effects due to prolonged exposure to high-intensity noise is a leading cause of occupational hearing loss. According the WHO there is an increase in prevalence of all grades of hearing loss in Europe. In 2019 it was 197 million people and estimated that it will be 236 million in 2050 [1]. Studies

in various industries, including automotive and textile manufacturing, have documented a high prevalence of Noise-Induced Hearing Loss (NIHL), often progressing to permanent sensorineural hearing loss if left unaddressed [6-7].

1.2 Impact on productivity and job satisfaction

Noise levels in production facilities has negative effect on human productivity which leads to decrease in organization productivity and decrease in quality and quantity of services and products [8]. Another study on press machine operators found that reducing reflected and direct sound levels improved both health outcomes and production quality [9]. Poor acoustic conditions can reduce job satisfaction and overall engagement. A study comparing two industries found that reducing noise levels led to greater environmental satisfaction and improved company attachment [5].

2. GENERAL INFORMATION ABOUT THE INDUSTRY HALL

The investigated industry hall is located near Antwerp in Belgium. The hall has different production lines used for the production of metal profiles, key activities include cutting metal sheets or coils into specific shapes, roll forming to shape the profiles, cutting to different sizes and punching to create holes or slots. The total production area covers 8000m^2 with an average ceiling height of 8,20m[1]. The hall has a concrete floor, brick and steel walls and the ceiling has an unperforated steel deck, see Fig. 1.

Figure 1. Production lines in the industry hall

3. ACOUSTIC PARAMETERS; METHODS, MEASUREMENTS RESULTS AND CALCULATIONS

Room acoustic measurements were conducted within the production hall to assess reverberation time (RT) and sound levels. Equivalent sound pressure levels (L_{Aeq}) were measured to determine the overall noise exposure. These measurements provide quantitative data on the noise environment to which workers are exposed. Dosimeter readings were also taken for some employees to assess personal noise exposure levels (L_{ex}), giving a more detailed understanding of individual noise exposure variations throughout the workday.

3.1 Acoustic measurements methods

Acoustic measurements are performed on Sept. 16th 2021 using a Class 1 calibrated sound level meter Norsonic type Nor140. The noise levels were measured in more than 150 points in the entire production hall. In all points, measurement durations of ca. 1 minute were appropriate since the noise field was sufficiently stable.

Figure 2. Employee with dosimeter

In total 6 workers were equipped with a noise dosimeter. This dosimeter measured the noise pressure level at about 10 cm distance from the ear, see Fig.2. The results of the measurement render a realistic representation of the daily noise exposure of each participant. According to the European and Belgian labour legislation this “daily dose” of noise exposure is the most important indicator for

determining the risk of noise induced hearing damage [10]. Raw measurement results were elaborated such that a correct interpretation of the legislation is possible. For the calculations of the $L_{EX,8h,}$ the working conditions during the measurement period were evaluated as representative for the activities during the whole day.

3.2 Measurements results

The data obtained from acoustic measurements are analysed to determine compliance with regulatory limits and assess the potential risk to worker health, see Table 1.

Table 1. Legal limits according the 2003/10/EU directive.

Legal limits	Doses	
	$L_{EX,8H}$ dB(A)	L_{peak} dB(C)
No legal health risk	< 80	< 135
Exceedance of the lower action value	≥ 80	≥ 135
Exceedance of the upper action value	≥ 85	≥ 137
Exceedance of the limit value when not wearing hearing protection	≥ 87	≥ 140

Equivalent sound pressure levels (L_{Aeq}) were measured to determine the overall noise exposure, see Fig. 3. The active production lines are highlighted in white, and the most important operator positions are indicated by grey rectangles. Numerous areas exhibit noise exposure levels exceeding 85 dB(A), with operators frequently working in close proximity to the noisiest zones. The decay of sound levels is rather limited, indicating that noise from one production line can easily affect adjacent lines. Acoustic measurements conducted on June 22nd 2020, revealed L_{Aeq} levels reaching even up to 92 dB(A).

All operators equipped with a dosimeter exceed the upper legal limit values according the 2003/10/EU directive, see Table 2. There is a substantial risk of noise induced hearing loss when not wearing hearing protectors. Five out of six operators even exceeded the limit value of 87 dB(A) when not wearing hearing protectors. The Lpeak-values values are less critical in determining health risk and remain within the legal limits. For a more detailed description of the noise sources that are responsible for the measured $L_{EX,8H}$-values, of one of the participants see Fig.4. The graphs shows the measurement dB(A) levels per minute.

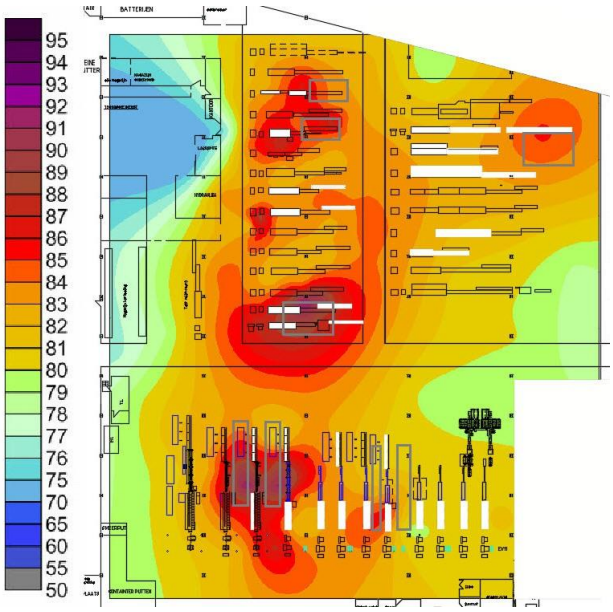

Figure 3. Noise map (L_{Aeq}) in dB(A)

Table 2. Measured dosimeter levels

Participant	Measurement duration (hr)	$L_{EX,8H}$ dB(A)	L_{peak} dB(C)
Operator 1.	5:25	87	131
Operator 2.	5:20	85	133
Operator 3.	5:25	88	127
Operator 4.	5:25	87	132
Operator 5.	5:19	89	132
Operator 6.	5:39	87	131

3.3 Acoustic modeling and calculations

To improve the indoor acoustic environment, it was recommended to add sound-absorbing materials. Given that the ceiling is the largest available surface, the impact of installing a highly sound-absorbing suspended ceiling was calculated. To predict the effect of the added sound-absorbing material on the ceiling, the production hall was modeled using Catt Acoustic / TUCT software. The reverberation time was measured at five locations and used to calibrate the model. During measurements, the signal-to-

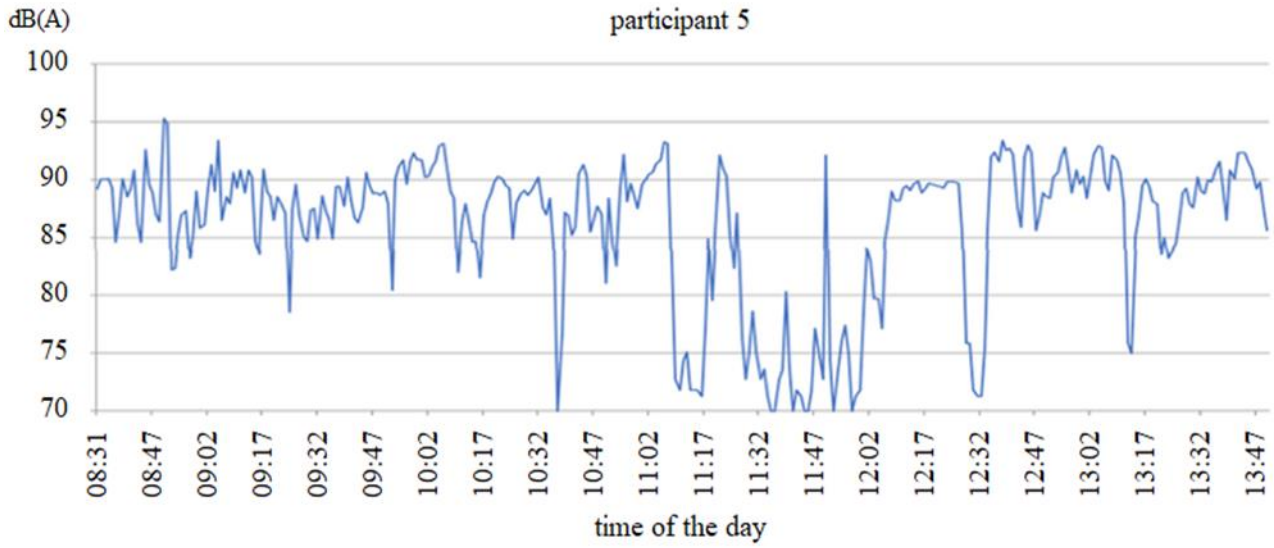

Figure 4. Dosimeter measurements per minute

noise ratio was often too weak in the 125 Hz octave band. The results of the reverberation time measurements are presented in Table 3. Room acoustic modelling shows that a Class A sound absorbing suspended ceiling will reduce the reverberant sound level by 5 to 6 dB(A).

Table 3. Measured reverberation times

Frequency	250 Hz	500 Hz	1 kHz	2 kHz	4 kHz
Reverb. time (sec.)	2,7	2,3	2,6	2,4	1,9

4. QUESTIONNAIRE; METHODS AND RESULTS

A survey was distributed among the employees to collect qualitative data on their experiences with noise exposure and its effects on their work environment. The survey aimed to capture the subjective impact of noise on various aspects of their work, including stress levels, wellbeing, productivity, concentration and communication. This feedback provides valuable insights into how workers perceive and are affected by the noise environment.

4.1 Questionaire methods

Surveys were administered from March 8 to March 14, 2022, to collect subjective feedback from employees (n=83). Participants used tablets and were provided with information about the study, along with a link to the questionnaire facilitated by the online tool 'SurveyMonkey'. Table 4 presents the age distribution of the participants, while Table 5 details their tenure with the company.

Table 4. Age range of the participants

Age	Number of employees	
(years)	(n)	(%)
18 - 24	9	11
25 - 40	21	25
41 - 56	31	38
57 - 67	22	26
Total	83	100

Table 5. Tenure with the company of the participants

Years working	Number of employees	
(years)	(n)	(%)
< 1	17	21

4.1 Questionaire results

From the participants of the survey 76% indicate (agree and totally agree) that their workplace it too noisy. Because of that, 81% indicates (agree and totally agree) that they have to raise their voices to be able to talk to their colleagues. See Table 6. Health and wellbeing related questions are shown in Table 7. One of the results that stands out is the questions about *"I hear a 'beeb' in my ear"*, which is related to tinnitus. Tinnitus is characterized by the perception of sound without an external source, often described as ringing or beeping in the ears, and can be constant or intermittent [11]. In the survey, participants reported their experiences with hearing a beeping sound in their ears as shown in Table 7. Seldom beeping might not necessarily indicate tinnitus, as transient auditory perceptions can result from temporary factors such as exposure to loud noise, earwax buildup, or certain medications [12]. However, persistent or frequent beeping is more indicative of tinnitus, a condition that significantly impacts quality of life [13]. The prevalence of tinnitus varies, but it is commonly reported that at least 10% of the global population experiences tinnitus at some point in their lives [13-14]. With 18% of participants indicating to have a beebing sound (often and always), we can conclude a very high average of workers in the industry hall suffer from tinnitus.

Survey results revealed that a significant number of workers found their workplace to be excessively noisy, negatively affecting their stress levels, wellbeing, productivity and concentration. Fig. 5 shows the percentage answers 'often' and 'always'.

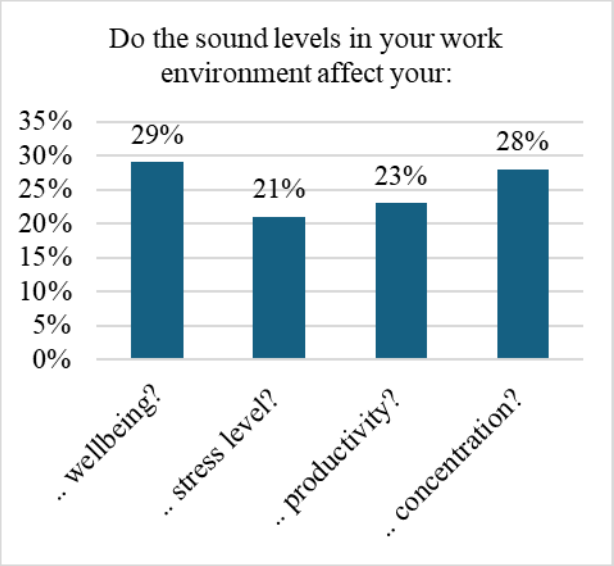

Figure 5. Subjective experience of sound levels

According to Directive 2003/10/EC [10], hearing protection must be worn when exposed to noise levels above 85 dB(A). When asking *'how often do you wear personal hearing protection'* only 20% replied with *'always'*, see Fig. 6. The stated reason is that some employees find hearing protection devices uncomfortable to wear for extended periods and some say they find it challenging to communicate with colleagues while wearing hearing protection, especially in areas where verbal communication is essential.

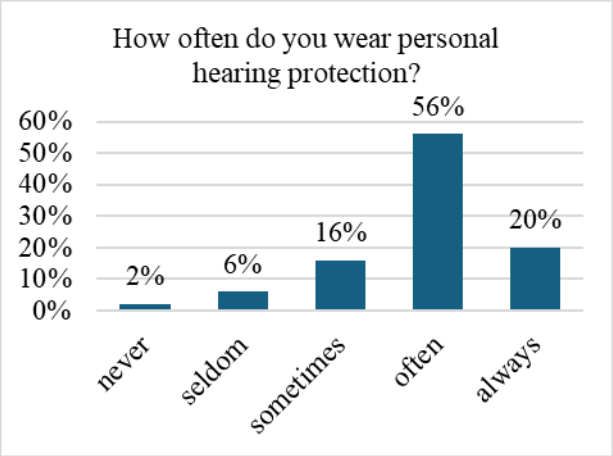

Figure 6. Personal hearing protection

5. CONCLUSION

This study evaluated the impact of high noise levels in an industrial hall, focusing on room acoustic measurements and employee feedback on their health, wellbeing and productivity. The measurements indicated noise levels (L_{eq}) reaching up to 92 dB(A), and dosimeter readings among employees showed noise levels (L_{ex}) between 85 and 89 dB(A), underscoring a challenging indoor acoustic environment. Survey results revealed that a significant number of workers found their workplace excessively noisy, negatively affecting their stress levels, wellbeing, productivity, concentration and communication. The findings suggest that implementing sound-absorbing materials, such as Class A sound absorbing suspended ceiling and wall panels, could reduce noise levels by 5 to 6 dB(A), thereby improving working conditions. This study emphasizes the importance of addressing noise in industrial settings to enhance worker wellbeing and productivity, indicating that effective acoustic treatments can lead to a healthier and more satisfying workplace. Future research should focus on long-term monitoring and the effectiveness of various acoustic interventions, specifically evaluating how the indoor acoustic environment is improved after installing the acoustic ceiling and wall panels, to ensure sustained improvements in industrial work environments.

6. ACKNOWLEDGMENTS

We would like to express our gratitude to acoustic consultant Tom Segers from Bureau De Fonseca in Belgium for his invaluable contribution to this study. Tom conducted the measurements and calculations, providing critical insights into the acoustic environment of the industrial hall.

ABSTRACT

Acoustics and vibrations improvement developments in household appliances is usually based on basic Source, path and receiver problem solving model. The engineering sector has moved across the years from simple additions of acoustic or vibration damping materials (focused on path improvement) towards optimization of sound sources (like motors, for source improvement) where greater gains were possible. Notably, the latest and modern appliances take advantage of variable speed inverter motors, running at minimal speeds most of the time, producing little noise and vibration, resulting in very low sound power level claims on energy labels. Authors of this text found out however that the applied algorithms to control speed of inverter compressors on refrigerators can vary significantly. This study aims to compare various approaches from appliance manufacturers to control the speed of inverter compressors, targeting greater customer satisfaction once the product is running at end user premises. It engages also into a debate which algorithms are more favorable from developmental engineering perspective as well from final customer.

Keywords: *inverter compressors, household appliances, noise control, psychoacoustics, sound quality*

1. INTRODUCTION

The research area of noise reduction in household appliances business, as well as adjacent businesses, is frequently modelled as “Source, Path and Receiver” [1]. In that model a source of noise is being considered a compressor or fan motor (in typical, simpler type of refrigerators [2]) as well as valves, gears, flow in tubes, etc. (in more efficient refrigerators). Since the primary goal of acoustic or noise reduction treatment is to not detriment the core function of a product (i.e. cooling in case of refrigerator), the majority of engineering interventions were focused on optimizing the path that leads from a source to receiver (i.e. microphone or final user). Typical ways of achieving this in refrigerators are additional rubber or viscoelastic components (or equivalently, bitumen or foam components in dishwashers). Since addition of these components has strong implications on cost of the product (serious concern for manufacturers), the producers of sources started to put more emphasis on the design of components, consequently moving the attention from path to source of the aforementioned model. The area of improvement is related to internal design of components, for example, compressors, such as internal tubing’s and suspension [3].

This paper analyzes another aspect of noise reduction engineering, related to the way the new type of inverter compressors are controlled in refrigerators. This is especially important, as according to information from suppliers [4], there are expected rather large differences in acoustic performance of inverter compressors when running at different speeds.

2. MOTIVATION

Authors of this text were motivated by the outcome of earlier studies [5], where survey participants were commenting how they perceive the noise of modern refrigerators at home. Especially the reflections on the responses to the questions "Can you particularly notice when the compressor works at high speed" and "How often do you notice that your refrigerator is working in high speed mode?" were worthy of further studies. Based on that survey, 43.4% of respondents indicated awareness of changes in the compressor operating condition in response to the question "Do you notice when the working condition of your compressor changes". It is a known phenomenon that human hearing is sensitive to small changes in sound [6], and since modern refrigerators are mostly equipped with inverter compressors (which changes speeds based on electronic system inputs), the motivation existed to measure how often that situation occurs in normal usage, what is the rate of change, how many different conditions are present, etc.

Authors suspected that this could be an area of differentiation between manufacturing brands, in an attempt to please its customers with a sound of product and avoid unnecessary annoyance and disturbances to achieve proper sound quality level. The experimental space of testing included various refrigerators' models from the European market, produced by locally available manufacturers. All of these were using inverter compressors.

3. MEASUREMENTS & ANALYSIS

3.1 Testing conditions

A key aspect was trying to obtain various working conditions of tested refrigerators. To achieve this goal the tested objects were put into two conditions:

- normal working mode, representing running explained in IEC 60704-2-14 standard [7] as "steady-state", where product is supposed to maintain the internal temperature with highly reproducible compressor running cycle
- first working mode, representing a situation as if a user would plug in the product for the very first time, where the product (initially warm) is supposed to start cooling down towards the desired nominal temperatures.

The idea behind the latter working mode is that authors expected the object would go through various modes along with the reduction of internal temperature. Indeed, later testing results proved the assumption, as it is revealed in the next sections.

3.2 Sensors position & software for analysis

Sound Power level (IEC) procedure microphone layout was used to record the sound from one of its microphones (the frontal one, which sits more or less 1m from the refrigerator front door and 1,5m above the floor). To have a better understanding of compressor speeds during the cycles, the additional accelerometer was used, mounted on the compressor. Registration of all signals was done in a hemi-anechoic chamber using HBK Pulse Labshop software, while the psychoacoustic analysis was done using Head Acoustics Artemis.

3.3 FFT spectrograms analysis

The FFT spectrograms below represent the vibrations obtained from the accelerometers mounted on compressors of three selected refrigerator models, each displaying a different method of controlling inverter compressor speed. Main emphasis in analysis is on tracing the vertical lines in frequency axis (x-axis), representing the changing fundamental frequency of compressor vibration, thus compressor speed. The next three spectrograms (Figures 1 - 3) represent first working mode cycles (as explained in 3.1) and the time span (Y-axis) covers the entire compressor running cycle, from the moment it was powered on until the natural stop (related to achievement of nominal temperatures) for three different brands. From the first look at the graphs, it is clear that the strategy of signal control is very different for each brand.

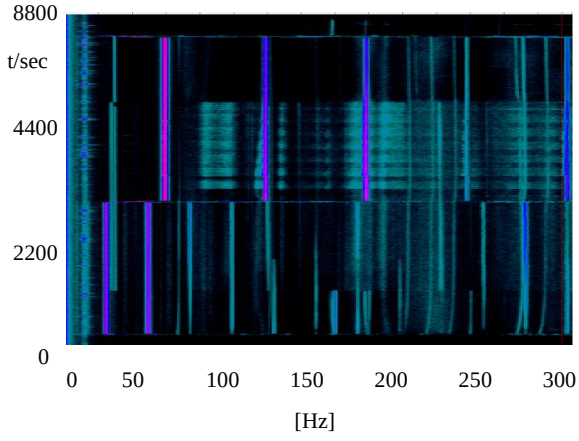

Figure 1. Vibration spectrogram of the first working mode, refrigerator brand 1.

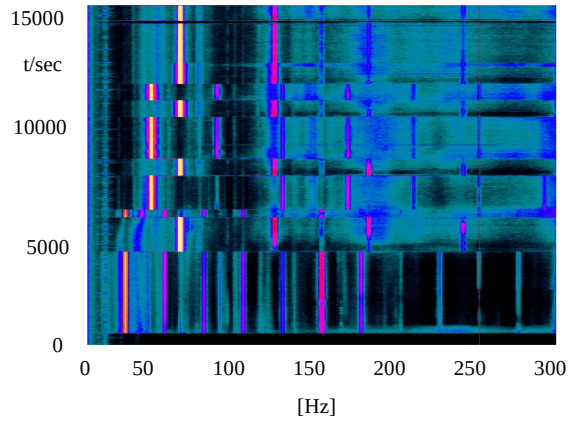

Figure 2. Vibration spectrogram of the first working mode, refrigerator brand 2.

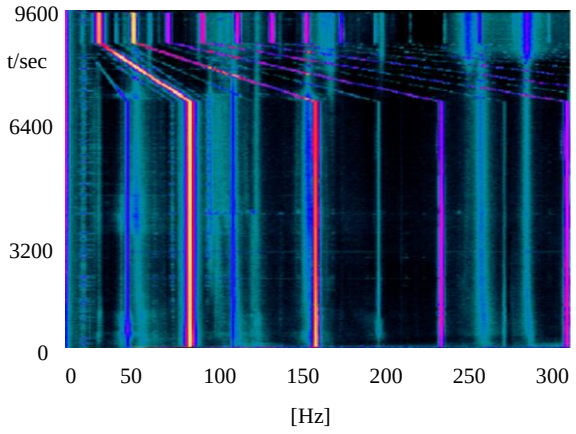

Figure 3. Vibration spectrogram of the first working mode, refrigerator brand 3.

Each brand has a different strategy engaging inverter compressors to cool down the product. Brand 1 is using just two discrete speed steps (lower fundamental frequency around 20 Hz corresponding to 1200 rpm, and higher frequency 60Hz, corresponding to 3600 rpm). Between these two, there is just one change in the middle of the running cycle (Figure 1).

On brand 2's refrigerator, the compressor is changing speed 8 times in the cycle. Time at each speed is unequal and three distinctive speed steps are distinguished (around 20, 40 and 60Hz, corresponding to, respectively, 1200, 2400 and 3600 rpm) (Figure 2).

The graph representing measures of brand 3 is again different. Again only 2 main speeds are detected (around 75Hz and 20 Hz, corresponding to 4500 and 1200rpm), but the majority of the time it works at first running speed, followed by a lengthy period of transition from initial speed to final speed (Figure 3). Figure 4 shows, zoomed in, the area of transition from one speed to the next with a highlighted time for brand 1.

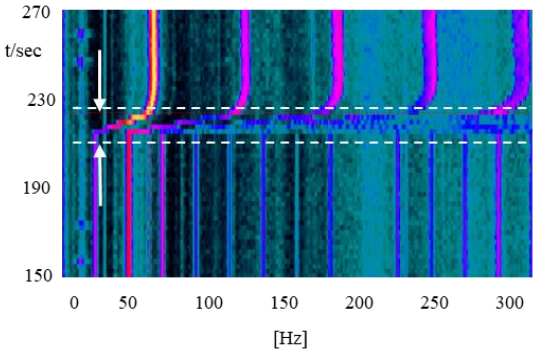

Figure 4. Vibration spectrogram of the area of transition from one speed to the next with the highlighted time for brand 1.

For each brand the respective time to transition between desired speeds was 60 seconds, 10 seconds and 18 minutes (respectively for brands 1, 2 and 3).Such varying transition times can have a significant impact on perceived sound quality, depending on the presence of structural resonances in the range of speeds selected. The next three spectrograms represent a different approach to speed control of the compressor during normal working mode (as in 3.1).

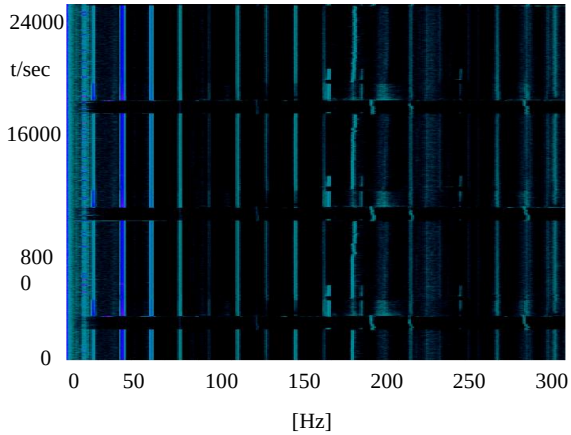

Figure 5. Vibration spectrogram of the normal working mode, refrigerator brand 4.

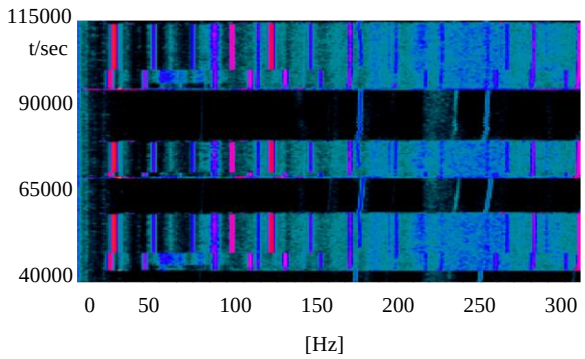

Figure 6. Vibration spectrogram of the normal working mode, refrigerator brand 5.

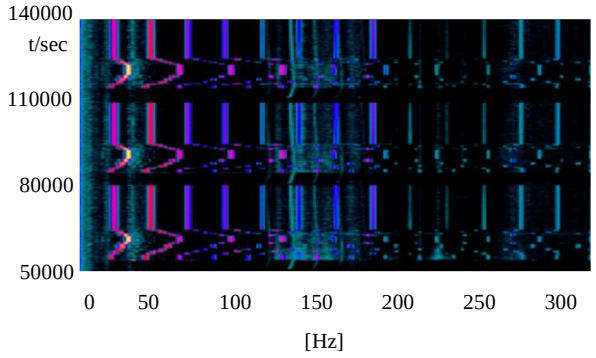

Figure 7. Vibration spectrogram of the normal working mode, refrigerator brand 6.

Compared to the first working mode, the normal working mode tends to engage only one compressor speed around 20Hz (corresponding to 1200rpm) for each of three brands, however still some noticeable differences between brands are present like either keeping one speed flat, changing sharply between two speeds or slowly modulating the speed close to the nominal.

3.4 Psychoacoustic analysis

The variation in compressor driving speed is primarily determined by the required cooling demand. Based on this demand, a specific RPM value is set. Accordingly, the compressor either accelerates from zero to reach this target speed (first working mode) or maintains a stable temperature by adjusting its speed accordingly (normal working mode). The decisions made at this stage—such as how quickly the compressor should reach the target RPM or which intermediate steps it should follow—significantly impact noise emissions and, to a large extent, psychoacoustic parameters. Different numbers of steps, varying frequencies (hence different RPMs), and different transition lengths all influence the compressor's operation. RPM changes can create BSR problems (buzz, squeak and rattle), lead to resonance issues, which not only elevate overall noise levels but also enhance tonal components, affecting the perceived sound quality.

To evaluate the various vibroacoustic issues that may arise from RPM changes and their corresponding psychoacoustic effects, a sample recording was analyzed. Figure 8 presents the spectrograms of this recording. The upper panel, plotted only up to 300 Hz with higher FFT resolution, focuses on better visualizing the compressor's operating conditions. In contrast, the lower panel displays all audible sound events. In this example, the compressor initially runs at approximately 60 Hz before gradually reducing its speed over an extended period. As expected, strong resonances can be observed during this deceleration phase, particularly in the lower panel as indicated by the yellow areas. Figure 9 presents a magnified view of the lower panel from Figure 8, providing a more detailed representation of time- and frequency-dependent sound events for better analysis.

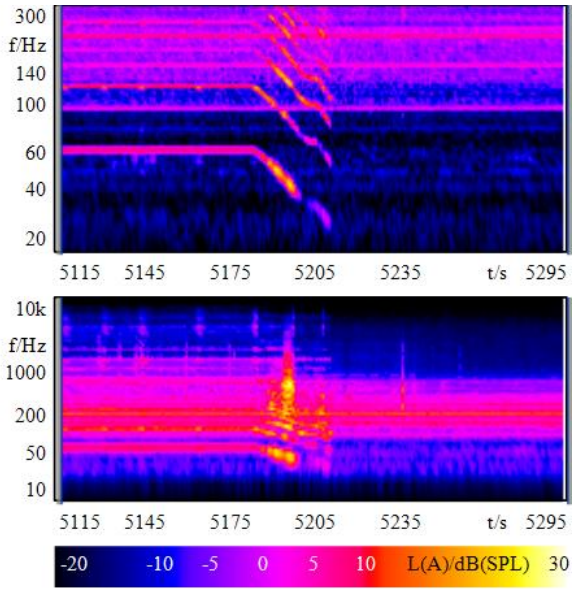

Figure 8. Spectrograms of an example compressor deceleration. (Upper panel spectrum size: 16384, lower panel spectrum size: 4096, A-weighted).

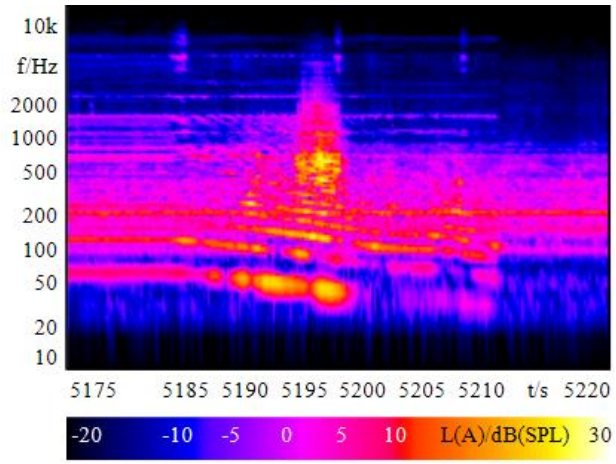

Figure 9. Spectrogram of an example compressor deceleration (detailed view of lower panel from Figure 8, spectrum size: 4096, A-weighted).

As expected, resonance issues arise during this transition, significantly degrading sound quality. Figure 10 illustrates the A-weighted sound level and the loudness level according to ISO 532 during this phase. Considering that these recordings were made in an anechoic environment—and that these values could be higher in a real room—it would not be incorrect to state that the refrigerator transitions from being "inaudible" to "noticeably disturbing" during this period [5]. Similarly, the hearing model tonality values during this resonance phase are presented in Figure 11. Even under anechoic conditions, the tonality values rise from very low levels to exceed the threshold value of 0.40 [8].

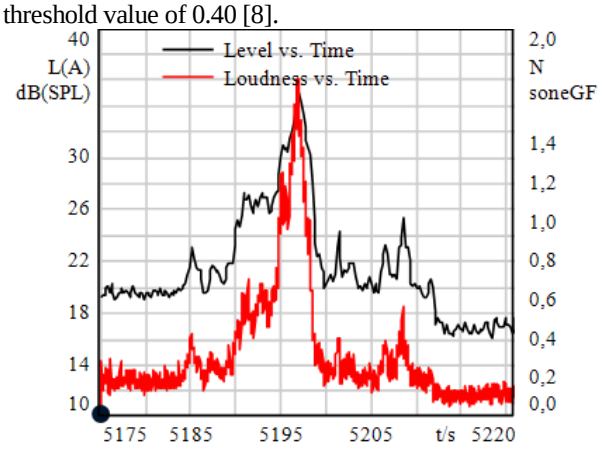

Figure 10. A-weighted levels and loudness levels (ISO 532) over time for the example case in Figure 9.

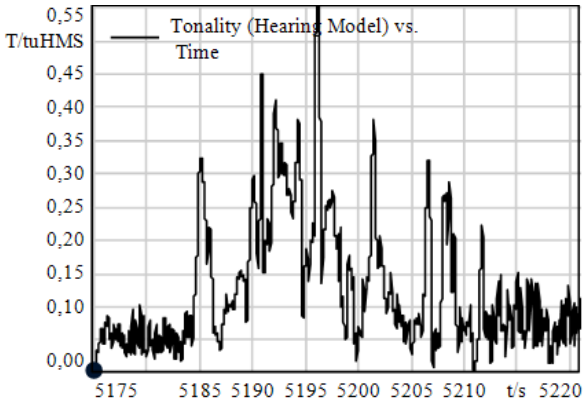

Figure 11. Hearing model tonality over time for the example case in Figure 9.

From this perspective, continuous and slow RPM changes can be considered detrimental to sound quality. The literature already suggests that compressors should operate in a stepwise manner rather than with continuous adjustments [9]. However, determining which RPM values should be used as steps becomes a challenging design problem, especially when considering the complex vibration transfer paths of the devices. Moreover, based on these specific insights on possible transfer paths, RPM steps and their durations should be selected and optimized for the particular characteristics of the device, ensuring better acoustic performance and reduced user annoyance. This approach demonstrates that significant improvements in sound quality can be achieved solely by modifying the compressor's operating algorithm, without the need for additional materials or components. As a result, manufacturers can enhance acoustic performance without incurring extra costs, making this an efficient and cost-effective solution.

As a general rule, higher RPM corresponds to higher noise levels [2, 9]. In particular, high RPM can push a modern refrigerator from being inaudible to clearly perceptible noise levels [5]. Due to both noise concerns and energy consumption, lower operating speeds are typically preferred. However, in specific cases—such as newly stored groceries—algorithms often opt for much higher speeds. High RPM directly translates to higher sound levels, increased loudness, and potentially elevated tonality, all of which contribute to increased annoyance and reduced sound quality. As a trade-off, rather than using the highest RPM values, a moderate speed can be employed, as long as it does not significantly reduce cooling performance and speed. This selected RPM should not coincide with any

resonance. In this way, a significant improvement in sound quality can be achieved with just an algorithm change.

Another important aspect is the speed at which transitions between defined RPM steps should occur. From a psychoacoustic perspective, two key points can be highlighted. While rapid changes are generally perceived as more disturbing and attention-grabbing, psychoacoustic evaluations focusing on product sound quality must also consider the operational context and user interaction. Although very short-duration changes may be noticeable, their low frequency of occurrence throughout the day reduces possible user exposure, ultimately contributing to a higher overall perception of sound quality. This hypothesis is based on initial observations and should be further investigated in future studies in controlled listening experiments.

From a control algorithm perspective, another factor that may not cause operational issues but can be highly detrimental to sound quality is the defined minimum RPM step size. Figure 12 provides an example illustrating this issue. This example presents the noise characteristics of a refrigerator, specifically detailing the 50–80 Hz range with high FFT resolution. As shown in this detailed view, the compressor undergoes very small speed variations, sometimes as little as 2–3 Hz. At this already high operating speed, the device's perceived noise level is elevated. One can argue that, even the elevated levels can be accustomed after some time as long as the stationarity can be achieved. However, this type of very small fluctuations can attract constant attention of the user, deteriorating the sound quality of the device. Ultimately, it can be argued that annoyance is, to some extent, linked to attention.

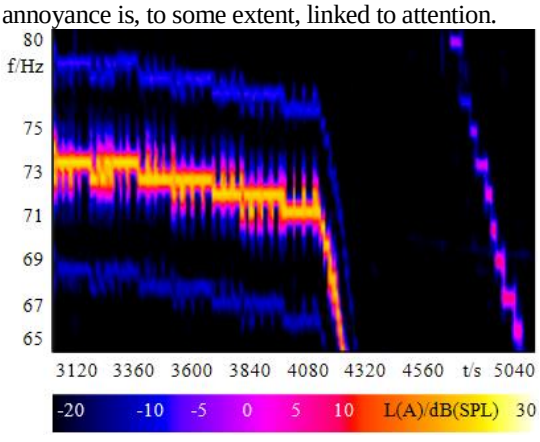

Figure 12. Spectrogram of an example refrigerator in the 50–80 Hz, illustrating small speed variations (2–3 Hz) of the compressor at high operating speeds (spectrum size: 65536, A-weighted).

4. CONCLUSION

The modern refrigerators, at the example of popular models from the European market, are built with inverter compressors [4]. These compressors usually have a significant range of speeds available and are an interesting challenge from acoustic and vibration-engineering standpoint. Authors have shown that although the majority of these products converged their claims (like on Energy Label, based on standardized conditions [7]) towards similar values, yet in practice, while running in a way similar to what end-users would experience, have substantial differences in control algorithms. These differences are related to how many different speed steps are used, how often they are engaged and how quickly the algorithm transitions from one to another speed.

The results show that speed changes have a significant impact on both sound levels and user perception (based on loudness and tonality examples). Therefore, optimizing the compressor's speed transitions, rather than just focusing on low RPMs (for the sake of Energy Label claim), is crucial for balancing effective performance with user satisfaction and preventing a poor overall product image.

In summary, as it was presented, the control algorithm adaptation becomes another interesting aspect of acoustic and vibrations optimization and a battlefield between the manufacturers trying to achieve customer greater satisfaction with the product. Consequently, manufacturers can improve acoustic performance without additional expenses, making it a practical and cost-efficient solution.

DOUBLE AND SINGLE ELASTIC SUPPORT FOR LARGE GENERATOR SETS

Sergio Anda[1*]
[1] Technical & Sales Manager, Viblens, Spain

ABSTRACT

Currently, when a high-level vibration and shock attenuation is required, a two-level series isolation (2 degree of freedom system) to get the highest filtration (very characteristic of naval environment). The present document shows a study case from the beginning selecting the best antivibration strategy to reach the targets.

Keywords: *bench, double, vibration, shock, 2DOF*.

1. INTRODUCTION

Large diesel generator sets generate considerable dynamic forces due to combustion, rotating mass imbalance, and torque pulsations. To prevent the transmission of vibrations and shocks to the surrounding structure, elastic support systems are employed. These systems, often using elastomeric or spring-type isolators, aim to reduce the transmissibility of both steady-state vibrations and transient shocks. In marine and industrial installations, proper mounting design is critical not only for operational efficiency but also for structural integrity, acoustic comfort, and to reduce noise radiated into the water.

This paper presents a comparative analysis between single and double elastic support configurations, focusing on a case study with a 10,000 kg generator set. The study first evaluates three different masses for the base frame in a single elastic support system. Then, a second stage of elastic isolation is introduced by adding an intermediate mass, forming a double elastic support configuration. The results illustrate the influence of support design on vibration isolation performance.

2. THEORETICAL BACKGROUND

2.1 Single Elastic Support

In a single elastic support configuration, the generator and its base frame are mounted on a set of vibration isolators directly coupled to the final foundation (either a ship structure or building). This forms a single-degree-of-freedom (SDOF) system. The vibration isolation depends on the ratio between the excitation frequency and the natural frequency of the mounted system, with better performance achieved when the natural frequency is much lower than the excitation frequency.

The natural frequency is calculated by Eqn. (1):

$$f_n = \frac{1}{2\pi}\sqrt{\frac{k}{m}} \tag{1}$$

Where k is the stiffness of the isolators and m is the total suspended mass.

The transmissibility T of the system, which expresses the ratio of transmitted force to input force, is given by Eqn. (2):

$$T = \frac{\sqrt{1+(2\zeta r)^2}}{\sqrt{(1-r^2)^2+(2\zeta r)^2}} \tag{2}$$

Where:

$$r = \frac{f}{f_n} \tag{3}$$

- Υ is the frequency ratio
- ζ is the damping ratio
- f is the excitation frequency
- f_n is the natural frequency

Copyright: ©2025 First author et al. This is an open-access article distributed under the terms of the Creative Commons Attribution 3.0 Unported License, which permits unrestricted use, distribution, and reproduction in any medium, provided the original author and source are credited.

As the excitation frequency increases beyond the natural frequency (especially for $r > \sqrt{2}$), the transmissibility drops below 1, indicating effective vibration isolation.

2.2 Double Elastic Support

A double elastic support introduces an intermediate base frame between two sets of isolators, effectively creating a two-degree-of-freedom (2DOF) system. This configuration allows for two distinct natural frequencies, offering improved isolation over a wider frequency range. However, it also introduces a second resonance that must be carefully managed through system tuning and damping.

Double elastic systems are especially effective in environments with strict vibration or shock limits, such as naval vessels or high-precision industrial setups.

3. CASE STUDY: 10,000 KG GENERATOR SET

3.1 Introduction

The isolators used in this study are Willbrandt SES 5010 series, selected based on the expected load per support and mounting layer:

3.1.1 First layer (primary supports)
Willbrandt SES 5010 55 ShA – designed for lower load per mount and optimized for vibration isolation.

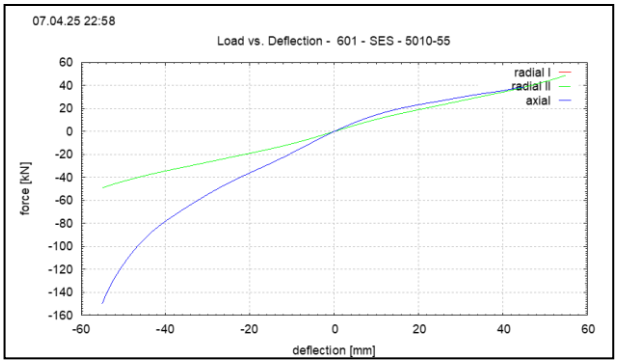

Figure 1. Load vs Deflection SES 5010 55Sh

3.1.2 Second layer (secondary supports):
Willbrandt SES 5010 65 ShA – suited for higher loads and structural damping.

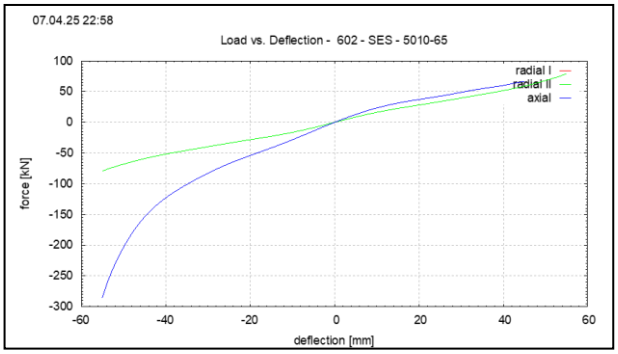

Figure 2. Load vs Deflection SES 5010 65Sh

3.2 Configuration Overview

A generator set with a total mass of 10,000 kg (engine + alternator) is considered. The analysis proceeds in two phases:

3.2.1 Phase 1: Single Elastic Support

The generator is mounted on three different base frames to study the effect of base mass on isolation. The entire set (generator + base) is mounted on a single layer of vibration isolators.

Table 1. Single Elastic Support Configurations

Case	Generator Mass (kg)	Base Frame Mass (kg)	Total Suspended Mass (kg)	Base Mass Ratio
1	10,000	1,000	11,000	10%
2	10,000	2,000	12,000	20%
3	10,000	4,000	14,000	40%

3.2.2 Phase 2: Double Elastic Support

For each configuration from Phase 1, a second base frame weighing 1,000 kg is added below a new layer of isolators. This forms a two-stage isolation system.

Table 2. Double Elastic Support Configurations

Case	Generator Mass (kg)	Base Frame Mass (kg)	Total Suspended Mass (kg)
1+BF2	11,000	1,000	12,000
2+BF2	12,000	1,000	13,000
3+BF2	14,000	1,000	15,000

4. COMPARATIVE DISCUSSION

The results show that increasing the base frame mass in a single support system effectively lowers the system's natural frequency, improving vibration isolation. However, this comes at the cost of added weight and structural demands. Introducing a second elastic support stage significantly improves isolation, particularly from approximately twice the natural frequency, due to the cascading effect of two mass-spring stages.

The double support reduces transmissibility by increasing system compliance and energy absorption capacity. This makes it ideal for marine environments where shock events are common.

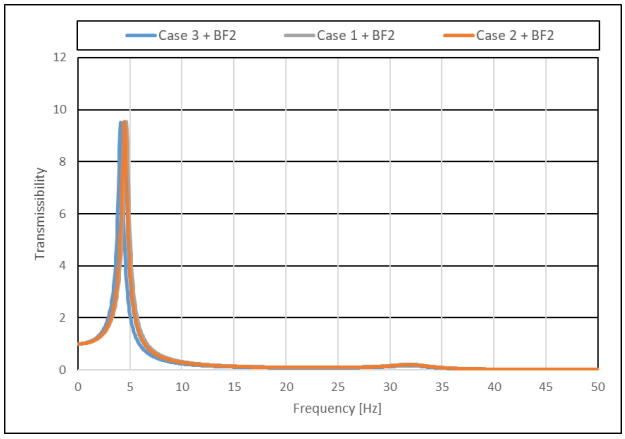

Figure 14. Cases 1, 2 and 3 + BF2 transmissibility (vertical axis)

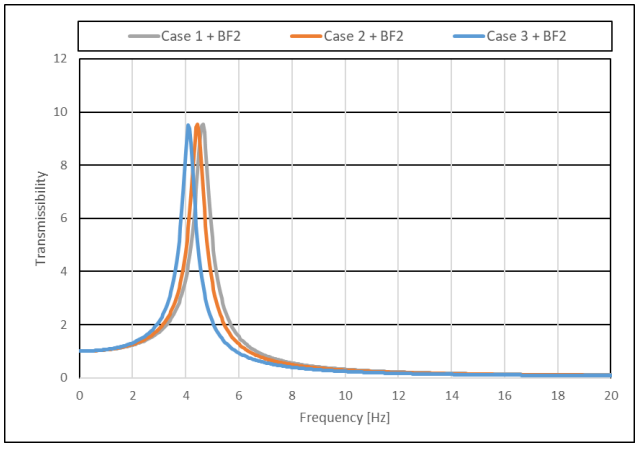

Figure 15. Cases 1, 2 and 3 + BF2 transmissibility (vertical axis)

5. CONCLUSIONS

Elastic mounting systems are essential for protecting structures and machinery from harmful vibrations and shocks. This study demonstrates how base frame mass impacts isolation in single elastic support systems and highlights the superior performance of double elastic support configurations.

For the 10,000 kg generator analyzed, using a base frame of 1,000–4,000 kg already yields substantial improvement, and adding a 1,000 kg intermediate frame further enhances isolation. These results support the adoption of double elastic support in high-demand installations, especially where acoustic, vibratory, or shock criteria are stringent.

ABSTRACT

One of the most effective methods to control the noise spreading of sound sources is to put them inside sound-absorbing/insulating enclosures. When such sources also generate a certain amount of heat, the panels separating the source and the receiver must be provided with ventilation openings that can greatly reduce the effectiveness of the enclosure from an acoustic point of view. The issue gets significantly more difficult if the system must be installed outdoors and only natural convection is to be used, as this requires taking into account the effects of wind, air temperature, and solar radiation. All these factors usually require increasing the dimensions of the openings and then a lower sound attenuation. The framework used to conduct a combined thermodynamic and acoustic investigation on a high-voltage device that produces impulsive sound and is intended for placement in residential areas is described in this paper.

Keywords: *high voltage switchgear, dynamic thermal analysis, sound insulation, noise spreading.*

1. INTRODUCTION

The availability of electricity and the possibility of dispatching it in a safe and sensible way, depending on the customers' needs, is becoming fundamental. In the past years, TERNA Rete Italia S.p.A. developed a number of solutions to improve the lines capacity [1] and to maintain the network with real-time operations [2].
In this framework, the new Compact Pole System (CPS) project was recently presented. The idea is to be able to install the switchgear needed for the operations also in urban areas, close to the receivers. Being the switches high-voltage elements that need to be protected from undesired access and based on mechanical parts producing impulsive noise, it is important to place these elements inside an enclosure. On the other hand, the heat generated by the high-voltage elements needs to be dissipated outside the volume of the enclosure. A further difficulty is that the CPS could be placed in any type of environment. This means that it must withstand not only low temperatures, but mainly the components must be able to survive the typical summer temperatures and the heat caused by the radiation of the sun. In this framework, it is necessary to perform a thermal study that considers not only the environmental variables but also the thermal characteristics of the materials used to assemble the building. Moreover, some openings are necessary to guarantee the heat exchange, and such openings must be small enough to avoid noise spreading from the switchgear to the surrounding area.
The paper is organized as follows: Section 2 describes the building where the CPS is located, and the thermal/sound sources placed inside. Section 3 shows the thermal model implemented in Energy+. Section 4 illustrates the acoustic model for the noise spreading. Section 5 discusses the thermal and acoustic results. Finally, Section 5 concludes the work.

2. DESCRIPTION OF THE CSP BUILDING AND OF THE THERMAL/ACOUSTIC SOURCES

The system is made of:
- a main volume, containing the switchgear and the accessories, called the GIS room;
- some panels with aesthetic functions, placed at 40 cm from the GIS room walls;
- a steel framework;
- a shelter containing the accessory devices.

Figure 1 shows an outline of the system.

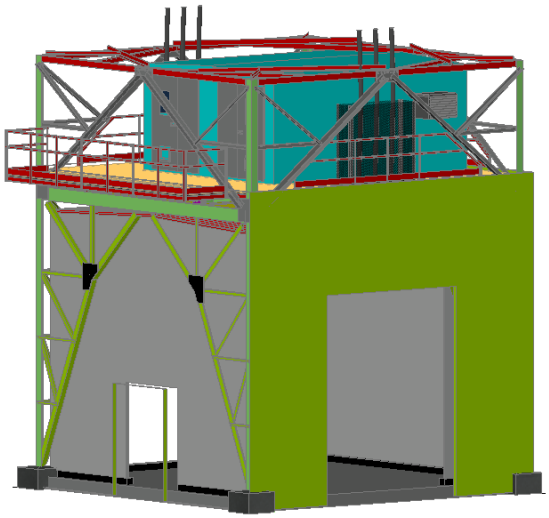

Figure 1. 3D outline of the system.

The green panels of Figure 1 are placed in the lower part of the trellis and have an aesthetic purpose. They are attached to the trellis beams and conceal a second set of inner panels, forming the vertical walls of the GIS room. The big hatch is normally closed and is used for the maintenance of the switchgear placed inside, while the small door is used for the access of the personnel. Above the GIS room is placed a small shelter, hosting the control and service devices.

The foot plant of the GIS room is 8 x 8 m^2, with a height of 6.5 m. To guarantee a sufficient number of air changes per hour due to natural convection, and thus the cooling of the high voltage devices, some openings are placed on two opposite sides of the room. These openings, represented in Figure 2, are:

- two inlets, placed in the lower part of the front side (dimensions 3.125 x 0.5 m^2);
- an outlet, in the higher part of the panel opposite the one where the inlets are located (dimensions 0.675 x 7.0 m^2).

The inlets are symmetrical to the vertical centreline of the panel. The openings will be protected by grilles, introducing a pressure drop of about 20 Pa. The position and dimensions of the openings have been decided after some fluid dynamic simulations carried out with COMSOL Multiphisics® in order to obtain a fair distribution of the air flows inside the GIS room.

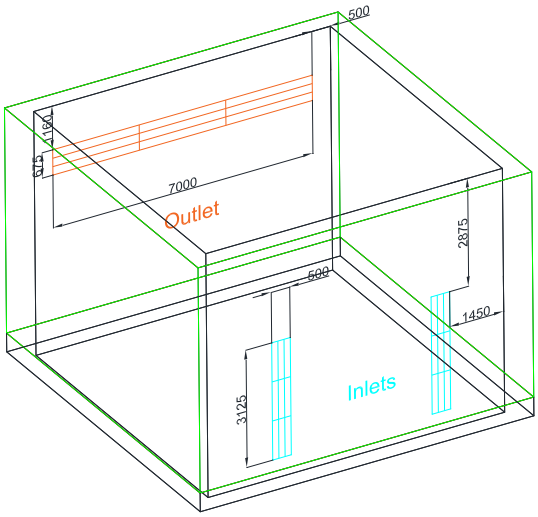

Figure 2. Positions of the inlets and the outlets.

3. THERMAL MODEL

The CPS will be subject to interactions with the environment: temperature changes, radiation of the sun, and wind. All these elements change with time and are a function of the location selected for the system. Using a finite element model such as COMSOL to predict the thermal behavior of the system is particularly challenging if the effect of non-stationary weather conditions must be captured. For this reason, after performing a validation of the COMSOL model [3], it was decided to switch to EnergyPlus. This software allows an estimation of the temperature inside the GIS room in non-stationary conditions. For this reason, EnergyPlus takes into account both the thermal conductivity and the thermal capacity of the walls. The assumptions adopted for the simulations are the following:

- Location: Catania. The weather data have been retrieved from those available from the local airport.
- To consider the increase of the temperature due to global warming, the weather data have been morphed to

simulate the conditions in 2050 (https://energy.soton.ac.uk/ccworldweathergen/)
- Time span for the calculation: solar year (01 January – 31 December)
- Time step: hour + day
- Aesthetic panels: trapezoidal steel sheet 1 mm; rockwool, density 70 kg/m^3, thickness 78 mm; perforated sheet steel, thickness 1 mm – overall thickness 80 mm.
- GIS room panels: trapezoidal steel sheet 1 mm; rockwool, density 70 kg/m^3, thickness 48 mm; perforated sheet steel, thickness 1 mm – overall thickness 50 mm.
- Distance between the aesthetic walls and the walls of the GIS room: 400 mm
- Height of the aesthetic panels from the floor: 500 mm
- Model used for the airflow in EnergyPlus: Airflow Network
- WindPressureCoefficientArray computed using fluid dynamic simulations (Figure 3) carried out on the system for 5 different angles of incidence of the wind on the structures (Table 1).

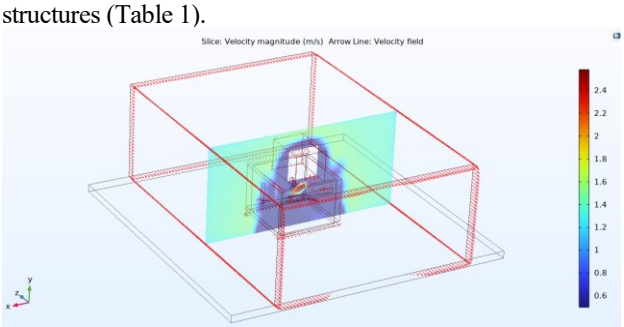

Figure 3. Example of fluid dynamic simulation for the computation of the wind pressure coefficients.

Table 1. Wind pressure coefficients.

	Wind pressure coefficients	
Angle of incidence	Inlet	Outlet
0	-1.99636	-1.09497
23	-1.08254	-0.14105
45	-5.79697	.1026984
68	0.38094	0.610374
90	0.14567	0.824607

- Thermal power to be dissipated in the GIS room: 5300 W
- The assumptions made allow us to consider also the effect of the wind
- The temperature computed by EnergyPlus must be intended as the average temperature inside the GIS room

4. ACOUSTIC MODEL

After defining the thermal characteristics of the CPS, it is possible to move on to the acoustic simulations. First, it is necessary to feed the simulation program with the acoustic emission characteristics of the source. For this purpose, the measurements conducted in the field for the switchgear of a specific supplier were used. On that occasion, the sound energy during the opening (O) and closing (C) events of the actuators was estimated. These characteristics were then composed to obtain the sound energy of an OCO+2CO event. Based on the hypotheses made with TERNA regarding the standard operations, this sequence occurs every 15 minutes.
As regards the sound power level to be associated with the sources was:

- Event power level OCO+2CO in 15 minutes = 93.2 dB(A)
- Event power level OCO+2CO diluted in 8 hours (night period) = 84.2 dB(A)

The spectrum associated with the events is reported in Figure 4, representing the average sound pressure level measured on the envelope surface during the tests.

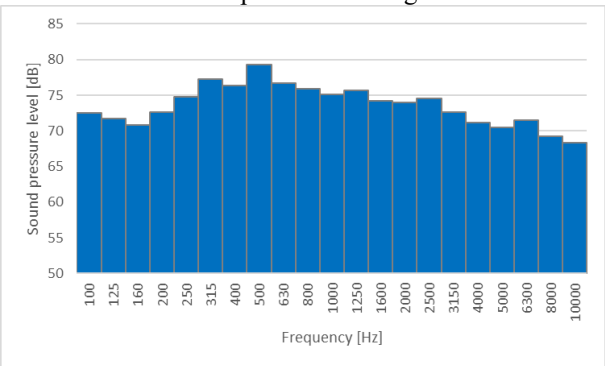

Figure 4. Spectrum used for the power levels.

The characteristics of the panels were derived, based on what was established for the thermal part, from the Metecno catalog for the "Wall Panel" type of products with the thicknesses indicated in the previous section. Figure 5 and Figure 6 show the graphs of the sound absorption and sound insulation offered by the Metecno panels respectively. These values were inserted into Ramsete to carry out simulations of the sound pressure level propagating outside the GIS room. The software can consider the diffraction effect and the transmission effect at the same time.

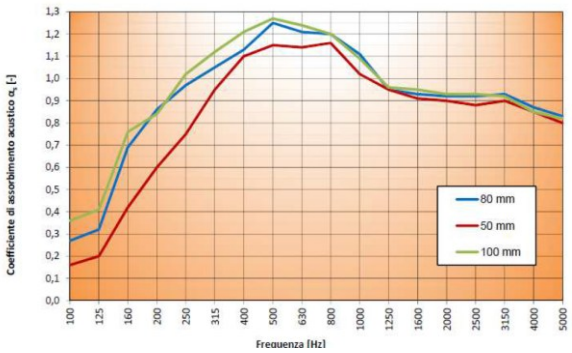

Figure 4. Sound absorption of the panels.

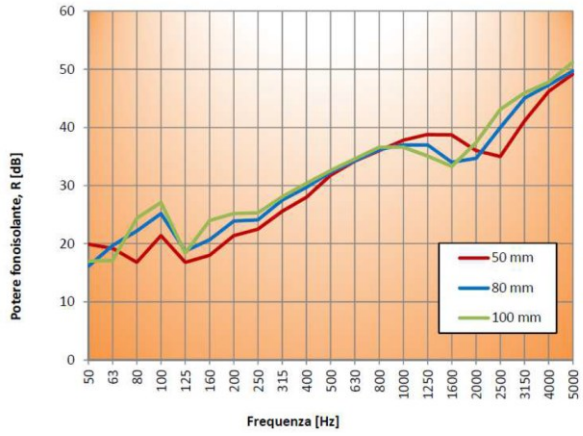

Figure 5. Sound insulation of the panels.

In Ramsete, the following assumptions were adopted:
- Insulation of the GIS room panels equal to that of the 50 mm Metecno panels
- Insulation of the openings equal to 0 dB
- Absorption of the GIS room panels and aesthetic panels equal to the absorption declared for the 50 and 80 mm panels
- Calculations at the receivers made at distances of 15 and 30 m and at heights of 2 m, 5 m, 8 m and 11 m.
- Distribution of sound pressure levels symmetrical to the axis that joins the two faces with the vents (only the series of receivers placed on the right side will be considered)

5. THERMAL AND ACOUSTIC RESULTS

Figure 6 shows the average temperature inside the GIS room on a 1-hour basis during the year. The limit temperature given by the company making the switchgear is 40 °C. It can be observed that this temperature is exceeded only in limited times:

o at 14.00 - 06 July (T_in=40.0 °C) with an outdoor temperature T_out=37.1 °C
o at 11.00 - 9 August (T_in=40.5 °C) with an outdoor temperature T_out=37.7 °C
o at 11.00 - 18 August (T_in=40.3 °C) with an outdoor temperature T_out=37.4 °C

Moreover:
- The thermal inertia of the panels leads to a phase shift in the thermal load due to solar radiation
- The maximum air speed in the inlet openings corresponds to 0.3 m/s for a volumetric flow rate of approximately 0.5 m^3/s

Since suppliers also ask not to exceed 35 °C of average temperature during the 24 hours, in Figure 7 the annual trend of the average daily temperatures is reported. The limit value of 35 °C is never exceeded.

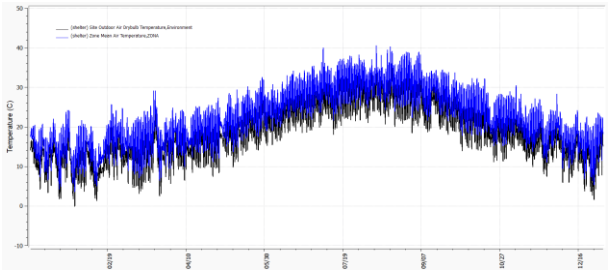

Figure 6. Indoor (blue line) and outdoor (black line) profiles with 1 hour time step.

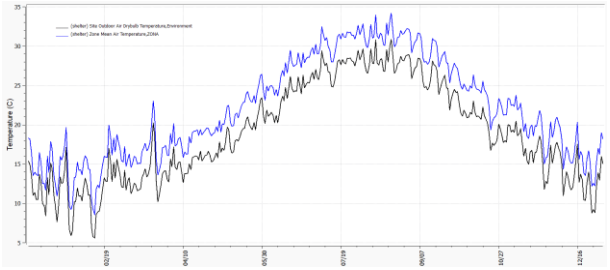

Figure 7. Indoor (blue line) and outdoor (black line) profiles with 1 day time step.

As concerns the acoustic results, Figure 8 shows the result of the simulation made with Ramsete. According to Italian legislation, the results of the simulations were compared to the emission, immission, and differential limits.
- Emission: is to be intended as the sound pressure level emitted only by the specific sound source to be investigated
- Immission: is the energetic sum of the sound pressure level emitted by the specific sound source that is intended to be investigated with the background sound pressure level

- Differential: difference between the immission levels and the background noise level (algebraic difference)

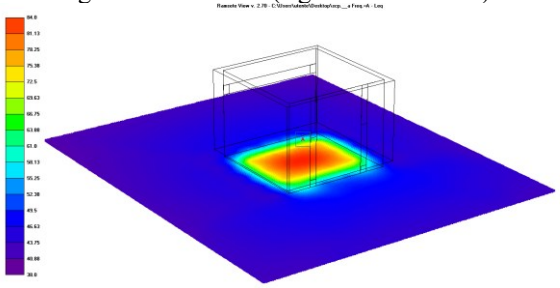

Figure 8. Sound pressure level computed by Ramsete.

The emission and immission limits are a function of the acoustic class being investigated and must be evaluated by diluting the source's contribution over the 16 hours for the daytime period (6-22) and 8 hours for the night-time period (22-6). The tables below provide the limit values and the predicted ones. The limits are based on the acoustic classes established by the Municipality where the installation will take place.

The differential must instead be evaluated in correspondence with the living environments and must not exceed 5 dB during the day and 3 dB during the night.

Table 2 shows, for the various measurement points considered, the values of the sound pressure levels estimated by the calculation code for the dilution of an event in 8 hours and for 15 minutes.

Table 2. Emission values and comparison with the legislation limits. A green cell indicates the limits are fulfilled.

O30_11	17	29.2	35	40	45	50	55	65

The estimation points are indicated with a code of the type XDIST_h where:

- X can assume the values: I (inlet face), L (lateral face), or O (outlet face)
- DIST indicates the distance from the side of the GIS room at which the estimate was performed (15 m or 30 m)
- h indicates the height from the ground at which the estimate was performed (2 m, 5 m, 8 m or 11 m).

It can be observed that the emission limits are always respected.

As regards the immission values, given by the energetic sum of emissions and background noise, some assumptions must be made on the value of the residual noise level, which depends on the position of the area considered, the quality of the acoustic classification, and the presence of sources in neighbouring areas. Since the most critical period is the night-time period, the assessment was made only in that period. In the calculations, the assumption was made that the residual noise is 5 dB lower than the night-time emission limit for the area considered.

Table 3 shows the immission values calculated for the various points and the class limits. In this case, the limit values are respected for all points. The values shown in grey are lower than the limit of applicability of the differential with open windows for the night-time period.

Table 3. Immission values and comparison with the legislation limits. A green cell indicates the limits are fulfilled.

As regards the comparison with the differential limit, the same assumptions made for the calculation of the emissions regarding the residual noise level apply. Since the most critical period is the night-time, the evaluation was made only considering a maximum differential of 3 dB. Table 4 shows the result of this calculation. The cells for which the value is higher than the legal limit for Class I (3 dB) have been highlighted in red, while the numerical values shown in grey refer to those points where the differential cannot be

applied because the emissions are lower than 40 dB(A) with the windows open.
The result is that, only for Class I there are exceedances below 15 m of distance. For the higher classes (II - V) the differential is always respected.

6. CONCLUSIONS

The non-stationary thermal simulations have provided comforting results, with occasional exceedances of the maximum temperature of 40 °C in the hypothesis of placing the SCP in Catania and projection of meteorological data to 2050. As regards the acoustic part, having maintained the size and position of the ventilation openings as studied with the thermal analyses, there would be exceedances of the legal limits only for the receptors positioned below 15 m. and belonging to Class I.

ABSTRACT

Noise pollution in industrial environments can significantly impact workers' health and productivity, necessitating effective control measures. This preliminary study investigates the feasibility of an active structural acoustic control (ASAC) system to mitigate noise radiated by an industrial cabin wall. A cabin mock-up was created for this purpose, designed with passive acoustic treatments to improve noise insulation on three walls, the floor and the roof. Conversely, one of the cabin walls was realized with a thin steel plate without passive acoustic treatments. The ASAC system, applied to this plate, uses a single inertial actuator to suppress noise induced by an acoustic source inside the cabin and radiated to the external environment. The system employs the remote microphone technique (RMT) to attenuate the noise at a specific distance from the cabin. The experimental validation was conducted for different types of disturbing noise signals. The results highlight the potentiality of this method to control radiated noise. This work lays the foundation for scalable ASAC solutions in industrial environments, offering a promising path toward quieter workplaces.

1. INTRODUCTION

In industrial environments, enclosures are commonly used to reduce airborne noise propagation and workers' exposure. These structures typically consist of a mass-spring-mass system, with an outer continuous plate, an inner perforated plate inside and a fibrous material in between, acting as both a spring of the system and noise absorber. However, these enclosures can often have untreated parts, such as panels and windows, reducing the overall effectiveness. In such cases, an active structural acoustic control (ASAC) system can help mitigate low-frequency noise radiation toward the external environment. An ASAC system employs one or more actuators on a vibrating surface to generate an anti-vibration signal that counteracts noise radiation. This signal is computed in real-time through an adaptive algorithm after the acquisition of some signals from error and reference sensors, similarly to an active noise control (ANC) system. Literature discourages the use of accelerometers as error sensors due to the need of multiple sensors and actuators [1]. Several studies explored the optimization of number and placement of actuators on radiating surfaces [2]. However, practical industrial applications [3] remain limited compared to numerical studies and laboratory experiments.

This study, part of the BRIC Inail 2022 ID-11 project, investigates the feasibility of applying an ASAC system to an industrial cabin mock-up. The system was applied on a thin steel plate representing one cabin wall, radiating noise generated by a simulated source enclosed in the cabin and emitting different types of signals. The system operates in a feedforward configuration with one reference microphone inside the cabin, one inertial actuator on the radiating plate and one error microphone near the outer plate. Additionally, a remote microphone technique (RMT) was employed for

far-field noise attenuation [4] and feedback compensation was used to prevent reference signal corruption [5]. The implemented adaptive algorithm was the filtered-X least mean squares (FXLMS) [6], chosen for its simple scalability for further developments. Section 2 provides an overview of the case study, detailing the ASAC system design and the implemented algorithm. Section 3 presents the study findings, including the preliminary characterization of the impulse responses and the attenuation obtained for different noise signals. Finally, Section 4 outlines the conclusions and potential future developments to enhance the system performance.

2. EXPERIMENTAL SETUP AND ASAC SYSTEM

The tests were conducted on the reproduction of an industrial enclosure, as shown in Fig. 1. The structure measures 1.5 × 1.5 × 2.0 m and features a 1 mm-thick steel plate on one side. The remaining walls and the roof are made of similar steel plates, internally treated with sound-absorbing fibrous material and a metallic mesh. Conversely, the floor features a 5 mm-thick steel plate instead of the metallic mesh. Inside the enclosure, an acoustic dodecahedron reproduces synthetized signals and recordings of industrial machineries as a simulated noise source.

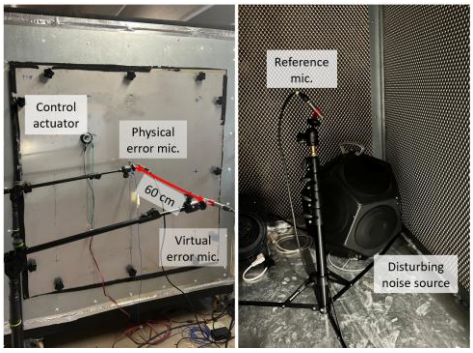

Figure 1. Experimental setup outside and inside the enclosure.

The ASAC system was implemented on the steel plate in a feedforward configuration. The reference microphone was placed inside the cabin, near the noise source. The inertial actuator, generating the control signal, was selected based on the frequency response comparison of several actuators and placed on the plate away from the edges, where distortions were observed in some preliminary tests probably related to the boundary rigidity. The system adopts the remote microphone technique (RMT), which virtualizes the error microphone position to prevent a physical obstacle during the real application [4]. In this setup, the physical error microphone was placed outside, near the steel plate, while the virtual error microphone was positioned 60 cm from the surface. The entire ASAC system is driven by a NI cRIO 9063 real-time target, acquiring and generating signals at a 3200 Hz sampling rate. Due to this rate and device placement, the system does not meet the causality constraint, making it ineffective for unpredictable signals. The algorithm employed to compute the adaptive filter was the feedforward filtered-X least mean squares with acoustic feedback compensation (FF_FBFXLMS) [5], chosen to prevent reference signal corruption caused by plate excitation.

The whole procedure executed by the ASAC system is hereinafter described. In a preliminary stage, the virtual and physical secondary paths (s_v and s_p respectively) and the feedback path (f) are estimated generating a white noise with the control source and computing the filter with a least mean square (LMS) approach [6]. Similarly, the virtual and physical primary paths (p_v and p_p) are estimated emitting white noise with the disturbing source. The impulse response h_{pv} between the physical and the virtual positions can be derived from the ratio of the two primary paths in the frequency domain. After this stage, the virtual error microphone is no longer involved in the ASAC operations and assumes a simple monitoring function. During the online operations, the ASAC system works iteratively as follows:

- the reference signal $u(n)$ is acquired and the contribution from the control actuator is subtracted:

$$x(n) = u(n) - f * y(n), \tag{1}$$

  where $y(n)$ is the output of the control source and $*$ is the convolutional operator.
- The disturbing signal in the physical position is computed from the physical error signal $e_p(n)$ as:

$$d_p(n) = e_p(n) - s_p * y(n). \tag{2}$$

- The virtual error signal $e_v(n)$ is evaluated as:

$$e_v(n) = h_{pv} * d_p(n) + s_v * y(n). \tag{3}$$

- The FXLMS computes the adaptive filter and drives the inertial actuator with the classical

procedure, using the virtual error signal $e_v(n)$ and the cleaned reference signal $x(n)$ as inputs.

3. RESULTS

3.1 Estimation of the impulse responses

The secondary and primary paths, used for the identification of the system impulse responses, are illustrated in Fig. 2 and Fig. 3, respectively, for both the physical and the virtual positions. These functions are shown in terms of transfer function magnitude in the frequency domain for easier interpretation. As can be observed, the secondary paths exhibit higher amplitude than the primary paths across the entire spectrum. This means that for equal power of the sources, actuator saturation can be avoided. The amplitude at the virtual position is lower than at the physical position due to the larger distance from the radiating surface. Fig. 4 shows the feedback path. The contribution of the control actuator on the reference microphone is particularly relevant at low frequency (< 50 Hz). However, its importance depends on the noise level produced by the disturbing source. A filter length of 2000 elements was assumed for primary, secondary and feedback paths.

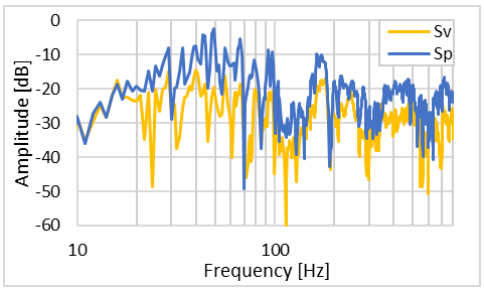

Figure 2. Physical and virtual secondary paths.

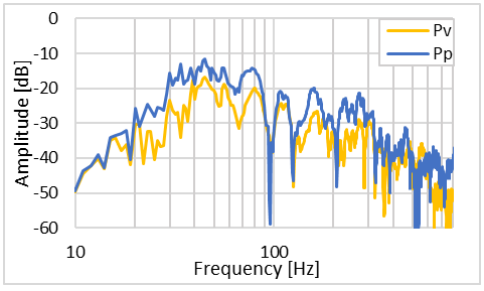

Figure 3. Physical and virtual primary paths.

The transfer function H_{pv} (with a capital letter to indicate the frequency domain) used to model the disturbance signal at the virtual position, is reported in Fig. 5. This function was obtained as the ratio between the spectra of the virtual and the physical primary paths. A positive value means that the sound pressure level at the virtual position assumes a larger value with respect to the physical position for that frequency. It should be noted that this function models the acoustic field at the virtual position starting from the sensing of the acoustic field in one point near the radiating plate. However, the noise at the virtual position can be radiated from different points of the plate. Thus, this function considers only a part of the disturbing noise. A filter length of 500 elements was considered for the physical-virtual impulse response.

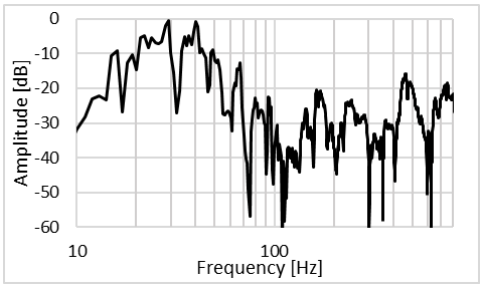

Figure 4. Feedback path.

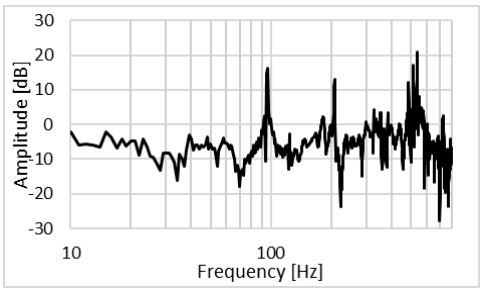

Figure 5. Physical-virtual transfer functions.

3.2 Attenuation of noises

The results obtained with different pure tones are shown in Tab. 1. These frequencies were selected as the central frequencies of the third octave bands within the range of interest, independently of the plate modal frequencies.
The ASAC system successfully attenuates noise at the virtual position for all the tones, except for the 125 Hz frequency, where a slight amplification occurs. This particular tone is characterized by a low level on the primary paths. Thus, the estimation of H_{pv} at that frequency can be not accurate. The 160 Hz tone coincides with a

radiating mode, as indicated by the peaks in the primary and secondary path spectra.
Secondly, a pseudo-random noise signal was used for the performance evaluation. This signal contains a broad frequency range but maintains a periodic pattern, repeating every 0.2 s. The results for this signal are shown in Fig. 6. In this case, the ASAC system faces more difficulties in providing a good performance, although noise attenuation is observed across all the bands of interest. This results in an overall noise attenuation of 1.6 dB – 1.9 dB(A).
Finally, Fig. 7 shows the effect of the ASAC system on the noise generated by an industrial compressor. The system reduces noise across the bands from 80 Hz to 500 Hz, especially on the main components at 80 Hz and 200 Hz, achieving an overall attenuation of 3.5 dB – 2.9 dB(A).

Table 1. Attenuation for different pure tones.

Frequency [Hz]	125	160	200	250	315	400
Attenuation [dB]	-2.3	4.8	3.9	7.0	13.6	2.4

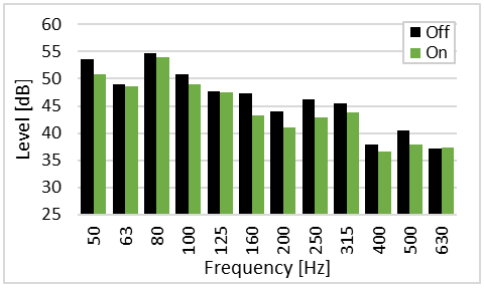

Figure 6. Results for a pseudo-random noise signal.

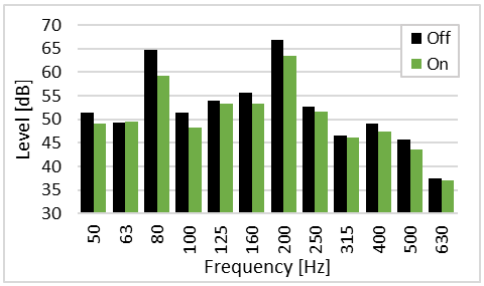

Figure 7. Results for an industrial compressor recording.

4. CONCLUSIONS

In this paper, an experimental study on the potentiality of a feedforward ASAC system with RMT and feedback compensation was analyzed. The results show that the ASAC system can act on all the components in the frequency range of interest, when the physical-virtual impulse response in effectively modelled. No tests with pure broadband signals were carried out, since the causality constraint was not respected. However, the ASAC system was effective in the cases of a pseudo-random noise signal and industrial compressor recording. The possible future steps of this study could regard the optimization of number and placement of error microphones and actuators, for extending the zone of quiet at the virtual position. Furthermore, tests with actuators applied to the treated panels could be explored.

ABSTRACT

Every active noise and vibration reduction system needs actuators capable of controlling the considered vibroacoustic system. Structural actuators are commonly utilized for this purpose. Inertial actuators are particularly convenient to use due to their simple audio-type amplifiers and relatively low cost. However, due to the fact that they are relying on inertia in order to generate force, they are rather inefficient for lowest frequencies. In this paper a novel concept is investigated, which adds a tripod structure to the seismic mass, allowing controlled structure displacement even for a constant voltage. Advantages and drawbacks of such a design are investigated numerically and experimentally.

Keywords: *mathematical modelling, actuation, experimental measurements*

1. INTRODUCTION

Vibration and noise control are vital aspects of many engineering applications, ranging from industrial machinery in manufacturing facilities to everyday household appliances. Effectively managing vibrations, and the noise they generate, has long been a focus of research aimed at enhancing both performance and acoustic comfort.

The most practical strategy for noise reduction is to address it directly at the source. While passive vibration and sound-absorbing materials are commonly used for this purpose, they come with significant limitations—particularly at low frequencies, where their effectiveness drops considerably. Achieving sufficient attenuation at these frequencies often requires barriers that are impractically thick or heavy. These constraints have driven growing interest in active control systems, which can effectively target low-frequency noise and serve as a valuable complement to passive solutions in areas where they fall short [1]. In recent years, various solutions have been developed [2], in which actuators are used to control the vibrations of thin barriers, thereby reducing both noise transmission and acoustic radiation. Numerous applications use thin panels and shells as sound barriers to reduce the spread of acoustic noise [3, 4]. Such an approach can be applied to many different types of structures, including aircraft fuselage [5, 6]. To improve the effectiveness of these barriers, active control systems with inertial actuators can are used. When applied to individual panels or entire device casings, active structural acoustic control (ASAC) systems exhibit superior performance [7]. However, to ensure efficient operation of an active system, the actuators must be efficiently controlling vibrations.

This paper introduces the design and preliminary analysis of a novel tripod-supported electromagnetic actuator intended to improve the effectiveness of vibration control, especially in the case of thin metal plates. Conventional electromagnetic inertial actuators often face challenges due to their single-point actuation, which can result in poor force transmission when placed on vibrational nodal lines. The proposed tripod structure overcomes this limitation by distributing the actuation force across multiple contact points, increasing the system's adaptability to various vibrational modes and enabling the use of a single actuator where traditionally multiple actuators might be required for successful vibration control.

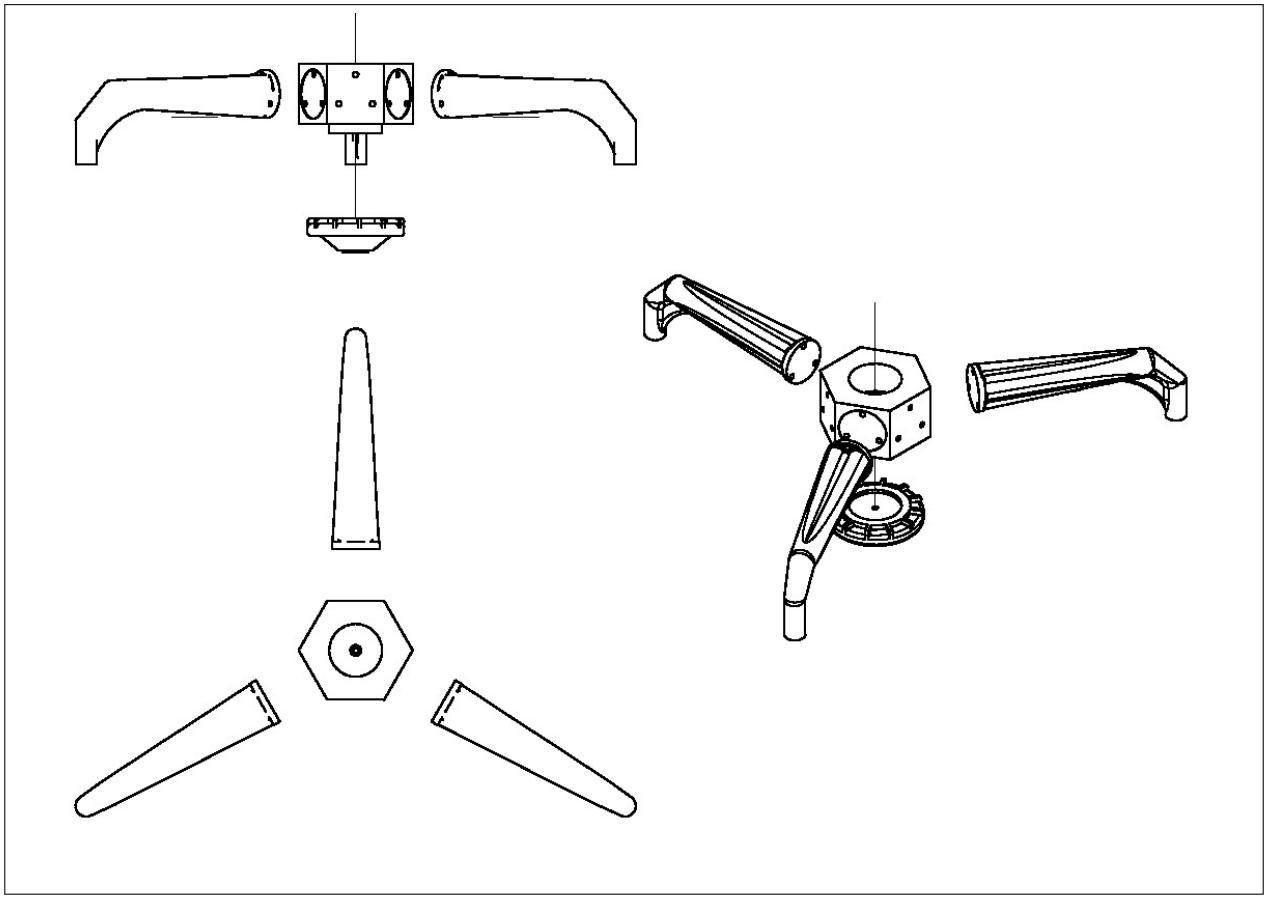

Figure 1. Schematic of a tripod structure attached to the inertial actuator. [8]

2. TRIPOD-SUPPORTED ELECTROMAGNETIC ACTUATOR

This study focuses on a novel electromagnetic actuator design that does not require a grounded frame for installation, nor relies on inertia. Instead, it can be directly mounted onto the target structure using a magnetic attachment system (employing neodymium magnets attracted to steel structures). The actuator features a unique tripod geometry, making contact with the vibrating structure at four distinct points: three legs provide mechanical support and anchorage, while a central piston, also magnetically coupled to the target structure, is actively driven by a control signal. As the piston applies force, a reactive force is simultaneously generated through the legs, resulting in a distributed stress and strain pattern across the contact area. This interaction enables the actuator, which becomes an integral part of the structure, to bend the target itself using it as the supporting frame. Conceptual schematic of the actuator is shown in Figure 1. The design is intended to deliver substantial actuation force and displacement, promoting consistent control over a distributed surface area. This minimizes the risk of ineffective operation due to the piston coinciding with a vibrational nodal line.

The prototype of the actuator, presented in Figs. 2-3, consists of 3D-printed body (the hexagonal central part), to which three 3D-printed legs are attached. To the bottom of the body, a formerly inertial actuator Dayton Audio DAEX32EP-4 if firmly attached, acting now as a voice coil actuator driving the piston.

Utilization of a ready-made inertial actuator not only solves difficulties in manufacturing our own dedicated voice coil actuator. It also allows a fair comparison of the exactly same actuator operating based on inertia principle and employing the tripod support.

Figure 2. Prototype of the actuator attached to the steel metal plate in the test rig.

3. EXPERIMENTAL MEASUREMENTS

In order to experimentally evaluate the performance of the actuator, it was attached to a thin steel plate of dimensions 420 mm × 420 mm × 1 mm. The plate was rigidly clamped to a heavy frame, as depicted in Fig. 3. The actuator has been evaluated in three configurations. The first consisted in using the actuator in its original form, basing of the inertia principle. In the second configuration, the 3D-printed hexagonal body was attached to the actuator. The actuator still operated basing of the inertia principle, but this test was done of investigate the impact of adding an extra mass to the actuator. Finally, in the third configuration, the legs have been attached, altering the actuator's operating principle. The actuator, in this paper, was always mounted centrally on the plate.

Two main measurement series were done for each aforementioned configurations. In the first series, the actuator excited the plate with a frequency sweep, generating single tone at a time, in the range between 20 Hz and 500 Hz, with an increment of 2 Hz. The vibrations of the excited plate were measurement with a laser vibrometer PDV-100 centrally, at the location of the actuator's piston. Based on this series, both excitation efficiency and non-

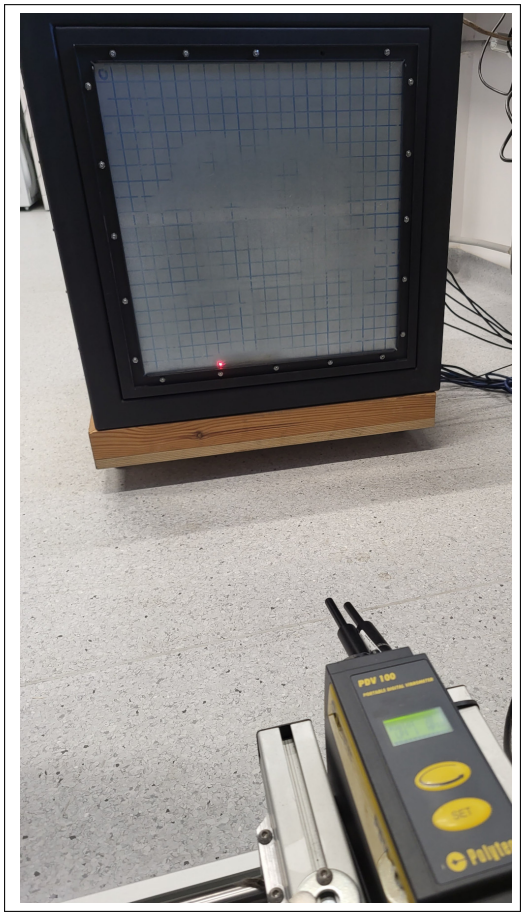

Figure 3. Other side of the steel metal plate, which vibrations are measured with a laser vibrometer PDV-100.

linearity was studied. The obtained plots are presented in Figs. 4-6. The Total Harmonic Distortion (THD) measure was calculated based on the following equation:

$$\mathrm{THD} = \frac{\sqrt{V_2^2 + V_3^2 + V_4^2 + \cdots}}{V_1}, \tag{1}$$

where V_n is the RMS value of the n^{th} harmonic voltage, and V_1 is the RMS value of the fundamental tone.

The second series was measured for a plate exposed to a broadband signal, exciting all frequencies in the considered frequency range at once. Then, the laser vibrometer measured vibrations at a grid of 22 × 22 points, uniformly distributed over the plate with an interval of 20 mm. The surface-averaged vibration frequency response of the plate

is presented in Fig. 7. This series allowed to capture all excited modes, showing a certain advantage of the tripod support—the third configuration of the actuator allowed to control more modes in the same frequency range than former two configurations. This leads to a conclusion that the multiple points of contact prevents the lack of controllability for certain modes with a nodal line going through the actuator's piston. The actual modes of the plates with and without the tripod support cannot be directly compared, because the presence itself of the additional structure at the plate surface alters its mode shapes, but there were no uncontrollable modes observed for the tripod configuration, which were present in the case of the former two actuator configurations.

4. CONCLUSIONS

This paper presented the design and preliminary analysis of a novel tripod-supported electromagnetic actuator. A series of tests were carried out to evaluate its performance. While the tripod configuration successfully excited multiple target modes at very low frequencies, the improvement over conventional inertial actuators was somewhat less than initially anticipated. However, the tripod configuration allowed to control more modes in the considered frequency range than the former two configurations, most probably due to multiple points of contact with the plate.

Another key outcome of the study was the measurement of Total Harmonic Distortion (THD), where the tripod actuator demonstrated significantly lower nonlinearity within the same frequency range compared to the inertial type. This results in notable benefits for signal fidelity, system efficiency, and operational stability. An actuator with low THD maintains signal clarity, allowing for accurate transfer of vibrational energy with minimal spectral distortion. This improves control precision, reduces unwanted harmonic components, and enhances the predictability of system behavior.

Although in this paper the actuator has been centrally mounted on the plate, it is noteworthy that the further study should involve the optimization of the tripod position and orientation, taking into account the overall mathematical model of the plate and attached actuator [9].

NOISE MEASUREMENTS PERFORMANCE GUARANTEE ON A FLOATING LIQUIFIED NATURAL GAS PLANT

Bruno Crivelli[1*] **Dominique Vincent**[1]
[1] Technip Energies France, 2126 Boulevard de la Défense - CS10266 – 92000 Nanterre, France

ABSTRACT

In the energy industry, noise impact is commonly evaluated during the engineering phase as part of the work process for new plant development. However, even if noise regulations shall be applied, a noise performance guarantee is generally not required, demonstrated or is limited to individual equipment. This situation is currently changing, and plant noise performance guarantee tends to become widespread in contracts. Its goal is to ensure compliance with local regulations, environmental and social impact assessment and/or clients' standards.
As a major energy industry engineering contractor, Technip Energies faces this challenge with the projects it executes. To deal with this emerging contractual requirement and due to the lack of acoustic measurements standards for offshore, Technip Energies has developed its own validation methodology for noise performance guarantee on a Floating Liquified Natural Gas (FLNG) facility.
This paper presents the methodology developed by Technip Energies to validate the noise performance guarantee on a FLNG, the feedback on the noise measurements and a summary of the measurements results recorded on an operational facility.

Keywords: *measurements, performance guarantee, offshore, industry.*

1. INTRODUCTION

Airborne noise control in the energy industry is of major importance to ensure safe work conditions. Information on the design methodology, including main noise sources and mitigation measures are provided in different papers such as "Controlling Vibration and Noise Hazards to Insure Safe Work Conditions in Oil and Gas Plants"[1] and "Acoustic Design of Alarming System in the Energy Industry"[2]. However, these scientific articles do not provide any information regarding noise performance guarantee that can be dealt with by the contracts.
In this paper, the methodology developed by Technip Energies to validate the noise performance guarantee on a FLNG is presented.
This methodology starts from the conformity criterion definition to the noise measurements results. Consequently, it completes the work performed for several years during the design phase.
The following sections will be developed in the context of a FLNG:

- Definition of conformity criterion,
- Definition of acoustic measurement procedure and measurement material,
- Encountered difficulties during measurements,
- Summary of measurement results and compliance.

2. MEASUREMENTS PREPARATION

2.1 Definition of acceptance criterion

As a FLNG is located offshore and most of the time there is no specific noise limit for airborne noise in the environment, it is necessary to define a specific acceptance criterion.
During the engineering phase, the noise generated by the FLNG has been modelled and noise maps have been issued for each module and each deck.
The acceptance criterion is based on these noise maps. Considering the loudest predicted noise level on the noise map (not less than 1m from a noise source) a different acceptance criterion is set for each deck. Due to the

[*] ***Corresponding author***: bruno.crivelli@ten.com.

measurement material, a positive tolerance of 1.5 dB is added to the maximum predictive noise level.
An extract of a noise map is presented below (see Fig. 1) with a major noise source hatched in the center and the highest noise level achieved identified by an arrow and surrounded with a rectangular shape.

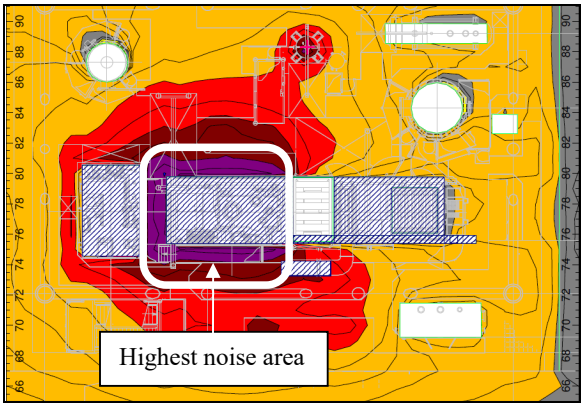

Figure 1. Extract of a noise map with a noise source and some equipment modelled as obstacles.

This criterion has been discussed and approved by all the parties involved in the project.

2.2 Measurement procedure and material

There is no recognized international standard specifically dedicated to noise measurements for offshore applications. The procedure presented in the following sections is influenced by ISO 11201 [3] and ISO 1996-2 [4] respectively related to noise measurements at a work station and related to description, measurement and assessment of environmental noise.

2.2.1 Measurements' locations and heights

For each deck or area, a minimum of 4 to 10 measurement points is defined depending on the deck or area size. Each measurement location is identified with a number on a plan, for example: see Fig. 2.
Noise measurements shall be performed 1.5 m above the floor.

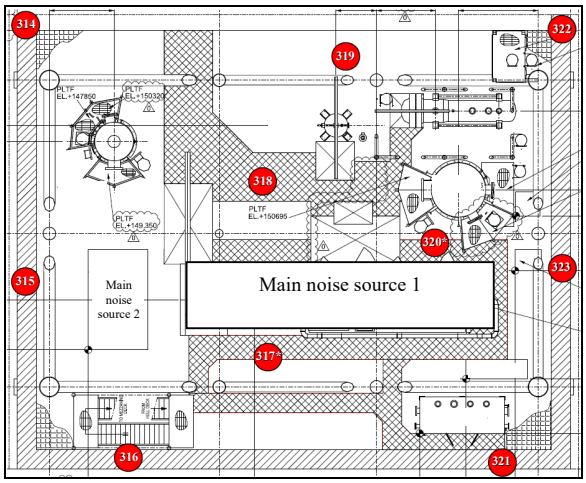

Figure 2. Example of measurement point identifications and locations.

2.2.2 Operating conditions

Noise measurements shall be performed during normal operation of the FLNG provided that:

- The rotating equipment and packages have proven stable reliable operation,
- All instruments related to the rotating equipment and packages are commissioned and have been operational for a sufficient period to prove their reliability.

During noise measurements, only necessary workers for the operation and the measurements shall be present in the area.

2.2.3 Measurement material

The following equipment used for the measurements shall be class 1 as per IEC 60942 [5], IEC 61260 [6] and IEC 61672-1 [7]:

- Calibrator,
- Sound level meter.

These devices shall be periodically verified by a national standard laboratory or a competent accredited laboratory.

2.2.4 Measurement time intervals and data to be recorded

For steady noise emissions the measurement time interval shall be at least 30 s.
If a noise level variation of more than 5 dB is identified during the 30 s measurement, the point shall be considered as non-steady, and the measurement shall cover one or more complete cycles to determine a representative average level. The source of the intermittence shall be investigated.

The operation time and time interval shall be noted and reported in the test results.
The equivalent sound pressure level shall be recorded in decibels using A-weighting filter (LAeq,1s). Additionally, during each measurement, octave band analysis between 31.5 Hz and 8000 Hz shall be recorded as well as the peak sound pressure level using C-weighting filter (LCpeak).

2.2.5 Calibration check

A calibration shall be performed before and after each series of measurements. If a gap higher than 0.5 dB is identified between the results of a calibration before and after the measurements, the results of this series shall be discarded, and the measurements shall be repeated.

3. MEASUREMENTS FEEDBACK AND RESULTS

3.1 Difficulties encountered during measurements

Conducting noise measurements on an FLNG is a challenging task due to the complexity of its environment. The combination of industrial activity, marine, weather conditions and spatial constraints creates a unique set of difficulties that must be carefully managed to ensure reliable results. This section outlines the challenges that could be encountered during the noise measurements.
To perform noise measurements on a FLNG, training and administrative work are necessary. This includes the Basic Offshore Safety Induction and Emergency Training (BOSIET) to access the FLNG. The specific regulations of the country and temporary admission for the measurement equipment shall also be considered, which means the need to gather all necessary documentation for foreign customs.
Additionally, one of the main challenges is that the noise measurement material may not be ATEX-certified. In these conditions, to conduct in-plant noise measurements, a hot work permit shall be requested daily. The purpose of the hot work permit is to ensure that the work is performed in safe conditions. Thus, it evaluates the different risks linked to the activity and details all necessary safety measures including the need for personal protection. As an example, a personal gas monitor to detect and prevent the presence of hazardous gas leaks could be permanently worn for field operations.
To validate the permit, the purpose of the noise measurements shall be explained to the different working areas safety representatives and their approval signatures shall be collected. This adds complexity and requires meticulous planning to ensure compliance and safety during noise measurements.

As the noise performance test occurs after the first start-up of the plant, unforeseen events could happen. This includes:

- Malfunctioning or under-maintenance equipment,
- FLNG shutdowns due to defective operation.

This would result in modification or cessation of ongoing measurements and therefore delays in the on-site measurements schedule.
Finally, unplanned measurements stoppages due to the noise generated by chopper traffic, bad or extreme weather conditions could further complicate the work progress.

3.2 Summary of measurements results and compliance

Despite the difficulties presented above, Technip Energies has implemented its procedure on an operational FLNG and the measurements have been performed. Main results are provided in Tab. 1.

Table 1. Measurements noise results.

Area	Number of measurements	Number of uncompliant measurements
Portside	265	13
Starboard	246	16
Hull Deck	173	25
Turret	15	0

The overall results of the noise measurements campaign show that 54 noise measurements exceed the acceptance criterion, over the 699 measurement points.
These exceedances are primarily located on the hull deck, resulting from:

- The main deck's configuration, which includes expansion holes not accounted for in the modeling phase,
- Reciprocating pumps generating high noise levels due to vibrations transmitted to the deck.

Exceeding measurement points on the topsides (portside and starboard) are mainly attributed to insufficient acoustic insulation on powerful compressors and pumps.

4. CONCLUSION

As previously mentioned, there are no specific international standards dedicated to noise performance tests for offshore applications. Consequently, it is incumbent upon acousticians to develop an appropriate methodology. The first step is the definition of the acceptance criterion.

This should be discussed with the different parties involved throughout the project.
Then, the noise measurement procedure shall be established to define the location of measurements points but also the measurement material, the interval duration of noise measurement points and the data to be recorded.
During the offshore noise measurements on a FLNG, safety shall not be compromised, and thus administrative work (permit to work) is of major importance.
In addition, measurement schedule can be impacted by unplanned events related to operation troubles, chopper traffic and/or extreme weather conditions.
Based on experience, it is advised to work with ATEX-certified sound level meters to reduce the risk associated with an explosion. Another point is to allocate extra time in case of unforeseen events that could disrupt the schedule.
Experience has demonstrated that the presented noise measurements procedure is appropriate for this type of work and environment.
Noise measurement results, with only 7% of the points exceeding the acceptance criterion, have been considered acceptable by all the parties. Thus, noise guarantee has been satisfied and FLNG is currently operating.

ABSTRACT

The growing demand for more comfortable and quieter household appliances reflects the increasing customer expectations for enhanced user experiences. In a competitive market, manufacturers are continuously seeking innovations that balance performance with noise reduction. To address this demand, experimental methodologies that characterize the vibroacoustic behaviour of devices can provide valuable support during the design phase. In this context, this paper focuses on a domestic coffee apparatus for coffee preparation as a case study to analyse its vibroacoustic behaviour, evaluating the acoustic emissions during operation and demonstrating the effectiveness of vibroacoustic testing for enhanced design insights. Noise and vibration measurements are conducted in a semi-anechoic chamber using accelerometers, microphones, a sound camera and a 3D sound intensity probe. The results of the proposed methodology highlight its potential for improving the acoustic performance of similar devices.

Keywords: *sound power, beamforming, sound intensity measurements, noise localization, vibroacoustic analysis*

1. INTRODUCTION

In recent years, domestic comfort has become a relevant aspect for customers, who require household appliances that are not only efficient but also quiet. In a competitive market, the attention to technical solutions that reduce acoustic impact without compromising performance is in constant growth. To this end, the adoption of experimental and numerical methods to study the vibroacoustic behaviour of such devices is one of the key elements in the process of product development and optimization.
The article presents a methodology to characterize in detail the vibroacoustic performance of a generic household appliance. The methodology is applied to a domestic apparatus for coffee preparation as a case study. The outcomes of a set of experimental approaches are compared, highlighting the potential benefits and the main limitations of adopting different measurement techniques and data processing methods. The procedure is designed to establish a setup that identifies the primary noise and vibration transmission paths, providing guidelines for acoustically driven design improvements or optimizing the acoustic performance of the product under analysis. The overview of the methodology is provided in Section 2. The preliminary acoustic analysis of the coffee machine is carried out in Section 3 through sound pressure and sound power measurements [1]. The detailed acoustic characterization of the product is described in Section 4. The identification of the main noise sources is conducted through beamforming algorithm [2] and sound intensity measurements [3]. The spatial reconstruction of the noise generated by the machine is suitable for the definition of a hybrid setup including accelerometers and microphones for the identification of the main acoustic and vibration transmission paths, which in turn allows for the definition

of possible mitigation actions and the evaluation of their effectiveness.

2. METHODOLOGY AND TEST CASE OVERVIEW

The most commonly performed acoustic tests for characterizing a product's acoustics rely on sound pressure measurements and sound power calculations (Figure 1a). These approaches only provide the possibility to have a general description of the product and do not allow for the identification of the location of the critical noise sources. In parallel with these measurements, noise source localization analysis is performed using a beamforming algorithm applied to a microphone array or by employing sound intensity measurements (Figure 1b). The combination of these two sets of tests enables a detailed characterization of the machine's acoustic behaviour, offering guidelines for developing a refined vibro-acoustic setup aimed at achieving a comprehensive vibroacoustic analysis (Figure 1c).

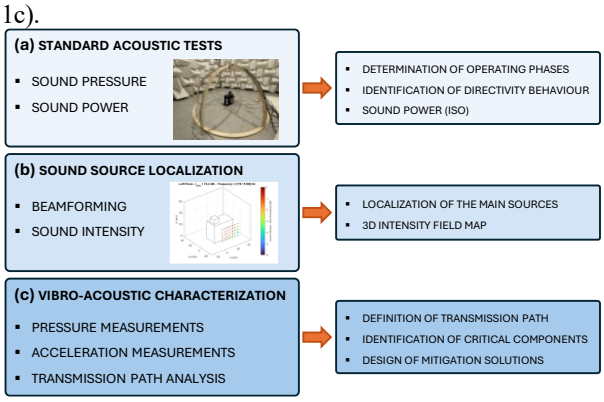

Figure 1. Overview of the methodology: (a) standard pressure and power measurements, (b) sound source localization techniques and (c) comprehensive vibro-acoustic characterization.

The machine under examination features an internal supporting frame that houses the components (motors, coffee grinder, handling and brewing systems) along with the external panels. Excluding components that are not involved in the grinding phase (the only operational phase analysed in this paper), the machine can be schematized as a combination of the following components. The "source group", consisting of the motor and grinding system, is positioned inside the machine and supported by the frame via supports. It is also connected to the coffee bean container through a channel passing through the upper panel. The external panels are, in turn, connected to the frame. Ventilation grids are installed on each panel, necessary for cooling the electrical circuits and for dissipating condensation (see Figure 2).

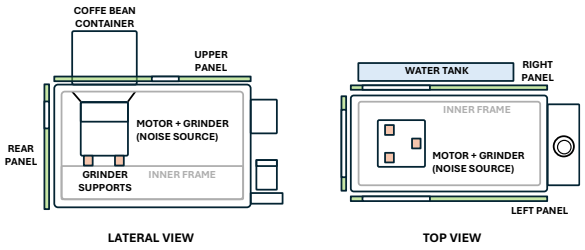

Figure 2. Schematic overview of the coffee machine. The ventilation grids on the external panels are indicated with a, b, c and d.

3. IDENTIFICATION OF THE ACOUSTIC BEHAVIOUR

The acoustic behaviour of the coffee machine is determined through a preliminary assessment of pressure measurements and sound power calculation. The analysis is carried out using a hemisphere (1m radius) designed for sound power measurements (ISO 3744 [1]). Measurements are conducted with 10 microphones located in different positions of the sphere, measuring the sound pressure in the position highlighted in Figure 3.

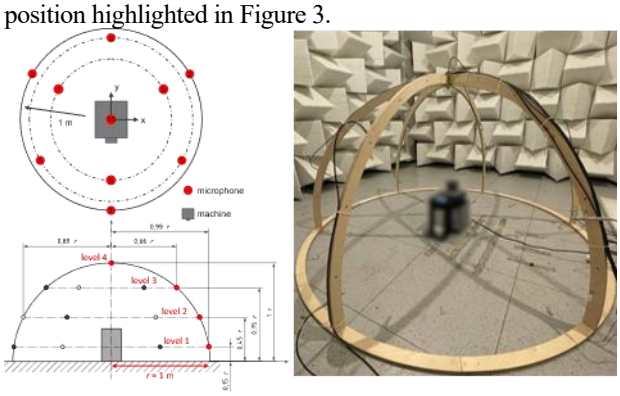

Figure 3. Setup of the sound power measurements [1].

Data from these microphones can be first used to highlight the different operating phases of the machine and to highlight possible non-stationary behaviour during each phase. This is performed by computing sound pressure levels using the fast-weighting data processing (see [4]), which allows for estimating the total sound level over time. The results of this procedure are collected in Figure 4a.

Microphone 10 is considered (see the scheme of Figure 3). The operating phases of the coffee machine (grinding, brewing and internal movement operations) are clearly evident when observing the overall Sound Pressure Level (SPL) over time ($p_{ref} = 2 \cdot 10^{-5}$ Pa). The grinding phase is the most critical and the loudest operational phase, as shown in Figure 4a. A time-frequency domain analysis is also conducted to highlight any critical frequencies associated with the noise phenomena. The spectrogram of the noise levels recorded by microphone 10 is shown in Figure 4b.

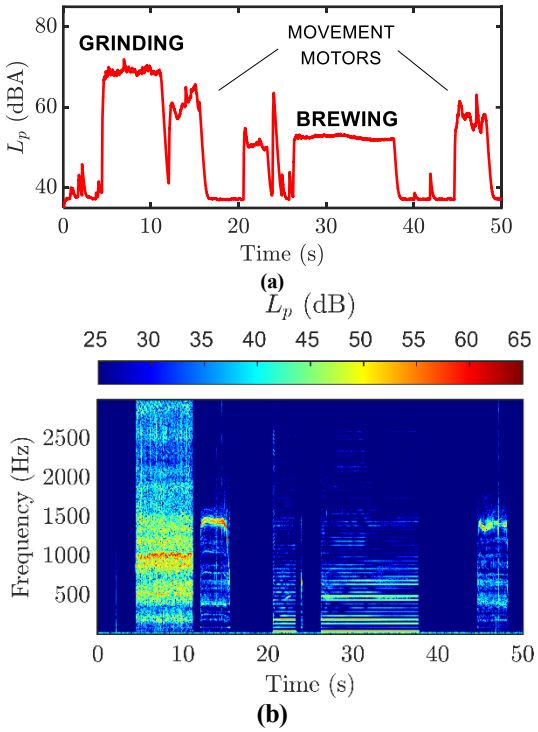

Figure 4. Identification of the machine operational phases (microphone 10): (a) fast weighted SPL (dBA) and (b) spectrogram (dB).

The noise generated during the grinding phase is mostly concentrated in the one-third octave band at 1 kHz and is related to the interaction between the grinder and the coffee beans. During the motor movement phase, it is possible to highlight that most of the noise is concentrated around 1500 Hz, which corresponds to the frequencies associated with the rotation of the motor that moves the coffee container to prepare the brewing phase. A peculiar frequency pattern is highlighted during the brewing phase, where it is possible to recognize the contribution of the motor pump, which is directly powered by household electricity (generating noise at the main electric frequency and at the higher order harmonics). In this research, the focus is given to the analysis of the grinding phase, which is, as explained above, the most annoying one considering the noise levels and the high-frequency content. All the following analyses are related to this phase only. One of the most important outcomes of the sound pressure measurements using a hemisphere in a hemi-anechoic chamber is the sound power of the machine, which can be computed following the procedure reported in ISO3744 [1]. Sound power provides an overall description of the noise generated by the machine and allows for comparison between similar products, as reported in Figure 5, where the sound power levels of the described reference Coffee Machine (CM1) are compared with those computed from sound pressure measurements of three other similar devices (CM2, CM3, CM4).

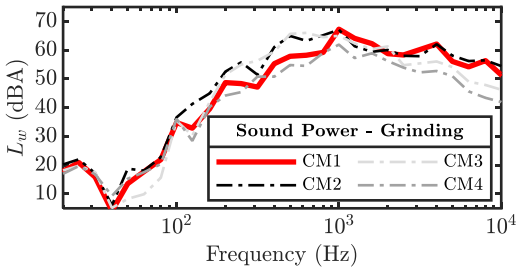

Figure 5. Third-octave band sound power levels of the grinding phase for different Coffee Machines (CM).

It must be noted that sound power can be considered a good index for initial assessment or for comparison between similar devices, but also to evaluate the overall impact of possible mitigation solutions. However, sound power is the result of the integration of the sound intensity normal to the hemisphere, so it represents the sum of the contributions of all the noise sources, which can also be localized in specific areas of the machine. Thus, to achieve a comprehensive acoustic characterization, further analysis is required, focusing on sound source localization and identification.
The techniques required to achieve these objectives are described in Section 4.

4. DETAILED ACOUSTIC CHARACTERIZATION

This section presents the techniques used for a detailed acoustic characterization by identifying the main noise sources. Preliminary sound source localization is conducted using a beamforming algorithm applied to measurements taken with a microphone array. Further investigation is carried out through sound intensity measurements.

4.1 Preliminary sound source localization through acoustic camera

The delay and sum algorithm, which serves as the foundation of beamforming [2], is one of the most common techniques adopted to locate the main sound sources on complex systems. Beamforming is typically employed to process the signals measured by one or more microphone arrays, enabling the generation of the beampattern, which is an acoustic map that highlights the loudest sound sources over a reference plane. In this research, preliminary sound source localization is carried out through the acoustic camera type 9712-W-FEN by Bruel & Kjer [5], which allows for obtaining real-time visualization of the acoustic field around the object analysed. In this context, the camera is used to scan each panel of the coffee machine by moving the microphone array. The acoustic maps of the left, right, rear, and top/upper panels are reported in Figure 6a, 6b, 6c, and 6d, respectively.

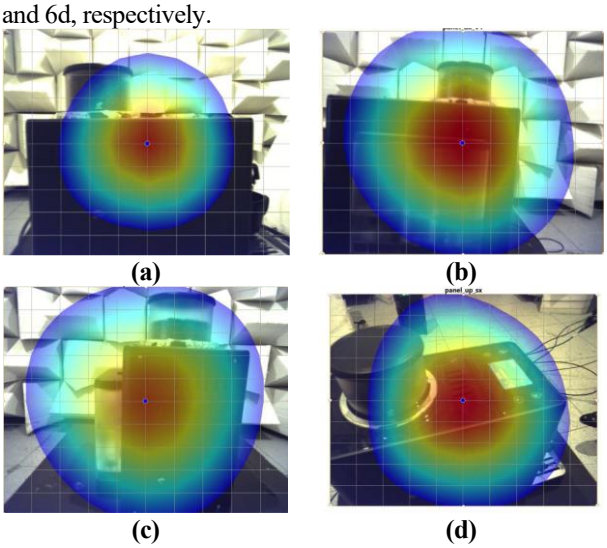

Figure 6. Results of the beamforming analysis through the acoustic camera: (a) left panel, (b) right panel, (c) rear panel and (d) upper panel.

The main noise emission is found to be located close to the ventilation grids, suggesting that this area may be the most significant transmission path for the noise produced in the internal part of the machine as a result of the vibrations generated during coffee bean grinding. However, the acoustic map produced by the camera may not always provide accurate noise level results due to several limitations. The operator's movement during the acoustic scanning process causes variations in the relative position between the microphone array and the source, introducing errors. Additionally, the beamforming technique has limited spatial resolution at low frequencies, making it less effective in accurately locating low-frequency noise sources. It is also sensitive to environmental reflections and background noise, which can distort the identification of sound sources. Moreover, when multiple noise sources are close to each other and operate at similar frequencies, beamforming may struggle to separate them clearly. In conclusion, it is able to provide only a qualitative representation of noise distribution rather than absolute sound intensity values. For this reason, in the next section, the noise generated by the machine will be accurately mapped using sound intensity measurements.

4.2 Detailed sound source identification: 3D sound intensity map

Sound intensity measurements can be used to refine the results obtained through the acoustic camera by reconstructing the sound intensity field surrounding the machine. To this end, a G.R.A.S. 3D sound intensity probe head type 60LK is used to estimate the sound intensity vector in different positions close to the left, right, rear, and top panels (see Figure 7).

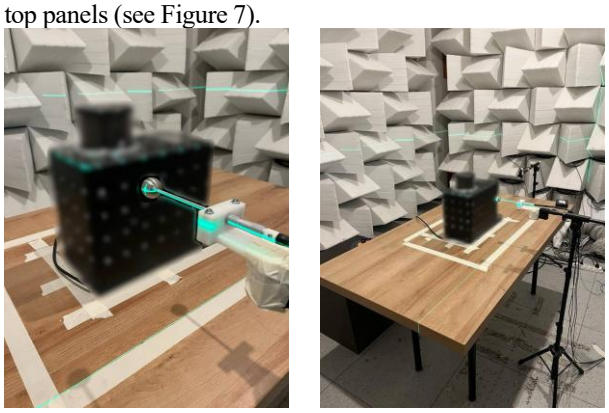

Figure 7. Measurement setup of the sound intensity measurements.

The measurements are carried out thanks to four ¼" microphones embedded in a rigid spherical shell with a diameter of 30 mm, which are organised in a regular tetrahedron configuration. A dedicated MATLAB software was developed to process and visualize the data acquired by the 3D sound intensity probe. In this process, a correction was applied to account for the acoustic scattering caused by the sensor's rigid spherical surface in the acoustic field, following the formulation proposed in [6,7]. The output of the algorithm is the estimation of the sound intensity vector at the centre of

the sphere, which allows tracking the magnitude and the direction of the sound intensity field in different positions surrounding the coffee machine. During the tests, the sound probe is positioned 15 cm from each of the panels. A total number of 118 measurement points is created, adopting a spatial distance between points of 5 cm. Unlike beamforming, sound intensity measurement offers higher accuracy in quantifying noise levels, is less affected by background noise, and allows for direct identification of sound transmission paths. Additionally, it enables analysis in low-frequency ranges and provides vectorial information about the direction of the sound energy flow, offering a more detailed characterization of noise sources. Another key advantage is its ability to analyse both near-field and far-field noise propagation, making it particularly useful for distinguishing between localized sources and the overall noise radiation of the machine. The results of the sound intensity measurements are reported in Figure 8. The sound intensity vectors are normalised with respect to the maximum value obtained in each panel. The analysed frequency range includes all one-third octave bands from 200 Hz to 10 kHz. A colormap of 6 dB is employed for the sound intensity field representation. The maximum value of sound intensity (78.1 dB) is obtained on the upper panel, just in front of the top grid. Slightly lower sound intensity magnitude is obtained on the rear panel (77.7 dB) and on the left and right panels (74.2 dB and 73.5 dB). The differences between the left and the right panels are due to the presence of the water tank on the right side, which creates an additional shield for sound transmission.

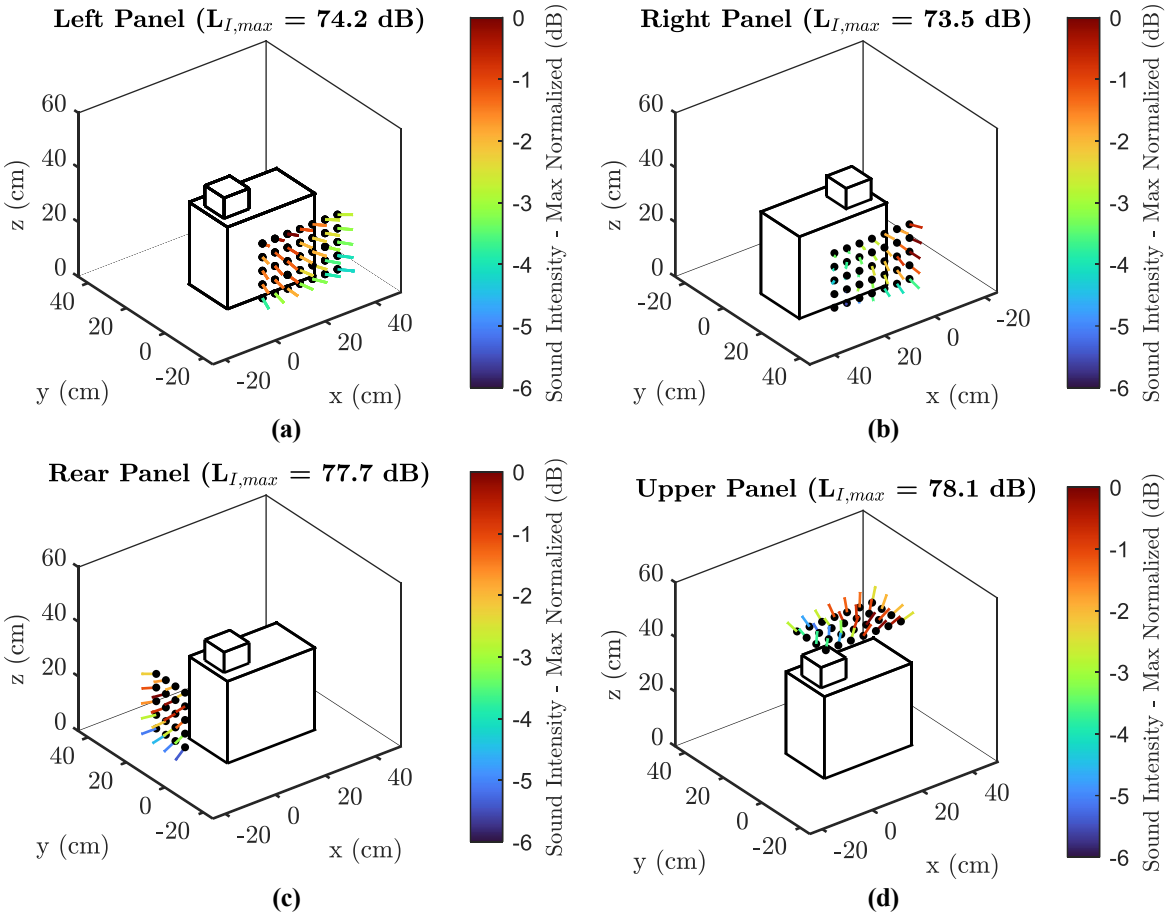

Figure 8. 3D sound intensity maps: (a) left panel, (b) right panel, (c) rear panel and (d) upper panel.

5. VIBROACOUSTIC ANALYSIS

The identification of the sound sources through beamforming and sound intensity measurements reveals some localized potential critical areas associated with noise emission during the grinding phase. Thus, a measurement setup dedicated to further refinement of these findings has been developed. The main scope of this third experimental session is to understand if the noise is mostly generated by acoustic leakages, such as the ventilation grids, or if there are other phenomena associated with structural contributions only. Determining noise and vibration transmission paths is fundamental to identifying potential mitigation solutions. This analysis requires not only pressure measurements but a combination of noise and vibration tests. A hybrid setup is therefore designed, including accelerometers and microphones mounted in different positions. The description of the measurement setup is provided in Section 5.1, while the results of the tests are analysed in Section 5.2.

5.1 Measurement setup

The final tests are carried out by organising sensors in three layers: source sensors (layer 1, accelerometers), "near field" sensors (layer 2, accelerometers and microphones at 5 cm relative to the ventilation grids) and "far field" sensors (layer 3, two microphones located 1m away from the front and the rear of the coffee machine). Please note that layer 3 has been designed to be representative of a generic customer position. These sensors are useful for estimating the average noise level to which the user is exposed during the coffee preparation and to investigate the possible impact of different design solutions on user annoyance. This is not the aim of the present paper, so the analysis of layer 3 is not reported here. The overview of the entire setup is illustrated in Figure 9.

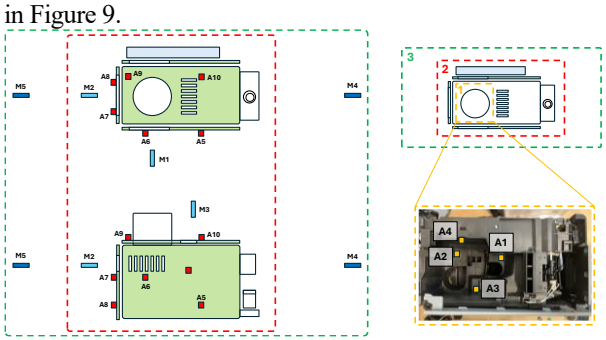

Figure 9. Refined setup for vibro-acoustic characterisation.

5.2 Transmission path analysis

Three of the four accelerometers of layer 1 are mounted close to the supports of the grinder, and they collect the vibration transmitted by the source to the main frame of the machine. As highlighted in Figure 10, these supports are not the only possible structural transmission path for vibration induced by the grinding process. In fact, the grinder is connected to the upper panel also through the canal for the passage of coffee beans from the coffee container. The main challenge is to determine the impact of the possible transmission path. This is carried out by comparing the vibration measured by the accelerometers mounted on layer 1 and the sensors mounted on layer 2.

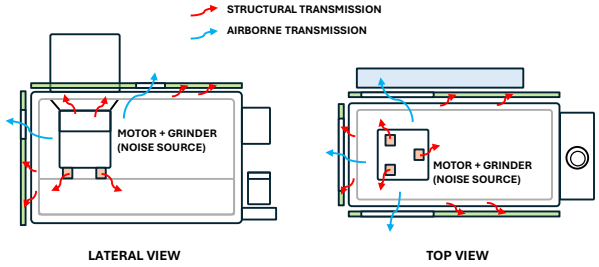

Figure 10. Identification of potential structural and acoustic transmission paths.

First, the comparison between the acceleration measured on the inner frame (layer 1) and that of the panels is performed. The spectrogram of the acceleration levels ($a_{ref}=1\cdot10^{-6}$ m/s) is employed. The most important results of the analysis are now presented. The accelerometer 1 (A1) is chosen as the reference channel for layer 1, while A5, A8, and A9 are the reference channels for the left, rear, and top panels, respectively. The results are reported in Figure 11. Similar vibration contributions are observed comparing the acceleration measured by A1 and the ones measured by A5 and A8 (left and rear panels). A low-frequency dynamic amplification is detected on the panel's accelerometers only (below 500 Hz) and it is therefore attributed to the panel dynamics. However, as it will be visible in the microphone data, the low-frequency vibration does not contribute significantly to the noise emission. The vibration peaks observed in A1 around 1 kHz are also partially visible on the left and rear panels, although they are significantly attenuated compared to the layer 1 measurements. A different vibration pattern is observed in the spectrograms of the levels of channel A9. The contribution at 1 kHz is much more evident here and is correlated with the measurements from the layer 1 accelerometers. Strong transient peaks in the vibration levels are observed at t=5s,

t=6s and t=7.5s. These vibration peaks are related to the random hits generated during the grinding of coffee beans and seem to be much more evident in the top panel vibration compared to the other panels or to the layer 1 accelerometers (see A1 spectrogram). This confirms that there is a direct structural transmission of vibration from the grinder to the upper panel, in addition to the transmission of the vibration from the grinder support to the inner frame (as highlighted by looking at the correlation in the spectrograms of A1, A5, and A8).

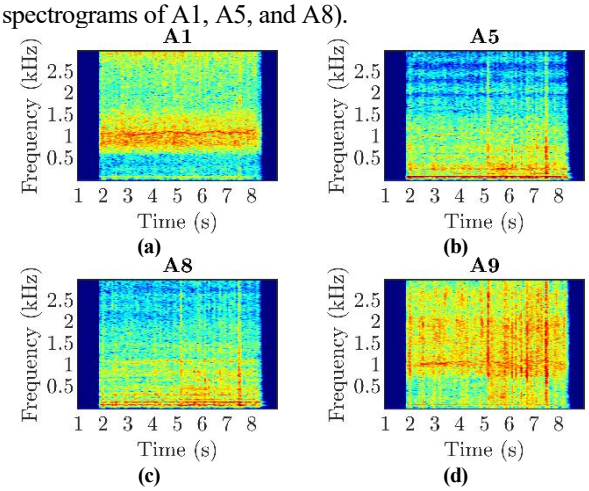

Figure 11. Spectrograms of the vibration levels (dB): (a) A1, (b) A5, (c) A8 and (d) A9.

The impact of the structural transmission on vibration can be evaluated by analysing the signal measured by the microphones located surrounding the coffee machine. The analysis of the grinding phase is repeated by closing the ventilation grids to discover if the noise emitted is mainly due to the structural transmission of the vibration from the grinder to the panel (which results in noise radiation) or if it is due to the acoustic transmission through ventilation grids. The results on the rear and the upper panels are shown in Figure 12 and Figure 13, respectively. As mentioned above, the low-frequency vibration of the panels is not found to generate a significant contribution to the noise emission (see Figure 12b). The rear panel vibration spectrogram (A8) is very similar to the one of the rear microphone (M2) at frequencies above 300-400 Hz. However, in the test with the ventilation grid closed, a significant reduction in the noise levels measured by M2 is observed (see Figure 12d). This confirms that a significant part of the noise radiated by the machine seems to be transmitted through the ventilation grids. Similar results are obtained by analysing the left panel.

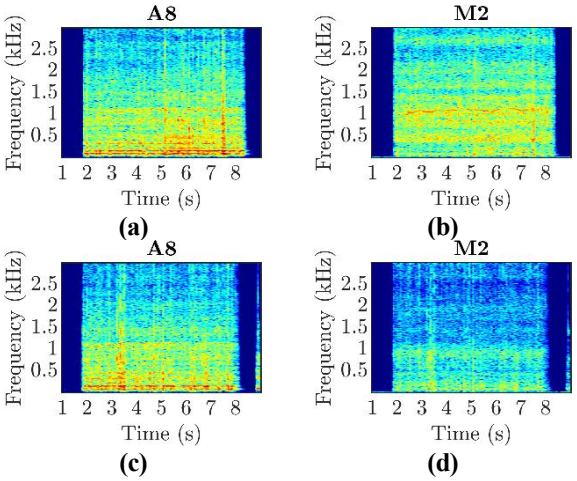

Figure 12. Spectrograms of noise and vibration levels (dB) on the rear panel: (a,b) with ventilation grids open, (c,d) with ventilation grids closed.

The analysis of the upper panel comparing the tests with the ventilation grids open and closed (see Figure 13) confirms the previous considerations regarding a possible structural transmission of vibration between the grinder and the upper panel.

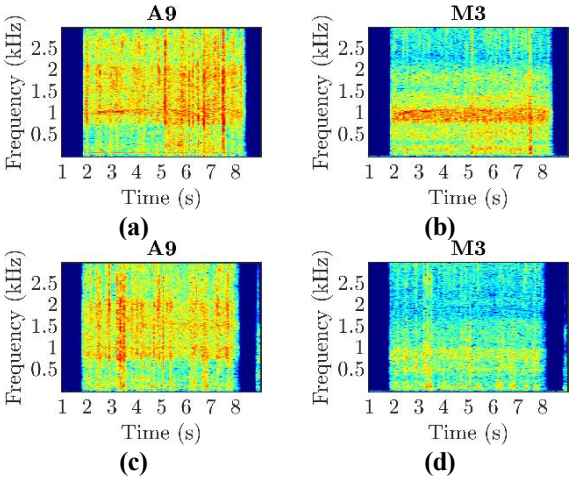

Figure 13. Spectrograms of noise and vibration levels (dB) on the upper panel: (a,b) with ventilation grids open, (c,d) with ventilation grids closed.

Noise emission is mainly related to the transmission through the ventilation grids, but the contribution from the hits of the coffee beans during grinding, along with some of the broadband vibrations around 1 kHz, is also transmitted to the upper panel through structural pathways (see Figure 13).

6. CONCLUSIONS

In this research, a methodology for vibroacoustic characterisation of household appliances is described. The use of standard sound pressure and sound level measurements, supported by noise source localisation techniques such as beamforming and sound intensity measurements, is shown to provide a comprehensive characterisation of the tested product. These experimental techniques also allow for the design of a dedicated setup in which, thanks to sound pressure and acceleration measurements, it is possible to identify the main noise and vibration transmission paths. The methodology is applied to a test case with the aim of characterising the vibroacoustic behaviour of a household coffee machine. The analysis shows that acoustic leakages, due to the presence of ventilation grids, may result in a significant impact on the overall noise emission. However, through combined noise and vibration analyses, a critical structural transmission path has also been identified. The results of these experiments highlight several key aspects of the product that can be optimized to reduce overall noise emission. The experimental techniques presented in this article can be adopted for the identification of potential mitigation measures for the noise generated by any kind of household appliance, or can be used for the definition of guidelines for an acoustically oriented design of new products.

7. ACKNOWLEDGMENTS

The authors would like to thank De'Longhi Appliances S.r.l for providing the tested product and for their technical assistance during the experimental phase. Their support has been a significant added value to our research.

ABSTRACT

This paper presents an optimization study of sustainable sound-absorbing panels made of jute fiber, developed for two different applications: the first, with a thickness of 40 mm, is optimized for wall mounting, while the second consists of a 20 mm thick panel designed for suspended ceiling installations with an air cavity. The design process began with an experimental study of the acoustic performance of loose jute fibers, with the objective of achieving Class A performance ($\alpha_w \geq 0.90$) according to ISO 11654. This study was conducted in collaboration with the Danish company Hubbub ApS.

Keywords: *acoustic optimization, sound absorption, jute fibers, natural fibers, sustainable material.*

1. INTRODUCTION

In recent years, the development of sustainable sound-absorbing materials has gained significant interest due to global CO_2 emission reduction targets. Natural and recycled fibers, which find applications both in building construction and industrial noise control engineering, may represent a more sustainable solution for thermal and sound insulation compared to traditional synthetic fibrous materials. While a knowledge gap still exists between traditional synthetic fibers, which have been studied for over fifty years, and natural fibers, an extensive body of literature is now available on fibrous materials of plant origin, such as hemp, wood fibers, and coconut fibers [1][2].

However, unlike traditional fibrous materials, whose acoustic performance can be optimized through the manufacturing process, the physical characteristics of natural fibers cannot be precisely engineered and generally exhibit significant variability in diameter, distribution, and orientation; factors that strongly affect their acoustic performance. Therefore, the acoustic optimization of sound-absorbing products made from plant-based fibers must consider and fine-tune other parameters that play a fundamental role in the acoustic behavior of the fibrous material and strongly affect its overall performance.
The present project was promoted by the company Hubbub ApS to develop fully natural indoor sound-absorbing panels, including both the fibers, the binder that provides structural cohesion, and the aesthetic covering.

2. MATERIALS AND METHODS

The aim of this study was to develop two jute fiber-based sound-absorbing panels for indoor environments: a thicker panel (40 mm) for wall applications and a thinner panel (20 mm) for suspended ceilings with an air cavity. The panels were manufactured in India using jute fibers and natural latex as a binder. The jute fibers were obtained without the use of chemicals from plants of the *Corchorus Capsularis species*, belonging to the *Malvaceae family*, which are abundant in the monsoon regions of the East. The production process, which employs natural latex as a binder, results in a panel that is 100% biodegradable.
The Johnson-Champoux-Allard (JCA) [3][4] equivalent dissipative fluid model was employed for the acoustic design

and optimization process of the two panels. The transport parameters, required as input data for implementing the JCA model, were determined through an inverse characterization approach, based on the experimental measurement of the normal incidence sound absorption coefficient on a small quantity of loose fibers (**Figure 1**), progressively compressed to test different densities. A variation of the sample density ρ implies a change in the material's open-cell porosity ϕ, which can be evaluated from the density of the solid skeleton ρ_s as:

$$\phi = 1 - \frac{\rho}{\rho_s} \tag{1}$$

The airflow resistivity σ can be related to the material porosity ϕ and to the effective radius r_e of the equivalent monodisperse fibrous medium:

$$\sigma = \frac{\eta}{(2r_e)^2} \times \frac{\sqrt{1-(1-\phi)}}{0.21\left(\frac{0.71}{1-\phi} - 3\sqrt{\frac{0.71}{1-\phi}} + 3 - \sqrt{\frac{1-\phi}{0.71}}\right)} \tag{2}$$

Analytical equations were used to express the remaining three transport parameters – tortuosity α_∞, viscous and thermal characteristics lengths Λ, and Λ' – either as a function of the porosity ϕ or the effective radius r_e:

$$\alpha_\infty = \left(\frac{1}{\phi}\right)^{0.9574} \tag{3}$$

$$\Lambda = A_1 r_e (1-\phi)^{-A_2} \tag{4}$$

$$\Lambda' = A_3 r_e (1-\phi)^{-A_4} \tag{5}$$

The effective radius r_e and the unknown coefficients A_i were determined through a minimization procedure, described in detail in reference [5], based on the experimental results of the normal incidence sound absorption coefficient, measured at different combinations of thickness and density according to the ISO 10543-2 standard. This approach allowed us to correlate variations in transport parameters with changes in material density. Considering these density-functions for the transport parameters used as input in a JCA model, along with the diffuse field assumption and the finite-size correction method proposed by Rhazi et al. [6], the panels' thickness and density were optimized. The optimization process involved evaluating different combinations of thickness, density, and air cavity, based on predictions of the random incidence sound absorption coefficient, which represents the acoustic performance measurable in a reverberation chamber according to the ISO 354 standard. The optimization target, requested by Hubbub ApS, was to develop two panels capable of achieving Class A performance ($\alpha_w \geq 0.90$) according to ISO 11654. The entire process was experimentally validated at the end of the design phase on 10.8 m^2 of panels, specifically produced in accordance with the optimization results, tested in a reverberation chamber.

Figure 1. Loose jute fibers and their installation in the plane wave impedance tube.

3. EXPERIMENTAL RESULTS

The experimental normal incidence absorption coefficients measured on loose fibers at different combinations of thickness and density are shown **Figure 2**.

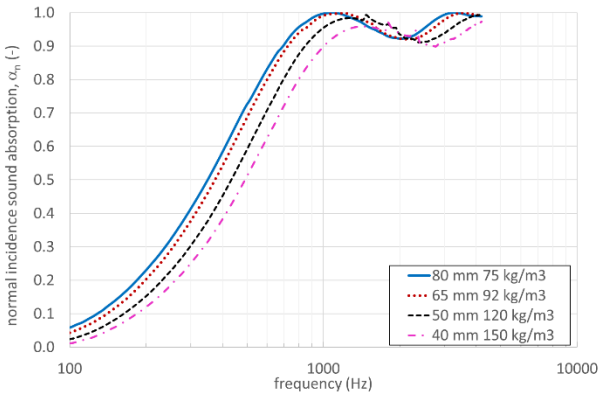

Figure 2. Normal incidence sound absorption: experimental measurements on loose fibers for different combinations of thickness and density.

The loose fibers were compressed from 80 mm to 40 mm, enabling the experimental measurement of densities within the range of 75 – 150 kg/m^3. The five transport parameters – including porosity, airflow resistivity, tortuosity, and the characteristic viscous and thermal lengths – were determined as a function of material density, as described in the previous paragraph. **Table 1** presents the values of these parameters for densities ranging from 120 to 240 kg/m^3.

A comparison between the experimentally investigated densities and the values for which the transport parameters were estimated suggests that the applicability of the optimization approach extends across the experimental interval. However, for values outside the investigated range, a higher degree of uncertainty should be expected. Since the target performance was expressed in terms of average sound absorption α_w, the random incidence sound absorption coefficients were computed from the density-dependent transport parameters and considering a finite-size correction for a 10.8 m² surface. The results are shown in **Figure 4**.

Table 1. Physical parameter values derived from measurements on loose fibers as a function of density.

ρ [kg/m^3]	ϕ [-]	σ [kNs/m^4]	α_∞ [-]	Λ [μm]	Λ' [μm]
120	0.91	15.9	1.10	65	133
140	0.89	21.1	1.12	50	123
160	0.88	27.3	1.13	39	115
180	0.86	34.8	1.15	32	108
200	0.85	43.7	1.17	27	102
220	0.83	54.3	1.19	23	97
240	0.82	66.8	1.22	19	93

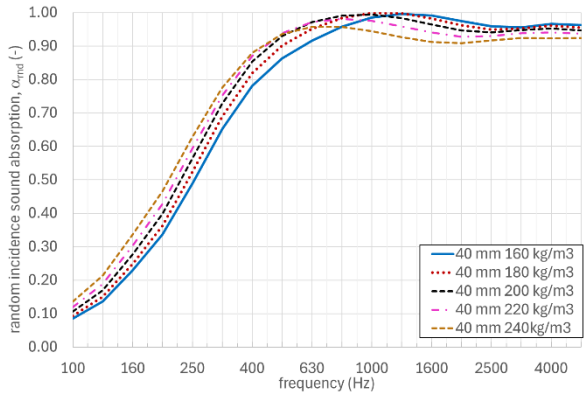

Figure 3. Random incidence sound absorption coefficient: JCA prediction at different densities.

From these results, the average sound absorption coefficient α_w was computed according to ISO 11654 for each density. For instance, **Figure 4** presents the calculated diffuse incidence sound absorption values in octave bands and illustrates the α_w computation procedure for the 40 mm panel at different densities.

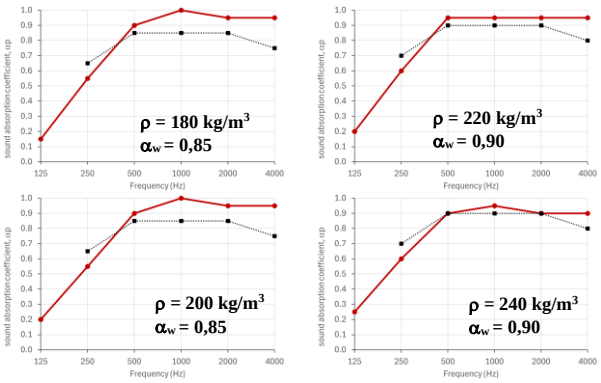

Figure 4. Diffuse incidence sound absorption values in octave bands, computed for the 40 mm panel at different densities, and the α_w reference curve as provided by the ISO 11654.

Table 2 summarizes the results of the optimization approach, presenting the average sound absorption coefficient α_w, which was evaluated from the random incidence sound absorption. This was computed using the transfer matrix method (TMM) at different densities, for two panel configurations: *i)* 40 mm wall-flush mounted, and *ii)* 20 mm ceiling mounted with a 200 mm airgap.

Table 2. Calculated α_w values as a function of panel density for wall-mounted and suspended ceiling configurations.

Density [kg/m^3]	***160***	***180***	***200***	***220***	***240***
α_w *wall- mounted*	0.80	0.85	0.85	0.90	0.90
Density [kg/m^3]	***120***	***140***	***160***	***180***	***200***
α_w *ceiling-mounted*	0.80	0.85	0.90	0.90	0.90

The performance target for Class A sound absorption is met for $\alpha_w \geq 0.90$. Therefore, results indicate that for the 40 mm wall-mounted panel, a minimum density of 220 kg/m^3 is required to achieve Class A performance,

while for the 20 mm ceiling panel with a 200 mm air cavity, a minimum density of 160 kg/m^3 is necessary. At the end of the analytical optimization phase, for each configuration nine prototype panels measuring 1 m x 1.6 m were produced for experimental testing in a reverberation chamber, according to ISO 354. The experimental results, representing diffuse incidence sound absorption (third-octave bands), are compared with the analytical predictions in **Figure 5**.

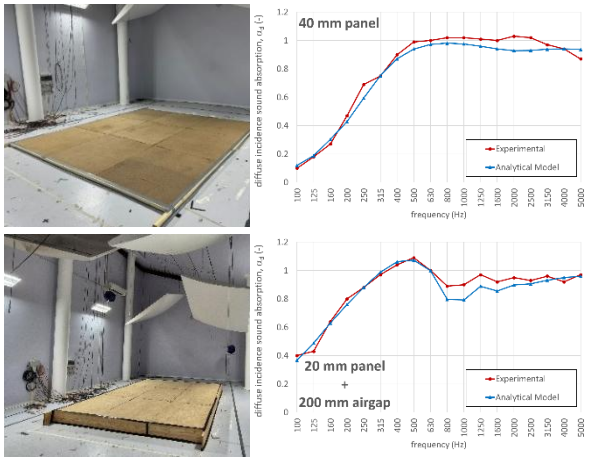

Figure 5. Comparison between experimental results and analytical predictions for 40 mm panels (wall-mounted, density 220 kg/m^3) and 20 mm panels (suspended ceiling with 200 mm air cavity, density 160 kg/m^3).

Reaching an average sound absorption coefficient $\alpha_w = 0.95$, both the configurations were certified with a Class A acoustic performance, thus confirming the predicted results. The analytical model proved to be reliable, accurately approximating the diffuse incidence sound absorption across the entire frequency range. However, it slightly underestimated the acoustic performance for $\alpha_{rnd} > 1.00$, which is physically meaningless and highly dependent on laboratory characteristics.

4. CONCLUSIONS

In this project, two sound-absorbing panels made of jute fiber were developed, both fully biodegradable, thanks to the natural origin of the fibers and the use of a natural latex binder. The adopted acoustic optimization process allowed the development of two Class A panels ($\alpha_w = 0.95$) for both the 40 mm wall-mounted and the 20 mm suspended ceiling solutions.

The proposed methodology demonstrated high reliability while minimizing experimental efforts, as measurements were conducted on a small quantity of fibers using a widely available plane wave impedance tube. These measurements were complemented by a fast analytical processing step, implemented in MATLAB, which enabled the calculation of the physical and acoustic properties of the fibrous material as a function of density.

The adoption of this procedure significantly reduces panel prototyping efforts, cutting costs and development time.

Additional technical information regarding natural-based fibrous panels can be find [7].

LOW-FREQUENCY ACOUSTIC AND VIBROACOUSTIC TREATMENTS TO REDUCE SOUND TRANSMISSION WITH DUCTS

Clément Lagarrigue* **Damien Lecoq**[1] **Julie Perchaud**[1]
Marianne Fruchart[1]
[3] Metacoustic, 57 Boulevard Demorieux, 72000 Le Mans, France

ABSTRACT

This study addresses the attenuation of low-frequency noise in ducts without modifying the cross-sectional geometry or introducing pressure losses. Conventional solutions, such as porous materials or reactive silencers, typically show limited effectiveness below 500 Hz and suffer from degradation under airflow. We propose two compact and robust alternatives: a mechanical elastic approach and an acoustic resonator-based approach. The elastic solution uses a soft viscoelastic material to create a mass–spring system that efficiently attenuates low frequencies through mechanical resonance. The acoustic solution is based on an array of quarter-wavelength resonators with a spatial gradient, designed to target a broader low-frequency band while minimizing flow-induced noise regeneration. Both silencers were manufactured and experimentally tested in laboratory conditions, including under airflow, to evaluate their acoustic performance and robustness. The results show significant transmission loss in the sub-500 Hz range without additional noise generation, confirming the relevance of resonance-based mechanisms for compact low-frequency silencers.

1. INTRODUCTION

Ventilation systems represent a significant source of noise pollution in both industrial and residential environments, necessitating the implementation of effective acoustic attenuation devices. Ventilation duct silencers have been extensively studied, but they still present major limitations, particularly concerning their size, low-frequency attenuation, and impact on airflow.

The most commonly used solution in the industry today is the parallel baffle. These consist of parallel sound-absorbing panels, typically made of mineral wool or fiberglass, covered with fabric or a perforated sheet. These devices provide effective attenuation at mid and high frequencies [1]. However, their limited performance in the low-frequency range (<500 Hz) is well known [2] and particularly problematic in many industrial applications, as they can induce significant aerodynamic pressure losses, which in turn increase the operating energy costs of ventilation systems [3-4]. Dissipative cylindrical silencers, used in circular ducts, are also widely employed in the industry and exhibit similar low-frequency limitations as parallel baffles [5]. To mitigate these issues, a larger-diameter casing can be used, with dissipative material applied to its inner walls. This design preserves the original duct cross-section, minimizing pressure losses. In any case, absorbing materials (such as mineral wool, foam, or fiberglass) are vulnerable to humidity and particulate contamination, reducing their durability, which can lead to delamination and potential health concerns when exposed to strong airflow. To address these issues and the low-frequency shortcomings of dissipative silencers, reactive silencers have been investigated as an alternative solution. By utilizing resonance phenomena, these silencers aim to

improve attenuation in targeted frequency ranges. Resonator silencers, such as Helmholtz or quarter-wave types, provide targeted attenuation of specific frequencies [6-7]. Furthermore, flow-induced noise regeneration remains a key limitation for many existing solutions, requiring careful design to prevent unwanted acoustic emissions.

This study focuses on developing new proposals for dissipative-like silencers that are effective at low frequencies, particularly below 500 Hz, while maintaining performance even in the presence of airflow without generating additional noise. By leveraging resonance-based mechanisms, these treatments aim to enhance sound attenuation while maintaining compactness and robustness in demanding environments. Two different strategies are investigated: an elastic approach utilizing soft and flexible materials, and an acoustic approach based on resonance gradients, offering a practical solution to mitigate flow-induced noise regeneration.

2. USE CASE CONFIGURATION

All results presented in this paper will be experimental transmission losses shown for "dissipative-like silencer" configurations (i.e. where the internal guide cross section remains unchanged). Two examples are displayed and each example has been tested with a different setup for practical reasons (Fig.1): A square duct with a cross-section of 10 cm × 10 cm for the elastic solution (a) and a circular duct with a 16 cm diameter for the acoustic solution (b).

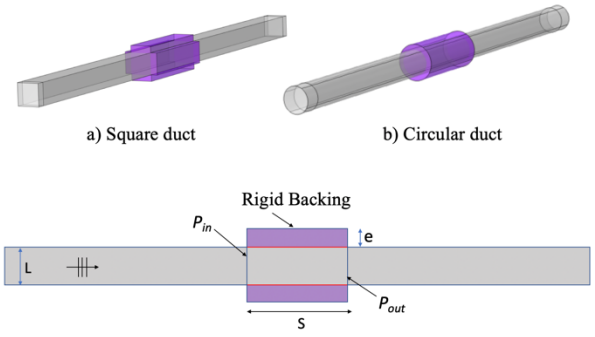

Figure 1. Experimental setups

A silencer is placed at the center of the duct, with the treatment thickness fixed at e = 3 cm in all cases to ensure compactness while addressing the target frequency ranges for attenuation. The transmission loss (TL) is determined by measuring the acoustic pressure upstream and downstream of the silencer using the microphone doublet method. In this configuration, the squared duct cutoff frequency is 1600 Hz, while the cutoff frequency of the circular duct is 1256 Hz. All configurations are first modeled and dimensioned numerically using the Finite Element Method (FEM) implemented in COMSOL Multiphysics. Once the numerical models are established, prototypes are fabricated and tested experimentally to validate the numerical predictions. In this paper, we will only present the experimental results.

3. MITIGATION STRATEGIES

3.1 Elastic Approach

In this approach, we aim to excite elastic phenomena to create, for example, a mass-spring system using a lightweight and flexible material, allowing us to control its resonance behavior. The objective is to fine-tune the system by either adjusting the mass (by adding elements to the flexible material) or modifying the stiffness (by softening the material). For practical reasons, we found no better compromise between mass and Young's modulus than using a porous material. Therefore, we utilize Melamine foam, but instead of exploiting its acoustic properties, we apply an impervious film to excite only its mechanical properties.

3.1.1 Simple case: soft elastic material

The film prevents acoustic propagation within the foam pores but allows mechanical deformation of the porous skeleton, effectively turning the foam + film system into a mass-spring resonator with a resonance frequency dependent on the Young's modulus of the foam and the mass of the system. With a Young's modulus of 100 kPa for Melamine foam, we estimate the resonance frequency to be 1200 Hz. However, this frequency is too high compared to our target of 500 Hz. To address this, we propose making the structure more flexible by introducing a periodic network of cylindrical holes filled with air, which allows local deformations of the foam and reduces the equivalent Young's modulus (Fig. 2). The experimental device

consists of cylindrical air inclusions with a diameter of 12 mm and a periodicity of 3 cm.

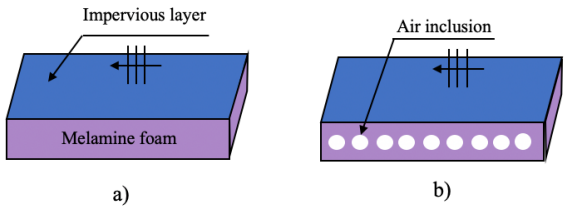

Figure 2. Liners constituting the dissipative-like silencer composed in both cases of 420x100x30mm melamine foam and 50 µm Mylar impervious layer.

Experimental results comparing these two configurations are shown in Fig. 3, where the mass-spring resonance of the homogeneous foam is clearly visible at 1150 Hz, achieving a dip with a maximum transmission loss of 30 dB. On the other hand, the TL of the sample with air inclusions shows multiple dips, achieving a significant TL enhancement over a large frequency range, particularly between 600 Hz and 1200 Hz.

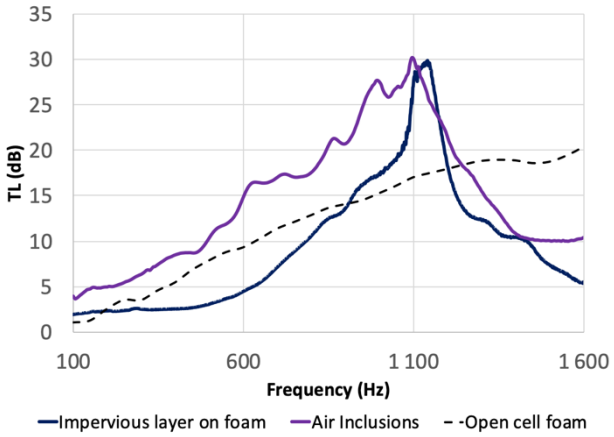

Figure 3. Experimental transmission loss comparison between the homogeneous liner and the air inclusion liner. Experimental TL of 3cm open cell foam is also plotted for information

Even though the TL is clearly enhanced, we did not achieve a sufficient improvement below 500 Hz with this solution, as we have already reached the manufacturing limit: Drilling larger holes can result in the destruction of the foam during the process. For this reason, we decided to change our approach by modifying the phenomenon involved and using local resonance instead of global deformation.

3.1.2 Elastic plate with locally resonant effects

By considering the foam with its impervious film as a soft elastic material it is relatively simple to create locally resonant phenomena by adding new elements within the plate thickness. This concept can be implemented using various types of inclusions, such as solid inclusions that act as local masses, with the matrix functioning as the spring, or flexural plates that bend and oscillate with the deformation of the soft material. By carefully tuning these inclusions, the system can be optimized to provide significant transmission loss at targeted low frequencies. In this study, we present results only for cylindrical aluminum inclusions with a diameter of 12 mm, embedded in the same foam as before, with a periodicity of 3 cm (Fig. 4). The thickness of the inclusions is 1 mm.

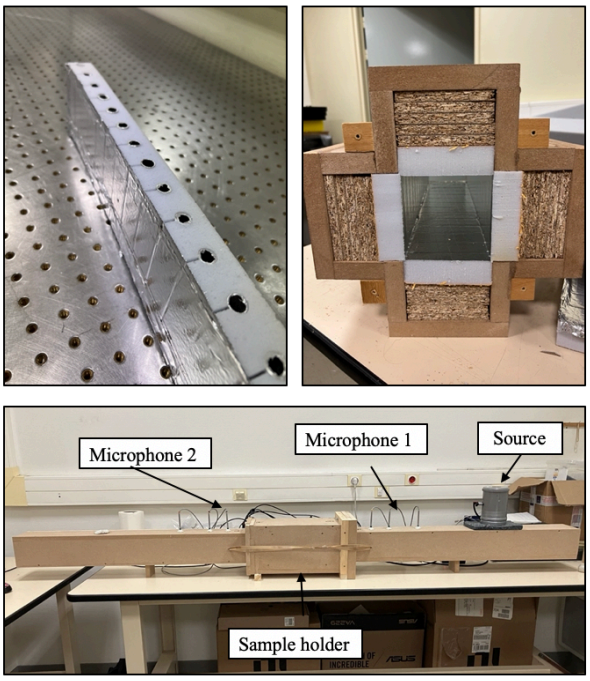

Figure 4. Pictures of the experimental setup for the elastic use case

Fig. 5 shows the experimental TL obtained with the homogeneous liner and with the sample containing aluminum inclusions. The effect of the inclusions is clearly visible between 200 and 500 Hz, with a TL of around 10 dB. As a result, beyond this frequency band, the system is no longer effective. It is therefore not suitable as a standalone solution, but it can serve as the low-frequency component of a hybrid silencer, incorporating an additional section to address mid- and

high-frequency noise, while maintaining a compact form factor and avoiding pressure drop or flow-induced noise regeneration. In parallel, we also investigated another way to reach the same target, but using an acoustic approach.

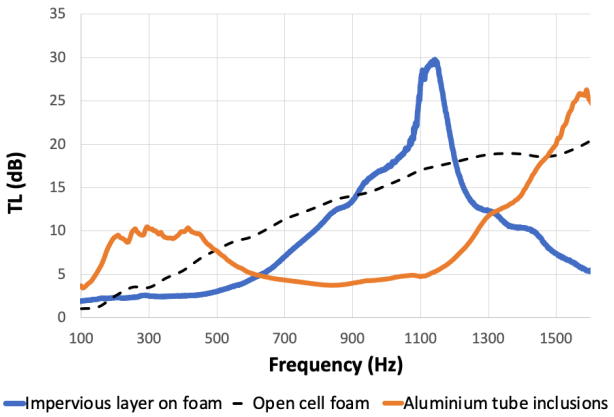

Figure 5. Experimental transmission loss comparison between the homogenous impervious foam liner and the rigid inclusion liner. Experimental TL of 3cm open cell foam liner is also plotted for information (dashed line).

3.2 Acoustic Approach

In many industrial applications, traditional porous materials cannot be used due to high temperatures, harsh environments (e.g., humidity, gas exposure, abrasion, or dust), or the need for high-pressure cleaning. Therefore, alternative transmission loss mechanisms based on reactive devices with resonator gradients are worth to investigate. In this study, we explore the potential of quarter-wavelength resonators. Unlike Helmholtz resonators, which require precise dimensional tuning due to the critical coupling of losses and sensitivity to aspect ratio, quarter-wavelength resonators are primarily controlled by the length of the duct. Although achieving low-frequency attenuation requires relatively long ducts, these can be coiled to fit within the available space. For this use case, we designed a 3 cm thick, 25 cm long silencer aimed at achieving a 10 dB transmission loss in the [250–450] Hz range (Fig. 6). The main challenge with this approach is maintaining performance in the presence of airflow. The addition of cavities directly connected to the duct walls increases local surface roughness and pressure losses, potentially inducing turbulence and noise regeneration at resonance frequencies. To address this issue, we covered the entire silencer surface with a micro-perforated mesh (25% perforation rate).

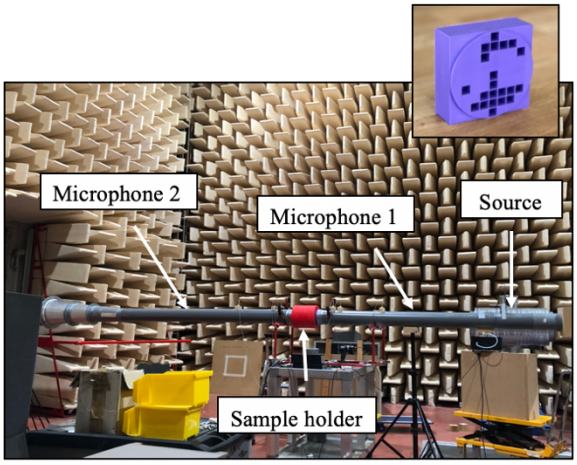

Figure 6. Experimental setup for the graded 1/4 wavelength resonator silencer with flow. Top picture depicts the unit cell sample used and wrapped to obtain the final circular silencer

The resulting transmission loss curve shows that at Mach 0.1, the device maintains 10 dB attenuation over the targeted frequency range (Fig. 7).

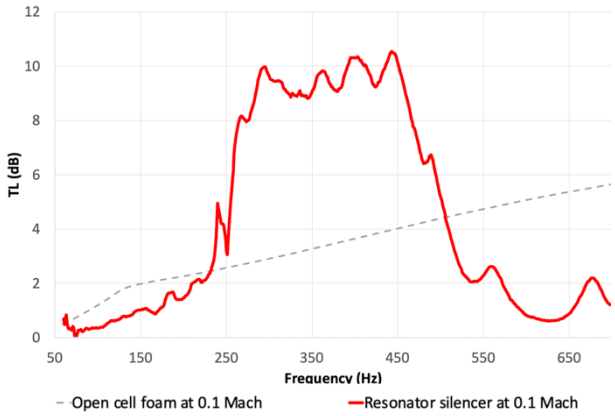

Figure 7. Experimental TL obtained for graded resonator device covered with 25% micro-perforated plate and measured with 0.1 Mach flow. Open cell foam TL for 0 and 0.1 Mach are also plotted for information.

Furthermore, we performed noise regeneration measurements and confirmed that with the micro-perforated mesh, the regenerated noise level is as low as that observed when the experimental setup is tested without a silencer. As previously mentioned, resonator-

based silencers are not effective beyond their frequency range of interest and must be combined with a mid- to high-frequency system to achieve broadband transmission loss. However, they can be highly valuable in meeting industrial constraints particularly in terms of compactness.

4. CONCLUSION

In this study, we have explored two alternative silencing strategies tailored for low-frequency noise attenuation while maintaining a constant duct cross-section. The elastic approach, based on a flexible material forming a mass-spring system, demonstrated its effectiveness in leveraging mechanical properties for improved low-frequency attenuation. The acoustic approach, using quarter-wavelength resonators, provided an alternative solution suitable for harsh industrial environments where porous materials are not viable. Both silencers were designed and tested in controlled laboratory conditions, ensuring a realistic evaluation by incorporating airflow considerations. The results confirm that these solutions achieve significant transmission loss in the targeted low-frequency range without introducing additional noise due to flow effects.

Looking forward, future work will aim to enhance the robustness and efficiency of these silencers under real operating conditions. This includes manufacturing, material choice, long-term performance assessments in the presence of humidity, dust, and temperature variations, as well as their integration into complex duct systems. Optimization strategies could be employed to fine-tune the geometric and material parameters for targeted industrial use cases. Additionally, hybrid designs combining both elastic and acoustic mechanisms may open new avenues for compact, broadband, and flow-resistant silencers, meeting the increasingly stringent acoustic and environmental requirements in ventilation and process industries.

Finaly, this paper has focused on the experimental validation of these concepts, providing key insights into their feasibility and limitations. Further details, including advanced numerical optimizations and potential industrial applications, will be discussed in our oral presentation.

ABSTRACT

Ventilated acoustic metamaterials have become increasingly popular among researchers given their ability to combine contrasting needs like sound insulation and air change, contributing to improved indoor environment quality. However, being a topic where contributions come from different disciplines, a literature review pointed out significant discrepancies in measuring (or more often simulating) approaches, used to both characterize acoustic and ventilation performances. Thus, published results are often difficult to compare. Starting from a preliminary subdivision of the metamaterial-based solutions into micro and macro-scale approaches and taking into account existing standardized procedures in use in acoustics and (more broadly) in building regulations, the present work investigates which might be the most reliable and appropriate techniques. This might represent a first important step towards defining consensus procedures and metrics to be used in acoustic metamaterial research, allowing for fully comparable results.

Keywords: ventilation, acoustic metamaterials, windows

1. INTRODUCTION

In recent years, ventilated acoustic metamaterials have emerged as promising candidates for novel window structures that attenuate transmitted sound waves while ensuring ventilation [1]. In urban areas, integrating metamaterials into window frames or glass can absorb or redirect traffic noise, enhancing indoor environmental quality by reducing sound transmission.

However, the design of acoustic metamaterials can be fine-tuned to balance noise control and airflow, ensuring proper air circulation. To this purpose, their ventilation performance should be carefully evaluated. A literature review [2] highlighted a critical lack of consistent metrics for assessing the ventilation properties of acoustic metamaterials. Additionally, the limited number of researchers studying ventilation performance resulted in further complicating comparisons among published results.

The real difficulty is to quantitatively determine the ventilation performance of the metamaterial unit. Most studies simply report open area or airflow resistance, without a consistent framework that defines how and where to measure the pressure difference, its magnitude, or how to evaluate the airflow rate.

A common method for evaluating the ventilation performance of metamaterials is to analyze the pressure drop across the material when an airflow occurs. The general idea is that, according to Bernoulli's equation, a change in velocity implies a change in pressure. In this way it is possible to evaluate the air flow resistance of the material. Higher-pressure drop indicates higher resistance offered by the material, reducing the efficiency of the ventilation system. Kumar et al. [3] showed the pressure drop versus flow rate characteristics for different opening percentages, registering an increase in the required pressure drop with increasing in airflow rate. A similar approach is followed by Fusaro et al. [4] and Kumar et al. [5] who analyzed the required pressure drop across the opening by varying the inlet airflow velocity. However, all authors studied the pressure drop resulting from modifying the opening percentage verifying that smaller openings offer high air flow resistance, establishing a high air pressure

drop across the window by wind and buoyancy forces. Dong et al [6] and Xiang et al [7] generated the air flow by an electric fan installed at the inlet of a tube containing the metamaterial in the middle section. The sample, obstructing the movement of air, reduces its velocity which is measured by an anemometer placed at the outlet of the tube.
To overcome the limitations related to the lack of a defined approach, this research aims to propose a methodology for testing the ventilation properties of metamaterials at the laboratory scale.

2. EXISTING STANDARDIZED METHODS

A survey of existing standards identifies three key metrics for characterizing and comparing ventilated metamaterials: airflow resistance *Rs*, discharge coefficient *Cd*, and air change rate *ACR*. *Rs* value evaluates pressure drop across a porous material, *Cd* value assesses efficiency through openings under varying pressures, and *ACR* value expresses basically the same concept but with reference to the room volume and under well defined pressure drop. Despite their different purposes, each test relies on measured pressure differences and air flow rate to calculate the figures of merit.
Specific airflow resistance is a key parameter in determining the acoustic properties of a material, as it measures how easily air can pass through it. According to ISO 9053-1 [8], *Rs* is defined as the ratio between the pressure drop Δp and the linear flow velocity w of air inside the testing rig:

$$Rs = \frac{\Delta p}{w} \quad (1)$$

A steady air source generates unidirectional laminar airflow through a cylindrical sample at velocities as low as 0.5 mm/s. A differential manometer, measuring down to 0.1 Pa, records the pressure drop to determine specific airflow resistance.
Standard EN 13141-1 [9] proposes a method to calculate the air flow rate value by gradually increasing the pressure difference across the device. The method involves the application of various static pressure differences (1–100 Pa) to an air transfer device, while measuring the corresponding volume flow rates and defining the flow rate vs pressure characteristic curve. Depending on the device type, 8 to 12 pressure measurement points are taken. The *Cd* can be obtained by regressing the measured values according to a generalized flow equation:

$$q = C \cdot \Delta p^n \quad (2)$$

where q is the volume airflow rate, Δp is the pressure difference, n is the flow exponent (n = 1 for laminar flow, n = 0.5 for turbulent flow) and C is the airflow coefficient.
The discharge coefficient is a dimensionless coefficient commonly used to characterize openings by quantifying the reduced flow resulting from the formation of the so called "vena contracta". It reflects the deviation of the actual flow rate from the ideal flow rate, accounting for factors like the geometry of the window opening, surface roughness, and turbulence. By analyzing the pressure difference across the opening and measuring the airflow, it is possible to calculate the coefficient *Cd*, which gives insight into how effectively air passes through the opening under specific conditions.
Mathematically, it is expressed as:

$$Cd = \frac{q_{actual}}{A} \cdot \sqrt{\frac{\rho}{2\Delta P}} \quad (3)$$

ISO 9972 [10] evaluates building infiltration rates through the measurement of the *ACR* value. The test is based on pressurizing or depressurizing the building using a fan to force airflow through the envelope. Airflow is measured at pressure from 50 Pa to 100 Pa. *ACR* is calculated by dividing the air leakage rate at 50 Pa *q50* by building volume V:

$$ACR = \frac{q_{50}}{V} \quad (4)$$

3. TOWARDS A UNIFIED APPROACH

Standardized methods previously analysed measures the same quantities (pressure differences and volume flow rate or average air velocity across the opening section), but they derive different parameters. In order to characterize the air permeability of ventilated metamaterial units (i.e. devices individually tested in a small equipment like standing wave tubes but intended for use in planar or spatial arrays), none of the test procedures fits perfectly In fact, flow resistance tests are suitable for porous materials with low-velocity laminar flow (≤15 mm/s), but may fail to detect pressure variations in open structures. Conversely, EN 13141 [9] method can induce turbulence in small metamaterial openings. Considering that it is known from the theory [11] that the pressure variation can be expressed as a function of the volume airflow (q) (and consequently of the mean velocity w across the section) as the sum of a linear and a quadratic term respectively representing the laminar and the turbulent component:

$$\Delta p = a \cdot w + b \cdot w^2 \quad (5)$$

Some authors also express the above relationship taking into account that the linear term related to laminar flow

($Re < 1000$) is strongly influenced by viscous losses, equivalent to the airflow resistance and quantified using the Hagen-Poiseuille equation [12] that assumes, for a circular orifice having radius *r* and length *L* and resulting in an open fraction $\phi = A_{open}/A_{tube}$:

$$a = R_s = \frac{8\eta L}{r^2 \phi} \quad (6)$$

where η is the fluid viscosity.

On the other hand, the second term applies to turbulent flow ($Re > 2000$) and can be expressed as a function of the inertial losses depending on the opening geometry, flow separation, etc., whose combined effect is given by the loss factor ($\xi = 1/Cd^2$) applied to the pressure variation resulting from the Bernoulli equation:

$$\Delta p = \frac{\zeta \rho w^2}{2} \rightarrow b = \frac{\xi \rho}{2} \quad (7)$$

Thus, the equation can be rewritten as a function of *Rs* and *Cd* as follows:

$$\Delta p = R_s \cdot w + \frac{\rho}{2C_d^2} \cdot w^2 \quad (8)$$

The two terms could be consequently determined from a proper regression analysis performed over a sufficiently large interval of *w* values, capable of keeping into account different flow rates, and, consequently, different Reynolds numbers (Re). However, as turbulence needs space to fully develop, in short openings it is not obvious that this condition takes place even at higher *Re*. Conversely, presence of sharp edges may promote flow separation and turbulence even at lower *Re*.

It is worth noticing that the standard procedure to determine air flow resistance is based on plotting *Δp* as a function of *w* and then fitting the values with a quadratic equation. Subsequent calculation of *Rs* as $\Delta p/w$ and plotting as a function of *w* should consequently return a linear distribution where the constant term coincides with the *Rs* term in Eqn. 8 which, consequently, corresponds to flow resistance when flow tends to zero.

In a similar way, collected data about pressure drops and flow rate might be directly used to calculate *Cd* for each combination. It is known from the theory that *Cd* is generally dependent on *Re* (or *w*) and becomes independent when high *Re* values are reached, while at low values viscous and laminar effects tend to reduce the value. As a consequence the EN 13141 [9] suggests to plot the values and use a power law for interpolation, assuming that, in the most general case, under fully developed turbulent flow the previous equation may not apply. However, if Eqn. 5 is assumed to be valid, it is possible to replace *Δp* in the *Cd* equation, which yields, after some steps:

$$C_d = w \cdot \sqrt{\frac{\rho}{2\Delta p}} \rightarrow C_d^2 = \frac{1}{a + \frac{2b}{\rho w}} \quad (9)$$

From which it appears that the *Cd* value appearing in Eqn. 8, and obtainable from the regression analysis, is actually corresponding to the limiting value towards which *Cd* tends when *w* grows.

In other words, plotting data and calculating regression parameters is consequently the best way to understand whether the data can fit the model represented by Eqn. 8 or more complex turbulent flows appear.

4. NUMERICAL VALIDATION

In order to test whether the proposed approach could be conveniently applied in practice, a "virtual experiment" was carried out using Comsol 6.3 and, considering that most experiments on ventilated metamaterials are carried out on simple "units" that are tested in impedance tubes, a comparable setup was explored. A simple metamaterial employing a labyrinthine structure built around a square opening [13] was modelled. A 3D printed sample of the same design was tested according to the ISO 9053-1 method [8] without success due to the very low pressure drops that appeared. So the device was modelled in Comsol and, for the sake of simplicity, only the open square was modelled. Square dimensions were 14 mm by 14 mm and 8 mm height. Inlet and outlet tubes were modelled as 60 mm cylinders long enough to let the streamline as regular as possible (Fig. 1).

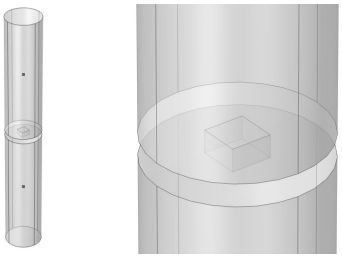

Figure 1. Schematic of the simulation set-up.

A pressure drop ranging from 0.1 Pa to 20 Pa was modelled obtaining the flow velocity distribution given in Fig. 2. Extraction of the parameters from the coefficients of the regression curve returns a Cd = 0.055 which is well aligned with analytical results given by Idelchick [16], while *Rs* shows bigger fluctuations compared to the theoretical value returned by Eqn. 4 and equal to 0.3 Pa.s/m. Extraction of values based only on the lowest *Δp* values and an increased number of

simulation points in that range, significantly improved the accuracy.

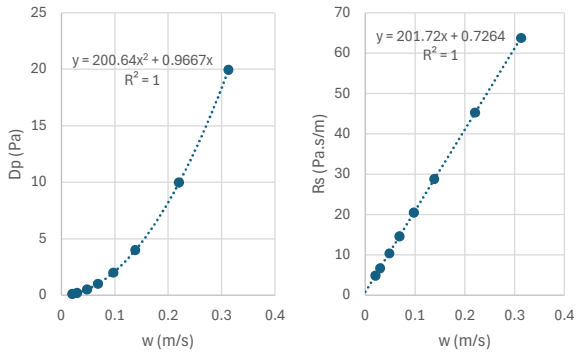

Figure 2. Velocity *w* versus Pressure drop *Δp* and air flow resistance *Rs*.

5. CONCLUSIONS

The method proposed by ISO 9053-1 can be considered, with the proposed amendments, a valid alternative for evaluating the ventilation performance of a metamaterial unit. In fact, the necessary adjustments to the velocity and pressure difference ranges make it suitable for applications with open structures and collected data can be interpreted obtaining representative parameters (Rs and Cd) that could ease comparisons among different devices.

ABSTRACT

Reducing traffic noise in urban environments has a proven positive effect on the wellbeing. It is known that sound absorbing façades can improve the noise level in streets and courtyards, but practical large-scale surface treatments are scarce. Porous absorbers are typically bulky, and resonant absorbers too expensive for this kind of application. We have shown previously that perforated mineral foams (PMFs) yield high sound absorption levels over a relatively wide frequency range, while requiring only a fraction of the thickness of open-pore absorbers. In this work, a multi-layer PMF absorber is demonstrated. In a first step, the optimal configuration of four PMF layers with a total thickness of 55 mm is shown to yield high diffuse-field sound absorption in the 500-1000 Hz range. Based on this result, a 12 m^2 surface is manufactured and its absorption coefficient measured in a reverberation room. Finally, the demonstrator is tested in realistic conditions, and shows a significant reduction of broadband noise transmission through a courtyard entrance. The controlled measurements are supported by finite element simulations to improve their effectiveness by optimal placement considerations.

1. INTRODUCTION

Acoustic absorbers are crucial in creating a pleasant environment. By reducing reflections and reverberation time, the overall noise level can be lowered, the intellegibility improved, or the musical quality enhanced [1]. Acoustic absorbers also play a crucial role in reducing engine, turbine, and ventilation noise. This paper presents a method to achieve high diffuse acoustic absorption in a chosen broad frequency range. Using an optimized layering of perforated mineral foams, the absorber can be devised considerably thinner than when conventional porous media are used. The effectiveness is illustrated with a large-scale demonstrator, designed to reduce street noise transmission through a courtyard entrance.

2. ACOUSTIC ABSORPTION BY PERFORATED FOAMS

2.1 Homogenization of the acoustic properties

The use of perforated rigid foams for low-frequency sound absorption was shown in previous studies [2, 3]. By combining foam properties (pore size and wall thickness) with an appropriate perforation pattern (diameter and spacing), the absorption spectrum can be tuned to a desired frequency range. The modelling is done in two steps. First, a numerical simulation of a representative volume element of the perforated foams allows us to calculate homogenized fluid properties, i.e. complex valued bulk modulus and mass density, based on the Johnson-Champoux-Allard description of viscous and thermal losses [4]. In a second step, a combination of the four foam parameters is chosen to achieve the desired absorption spectrum.

In our previous work, we showed that the tortuosity of such structures is considerably higher than for open-pore

foams [3, 5]. However, high tortuosity typically comes at the cost of higher flow resistivity. Therefore, a compromise between absorption amplitude and the frequency of maximum absorption has to be found. It is practically possible to achieve absorption levels higher than 0.8 for a layer thickness equal to or smaller than 1/15 of the wavelength in air. This is similar to several advanced absorber designs based on coiled or resonant structures.

2.2 Optimization of layered sound absorbers

The homogenization step allows to generate a library of acoustic materials with various sound propagation properties. In collaboration with a foam manufacturing company, de Cavis AG, gypsum foams with pore sizes varying between 1 and 3 mm, and a constant wall thickness between 0.1 and 0.3 mm, can be reliably produced in batches of 1 m^3. Due to advanced stabilizers, a total porosity higher than 90% can be achieved, yielding a mass density below 150 kg/m^3 for the lightest materials. The foams are cut to the desired thickness, and can be perforated by needle punching or water jet cutting.

It is known that layered sound absorbers can outperform homogeneous porous media in terms of thickness and band width [6,7]. For our application, we aim for high sound absorption in the range between 400 and 1000 Hz. To achieve this, we can use three foam types, combined with several perforation patterns. The perforations can be either 0.5 or 1 mm in diameter, and 5 or 10 mm apart in a rectangular pattern. In total, ten combinations have desirable acoustic properties and are considered useful for the absorber design.

The optimization process aims to achieve a minimal absorption level within prescribed frequency bounds, by finding a suitable stack of materials with optimized thickness and order. Limitations such as total thickness, minimal layer thickness, and maximum amount of layers can be easily introduced. The absorption of the rigidly backed stack is calculated by a transfer matrix approach, and the optimization is done by a particle swarm optimization. To further improve the design space, air is allowed as one of the layers.

3. LARGE ABSORBER DEMONSTRATOR

3.1 Optimized absorber layout and construction

For a practical implementation, we aim for absorption levels higher than 0.8 starting at 400 Hz and up to 1000 Hz. The absorber stack should not be thicker than 55 mm, which is thinner than 1/15 of a wave length in air and thus considerably thinner than traditional porous absorbers. In order to reduce fragility, the layers should not be thinner than 10 mm and the amount of layers cannot be higher than 4.

Figure 1. Top: layered setup of the opimized absorber panel. Bottom: Placement of the absorber panels in the courtyard entrance.

Several combination of layers yield a suitable absorption spectrum, and further practical considerations can be taken into account for the final choice. In this case, it turns out that only one foam type is necessary: a lightweight gypsum foam with 3 mm pore size and 0.1 mm wall thickness. Combining one type of perforated and one non-perforated layer, in which case only the inherent microporosity is considered, the prescribed absorption can be achieved. The layers are cut to size and placed in wooden frames for easy transportation and placement. In total, 72 panels of 40×40 cm^2 are made, yielding a 12 m^2 surface. Each panel weighs less than 1.5 kg and has a total thickness of 57 mm, making it ideal for treating walls without increasing the demands on bearing capacity, or taking too much space. the structure of the panels is shown in Fig. 1.

3.2 Reverberation room measurement

In order to validate the optimization and the models, the diffuse sound absorption is measured according to EN ISO 354. The entire sample is placed on the floor of a reverberation room, including the beams that will be used for installation in situ (see Fig. 2). This slightly increases the total surface, and therefore reduces the diffuse absorption coefficient. Despite this small difference, it can be seen in Fig. 2 that the absorption reaches a peak value of 1.1 at 400 Hz. At frequencies higher than 1200 Hz the absorption is reduced, since the stack was not optimized in this range. This is however not necessarily negative. In many real situation, the higher frequency range is sufficiently absorbed by other effects, and additional absorption might reduce intellegibility and could make the room sound too dry.

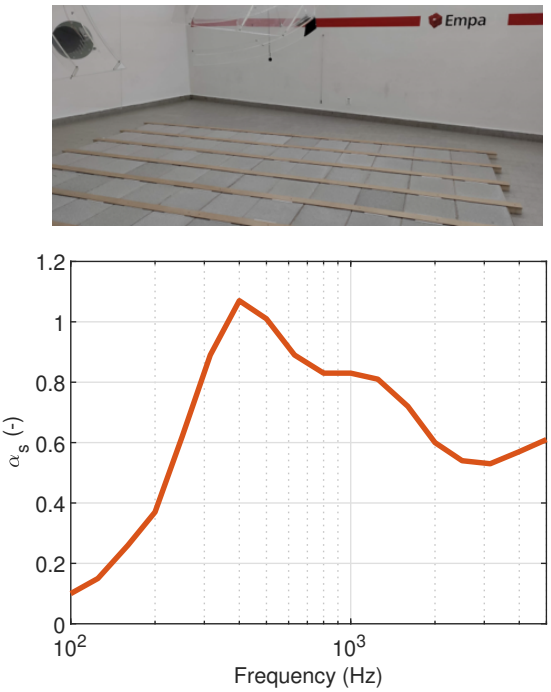

Figure 2. Diffuse absorption coefficient measurement according to EN ISO 354. Top: experimental setup in the Empa reverberation room. Bottom: measured absorption curve.

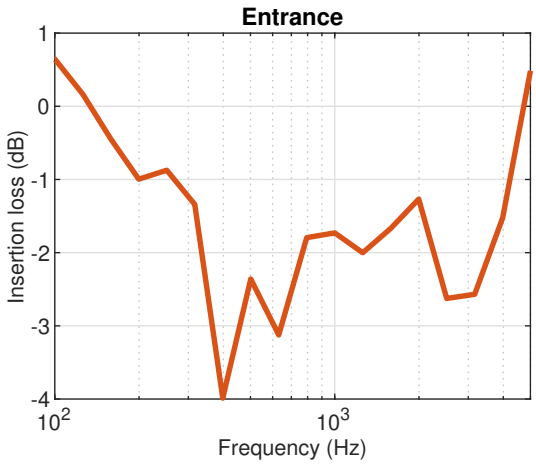

Figure 3. Measured insertion loss comparing the sound transmission through the entrance with and without absorber panels.

3.3 Noise transmission reduction in a courtyard entrance

The efficiency of the absorber panels to reduce street noise transmission is tested in a passage to a courtyard with dimensions 3 × 3 × 12 m^3. The panels are placed on both side walls in a symmetric way, close to the street side entrance, in a 3 × 12 panel arrangement. This way, 1.2 × 4.8 m^2 of each wall is covered, which is around 1/6 of the walls' surface. The final setup is shown in the bottom image of Fig. 1.

Pink noise is generated by an omnidirectional loudspeaker, placed 3 m away from the entrance, and measured by microphones placed at the entrance and exit of the passage. To mimic a car pass-by, the loudspeaker is moved parallel to the street, starting in the middle of the passage and spanning 6 positions with 0.5 m steps. The sound transmission loss is calculated as the transfer function between the entrance and exit in third octave bands for each loudspeaker position, for the situation with and without absorbing panels. Finally, the insertion loss is calculated as the difference between the situations with and without absorbers of the mean SPL.

The correlation between the insertion loss and the diffuse sound absorption spectrum is clearly seen in Fig. 3. At the frequency of maximum absorption, an insertion loss of 4 dB can be measured. At very low (¡200 Hz) and at very high (¿4000 Hz) frequencies, the insertion loss is minimal.

4. CONCLUSION

Layered sound absorbers consisting of perforated mineral foams can be optimized to achieve broadband high absorption, while only needing a fraction of the thickness of conventional porous absorbers. Since the base material is a mineral foam, their application is similar to standard absorbing materials, and they can be fabricated in bulk. Moreover, mineral foams offer unique properties, e.g. external use (in case of cement foams), or high-temperature environments (in case of ceramic foams). A large demonstrator of 12 m^2 allowed us to confirm the validity of the optimization by standardized absorption testing. Moreover, it was possible to measure a 4 dB sound transmission reduction in realistic conditions, showing that effective acoustic treatments can be realized with thin structures.

A Study on the Prediction Method of Bush Dynamic Characteristics in Used and High Frequency Domain

Young Eun Ahn[1]

[1] Hyundai Motor Company, Korea

ABSTRACT

As electric vehicles become more prevalent, NVH (Noise, Vibration, and Harshness) performance requirements extend into higher frequency bands (1 kHz and above) due to motor excitation characteristics. Performance verification is often conducted at the concept stage using virtual models. In the medium and high frequency ranges, where mode density is high, NVH problems are typically addressed by reducing the response magnitude rather than designing for mode avoidance. This highlights the critical role of the bush system. However, obtaining bush characteristics that accurately capture the high frequency response remains challenging. This study performs a dynamic stiffness analysis of bushes using a three-dimensional finite element (3D FE) model to validate the approach and explores a method for extending the analysis to the medium and high frequency domains for direct application in vehicle development.

Keywords: NVH Performance, Bush and Mount System, Dynamic Stiffness, Rubber, System Analysis, Prediction Methodology

1. INTRODUCTION

Recently, in the automotive industry, performance evaluations extending to high frequency bands of 1 kHz or more have become necessary for NVH performance, due to motor excitation characteristics and the shift to electric vehicles. Unlike low frequency bands—which check mode frequencies to avoid resonance—medium and high frequency bands have high mode density. Therefore, NVH issues are generally addressed by reducing the magnitude of the response rather than by designing to avoid specific modes. This necessitates the efficient design of vibration-proof and sound-absorbing materials within a bush system or a final response system that reduces vibration transmission through insulation during electric vehicle development.

Performance verification is carried out at the conceptual stage using virtual models to secure target vehicle performance early. In particular, bush characteristics represent a critical factor that often conflicts with both NVH and ride & handling (R&H) performance. Thus, it is important to promptly evaluate NVH performance in a design review that meets both criteria.

In a typical bush virtual model for predicting NVH performance, the dynamic characteristics for six degrees of freedom are represented as constants using a spring element. These dynamic properties are usually derived by applying a lump sum multiplier—typically 1.5 or 2 times—to the static characteristic design targets. Additionally, when the developed bush is applied to a new vehicle, dynamic properties measured at a specific frequency (usually 100 Hz) from test reports are used. Although this method offers a simple approach for constructing a performance prediction model during the design stage, it is somewhat insufficient for addressing vibration noise problems that require precise frequency response characterization. Moreover, while test reports typically provide dynamic characteristics in the translational direction (owing to test equipment limitations), evaluating dynamic characteristics in the rotational direction remains challenging.

Furthermore, although recent dynamic characteristic test equipment can evaluate up to approximately 1 kHz, obtaining bush dynamic data at this frequency is not

*Corresponding author: ahnyoungeun@hyundai.com

straightforward. More importantly, to address NVH issues arising from electric vehicle motor excitation forces, bush characteristics at even higher frequency ranges (e.g., 1.5 to 2 kHz) are required.

To overcome this limitation, a bush dynamic analysis method using an FE model was investigated to achieve a high correlation between test and analysis results. However, securing accurate rubber material properties—which critically influence the analysis—proved difficult, rendering the method unsuitable for immediate application in vehicle development.

In this study, a bush dynamic analysis using a 3D FE model was conducted to verify its accuracy, and a method applicable to actual vehicle development—with extension to the medium and high frequency domains—was explored.

2. MAIN TEXT

2.1 Rubber properties for analysis

In order to determine the characteristics of the bush through analysis, the following analytical properties, obtained from rubber specimen tests, are required:

1. Static Properties: Strain-energy function and material constants for expressing hyper-elastic behavior.
2. Dynamic Properties: Storage modulus and loss factor for viscoelastic characterization.
3. Poisson's Ratio.

Conventional elastic materials, such as metals, exhibit linear elastic behavior, meaning that they maintain a proportional relationship between load and deformation and return to their original state once the load is removed. In contrast, rubber materials exhibit elastic behavior even under large deformations where the relationship between load and deformation becomes nonlinear; this behavior is known as hyper-elasticity. When the strain-energy function is modeled as a polynomial that accurately represents this behavior, and the corresponding material constants are determined through tensile and compression tests on the rubber specimen, these properties can be used for analysis. In this study, the hyper-elastic behavior is modeled using the Yeoh function, as illustrated in Figure 1.

$$U = \sum_{i=1}^{N} C_{i0}\left(\bar{I}_1 - 3\right)^i + \sum_{i=1}^{N} \frac{1}{D}\left(J^{el} - 1\right)^{2i}$$

Yeoh (N=3)	Ci0	D
i=1	security	
i=2		
i=3		

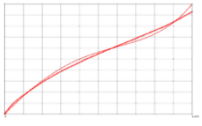

Figure 1 Hyper-elastic Material Constants of Rubber

Viscoelasticity refers to the coexistence of viscosity and elasticity in a material. Unlike metals, rubber materials dissipate energy through internal friction. This behavior is characterized by a complex modulus comprising two components: the storage modulus and the loss factor. These parameters are obtained by subjecting rubber specimens to dynamic strain testing. In this study, the storage modulus and loss factor measured up to 300 Hz, as shown in Figure 2, were used.

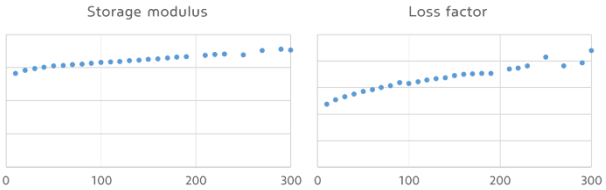

Figure 2 Complex Elastic Modulus of Rubber

Since rubber materials are generally considered to be nearly incompressible, a Poisson's ratio appropriate for this is used.

2.2 3D Bush Dynamic Characteristics Analysis Accuracy Verification

The accuracy of the 3D FE analysis was verified using a G BUSH component from a midsize sedan, which allowed for accurate rubber material characterization. Based on the physical property evaluation of the rubber specimen, the rubber properties used in this analysis included the viscoelastic (hyperelastic, Yeoh model) modulus and the viscoelastic modulus and loss factor measured up to 300 Hz. The static properties of the G BUSH were determined by averaging the stiffness between displacements of 0.5 mm and 2 mm, and the error defined as the difference between the test report and the analysis results is at the level of 7%.

For the dynamic characteristic analysis, although the viscoelastic properties of the rubber specimen were evaluated up to 300 Hz, the analysis was performed at 100 Hz for accuracy verification. The corresponding analysis results were compared with the test report values. As illustrated in Figure 4, the static characteristics in the translational direction were predicted with a maximum error of 7%. Regarding the dynamic characteristics, although the Q direction could not be compared due to the absence of test data, the errors in the P1 and P2 directions were 2% and 14%, respectively, indicating that the dynamic characteristics were predicted with an error within 15%. In the rotational direction, the error in the static characteristics was relatively larger—up to 24% compared to the translational direction—

but this is considered acceptable given that dynamic evaluation in the rotational direction is not feasible, and the analysis method provides values under conditions similar to those used in the static evaluation with high accuracy.

S2				-			
R				22%			

Figure 4 Comparison of Test/CAE results and errors in all directions

2.3 2.3 Problems and Hypothesis Establishment and Verification

For conventional elastic materials such as metals and glass, "standard physical properties" are typically used to predict performance under uniform conditions, regardless of variations in vehicle type or the personnel responsible for the virtual model. In contrast, due to significant variations in rubber material properties—dependent on material type, mixing ratio, and manufacturing process—it is challenging to adopt a single set of standard physical properties for rubber. When accurate rubber properties corresponding to the manufactured parts (such as those of the G BUSH in a medium-sized sedan) are available, bush characteristics can be predicted within the test error range. In particular, using viscoelastic properties that incorporate frequency characteristics enables the development of bush models that accurately reflect NVH performance.

However, it is impractical to secure all the appropriate rubber material properties for every bush, given the wide range of bush types, manufacturers, hardness levels, and other factors present in actual vehicles. To address this limitation, the hypothesis was proposed that if the ratios of the characteristics in all six degrees of freedom are proportional to the shape of the rubber part, the primary characteristics could be determined using the available properties. Consequently, it was hypothesized that the static and dynamic characteristics in all directions could be obtained through post-processing of the test results available in some directions. The conceptual diagram illustrating this approach is shown in Figure 5.

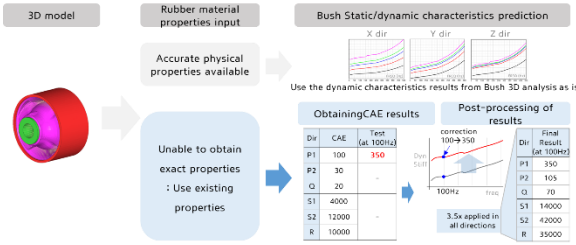

Figure 5 Conceptual diagram for predicting characteristics of Busch 3D analysis

For verification, the previously validated G BUSH model of a medium-sized sedan was employed. The analysis was performed using rubber material properties obtained from other manufacturers that did not match the properties used for the G BUSH model. As shown in the left table of Figure 6, the positive characteristics in the translational and rotational directions exhibited errors of 38% and up to 58%, respectively, compared to the test report.

To adjust for these discrepancies and align the analysis results more closely with the test report, a correlation coefficient of 0.79 was derived by dividing the test report value (237) in the P2 direction by the analysis result (300). This coefficient was then applied uniformly to the basic analysis results in all six directions, as illustrated in Figure 7. The adjusted results yielded a final error of up to 9% in the translational direction and up to 28% in the rotational direction, which is comparable to the results obtained using the accurate rubber properties for the actual G BUSH (with errors of up to 7% and 24% in the translational and rotational directions, respectively).

Fig. 6 G BUSH Static Characteristics Results

Figure 7 Prediction Results of Using and Aftertreatment of Physical Properties

To extend the validated hypothesis to various types of bushes, the static characteristics of all bushes in a small SUV were evaluated using the same methodology previously applied to the G BUSH of a medium-sized sedan. First, the primary direction—typically the VOID direction (P2) or the axial direction for a shock absorber bush—was identified. The ratio of the test report value to the analysis result in this primary direction was then used as a correlation coefficient, which was uniformly applied across all directions.

Figure 8 presents the static and dynamic characteristics calculated using the proposed method. For static characteristics, the final adjusted results closely matched those from the test report. For dynamic characteristics, values for the remaining five directions—where test data were unavailable—were successfully obtained. Notably, both the static correlation coefficient (c = a/b) and the dynamic correlation coefficient (C = A/B) were determined to be 1.3, an observation that merits further attention.

	dir	Static				Dynamic

	R								

Figure 8. Prediction Results of G BUSH Static and Dynamic Characteristics of Small SUV

Since the dynamic characteristic correlation coefficient cannot be determined without results from the dynamic test report (as illustrated by the strut insulator in Figure 9), the final static characteristic value (d) was first calculated using the static characteristic correlation coefficient (c = a/b), as described above. The final dynamic characteristic value (F) was then obtained by multiplying this static value (d) by the dynamic ratio (E = B/b) between the static and dynamic characteristics.

	Dir	Static				Dynamic		
		Test (a)	CAE (b)	Correlation Coefficient1 (c=a/b)	Static (d=b*c)	CAE (B)	Ratio (Dynamic/Static) (E=B/b)	Dynamic (F=d*E)

Fig. 9 Prediction method of FR STRUT INSULATOR static and dynamic characteristics of a small SUV (1)

However, given that the static and dynamic characteristic correlation coefficients derived from the G BUSH results for the small SUV (as shown in Figure 8) are identical, the final dynamic characteristic can be calculated as illustrated in Figure 10. This result is consistent with the final dynamic characteristic obtained in Figure 9.

Figure 10. FR STRUT INSULATOR Static and Dynamic Characteristics Prediction Method (2)

Based on two prediction methods—one utilizing the dynamic test report and one without—it was possible to predict both static and dynamic characteristics for a total of 10 bushes in small SUV vehicles, and compare them with the test report. Although verifying the accuracy of dynamic characteristics is challenging—since most bushes provide test data for only one major direction—the excellent prediction accuracy for static characteristics, using the same model and analysis method, suggests that the derived dynamic characteristic values are reliable for use in the NVH performance review model.

2.4 Dynamic Properties Prediction Frequency Extension and Application Method

Finally, an approach was reviewed to expand the frequency range over which dynamic characteristics can be predicted. Since the viscoelastic properties of the rubber specimen are measured only up to 300 Hz, the bushing characteristics for a single component are likewise limited to this range. Due to equipment limitations, evaluating material properties at higher frequencies is challenging. Therefore, a linear extrapolation method was employed to extend the available physical property data into the higher frequency domain.

As illustrated in Figure 12, the linear trend of the storage modulus as a function of frequency is first extracted from the measured data (up to 300 Hz). This trend is then extended into the desired higher frequency range, with the measured data used directly up to 300 Hz and the extrapolated data applied beyond that, as shown in Figure 13. The loss factor was similarly extended to 1000 Hz using the same method.

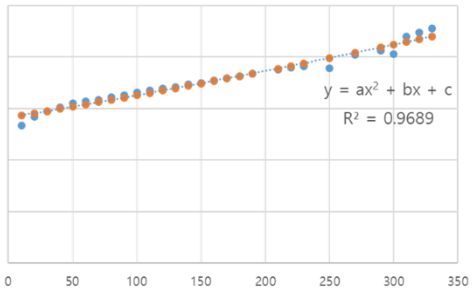

Figure 12 Extracting the Storage Modulus linear trend line of viscoelastic elasticity

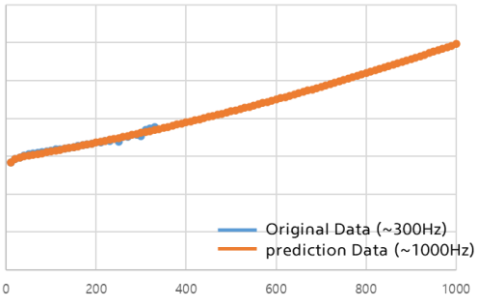

Fig. 13 0~1000 Hz Storage Modulus Prediction Data

The predicted dynamic characteristics of the G BUSH for a small SUV—obtained by extending the rubber properties to a frequency domain of 1000 Hz—are presented in Figures 14.

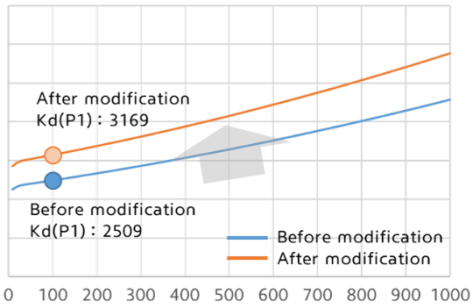

Figure 14 Prediction Results of G BUSH P1 Dynamic Characteristics of Small SUV (~1000 Hz)

3. CONCLUSION

3.1 Conclusion

In this study, we addressed the challenge of obtaining bush dynamic characteristics—required for predicting NVH performance in the middle and high frequency domains—that are difficult to measure in all six degrees of freedom due to limitations of test equipment. To overcome this issue, a 3D shape-based bush dynamic characteristics prediction method was developed, and the following conclusions were reached:

1. Comprehensive Data Acquisition: To improve the accuracy of NVH performance predictions, it is essential to obtain dynamic characteristic values in all six degrees of freedom over the frequency region of interest and incorporate these values into the analysis model. By inputting accurate material properties specific to the bush and utilizing its 3D shape, it is possible to predict properties that fall within the test error range across all directions.
2. Use of Correlation Coefficients: When accurate material properties are unavailable for all directions, a correlation coefficient can be derived using dynamic test results from a specific primary direction (obtained via the initial 3D shape-based analysis and previously secured physical properties). This coefficient can then be applied uniformly to estimate accurate dynamic characteristics in all directions.
3. Frequency Range Extension via Extrapolation: Even when viscoelastic material properties of the rubber specimen are evaluated, securing data up to the desired high frequency range remains challenging. In such cases, extending the measured material property data to the required frequency range via linear extrapolation enables the calculation of bush dynamic characteristics over the higher frequency domain.

Overall, the study demonstrates that predicting bush dynamic characteristics in the middle and high frequency domains using a 3D shape-based approach is a promising method. This approach effectively overcomes equipment limitations and reduces time and cost constraints, ensuring that sufficient dynamic characteristics can be secured for accurate NVH performance evaluation.

MEASUREMENTS OF THE ACOUSTIC PROPERTIES OF MYCELIUM-BASED MATERIALS USING AN IMPEDANCE TUBE

György Wersényi[1*] **Zsófia Németh**[1] **Attila Schweighardt**[2]
[1] Department of Telecommunications, Széchenyi István University, Hungary
[2] Department of Whole Vehicle Engineering, Széchenyi István University, Hungary

ABSTRACT

Mycelium-based materials were tested for acoustic purposes. Different fungi were grown on substrates and formed to fit into the available impedance tube for transmission loss (TL) and absorption rate (AR) measurements. Results supported previous findings about mycelia being acoustically appropriate for sound insulation, especially in the spectral region of speech. Absorption rates between 0.1 and 0.6 were measured. Furthermore, thickness appears to be the most important factor. However, large-scale production, design, and lifespan are critical issues, and further experiments are needed to develop industry-level products.

Keywords: *transmission, impedance tube, speech intelligibility, mycelium, sustainability*

1. INTRODUCTION

Acoustic paneling for room acoustic or automotive solutions incorporate various materials. These are generally foams, porous structures with high absorption coefficients allowing for acoustic damping and isolation in many application areas. On the other hand, the use of natural materials can contribute to sustainability. Especially, biodegradability plays a significant role in environment friendly production and recycling. It is the capability of a material to be broken down by living organisms, such as bacteria, fungi, or water molds, and reabsorbed by the natural environment.

1.1 Mycelium as material

The mycelium is a root-like structure of a fungus consisting of a mass of branching, a network of fungal threads or hyphae. Mycelia often grow underground, but can also thrive in other substrates. The fruiting bodies of fungi, such as mushrooms, can sprout from a mycelium.
To create the optimum substrate for culturing and breeding, a temperature of 18-25 Celsius, HEPA-filtered air, and a sequentially operated mixer are needed. An additional cold vaporizer with hydrogen peroxide would be an innovative solution in optimization. In the substrate, the mycelium will grow and penetrate 1-4 weeks in case of constant temperature. For the substrate, different materials can be used - i.e., hemp, sawdust, wood waste, coffee-ground - anything with high cellulose content. The substrate must be pasteurized, free from fungicide materials and other fungus (this happens in heat stress for several hours around 80°C), and dried on air or in a heated oven. In contrast to usual materials, mycelium is different in production, storage and design. Only a few companies offer industry grade and high quality solutions, e.g., by providing pre-mixed substrate and mycelium [1, 2].
Mycelium has an uneven growth, it is inhomogeneous, especially by contrasting surface and internal part. The substrate (which is generally responsible for the mass) produces larger cavities and gaps that are filled by the mycelium. Some strains of fungus have good water solubility, and thus, the liquid can be sprayed over the substrate. For example, the *Ganoderma* fungi can be breed in big tanks under sterile circumstances (Fig.1.).
At the end, high temperature (overheating) is used to stop the growing process. Forming, cutting and designing can be performed before and/or after the heat stress. For example, if the material is to replace wood or plastic, the overheating

and forming take place in a pneumatic heat press. If the application area is acoustics, a foam-like state without pressing is recommended. Fire, moisture resistance, tension and compression tests are also important for usability [3].

Figure 1. Example of mycelium-based materials of different forms and sizes.

More research is needed to optimize the manufacturing process, especially in larger "industrial" scale in a time- and cost-effective way. Currently, industry-grade production offers a wide range of applications on large scale, especially on the field of packaging [4]. Acoustic paneling is very similar in size and form. Furthermore, on a smaller scale, local production contributes to sustainability (by avoiding long-distance shipping and enabling local recycling), to local employment and individual production.

1.2 Acoustic measurements

The most important material properties to describe acoustic behavior of porous absorbers are tortuosity, porosity, flow resistivity, and surface openness [5, 6]. They can be measured directly with dedicated equipment or indirectly.

There are two main methods to measure acoustic properties (indirect methods). One of them is using a Kundt's tube also known as an impedance tube [7, 8]. The material is located at the one end of a tube, while the other end is closed with a loudspeaker producing a standing wave. Microphones are fixed along the tube, and the acoustic properties can be calculated by the transfer function method. This compares the sound pressure levels as function of frequency. Small sample sizes can be used, but it is assumed to have perpendicular sound incidence, which is usually an invalid assumption in real life environments. The other method is having a reverberant or anechoic room. This is more realistic, but deals with very large sample (and room) sizes.

This paper presents the method of breeding, followed by the acoustic measurement setup to determine the basic acoustic properties. Based on the results, current state and future perspectives will be discussed from the engineering point of view, focusing on the spectral range of speech.

2. MEASUREMENT SETUP

To create the samples, different types of fungal germ were used on different substrates. After 5-6 weeks, six samples were selected for the measurement. Beech wood chip substrate was used for two *Ganoderma* and two *Pleurotus* samples (see Fig.2.). The diameter of the samples shrank from 45 mm to 42 mm after drying, thickness was 36 mm. Two additional *Ganoderma* samples were grown on a mixture of fine beech wood sawdust and hemp junk (thickness only 12 mm). These were then compressed in a heat press, followed by CNC cutting.

Figure 2. Examples of homemade breeding on beech wood chips substrates using *Ganoderma lucidum* and *Pleurotus* in small size for acoustic testing.

In the experiment, the measurement system of the Mecanum company was used. A detailed description of the equipment with a video of the procedure can be found on the homepage [9]. Although the two- and four-microphone methods are the most common, we opted for a three-mic solution (Fig. 3.) [10]. Both absorption and transmission loss could be measured simultaneously. During repeated sessions, all six samples were measured with both sides (flipped) facing the sound source, thus,

12 curves were plotted on AR and TL diagrams, respectively.

Figure 3. The measurement setup with the impedance tube and data acquisition device.

The frequency range was from 115 Hz to 4300 Hz, sufficient for most of transportation noise and speech experiments.

3. RESULTS

Absorption coefficient is measured directly, whilst transmission lost is calculated. In a normal Sound Transmission Loss (TL) test, a sample is placed between two test chambers in the tube. Based on the sound level reduction the material provides and various acoustical characteristics of the test chambers, the TL can be determined. Generally, heavier walls and acoustic barriers have a higher transmission loss than lighter materials.

Figures 4-5 show measurement results of the sound absorption coefficient and transmission loss for all samples on a linear frequency scale. GBSH denotes the thin, GBC denotes the thick *Ganoderma* samples, PBC denotes the *Pleurotus* samples. The numbers and the letter indicates sample number and side.

4. DISCUSSION

There exist only a few products commercially available for acoustic purposes, i.e., the Sinewave panel (diffusor), or the Mogu, based on textile waste substrate with only a thin layer of mycelium on top [1, 2]. As a result, only a few papers are available about acoustic testing, focusing on the role of the substrate mix and density during absorption [5, 11-13]. It was demonstrated that the mycelium performs well in contrasted to conventional materials (plywood, foam, etc.). The measurements were generally between 300 Hz and 4 kHz using road noise for vehicle industry applications. However, this range is also important for building acoustics and speech technology (intelligibility measurements). The main finding is that lower density gives a higher absorption and lower through transmission protection. Denser material results in better through transmission shielding and lower absorption.

In a master thesis, results were presented using two tubes with 100 mm and 29 mm diameter [3]. The upper working frequency for the smaller tube was 6860 Hz, and only 1990 Hz for the larger tube. The measurement was evaluated from 50 to 6400 Hz and 1600 Hz respectively. Results showed good acoustic absorption. Most of the hemp/straw samples performed equally with low effects of thickness and density. Denser and samples with a closed surface showed a shift to the lower spectrum. Increasing density generally improved the absorption until a certain point, and it can contribute to lower fragility as well. Reverberation room results supported the main findings, absorption values were all above 0.8 in the one-third-octave-band 315 Hz and up [3, 14]. Impedance tube tests were not too optimistic; absorption can be even better in reality.

In our measurement, absorption greater than 0.1 can be observed above about 500 Hz, reaching a maximum of about 0.6. There are large differences among the samples and also between the two sides of a sample indicating an inhomogeneous inner structure. Absorption results are noisy below 400 Hz, because the setup was originally optimized for measurements focusing on the 800-3500 Hz frequency range. The results could be improved at lower frequencies by increasing the tube diameter (and with different microphone spacing).

The pressed GBSH samples are more effective at lower frequencies, below 2500 Hz, while the PBC is more linear over the entire range. On the other hand, one PBC sample showed a continuous rise as function of frequency. Large differences are present in the absorption using the same sample reversed, which makes a conclusive evaluation difficult.

TL is a quantification of how much sound energy is prevented from traveling through an acoustic treatment, it is the ratio of the sound energy transmitted through a sample versus the amount of sound energy on the incident side of the material. TL values were calculated from measurement data and show very low level of noise. The thin samples (brown curves) are the least effective, while the thicker samples provide better results. Although there are variations among the samples based on the placement (which side faces the source), thickness seems to be the most important parameter, as expected.

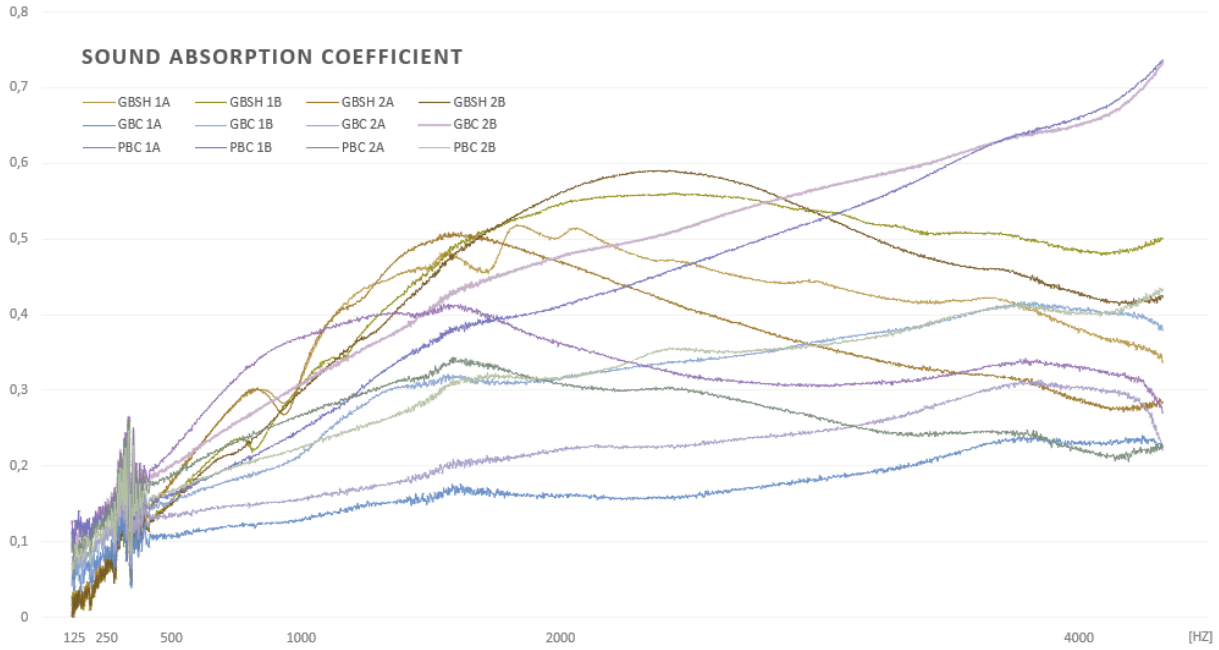

Figure 4. Results of six samples, each with both sides facing the sound source (denoted side A and side B).

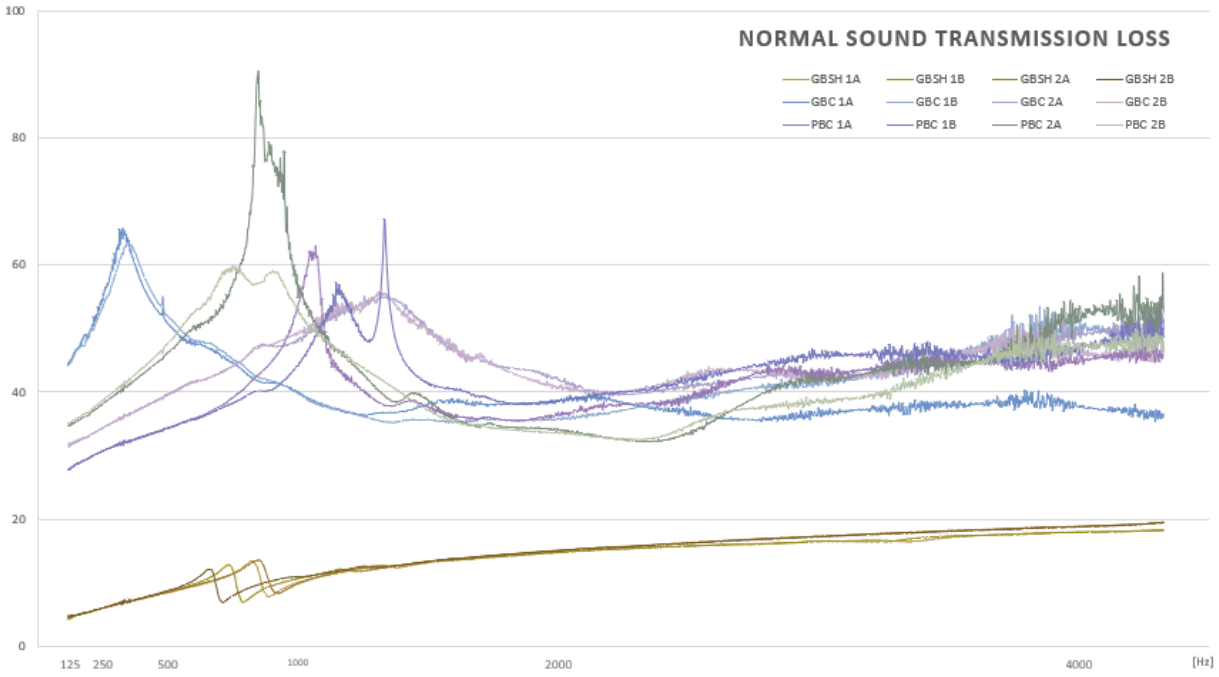

Figure 5. Results of six samples, each with both sides facing the sound source (denoted side A and side B).

4.1 Planting and harvesting

Creating larger size samples and panels takes more time than conventional materials used in sound proofing. Particle size can matter during compression. Using beech saw dust it was shown that reducing the particle size and increasing the compression pressure and/or temperature, results in increasing density that is significant from the point of view of friction [15].
A literature study on material properties shows that acoustic absorption and thermal insulation are suitable functions for this material [16-19]. A designed panel was compared with existing mycelium, other bio-based and more conventional products in terms of acoustics, safety, health, durability, sustainability and price [3]. Balancing acoustic absorption with mechanical properties and connecting the panels to the wall are important issues.

4.2 Future perspectives in sound engineering

Mycelium is a biodegradable material with light weight, good thermal and acoustic properties. On the other hand, samples could be fragile that makes production, design and application (screwing on the wall) difficult [20-23]. Furthermore, the effect of aging is unknown. More research is needed on mechanical properties and optimization, but both building acoustics (speech intelligibility) and automotive industry (traffic noise) could benefit, as the lower frequency range up to 4 kHz can be damped effectively.

5. CONCLUSION

This paper presented impedance tube measurements of acoustic properties of mycelium based materials. Two strains and two different substrates were used for sample sizes with different thickness. Impedance tube measurements were performed for determining the absorption and transmission loss in the 115-4300 Hz range using a 3-microphone method. Differences between the samples showed large variability. Due to the unsymmetrical structure of the samples, measurements were sensitive to the placement of the samples (which side is facing the sound source). Mycelium-based materials can be a good alternative for sound absorbing. Durability (fragility) and lifespan (unknown aging) are the most important problems. Although production is more difficult, sustainability could be a key issue in future developments.

ABSTRACT

Polypropylene is widely used nowadays, generating an important volume of waste that, in general, has a very low recycling rate. This study proposes the use of non-woven polypropylene, discarded in hospital - sanitary uses and not reused for other uses, as an absorbent layer for acoustic ceilings. For this purpose, and in comparison with absorbent layers of mineral wool from international manufacturers commonly used in the construction sector, the combination of thickness and treatment of the waste is sought, which offers the most suitable acoustic absorption coefficient depending on the density for the usual thicknesses used by commercial houses. The results obtained are comparable to or better than those of mineral wool. The study is complemented by a comparative life cycle analysis of both materials, considering the optimal combination of density and treatment of polypropylene waste. This analysis shows an improvement for non-woven polypropylene over mineral wool in all impact categories.

Keywords: *Sustainable materials, Sound absorption, Acoustic ceilings, Life cycle assessment, Polypropylene nonwoven waste.*

1. INTRODUCTION

The challenge of sustainability in the building materials sector leads to the prioritization of the use of environmentally friendly materials to reduce environmental impact. At the same time, comfort standards in buildings constructed today establish acoustic insulation as a fundamental aspect [1-2]. In this line of research Pedroso *et al.* [3] analyse different materials available in the market, concluding that there are alternative materials that, from the point of view of their acoustic behaviour, embodied energy and costs, are a viable alternative to replace those commonly used in the sector.

The use of natural fibres as thermal and acoustic insulation material has been analysed by different researchers [4-6]. However, researchers point out limitations regarding the behaviour of these materials against humidity, parasites and fungi that may make it necessary to spray the fibres with silicones and apply specific treatments, thus reducing sustainability. Another aspect to be considered is the limitation of the fire performance of natural fibres, which must conform to the requirements of the inherent limitations of building materials.

Islam and Bhat [7], jointly analyse different investigations, observing that recycled polyester, wool, cotton and jute fibres have good acoustic absorption properties at medium and high frequencies. With respect to polypropylene, they analyse studies using composite materials (polypropylene (PP) with bamboo, banana, cotton, wool, jute), with the absorption coefficients being more favourable when incorporating PP.

The significant increase in demand for nonwoven fabric products, including PP, was a consequence of the COVID 19 pandemic, although in later years, such as in 2023, with the critical stage of the pandemic over, a growth trend in the volume of this waste generated continued to be observed [8]. As indicated by Karimi *et al*. [9], the good chemical behaviour, low moisture absorption and density, as well as its good thermal and acoustic properties, make PP fabrics a material with potential use in the field of construction. Therefore, the increase in the volume of waste produced, its good acoustic behaviour and the opportunity to give a second life to waste products, focus the interest on the study of PP nonwovens for applications in the field of construction.

In this field, the works carried out by Ali *et al*. [10], Maderuelo *et al*. [11], Fabiani *et al*. [12] and Dehdashti *et al*. [13] should be highlighted. The joint analysis of the four referenced investigations allows us to establish the significant aspects when analysing the possibility of using nonwoven fabric from recycled face masks as an acoustic absorber. The main ones are the following:

- Disinfection treatment: To eliminate biological contaminants only Ali and Maderuelo introduce in their methodology disinfection processes applying temperature on the samples, Ali at 120ºC for 1 h and Maderuelo 70ºC for 30 minutes. In the case of Ali's research, the result of heating at 120ºC is to melt the material generating a rigid sample.

- Sample treatment: Maderuelo crushed short fibres, Fabiani 1x1 cm^2 squares and the samples analysed by Dehdashti are prepared using a fibrous mass to which he adds bio-base binder. Finally, Ali keeps the masks stacked one on top of the other.

- Thickness: The investigations analyse varying thicknesses. Ali 1.2 cm, Maderuelo 3, 6 and 9 cm, Fabiani 0.5, 1, 2 and 3 cm and Dehdashti between 1 and 3 cm with steps every 0.5 cm.

- Density: Expressing densities in g/cm^3, Ali 0.11, Maderuelo, variable for the different thicknesses between 0.05 and 0.15, Fabiani 0.127 and Dehdashti between 100 and 300.

- Test method: In all cases the impedance tube is used.

- Life cycle study: Only Fabiani and Dehdashti analyse the life cycle for the tested material, although they do not compare with life cycles of materials commonly used as acoustic absorbers in construction processes.

As for the results Ali and Fabiani obtain the absorption coefficient α, although in the case of Ali for 580 Hz and Fabiani for 2 kHz. The Sound Absorption Average (SAA) values vary between 0.58 and 0.83 for Maderuelo's tests and between 0.28 and 0.53 for Dehdashti and, finally, only Maderuelo obtains the Noise Reduction Coefficient (NCR=0.60, 0.75, 0.75 values, (density=0.10, 0.07, 0.005 g/cm^3). The values obtained are hardly comparable since the treatments used for the samples are disparate, as well as the thicknesses and densities.
The research work presented here has been developed within the RAECE research project, which analyses the treatment of these materials, with special emphasis on the analysis of the sustainability of the proposal based on the life cycle study in comparison with mineral wool insulation. The full results can be found in the publication by Galindo et al. [14].

2. ACOUSTIC TESTING

For the acoustic analysis, several factors were studied on which the sound absorbing layer depends: disinfection of the waste, its treatment, density and thickness.

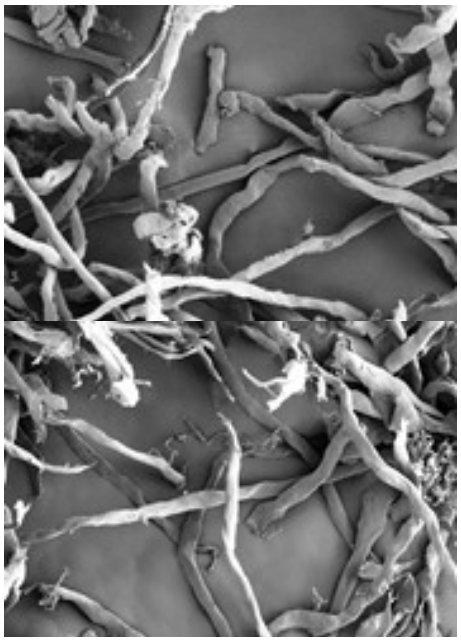

Figure 1. Microscopy. Detail of nonwoven fabric fibre from face masks. Up. Unwashed fabric. Down. Washed fabric.

For disinfection, a treatment with a bleach wash cycle at concentrations between 500 mg/L and 1000 mg/L was chosen [15-17]. In addition, the possibility that the mechanical properties of the material are affected by the washing cycle has been investigated [18]. Fig. 1 shows an electron microscopic scan of fibres of the material used before and after the washing process. It can be seen that the fibres do not undergo a structural change after the washing cycle.

The treatment of the material summarises the two possibilities most commonly used by other researchers, a finish after shredding the sample or its execution in strips (see Fig. 2). For this, a treatment has been carried out that can be faithfully reproduced. In the case of shredding, the RESTCH SM 2000 cutter was used, which produces pieces of material with a fineness of 2 mm. For the strips, an A3 PROFESSIONAL GUILLOTINE from MTEXTIL was used.

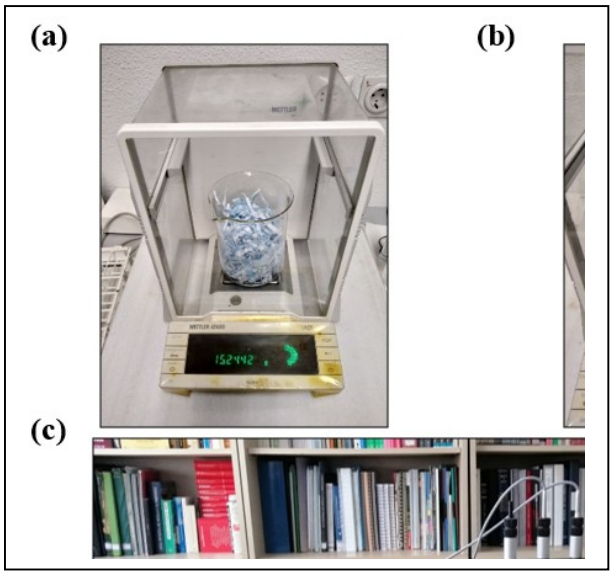

Figure 2. Tested samples. a) Strips of PP, b) Shredded PP, c) Impedance tube and power amplifier.

The density of each treatment is closely linked to the measuring equipment used to determine the sound absorption. An Impedance Tube Kit Type 4206 from B&K has been used (Fig. 2), which combines the material in a fixed diameter portion of the tube, so the densities are limited by this diameter. The layer of material tested must be uniform, without the material collapsing due to low densities or becoming reflective due to excess density. The described equipment complies with ISO 10534-2:2023 [19] and ASTM E1050 [20], which allows the determination of the sound absorption coefficient, the complex reflection coefficient and the acoustic impedance of the material, under conditions of normal sound wave incidence. In addition, the dimensions of the impedance tube also force a certain frequency range corresponding to the interval from 50 Hz to 6.4 kHz. Two different tubes are used to cover this range. The large 100 mm tube covers the range from 50 Hz to 1.6 kHz, while the small 29 mm tube covers the range from 500 Hz to 6.4 kHz.

Under these conditions, the shredded PP layer has been tested for three densities (0.15, 0.20 and 0.25 g/cm^3), while seven different densities (0.050, 0.075, 0.080, 0.085, 0.090, 0.095 and 0.100 g/cm^3) have been tested for the strip-finished layer.

In order to compare the results obtained, a sample of mineral wool (MW) from an international manufacturer was tested and used as a reference. This fact has conditioned the thickness of the tested solutions, as the usual thicknesses used by this manufacturer have been used, which are approximately the same as those used worldwide by the rest of the manufacturers (20, 48 and 65 mm).

All these factors resulted in tests of 33 layers of absorbent (PP and MW).

The Impedance Tube Kit Type 4206 from B&K allows the transfer function of the sample to be obtained by measuring the sound pressure at two fixed positions on the tube. For this purpose, two B&K Type 4187 ¼' condenser microphones and a stationary acoustic signal generated by a sound source located at the opposite end of the tube to the sample location are used. This signal is adjusted with a 2735 B&K power amplifier. During the measurement, the atmospheric conditions of air pressure, temperature and relative humidity are adjusted. In addition, the impedance tube rested on an elastic anti-vibration material.

3. RESULTS

The results correspond to the averaging of 3 different samples for each diameter analysed. For the 33 samples and in order to compare and qualify them on a commercial and

technical level, different single number or letter indices have been calculated. These correspond to the Noise Reduction Coefficient (NRC), ASTM C423-22 [21], Sound Absorption Average (SAA), ASTM C423-22, Practical Sound Absorption Coefficient (α_p), ISO 11654 [22], Weighted Sound Absorption Coefficient (α_w), ISO 11654 and Absorption Class (A_E), ISO 11654.

Table 2 shows all samples tested, labeled as S1 to S33. These correspond to the reference MW and the two different PP finishes, for each density and thickness, together with the single letter or number indices. The results of these indices appear in bold when they are better for the PP than for the MW, remaining unemphasized when the results are equal, or underlined when they are lower.

Table 2. Tested materials, densities, thicknesses and rating indexes

		S33	6.5	0.75	*0.73*	**0.75**	C

The results of the table show equal or better index values for PP than for MW for PP densities higher than MW.

The values for shredded PP only exceed or equal all single number or letter indices for the densities of 0.200 and 0.250 g/cm^3 and a thickness of 2 cm, so no better results are found for the usual thicknesses of acoustic ceilings. Only the value of α_w is exceeded by PP versus MW for all thicknesses when the density is 0.150 g/cm^3. This rules out the results of crushed PP samples versus strips for use in an acoustic ceiling.

For PP strips, similar or better results than for MW are achieved at densities of 0.075 g/cm^3 and above. In addition, all single letter or number indices improve for the 2 cm and 4.8 cm thicknesses. For the 6.4 cm thickness, the only exception is for the SAA index with values slightly lower than those of the MW. Taking into account these variables, the most appropriate density is 0.095 g/cm^3, which manages to improve, compared to MW, the single letter index for each thickness. This seems to worsen at higher densities.

Fig. 3 presents the values of the sound absorption coefficient versus frequency in thirds of octave for the operating range of the impedance tube. For each thickness, the values for MW, shredded PP and strips are presented. For each of the finishes, three densities are shown. These correspond to the 3 densities used in the crushed material and, for reasons of visual clarity, to only 3 of the 7 tested in the strips, one of them being the one with the best acoustic performance.

Figure 4 shows the absorption coefficient against frequency, measured in third-octave bands, for four densities of PP across all thicknesses tested. MW is included as reference. Figure 4(a), with the lowest density, relates to shredded PP, while the other three depict PP strips. Looking at the ratings, only this shredded PP option is considered commercially viable. Furthermore, Figure 4(d) is deemed the optimal choice within the studied density range (0.080 to 0.100 g/cm³). Figures 4(b) and (c), which represent the lower density values, are included to demonstrate how the absorption behaviour changes as density increases.

Across all samples, the absorption characteristics of PP closely resemble those of MW. The shredded layer, within the impedance tube's limitations, effectively eliminates any air gap between the sample and the tube's rigid wall. This leads to an increase in absorption with increasing frequency. The three PP strip densities exhibit behaviour like MW, thus validating PP's correctness as a porous sound-absorbing material.

4. LIFE CYCCLE ASSESMENT

A Life Cycle Analysis has been carried out, comparing the absorbing material layer selected for the PP with the commercial MW one. MW is the most common insulating and acoustic material in the Spanish construction market.

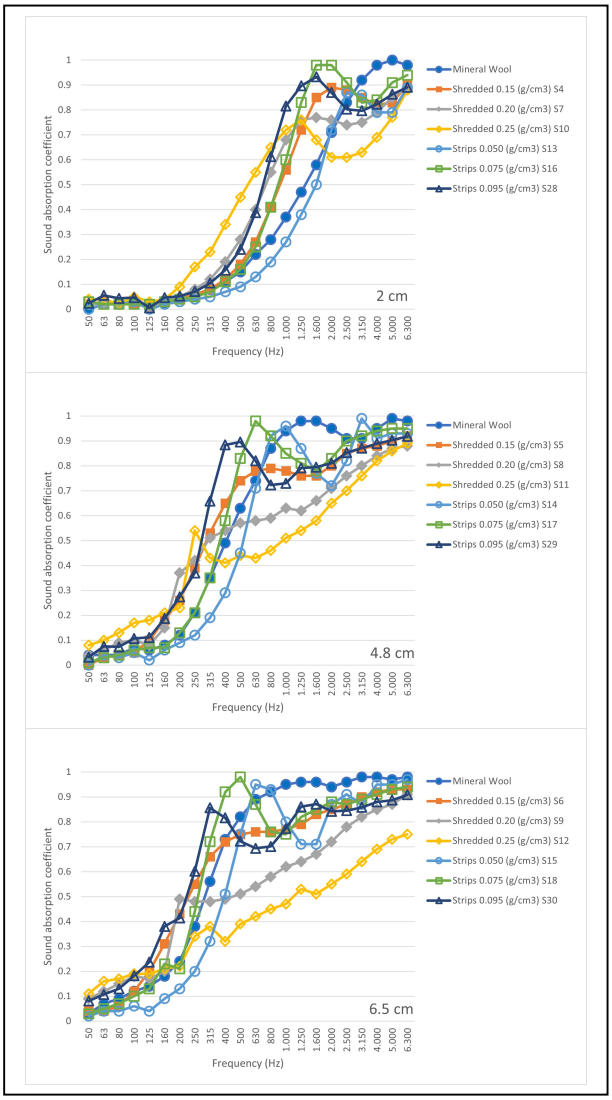

Figure 3. Sound absorption coefficient versus frequency in third octave bands for the different materials and thicknesses.

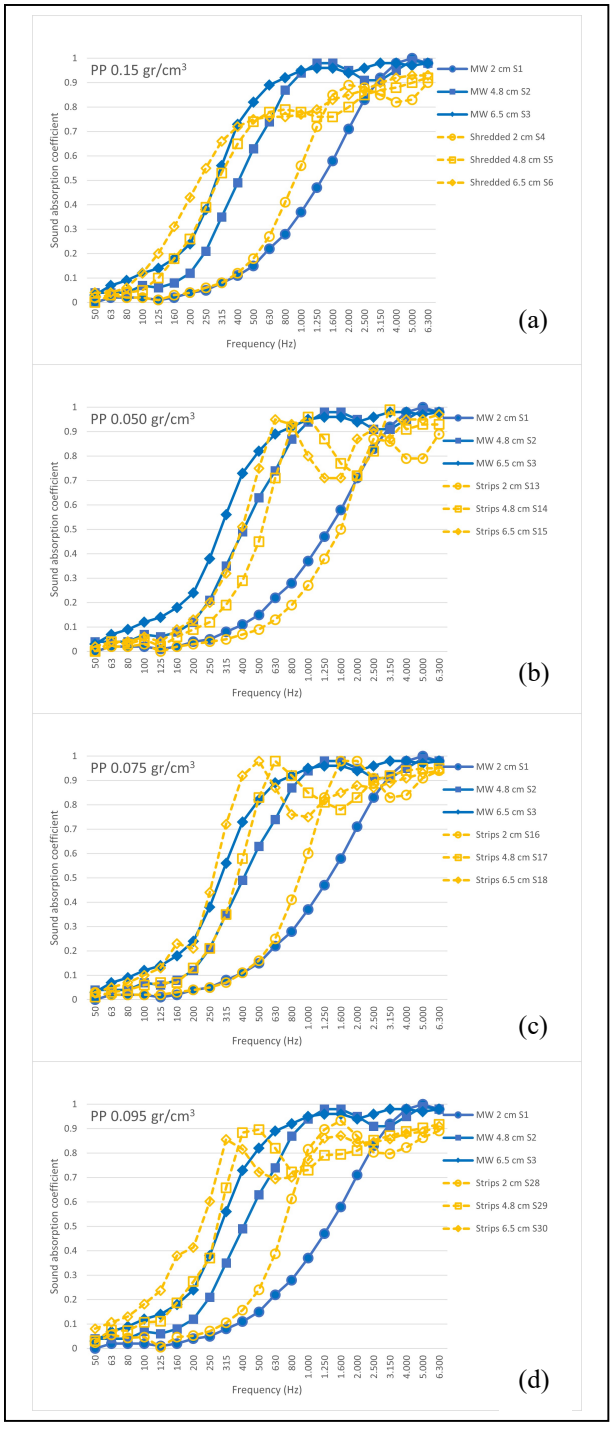

Figure 4. Absorption coefficient versus frequency in thirds of octave for the different materials and sample thicknesses.

A "cradle to gate" analysis (Stages A1 to A3, EN 15804 [23]) was performed. The data obtained to evaluate the consumption and emissions of the samples tested for the PP have been obtained from the prototype production process. The environmental data used for the MW were obtained from the corresponding Environmental Product Declaration of the commercial product.

This LCA study follows the attributional approach, which represents current market conditions in Spain. The impact score calculations have been calculated according to the Ecoinvent and ELCD databases [24], which represent the current technology in Europe. The Simapro tool from Pré Consultants was used to calculate the impact scores.

The result of the calculation shows significantly lower scores for PP in all impact categories evaluated.

In addition, the sensitivity analysis performed shows that the reduction of electricity use in PP production results in a further reduction of the impact scores obtained in all categories. It should be emphasized that this scenario can be achieved following current trends in the green electricity market.

5. CONCLUSIONS

The present work studies discarded materials from healthcare protective equipment made of non-woven polypropylene, for use as an absorbent layer in acoustic ceilings.

Two forms of waste treatment have been analysed, strips of 4×100 mm^2 and shredded PP with a fineness of 2 mm. The study contemplates samples for different thicknesses, typical of commercial solutions common in the international market for mineral wool layers, and different densities, making it possible to obtain the most suitable density of PP for use as an absorbent layer in acoustic ceilings.

For this purpose, we have compared the achievable values obtained for PP, of acoustic indices to number or single letter, with those declared for the reference mineral wool. These indexes have been obtained from the results of the acoustic absorption coefficient for each sample obtained in impedance tubes under normal incidence conditions.

According to the results, the environmental performance of the PP layer outperforms that of conventionally produced acoustic MW and benefits environmental sustainability.

Future research will analyse the acoustic performance and life cycle of the complete acoustic ceiling solution, including the thickness of the air gap and the plasterboard sheet.

6. ACKNOWLEDGMENTS

The project PID2021-123192OB-I00 was financed by the Spanish Ministry of Science and Innovation, the State Research Agency and the EU ERDF. (Ministerio de Ciencia e Innovación, la Agencia Estatal de Investigación y por el Fondo Europeo de Desarrollo Regional de la Unión Europea).

The authors would like to thank the FCT (Fundação para a Ciência e Tecnologia) and the support of the CERIS Research Centre (UIDB/04625/2020). The cutting process for the shredded PP was performed in the LAPIST lab at CERENA (Centro de Recursos Naturais e Ambience).

A VIBRATION BASED HEALTH MONITORING SYSTEM FOR AN AUTOMATIC PACKAGING MACHINE

Ilaria Rizioli[1] **Giulia Cristofori**[1]
Mattia Battarra[1] **Emiliano Mucchi**[1]
[1] Department of Engineering, University of Ferrara, Ferrara FE-44121, Italy

ABSTRACT

This study focuses on the design and development of a condition monitoring system for automatic packaging machines using accelerometer-based measurements. The purpose is to detect defects on the rotating components to enhance machine reliability and operational efficiency. A critical aspect of the study involved determining the optimal placement of accelerometers to maximize sensitivity to wheel defects. The investigation involved extensive testing under controlled conditions with several combinations of working conditions, various artificially induced defects and sensor locations. Data collected from the accelerometers were processed and analyzed using multiple statistical indicators, including bearing-related techniques and cyclostationary approaches. These analyses enabled the identification of key patterns and thresholds indicative of wheel defects. Preliminary results demonstrate the feasibility of detecting early-stage anomalies through accelerometer data and highlight the relevance of sensor positioning in capturing meaningful signals. The ongoing phase of the project focuses on refining the system's accuracy and robustness through additional testing and refining of the data processing procedure. Future developments aim to integrate the system into machine control units for automated defect detection and alerts.

1. INTRODUCTION

In modern industrial environments, ensuring the reliability and efficiency of machinery is critical for maintaining productivity and reducing operational costs. Predictive maintenance, driven by advanced diagnostic techniques, plays a key role in detecting potential failures before they lead to costly downtime. Among various approaches, as also shown by Jardine A. et al. in [1], vibration-based health monitoring has proven to be effective in assessing rotating and mechanical components.

The effectiveness of accelerometers in condition monitoring is well-documented in several books, including the work by Wu et al. [2] that discusses the application of vibration-based condition monitoring in hydraulic machinery. The authors emphasize the role of accelerometers in measuring the absolute vibration of machine components. In this context, it is crucial to underline that acceleration measurements are used to assess the health conditions of the most critical components of automatic machines, e.g. rolling element bearings [3,4] and gears [5,6]. In this context, it is mandatory to underline that acceleration measurements have become the reference approach, also thanks to a vast community of research groups that have continuously developed a variety of signal processing techniques with the purpose to maximize the extraction of information. Their use is currently so widespread that acceleration signals represent a reference source of information also in physics-based diagnostic and prognostic protocols, since they are used for tuning and validation of digital twins of faulty mechanical components [7–9].

As a matter of fact, signal processing techniques play a pivotal role in vibration-based condition monitoring. Feature extraction methods, such as time-frequency analysis, enhance the detection of faults in machinery com-

ponents such as rolling bearings. A study by Zhang et al. [10] provides a review of these techniques, emphasizing their application in estimating degradation trends in low-speed slew bearings. This context is particularly proficient in the case of mechanical rotating machines, which have been largely proven to behave as cyclo-stationary systems [11]. Based on this observation, several techniques have been developed with the purpose to define diagnostic indicators from acceleration signals by taking advantage of the cyclo-stationary behavior of the system. In this framework, works such as the one reported in [12] propose approaches to detect the appearance of pitting phenomena in gears, while others such as the one in [13] are devoted to define specific techniques for rolling element bearings.

The described scenario clarifies as the specialized literature may currently provide a relevant variety of case studies, open-source datasets with experimental results and innovative research project outcomes regarding the diagnostics of rotating mechanical components, however their application on actual machines and production lines is certainly less common. Within this context, the present work has the purpose to provide insights regarding the use of well-established indicators, commonly adopted for the diagnostics of single mechanical components, in real machines adopted in an industrial environment. In particular, the study focuses the attention on automatic packaging machines, which are widely used in packaging industries and are commonly subject to wear and mechanical degradation over time. Implementing a vibration-based monitoring system can enhance their operational efficiency by identifying early signs of malfunction, enabling timely maintenance interventions.

The following section is devoted to the description of the mechanical system under study and the experimental tests carried out to characterize the vibration behavior of the machine. Section 3 reports the results of the analysis applied to the experimental results. Eventually, the last section is devoted to concluding remarks.

2. MECHANICAL SYSTEM DESCRIPTION

The study focuses on a automated packaging machine with rotative mechanical subsystems, which are supported by groups of wheels located in circle. Each group is constituted by three polymer wheels, two of them with axes of rotation disposed along the ring radial direction and the remaining one with axis of rotation disposed along the ring axial direction.

The experimental study has been carried out with the purpose to fully characterize the behavior of a complete wheel group through the entire available working conditions of the machine. In this context, three triaxial accelerometers have been placed on top of the bearings of the three wheels constituting a wheel group, while other three triaxial accelerometers have been placed on the ring frame. An optical tachometer is used to assess the wheel position and the instantaneous rotational speed of the machine. Tests have been conducted at four different workin conditions, with speed varied from 25% to 100% of the maximum available value, with each acquisition lasting for 60 s and the sampling frequency set to 25600 Hz. The test campaign involved the baseline condition, i.e. the machine in nominal condition, and eight different artificial faults.

3. RESULTS AND DISCUSSION

The present section reports the results of the different signal processing techniques applied on the data obtained from the experimental study described in section 2. Figure 1 reports Root Mean Square (RMS) and Kurtosis values referring to the data acquired from the two accelerometers placed on the radial axes wheels of a wheel group. Data are expressed as the difference with respect to the analogous value computed from the baseline condition. As it may be observed, both statistical indicators are capable to recognize the presence of defects located on the wheels of the same wheel group where the accelerometers are mounted, while their sensitivity to faults located on other wheel groups is almost negligible. Moreover, both RMS and Kurtosis appears to be highly sensitive to faults involving faceted wheels, while other modifications do not seems to produce significant modifications in the values of the indicators.

The analysis is then repeated for the data acquired with the accelerometers located on the ring frame, as reported in Fig. 2. As it may be observed, the presence or absence of the film does not alter the results significantly, with the x direction, which coincides with the radial one, being the most sensitive. Again, artificial faults involving the faceted wheel appear to have a more significant effect on both indicators, while other modifications, such as displacing the gear along the ring center, lead to RMS and Kurtosis values almost superimposed to the baseline condition.

In order to deepen the analysis and define a wider set of indicators with significant sensitivity to all the simu-

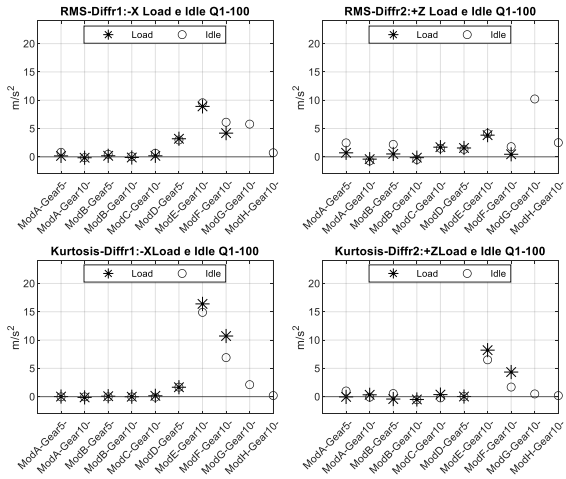

Figure 1. RMS and Kurtosis values for the two accelerometers placed on the radial axis wheels of a wheel group, expressed as difference with respect to the values computed from baseline conditions.

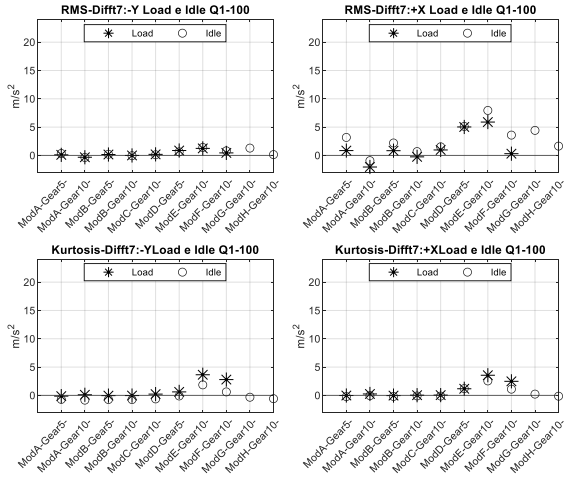

Figure 2. RMS and Kurtosis values for one of the accelerometers placed on the ring frame, expressed as difference with respect to the values computed from baseline conditions.

lated faults, the acquired data have been further processed by using five additional indicators: skewness, Teager-Kaiser Energetic Operator (TKEO), Power Spectral Entropy (PSE), Peak-to-Peak value and the Hillbert indicator. Figure 3 reports the results of this analysis applied to the same accelerometer observed in Fig. 1. The results show that most of the indicators demonstrate a relevant sensitivity to the proposed modifications, with the Hillbert indicator that certainly achieve the highest sensitivity while PSE seems almost not-influenced by the considered faults. Moreover, it is worth underlining that similar results have been obtained from the signals collected by all the involved accelerometers, both located on the wheel group and the ring frame.

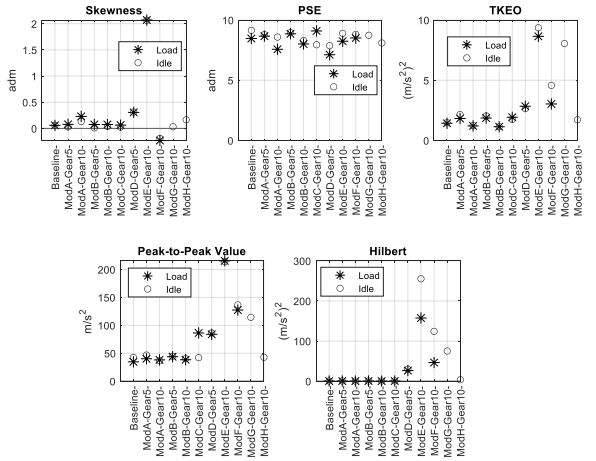

Figure 3. Computation of additional indicators on the data obtained from the same accelerometer adopted in Fig. 1.

4. CONCLUDING REMARKS

This study focused on the design and development of a condition monitoring system for automatic packaging machines using accelerometer-based measurements. The purpose was to detect defects on the wheels to enhance machine reliability and operational efficiency. The study is based on an extensive experimental analysis, involving six triaxial accelerometers, 16 different working conditions and 8 artificial faults, from wheel displacement to wheel faceting.

The acquired signals have been post-processed with different techniques: the first analysis is focused on statistical indicators, such as RMS and Kurtosis, showing that faults involving faceted wheels have significant effects on them. On the other hand, artificial faults involving wheel

displacements are less observable. The analysis has been further deepened by including additional indicators such as skewness, Teager-Kaiser Energetic Operator (TKEO), Power Spectral Entropy (PSE), Peak-to-Peak value and the Hillbert indicator. The outcomes of this second round of post-processing demonstrated that faceted wheel faults produce significant effects on several indicators, on all the applied accelerometers. Conversely, wheel displacement faults probably do not alter the energy content of the phenomenon and therefore are less prone to be observed with these indicators. In addition, as a whole consideration, the analysis has demonstrated that the diagnostic protocol could be applied during both load and idle conditions. Further works will be focused on defining an artificial intelligence approach capable to take into account all the defined indicators in order to classify faults according to their nature.

A MATHEMATICAL MODEL BASED DIGITAL TWIN FOR GEARBOXES OPERATING AT VARIABLE SPEEDS

Shahis Hashim **Sitesh Kumar Mishra** **Piyush Shakya***

Engineering Asset Management Group, Indian Institute of Technology Madras, Chennai, India

ABSTRACT

The gearboxes are vital components of most drive trains. The operation of gearboxes in applications such as wind turbines and manufacturing tools is characterised by sudden changes in loads, which may lead to variations in operational speed. Hence, visualising system dynamics in varied conditions becomes vital to operation planning. The role of the digital twins in industrial applications has led to streamlined virtual learning of the system dynamics. Further, the mathematical model-based digital twin is faster in computation than its counterpart, the finite element model, thus meeting the demand for real-time system simulations. The study presents a digital twin based on a mathematical model for simulating the vibration response of a fixed-axis single-stage spur gearbox operating at variable speed. A detailed study of the simulated vibration response and a detailed discussion of its time, frequency, and time-frequency domains are also presented.

Keywords: *Dynamic model, vibration analysis, gearbox, digital twin*

1. INTRODUCTION

Lack of proper maintenance is the most prominent reason for gearbox failures [1]. Further, the failure of gearboxes may lead to extensive hazards ranging from operational downtime to loss of personal life [2]. Historically, gearbox failure has been the primary cause of aviation hazards. Notably, gearbox failures of the Boeing-made V-22 Osprey and the Airbus-made super-puma family helicopters have resulted in multiple fatal accidents over the years, with loss of life amounting to dozens [3]. Hence, visualising the gearbox's operation and the associated system dynamics is paramount for operation planning [4, 5]. The analyst may simulate varying operational conditions of the gearbox in a virtual system to understand the safe operational parameters. Such virtual visualisations are aided by a Digital twin (DT) capable of simulating the operational characteristics of the gearbox in a display unit.

A vast range of research addresses the DT analysis by Finite element modelling (FEM). However, the FEM is computationally intensive, requiring dedicated workstations and associated equipment. The FEM-based DTs are thus limited to industrial units that may afford such costly tools for operational optimisation. Most industrial units and primary employment providers in the developing and under-developed nations are categorised as micro, small, and medium enterprises (MSMEs). The non-availability of advanced algorithms for optimised operations significantly hinders developing nations' inclusive progress. As such, the dynamic model-based DTs that provide low-cost computation may be more suited to the context of MSMEs [6].

Researchers have tried to generate a dynamic model-based DT for gearboxes at various degrees of freedom [7]. Patel and Shakya demonstrated a model capable of addressing the variable speed but limited the study to signal processing of the simulated vibration response [8]. The present study explores the characteristics of the simulated vibration response during the presence of the fault, as well as during variations in speed, a vital aspect of the digital twin's onboard application.

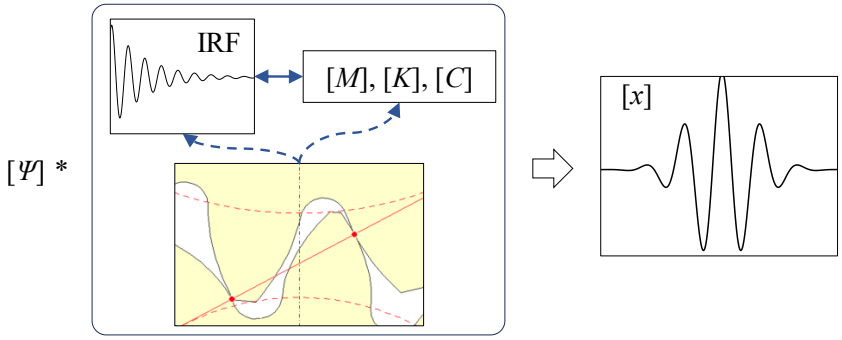

Figure 1: Schematic representation of vibration response during gear tooth meshing

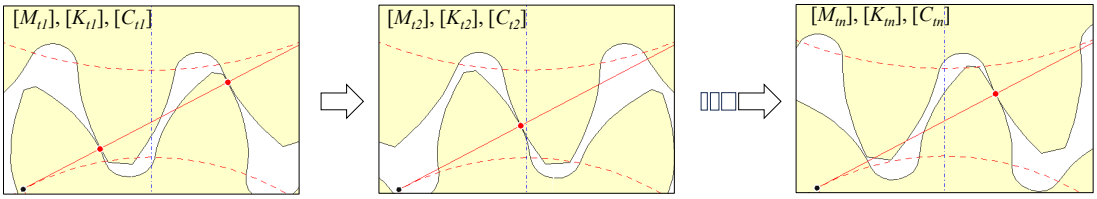

Figure 2: Gear mesh at different instants

2. VIBRATION RESPONSE SIMULATION

The vibration response-based analysis has emerged as the norm in contemporary gearbox monitoring practices. The wide acceptance of vibration analysis is due to its ability to reflect highly correlated fault information swiftly. The vibration response of a structural element is governed by its Impulse response function (IRF), which is dependent on the system's dynamic properties. The Figure 1 illustrates the instantaneous vibration response ($[x]$) generation during the gear tooth meshing under the influence of external and internal forces ($[\Psi]$). At any instant, the meshed gear tooth may be assumed as a structure with a set of dynamic properties dependent on the combined meshed geometry of the interacting gear tooth. The dynamic properties such as the mass ($[M]$), stiffness-coefficient ($[K]$), and damping-coefficient ($[C]$) influence the IRF of the said structure. However, the meshing of the gearbox generates complex meshed structures and dynamic forces at every instant, generating a complex vibration response over time (Figure 2). Nonetheless, understanding the vibration response is fundamental to the study. The following sections of the current study analyse the gearbox vibration response using the proposed dynamic model. The vibration response's time, frequency, and time-frequency domain characteristics are studied.

3. THE DYNAMIC MODEL

The dynamic property most influential in the vibration response generation is the instantaneous stiffness during the gear tooth meshing, termed the time-varying mesh stiffness (TVMS). The dynamic model consists of two integral parts: the TVMS calculation and the lumped-mass dynamic model. The root-crack growth under different speed variations is analysed in the present discussion to understand the complex nature of gearbox vibration response under fault growth and operational variations.

3.1 TVMS calculation

The dynamics of a single tooth during the gear mesh is assumed to be that of a cantilever beam under a moving load (Ψ). The Ψ results in a set of deformation modes of the gear tooth governed by the associated stiffness. Specifically, the gear tooth undergoes axial deformation, bending and shearing, fillet foundation deflection, and contact deformation. The present analysis adopts the Mohammed et. al. [9] model for the axial, bending, and shear stiffness (K_a, K_b, and K_s); Sainsot model [10] for fillet foundation stiffness (K_f); and Yang model [11] for the Hertzian contact stiffness (K_h).

The strain energies (U_a, U_b, and U_s) stored in the gear tooth due to the axial, bending, and shear deformation are

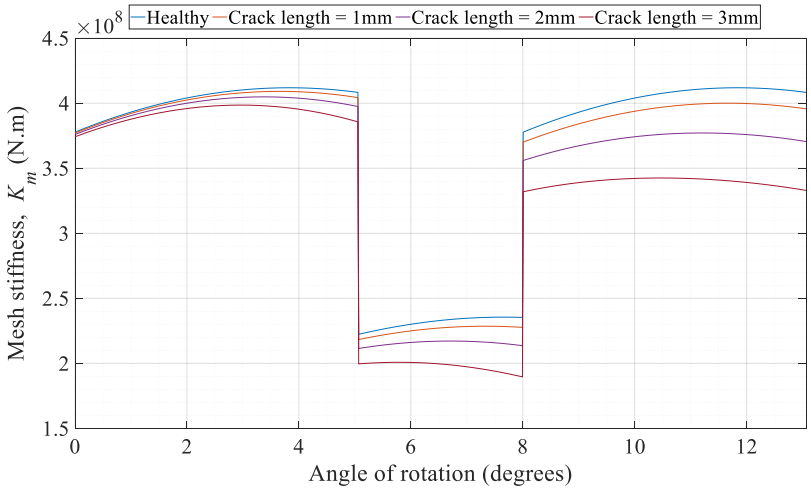

Figure 3: Calculated mesh stiffness for contact ratio of 1.5

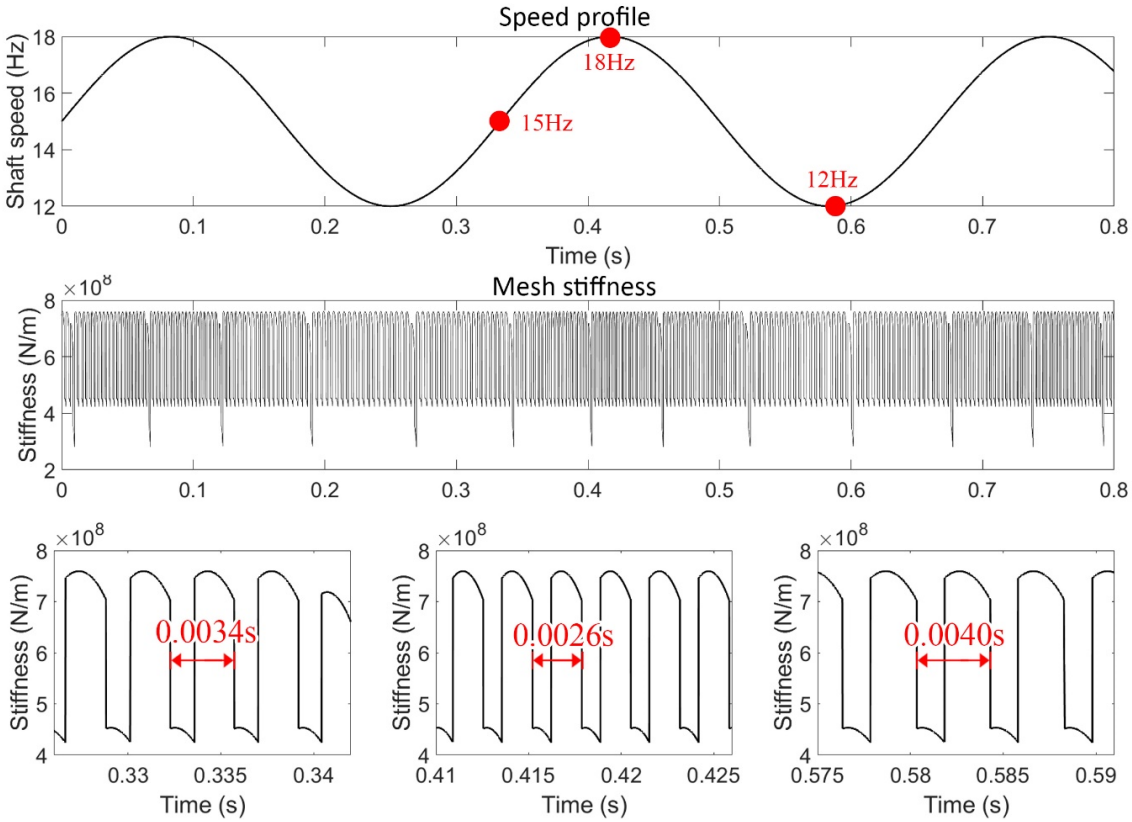

Figure 4: Instantaneous shaft speed and corresponding mesh stiffness of the gear operating at 15% speed fluctuation.

as follows:

$$U_a = \frac{\Psi^2}{2K_a} = \int_0^d \frac{\Psi_a^2}{2EA_X} dX \ , \Psi_a = \Psi \cos(\theta_1) \quad (1)$$

$$U_s = \frac{\Psi^2}{2K_s} = \int_0^d \frac{\Psi_b^2}{2EA_X} dX \ , \Psi_b = \Psi \sin(\theta_1) \quad (2)$$

$$U_b = \frac{\Psi^2}{2K_b} = \int_0^d \frac{J^2}{2EI_X} dX \ , \quad J = [\Psi_b.(d-X)] - [\Psi_a.h] \quad (3)$$

Here, the variables h, d, and X are associated with the gear tooth geometry and the point of contact. The E and G are the elastic and shear modulus. The I_X and A_X are the moments of inertia and cross-sectional area of the tooth section at a distance of X. The I_X and A_X are calculated as follows:

$$I_X = \begin{cases} \frac{1}{12}(h_X + h_X)^3 db; & h_x \leq H_o \\ \frac{1}{12}(h_X + H_o)^3 db; & h_x > H_o \end{cases} \quad (4)$$

$$A_X = \begin{cases} (h_X + h_X) db; & h_x \leq H_o \\ (h_X + H_o) db; & h_x > H_o \end{cases} \quad (5)$$

Here, H_o is the geometric parameter associated with the crack.

Further, the fillet foundation stiffness (K_f) and the Hertzian contact stiffness due to the Ψ is calculated by the following equation:

$$\frac{1}{K_f} = \frac{\cos^2(\alpha_1)}{bE} \left\{ L^* \left(\frac{d}{S_f}\right)^2 + M^* \left(\frac{d}{S_f}\right) + P^* \left(1 + Q^* \tan^2(\theta_1)\right) \right. \quad (6)$$

$$\frac{1}{K_h} = \frac{4(1-\nu^2)}{\pi E b} \quad (7)$$

Here b is the tooth width, and S_f is the tooth thickness at the fillet foundation. The $L*$, $M*$, $P*$, and $Q*$ are coefficients calculated empirically.

The total mesh stiffness (K_m) for the gear pair [1] at any instant is given by the following equation [2]:

$$\frac{1}{K_m} = \left(\frac{1}{K_{ag}} + \frac{1}{K_{bg}} + \frac{1}{K_{sg}} + \frac{1}{K_{fg}} + \frac{1}{K_{hg}}\right) + \left(\frac{1}{K_{ap}} + \frac{1}{K_{bp}} + \frac{1}{K_{sp}} + \frac{1}{K_{fp}} + \frac{1}{K_{hp}}\right) \quad (8)$$

[1] Note that the calculation shown here is for a single gear pair. Twice the value may be taken when multiple gear pairs are in mesh, i.e. when the contact ratio is more than one.

[2] The annotations p represents the pinion and g represents the gear.

The mesh stiffness for healthy and cracked gear tooth pair is simulated using the gear parameters given in [8] (Figure 3). It may be noted that the stiffness reduces with the increase in crack length. Also, at angular positions of multiple gear meshes, the K_m is higher due to the combined geometry. The period of engagement and disengagement of the gear tooth pair varies according to the instantaneous speed. The meshing is faster at higher speeds, while the meshing is slower at lower speeds. Hence, the mesh stiffness follows a scaling pattern driven by the speed of the instantaneous shaft. Figure 4 shows the speed profile, corresponding mesh stiffness and enhanced portions of the mesh stiffness time snippets. The scaling effect of the mesh stiffness across the time domain may be visualised by the period of engagement and disengagement at different speeds (15Hz, 18Hz and 12Hz).

3.2 Lumped mass model

A six-degree-of-freedom lumped mass model is used for the analysis [8]. Figure 5 shows a schematic representation of the model. A set of ordinary differential equations governs the dynamics of the said system. The equations of motion of the model are as follows:

$$I_g\ddot{\theta_g} = T_{fg} + r_g W_0 + T_g \quad (9)$$

$$I_p\ddot{\theta_p} = T_{fp} - r_p W_0 + T_p \quad (10)$$

$$m_g\ddot{v_g} + c_{gv}\dot{v_g} + k_{gv}v_g = -W_0 \quad (11)$$

$$m_p\ddot{v_p} + c_{pv}\dot{v_p} + k_{pv}v_p = W_0 \quad (12)$$

$$m_g\ddot{u_g} + c_{gu}\dot{u_g} + k_{gu}u_g = -\Psi \quad (13)$$

$$m_p\ddot{u_p} + c_{pu}\dot{u_p} + k_{pu}u_p = \Psi \quad (14)$$

$$W_0 = C_m(r_p\dot{\theta_p} - r_g\dot{\theta_g} + \dot{v_p} - \dot{v_g}) + K_m(r_p\theta_p - r_g\theta_g + v_p - v_g) \quad (15)$$

In the above-given equations, u, v, and θ represent the horizontal, vertical, and angular displacements; m is the mass, and r is the base radius; c and k represent the damping coefficient and stiffness of the gearbox bearings; T represents the input/output torque; T_f represents the frictional torque; K_m and C_m represent the mesh stiffness and the mesh damping coefficient respectively. The following paragraphs analyse the vibration response generated by the above-described dynamic model. Analyses based on time, frequency, and time-frequency domains are presented. Two cases of analyses are presented: Case 1, crack growth model and Case 2, speed variation model.

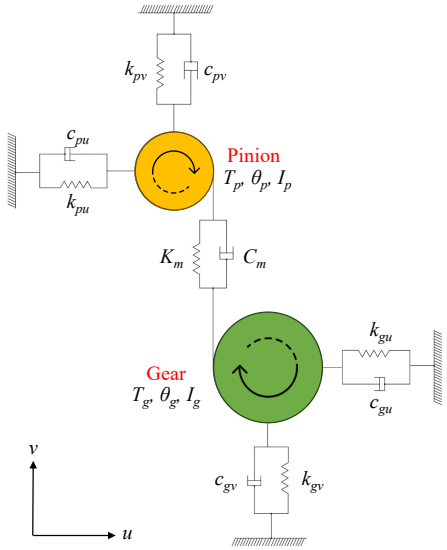

Figure 5: Six degree-of-freedom lumped mass model of a single-stage fixed-axis gearbox

The Case 1 is analysed using responses generated for K_m values given in the Figure 3. A sinusoidal variation with fluctuations 0%, 1%, 2.5%, and 5% are considered for Case 2.

4. RESULTS AND DISCUSSION

Analyses based on time, frequency, and time-frequency domains are presented in the following paragraphs. Two cases of analyses are presented: Case 1, crack growth model and Case 2, speed variation model. Case 1 is analysed using responses generated for K_m values in Figure 3. A sinusoidal variation (Figure 6) with fluctuations (F_l) 0%, 1%, 2.5%, and 5% are considered for Case 2.

4.1 Time domain analysis

The time domain representations of the vibration response generated for both cases are shown in Figures 7 and 8. The crack growth model shows the transient response in faulty gear mesh instances. Further, the transients correspond to the diminished stiffness of the meshed tooth pair, as shown in Figure 3. It may be noted that the damping of transient response after the impact of the faulty gear pair meshing has shown visible Amplitude Modulation (AM) (as shown in Figure 7). However, the direct visualisation of fault information from the time domain is impossible

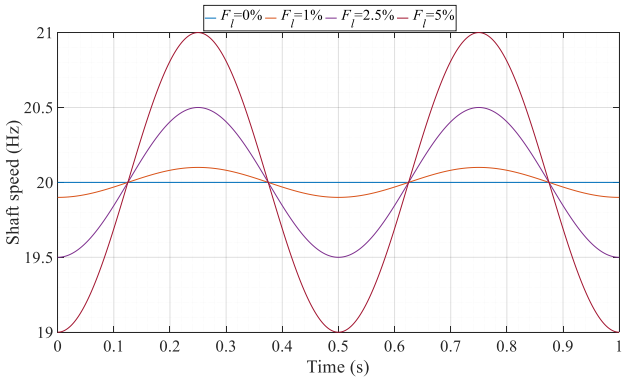

Figure 6: Speed variation for the simulation model

for very early faults. The said conundrum is multi-fold for real-life systems where external noise, sub-component vibrations, and transfer path effect mask the sensor-acquired vibration response. The variation in tooth contact force during the speed variation has resulted in a corresponding variation in the vibration response for Case 2 [3]. AM corresponding to the speed profile is apparent only in the vibration response corresponding to higher speed fluctuations. Intuitively, since the angular displacement is non-constant during the rotation of the gear pair, Frequency modulation (FM) is also expected in the response.

4.2 Frequency domain analysis

The frequency domain representation is a global illustration of the energy distributed among the constituent frequencies of the vibration response. The basis of the frequency domain representation is the Fourier transform. The Fourier transform facilitates any function to be represented as a combined set of scaled sinusoidal functions at different frequencies and phases. The Fourier transform of the vibration response ($x(t)$) is as follows:

$$\hat{x}(\omega) = \int_{-\infty}^{\infty} x(t) \mathrm{e}^{-i\omega t} dt \tag{16}$$

Theoretically, the gear pair meshes at constant operational speeds at a constant frequency, termed the Gear Mesh Frequency (GMF) [4]. Hence, the vibration responses will have a higher energy concentration at the GMF harmonics. Further, the gear tooth bends at every gear mesh. Hence, a

[3] The variation in shaft speed corresponds to variation in power transmission. Correspondingly, the torque load changes with respect to the speed variation.

[4] GMF is the fault frequency (f_0) for gearboxes.

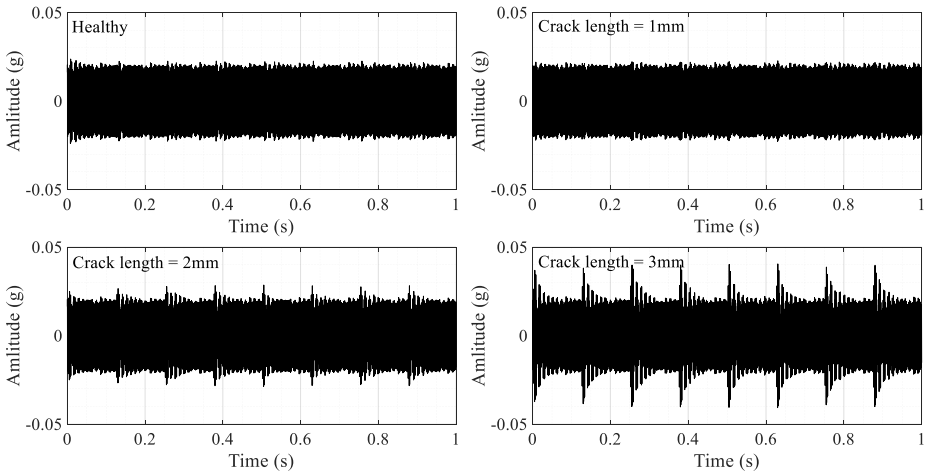

Figure 7: Time domain representation of the dynamic model simulated vibration response for different crack size

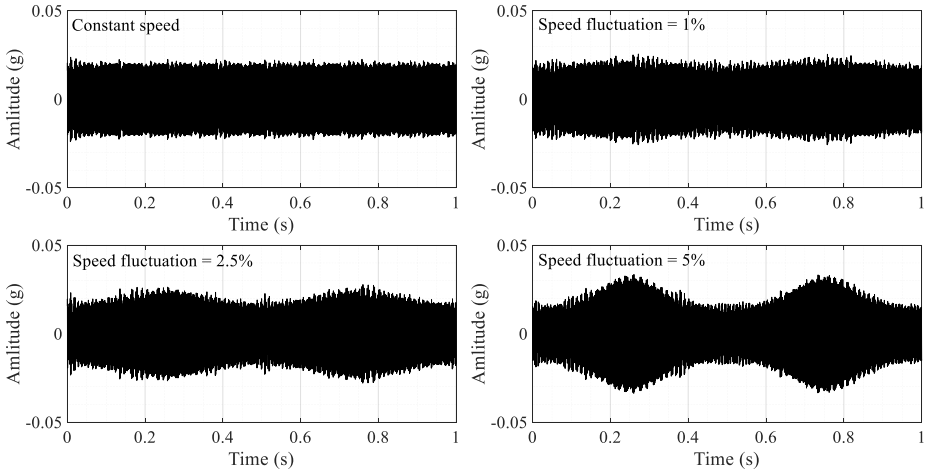

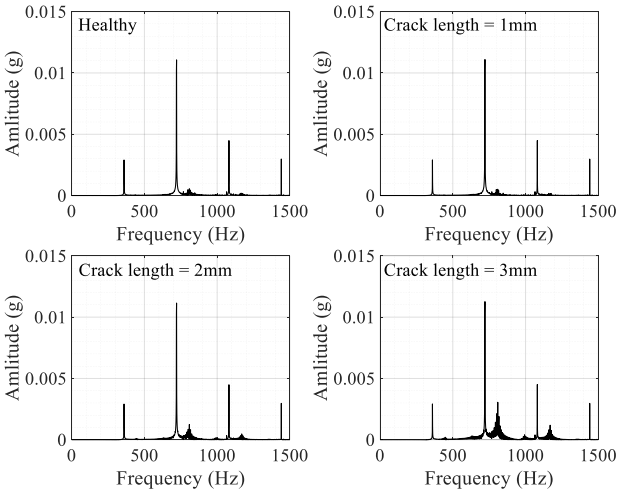

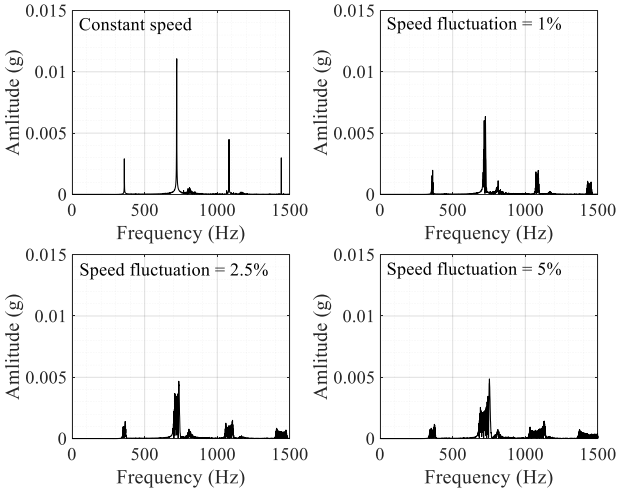

Figure 8: Time domain representation of the dynamic model simulated vibration response for different speed fluctuation

slight variation in transmission ratio at the tooth meshes leads to FM, which, along with the AM due to gear mesh impacts, leads to sidebands around the GMF. Further, the AM-FM at the faulty gear pair mesh is higher than the rest due to the relatively lower K_m. Hence, the presence of the fault leads to disturbance in the sideband energy, which is apparent in the frequency domain representation of the crack growth model's vibration response (Figure 9a). The basic assumption of frequency domain representation is the constant operational speed. As such, the frequency domain representation of the vibration response of gearboxes operating at variable speeds results in a smeared spectrum (Figure 9b). Specifically, the global GMF variation across the gearbox's operation varies; hence, the vibration response energy gets smeared across those frequencies. Further, a decrease in the spectral amplitude is also apparent, possibly due to the smearing of energy across the earlier frequencies concentrated at singular frequency values [5] .

[5] Note that the total vibration energy stays conserved.

(b) Frequency domain representation of the dynamic model simulated vibration response for different speed fluctuations.

Figure 9: Frequency domain representations of simulated vibration responses for different conditions.

(a) Time-frequency domain representation of the dynamic model simulated vibration response for different crack sizes.

(b) Time-frequency domain representation of the dynamic model simulated vibration response for different speed fluctuations.

Figure 10: Time-frequency domain representations of simulated vibration responses for different conditions.

4.3 Time-frequency domain analysis

In contrast to the frequency domain representation, a global representation of vibration response energy across the frequencies, the time-frequency domain representation illustrates a temporal localised frequency distribution. The time-frequency domain is the frequency domain amalgamation of time-windowed signal sections of the vibration response.

$$\hat{x}(\tau,\omega) = \int_{-\infty}^{\infty} x(t)w(t-\tau)\mathrm{e}^{-i\omega t}dt \qquad (17)$$

Here, $w(.)$ represents the windowing function. The time-frequency domain representation provides insights into the localised variation in frequencies. Specifically, the

frequency variations, which are difficult to capture by the frequency domain analysis due to spectral smearing, are easily comprehensible in the time-frequency domain representation.

Figures 10a and 10b show the time-frequency domain representations of vibration responses generated for the crack growth and speed variation models. The variations in instantaneous frequency are apparent in both cases [6]. Specifically, the crack growth model was simulated at a constant speed; hence, the GMF stays constant over time. However, in the speed variation model, the time-frequency representation aptly illustrates the variations in GMF due to shaft frequency fluctuation. In the crack growth model, frequency variations may be observed at the fault transients due to their FM nature. The time-frequency representation provides clear insight into the frequency variation of the vibration response across time. However, the spectral coherence of the representation is limited by the time and frequency resolution balance across the respective axes [7]. Hence, spectral energy quantification for fault severity estimations is not easily possible in the time-frequency domain. When combined with appropriate fault enhancement algorithms, the frequency domain analysis has shown better quantification of fault severity. Nonetheless, the time-frequency representation is ideal for reverse estimation of instantaneous frequency in the unavailability of tacho-pulse signals.

5. CONCLUSION

The study presents a digital twin based on a dynamic model for simulating gearbox vibration response in the presence of a fault and variable operational speed. The six-degree-of-freedom model successfully simulates the vibration response characteristic of a gearbox with root cracks and operates at variable speed. Further, a detailed study of the vibration response in its time-domain, frequency-domain, and time-frequency domain is presented. The presented model can simulate the vibration response's spectral distortions and amplitude-frequency modulations indicative of fault information and speed variations.

[6] The second GMF harmonic is shown in the figures due to its higher spectral energy concentration, as apparent in the frequency domain representations.

A NEW FEATURE EXTRACTION FRAMEWORK FOR SOURCE-FREE DOMAIN ADAPTATION IN BEARING FAULT DIAGNOSIS

Sakthisandron Arunagiri **Sitesh Kumar Mishra** **Piyush Shakya***
Engineering Asset Management Group, Department of Mechanical Engineering,
Indian Institute of Technology Madras, Chennai-36, India

ABSTRACT

Condition monitoring of machine elements is critical in industrial applications, drawing significant attention to cross-domain bearing fault diagnosis. However, data privacy concerns and storage limitations pose significant challenges. To address these issues, source-free domain adaptation networks, consisting of a feature extractor and a fault classifier, have been developed. In these frameworks, the parameters of both components are trained using only source-domain data. During testing on target-domain data, the extractor's parameters are initialized with the learned source-domain parameters and allowed to adapt, while the classifier's parameters remain fixed. Although the proposed approach effectively tackles privacy and storage concerns, it falls short in providing a unique feature representation for each domain, limiting its generalization capability. The present work seeks to overcome the mentioned limitation by employing auto-regressive models to generate unique feature representations for individual domains. Additionally, self-organizing maps are utilised to explore similarities across domains and various fault types. The robustness of the proposed approach is validated through extensive experiments, demonstrating its effectiveness in improving cross-domain fault diagnosis performance.

1. INTRODUCTION

In modern industrial systems, predictive maintenance plays a crucial role in ensuring safety and minimizing downtime. Significant research efforts have been dedicated to developing data-driven methods for early fault detection [1, 2], which can assist in effective decision-making. However, real-world implementation faces several challenges, including large data storage requirements, data privacy concerns, and the increased difficulty of domain adaptation when applying models across different operating conditions. Recent studies [3,4] have attempted to address these issues by developing source-free domain adaptation frameworks. This work aims to tackle these challenges by introducing a novel feature extraction approach that provides a unique representation of the dataset, ensuring more distinctive and domain-specific feature learning.

A source-free domain adaptation approach for bearing fault diagnosis begins with feature extraction from the source-domain bearing data followed by training a classifier using the corresponding fault labels. Notably, training is performed exclusively on the source data, without access to target labels. Once trained, the same feature extraction procedure is applied to the target-domain bearing data, and the classifier is expected to accurately classify faults in the target domain despite distributional differences.

Mathematically, the labelled source-bearing dataset is represented as $D_S = \{x_i^S, y_i^S\}_{i=1}^{N_S}$, where x_i^S and y_i^S denote the vibration signal and the corresponding fault label for the i^{th} sample, respectively. The unlabelled target-bearing dataset is given by $D_T = \{x_i^T\}_{i=1}^{N_T}$, where N_S and N_T represent the number of samples in the source and target datasets, respectively. Since the source and target data distributions may differ, the key challenge is to

learn a mapping function: $f : x_i \rightarrow y_i$ using only the source data, such that it can effectively classify faults in the target domain despite the absence of target labels.

2. PROPOSED METHOD

2.1 Overview

The proposed method consists of three main stages: feature extraction, feature representation, and classification. In the feature extraction stage, the vibration signal is modelled as the output of an Auto-Regressive (AR) process [5]. The AR model parameters and the residual variance are extracted as features to ensure a unique representation for each sample. In the feature representation stage, the extracted features are structured using Self-Organizing Maps (SOMs) [6]. The transformation organizes the samples based on similarity, improving feature discrimination and clustering. In the classification stage, a deep neural network (DNN) is trained on the SOM-structured feature representations of the source domain. Once trained, the parameters of both the SOM and the classifier are frozen. The same feature extraction and representation process is then applied to the target domain data. The structured representations of the source and target samples are clustered independently. To facilitate unsupervised domain adaptation, the target clusters are mapped to the closest corresponding source clusters. Finally, the mapped target samples are classified using the trained DNN. An overview of the proposed method is illustrated in Fig. 1.

2.2 Mathematical Framework of the Proposed Method

2.2.1 Feature Extraction Using AR Model

All vibration signals in the dataset are modelled as the output of an AR process of order five as

$$x(k) = \sum_{j=1}^{5} \alpha_j x(k-j) + \epsilon(k) \tag{1}$$

where $\epsilon(k)$ is white noise with variance σ^2, and α_j represents the j^{th} coefficient. These coefficients, along with the residual noise, constitute the feature vector for each vibration signal, expressed as $\mathbf{f} = [\alpha_1, \alpha_2, \alpha_3, \alpha_4, \alpha_5, \sigma^2]$. Consequently, the transformed dataset is given by $\bar{D}_S = \{\mathbf{f}_i^S, y_i^S\}_{i=1}^{N_S}$ and $\bar{D}_T = \{\mathbf{f}_i^T\}_{i=1}^{N_T}$.

2.2.2 Structured Representation via SOM

The extracted features are mapped to a structured 2D latent space using a SOM consisting of a 20×20 neuron lattice, with $\mathbf{w_{ij}}$ representing its weights. The iterative process for updating these weights is as follows:

- Find the Best Matching Unit (BMU):

$$(i^*, j^*) = \arg\min_{(i,j)} \|\mathbf{f}_i - \mathbf{w}_{ij}\|$$

- Update neuron weights:

$$\mathbf{w}_{ij} \leftarrow \mathbf{w}_{ij} + \eta.h(i,j)(\mathbf{f}_i - \mathbf{w}_{ij})$$

  where η is the learning rate, and $h(i,j) = e^{\frac{(i-i^*)^2+(j-j^*)^2}{2\beta^2}}$ is the Gaussian neighborhood function with β as the neighborhood radius.
- Repeat until the weights converge.
  After convergence, the structured representations from SOM_S and SOM_T are denoted as $\mathbf{w}_{ij}^S$ and $\mathbf{w}_{ij}^T$, respectively.

2.2.3 Training DNN-Based Classifier

The updated weights $\mathbf{w}_{ij}^S$ from SOM_S are stacked to form $\mathbf{z}^S$, which serves as input to the DNN for training its weights and biases. The DNN architecture is mathematically expressed as:

$$\hat{y}_S = \sigma_3(\mathbf{W}_3(\sigma_2(\mathbf{W}_2(\sigma_1(\mathbf{W}_1\mathbf{z}^S + \mathbf{b}_1)) + \mathbf{b}_2) + \mathbf{b}_3)) \tag{2}$$

where $\mathbf{W}_*, \mathbf{b}_*$, and σ_* denote the weights, biases, and ReLU activation functions, respectively. Training is performed for 2000 epochs to minimize the cross-entropy loss between $\hat{y}_S$ and the true source labels using the Adam optimizer.

2.2.4 Unsupervised Domain Adaptation and Classification

After training, the weights $\mathbf{w}_{ij}^S$ of SOM_S and the parameters of the DNN are frozen while adapting to the target dataset. The procedure for aligning $\mathbf{w}_{ij}^T$ to $\mathbf{w}_{ij}^S$ is as follows:

- Apply K-means clustering to the neurons of SOM_S and SOM_T:

$$C^S = \{c_{ij}^S\}_{(i,j)\in \text{SOM}_S}, \quad C^T = \{c_{ij}^T\}_{(i,j)\in \text{SOM}_T}$$

  where c_{ij}^S and c_{ij}^T represent the cluster assignments for each neuron.

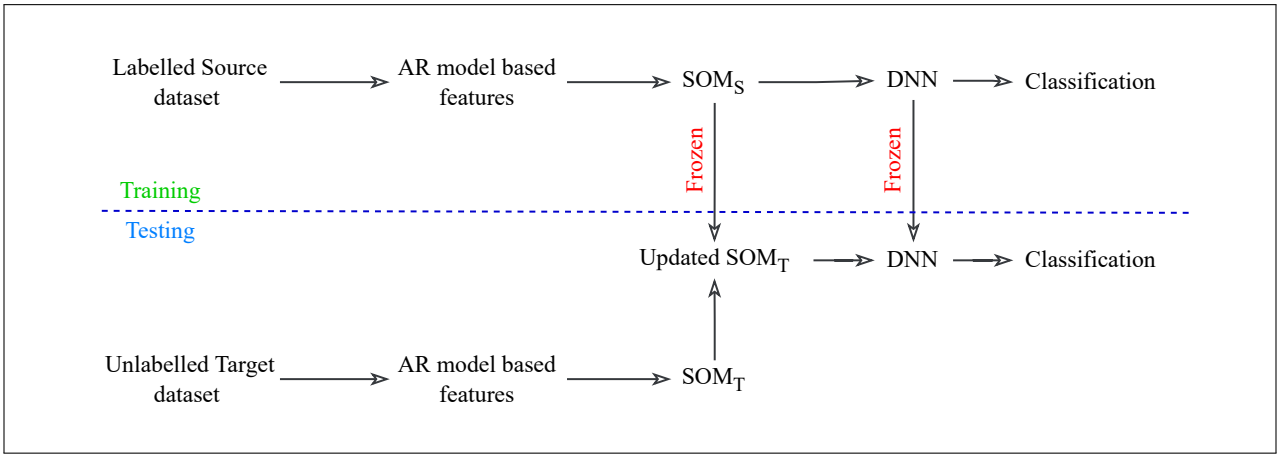

Figure 1. Overview of the proposed method.

- Compute the centroid of source clusters:

$$\mu_k^S = \frac{1}{|C_k^S|} \sum_{(i,j)\in C_k^S} \mathbf{w}_{ij}^S$$

where C_k^S is the set of neurons assigned to cluster k.

- Update target weights iteratively:

$$\mathbf{w}_{ij}^T \leftarrow \lambda \mathbf{w}_{ij}^T + (1-\lambda)\mu_k^S$$

Finally, the updated $\mathbf{w}_{ij}^T$ is fed into the DNN for fault classification:

$$\hat{y}_T = DNN(\mathbf{w}_{ij}^T) \tag{3}$$

3. DISCUSSION

3.1 Dataset and Tasks

The proposed method is validated on both same-domain and cross-domain tasks using bearing vibration data from the CWRU dataset [7] and the IMS dataset [8]. For the CWRU dataset, vibration data collected from both the drive end (CWRU$_d$) and fan end (CWRU$_f$) are used. The fault types considered are Rolling Element (RE), Outer Race (OR), Inner Race (IR), and the Healthy condition. To ensure uniformity, vibration signals from both datasets are resampled to 12 kHz and 20 samples are used for each fault type. The tasks defined for evaluation are summarized in Tab. 1.

Table 1. Description of diagnostic tasks for same-domain and cross-domain fault classification.

Task	Type	Source	Target
T1	Same-domain	CWRU$_d$	CWRU$_f$
T2	Same-domain	CWRU$_f$	CWRU$_d$
T3	Cross-domain	CWRU$_d$	IMS
T4	Cross-domain	CWRU$_f$	IMS
T5	Cross-domain	IMS	CWRU$_d$
T6	Cross-domain	IMS	CWRU$_f$

3.2 Comparison

The classification accuracy of the proposed method is compared with three existing methods: Source HypOthesis Transfer (SHOT) [9], Contrastive Test-Time Adaptation (AdaContrast) [10] and Tent [11]. The accuracy results for each task are presented in Tab. 2.

3.3 Observations

The observation of the confusion matrices reveals that SHOT, AdaContrast, and the proposed method successfully cluster the fault types, whereas Tent struggles significantly. However, the relatively low accuracy scores across all methods highlight the inherent challenge of unsupervised domain adaptation in a source-free setting. The slight improvement in accuracy observed with the proposed method can be attributed to the adaptive weight

Table 2. Classification accuracy (%) of different methods for same-domain and cross-domain diagnostic tasks.

Task	SHOT	AdaContrast	Tent	Proposed
T1	50	50	22.45	50
T2	50	46.06	27.98	50
T3	50	25	23.94	50
T4	0	25	27.02	47.34
T5	75	25	28.94	50
T6	25	25	22.13	25
Avg	41.67	32.67	25.41	45.39

update strategy, wherein the SOM_T cluster centroids are adjusted towards the nearest cluster centroid in SOM_S. This adjustment enhances feature alignment between the source and target domains, leading to better classification performance. For instance, in Task 4 (cross-domain adaptation), the SHOT approach successfully identified three distinct fault types in the target dataset. However, it failed to assign the correct labels, leading to significant misclassification. The corresponding confusion matrix for Task 4 using SHOT is shown in Fig. 2. The proposed method consistently achieved around 50% accuracy in all tasks except Task 6 and was outperformed only in Task 5 by the SHOT approach.

4. CONCLUSION

The current study presents a source-free domain adaptation approach for bearing fault diagnosis, leveraging AR modelling, SOM, and a DNN. While AR modelling captures a unique representation of vibration data, the structured feature representation via SOM enhances clustering, leading to improved classification accuracy. Experimental results demonstrate that the proposed method outperforms existing approaches in both same-domain and cross-domain tasks. By addressing the challenge of domain shift in a source-free framework, the proposed method improves the feasibility of deploying machine learning models in real-world fault diagnosis applications. While the results are promising, further research is needed to refine pseudo-labelling strategies for better accuracy and to enhance robustness in noisy environments.

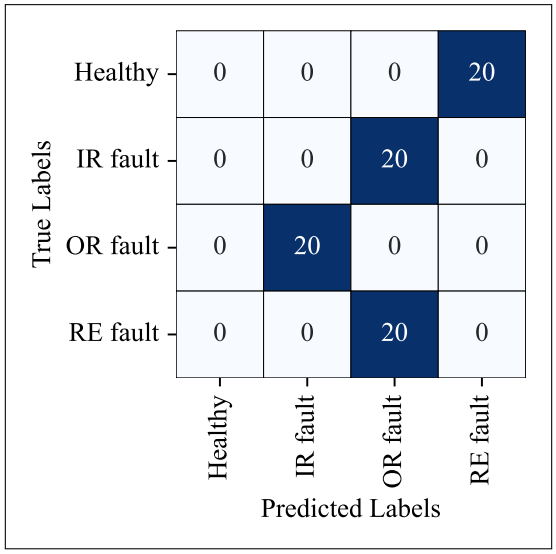

Figure 2. Confusion matrix for Task 4 using the SHOT approach.

ABSTRACT

This study explores the comparative effectiveness of microphones (standard and ultrasonic) and accelerometers in detecting defects in bearings. Defects in rolling bearings generate acoustic waves with a rich content in high frequencies. Both accelerometer and microphone data allow for Envelope Analysis or Amplitude Demodulation (low frequency), while only ultrasonic microphone data enable high-frequency analysis. The study investigates the advantages of using non-contact microphones to capture this high-frequency content easily. The non-contact nature of microphones also eliminates the risk of altering the machine's operational conditions, ensuring easy and secure data collection. Various bearings with different defects were investigated by conducting controlled experiments on a test bench. The analysis was carried out by exploiting statistical indicators, e.g., Kurtosis, Crest Factor, Impulse Factor, etc., and energy-based analysis techniques to compare low- and high-frequency results. Results of the different analyses were presented and discussed, showing the potential use of mixed accelerometric, acoustic, and ultrasonic measurements for practical predictive maintenance of rotating machines.

Keywords: *bearings, predictive maintenance, ultrasound microphone, microphone, accelerometer.*

1. INTRODUCTION

In recent years, predictive maintenance has become increasingly important in industry due to its ability to predict failures and reduce downtime [1-3]. Vibration analysis, primarily based on the use of accelerometers, is one of the most established techniques for monitoring the condition of rotating machinery [4]. In fact, it can provide accurate and repeatable data for condition monitoring of industrial machines, and it is a well-developed and thoroughly studied technique. However, accelerometers need to be installed on the machine in close proximity to the component being analyzed [5-7]. This can pose a challenge since there are practical situations where the sensors cannot be mounted properly or may interfere with the machine's structure. In more severe cases, they might not be installable close to the area that needs monitoring, or, even more critically, they cannot be utilized at all, such as for safety concerns. Compared to acceleration analysis, acoustic analysis using microphones offers several advantages, including the ability to detect signals at higher frequencies than traditional accelerometers and the capability to monitor machines without direct contact. In this context, this paper investigates the use of microphones, particularly ultrasonic microphones, in addition to accelerometers for monitoring the condition of mechanical components, particularly rolling bearings [8]. In addition, the combined use of vibration and acoustic signals could improve the accuracy of early fault detection, allowing more timely and efficient maintenance intervention. The paper focuses on the analysis of the energy content in the acoustic signal and the use of statistical indicators, without going into details of advanced spectral processing or machine learning techniques. The aim is to assess the effectiveness of an approach based on simple, yet meaningful, metrics that complement traditional

predictive maintenance methods, enhance early failure detection, and to evaluate the effectiveness of the hybrid accelerometric-microphonic approach applied to these techniques.

2. ANALYSIS PARAMETERS

This study uses low-complexity signal analysis parameters to assess their applicability in industrial predictive maintenance [9-10].
Kurtosis is here applied as a key indicator. It measures the deviation from the mean and reflects the presence of sharp peaks or heavy tails in a signal. Statistically, it is defined as the fourth standardized moment:

$$Kurtosis = E\left[\left(\frac{X-\mu}{\sigma}\right)^4\right] = \frac{\mu_4}{\sigma^4}$$
$$\frac{\mu_4}{\sigma^4} = \frac{\frac{1}{N}\sum_{i=1}^{N}(x(i)-\mu)^4}{\left(\frac{1}{N}\sum_{i=1}^{N}(x(i)-\mu)^2\right)^2} \quad (1)$$

A normal distribution of data presents a kurtosis equal to 3, and distributions with a kurtosis greater than that value are defined as leptokurtic. Leptokurtic distributions present thicker tails, i.e. have more data far from the mean value; typically, vibrations produced by defects in rolling bearings show Leptokurtic behavior.
The second indicator used is the RMS (Root Mean Square), defined as:

$$RMS = \sqrt{\frac{1}{N}\sum_{i=0}^{N}\left(x^2(i)\right)} \quad (2)$$

The RMS value of vibrations produced by a damaged bearing is sensibly greater than a healthy bearing one.
Some impulsive metrics indicators, such as the crest factor and the impulse factor were used to evaluate the peak component of the signal. Crest factor is defined as the peak value divided by the RMS value:

$$Crest\ Factor = \frac{|x_{peak}|}{\sqrt{\frac{1}{N}\sum_{i=0}^{N}\left(x^2(i)\right)}} \quad (3)$$

The impulse factor is defined as the ratio of the peak value to the arithmetic mean of the absolute values of the signal:

$$Impulse\ Factor = \frac{|x_{peak}|}{\frac{1}{N}\sum_{i=0}^{N}|x(i)|} \quad (4)$$

Impulsive metrics are important in bearings fault analysis because the formation and growth of defects cause impulsive forces to be generated during bearing operation.

To conclude, spectral energy was used to represent the energy contained in the various third octave frequency bands. Spectral energy is defined as the sum of the squared absolute value of the Fourier-transformed signal:

$$E(f) = \sum |X(f)|^2 \quad (6)$$

According to Percival's theorem, the spectral energy calculated over the whole spectrum is equal to the overall signal energy. In this study, particular attention was paid to the relationship between the spectral energies calculated from the signals of damaged bearings to those from healthy bearings for each data acquisition batch.

3. METHODOLOGY

3.1 Data Acquisition

Several data acquisitions were conducted by varying both fault type and bearing operating condition. This section details the equipment and sensors used, including their technical specifications. In addition, a brief overview of the test environments and experimental settings are provided. All the measurements were carried out at the laboratories of the University of Modena and Reggio Emilia.

3.1.1 Sensors and data acquisition devices

The same data acquisition systems were used in the tests to ensure consistency and comparability of results. The whole system is composed of a data acquisition system, one measurement microphone, one ultrasound microphone and one accelerometer. The ZoTech[1] Data Acquisition System (DAQ) was used to record the microphone and accelerometer signals, composed of a Sensor Network Interface (DIN0264) and a Sensor Acquisition Node (AIN0824). This architecture makes use of a digital bus implemented on an Unshielded Twisted Pair to connect one or more AIN0824 boards to a data storage system (e.g., a laptop or an industrial PC) using a DIN0264 board. The implementation of a digital communication guarantees perfect synchronization between the acquired signals, both in term of jitter and latency [9-10] making it a perfect system for acquiring many transducers with time synchronization, mandatory for the computation of the most advanced diagnostic metrics [11-12]. The system operates at a sampling rate of 48 kHz with a resolution of 24 bits, ensuring accurate signal representation. A full-scale range of ±5V was configured for both sensors to optimize

[1] www.zotech.it/en

dynamic range and measurement fidelity. Further specifications are given in Tab. 1.

Table 1. ZoTech data acquisition system

Specification	Value
Number of inputs	64
Sampling Rate	48 kHz
Resolution	24 bits
Connection	USB 2.0

The Ultramic 384K WIND ultrasonic microphone (Tab. 2) has a built-in recording system with a sampling rate of 384 kHz and a resolution of 16 bits. This configuration allows accurate acquisition of ultrasonic signals up to 192 kHz, effectively covering the entire operating range of the microphone, which is critical for detecting high-frequency fault signatures.

Table 2. Ultrasound Microphone Ultramic 384K WIND (Dodotronic), technical data.

Specification	Value
Frequency Range	1 to 100 kHz
Sampling Rate	384 kHz
Resolution	16 bits
Connection	USB 2.0

For vibration measurements, the Piezotronics 603M170 PCB sensor was used (Table 3), which offers a frequency range up to 14 kHz and a sensitivity of 100 mV/g over one axis (mono-axial). This ensures the detection of mechanical vibrations in the typical range of failure frequencies.

Table 3. Accelerometer PCB Piezotronics 603M170, technical data.

Specification	Value
Sensitivity (±10%)	100 mV/g
Measurement Range	±80g
Frequency Range	0.4 Hz to 14 kHz

The Brüel & Kjær 4189 omnidirectional microphone was used as the acoustic transducer (Table 4), which offers a flat frequency response from 6 Hz to 20 kHz with a sensitivity of 50 mV/Pa. Its wide and stable response range enables accurate capture of low-frequency and high-frequency acoustic emissions, facilitating a comprehensive analysis of how potential damage affects the entire acoustic spectrum.

Table 4. Microphone and Preamplifier Bruel&Kjaer 4189-1706, technical data.

Specification	Value
Diameter	½inch
Sensitivity	50 mV/Pa
Frequency Range	6.3 Hz to 20 kHz

3.1.2 First test condition

In Fig. 1(a), a schematic diagram illustrates the configuration of the first test condition. The system consists of a three-phase motor with a bearing mounted directly on the shaft. An accelerometer is placed over the bearing seat to capture vibrations in the radial direction.
The Ultramic 384K WIND is placed 20 cm in front of the bearing, directly aligned with it. The microphone is connected via USB 2.0 to a PC running Audacity software, which records the signal at 384 kHz.
The measurement microphone (Brüel & Kjær 4189) is placed 45 cm from the bearing to capture the machine's overall acoustic emissions. This microphone and accelerometer are connected to the ZoTech data acquisition system. Data from these sensors are recorded on a separate PC, as different interfaces are needed for different sampling rates.
The motor speed was set to 1000 rpm, and all test bearings were evaluated under this nominal operating condition. Measurements were conducted on a series of three SKF 6205 bearings, each subjected to different laboratory-induced wear conditions. The first bearing was new and served as a reference. The second bearing had damage to the outer ring induced by acid exposure, and the third was damaged by compression with a force greater than its rated load capacity. SKF 6205 bearing specifications are given in Tab. 5.

Table 5. SKF 6205 bearing specifications.

Specification	Value
Number of balls	9
Diameter of balls	7.94 mm
Pitch diameter	39.04 mm
Contact angle	0°

3.1.3 Second test condition

The second set of measurements, shown in Fig. 1.b, was conducted on a test bench specially designed for bearing analysis, the AV TEST BENCH, manufactured by AMC Vibro. This test bench consists of two three-phase asynchronous motors, one operating as a main motor and the other as a braking system, together with a gearbox

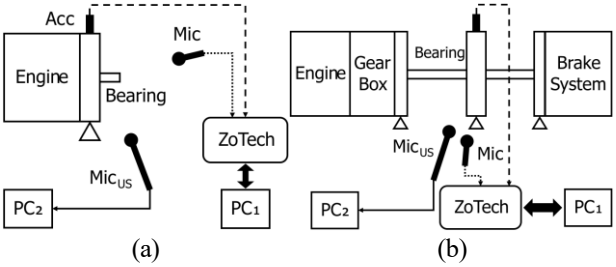

Figure 1. (a) First test condition, (b) second test condition

(transmission rate 2,91:1) and a shaft supported by three rolling bearings. The test stand was used with a three-stage speed profile consisting of three constant-speed strokes at 1000-1500-2000 RPM measured on the motor side. The corresponding shaft speeds at which the bearing was tested were 343.64 RPM, 515.46 RPM and 687.29 RPM, due to the speed reduction of the gearbox. For these measurements, the accelerometer was mounted on the center bearing, and the two microphones were placed 15 cm in front of the bearing. The parameters of the data acquisition system remained unchanged from the previous test to ensure consistent measurement conditions. Measurements were conducted using two SKF YAR 204-2F bearings: the first bearing was healthy, with a minimum number of operating hours, while the second had a lab welding-induced damage on the outer ring. SKF YAR 204- bearing technical specifications are given in Tab. 6.

Table 6. SKF YAR 204 2F bearing specifications.

Specification	Value
Number of balls	8
Diameter of balls	7.938 mm
Pitch diameter	33.5 mm
Contact angle	0°

3.2 Data Processing

To ensure consistent and reliable statistical parameters for the detection of potential failures, the acquired signals were subjected to pre-processing, which included data slicing and filtering. Next, theoretical failure frequencies of the tested bearings were calculated based on their geometric parameters and rotational speed. Finally, envelope analysis and spectrogram visualization were performed to characterize the damage signatures of the defective bearings with respect to the healthy reference. The following subsections detail each step of the data processing workflow.

3.2.1 Pre-processing

In all test conditions, at least 1 minute of audio was recorded to ensure that the system reached a steady state condition. From each recording, 15 seconds of steady-state data are selected. In Fig. 2, an example of the raw, trimmed signal data from the three sensors is presented in both "healthy" and "damaged" conditions of the bearing. The data are then filtered with a Butterworth-type bandpass filter of order 5, matched to the characteristic frequency range of each sensor: for the accelerometer, the used filter range is 2 Hz to 14 kHz; for the microphone, the range is 6 Hz to 20 kHz and for the ultrasonic microphone goes from 1 to 100 kHz.

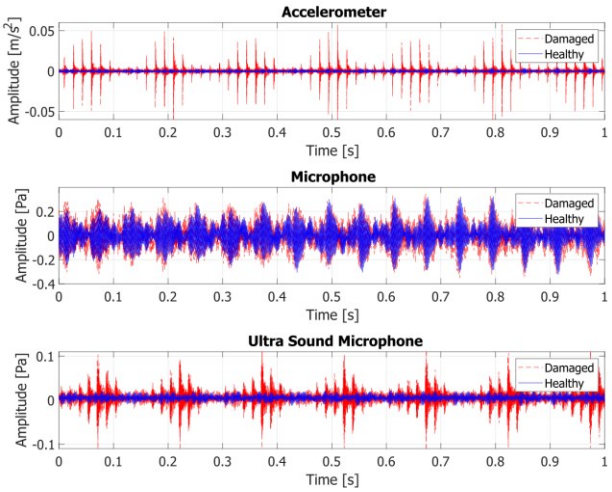

Figure 2. Time plot of 1 s for each sensor.

3.2.2 Calculus of bearings fault frequencies

To confirm and characterize the presence of defects manually induced on the bearings, characteristic failure frequencies were calculated based on bearing's geometric parameters and rotational speed, following the methodology described in [13]. These failure frequencies aid in identifying specific types of defects. The equations used are as follows:

$$f_{BPFO} = \frac{n}{2} f_r \left(1 - \frac{BD}{PD}\cos\beta\right) \quad (7)$$

$$f_{BPFI} = \frac{n}{2} f_r \left(1 + \frac{BD}{PD}\cos\beta\right) \quad (8)$$

$$f_{BFF} = \frac{PD}{BD} f_r \left[1 - \left(\frac{BD}{PD}\cos\beta\right)^2\right] \quad (9)$$

$$f_{FTF} = \frac{1}{2} f_r \left(1 - \frac{BD}{PD}\cos\beta\right) \quad (10)$$

where f_r is the shaft rotational frequency (in Hz), BD is the ball diameter and PD is the pitch diameter (distance

between opposite rolling elements). The n parameter indicates the number of rolling elements and β is the contact angle of the rolling elements. The frequencies f_{BPFO}, f_{BPFI}, f_{BFF} , f_{FTF} are respectively: the Ball Pass Frequency Outer Race (characteristic of an outer ring fault), the Ball Pass Frequency Inner Race (for inner ring faults), the Ball Spin Frequency (related to rolling element defects), the Fundamental Train Frequency (associated with cage or retainer faults). The results are collected in Table 7.

Table 7. Bearings' fault frequencies with shaft speed respectively of 1000 and 343.64 rpm.

Parameters [Hz]	SKF 6205	SKF YAR204
Rotation Freq.	16.67	5.73
BPFO	59.75	20.53
BPFI	90.25	31.01
BFF	78.56	27.00
FTF	6.64	2.28

To confirm the presence of these defects in the recorded signals, Hilbert envelope analysis was applied to the accelerometer signal [13] to enhance the impulsive components caused by the bearing defects, making the defect-related frequencies more visible in the frequency domain. The Hilbert envelope spectrum, shown in Fig. 3, reveals the dominant spectral components associated with different types of damage. In the healthy bearing (black solid line), the spectrum is predominantly characterized by the shaft rotation frequency of 16.67 Hz and its harmonics, indicating normal operation. In contrast, for the first type of damage (dashed blue line), the spectrum has a distinct peak at the ball passage frequency on the outer raceway (BPFO) of 59.75 Hz, confirming the damage on the outer raceway. In addition, the presence of a peak at the train fundamental frequency (FTF) suggests a cage defect, while the side bands around the BPFO, spaced twice the FTF, indicating modulation effects due to the interaction between these fault components. For the second type of damage (dashed red line), the dominant peak at 78.6 Hz corresponds to the ball rotation frequency (BFF), while distinct peaks at the ball passage frequency within the stroke (BPFI), BPFO and FTF further confirm the presence of the multiple damages, induced by compression of the bearing.

3.2.3 Calculus of parameters in ⅓-octave band approach

To calculate statistical parameters for bearing defect detection, a preliminary analysis was performed on the entire spectrum of the pre-filtered signal.

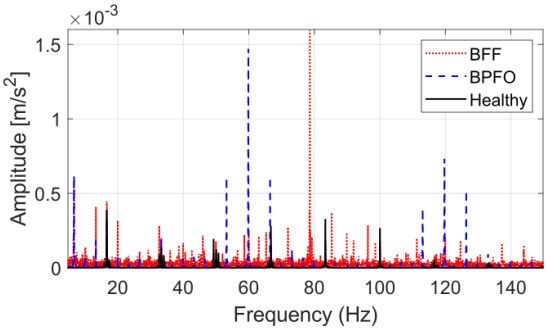

Figure 3. Spectrum of the Hilbert envelope of the accelerometer signal (SKF6205).

Subsequently, a ⅓-octave band approach was adopted to obtain a more in-depth view. This method was chosen because it offers an optimal compromise between frequency resolution and data manageability. Starting from the pre-processed signal (section 3.2.1), the data were segmented into one-third octave bands spanning the frequency range defined by the minimum and maximum central frequencies reported in Tab. 8. For each band, a 4th-order bandpass Butterworth filter was applied. The cutoff frequencies were calculated as:

$$f_{low} = \frac{f_c}{2^{1/6}} \;\; ; \;\; f_{high} = f_c \times 2^{1/6} \qquad (11)$$

where f_c is the central frequency of each band. Once the signal was filtered into its component ⅓ octave bands, the statistical parameters described in section **Errore. L'origine riferimento non è stata trovata.** were calculated for each band. These parameters provide insights into the signal's energy distribution and impulsiveness, which are critical in identifying the occurrence of bearing failures.

Table 8. 1/3 octave maximum and minimum central frequencies for all the sensors.

[kHz]	Acc	Mic	UltraMic
f_{c_min}	1	1	20
f_{c_max}	12.5	16	100

4. RESULTS AND DISCUSSION

This chapter presents the overall results of the two test conditions described in Sections 3.1.2 and 3.1.3, analyzed in terms of statistical parameters and spectral energy factor. Section 4.1 focuses on the first test condition, illustrating the results obtained for different types of damage at constant velocity. Section 4.2, on the other hand, examines the effects of a single type of damage at varying speeds.

4.1 Results at constant speed

The first testbed demonstrated promising results, showing clear distinctions in both statistical parameters and spectral energy analysis.

4.1.1 Statistical Parameter

Before calculating the parameters within one-third-octave bands, as shown in section 3, they were calculated over the entire spectrum. In Tab. 9, only the results for the ultrasonic microphone are presented because previous research has already validated the use of these statistical parameters with accelerometers. As is evident from the data, both types of bearing damage result in significant deviations from the "healthy" case, making these parameters an effective means of distinguishing between undamaged and damaged bearings. Fig. 4 shows the results obtained for the kurtosis for the three sensors, applying it to the one-third-octave bands as described in section 3.2.3. As expected, the accelerometer provided excellent results, particularly in the mid-to-high frequency ranges (3.5-5 kHz and 6-12 kHz), where the damage effects were most pronounced. The results obtained from the two microphones are also interesting, showing a significant increase in kurtosis at higher frequencies, particularly between 8 and 16 kHz. Although the difference between the "healthy" and the "damaged" cases is relatively small compared to the accelerometer results, it is noteworthy that despite being placed at a considerable distance from the bearing, the microphone still managed to detect the changes between the two conditions. The ultrasonic microphone, on the other hand, provided even sharper and more reliable results. It differentiated effectively between the two bearings, with damage to the outer ring (red bars) mainly affecting bands between 20 and 31.5 kHz. In the case of compression damage (ochre bars), the affected frequency range was from 20 to 63 kHz, with a peak at 40 kHz.

Table 9. Mean Statistical Parameters of different condition of the bearing, computed using ultrasonic microphone recordings.

	Healthy	BPFO Damaged	BFF Damaged
Kurtosis	2.4849	15.1926	11.1764
Impulse Factor	4.8443	19.7021	22.8560
Crest Factor	4.0316	12.0241	15.3572
RMS	0.0016	0.0105	0.0181

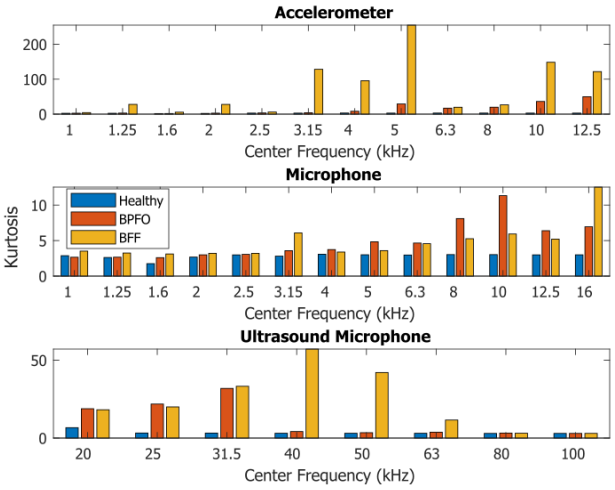

Figure 4. Kurtosis parameter in 1/3 octave bands representation, calculated for each sensor.

4.1.2 Spectral Energy Confrontation

Although spectral energy is not typically used as an absolute indicator of defects, the energy comparison between healthy and damaged bearings demonstrated significant results in this sense. As we did for the previous parameters, the spectral energy ratio was calculated in one-third octave bands to highlight the differences between damaged and healthy bearings. As shown in Fig. 5, the accelerometer reveals that the most significant energy differences between healthy and damaged bearings are concentrated in the mid- to high-frequency range, between 4 and 12.5 kHz, with a clear increase in spectral energy in the damaged cases. An interesting observation emerges from the analysis of the microphone measurement. In the case of compression damage, the increase in spectral energy is mainly in the low-mid frequencies, with a prominent peak at 1 kHz. In contrast, for outer ring damage, the frequencies affected are mainly in the upper-mid range, between 4 and 16 kHz, similar to what was observed with the accelerometer. For the ultrasonic microphone, the spectral energy increases significantly in the 20–40 kHz range, particularly in the compression-damaged bearing. The peak distribution differs with damage type: outer ring damage shows a dominant increase in the 20 kHz band, while compression damage peaks in the 35 kHz band.

4.2 Results at varying speed

This section presents the results referred to the second testbench, described in section 3.1.3. In Fig.6, we can observe the most statistically significant parameters (section

2) calculated over the entire signal spectrum at all three speeds tested.

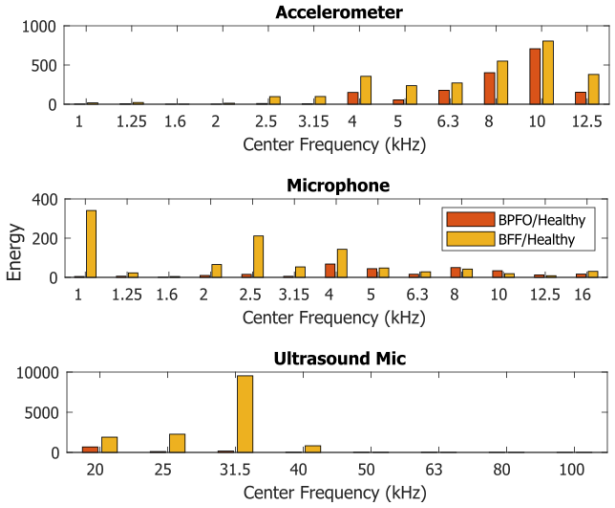

Figure 5. Spectral energy ratio between the damaged and healthy bearing signal, calculated for each sensor.

The first notable observation is that both the accelerometer and the ultrasonic microphone clearly distinguish between healthy and damaged bearings across all calculated parameters. Among these, impulse factor and kurtosis stand out as the most effective indicators. This demonstrates that full-band statistical analysis alone can reliably detect potential damage, regardless of shaft speed. In contrast, the standard microphone shows minimal variation across different speeds and conditions, indicating limited effectiveness over the entire frequency range. However, as shown in Fig. 7, when the analysis is narrowed to third-octave bands, this sensor also reveals useful information about fault presence. The plots illustrate only the kurtosis parameter for simplicity and clarity. A particularly noteworthy result is shown in Fig. 8, which illustrates the spectral energy ratio between damaged and healthy signals for both sensors, calculated on the 1/3-octave spectrum. The results clearly indicate a gradual increase in the energy ratio with increasing shaft speed for both microphones. In particular, the measurement microphone shows an increase in spectral energy in the range from 6.3 to 16 kHz, peaking at 8 kHz. On the other hand, the ultrasonic microphone reveals two distinct regions of energy increase: one between 20 and 25 kHz and the other between 31.5 and 63 kHz. Interestingly, both microphones' effectiveness is significantly influenced by shaft speed, revealing weaker energy ratios at lower speeds. This tendency is more pronounced in the ultrasonic microphone but is also slightly evident in the measurement microphone. The accelerometer does not exhibit this velocity-dependent behavior, showing the highest energy ratio in the upper bands, particularly from 8 to 12.5 kHz. As might have been expected, in terms of amplitude of the spectral energy ratio, the accelerometer provides the most pronounced and reliable results.

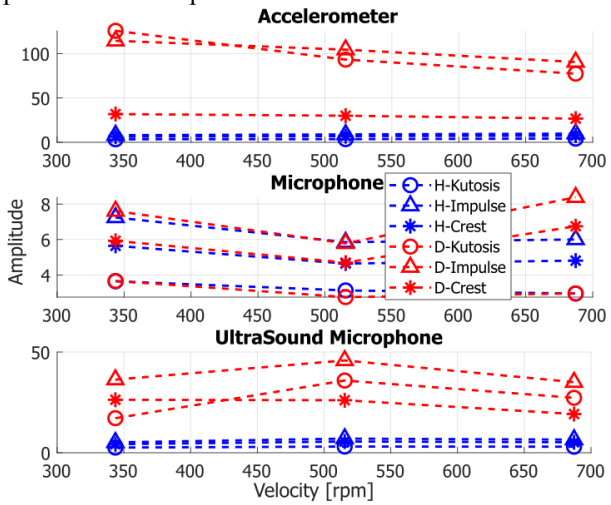

Figure 6. Statistical indicators at varying speeds.

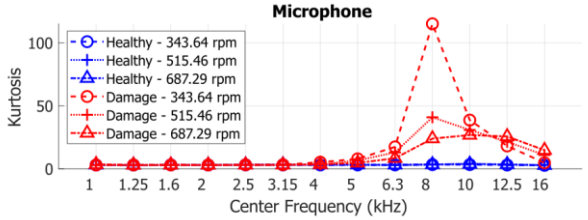

Figure 7. Microphone signal kurtosis in 1/3-octave bands.

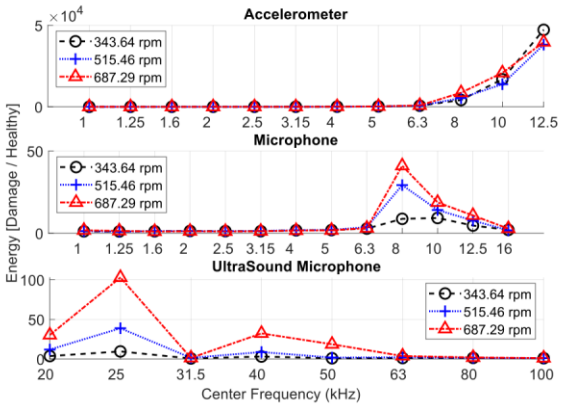

Figure 8. Energy Ratio between damaged and healthy bearings at varying speeds.

5. CONCLUSION

Microphones have proven to be a viable solution for detecting faults in rolling bearings under controlled conditions, offering a useful alternative in scenarios where accelerometers cannot be used. This study explored two basic data analysis techniques, both of which yielded promising results. In particular, the energy ratio method demonstrated strong potential for predictive maintenance applications, with performance comparable to that of traditional statistical indicators. While kurtosis can be an absolute indicator of failure, this is not necessarily true for the other statistical parameters or energy-based approaches. These methods were selected for their low computational cost and practical applicability in real-world predictive maintenance systems. The findings suggested that integrating ultrasonic microphones into vibroacoustic analysis frameworks can enhance the monitoring and maintenance of industrial systems. This approach was shown to be promising for improving the sensitivity of defect detection and providing, at the same time, practical benefits regarding ease of installation and maintenance.

6. FUTURE WORKS

This preliminary study applied classical statistical parameters and energy-based analysis techniques to signals acquired from accelerometric, acoustic, and ultrasonic measurements. Future work will explore advanced diagnostic signal processing methods and compare sensor performance under varying operating conditions, including changes in position and rotational speed. In particular, the influence of microphone distance will be investigated to simulate scenarios in which contact sensors, such as accelerometers, are not a feasible solution.

ABSTRACT

This paper introduces a novel method for predicting tool wear in CNC turning operations, combining ultrasonic microphone arrays and convolutional neural networks (CNNs). High-frequency acoustic emissions between 0 kHz and 60 kHz are enhanced using beamforming techniques to improve the signal-to-noise ratio. The processed acoustic data is then analyzed by a CNN, which predicts the Remaining Useful Life (RUL) of cutting tools. Trained on data from 350 workpieces machined with a single carbide insert, the model can accurately predict the RUL of the carbide insert. Our results demonstrate the potential gained by integrating advanced ultrasonic sensors with deep learning for accurate predictive maintenance tasks in CNC machining.

Keywords: *condition monitoring, predictive maintenance, ultrasound signal processing, deep learning, beamforming*

1. INTRODUCTION

Predictive maintenance is the process of using sensor data to infer the state of a machine, and detect flaws or failures before they happen from that sensor data [1, 2]. Predictive maintenance is a rising trend in virtually all industry branches, ranging from bearing fault detection [3], gear wear detection [4] or piston wear in reciprocating machines [5] amongst many other examples. A plethora of sensors is being applied for predictive maintenance, ranging from acoustics, vibration signals, thermal sensors, current sensors, and virtually any other sensing modality that can be imagined [1, 3]. In previous work, we demonstrated bearing fault detection using ultrasound signals in the band of 0 kHz to 60 kHz, measured with a microphone array and subsequent beamforming techniques [6].

When machining complex parts with axis-symmetry, CNC lathes are the de-facto standard manufacturing technique. In a CNC lathe, the work piece is mounted to a spindle which is then being rotated, and cutting is performed by means of a stationary cutting tool. There is a wide variety of cutting tool geometry and materials, with carbides being the dominantly used material for fabricating these cutting tools. While the variety in geometry and material type is vast, one recurring and important feature of these tools is the sharpness. Indeed, the sharpness of the cutting tool often directly correlates to the finished quality of the workpiece [7, 8]. A tool that is too dull will not cut adequately, leaving a poor surface finish, while a tool that is overly sharp is brittle and wears quickly. Manufacturers of CNC tools often specify a tool life parameter, expressed in hours, which indicates how long a tool can be utilized. However, these estimates are sometimes too conservative [7, 9], and therefore lead to premature replacement of still useful tools. Furthermore, some tools might fail prematurely, causing problems in automated manufacturing applications, which results in scrapped parts and lost revenue.

To combat the problem with tool wear inherent to CNC machining, various techniques for automated tool wear estimation have been devised [9, 10]. Similar as to

the general field of predictive maintenance, a wide range of sensing modalities is being used, such as consumed spindle power/current [11], vibration measurements [12], Doppler radar [13] and acoustics [14–16]. In many previous publications, combinations of these aforementioned sensor modalities are used to perform the tool wear or tool life prediction.

In this paper, we will focus on the use of ultrasonic acoustic signals in the range of 0 kHz to 60 kHz using an array sensor, similar to our previous work on bearing fault detection [6]. The sensor is based around our eRTIS ultrasonic sensor [17] which allows the implementation of broadband spatial filters through beamforming. Using beamforming in high-noise scenarios such as CNC operations should improve the SNR of the signal, by filtering out unwanted noise sources. We will use our eRTIS sensor to measure the ultrasonic spectrogram acoustic signals generated by the cutting operation, and use beamforming to remove unwanted interference. Then, we will employ a convolutional neural network to perform Remaining Useful Life (RUL) prediction [18] of the cutting tool, using data obtained from 350 work pieces turned using a single carbide insert.

2. HARDWARE SETUP

In this section we will provide some details on the experimental setup. We used an industrial CNC lathe (Mazak QT10N), which is shown in figure 1 panel b). On this lathe, we turned a batch of tensile test specimen used in the mechanical engineering curriculum of our university until tooling insert failure (350 pieces). The model of this tensile test specimen can be seen in figure 1, panel e). We used two materials for making these test pieces, more specifically 1.1191 (C45) and 1.7225 (Chromoly), distributed as randomly as possible during the production run. We used a depth of cut of 0.3 mm, a feed rate of 0.5 mm per revolution and a surface speed of 120 m min^{-1}. As tooling insert we used an Iscar GRIP 3015Y in grade IC808.

As ultrasonic sensors we used two eRTIS sensors [17], which are ultrasonic microphone-array sensors with 32 microphones, sampled at 450 kHz. The individual sensors are synchronized using our pseudo-random 1-bit synchronization method described in [19]. One eRTIS sensor was placed inside of the lathe, another outside right where the operator would stand. In addition, we recorded the spindle current using a Fluke i1000s current clamp, connected to a National Instruments NI-USB6363 DAQ, which sampled both the current signal as well as the synchronization signal at 500 kHz. The eRTIS sensors measured chunks of acoustic data of 40 ms at a rate of 10 Hz (i.e., the signal is sampled intermittently).

3. SIGNAL PROCESSING AND EXPERIMENTAL RESULTS

In this paper, we treat each eRTIS sensor independently - i.e. there is no sensor fusion using multiple sensors. Each sensor measures 32 microphone signals $s_m(t)$. These microphone signals are passed through a beamformer B_ψ pointing in direction ψ, which is the vector pointing from the sensor to the tool position. The beamformed signals are also filtered using a bandpass filter $h_{bp}(t)$, which is set to be a Butterworth filter of order 6 between 0 kHz and 60 kHz. The overall output of each datasample of 40 ms can then be calculated as:

$$s_o(t) = h_{bp}(t) * \sum_{i=1}^{32} B_\psi \Big(s_m(t) \Big) \tag{1}$$

This output signal is then transformed to a magnitude spectrum $S_n(\omega)$ using a Welch Power Spectral Density estimator, using a window length of 1024 samples and Hamming weighting. In this spectrum $S_n(\omega)$, the index n represents the frame number of that data section (sampled at 10 Hz, and 40 ms). These spectra are all concatenated into a large matrix S, which then represents a spectrogram-like representation:

$$S(\omega, n) = \Big[S_1(\omega) \quad S_2(\omega) \quad \dots \quad S_N(\omega) \Big] \tag{2}$$

Examples of these spectrogram-like representations can be seen in figure 2. Panel a) shows the spectrogram of a run recorded using an eRTIS outside of the lathe, and panel b) shows the spectrum recorded inside the machine. The main difference between the data recorded by these two sensors can be found in i) the low-frequency motion sounds, which are more clearly visible in the spectrum measured outside of the machine, and ii) the cutting noise, which is high in frequency and more prominent in the data in panel b). Both representations are shown on a logarithmic dB scale, normalized between 0dB and 90dB. One of these spectrograms is recorded for each of the 350 pieces that is being manufactured.

Finally, we implemented a convolutional neural network which solves the following regression task: estimating the work-piece number based on a acoustic spectrogram data (ie, a number between 1 and 350). The CNN

Figure 1. Overview of the hardware setup used in this paper. Panel a) shows the eRTIS sensor, an ultrasonic array sensor with 32 microphones arranged in a pseudorandom pattern. The sensor is waterproofed using a membrane material from the Acoustic Protective Material line manufactured by W. L. Gore and Associates. Panel b) shows the CNC lathe being used, a Mazak Quickturn 10N, using Iscar GRIP 3015Y grade IC808 inserts. Panel c) shows the inside eRTIS sensor mounted in the lathe. Panel d) shows the turned materials, and e) shows the model of the piece that has been turned during this experiment.

is a standard feed-forward CNN with four convolutional layers, leaky ReLu function, max pooling, layer normalization and dropout (10 percent). After the four convolutional layers the output gets flattened into a vector, and passed through two fully connected (FC) layers, where the first FC layer has an output dimension of 10 and a ReLu nonlinearity, and the last FC layer has a single output. We trained the neural network using the Adam optimizer, with a learning rate of 0.01 for a maximum of 100 epochs, and used the best validation loss checkpoint as the final network. We used data augmentation (shifting in the time dimension and additive noise), and split the augmented dataset randomly into a training set (75%), validation (10%) and test (15%) sets. In the ideal case, we would perform this split before augmentation (or even use a complete second run), which would required a more extensive dataset, and that was not available at the time of writing. Training of the CNN on a single NVidia RTX4090 took around one hour, including data pre processing.

After training we used our test data to evaluate the model's performance, for which the results can be seen in figure 4. In that figure, panel a) shows the run number prediction based on a single acoustic spectrogram, and panel b) shows the prediction when combining the predictions of five spectrograms centered around the desired run number. Panels c) and d) show the mean run number prediction error including the variance bands on the prediction (grey shadows), in percentage of the total tool life. The maximum error of this prediction is plus or minus 6 percent of the total tool life when using the averaged result. This estimator allows tracking the health of the cutting tool, and allows interventions or continued operation based on the real-world state of tool sharpness. Including a window around the current run number decreases the variance on the estimation and estimation error, as is to be expected.

4. DISCUSSION AND CONCLUSION

In this paper, we showed a multi-modal sensor setup for estimating tool wear in CNC turning operations. We discussed the data-acquisition process, and explained what pre-processing steps were taken in data preparation. Subsequently, we detailed the architecture of a convolutional neural network which was applied to the prediction of remaining useful life of the CNC cutting insert. Using an extensive dataset, consisting of 350 tensile test pieces in two materials, we showed the performance of the regression capabilities of these CNNs. We showed that these CNNs are able to estimate the tool life with a maximum error of 6 percent within the total tool life, illustrating the rich data that ultrasonic sensing provides to extract the relevant metrics for predictive maintenance. In future work, we will benchmark our approach to existing approaches in the literature, and evaluate in detail which aspects of the system are relevant: what advantages does a microphone array bring, what benefit has a CNN, and how important is the CNN architecture.

Furthermore, we will evaluate the problem of generalizing this method to different machines/parts. The system

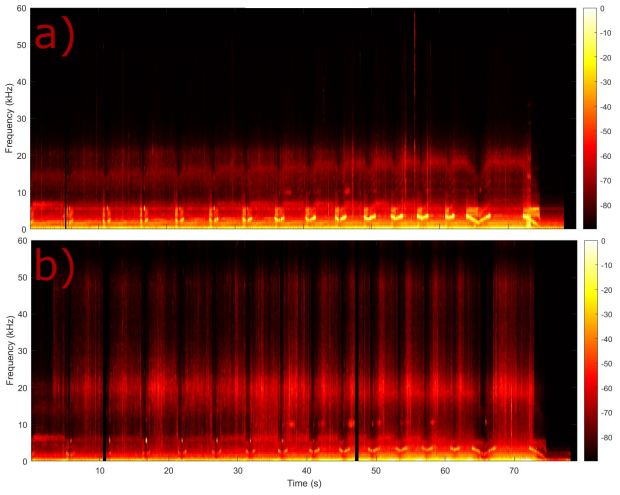

Figure 2. Spectrogram representation of the acoustic data recorded by the eRTIS sensors during a turning run. Panel a) shows the data of measured by the eRTIS sensor ouside of the machine, and panel b) shows the data recorded from inside the machine. In the low frequency parts, the signal is dominated by the motion sounds of the machine, and the high frequency parts of the spectrogram are generated by the cutting operations.

as it is currently proposed, requires a training run for each machine/part/tool combination. In industrial practice, this is not a major hindrance, because each part is often run over multiple weeks, and performing a single training run on an insert is not a large hindrance. However, it would be interesting to implement models which are capable of generalization. For this, larger datasets need to be captured on different machines, making different parts, which is why we classify this as future work.

ABSTRACT

The Linearized Euler Equations (LEE) are a system of partial differential equations that provide a framework for modeling outdoor acoustic wave propagation, capturing atmospheric and topographic effects. Solving LEE using traditional numerical methods demands fine spatial and temporal resolutions, leading to high computational costs over large domains. This study uses established neural network approaches to solve LEE and evaluates their performance and scalability for outdoor acoustic wave propagation. Included approaches are Physics-Informed Neural Networks (PINNs) and the sampled network-based Extreme Learning Machine Ordinary Differential Equations (ELM-ODE). We use a SIREN-based architecture in our PINNs for wave-like solutions. In the 1D case, PINNs achieved higher accuracy but required significantly more training time due to the complexity of training over a spatiotemporal domain. Meanwhile, ELM-ODE provided competitive accuracy with much lower computational cost. In the 2D case, ELM-ODE again showed computational advantages over SIREN-PINNs while delivering great accuracy. However, its scalability is constrained by the coupled velocity–pressure matrix, which increases costs in cases like outdoor noise mapping, where velocity data eventually are unused. Addressing boundary conditions, such as frequency-dependent impedance, remains a challenge.

1. INTRODUCTION

Modeling outdoor acoustic wave propagation is important with a lot of applications, including noise mapping for urban planning [1], environmental monitoring [2], and aviation acoustics [3]. The propagation of sound in the atmosphere is affected by atmospheric factors such as wind, temperature gradients, and topographic features [2]. These factors introduce complexities into predicting acoustic wave behavior accurately, especially when considering high-frequency waves or large spatial domains.

The Linearized Euler Equations (LEE) provide a mathematical framework for modeling outdoor acoustics by capturing the interactions among acoustic velocity, pressure fluctuations, and the background atmospheric flow [4, 5]. Unlike simpler acoustic models, the LEE take account for the convective effects and the compressible nature of sound waves, making them particularly well-suited for simulating realistic outdoor conditions. However, traditional numerical methods for solving the LEE, such as finite-difference time-domain (FDTD) schemes [6, 7], often require substantial computational resources. This is especially true for scenarios involving high frequencies or extended spatial domains [8].

Recent advances in machine learning offer a new way to solve LEE. In particular, *physics-informed neural networks* (PINNs) have been proposed as an effective means to solve partial differential equations (PDEs) by embedding the governing equations directly into the loss function during training [9]. This approach ensures that the neural network follows the underlying physics. How-

ever, PINNs can be computationally demanding and may encounter convergence issues when dealing with high-frequency oscillations and multi-scale features [10], especially for solving time dependent PDEs like LEE which need to be trained for the whole time domain.

An alternative strategy, the *sampled neural network method* to solve PDE has been introduced to overcome some of these challenges. In the work of Datar *et al.* [11], the authors propose the *Extreme Learning Machine Ordinary Differential Equations* (ELM-ODE) framework, which applies a shallow neural network with fixed, randomly sampled weights to represent spatial basis functions. The time evolution of the solution is then captured by solving a system of ordinary differential equations for the time-dependent coefficients. This decoupling of the spatial and temporal components leads to a dramatic reduction in training time while still achieving high accuracy in modeling the wave dynamics inherent in the LEE.

In this paper, we present a comparative study of the PINNs and ELM-ODE approaches for solving the Linearized Euler Equations in the context of outdoor acoustic propagation. We present how to implement each framework to solve LEE and assess the methods' performance in terms of accuracy and computational efficiency. Our goal is to explore the strengths and limitations of these techniques for simulation of outdoor acoustics.

2. METHODS

2.1 Linearized Euler Equations

The linearized Euler equations have become a widely accepted model for simulating outdoor sound propagation. Their time-domain formulation offers several key advantages. First, a single simulation can generate comprehensive frequency responses. Second, they accommodate nonlinear effects while accounting for moving, realistic sources. When dealing with a moving medium, it is essential to use numerical methods that accurately capture both the medium's velocity and the acoustic pressure [12]. For instance, models described in [7] employ finite-difference time-domain (FDTD) methods to simulate sound wave motion in a moving medium. Atmospheric conditions significantly influence outdoor sound propagation, further highlighting the need to consider the medium's dynamics. The LEE consists of coupled equations for the velocity and pressure components, defined as follows:

The velocity component of LEE is given by:

$$\begin{aligned}\frac{\partial \mathbf{v}_{\text{acc}}}{\partial t} + (\mathbf{v}_{\text{met}} \cdot \nabla)\mathbf{v}_{\text{acc}} + (\mathbf{v}_{\text{acc}} \cdot \nabla)\mathbf{v}_{\text{met}} \\ = -\alpha_{\text{met}} \nabla p_{\text{acc}} - \alpha_{\text{acc}} \nabla p_{\text{met}} + \nu \nabla^2 \mathbf{v}_{\text{acc}}.\end{aligned} \tag{1}$$

Similarly, the pressure component is given by:

$$\begin{aligned}\frac{\partial p_{\text{acc}}}{\partial t} + \mathbf{v}_{\text{met}} \cdot \nabla p_{\text{acc}} + \mathbf{v}_{\text{acc}} \cdot \nabla p_{\text{met}} \\ = -\kappa p_{\text{met}} \nabla \cdot \mathbf{v}_{\text{acc}} - \kappa p_{\text{acc}} \nabla \cdot \mathbf{v}_{\text{met}}.\end{aligned} \tag{2}$$

The coefficients are defined as:

$$\alpha_{\text{met}} = \frac{1}{\rho_{\text{met}}}, \alpha_{\text{acc}} \quad = -\frac{1}{\kappa} \frac{p_{\text{acc}}}{p_{\text{met}}} \frac{1}{\rho_{\text{met}}}, \kappa = \frac{c_p}{c_v}.$$

The numerical solver will then solve for $\mathbf{v}_{\text{acc}}$ (the velocity of the particle) and p_{acc} (the pressure of the acoustic wave), with other variables such as p_{met} (the pressure of the flow field), $\mathbf{v}_{\text{met}}$ (the velocity of the flow field), ρ_{met} (the air density), and κ (the ratio of specific heats at constant pressure (c_p) and constant volume (c_v)) given. Note that κ can also be obtained from the speed of sound (c), p_{met}, and ρ_{met}.

2.2 Physics-Informed Neural Networks (PINNs)

Physics-Informed Neural Networks (PINNs) are neural networks trained to satisfy partial differential equations (PDEs), initial conditions (IC), and boundary conditions (BC) simultaneously [13]. The network receives spatiotemporal coordinates as input and outputs the physical fields to be learned. These outputs are differentiated with respect to the inputs using automatic differentiation [14], and then substituted into the PDE to obtain the residual. The residual quantifies how much the predicted fields violate the governing equations and is evaluated at a set of collocation points in the domain. The total loss is defined as:

$$\mathcal{L} = \mathcal{L}_{\text{phys}} + \mathcal{L}_{\text{IC}} + \mathcal{L}_{\text{BC}}, \tag{3}$$

where each term is a mean-squared error loss for the PDE residual $\mathcal{L}_{\text{phys}}$, the initial condition loss $\mathcal{L}_{\text{IC}}$, and the boundary condition loss $\mathcal{L}_{\text{BC}}$. Note that it can also include additional loss term if data are available such as from old simulation or measurements.

When applied to the Linearized Euler Equations (LEE), the neural network takes spatial-temporal input coordinates (x, t) or (x, y, t) and outputs pressure and velocity components as continuous functions. The network utilizes sinusoidal activation functions based on the SIREN

architecture [15], where each layer applies

$$\sigma(z) = \sin(\omega_0 z)$$

with a fixed frequency scaling constant ω_0 in order to approximate the wavy behaviour better.

2.3 Sampled Neural Network Approach

The Sampled Neural Network approach used in this study follows the Extreme Learning Machine-based ODE (ELM-ODE) method introduced in [11]. This method approximates the solution of a time-dependent PDE by separating spatial and temporal components. The spatial part is represented using a shallow neural network with fixed, randomly sampled weights, while the temporal part is evolved by solving an ordinary differential equation (ODE) system.

Let $\phi_k(x) = \sigma(w_k^\top x + b_k)$ denote the k-th basis function, where σ is a nonlinear activation function also w_k and b_k are weights and biases sampled from prescribed distributions (e.g., $w_k \sim \mathcal{N}(\eta_1, \eta_2)$ and $b_k \sim \mathcal{U}[-\eta_3, \eta_3]$), as originally proposed in the Extreme Learning Machine framework [16]. The solution is expressed as:

$$\hat{u}(x,t) = \sum_{k=1}^{K} c_k(t) \cdot \phi_k(x), \tag{4}$$

where $c_k(t)$ are time-dependent coefficients.

This ansatz is substituted into the governing PDE, and the residual is evaluated at a set of collocation points. The resulting system is projected onto the fixed spatial basis, resulting an ODE system for the temporal coefficients $c(t) = [c_1(t), \ldots, c_K(t)]^\top$, which is then integrated forward in time using standard solvers. For linear PDEs such as the simplified Linearized Euler Equations (LEE), the resulting ODE system remains linear.

Boundary conditions can be incorporated in two main ways, either by constructing basis functions that satisfy the boundary constraints, or by introducing additional terms to the ODE system that enforce the conditions weakly.

3. FORMULATING SOLUTIONS TO LEE WITH NEURAL NETWORKS

We started from the full Linearized Euler Equations given in Equations (1) and (2), however, in order to focus on the dominant convective and acoustic effects, we neglect the nonlinear advection due to acoustic perturbations, the weak coupling with background pressure gradients, viscous dissipation, and the divergence of the background flow.

Therefore, omitting these effects, the governing system simplifies to:

$$\frac{\partial \mathbf{v}_{\text{acc}}}{\partial t} = -\left(\mathbf{v}_{\text{met}} \cdot \nabla\right) \mathbf{v}_{\text{acc}} - \frac{1}{\rho_{\text{met}}} \nabla p_{\text{acc}}, \tag{5}$$

$$\frac{\partial p_{\text{acc}}}{\partial t} = -\left(\mathbf{v}_{\text{met}} \cdot \nabla\right) p_{\text{acc}} - \kappa\, P_{\text{met}}\, \nabla \cdot \mathbf{v}_{\text{acc}}. \tag{6}$$

3.1 Formulation of LEE in the PINNs Framework

We first nondimensionalize the governing equations. Let L_{ref} denote a characteristic length scale, and define the reference time scale as $T_{\text{ref}} = L_{\text{ref}}/c$, where c is the speed of sound. Pressure is scaled by a reference value p_c, and velocity by $v_c = p_c/(\rho_{\text{ref}} c)$, where ρ_{ref} is the reference density. This yields a nondimensional domain $(x, y, t) \in [-1, 1]^2 \times [0, 1]$, with all physical constants absorbed into the transformed variables. The nondimensional background wind velocities are defined as $M_x = v_{\text{met},x}/c$ and $M_y = v_{\text{met},y}/c$. Note that this can vary along the spaces or be constant values.

We apply this nondimensionalizing to Equations (5) and (6), resulting in the following system:

$$\frac{\partial v_{acc,x}}{\partial t} = -M_x \frac{\partial v_{acc,x}}{\partial x} - M_y \frac{\partial v_{acc,x}}{\partial y} - \frac{\partial p}{\partial x}, \tag{7}$$

$$\frac{\partial v_{acc,y}}{\partial t} = -M_x \frac{\partial v_{acc,y}}{\partial x} - M_y \frac{\partial v_{acc,y}}{\partial y} - \frac{\partial p}{\partial y}, \tag{8}$$

$$\frac{\partial p}{\partial t} = -M_x \frac{\partial p}{\partial x} - M_y \frac{\partial p}{\partial y} - \frac{\partial v_{acc,x}}{\partial x} - \frac{\partial v_{acc,y}}{\partial y}. \tag{9}$$

Then, we define a neural network that takes spatiotemporal coordinates (x, y, t) as input and outputs the predicted fields $\tilde{v}_{acc,x}$, $\tilde{v}_{acc,y}$, and $\tilde{p}$. The residuals are defined as:

$$\mathcal{R}_{v_{\text{acc},x}} = \frac{\partial \tilde{v}_{\text{acc},x}}{\partial t} + M_x \frac{\partial \tilde{v}_{\text{acc},x}}{\partial x} + M_y \frac{\partial \tilde{v}_{\text{acc},x}}{\partial y} + \frac{\partial \tilde{p}}{\partial x}, \tag{10}$$

$$\mathcal{R}_{v_{\text{acc},y}} = \frac{\partial \tilde{v}_{\text{acc},y}}{\partial t} + M_x \frac{\partial \tilde{v}_{\text{acc},y}}{\partial x} + M_y \frac{\partial \tilde{v}_{\text{acc},y}}{\partial y} + \frac{\partial \tilde{p}}{\partial y}, \tag{11}$$

$$\mathcal{R}_p = \frac{\partial \tilde{p}}{\partial t} + M_x \frac{\partial \tilde{p}}{\partial x} + M_y \frac{\partial \tilde{p}}{\partial y} + \frac{\partial \tilde{v}_{\text{acc},x}}{\partial x} + \frac{\partial \tilde{v}_{\text{acc},y}}{\partial y}. \tag{12}$$

These residuals are evaluated at collocation points and minimized during training. In the one-dimensional variant, all y-dependent terms are removed.

The neural network takes as input the spatiotemporal coordinates (x, y, t) and outputs the nondimensional fields p, v_x, and v_y. We employ a fully connected deep neural network using sinusoidal activation functions (SIREN) [15]. Derivatives of the output fields with respect to the inputs are computed via automatic differentiation [14].

The total loss minimized during training is composed of three terms such as in Equations (3), where the physics-based residual loss is defined as

$$\mathcal{L}_{\text{PDE}} = \text{MSE}(\mathcal{R}_{v_x}) + \text{MSE}(\mathcal{R}_{v_y}) + \text{MSE}(\mathcal{R}_p). \quad (13)$$

The initial condition loss $\mathcal{L}_{\text{IC}}$ is computed from a Gaussian pressure pulse centered in the domain with zero initial velocity. Boundary conditions are incorporated through $\mathcal{L}_{\text{BC}}$, enforced by included as supervised data points.

Training points are sampled uniformly across the nondimensional domain. The network is optimized using the AdamW optimizer, combined with a cosine annealing learning rate schedule [17]. Optionally, dynamic loss weighting based on Neural Tangent Kernel (NTK) sensitivity are applied in 2D case to balance contributions from different residuals during training [18, 19].

3.2 LEE Solution via ELM-ODE

Following the sampled neural network approach described above, we approximate the acoustic fields using a shallow NN with fixed, randomly sampled weights and biases. In this formulation, the only unknowns are the time-dependent coefficients. In particular, we write the Galerkin ansatz for the fields as

$$v_{acc,x}(t,x,y) = c_0(t) + \sum_{k=1}^{K} c_k(t)\,\phi(w_k^1\,x + w_k^2\,y + b_k), \quad (14)$$

$$v_{acc,y}(t,x,y) = d_0(t) + \sum_{k=1}^{K} d_k(t)\,\phi(w_k^1\,x + w_k^2\,y + b_k), \quad (15)$$

$$p_{acc}(t,x,y) = e_0(t) + \sum_{k=1}^{K} e_k(t)\,\phi(w_k^1\,x + w_k^2\,y + b_k), \quad (16)$$

where ϕ is the chosen activation function, and $\{w_k^1, w_k^2, b_k\}$ are fixed through random sampling. In this way, we seek only the time-dependent coefficients $c(t)$, $d(t)$, and $e(t)$ rather than training the full set of network parameters.

3.2.1 *Galerkin Projection of the Derivatives*

The time derivatives of the fields are obtained by differentiating the coefficients:

$$\frac{\partial v_{acc,x}}{\partial t} = c_{0,t}(t) + \sum_{k=1}^{K} c_{k,t}(t)\,\phi(w_k^1\,x + w_k^2\,y + b_k), \quad (17)$$

$$\frac{\partial v_{acc,y}}{\partial t} = d_{0,t}(t) + \sum_{k=1}^{K} d_{k,t}(t)\,\phi(w_k^1\,x + w_k^2\,y + b_k), \quad (18)$$

$$\frac{\partial p_{acc}}{\partial t} = e_{0,t}(t) + \sum_{k=1}^{K} e_{k,t}(t)\,\phi(w_k^1\,x + w_k^2\,y + b_k). \quad (19)$$

Spatial derivatives are computed by differentiating the NN ansatz. For instance, the x-derivative of p_{acc} is given by

$$\frac{\partial p_{acc}}{\partial x} = e_0(t) + \sum_{k=1}^{K} e_k(t)\,\phi'(w_k^1\,x + w_k^2\,y + b_k)\,|w_k^1|, \quad (20)$$

with analogous expressions for the spatial derivatives of $v_{acc,x}$ and $v_{acc,y}$.

These evaluations at the collocation points are collected into matrices: let $\mathbf{A}^{(i)}$ denote the matrix of basis function evaluations for the i-th field and $\mathbf{B}_x^{(i)}$ and $\mathbf{B}_y^{(i)}$ denote the corresponding spatial derivative matrices (with $i = 1$ for $v_{acc,x}$, $i = 2$ for $v_{acc,y}$, and $i = 3$ for p_{acc}). We then form the block matrices

$$\mathbf{A} = \begin{bmatrix} \mathbf{A}^{(1)} & 0 & 0 \\ 0 & \mathbf{A}^{(2)} & 0 \\ 0 & 0 & \mathbf{A}^{(3)} \end{bmatrix}, \quad (21)$$

$$\mathbf{B}^{(x)} = \begin{bmatrix} \mathbf{B}_x^{(1)} & 0 & 0 \\ 0 & \mathbf{B}_x^{(2)} & 0 \\ 0 & 0 & \mathbf{B}_x^{(3)} \end{bmatrix}, \quad (22)$$

$$\mathbf{B}^{(y)} = \begin{bmatrix} \mathbf{B}_y^{(1)} & 0 & 0 \\ 0 & \mathbf{B}_y^{(2)} & 0 \\ 0 & 0 & \mathbf{B}_y^{(3)} \end{bmatrix}. \quad (23)$$

3.2.2 Assembly of the ODE System

The coupling terms from the Linearized Euler Equations, such as the pressure gradient and the divergence of velocity, are incorporated into the coupling matrix

$$\mathbf{K} = \begin{bmatrix} 0 & 0 & \alpha_{met}\,\mathbf{B}_x^{(3)} \\ 0 & 0 & \alpha_{met}\,\mathbf{B}_y^{(3)} \\ \kappa p_{met}\,\mathbf{B}_x^{(1)} & \kappa p_{met}\,\mathbf{B}_y^{(2)} & 0 \end{bmatrix}. \quad (24)$$

Defining the combined coefficient vector

$$\mathbf{Y}(t) = \begin{bmatrix} c(t) \\ d(t) \\ e(t) \end{bmatrix}, \quad (25)$$

the Galerkin projection leads to:

$$\mathbf{A}\frac{\partial \mathbf{Y}}{\partial t} = -\Big[V_{met,x}\,\mathbf{B}^{(x)} + V_{met,y}\,\mathbf{B}^{(y)} + \mathbf{K}\Big]\mathbf{Y}.$$

Because the NN weights and biases are already obtained by sampling, we solve only for the coefficients. Inverting $\mathbf{A}$ (or solving the associated least-squares problem) yields

$$\begin{aligned} \frac{\partial \mathbf{Y}}{\partial t} &= -\mathbf{A}^{-1}\Big[V_{met,x}\,\mathbf{B}^{(x)} + V_{met,y}\,\mathbf{B}^{(y)} + \mathbf{K}\Big]\mathbf{Y} \\ &\equiv \mathbf{B}_{combined}\,\mathbf{Y}. \end{aligned} \quad (26)$$

This linear ODE system for $\mathbf{Y}(t)$ is then integrated in time using standard solvers, after which the full solution is reconstructed by evaluating the NN basis functions weighted by the computed coefficients.

4. PARAMETER DETAILS

4.1 One Dimensional Case

The one-dimensional case serves as a preliminary test to compare the accuracy, convergence, and computational performance of both PINNs and ELM-ODE methods under simplified conditions. The physical parameters used in this setup are listed in Tab. 1, while the configuration details for the PINNs and ELM-ODE implementations are given in Tab. 2 and 3, respectively. Both methods are tested on the same domain and initial conditions, allowing for a fair comparison. This setup provides insights into the strengths and limitations of each approach before scaling up to higher-dimensional problems.

Table 1. Physical parameters for 1D simulation

Parameter	Value
Space Domain	$x \in [-100, 100]$ m
Time Domain	$t \in [0, 1]$ s
Medium flow velocity	5 m/s
Speed of sound	340 m/s
Initial pressure	Gaussian at $x = 0$, $\sigma = 5$ m
Boundary condition	Total reflection

Table 2. PINNs configuration for 1D simulation

Component	Value
Architecture	3 hidden layers, 30 neurons each (SIREN)
Activation	Sinusoidal, $\omega_0 = 3.0$
Input/Output	(x, t) input; $(v_{acc},\ p_{acc})$ output
Collocation points	8,000 (PDE), 200 (BC), full grid (IC)
Optimizer	Adam (lr=10^{-3}, exponential decay)
Epochs	500,000
Computing Device	Nvidia P100

Table 3. ELM-ODE configuration for 1D simulation

Component	Value
Neuron Basis	600 per field (velocity and pressure)
Activation	$\tanh$
Sampling	Randomized with scaling
Boundary	Total Reflection
Basis Fitting	Least-squares projection with regularization (10^{-6})
Spatial Resolution	400 points over the domain
Time Integration	RK45
Computing Device	Intel Xeon Gold 5218R (1 core)

4.2 Two Dimensional Case

The two-dimensional case extends the previous 1D setup to a more realistic scenario of outdoor sound propagation

with a horizontal background wind. It evaluates the methods' performance in capturing wavefront changes, directional propagation, and boundary interactions.

Table 4. Physical parameters for 2D simulation

Parameter	Value
Space Domain	$x, y \in [-100, 100]$ m
Time Domain	$t \in [0, 1]$ s
Medium Flow velocity	$V_x = 40$ m/s, $V_y = 0$ m/s
Initial pressure	Gaussian, $\sigma = 20$ m
Boundary condition	Total reflection

Table 5. PINNs configuration for 2D simulation

Component	Value
Architecture	6 hidden layers, 80 neurons each with SIREN activation ($\omega_0 = 1$)
Input/Output	(x, y, t) input; (p, v_x, v_y) output
Collocation points	50,000 (PDE), 3,000 (BC), 5,000 (IC)
Optimizer	AdamW (lr=10^{-3}, cosine annealing)
Epochs	400,000
NTK	EMA with $\beta = 0.99$
Computing Device	Nvidia A100

Table 6. ELM-ODE configuration for 2D simulation

Component	Value
Neuron Basis	1500 per field (velocity v_x, velocity v_y, pressure)
Activation	$\tanh$
Sampling	Randomized with scaling
Boundary	Total Reflection
Basis Fitting	Least-squares projection with regularization (10^{-8})
Spatial Resolution	500 points per dimension
Time Integration	RK45
Computing Device	Intel Xeon Gold 5218R (1 core)

5. RESULTS AND DISCUSSION

5.1 1D Cases

Fig. 1 compares the solutions of the 1D Linearized Euler Equation obtained using finite-difference (FD), ELM-ODE, and PINNs approaches. The FD solution acts as the ground truth for evaluating the performance of neural network-based methods.

Both ELM-ODE and PINNs solutions accurately reproduce the overall wave dynamics, including reflections at domain boundaries and the propagation of the pressure pulse across the simulation domain. However, noticeable differences exist in their error distributions. The absolute error for the ELM-ODE solution (bottom-left panel of Fig. 1) primarily concentrates along the primary wavefront paths, indicating that ELM-ODE slightly underpredicts rapid changes. In contrast, the error distribution for the PINNs solution (bottom-right panel) shows more evenly dispersed, finer-scale errors across the domain. This behavior suggests that while PINNs captures the overall wave patterns very well, it exhibits smaller-scale oscillations or numerical artifacts.

Quantitatively, as shown in Tab. 7, PINNs achieve a lower mean absolute error (0.001851 Pa) than the ELM-ODE method (0.007404 Pa), confirming that PINNs offer better accuracy overall in the tested scenario. However, this comes at the cost of significantly higher computational demands, PINNs require approximately one hour of training, while ELM-ODE produces results within seconds.

Table 7. Accuracy and cost for 1D simulation

Metric	PINNs	ELM-ODE
MAE	1.851×10^{-3}	7.404×10^{-3}
Training Time	1 h 2 min	2.98 s

5.2 2D Cases

Extending the methods from Section 5.1 to two dimensions allows for more realistic outdoor acoustic propagation scenarios, such as a planar Gaussian pressure pulse advected by a horizontal background wind. Fig. 2 compares the solutions at two different time instants, $t = 0.2$ s and $t = 0.6$ s. Both PINNs and ELM-ODE solutions closely match the finite-difference (FD) reference, capturing wavefront propagation and boundary reflections effectively. At early times ($t = 0.2$ s) (as it is written in Tab. 8),

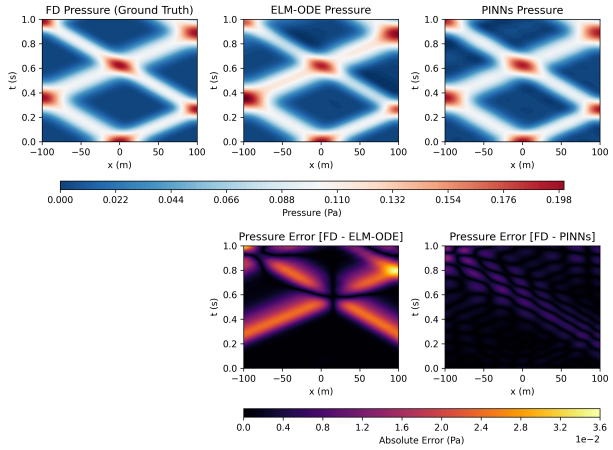

Figure 1. Comparison of pressure fields (top row) and absolute error (bottom row) for the 1D Linearized Euler Equation simulation. The FD solution serves as ground truth.

both methods yield mean absolute errors (MAE) in the order of 10^{-3}. At later times ($t = 0.6\,\mathrm{s}$), the error increases to the order of 10^{-2}, consistent with expected dispersion and diffusion. Spatially, PINNs errors are more uniformly distributed across the domain, while ELM-ODE shows errors along high-gradient regions.

Despite these similar accuracies, the two methods differ significantly in runtime. The PINNs approach required roughly 7.6 hours of training, whereas ELM-ODE finished in about 23 minutes. Important is, most of the ELM-ODE cost does not come from integrating the ordinary differential equation system, rather, it is spent assembling and factorizing the large block matrices (as discussed around Equations (21), (22), (23), (24), and (26)). Once those matrices are formed and factorized, the subsequent time-integration step involves repeated matrix-vector multiplications, which are relatively cheap.

An additional observation is that both methods must solve for all three fields (v_x, v_y, p). Even if we are mainly interested in the acoustic pressure p, the Linearized Euler Equations intrinsically couple pressure and velocity via gradients and divergences, making it physically incorrect to omit the velocity unknowns. Consequently, the coefficient vector in ELM-ODE must span three fields, substantially inflating the block matrices and their factorization cost. In three dimensions, the velocity field gains a third component, further increasing memory usage and computational effort. Nevertheless, for moderate 2D problems at practical accuracy, ELM-ODE can be significantly faster than a PINN-based solution while maintaining physically consistent results.

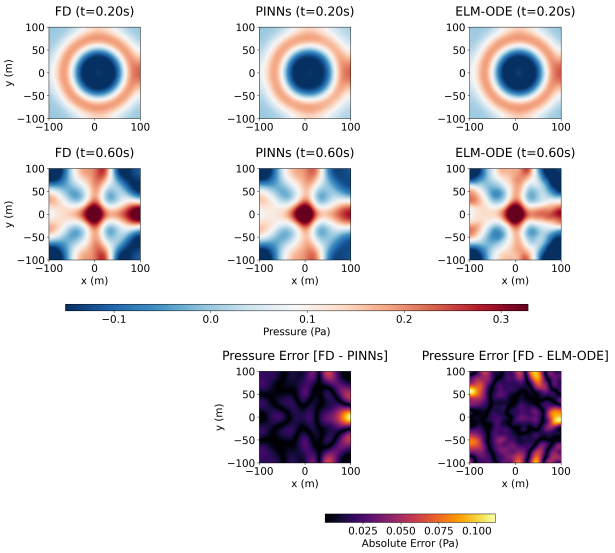

Figure 2. Comparison of FD, PINNs, and ELM-ODE solutions at $t = 0.2\,\mathrm{s}$ and $t = 0.6\,\mathrm{s}$ for the 2D domain. The bottom row shows the absolute errors for PINNs and ELM-ODE compared to the FD reference.

Table 8. Accuracy and cost for 2D simulation

Metric	PINNs	ELM-ODE
MAE $(t = 0.2)$ s	6.2221×10^{-3}	2.8990×10^{-3}
MAE $(t = 0.6)$ s	1.6631×10^{-2}	2.5553×10^{-2}
Training Time	7h 36m 52s	1362.424 s

6. CONCLUSION AND FUTURE WORK

We applied PINNs and ELM-ODE to solve the Linearized Euler Equations for outdoor acoustics in both 1D and 2D. ELM-ODE decoupled the spatial approximation from time integration and delivered faster solutions, despite with slightly larger errors in the same order. By contrast, PINNs attained slightly higher accuracy but demanded extensive training due to the full spatiotemporal residual.

Future work requires applying complex boundary conditions with frequency-dependent impedance and realistic ground surfaces to better match real-world acoustics. Scaling these methods to 3D remains challenging due to increased computational costs from the additional velocity component. Moreover, exploring alternative PDEs such as the convective Helmholtz equation or combining neural PDE solvers with measurement data or precomputed simulations appears promising.

UTILIZING LARGE LANGUAGE MODELS FOR OPTIMIZING SOUND SELECTION IN DEMENTIA CARE ENVIRONMENTS

Arezoo Talebzadeh[1*]

[1] Department of Information Technology - Ghent University.
Technologiepark 126, 9052, Ghent, Belgium

ABSTRACT

The effect of soundscape on people with dementia has been studied, with established links between acoustic environments and Behavioral and Psychological Symptoms of Dementia. Previous research has demonstrated promising results in using soundscape augmentation for dementia care interventions. However, selecting appropriate sound segments remains challenging due to the heterogeneous nature of dementia and varying individual needs. This study explores the innovative application of Large Language Models (LLMs) in selecting appropriate sound segments for soundscape augmentation. By analyzing responses from Claude 3.5 and GPT-4 to systematically designed prompts, the potential to recommend suitable sound segments based on the specific auditory deficits associated with different types of dementia was investigated. The LLMs were provided with semantic complexity ratings and affective information of pre-labelled sound segments and then tasked with matching appropriate sounds to various dementia types. Results demonstrate LLMs' capability to consider multiple factors, including semantic complexity, emotional impact, and specific auditory processing challenges when making recommendations. Key findings indicate that LLMs can effectively differentiate between suitable sound segments for various dementia types. This research suggests potential benefits in using AI-assisted sound selection to enhance personalized soundscape design in dementia care while acknowledging the importance of human oversight and individual patient preferences.

Keywords: *Large Language Models, Soundscape, Dementia, Prompt Engineering.*

1. INTRODUCTION

The effect of soundscape on people with dementia has been studied [1-3], with established links between acoustic environments and Behavioral and Psychological Symptoms of Dementia [4]. Previous research has demonstrated promising results in using soundscape augmentation for dementia care interventions [5]. However, selecting appropriate sound segments remains challenging due to the heterogeneous nature of dementia and varying individual needs (Talebzadeh, Botteldooren et al., 2023). Recently, there has been an interest in using large language models (LLMs) in soundscape studies. Hou et al. used LLM for soundscape captioning, identifying sound sources, and predicting annoyance [7-8].

Selecting suitable sound segments for soundscape augmentation is challenging as human bias and prejudice may unknowingly play a role. LLMs and Generative Pre-Trained transformers (GPT) have shown promising results in minimizing bias when prompted correctly and monitored.

This study aims to use LLMs to select suitable sounds for soundscape augmentation in dementia care settings based on specific subtypes of dementia, the auditory symptoms and deficits related to each type and the appropriate sound segment based on theoretical frameworks. To examine the

possibility of LLMs as a tool to help select suitable sound, Claude 3.5 and Chat GPT 4o were prompted, and results were analyzed for homogeneity and reliability.

2. METHODOLOGY

2.1 Experimental Design

This study employed a methodological approach to evaluate the potential of LLMs in selecting appropriate sound segments for people with dementia. Claude 3.5 and GPT-4o were utilized to analyze and recommend suitable sound segments based on different types of dementia and their associated auditory deficit. The study followed a three-phase process:

1. Initial general prompting to access LLM understanding of sound selection for dementia
2. Specific prompts addressing specific dementia types and their auditory deficit
3. Complex scenario-based prompts with detailed sound segment information to design a soundscape

2.2 Prompt Engineering

To evaluate the LLM's capabilities, a series of specific prompts were developed from general to specific, using four elements: instruction, context, input data, and output indicator [9].

1. **General question**: "How can LLM be used to enhance sound segment selection for people with dementia when designing soundscapes?"
2. **Specific segment selection**: "I need your help locating the most suitable sound segments to enhance the auditory environment for individuals with dementia."
3. **Auditory deficit inquiry**: "What are the auditory deficits of each type of dementia?"
4. **Scenario**-based prompts: Two specific scenarios were presented:
    a. **Scenario A:** Sound selection for frontotemporal dementia in long-term care home
    b. **Scenario B:** Comparison of sound selection for Alzheimer's disease (AD) vs. frontotemporal dementia (FTD)

2.3 Sound Segment Analysis

The sound segment labelling was conducted online through online Audio Captioning: https://huggingface.co/spaces/wsntxxn/efficient_audio_captioning

The program labelled a comprehensive set of sound segments from previous research [6]. Each segment was then characterized by:

1. Identification number (e.g., W0004, W00026)
2. Audio caption (e.g., "rain falling on a surface", " a crowd of people are talking")
3. Semantic complexity rating (low, moderate and high)

Recognizing the inability of LLMs to directly process audio files (at the time of experience), the pre-labelled sound segments were utilized for the study. LLMs were provided with this information to make recommendations.

2.4 Evaluation Framework

LLM responses were evaluated based on:

1. Understanding of dementia-specific auditory deficits
2. Appropriate matching of sound segments to dementia type
3. Consistency of recommendation across models

3. RESULTS

3.1 LLM Understanding of Sound Selection for Dementia

Both LLMs demonstrated a sophisticated understanding of using sound segments for dementia interventions. In response to general prompts, both models provided structured approaches:

GPT-4o outlined a six-stage process:

1. Personalized Sound Recommendations
2. Tailoring to Specific Auditory Deficits
3. Adapting to Cognitive and Emotional States
4. Contextual Sound Placement
5. Data-Driven Sound Optimization
6. Combining with Assistive Technologies

Claude 3.5 proposed an eight-step framework:

1. Content analysis
2. Personalization
3. Emotional response prediction
4. Narrative generation
5. Temporal sequencing
6. Interaction analysis
7. Metadata enhancement
8. Contextual adaptation

3.2 Dementia-Specific Auditory Deficits

Both LLMs were able to identify and describe the distinctive auditory deficits associated with the most known types of dementia:
For Alzheimer's Disease (AD):

- Auditory agnosia
- Impaired sound localization
- Reduced auditory memory
- Speech comprehension difficulties

For Lewy Body Dementia (LBD):

- Auditory hallucinations
- Impaired speech understanding
- Auditory distortion

For Frontotemporal Dementia (FTD):

- Auditory neglect
- Difficulty with voice recognition
- Impaired auditory attention

For Vascular Dementia (VD):

- Auditory processing deficits
- Reduced speech discrimination
- Slower auditory processing

3.3 Sound Segment Recommendations for Specific Scenarios

For **Scenario A** (FTD), both LLMs recommended similar sound segments with GPT-4o using a time-sequenced approach.

GPT-4o suggestion:

1. Soft Outdoor Ambience (7:00-7:15 am): birds chirping, distant wind through trees, soft morning rain
1. Subtle Household Sounds (7:15-7:30 am): muffled kitchen activity, footsteps, water running
2. Neutral, Natural Soundscapes (7:30-7:45 am): ocean waves, rustling grasses, distant farm animals
3. Morning Outdoor Ambience (7:45-8:00 am): urban morning sounds, faint church bells, light wind chimes

Claude 3.5 recommendation:

1. Gentle nature sounds: birds chirping, rain, rustling leaves
2. Household sounds: kitchen noises, clock ticking, footsteps
3. Animal sounds: purring cat, quiet dog barking, cow mooing
4. Weather sounds: light wind, distant thunder, waves
5. Human voices: soft speech, quiet laughter, humming
6. Ambient outdoor sounds: park sounds, street sounds, market sounds
7. Calming white noise: fan or air conditioning hum, soft static

For scenario B (comparing AD to FTD), both LLMs highlighted specific distinctions:

For AD:

- Familiar, memory-evoking sounds
- Simple and repetitive patterns
- Emotionally positive or natural sounds

For FTD, both emphasized on:

- Non-social, neutral sounds
- Simple, non-triggering sounds
- Avoiding complex social cues

3.4 3.4 Comprehensive Sound Segment Matching

When provided with detailed information about sound segments (including ID, labelling, semantic complexity, and affective information), both LLMs demonstrated matching capabilities with some similarities:

GPT-4o recommended:

- For AD: W0026 (rain falling), W0211 (birds chirping), W0088 (stream flowing), W0013 (music)
- For LBD: W0026, W0088, W0211, W0107 (crickets chirping)
- For FTD: W0088, W0016 (birds chirping), W0006 (frogs croaking), W0026
- For Posterior Cortical Atrophy: W0026, W0088, W0010 (ocean waves), W0211

Claude 3.5 recommended:

- For AD: W0016, W0026, W0088
- For VD: W0212, W0072, W0013
- For FTD: W0162, W0144, W0015
- For LBD: W0060, W0152, W0213

4. DISCUSSION

4.1 Comparative Analysis of LLM Performance

Both LLMs demonstrated some capabilities in understanding the complex relationship between dementia types, auditory deficits, and appropriate sound selection. However, notable differences emerged in their approaches:
GPT-4o tended to provide more structured, sequential recommendations with detailed explanations of why particular sounds would benefit specific dementia types. Its recommendations align with established therapeutic approaches, emphasizing familiarity for Alzheimer's and neutral, non-triggering sounds for frontotemporal dementia.
Claude 3.5 offered more diverse sound segment suggestions with greater attention to the affective dimensions and semantic complexity. It demonstrated some potential in distinguishing subtle differences between dementia types and providing tailored recommendations based on specific auditory deficits.

4.2 Semantic Complexity Considerations

The LLMs effectively utilized semantic complexity ratings in their recommendations, showing appropriate general selection patterns:

- Low complexity sounds (e.g., rain falling, stream flowing) were consistently recommended for Alzheimer's disease and other conditions with significant auditory processing deficits
- Moderate complexity sounds were selectively recommended for conditions where some auditory processing remained intact
- High-complexity sounds were generally avoided for most dementia types, with exceptions made for specific therapeutic purposes

4.3 Integration of Affective Information

Both LLMs demonstrated sophisticated use of affective information in their recommendations. They consistently preferred segments described as "pleasant," "calming," or "soothing" for conditions with anxiety features, while moderately stimulating sounds described as "vibrant" or "engaging" were recommended when appropriate for maintaining cognitive engagement.

4.4 Discrepancy between LLMs

Although both LLMs demonstrated the ability to select suitable segments based on specific dementias, their choices were inconsistent on specific segments.

4.5 Limitations and Ethical Considerations

Several limitations must be acknowledged:

1. Lack of direct audio processing: Current LLMs cannot directly analyze audio files, necessitating pre-labeled segments
2. Absence of personalization: Recommendations were based on dementia types rather than individual preferences and histories
3. Limited validation: The recommendations have not been extensively validated in clinical settings
4. Ethical considerations: The use of AI in dementia care raises important questions about agency, consent, and technological dependency

5. CONCLUSION

This study demonstrates the potential of LLMs to assist in selecting appropriate sound segments for soundscape augmentation in dementia care. By leveraging their ability to process complex information about dementia types, auditory deficits, semantic complexity, and affective dimensions, LLMs can provide nuanced recommendations that may enhance therapeutic interventions.
The findings suggest that LLMs could serve as valuable co-creators in designing personalized soundscapes, particularly in addressing the heterogeneity within dementia and tailoring interventions to specific auditory needs. However, LLMs should complement rather than replace human expertise at this time, with the final selection incorporating patient preferences, caregiver insights, and clinical judgment.
Future research should focus on:

1. Developing LLMs capable of directly processing audio files
2. Creating more personalized approaches that incorporate individual histories and preferences
3. Conducting clinical validation studies to assess the effectiveness of LLM-recommended sound segments
4. Establishing ethical frameworks for AI integration in dementia care
5. Exploring longitudinal applications to accommodate the progressive nature of dementia

This initial exploration suggests that integrating LLMs in soundscape design for dementia care represents a promising direction for enhancing the quality of life and reducing behavioural and psychological symptoms through personalized auditory environments.

ABSTRACT

In a cocktail party scenario, the human auditory system can focus on a single stimulus while suppressing others identified as noise [1]. In the context of neuro-steered hearing devices, auditory attention decoding (AAD) aims to replicate this process using different algorithms that decode electroencephalography (EEG) signals to identify the attended stimulus. Traditional approaches often rely on linear models to establish relationships between neural activity and auditory inputs. However, linear algorithms face significant limitations when decoding a complex non-linear system like the brain. The emergence of deep learning has enabled the development of novel non-linear algorithms, which have shown promising results. In this study, different linear and non-linear algorithms are implemented and evaluated using publicly available data. Furthermore, different methods for training deep learning models are considered to enhance the final model accuracy. The results are analyzed to assess the advantages and limitations of linear versus non-linear approaches in real-world scenarios. This work provides a detailed comparison between different AAD methodologies, offering valuable insights for applications in smart hearing aids, auditory prostheses, and hearing-related medical diagnoses.

Keywords: *Auditory attention decoding (AAD), electroencephalography (EEG), speech envelope, deep learning.*

1. INTRODUCTION

In scenarios where multiple speakers, background noise, or music are present, our auditory system can distinguish the attended speaker from other sources by suppressing or ignoring them [1]. This auditory ability diminishes with age, and individuals with congenital hearing impairment are similarly affected. Current hearing devices and cochlear implants often perform poorly in complex listening environments—such as at a cocktail party, in eavesdropping situations, or while driving—because they typically identify the attended source based on loudness or location. Decoding the desired auditory source directly from the user's brain activity could provide crucial information for neuro-steered hearing devices, thereby enhancing the performance of traditional devices in challenging scenarios.

The electroencephalogram (EEG) is the preferred method for measuring brain activity for auditory attention decoding (AAD) because it is non-invasive, cost-effective, and scalable; features that facilitate its use in everyday settings. In [2,3], the authors established a direct relationship between the EEG signal and the low-frequency envelope of the attended stimulus. When linking the attended stimulus with the brain activity, researchers distinguish between forward and backward models based on whether the stimulus or the EEG signal is predicted. Backward

models have demonstrated superior performance by predicting the attended speech envelope from the EEG signal [4]. Consequently, this study primarily considers the backward paradigm (see Fig. 1 a)).

Several real-time [5] and real-life [6] AAD implementations have been conducted, and new portable, comfortable EEG devices continue to emerge [6]. These experiments only considered classical approaches—specifically linear methods—which have been regarded as state-of-the-art in terms of efficiency and performance. However, in recent years the advent of deep learning techniques significantly impacted data processing tasks. In the field of AAD, recent studies introducing new non-linear methods [7–9] and more extensive datasets [10] have enabled the development of complex non-linear models that outperform classical methods.

Unlike previous works, our study incorporates innovative deep learning models using the same dataset, allowing for a rigorous analysis of their advantages and limitations compared to traditional methods. This provides a comprehensive evaluation of the current state of auditory attention decoding.

2. AAD ALGORITHMS REVIEW

2.1 Linear models

2.1.1 Linear regression

Linear supervised AAD models facilitate the estimation of the attended stimulus by reconstructing the speech envelope ($\hat{\mathbf{s}}_\mathbf{a}$) applying a decoder matrix on the EEG lagged signal [3]. This reconstruction is achieved by linearly combining time-lagged sequences from the EEG channels, as expressed by:

$$\hat{s}_a(t) = \sum_{c=1}^{C} \sum_{l=0}^{L-1} d_c(l) x_c(t+l) \tag{1}$$

where $x_c(t)$ denotes the value of the c-th EEG channel at time t, $d_c(l)$ represents the decoder coefficient corresponding to the l-th time lag corresponding to the c-th channel, and L and C indicate the total number of time lags and EEG channels, respectively.

Assuming T samples, the decoding coefficients are obtained by minimizing the mean squared error (MSE) between the predicted speech envelope $\hat{\mathbf{s}}_\mathbf{a} = \mathbf{Xd}$ and the actual envelope $\mathbf{s_a}$:

$$\mathbf{argmin}||\mathbf{s_a} - \mathbf{Xd}||_\mathbf{2}^\mathbf{2} \tag{2}$$

with $\mathbf{X} = [x(0)...x(T-1)] \in \mathbb{R}^{T \times LC}$ and $\mathbf{s(a)} = [s(0)...s(T-1)] \in \mathbb{R}^{T \times LC}$. This leads to the solution $\hat{\mathbf{d}} = (\mathbf{X^T X})^{-1} \mathbf{X^T s_a}$ [4], where $\mathbf{R_{xx}} = (\mathbf{X^T X})^{-1}$ corresponds to the autocorrelation matrix and $\mathbf{R_{xs_a}} = \mathbf{X^T s_a}$ represents cross-correlation matrix. Thus, the decoder matrix is estimated as: $\hat{\mathbf{d}} \in \mathbb{R}^{LC \times 1}$.

Although these linear models offer simplicity with considerable performance, overfitting remains a common issue in AAD due to the typically limited size of available datasets. To mitigate this, Ridge regression is frequently employed, incorporating to Equation 1 an L2-norm regularization term when computing the decoder matrix: $\lambda \mathbf{z} ||\mathbf{d}||^\mathbf{2}$ with $\mathbf{z} = \mathbf{trace(XX^T)}/LC$ [11] Here, λ denotes the regularization hyperparameter that penalizes large decoder weights, and it is determined by selecting an optimal value from a predefined range using a validation procedure.

In this model the reconstructed envelope is correlated with both the attended (ρ_1) and the ignored (ρ_2) real envelopes. The higher correlation coefficient, ρ, is associated with the attended stimulus, providing a measure of the model's accuracy in decoding auditory attention in a multi-speaker scenario (Fig. 1 a)).

2.1.2 Canonical correlation analysis CCA

In section 1, backward models are presented as the top-performing models in Auditory Attention Decoding (AAD). However, Canonical Correlation Analysis (CCA) offers a hybrid approach (see Fig. 1 b)), integrating both forward and backward modeling techniques to enhance decoding performance. This model proposed in [12] to solve the AAD problem, identifies optimal linear transformations for both EEG signals and speech envelopes, thereby minimizing irrelevant variance and maximizing mutual correlation between the transformed domains.

Mathematically, CCA seeks to determine a set of backward spatiotemporal filters, denoted as $\mathbf{w_x} \in \mathbb{R}^{LC \times 1}$, and forward temporal filters, $\mathbf{w_{s_a}} \in \mathbb{R}^{L_a \times 1}$, applied to the EEG and stimulus domains, respectively. These filters maximize the correlation:

$$\max_{\mathbf{w_x}, \mathbf{w_{s_a}}} \frac{\mathbf{w_x^T R_{xs_a} w_{s_a}}}{\sqrt{\mathbf{w_x^T R_{xx} w_x}} \sqrt{\mathbf{w_{s_a}^T R_{s_a s_a} w_{s_a}}}} \tag{3}$$

This optimization is typically solved via generalized eigenvalue decomposition, where the optimal filters correspond to the eigenvectors with the largest eigenvalues. By selecting the top J eigenvectors, we obtain filter matrices $\mathbf{W_x} \in \mathbb{R}^{LC \times J}$ and $\mathbf{W_{s_a}} \in \mathbb{R}^{L_a \times J}$. As depicted

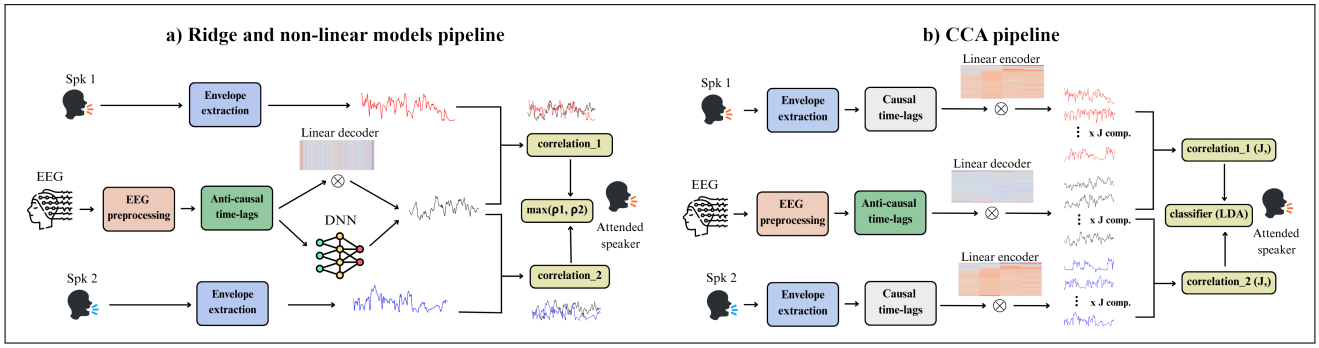

Figure 1. Different analytical pipelines followed for Auditory Attention Detection (AAD). (a) Implements only a backward decoder for Ridge regression and non-linear models. (b) Incorporates both a backward decoder and a forward encoder for Canonical Correlation Analysis (CCA), extracting multiple components.

in Fig. 1 b) for the classification task, these J correlation coefficients, both the ignored and the attended, serve as features for linear discriminant analysis (LDA) classifiers. Further details regarding specific model parameters and implementation can be found in Section 4.

2.2 Non linear models

2.2.1 CNN

In [8], two deep-learning-based backward models (map EEG signal to stimulus) are proposed. These algorithms predict the ongoing sample of the input sequence, operating in an anti-causal fashion. Among the two models presented in the study, we selected the Convolutional Neural Network (CNN) model, based on the original network EEGNet [13], as it proved to be a more efficient network when compared with the alternative Fully-Connected Neural Network (FCNN) solution. This model applies convolution operations along both temporal and channel dimensions to extract features from the EEG. After that, a depth-wise separable convolution is employed to capture global features, which are fed into a linear classifier to predict the initial sample of attended stimulus.

2.2.2 EEG Conformer

Recognizing that the CNN model is relatively simple, we explored more complex architectures in this study. The network proposed in [9], known as EEG Conformer, is considered state-of-the-art for EEG classification, having achieved superior results on motor-imagery (MI) and emotion detection datasets. This network integrates some Convolutional modules from EEGNet with a transformer self-attention block, thereby combining local feature extraction with global context modeling. For adaptation to the auditory attention decoding (AAD) paradigm, the network was modified to predict the ongoing segment of the envelope, as for the CNN approach, and an extensive hyperparameter search was conducted.

2.2.3 VLAAI

The study in [7] describes a convolutional network architecture, VLAAI, which was evaluated on the SparrKULee dataset [10] and outperformed both CNN (see section 2.2.1) and linear models. The architecture comprises N distinct blocks, each containing a CNN module with M consecutively stacked convolutional layers. The model also includes an output context module that applies a left zero padding to the convolutional operation. Unlike the previous non-linear models, which predict only the ongoing segment of the sequence, VLAAI predicts the entire window at each forward pass. Moreover, since the dataset used differed from that used in the original study, we performed an independent parameter search.

3. DATA: DTU DATASET

This work relies on a well-established dataset, known as the DTU dataset [14], to train and evaluate the models described in previous sections. The dataset comprises recordings from 18 subjects who listened to one of two competing audio streams, each featuring a male and a female narrator reading a book in Dutch. All subjects were young, normal-hearing individuals, and the recordings were obtained under various simulated reverberation

scenarios. A 64-channel BioSemi ActiveTwo system sampled at a frequency of 512 Hz is employed to obtain the EEG signals.

The extraction of the speech envelope was conducted using the `COCOHA MATLAB toolbox` [15]. The function `co_auditoryfilterbank.m` is used to implement a Gamma-tone filter bank on the unprocessed audio signal, sampled at $f_s = 44100Hz$. The signal is decomposed into 31 frequency bands, with center frequencies equally spaced on the Equivalent Rectangular Bandwidth (ERB) scale, ranging from 80 Hz to 8000 Hz. The envelope of each sub-band is then computed by taking the absolute value of the filtered signal and applying a nonlinear compression by raising it to the power of 0.3. Subsequently, the audio is down-sampled to align with the EEG sampling rate ($f_s = 64Hz$), and all frequency components are aggregated to compute the average and establish the final envelope.

The `COCOHA MATLAB toolbox` was also utilized to preprocess the EEG signal for the Auditory Attention Decoding (AAD) task. The signal is down-sampled to $f_s = 64Hz$ and subjected to a second-order Butterworth filter operating within the frequency range of $f_l = 0.5Hz$ to $f_h = 32Hz$. For further details on EEG preprocessing and artifact removal, refer to the preprocessing pipeline implemented in `preproc_data.m`, as described in [14].

4. METHODS

4.1 Validation procedure

AAD datasets contain subject-specific information recorded across different trials. Including data from the same trial in both training and validation could lead to misleading results, as models might learn trial-specific patterns, causing overfitting [16]. To prevent this, we implement a cross-trial validation procedure, distinguishing between three different approaches: subject-specific (SS), subject-independent (SI) and population procedures.

For subject-specific decoders (SS), models are trained and evaluated using data from the same individual, resulting in one model per subject. Given the limited availability of subject-specific data, we applied a 5-fold cross-validation strategy. The total number of trials was divided into five equal sets (e.g.: 12 trials per set in the DTU dataset). One set was used for validation, another for testing, and the remaining three for training.

For subject-independent decoders (SI), we used a leave-one-subject-out (LOSO) validation approach. The test set consisted of a single subject, while the remaining subjects were included in the training and validation sets. Five randomly selected subjects were assigned to the validation set and the rest of them formed the training set. A single model per subject is obtained when using this validation paradigm.

In addition to these validation strategies, we implemented a population-level baseline model, trained on data from all subjects. In this case, we applied the same 5-fold cross-validation strategy as in the subject-specific approach to enhance robustness. This resulted in a single model per dataset per fold. The population model served as a baseline for the subject finetuning (SF) training strategy (see Section 4.3).

4.2 Evaluation metrics

4.2.1 Decoding accuracy

The accuracy obtained by the model is calculated by comparing the Pearson r coefficients of the attended and unattended stimuli. This Pearson correlation coefficient r quantifies the similarity between two temporal sequences ranging from -1 to 1, where 1 indicates maximum correlation and 0 denotes no correlation. The envelope corresponding to the higher coefficient is identified as the attended one. Classification accuracy is determined as the ratio of correctly predicted windows to the total number of windows. Accuracy depends on window size, as larger windows incorporate more samples, increasing the likelihood of correct classification. Six window sizes were evaluated, ranging from 1s to 50s, the last one corresponding to the trial length of the DTU dataset.

4.2.2 MESD

Decoding accuracy, as previously mentioned, is a length-dependent metric that yields varying results based on the evaluation window. In [17], a unique metric is introduced to assess overall model performance. This metric offers insight into the model's potential performance in a real hearing-aid device by quantifying the minimal-expected switch duration (MESD) using a Markov chain approach. It is measured in seconds, and a lower value is preferable for the model, as it indicates the minimum expected duration required for an attention shift. Its computation relies on an adaptive gain system that depends on a hypothetical number of gain levels. All calculations were performed using the `MESD-toolbox` implemented in Python [18], which processes classification window results and returns

an estimate for the duration of a hypothetical attention switch.

4.3 Training process

In linear decoders, time-lag matrices were computed by fixing the time-lag value to $L = 26$ in LSR, which left-shifts the EEG signal by up to 400 ms. For CCA, we set $L_a = 80$ for the encoder and $L = 16$ for the decoder, corresponding to a right-shift of the stimulus by up to 1.25 s and a left-shift of the EEG by up to 250 ms. These time-lag values were chosen based on previous studies [3,4]. To determine the optimal number of components J for CCA, we first trained a CCA model with $\min(L_a, L)$ components and then optimized an LDA classifier via grid-search over J (ranging from 1 to $\min(L_a, L)$); the J yielding the best validation performance was selected. Similarly, for Ridge regression, a grid-search was performed for the regularization parameter λ over the range 10^{-7} to 10^{7}. Both linear models were implemented using the scikit_learn library, specifically `cross_decomposition.CCA` and `linear_model.Ridge` functions.

For non-linear models, the optimization objective was to minimize the negative correlation coefficient. The Adam optimizer was employed and models were trained for up to 200 epochs with early stopping after 5 epochs without improvement in validation loss. A hyperparameter search was conducted for the VLAAI and Conformer models, as they were originally designed for different tasks and datasets. All deep learning models were implemented in PyTorch using an NVIDIA A600 GPU.

Two training strategies were adopted to obtain the best subject-specific model. For non-linear models, we compared performance when training the model from scratch (see SS in 4.1) versus fine-tuning a pre-trained baseline model (see population in 4.1), where the final classification layers were adapted to subject-specific data while the rest of the model remained with the same parameters. A parametric paired test with Bonferroni correction was used for the statistical analysis.

5. RESULTS

5.1 Hyper-parameter search

To ensure a fair comparison among the reviewed models, we performed a hyperparameter search for all models except the CNN, which was already optimized in [8] for the dataset used.

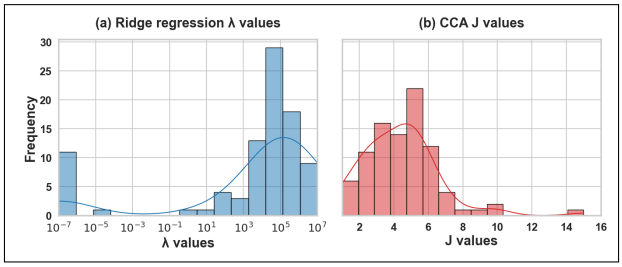

Figure 2. Linear models parameter distribution: a) Ridge regression λ values b) CCA J values

Fig. 2 a) illustrates the λ values for the Ridge regression model during subject-specific validation, selected based on validation loss. Most models yielded high regularization values that penalize large weights.

Fig. 2 b) displays the optimal J values for the CCA models under subject-specific validation. Typically, the best J values involve seven or fewer components, indicating that additional components are unnecessary.

For the non-linear models originally trained on different datasets, we conducted a hyperparameter search on the VLAAI and Conformer models. Tab. 1 summarizes the differences in model sizes and validation performance, with results averaged across folds. Note that the window sizes differ: the VLAAI model was trained on 5-second windows, while the Conformer and CNN models predicted 2-second windows on the training stage.

Table 1. Model sizes and validation results for non-linear models

Model	Size	Loss (ρ)	Accuracy (%)
CNN [8]	**9.65K**	**0.150**	**61.32**
VLAAI [7]	1.71M	0.058	56.40
VLAAI (enhanced)	**1.71M**	**0.069**	**57.08**
Conformer [9] (adapted)	241K	0.139	60.34
Conformer (enhanced)	**508K**	**0.144**	**60.62**

5.2 Subject-finetuning (SF)

Each population model was fine-tuned with subject-specific data to compare two training methodologies: subject-specific versus subject-fine-tuned (see Section 4.3). As shown in Fig. 3, except for VLAAI, fine-tuning did not improve validation accuracy, with Con-

former and CNN models showing no significant differences between the two strategies. Therefore, we will use subject-specific validation for these models. In contrast, the VLAAI model exhibited a significant improvement with fine-tuning ($p < 0.01$), consistent with [7]. Hence, this strategy will be applied to VLAAI in the subsequent evaluation.

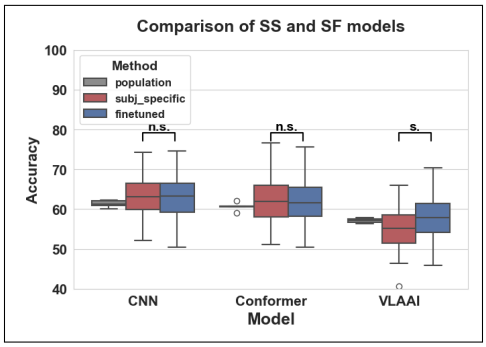

Figure 3. Subject specific and subject finetuned comparison based on the validation accuracy. Statistical analysis: **n.s.** : $p > 0.01$; **s.** : $p < 0.01$

5.3 Subject-specific (SS) and Subject-independent (SI)

Fig. 4 a) presents the subject-specific evaluation results, comparing accuracies across different window lengths and corresponding inter-model MESD values. The CNN and Conformer models achieve the best median MESD values, at 16.7 and 17.4 respectively. Although the CCA model appears to perform better for long windows, for short decision windows (1–2 seconds) the CNN and Conformer models outperform the others, thereby significantly influencing the overall MESD. Conversely, for long windows the CCA model performs better, reaching 92.2% at 50s, also producing fewer MESD outliers. The Ridge regression model performed substantially worse in both MESD and accuracy, while the VLAAI model performed close to the singnificance level, indicating its unsuitability for this dataset.

The results for subject-independent methodology, which renders the system ready for use (see Section 4.1), are illustrated in Fig. 4 b). As expected, subject-independent models performed significantly worse than subject-specific ones; the VLAAI model was excluded since it did not exceed the significance level. Nevertheless, the remaining models achieved above-chance, and even acceptable accuracies with long decision windows. The CCA model attained the best performance for long windows, reaching an accuracy of 83.6% on a 50-second window, whereas the CNN model—excelling in short decision windows—delivered the best MESD at 33.3 seconds. These findings indicate that the models can generalize across subjects when subject-specific data is unavailable.

6. DISCUSSION

6.1 Linear vs. non-linear models

Results in Section 5.3 show that the best linear model (CCA) and the CNN performed similarly in terms of MESD. However, these models differ in accuracy across different window lengths, highlighting the MESD metrics sensitivity to short-time windows. We attribute the superior performance of these models to two factors. First, CCA leverages both stimulus and EEG information to capture relevant variance from each domain [12]. Second, the performance of the CNN and Conformer nonlinear models can be attributed to their ability to adapt to a relatively small dataset, such as the DTU dataset.

In many machine learning applications, the trend is to develop larger, more complex models trained on extensive datasets. Following this approach, a non-linear model that integrates both stimulus and EEG signals could potentially yield even better performance. Nonetheless, when selecting an algorithm for AAD, linear models offer clear advantages: they provide lightweight solutions and simpler, more interpretable pipelines. In many cases, these characteristics may be prioritized over marginal gains in final performance.

6.2 Non-linear models prediction

In Section 5.2, the only model that benefited from subject fine-tuning was VLAAI. However, this model exhibited the poorest overall performance, in contrast to [7]. We attribute this discrepancy primarily to the window prediction paradigm, as other linear models predicting the ongoing sample performed much better. Furthermore, the DTU dataset [14] differed substantially in both experimental design and size from that in [7], which further explains the under-performance of VLAAI in Section 5.3. In contrast, the CNN and Conformer nonlinear models adequately fit the dataset, achieving the best results in terms of MESD and accuracy for small window sizes. When comparing these two models, despite expectations regarding model

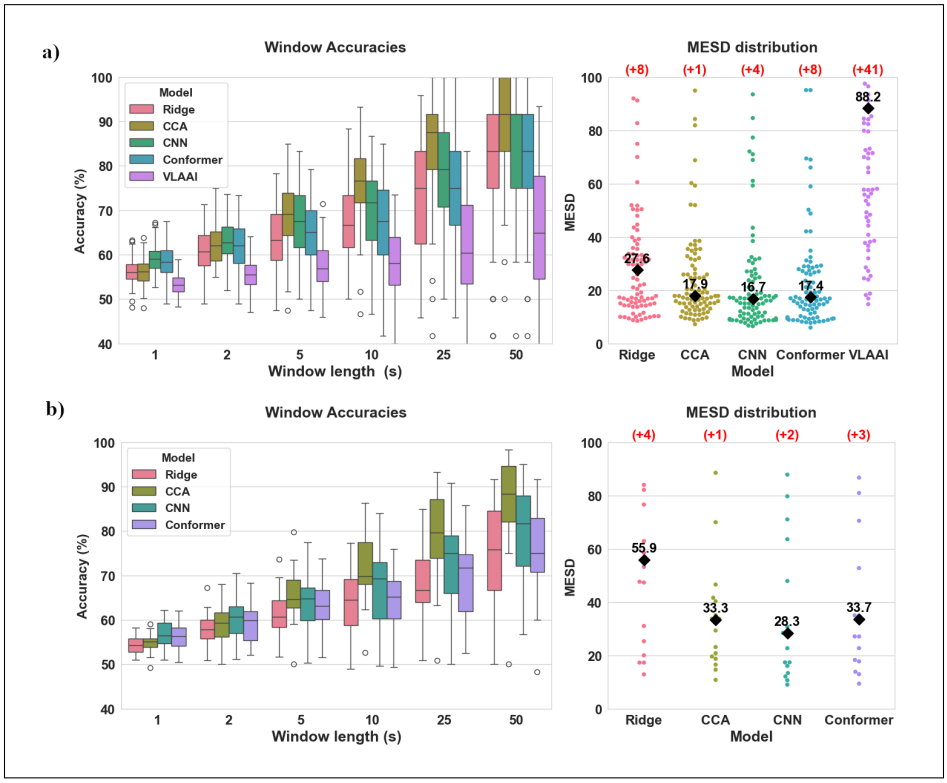

Figure 4. a) Subject-specific (SS) model comparison, b) Subject-independent (SI) model comparison.

size and complexity, empirical results indicate that the CNN outperformed the Conformer model. This results suggest that a depth-wise block is sufficient to learn from EEG signals, rather than relying on a self-attention layer.

6.3 AAD feasibility and actual constraints

The reviewed models demonstrated robust performance for the AAD paradigm. However, when implementing an AAD system in real-life scenarios, several constraints must be considered. First, all algorithms rely on access to clean envelopes, which requires an effective speech separation algorithm. Second, the data in this study were recorded using a wet 64-electrode EEG system in a controlled environment, a setting that does not reflect real-world conditions. Another critical factor is the computational cost and real-time feasibility, both aspects not addressed by the pipelines developed in this work.

Ultimately, accurately measuring attention remains challenging. In experimental settings, attention is typically inferred from participant's responses to a series of questions after completing the trials. However, in real-world situations, attention fluctuates dynamically and cannot be directly measured, making it fundamentally different from controlled experimental assessments. Thus, future studies must search for an adequate trade-off between window length and accuracy and incorporate an adaptive gain system that allows users to switch attention.

Although significant progress has been made to overcome these issues [5, 6], further research is essential to transform neuro-steered hearing aids into a practical solution.

7. CONCLUSION

In this study, different linear and non-linear auditory-attention decoding (AAD) models were presented and evaluated using the same dataset. All models were adjusted to the dataset through a hyperparameter search to obtain the optimal configuration. For non-linear models, a subject fine-tuning training strategy was considered. The CNN model of [8], performed the best on short de-

cision windows achieving the lowest MESD on both SS and SI models by predicting the ongoing sample of the introduced context. Nevertheless, the CCA linear model achieved higher accuracies on long decision windows and similar MESD results, offering a simpler and more interpretable alternative to non-linear models. In conclusion, this work provides a fair comparison between different AAD algorithms using the same dataset and may serve as a basis for future studies evaluating alternative AAD approaches. It also contributes to further research by linking brain activity with auditory stimuli, thereby providing useful insights for neuro-steered hearing aids and hearing-related medical diagnoses.

Comparison of Deep Learning and Psychoacoustic Models to Predict UAV Noise Impact in Soundscapes

Max W. Ellis[1*] **Marc C. Green**[1] **Michael J. B. Lotinga**[1]
Antonio J. Torija Martínez[1]

[1] Acoustics Research Centre, University of Salford, England (UK)

ABSTRACT

The increasing prevalence of Unmanned Aircraft Systems in urban environments necessitates a deeper understanding of their impact on the experience of urban soundscapes. This study presents Machine Learning models aimed at predicting perceived annoyance of UAS noise. Deep learning models were generated using convolutional recurrent neural networks, trained on a dataset incorporating data from multiple listening experiment. The model predictions are compared with various existing nonlinear models for Psychoacoustic Annoyance. Our expanded dataset includes recent field studies across England and Greece, enhancing the robustness and generalisability of our models. The broader aim of this research is development of a comprehensive soundscape model for UAS noise, which could be incorporated into future 'next generation' smart sound level meters and be used to inform urban planning decisions.

Keywords: *Artificial Intelligence, Machine Listening, Psychoacoustic Annoyance, Soundscape, UAS*

1. INTRODUCTION

Noise signatures from emergent technologies in both civil and commercial domains have prompted growing concern regarding their acoustic impact on the perception of urban soundscapes. As frameworks develop for UAS, commonly referred to as *drones,* to integrate into transport infrastructure, small drones are already employed in agriculture for crop sowing, health monitoring, and logistics for both NHS and Royal Mail deliveries. These drones elicit complex perceptual responses by introducing novel, often highly tonal noise signatures that deviate from broadband noise typical of road or rail transport. Conventional noise assessment methods – historically reliant on A-weighted scales – are insufficient in capturing these effects.

Recent years have seen increased emphasis on applying the soundscape approach [1], acknowledging human perception of environmental sound is shaped not only by acoustic levels but also by context and emotional affect. This shift has encouraged the development of methods that predict perceived affect directly from audio features, whether through psychoacoustic modelling or data-driven approaches such as deep learning. However, while psychoacoustic metrics have been widely used in industrial noise prediction, their application to UAS noise, particularly in complex or multi-source sound environments, remains under investigation.

Our previous work using convolutional neural networks (CNNs) to predict perceived annoyance ratings from mel-spectrograms indicated that deep learning may offer enhanced predictive capabilities for UAS noise perceived annoyance [2]. This study introduces a new convolutional recurrent neural network (CRNN) architecture and three new soundwalk datasets (on top of the previous CNN model and 5 datasets). The objective is to determine which model architectures best predict subjective UAS noise annoyance ratings.

2. BACKGROUND

2.1 Soundscapes and Contextual Perception

The concept of soundscapes, introduced by R. M. Schafer [3], describes how sound interacts with environments and shapes human perception. ISO-12913 [1] formalised this

[*] ***Corresponding author***: *M.Ellis6@edu.salford.ac.uk*

framework, defining soundscapes as "the acoustic environment as perceived or experienced and/or understood by a person or people, in context". A significant advancement in soundscape research is the Circumplex Model [4], which organises soundscapes along dimensions of pleasantness and eventfulness, varying combinations of which can yield soundscapes described as calm, exciting, monotonous, and chaotic. Despite these advances, the influence of *auditory salience* – the prominence of a sound object – remains understudied [5], particularly in relation to electric vehicles (EV's) and UAVs. As next-generation technologies introduce novel noise sources, often containing high-frequency tonal components, their interaction with existing soundscapes can vary dramatically depending on listener expectations, use case, emotional factors and context [6].

2.2 Psychoacoustic Modelling and Annoyance Frameworks

Psychoacoustic annoyance refers to a modelled estimate derived from quantifiable sound quality metrics such as loudness, sharpness, fluctuation strength, and tonality. In contrast, perceived annoyance (PA) is a subjective judgement made by listeners, typically gathered through listening tests, and reflects the complex interplay of acoustic, contextual, and individual factors not fully captured by existing models. Widmann's annoyance model, originally developed for traditional noise sources [7], has required significant adaptations for UAS noise profiles. Di *et al.* [8] enhanced the model by integrating tonality penalties that account for an additional 0.5 – 1.5 units of annoyance depending on tonal strength and frequency, and an adjusted sharpness rating that is approximately 20% higher than ISO and DIN standards [9]. This adaptation improved prediction accuracy with a reduction in Root Mean Squared Error (RMSE) from 1.27 to 0.89, though limitations remain when analysing complex environments with non-tonal noise characteristics. Ramos-Romero *et al.* (2024) [10] developed a comprehensive taxonomy for assessing UAS noise, examining relationships between design parameters, operational conditions, and psychoacoustic metrics. Their measurements revealed that multirotor UAS produced noise with higher sharpness and tonal components compared to fixed-wing designs. UAS noise typically ranges between 500 Hz – 5 kHz, with tonal peaks in the 1 kHz – 2 kHz range contributing significantly to perceived annoyance. Contextual variations were notable, with sharpness levels measuring 1.9 acums in urban settings versus 1.5 acums in rural areas. Lotinga *et al.* (2023) [11] investigated psychoacoustic metrics for potential integration into UAS noise regulations. Smaller UAVs (e.g. DJI Matrice 300) exhibited higher levels of sharpness and roughness, while larger aircraft produced greater tonal fluctuation strength. Tonal components between 200 Hz – 800 Hz were found to significantly increase annoyance, with sharpness levels exceeding 1.5 acum, correlating with a 25% increase in reported annoyance even when overall sound levels remained constant. Subsequent research from Lotinga [12] found that the adapted Torija et al. [13] PA model demonstrated superior performance to Widmann, More [14] and Di et al. The Sottek Hearing Model [15] offers an advanced framework that simulates human auditory perception by modeling the basilar membrane's response to sound. This physiological approach accounts for nonlinear auditory filtering and is particularly effective for analysing drone noise in varying flight conditions, due to its increased precision in quantifying slow amplitude modulation. While psychoacoustic annoyance models offer interpretable predictions based on engineered features, they are limited by their reliance on fixed-weight formulations and assumptions derived from traditional noise sources. These models often fail to account for contextual variation, spectral complexity, and perceptual non-linearity present in UAV noise. A deep learning approach could learn context-sensitive acoustic representations directly from data, across varying environments and sound source types, perhaps resulting in more accurate predictions.

2.3 Deep Learning Models for Noise Analysis and Prediction

Green and Torija [2] demonstrated that CNNs, an architecture ideal for processing gridlike data such as audio spectrograms, achieves 85% accuracy in predicting perceived annoyance from UAV noise using mel-spectrograms, substantially outperforming traditional regression models that reach only 70% accuracy. The optimal time-frequency resolution parameters were found to be a Fast Fourier-Transform (FFT) length of 256 and hop length of 64 samples, yielding a Mean Absolute Error (MAE) of 0.58 and an R^2 value of 0.72. This performance exceeded traditional PA metrics that predominantly emphasise loudness, suggesting CNNs can identify additional perceptually relevant features such as fluctuation strength and roughness. However, challenges remain in generalising these models across varied environments and UAS types due to differences in noise profiles based on altitude, speed, and environmental conditions. For sequential audio analysis, Recurrent Neural Networks (RNNs) have proven effective in capturing temporal patterns. Grekow's

research on music emotion recognition demonstrated RNNs achieving 83% accuracy in predicting emotional responses along arousal and valence dimensions [16], analogous to the affective eventfulness and pleasantness dimensions specified in ISO 12913. The model showed stronger performance in predicting arousal (correlation coefficient of 0.72) than valence (correlation coefficient of 0.55), using features including tempo, loudness, pitch, and timbre across a dataset of 5,000 music tracks. Addressing the complexity of polyphonic soundscapes, Çakır *et al.* [17] proposed a CRNN utilising convolutional layers to extract spectral features while recurrent layers model temporal dependencies. This resulted in a 10 – 15% improvement in F1 scores compared to standard CNN and RNN models when applied to overlapping urban sounds. This architecture is particularly suitable for UAV noise detection within complex soundscapes, though computational demands may challenge realtime deployment. Casabianca and Zhang [18] introduced a late fusion ensemble approach for acoustic UAV detection, combining multiple deep neural networks through both hard and weighted soft voting strategies. Their ensemble, comprising CNNs trained on mel-spectrograms, achieved up to 94.7% accuracy on unseen augmented datasets, significantly outperforming individual models. The study also highlighted the role of data augmentation in improving scalability across drone types and recording conditions.

3. METHODS

3.1 Datasets

This study retains the five datasets introduced in Green and Torija [2], comprising a total of 587 audio clips with associated annoyance ratings. These were recorded across various controlled listening studies involving both conventional and UAV aircraft, with annotations collected using continuous ratings (KTH dataset) rescaled to match. To extend the data and explore the applicability of existing models, in this work, three new datasets are introduced, collected in: (i) Crescent Meadow, Salford, UK (23 clips) (Green and Torija, 2024) [19]; (ii) Athens, Greece (56 clips) (Green *et al.*, 2025) [20]; (iii) the Isles of Scilly, UK (27 clips) (Green and Torija, 2025) [21], amounting to an increased total of 693 clips. These datasets are distinct from those included in the previous study in that they were collected in field-based soundwalk studies, rather than in a lab-based setting. Participants were exposed to take-off, flyover, and landing UAS maneuvers, conducted at a range of altitudes, and responses were gathered along soundscape dimensions specified in ISO 12913-2, as well as annoyance based on ISO 15666 [22]. The latter were used as target ratings in the present study. Baseline annoyance ratings were gathered from soundwalk locations prior to the commencement of drone operations, and the average annoyance of all respondents at each stop/location were assigned to audio clip names from all eight datasets. Audio recordings were made at each stop using the Zoom H3VR portable Ambisonic recorder[1], with the omnidirectional channel used to derive monaural stimuli for the present study. These soundwalks were conducted as part of a series with the specific aim of investigating the perception of UAS noise introduced within a variety of existing environmental contexts, including a busy city street, quieter park and meadow, and a remote rural island. The extracted clips include both ambience and UAS noise. In line with the original methodology, all audio clips were resampled and trimmed to the loudest six-second segment based on total spectrogram amplitude. Mel-spectrograms were then generated for each clip up to a frequency of 8 kHz, represented by 96 mel-spaced bins with a total dynamic range of 60 dB.

Table 1. Summary of included datasets

Dataset	Participants	Clips	Response Type
MJL	42	80	Single
NG23	41	71	Single
NG22	30	51	Single
RN	50	120	Single
AJ	25	9	Continuous
Meadow	16	24	Single
Scilly	22	27	Single
Athens	110	56	Single

3.2 Psychoacoustic Annoyance Models

Sound quality metrics required for Widmann's psychoacoustic annoyance model were derived from the raw audio files using the SQAT library in MATLAB [19]. Pearsons *R* was used to quantify correlations between the Mean Perceived Annoyance's (MPA) and the sound quality metrics. Scatter plots showing correlations between perceived and psychoacoustic annoyance, as well as those with individual SQMs, are shown in Figure 1.

3.3 Deep Learning Models

Two deep neural network architectures were developed to predict perceived annoyance directly from audio spectrograms: a CNN and a CRNN. Similarly to the previous study [2], input spectrograms were generated using the *torchaudio* library [20], with particular attention to time-frequency resolution parameters which were previously found to significantly impact model performance. The CNN architecture consists of two convolutional layers with 3×3 kernels outputting 96 and 32 channels respectively, each followed by 2×8 max pooling and batch normalisation. These feed into three fully-connected layers of 1000, 100, and 1 output units with ReLU activation functions and dropout regularisation (p=0.2) between all layers except the final output. The CRNN extends this architecture by incorporating recurrent processing after the convolutional feature extraction. It utilises the same initial convolutional layers but then reshapes the output for sequential processing through two bidirectional LSTM layers with 128 and 64 hidden units respectively. An attention mechanism focuses on the most relevant temporal features before passing through fully-connected layers of 512 and 128 units, then finally one single unit. The CRNN employs higher dropout (p=0.3) and gradient clipping at a maximum norm of 5.0 to stabilise training. Through systematic grid search of FFT lengths {512, 256, 128, 64} and hop lengths {256, 128, 64, 32}.

3.4 Training & Testing

The models were implemented using PyTorch [21] and trained with MSE loss and Adam optimiser (learning rate 1×10^{-3} for CNN, 5×10^{-4} for CRNN). Early stopping with 40 epochs patience prevented overfitting across a maximum of 200 epochs with batch size 16. The dataset was randomly split into training (75%, n=520), validation (13%, n=91), and test (12%, n=83) sets, with shuffling to ensure even distribution across data sources. Performance was evaluated using MAE and coefficient of determination (R^2).

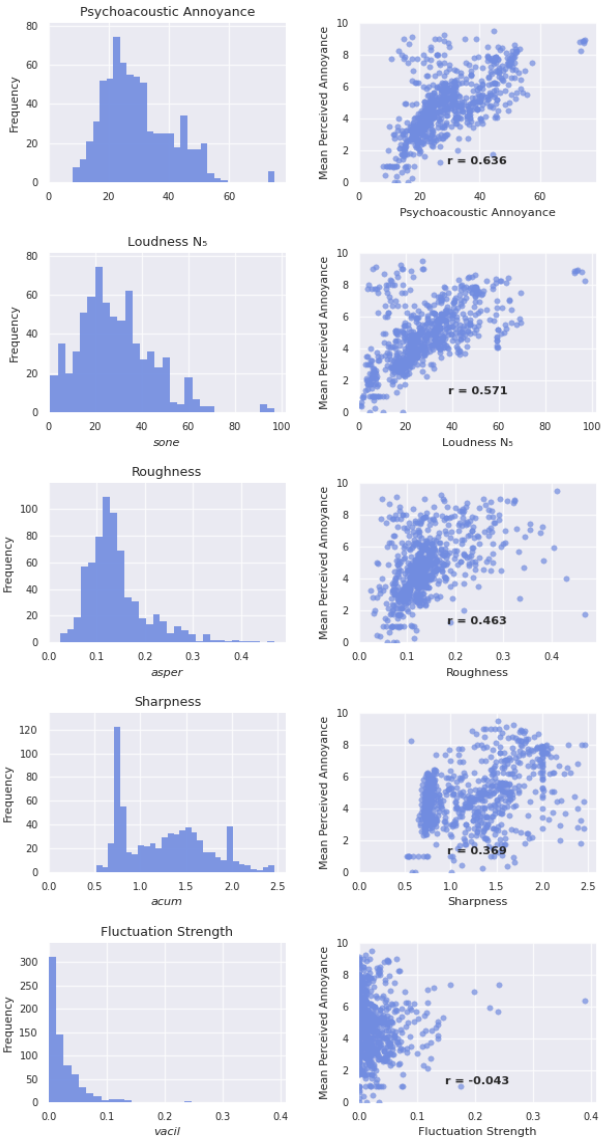

Figure 1. Histograms of psychoacoustic features and correlations of these to perceived annoyance.

Regularisation techniques included weight decay (1×10^{-5}) and gradient clipping at a maximum norm of 5.0 to prevent overfitting and stabilise training. Computation time per epoch ranged from 70 to 120 seconds, with training conducted on a Mac Mini M2 to utilise Metal Performance Shaders (MPS) backend for GPU training acceleration [22]. For comparison, two Support Vector Regression (SVR) baseline models were implemented: one with sigmoid kernel fitted directly to Widmann psychoacoustic annoyance values, and another with polynomial kernel (degree 3)

trained on the raw sound quality metrics.

4. RESULTS AND DISCUSSION

The SVR model trained on PA values using a sigmoid kernel achieved an MAE of 0.87 and an R^2 of 0.49, while the polynomial SVR trained on raw psychoacoustic features yielded a marginally better performance, with an MAE of 0.77 and R^2 of 0.56. As seen in the previous study, this suggests that a model trained directly on the constituent features of PA can outperform the composite metric itself. The sigmoid curve fit, shown in Figure 2, follows a similar logistic shape to that reported in earlier work, with perceived annoyance values beginning to plateau at higher PA levels. A notable concentration of moderate-to-high annoyance ratings (7-10 range) was identified, predominantly originating from the Athens dataset. This clustering suggests potential contextual influences beyond the immediate acoustic stimuli. Qualitative observations during the soundwalk revealed localised environmental factors that may have significantly influenced participant responses. Specifically, the Athens dataset exhibited a marked tendency toward elevated annoyance ratings, potentially attributable to pre-existing environmental disturbances independent of the specific acoustic stimulus. Despite these potential outliers, the SVR model maintained robust predictive performance, demonstrating remarkable resilience to dataset heterogeneity.

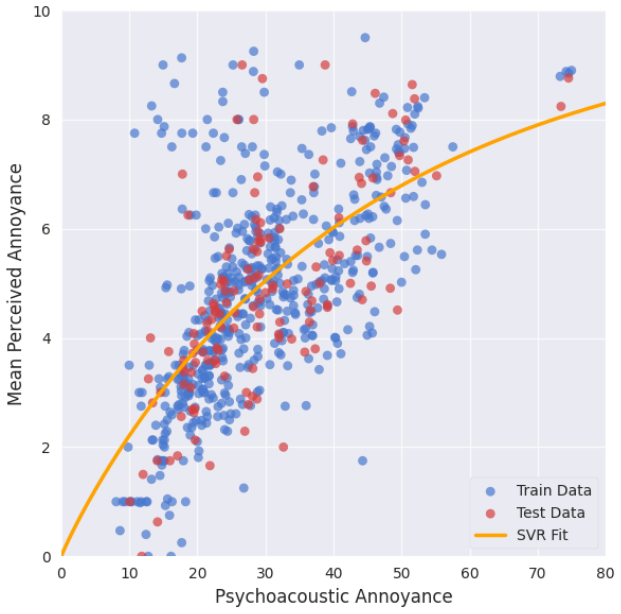

Figure 2. Fit of perceived annoyance to Widmann psychacoustic annoyance values by SVR model.

Table 2. Results for each network architecture and frame/hop length combination.

Frame / Hop	CNN		CRNN	
	MAE	R^2	MAE	R^2
512 / 256	0.77	0.55	0.65	0.66
512 / 128	0.84	0.29	0.62	0.7
512 / 64	**0.56**	**0.75**	0.55	0.76
512 / 32	0.85	0.54	0.7	0.78
256 / 128	0.76	0.62	0.56	0.81
256 / 64	0.64	0.71	**0.49**	**0.86**
256 / 32	0.87	0.39	0.83	0.46
128 / 64	0.72	0.56	0.58	0.79
128 / 32	0.81	0.46	0.71	0.63
64 / 32	0.77	0.5	0.94	0.44

Table 2 shows that CNN models exhibited varied performance across different time-frequency resolutions. The optimal configuration was identified as an FFT length of 512 samples and hop length of 64 samples, achieving MAE 0.56 / R^2 0.75. This configuration demonstrated a robust balance between spectral and temporal feature extraction. Configurations with shorter hop lengths (32 samples) consistently underperformed, with MAE values ranging from 0.85 to 0.87 and lower R^2 values. The 256 / 64 configuration also showed strong performance, with MAE 0.64 / R^2 0.71.

The CRNN models demonstrated superior performance compared to the CNN models. The 256 / 64 configuration in particular emerged as the standout, with an impressive MAE 0.49 / R^2 0.86, indicating a significant improvement in predictive accuracy over the CNN. The recurrent architecture showed more consistent performance across different FFT and hop length configurations. The 512 / 64 configuration also performed well, with MAE 0.55 / R^2 0.76. Configurations with 32-sample hop lengths showed decreased performance, with the 512 / 32 configuration achieving an R^2 of 0.78 but other configurations showing less consistent results.

The lower MAE and higher R^2 values of the CRNN results suggest that the bidirectional LSTM layers and attention mechanism provide additional context for predicting perceived annoyance. All models achieved their best ratings with hop 64 and FFT 256 or 512, aligning with the previous hypothesis about capturing perceptually relevant acoustic fluctuations. This configuration provides a 4ms time resolution, potentially capturing psychoacoustic features analogous to roughness and temporal modulation.

5. CONCLUSIONS AND FUTURE WORK

Several promising avenues for future research emerge from this study. First, investigating transfer learning techniques could potentially enhance model generalisability. The incorporation of additional datasets from various acoustic environments might improve model robustness and predictive capabilities. Expanding the research to other sound sources beyond UAS could establish a more comprehensive framework for sound affect prediction. As tonal, high-frequency and synthetic novel noises from e-mobility proliferate into urban environments, it would be invaluable to expand on the current models to classify sounds in noise clips and apply weightings based on source type, detectability and intermittency to better measure more eventful soundscapes. Finally, exploring objective ratings of annoyance from psychoacoustic models from Di, More, Torija *et al*. and NASA, along with their relative metrics, could help better calculate both subjective target annoyances and objective annoyance-model based ratings. This could, in theory, lead to a framework for open-source sound libraries to become extremely useful and adaptable to noise annoyance prediction, classification, training and learning.

6. ACKNOWLEDGMENTS

The authors would like to sincerely thank Abertay University, Dundee, for the support and supervision of work carried out during Max W. Ellis' postgraduate study, where the research framework, spectrograms, and data processing of this study were developed.

ABSTRACT

We present an open-source system designed for multilingual translation and speech regeneration, addressing challenges in communication and accessibility across diverse linguistic contexts. The system integrates Whisper for speech recognition with Voice Activity Detection (VAD) to identify speaking intervals, followed by a pipeline of Large Language Models (LLMs). For multilingual applications, the first LLM segments speech into coherent, complete sentences, which a second LLM then translates. For speech regeneration, the system uses a text-to-speech (TTS) module with voice cloning capabilities to replicate the original speaker's voice, maintaining naturalness and speaker identity.

The system's open-source components can operate locally or via APIs, offering cost-effective deployment across various use cases. These include real-time multilingual translation in Zoom sessions, speech regeneration for public broadcasts, and Bluetooth-enabled multilingual playback through personal devices. By preserving the speaker's voice, the system ensures a seamless and immersive experience, whether translating or regenerating speech.

This open-source project is shared with the community to foster innovation and accessibility. We provide a detailed system performance analysis, including latency and word accuracy, demonstrating its potential to enable inclusive, adaptable communication solutions in real-world multilingual scenarios.

1. INTRODUCTION

In an era where global collaboration and mobility are redefining human interaction, the ability to communicate across languages in real time has transitioned from a futuristic vision to a technological imperative. Traditional translation pipelines, reliant on sequential human intervention or disjointed automated tools, are ill-suited for dynamic environments—from international conferences to emergency response scenarios—where managing latency and coping with naturalness is critical [26]. Artificial intelligence (AI)-powered speech translation systems promise to address this gap. Yet, their practical use remains constrained by competing priorities: the need for accuracy, computational efficiency, and the preservation of speaker identity [12, 5]. While recent breakthroughs in neural architectures have accelerated progress, the field remains divided between two competing paradigms—end-to-end and cascade systems—each with distinct trade-offs in performance, adaptability, and scalability [1].

End-to-end speech translation systems, which directly map source-language speech to target-language text or audio, have gained prominence for their potential to minimize error propagation through joint optimization of transcription and translation tasks. Pioneering works [7, 13, 15, 16] demonstrated the feasibility of unified frameworks implemented on neural networks, while recent breakthroughs like Meta's SeamlessM4T [5] have elevated the paradigm by supporting multilingual translation across 100+ languages. SeamlessM4T exemplifies the allure of end-to-end architectures: it eliminates modular bottle-

necks by training on massive multimodal corpora, achieving state-of-the-art BLEU scores [19] while preserving prosody. However, as Bahar et al. [3] note, such systems remain constrained in streaming applications due to their reliance on full input sequences. The same ability to cope with extended semantic contexts, from which they excel in performance, makes them prone to latency spikes in real-time scenarios. Moreover, end-to-end models struggle with interpretability and robustness, mainly when dealing with noisy input or domain shifts. Anyhow, SeamlessM4T is not yet publicly available, and its real-world applicability beyond controlled demonstrations remains to be thoroughly evaluated.

By contrast, cascade systems modularize translation into discrete stages—ASR, text refinement, Machine Translation (MT), and TTS—leveraging specialized models optimized for each subtask. This decoupled architecture, as explored by Iranzo-Sánchez et al. [12] and Arivazhagan et al. [2], benefits from abundant monolingual ASR and MT datasets, enabling robust performance in high-resource settings. However, cascade pipelines inherit vulnerabilities from the accumulation of errors between stages and segmentation challenges in continuous speech streams [9, 17]. Despite these challenges, recent evaluations confirm that cascade systems retain a performance edge over end-to-end models in standardized benchmarks, particularly for high-resource language pairs [1]. Like those by Bahar et al. [4], hybrid solutions integrate streaming ASR with simultaneous MT models to mitigate latency. Their reliance on proprietary components limits reproducibility, a critical barrier for academic and low-budget implementations.

This work presents a fully open-source, modular cascade system designed for conferences to harmonize the strengths of pre-trained models while mitigating their weaknesses and delivering a complete end-to-end experience. Figure 1 shows the schematic of our solution. Implements a four-stage pipeline. Unlike end-to-end frameworks, our system emphasizes transparency and adaptability by integrating best-performant, independently validated, state-of-the-art open-source modules. We selected the following for our implementation: 1) Whisper [20] for low-latency ASR; 2) a Llama 3 model [10] serves as a contextual buffer, correcting or substituting misrecognized phonemes and deciding whether the sentence is ready for translation, by leveraging contextual and syntactic cues; 3) a second Llama 3 LLM conditioned to perform translation; and 4) MeloTTS [27], offline fine-tuned for voice cloning to mimic the speaker.

We have developed and publicly released this solution for general use, [1] including detailed descriptions of the system and demo's software and hardware implementations. Specifically, we created a low-power analog radio transmitter setup to take advantage of the limits of commercial FM band frequencies, allowing easy reception through standard consumer radio devices. The design simplifies accessibility, accommodating users less comfortable with advanced technology. Additionally, we provide clear instructions for integrating the system with video conferencing sessions and Bluetooth-enabled devices, enhancing its versatility and user-friendliness.

We have validated this solution objectively by measuring latency (between both ends), Word Error Rate (WER) for ASR, and BLEU [19] and COMET [21] scores for translation quality. Regarding the speech synthesis module, we conducted a subjective evaluation of the voice cloning component using a speaker and a small group of evaluators. While this subjective evaluation is informal and not exhaustive in terms of languages or vocabulary, we deem it sufficient for our demonstration.

The remainder of this document is as follows. Section 2 describes the software development aspects, including system architecture and implementation details. Section 3 covers the hardware development, particularly the analog radio setup designed for ease of use. Section 4 discusses the tests conducted and the validation metrics obtained to ensure the system's reliability and effectiveness. Finally, Section 5 concludes the document.

2. SOFTWARE IMPLEMENTATION

2.1 Automatic Speech Recognition (ASR)

The ASR module forms the foundational layer of our cascade system, delivering timely transcriptions from the input speech. For this module, we use Whisper [20], an open-source, multilingual model pre-trained on five million hours of diverse labeled audio data. We selected it for its proven robustness to accents, background noise, and streaming compatibility. Unlike proprietary alternatives (e.g., Google Speech-to-Text, Amazon Transcribe), Whisper's architecture and weights are publicly accessible. Specifically, we utilize whisper.large-v3.turbo [2] (1,550M parameters), which achieves a WER of 9.5% on average for the 15 most common languages, just 1% higher than

[1] https://github.com/MateoCamara/speech-translator-with-voice-cloning

[2] openai/whisper-large-v3-turbo

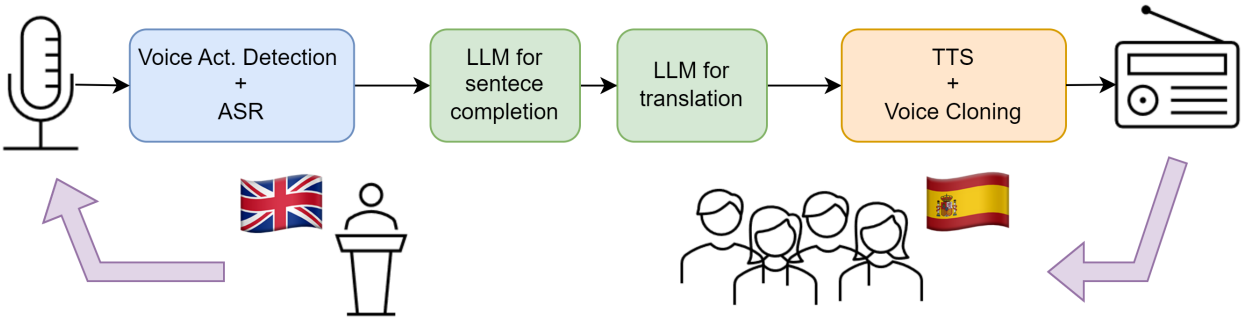

Figure 1: Schema of the solution for multilingual speech recognition (left), translation, and synthesis (right).

the non-distilled version of the model, being 5.4 faster on inference.

A critical limitation of conventional ASR systems in real-time applications is in managing non-speech intervals (e.g., silence, background noise), wasting computational resources, and introducing additional latency with spurious outputs. To minimize computational overhead and false activations, we integrated Silero VAD [24], a lightweight, open-source voice activity detector optimized for real-time applications. Silero VAD processes audio 30 times faster than real-time on CPU, achieving an accuracy score of 91% on their validation dataset. We use it to activate Whisper only when speech probability exceeds a threshold of 0.5, reducing idle inference cycles.

2.2 LLMs for Context Refinement and Translation

To address the inherent challenges of real-time speech processing—such as disfluencies, fragmented phrases, and contextual ambiguity—we deploy two specialized LLMs in cascade. This modular design ensures robustness while balancing latency and semantic coherence.

2.2.1 Context-Aware Phrase Refinement

The first LLM acts as a linguistic validator tasked with resolving ambiguities, correcting ASR errors, and determining phrase completeness. Built on LLama-3 architecture [25], the module leverages a five-sentence context stored in a buffer for semantic continuity. We found this effectively complements Whisper's 30-second speech context. Specifically, we use the LLaMA 3.3-70B-Instruct [3] model, which offers an optimal balance between quality and inference speed, achieving 51.14 tokens per second.

[3] `meta-llama/Llama-3.3-70B-Instruct`

As a new chunk of transcription arrives from Whisper, this LLM is prepared to account for:

- Completeness: Whether the chunk forms a grammatically and semantically self-contained unit (e.g., ending with punctuation or a natural pause).
- Anomaly Detection: Identifies and removes extraneous elements (e.g., filler words, misrecognized phonemes) using syntactic and contextual cues.

The module retains incomplete phrases in a rolling buffer with a capacity of five chunks. If the buffer reaches its maximum capacity, the chunks are forcibly flushed to the translation module, prioritizing low latency over prosodic perfection.

2.2.2 Translation

The second LLM handles translation, converting validated phrases into the target language. Built on LLaMA 3.3-70B, it offers native high multilingual performance, supporting eight languages, including English, Spanish, French, and German. Each complete phrase from the previous LLM is translated, preserving semantic integrity.

Alternative implementations may merge these two LLM instances. For the sake of simplicity and at the cost of increased latency, we did not address such considerations, leaving them for future work.

2.3 Text-to-Speech with voice cloning

To bridge the gap between translated text and natural-sounding speech, our system integrates a hybrid TTS pipeline that combines high-quality synthesis and voice cloning for a specific speaker. This dual-stage approach ensures linguistic clarity and preserves the original speaker's vocal identity.

2.3.1 *MeloTTS for Speech Synthesis*

For the text-to-speech process, we employ MeloTTS [27], an open-source, non-autoregressive TTS framework optimized for low-latency streaming. It supports real-time inference (i.e., speech synthesis) on both CPU and GPU, delivering 44.1 kHz audio with high fidelity. Despite its quality, the model remains efficient, operating smoothly even on mid-range hardware. MeloTTS leverages non-autoregressive architectures, allowing for single-step audio generation. It supports multiple languages and accents, including English, Spanish, French, Chinese, Japanese, and Korean. Additionally, it enables speech rate adjustment, offering flexibility for various applications.

2.3.2 *Voice Cloning Via Full Retraining*

Unlike methods that adapt pre-trained models through style transfer (e.g., "voice color" tuning with 30 seconds of audio), we adopt a full retraining strategy to clone speaker identities with high fidelity. This approach addresses the limitations of zero-shot cloning systems, which often struggle to preserve personal vocal traits (e.g., breathiness, pitch contours) in low-resource scenarios. The implementation workflow is as follows:

- Base Model Selection: We initialize MeloTTS with weights pre-trained on a target-language corpus (in the case of Spanish, 25 hours of clean and consistent audio), prioritizing phonetic coverage of the target deployment language.
- Speaker-Specific Retraining: We used 30 minutes of clean audio from the target speaker (industry-standard duration) to fine-tune the model parameters. For the MeloTTS, these included the audio generator, the duration predictor, and the audio discriminator models. Based on our tests, the latter could be frozen, accelerating the process.

We trained our base model for a male Spanish speaker on the LibriVox datasets [14]. The retraining of the speaker-specific model was covered on a NVIDIA A100@40GB GPU for 56 hours. The process stopped after 235k epochs as the losses stabilized.

3. HARDWARE IMPLEMENTATION

To ensure inclusivity across diverse user demographics—particularly those with limited technological literacy, such as elderly populations—our system prioritizes analog FM radio transmission while retaining compatibility with modern digital interfaces. The FM-based design guarantees universal accessibility through low-cost, widely available receivers (e.g., portable transistor radios). Bluetooth multicast and virtual audio routing remain as supplementary options for tech-literate users.

Figure 2: Radio Transmitter and laptop.

3.1 Analog FM Radio for Universal Deployment

The core hardware deployment lies in a compact, low-power FM transmitter designed to operate at the edges of commercial frequency bands (87.5-108 MHz). It allows reception on conventional devices while avoiding interference with licensed broadcasts. The system comprises three key components:

- Transmitter Module: We included a DSP PLL FM transmitter module operating at carrier frequency 105.1 MHz with a default output power of 0.5 W.
- Amplification Stage: A Class-A amplifier (gain ×100, 12 V input) boosts the signal to 2.0 W, enabling coverage of large indoor spaces (e.g., auditoriums).
- Antenna System: A vertically polarized mini patch panel antenna with +3 dB gain, 50 Ω impedance ensures robust coverage while minimizing signal leakage beyond 100 m.

It supports 12 V DC input from batteries or wall adapters. Thermal fuses and current limiters prevent overheating. Figure 2 shows a picture of the hardware display used in our tests, housed in a PBS enclosure. The system offers versatile audio input via a 3.5 mm jack, micro-USB, or built-in microphone. It features an LCD screen that displays transmission information with volume, play/pause, and frequency selector buttons.

3.2 Complementary Digital Interfaces

For users with smartphones or computers, the system optionally routes translated audio to Bluetooth headphones (via multicast pairing) or virtual microphone outputs for video conferencing tools. However, these interfaces are secondary to the FM radio, which remains the primary channel for its simplicity, cost-effectiveness, and compatibility with legacy devices. The associated GitHub page provides an explanation of how to set these up.

4. EXPERIMENTS AND EVALUATION

We evaluated our solution using the Europarl dataset [11], which contains recordings from the European Parliament. Speeches are delivered and translated into multiple languages. We selected the test subset for validation and assessed the system's performance in translating from English to Spanish on up to three hours of speech and the corresponding transcripted sentences.

The analysis included hereafter covers several key aspects: system latency, errors in speech recognition and translation, voice cloning quality (for a single user), and the performance of the hardware radio setup.

4.1 Latency Tests

This experiment quantifies the latency from the moment a speaker begins a sentence until playback starts. Figure 3 presents an example of a 10-minute speech, illustrating latency variations over time. This fragment is the first eight audio files of the Europarl test set, consisting of political speeches delivered by different speakers. These speeches offer a variety of vocal characteristics, accents, and speaking styles. The total latency averages around 2.5 seconds, with peaks reaching 5 seconds, highlighting the system's behavior with diverse input signals. Most components remain within a stable range. The literature considers 2.5 seconds a valid threshold for real-time translation [1].

Whisper and MeloTTS ran in parallel on an RTX 5090 GPU, while LLM tasks relied on cloud-hosted A100 units accessed via API. The primary latency contributors are the LLM-related tasks, which are challenging to control due to shared cloud resources. Dedicated inference services could help reduce variability. The peak latencies are infrequent and not representative of typical system performance. Latency would likely increase significantly on less powerful hardware. Therefore, deploying cloud-based resources similar to those used in our experiments is recommended.

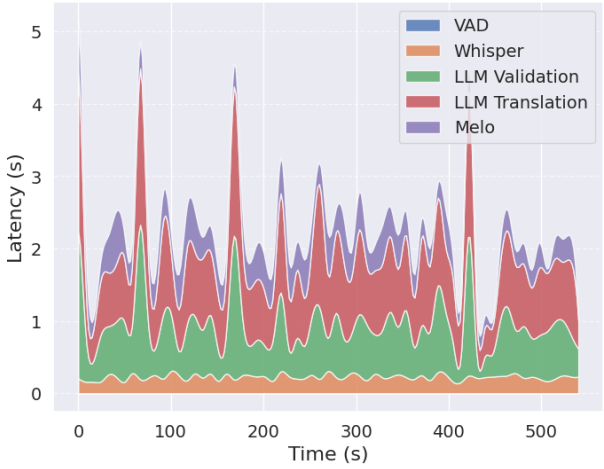

Figure 3: Results on the latency test with 10 minutes speech including all pipeline modules.

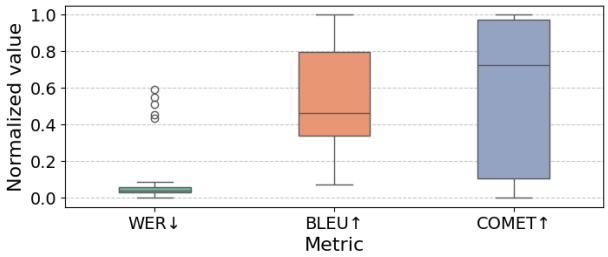

Figure 4: WER for Whisper evaluation and BLEU and COMET for LLM-translation evaluation.

4.2 Intelligibility tests

Figure 4 presents the intelligibility results, with WER evaluated for Whisper, and BLEU and COMET scores for the translation LLM. The reported WER agrees with the values found in the literature. The reference WER for this Whisper model is approximately 9.5%, while our dataset evaluation yielded a median value of 4.5%. This slightly improved performance may be attributed to the dataset-specific characteristics, as no modifications were made to the model.

Regarding translation quality, the BLEU score shows a median of around 0.5, indicating that the translations are not highly reliable and contain significant errors. Meanwhile, the higher COMET score suggests that translations are generally acceptable despite existing errors, with some sentences being mistranslated. The translation direction is

from English to Spanish. While Llama 3.3 does not explicitly report BLEU or COMET scores for Spanish-to-English, it scored 91.1 in the Multilingual MGSM (zero-shot) test [23], demonstrating strong overall performance.

The discrepancy between our results and those reported in the literature may be primarily due to how our pipeline processes the data. Our evaluation does not merely compare two languages but assesses real-world speech records. To minimize latency, some segments may be truncated, and pauses made by the speaker may be misinterpreted as sentence boundaries. Although an additional validation LLM is used to mitigate these issues, the results remain below the state of the art. This bottleneck in translation quality has been identified as a critical area for improvement, and future iterations of the system should focus on enhancing this aspect.

However, research has indicated that automatic translation metrics may be unreliable for evaluating translation quality [28], as human evaluation remains a superior approach. Our observations confirm this: in many cases, translations are perfectly understandable, yet the metrics assign poor scores due to word order changes or structural variations introduced by the LLM. We report the standard metrics used in the recent literature without highlighting their absolute values, as we concur that their relevance is limited.

4.3 Voice cloning subjective evaluation

We conducted subjective evaluations to assess the quality of the generated speech based on user perception, following [22]. Participants were required to use wired headphones, have no hearing impairment, and complete the test in a quiet environment. We also collected information about their native language and proficiency in Spanish: speaking, writing, and listening.

The evaluation followed a standardized MOS rating system implemented using the GoListen platform [6]. The online test consisted of 28 questions across two parts: (1) synthesized audio without reference to the original human recordings, [8], and (2) comparisons between synthesized and original recordings, [18]. Each question was rated on a scale of 1 (poor) to 5 (excellent). The audio samples included phonetically balanced sentences.

The analysis was structured into two parts. First, we evaluated items across all subjects per sentence. Second, we analyzed the dispersion for each sentence on all evaluated items. Thirty evaluators completed the test. Sentences 1 and 3 received the highest ratings overall, as shown in Fig.5a. Sentence 3 particularly excelled in listening effort, comprehension, and speaking rate, with most ratings at 5 (Fig.5b). However, pleasantness scored slightly lower. Sentence 4 showed good overall quality but required more listening effort and had articulation issues. Sentence 2 performed well in comprehension but struggled with pronunciation and speaking rate.

In summary, evaluators rated the synthetic audio highly, especially compared to original human recordings. These promising results highlight the potential of our solution while identifying areas for improvement, such as voice pleasantness and articulation. For further details, refer to the test [4] and to the published repository. [5]

4.4 Hardware Tests

To validate the performance of our FM transmitter, we assessed operational reliability and signal confinement within the designated area. We collected our measurements in the ETSIT-UPM auditorium, where irregular wall absorption, physical obstructions, and ambient noise affected propagation. The room can accommodate up to

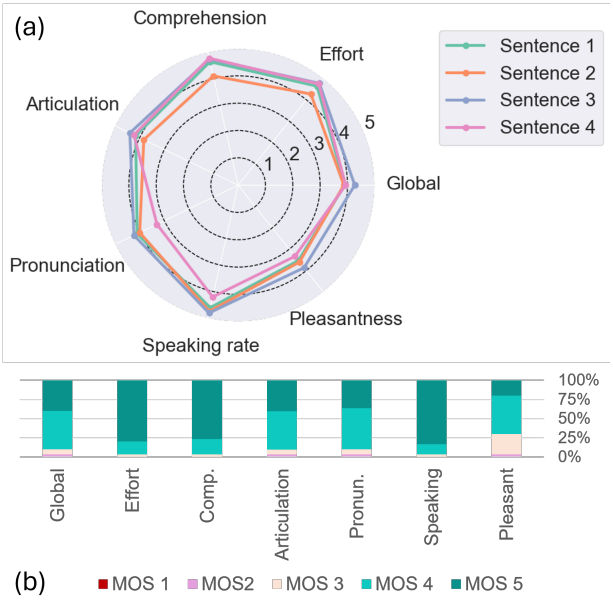

Figure 5: Results of the subjective tests: (a) chart on all sentences, (b) stacked ratings on Sentence 3.

Table 1: Measured performance parameters of the FM transmitter at various auditory locations

Location	Peak Power (dBm)	Signal Power (dBm)	SNR (dB)
Antenna	-53.8	-56.0	59.1
First Row Middle (Best Case)	-75.4	-77.6	47.3
Interior (Avg ± S.D.)*	-82.0±7.3	-83.1±7.0	38.2±5.7
Far Corner (Worst Case)	-93.2	-95.1	33.7
Adjacent Room	-106.0	-108.3	20.5

* Average room values were computed by excluding the antenna and adjacent room locations.

195 people. The floor plan is 12.50 m × 14.60 m. The transmitter antenna was centered in the stage 2 m high, oriented toward the audience to optimize coverage.

In this controlled environment, we used a calibrated handheld spectrum analyzer N9342C with a test antenna from the ETS Lindgren Model 7405 kit. We used a set of reference signals, a constant 440Hz (A note), white noise, and a 20-second-long speech record. Measurements were collected in strategic locations within the auditorium to capture spatial variations in signal performance and assess leakage in adjacent rooms.

Average measures on signal-to-noise ratio (SNR), frequency band leakage, and signal strength are listed in Table 1. In the auditory area, the SNR was consistently above 30 dB, which indicates good reception quality. In contrast, measurements outside the auditorium produced SNR values around 20 dB, suggesting minimal signal quality; however, the observed leakage remains below acceptable interference thresholds. We also observed frequency shifts of 33.31 ± 10.2 kHz, which falls within reasonable limits. A subjective test with three volunteers provided uniformly positive feedback on audio clarity.

5. CONCLUSION

We successfully designed, implemented, and tested a system for multilingual translation and cloned speech synthesis, adapting state-of-the-art open-source components. Users can listen to our broadcast using standard radio or Bluetooth devices.

In our tests on English-to-Spanish translation, the system introduced a 5-second delay in the communication, with an average of 4.5% WER in the transcription, 0.5 BLEU, and 0.75 COMET scores, respectively.

From our subjective tests, we conclude that the results achieved an average rating of 4.20 on the MOS scale. In addition, our hardware tests verified reliable signal confinement and robust performance in the real environment under varying conditions, with an average SNR of 38.2 dB inside the auditorium.

The proposed system is subject to several improvements. The MeloTTS essentially conditions the latency. Optimizations to the model, particularly in how the models are handled internally, could reduce this number. The two LLM models, used for sentence completion and translation, may be integrated to accelerate execution without compromising performance.

A MODEL FOR IMPROVING THE PERFORMANCE OF LARGE LANGUAGE MODELS ON SOUNDSCAPE DESCRIPTION TASKS

Zhongju Yuan[1] **Dick Botteldooren**[1*]

[1] Department of Information Technology, Ghent University, Belgium

ABSTRACT

Generative AI is increasingly used in acoustic scene analysis and environmental soundscape description. Audio Language Models (ALMs) are key in this field but have two main drawbacks: they don't provide human-like survey responses and require significant computational resources, making real-time monitoring impractical. These issues stem from differences in how ALMs and humans assess and store sensory experiences. We propose a computationally efficient model with a three-layer architecture. The top layer features an advanced ALM for recognizing, grouping, and remembering audio events. The intermediate layer includes a local salient change detector based on sound feature embedding, which identifies meaningful changes in the auditory environment. When a change is detected, the ALM interprets and remembers the sound. The bottom layer has a memory cell mimicking echoic memory, retaining and reconstructing recent audio inputs. This reconstructed memory is passed to the ALM for recognition when triggered by the salient detector. Tested on the Urban Soundscapes of the World dataset, our model balances computational efficiency with real-time recognition accuracy, paving the way for scalable, intelligent acoustic monitoring solutions.

Keywords: *soundscape, saliency, large language models*

1. INTRODUCTION

Soundscape, the sonic environment as perceived and understood by persons of society within context, is increasingly used to assess and design the (urban) sound environment. With this definition in mind, measuring the soundscape remains a challenge. The ISO/TS 12913-2 standard series suggests surveys, sound walks, and focused listening to assess the soundscape. Artificial intelligence (AI) today allows us to recognize sounds and relate them to emotional attributes, e.g. annoyance [1]. However, such models are not very biologically plausible. Generative AI has recently seen tremendous expansion. Audio Language Models (ALMs), a special branch of large language models, offer the advantage that they can take into account context and common expectations, aspects that were shown to be extremely important in soundscape evaluation [2], [3], [4].

However, a direct use of ALMs on continual sound streams detected in urban public places does not account for the critical role of human attention in urban sound perception, which has often been overlooked in soundscape research. In fact, in daily life, the urban sound environment is seldom the focus of attention of the space user. Therefore in previous work, we have introduced an additional dimension orthogonal to the two-dimensional pleasure - arousal plane, backgrounding, measuring the degree of influence on overall perception of the space [5].

Allowing the sound to be backgrounded, that is gated out from further cognitive processing, also alows to reduce the amount of effort the ALM needs to put in analyses of the sound. Inference of answers from generative AI is a highly energy consuming process [6]. When connected to edge devices for monitoring soundscape, the combined process becomes extremely energy unfriendly and expensive. Nature has solved this problem also encountered by biological brains by allowing to gate out any repeated, continuous or otherwise uninformative sound. To assure that the function of hearing as an alerting and situation monitoring system is kept intact, gating out or in-

hibition must be accompanied by a saliency detection that triggers attention bottom up [7]. Auditory saliency has been widely studied [8] and has been related to changes in acoustical features [9], extending the classical Kayser-model [10].

In this paper, we propose a hierarchical framework to model the auditory processing system. The bottom layer functions as the echoic memory, responsible for memorizing and retrieving short audio segments. These sliding short segments are passed to the upper short-term memory layer for pattern change detection. When a change in the pattern is detected compared to the previous segment, the higher cognitive layer—referred to as ALM in our context—takes over the processing. At this stage, a longer auditory memory span is analyzed, and responses to several predefined questions are generated.

The proposed framework demonstrates that the model can significantly reduce the workload of the ALM by decreasing query frequency, while maintaining overall performance. By offloading routine pattern recognition and memory operations to the lower layers, the ALM is only engaged when higher-level cognitive processing is required. This hierarchical design not only improves computational efficiency but also better reflects the biological plausibility of human auditory processing. Furthermore, the reduction in unnecessary queries enables the ALM to allocate more resources to complex tasks, thereby enhancing the system's scalability and responsiveness in dynamic auditory environments.

2. MODEL

The proposed model is subdivided in large blocks that roughly correspond to functions in the biological system. The cochlear and brain-stem model conducts the primary spectral filtering. For the purpose of this paper, a simple gammatone filter bank is used for calculation speed, but this block can easily be replaced by a more precise model such as CONNear [11].

The block labeled "echoic memory" stores time traces of the (filtered) sensory input. In line with observations in humans, it allows to go back in time for about 4 seconds. This is essential to allow analysing a salient event that might be detected slightly after it has actually happened. Biologically plausible implementations of sensory, echoic memory might reveal special effects in real-time applications, but for the current paper the stored audio file is simply recalled when needed.

A central element is the predictive model used for detecting changes and saliency. In contrast to earlier work, no attempt is made to extract features that might influence the detection of sensory salient signals. Instead, it is assumed that a convolutional neural network (CNN) trained to detect sounds that are of relevance for humans will identify those features that define a sound object. Thus unpredictable changes of the embedding resulting from encoding a short epoch of sound can be seen as changes in the sound environment that might warrant re-evaluation of the soundscape. If such detections occur, the gate connecting the sensory memory to the large language model is opened for a predefined amount of time. The latter could still be a point of discussion. If the sound is of low interest for the person visiting the environment, top down attention will fade quickly and further processing will stop. However, conversations or longer bird songs may keep attention focussed. In earlier work on notice events we estimated that the decay time of top down attention for uninteresting sounds could be up to 10 seconds [12]. In this paper a fixed time interval of 15 seconds is used.

Any pretrained large generative model can be used as a cognitive model in this framework. We associate these models with human cognition because for soundscape assessment they fulfill roles that are usually associated with cognitive processes: (1) recognizing sounds and associating meaning where meaning is seen as the complex set of associations that are triggered by the sound; (2) putting the sound in a context, e.g. by specifying that a recording is made in an outdoor public place; (3) associating affect (e.g. calming, stimulating). The appropriateness of using the ALM for the latter could be debated as it probably only covers the common sense evaluation. For example, such models may easily link voices of people and traffic to lively environments and birds and water to calming environments, but they do not adequately account for the complexity of sound mixtures [13], where complexity is understood as the effort needed to analyze the auditory scene [14].

Prompt engineering, the craft of prompting a generative model properly, requires some attention. Here, we employ *Qwen-audio* [15] to generate the final responses. After several preliminary experiments, the following prompt was selected for use in the experimental setting:

> **Prompt:** Assume that you are a human in a public place, answer the following questions:
>
> 1. Can you describe what sounds you

hear?

2. What type of public place do you think you are in?
3. In general, how would you categorize the environment you just experienced?
(Options: calming / tranquil, lively / active, or neither)

Provide a structured response for all these questions.

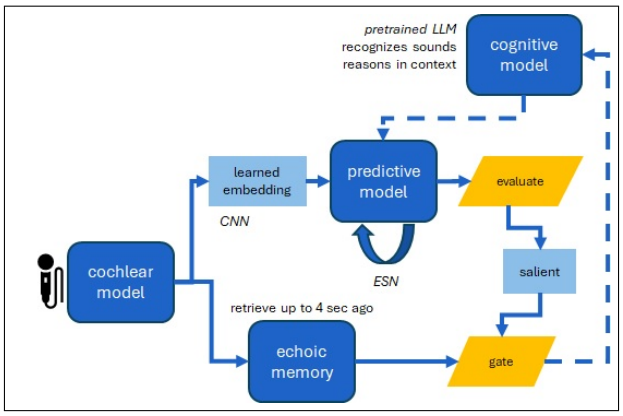

Figure 1. Connection between main components in the proposed model: the predictive model uses a learned embedding of the sound to detect any unpredictable changes in the sound; if such a change occurs it opens the gate to feed the cognitive model with new sound input; the echoic memory allows to retrieve the sound up to 4 seconds before the detection of a change, a salient event.

3. URBAN SOUNDSCAPES OF THE WORLD

As a test case for the approach, we used the Urban Soundscape of the World dataset. This database has been recorded at carefully selected locations in multiple cities across the globe [16]. The database contains high quality 4-channel ambisonics and binaural recordings and is supported by 360 degree video. The original recordings are around 10 minutes long, but 1-minute excerpts have been used in this work [17].

The Urban Soundscapes of the World database has been used in several lab studies. Here, the evaluation of each audiovisual recoding by 20 persons in a carefully constructed virtual reality experiment will be used [5]. In this work, participants are questioned in a much more subtle way than ISO/TS 12913-2. In brief: participants are first ask to rate the environment as a whole on a calming/tranquil to lively/active scale; then they are triggered to reflect on the activities that they could do in this environment in order to set a context for further evaluation; they are then asked whether the sound has drawn their attention during the AV experience (this leads to a rating on the *backgrounded* axis); they are then queried about the possible interruption of the activities they had in mind by the sound (this leads to a rating on the *disruptive* axis); depending on their answer to the first question, they are then asked to rate to what extend the sound environment contributed to that experience (this leads to a rating on the *calm/tranquil* and *lively/active* rating dimensions).

4. RESULTS

4.1 Overall accuracy

The model proposed in this paper is purely auditory, hence it has no visual context or any other stimulus. Thus, it is not possible for the model to rate whether the sound environment would be *backgrounded*. For the same reason *disruption* of potential activities is hard to rate as these potential activities depend largely on the overall knowledge about the place that human participants in an experiment would largely get from visual input. Therefore, this evaluation is restricted to the *calm/tranquil* and *lively/active* dimensions. 2 shows the distribution of average rating by the 20 participants from [5] for two classes predicted by the model: tranquil and lively. In the left figure, all sound fragments are used, in the right figure only those where the people rated that the sound environment had at least a moderate influence on the overall perception. By restricting the evaluation to sound environments that were rated by people, on average, to have an influence on the perception, the two distributions become more disjoint. Yet the model still classifies several sound environments as tranquil while persons would give them a more lively rating.

4.2 Ablation study

The proposed framework improves the ALM's ability to handle real-time scenarios. In this subsection, we demonstrate the performance of the framework. We evaluate its efficiency based on two metrics: the final tranquility level output by Qwen, and the total audio duration processed

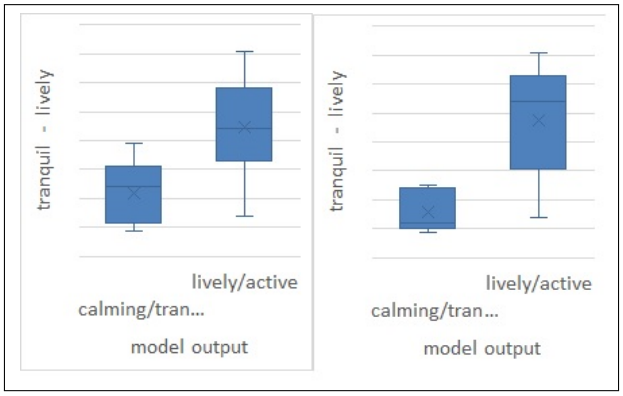

Figure 2. Box plot of the rating by participants of the environments on a *calm/tranquil* and *lively/active* dimension for the group of soundscapes rated as tranquil or lively by the model; left: all recordings, right: only environments where the sound is rated as influential by people.

per sample—since it's not feasible to send audio to the ALM every second for description generation.

First, we compare the tranquil/lively classification produced by Qwen using the complete sound fragment and the excerpt selected by the proposed model (cosine similarity threshold 0.9). We remind the reader that our model only sends a 15-second segment for evaluation when a pattern change is detected. The description from the most recent segment is used to determine tranquil/lively.

A confusion matrix has been calculated comparing the classifications based on analysing the full minute and a classification based on the proposed model. This showed that 54 recordings are classified as *lively/active* by both approaches and 10 recordings are classified as *calm/tranquil* by both approaches. However, 9 recordings that were classified as classified as *lively/active* on the basis of the full minute get classified as *calm/tranquil* by the proposed model and 4 recordings that were classified as *calm/tranquil* on the basis of of the full minute get classified as *lively/active* by the proposed model.

Figure 3 shows the same results as Figure 2 but now using the classification based on an evaluation of the full minute recording by Qwen. Both results are very similar and small differences tend to show that the proposed model slightly better predicts the evaluation by people. The latter observation should be interpreted with caution as no statistical significance of this difference is shown.

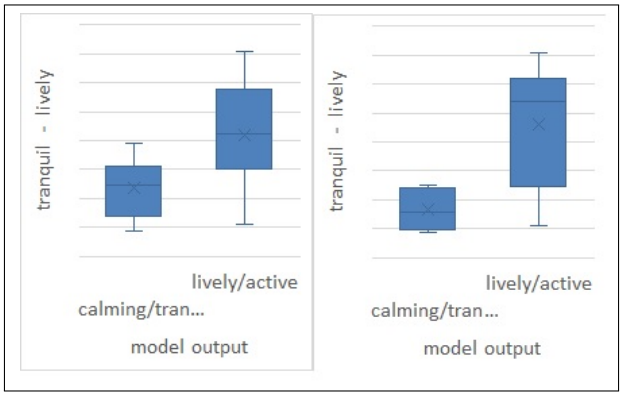

Figure 3. Box plot of the rating by participants of the environments on a *calm/tranquil* and *lively/active* dimension for the group of soundscapes rated as tranquil or lively based on the full one minute recording; left: all recordings, right: only environments where the sound is rated as influential by people.

To clarify that the time length processed by Qwen is significantly shorter, we provide statistical analysis of the processed durations across all audio samples. The results are presented in Fig. 4.

This violin plot shows the distribution of audio segment lengths sent to the Qwen model at a 0.9 threshold, combining density, individual data points, and a box plot. The distribution is bimodal with peaks at 15 and 30 seconds. The mean (22.51s) exceeds the median (15.00s), indicating right skew due to longer segments. Most data range from 15 to 60 seconds, with clusters in the lower range and a few high-value outliers. From Fig. 4, it is evident that approximately half of the audio fragments in the dataset do not exhibit significant pattern shifts. As a result, the framework sends only the initial 15 seconds to Qwen. This shortened processing time does not affect the resulting tranquility level.

5. DISCUSSION

Acoustic Language Models, a special subbranch of Large Language Models that combine sound recognition with the *common sense* knowledge embedded in these pretrained models are becoming notoriously powerful for describing acoustic scenes. However, directly applying such models to continuous sound streams recorded in urban

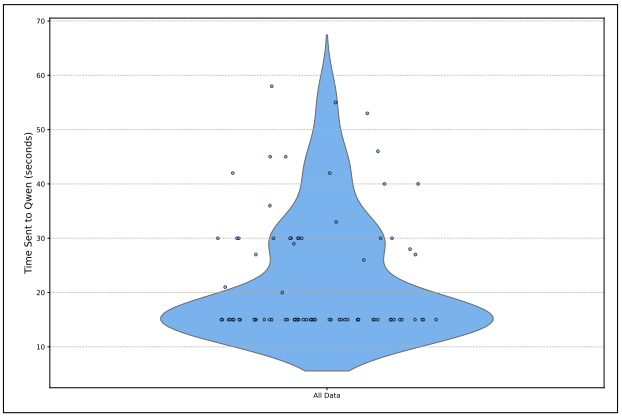

Figure 4. Distribution of Time Length Sent to Qwen at Threshold 0.9. This violin plot illustrates the distribution of audio time lengths processed and sent to the Qwen model at a threshold of 0.9.

sound monitoring for example, is extremely energy consuming and expensive. Inspired by human auditory scene analysis, we propose a model that decides which sound can safely be gated out without losing any essential information.

Environmental sounds often fade into the background for individuals enjoying public spaces. After an initial assessment of the sonic environment, the human mind tends to wander, only reassessing the surroundings when a notable sound event occurs. Numerous models have been proposed to identify these salient sounds, typically grounded in psychoacoustic principles. The proposed model, however, takes a different path. It posits that Artificial Learning Models (ALMs) trained to recognize sounds relevant to humans will develop embeddings that emphasize the features the human auditory system is attuned to. Consequently, a change in these embeddings would signal a shift in sounds significant to human perception, thereby suggesting triggering a release of gating.

This model is used here to assess sound environments available in the urban soundscape of the world database, with soundscape in mind. In particular, the labeling of the sound environment as *lively/active* or *calm/tranquil* is considered. For this, results obtained by human participants evaluation an audiovisual environment in virtual reality [5] can be used as a reference. It is shown that the proposed model predicts human evaluation at least as good as an evaluation based on the whole fragment. At the same time, very often, processing as little as 15 seconds using the ALM is sufficient. Only very seldom more than 30 seconds of sound is needed to reach the decision.

SOUND ENVIRONMENTS CLASSIFICATION OF A UNIVERSITY CAMPUS USING UNSUPERVISED MACHINE LEARNING TECHNIQUES

Jose Montoya Belmonte[1*] **Antonio Pita Lozano**[1] **Juan Miguel Navarro Ruiz**[1]
[1] Research Group in Advanced Telecommunications (GRITA),
UCAM Universidad Católica de Murcia, 30107 Guadalupe, Spain

ABSTRACT

A university campus, often comparable to a small city, faces similar challenges in monitoring and managing noise pollution within their environments. This study presents a methodology to classify the diverse soundscapes of a university campus using long-term acoustic measurements collected through a network of acoustic sensors. The research was conducted at the Catholic University of San Antonio in Murcia, where sound data was captured and analyzed based on sound pressure levels. In addition to using overall sound pressure levels data, the study explores the advantages and limitations of incorporating more detailed information, such as sound pressure levels segmented by frequency bands, for identifying acoustic patterns. Unsupervised machine learning techniques, specifically the k-means clustering algorithm, were applied to process the extensive dataset generated by continuous monitoring. This methodology facilitated the identification of distinct acoustic patterns across the campus. The results demonstrate the potential of combining acoustic sensor networks with machine learning algorithms to efficiently monitor and categorize urban-like environments such as university campuses. This approach provides a scalable and cost-effective solution for soundscape management, while highlighting the potential benefits of integrating more granular acoustic data for enhanced pattern recognition.

1. INTRODUCTION

The contemporary university campus presents a complex acoustic environment where diverse sound sources, ranging from human activities to transportation noise, affect both outdoor and indoor soundscapes [1], [2]. The soundscape of university environment plays a pivotal role in influencing students' well-being, cognitive performance, and academic satisfaction [3]. Furthermore, in recent years, the concept of soundscape has gained increasing relevance in the design and management of campus environments [4].

The implementation of Wireless Acoustic Sensor Networks (WASN) has revolutionized acoustic monitoring methodologies by providing systems for real-time data collection and transmission in a distributed and scalable manner [2]. These networks enable a more precise and dynamic characterization of soundscapes, facilitating the detection of relevant acoustic events and the spatial and temporal analysis of noise. The measurement of sound pressure level (SPL) serves as a fundamental indicator to characterize acoustic environment and evaluate exposure to noise and its potential health impacts [5]. Despite its widespread use, conventional approaches to noise assessment typically emphasize the average SPL values, which can overlook the intricate temporal and spatial fluctuations present in complex soundscapes.

To address these shortcomings, unsupervised machine learning methods, such as k-means clustering, have gained traction as effective strategies for analyzing large acoustic datasets. These techniques allow for the automatic grouping of sound pressure data into clusters that exhibit similar properties, thereby facilitating the discov-

ery of distinct noise patterns and acoustic zones that traditional methods might miss.

This paper is focused on evaluating the suitability of applying a WASN-based system for long-term temporal monitoring of acustics parameters in order to assess the acoustic environment in a High Education institutions for this purpose. This work explores the integration of unsupervised machine learning techniques, specifically k-means clustering, for analyzing SPL data in complex environments, with the aim of enhancing noise management strategies and improving acoustic comfort.

2. MATERIALS AND METHODOLOGY

This smart campus initiative involves the design and implementation of WASN strategically placed at various indoor and outdoor locations. For this work, four sensor nodes are deployed, one of then are located outdoor. The outdoor area is a highly frequented space utilized by staff and students during break periods and for hosting special events such as forums and exhibitions. Consequently, it serves as an open venue for the entire university community, with the primary source of noise being predominantly anthropogenic. While the rest of nodes are indoors, in particular, an office, a classroom and an entrance hall.

Each WASN is capable of continuously acquiring valuable acoustic data over extended periods. Each node is equipped with sensors for capturing sound signals, and calculating acoustic metric such as the sound pressure level (SPL) in dB, along with the SPL values in several octave frequency bands (dB), specifically 125 Hz band, 250 Hz band, 1 kHz band, 2 kHz band, 4 kHz band. Moreover, As well as embedded software for processing audio inputs and computing key acoustic parameters.

Monitoring is performed for four months, twenty four hours per day, with data capture every minute in different scenarios.

For the input data, no preprocessing or aggregation is applied; thus, the model's input consists solely of the metrics corresponding to the octave frequency bands.

Subsequently, the collected data are analyzed, preprocessed, and cleaned to ensure quality and reliability. Once the data is properly prepared, it is utilized in an unsupervised learning approach using the k-means clustering algorithm, For a given value of k, k-means algorithm groups the nodes in k-clusters. This technique enables the identification of homogeneous groups within the dataset, thereby facilitating the classification of different acoustic environmental sound patterns. Where the parameter K denotes the predetermined number of clusters specified prior to the execution of the algorithm, guiding the iterative assignment of data points to the nearest cluster centroid based on a defined distance metric.

The algorithm iterates in two steps until the centroids have stabilized. In the first stage of the process, known as the assignment step, each node is associated with the closest centroid according to the computed distance. The second step, known as the update phase, involves recalculating the centroid positions by determining the element-wise arithmetic mean of all data points associated with each cluster [6].

Software and Technology

Data preparation, transformation, analysis, and modeling were carried out using the open-source programming language R [7], version 4.3.2. The computational environment included an AMD Ryzen 7 5800X 8-core processor running at 3.80 GHz, 32 GB of RAM, and an Nvidia GTX 3050 GPU with 8 GB GDDR6 memory. The analysis utilized several R libraries: dplyr (version 1.1.4), lubridate (version 1.9.3), tidyr (version 1.3.0), cluster (version 2.1.4), clValid (version 0.7), mclust (version 6.1.1), Kohonen (version 3.0.12) and ggplot2 (version 3.4.4). To ensure the reproducibility of results, a fixed seed was set using the `set.seed()` function for all tasks involving random processes. Furthermore, given the changes in random number generation introduced in R version 4.0.0, additional steps were taken to standardize the methodology and guarantee consistent outcomes across different R versions.

3. RESULTS AND DISCUSSION

In this section, results obtained from applying the clustering technique, K-means, to the collected data are analyzed and discussed.

To determinate the appropriate amount of clusters, k-means algorithm has been trained for k = 1, . . . , 12, being this one with 5 clusters the best of them for Silhouette metric [8]. Therefore, the model has been trained with k=5, as it maximizes the Silhouette. This indicates that clusters of sounds are formed based on their similar behavior with respect to the five selected variables, namely, the SPL in several octave frequency bands, i.e. from 125 Hz to 4,000 Hz. Centroids, in dB, are calculated according to [9].

Tab. 1 shows the clusters' centroids created by clustering.

The data obtained allow for the identification of multiple sound sources impacting the acoustic environment of

Table 1. Centroid of clusters using data collected during monitoring the university.

Group	125 Hz band	250 Hz band	1 kHz band	2 kHz band	4 kHz band	Colour
1	32.94	30.20	23.97	21.11	18.45	black
2	36.72	18.29	18.28	48.81	24.57	pink
3	39.53	38.55	33.43	26.68	22.84	cyan
4	51.32	43.08	40.77	31.81	30.02	brown
5	56.32	47.38	48.13	54.76	33.72	blue

the university.

Group 1 shows a constant decreasing trend from 125 Hz band to 4 kHz band.This reduction suggests a predominance of low-frequency sound sources, potentially associated with structure-borne noise. Additionally, the presence of furniture in the area may contribute to acoustic absorption, while the attenuation of high frequencies indicates that they are being absorbed or dispersed within the environment.

Group 2 has a sharp drop at 250 Hz band, staying at low values until 1 kHz band.Then, at 2 kHz band, it experiences a sharp peak before dropping again at 4 kHz band.This suggests that this group is very sensitive to certain frequencies, especially in the 2 kHz region, where the dB level is the highest.

Group 3 also presents a progressive reduction in dB, although less pronounced than group 1.

Group 4 exhibits a higher value in the 125 Hz frequency band, suggesting the influence of ventilation systems and structure-borne noise.

Group 5 highlights two frequency bands: 2 kHz frequency band and 125 Hz frequency band. This cluster represents an outdoor node where students gather on benches during breaks. The 2 kHz frequency band is associated with human speech, indicating that conversations significantly contribute to the acoustic environment in this area. Meanwhile, the 125 Hz frequency band component is influenced by its proximity to the transportation zone, where external noise sources, such as vehicle traffic, play a role.

The values obtained from the Tab. 1 are represented in Figure 1, which illustrates the variation in dBA levels across different frequency bands for distinct groups.

Group 3 and 5 have peaks in 2 kHz band, suggesting that this band has a greater impact in certain scenarios.

Group 1 and 2 show a downward trend, which may be related to energy loss at high frequencies.

In order to show the relevance and the relation between these indicators 125 Hz Band, 250 Hz band, 1 kHz band, 2 kHz band and 4 kHz band. A smoothed color density scatterplot representing all monitoring can be seen in

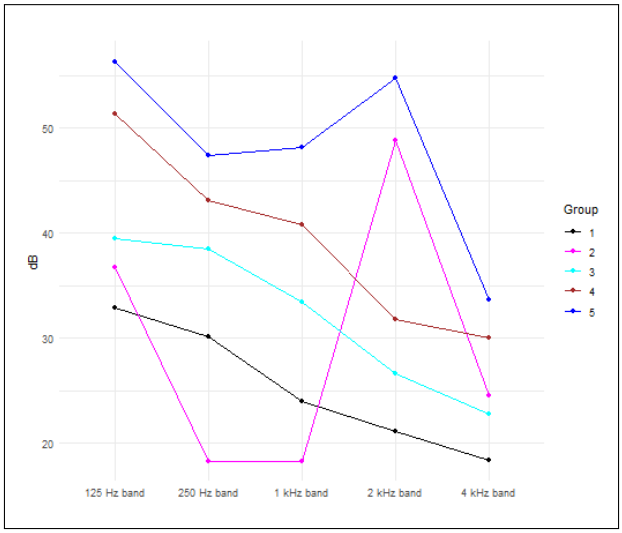

Figure 1. Centroids according to cluster and their respective frequency bands.

Figure 2. The smoothed color density helps to identify dense zones that groups nodes with similar behavior.

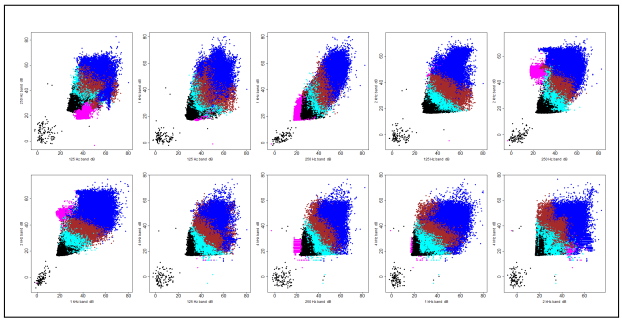

Figure 2. Scatter plot of the 125 Hz band, 250 Hz band, 1 kHz band, 2 kHz band and 4 kHz band metrics representing all time frames.

4. CONCLUSIONS

The acoustic environment within a university setting should be continuously monitored, as various sound sources can significantly impact the well-being and academic performance of the university community. WASN represents an effective tool for environmental acoustic monitoring, enabling the collection of large volumes of data. However, due to the magnitude of the captured in-

formation, conventional data processing methods may be insufficient. To address this challenge, the implementation of machine learning algorithms allows for data analysis, pattern recognition, predictive modeling, and the extraction of meaningful insights, enhancing decision-making in acoustic management.

This study presents a preliminary analysis of an urban acoustic environment within a university setting, employing unsupervised machine learning techniques, specifically the k-means clustering algorithm to determine whether the analysis of the values obtained from sound pressure level bands allows for the identification of specific acoustic characteristics. This technique is a good tool for analyzing large amounts of data obtained from the monitoring of sound environments. According to the data obtained, higher SPL values are observed in the low frequency values, 125 Hz band, which present higher SPL than at higher frequencies, Based on the obtained data, it is valid for identifying different sound sources that impact the university environment. In future projects, subjective values such as loudness and sharpness will be added in order to know the correlation that may exist with the band values and to be able to know how these sources are affected.

ABSTRACT

This study evaluates the effectiveness of automated bioacoustic classifiers in detecting the vocal activity of the common cuckoo (*Cuculus canorus*) within the Chornobyl Exclusion Zone (CEZ). Data were collected from 12 recording locations using Wildlife Acoustics Songmeter 3 (SM3) units during May 2015. Acoustic data were analysed using Kaleidoscope Pro, focusing on the left channel to avoid duplicate detections. The classifier scanned recordings for target sounds based on specified signal parameters and employed cluster analysis to categorise events. The classifier demonstrated high precision (95.1%) and a low false negative rate (0.5%), with most misclassifications due to other bird species with similar frequencies. The recall rate averaged 61%, varying from 40% to 100% across different recorders. Variations in recall rate were influenced by habitat structure, environmental noise, and distance between the target species and the recorder. This study highlights the potential of automated classifiers in ecoacoustic monitoring.

Keywords: *ecoacoustics, biodiversity, monitoring,*

1. INTRODUCTION

Ecoacoustics, the study of environmental sounds and their relationship with the ecosystem, plays a crucial role in monitoring biodiversity. Automated classification, a method that uses machine learning algorithms to identify species from acoustic data, enhances the efficiency and accuracy of such studies. By leveraging these technologies, researchers can effectively monitor species.

The common cuckoo (*Cuculus canorus*) is a migratory brood parasite that relies on other species to raise its young. Females remove host species' eggs and nestlings before laying their eggs in the nest [1]. Common cuckoo breed extensively in Europe and parts of North Africa, and winter in Africa and southern Asia. In Europe, they are summer visitors from April to September, with peak breeding in May and June [2,3]. They inhabit diverse habitats, including woodlands, forests, scrub, heathland, meadows, reedbeds, lowlands, and moorlands. Their diet mainly consists of insects, particularly caterpillars, crickets, and dragonflies [2].

Common cuckoos are solitary outside the breeding season but communicate vocally during breeding [2]. Detection through traditional methods like point counts and line transects is challenging due to their isolated behaviour. The species is characterised by distinct vocalisations, with males emitting loud "cu-coo" calls audible over 2-3 km. These vocalisations make acoustic monitoring highly effective for detecting common cuckoos [4].

Here, the vocal activity of the common cuckoo was monitored throughout May 2016, one of the most active months for this species [5], to investigate the common cuckoo across the CEZ. The objective of the study was to evaluate the effectiveness of automated detection for this species.

2. METHODS

2.1 Data Collection

Wildlife Acoustics Songmeter 3 (SM3) units were deployed in the CEZ. In total, 12 locations were used. Data were collected continuously between 10th May 2016 and 3rd June 2016.

2.2 Acoustic Data Analysis

The data collected during the specified period was analysed using Kaleidoscope Pro (ver 5.3.6) (Wildlife Acoustics, https://www.wildlifeacoustics.com). To avoid duplicate detections, only the left channel of the recordings was used (channel 0), a method validated by previous studies [6,7,8]. Kaleidoscope Pro scanned recordings for target sounds based on specified signal parameters, including minimum and maximum frequency (Hz), minimum and maximum length of detection (s), and maximum inter-syllable gap (ms). These parameters were determined using 40 manually located cuckoo calls from the study area with Raven Pro 1.5 (Bioacoustics Research Program 2014). Kaleidoscope Pro's cluster analysis function was used, extracting the Discrete Cosine Transform coefficient (DCT) of the spectrum of candidate sounds. A Hidden Markov Model (HMM) was constructed using the vector of the DCT of each signal frame, and vectors were grouped based on K-Means clustering. Clusters were labelled as "cuckoo" or "other sounds" based on the first 50 events of each cluster. Each sound was visually/acoustically checked to determine classifier performance, including precision and recall rate.

Table 1. Signal parameters derived from Raven Pro were input into Kaleidoscope to detect common cuckoo calls.

Species	Min Freq (Hz)	Max Freq (Hz)	Min Length (s)	Max Length (s)	Intersyllable Gap (s)
Common Cuckoo	250	900	0.3	1	0.6

The recall rate was estimated by dividing the total number of calls detected by Kaleidoscope Pro by the total number of actual cuckoo vocalizations (determined by manual analysis). A total of 108, 15-minute recordings were randomly selected to determine the recall rate.

3. RESULTS

The common cuckoo was detected through the cluster analysis function within Kaleidoscope Pro at every recording location across the CEZ. The number of calls detected ranged from 2163 to 16,062. Kaleidoscope Pro reported a total of 128,527 events matching the signal parameters. These were divided into "other sounds" (29,437 events, 22.9%) and "cuckoo" (99,090 events, 77.1%).

The precision of the classifier was 95.1%, with a false positive rate of 3.3%. Most false positives were vocalisations from birds with similar frequencies, including the common woodpigeon (*Columba palumbus*), Eurasian hoopoe (*Upopa epops*), Eurasian collared dove (*Streptopelia decaocto*), and tawny owl (*Strix aluco*). The mean recall rate for the entire dataset was 61% (5058 calls detected out of 8363 calls annotated in the 108 recordings of the validation dataset), ranging from 40% to 100% for each recorder.

Table 2. Recall rate for each acoustic recorder used in this study. The number of manual annotations represents the number of calls detected through manually inspecting the validation dataset, whereas the number of calls detected through automated classification represents how many calls the classifier in Kaleidoscope Pro detected. The recall rate column expresses the percentage of calls correctly detected by the automated classifier in relation to the calls detected through manual annotations.

Recorder	No. of calls manual annotations	No. of calls automated classifier	Recall Rate
303715	1158	773	67%
303712	2087	1145	55%
303160	1074	434	40%
303727	403	205	51%
303719	302	265	88%
303724	331	178	54%
303137	563	298	53%
303138	25	25	100%

303736	794	614	77%
303183	548	271	50%
303146	425	379	90%
303139	653	471	72%

4. DISCUSSION

The classifier showed high precision (95.1%) and a low false negative rate (0.5%), indicating few misclassifications, mainly due to other bird species with similar frequencies. It performed well in detecting common cuckoo calls within the CEZ, achieving a recall rate of 61%, though this varied from 40% to 100% across different recorders.

Variations in recall rate were likely influenced by factors such as habitat structure, environmental noise, and the distance between the target species and the recorder. Habitat characteristics can affect sound transmission, leading to signal attenuation and impacting detectability. Environmental noise, especially during adverse weather conditions and high biophonic noise during the dawn chorus, can also challenge accurate detection. The distance between the target species and the recorder further affects the classifier's ability to detect vocalisations.

ABSTRACT

In computational bioacoustics, deep learning models are composed of feature extractors and classifiers. The feature extractors generate vector representations of the input sound segments, called embeddings, which can be input to a classifier. While benchmarking of classification scores provides insights into specific performance statistics, it is limited to species that are included in the models' training data. Furthermore, it makes it impossible to compare models trained on very different taxonomic groups. This paper aims to address this gap by analyzing the embeddings generated by the feature extractors of 15 bioacoustic models spanning a wide range of setups (model architectures, training data, training paradigms). We evaluated and compared different ways in which models structure embedding spaces through clustering and kNN classification, which allows us to focus our comparison on feature extractors independent of their classifiers. We believe that this approach lets us evaluate the adaptability and generalization potential of models going beyond the classes they were trained on.

Keywords: *deep learning, bioacoustics, embeddings*

1. INTRODUCTION

Human-driven climate change and deforestation have caused a rapid decline in global biodiversity [1]. Using sensor arrays for biodiversity monitoring, ecologists can gather information on environments and investigate how human pressures affect biodiversity and how we can halt its decline [2]. Passive acoustic monitoring (PAM) is one method that provides a low-cost and non-invasive way to monitor biodiversity [3]. The vast amount of data generated by PAM sensors has led to the rapid development of bioacoustic deep learning models to help researchers reduce the annotation effort [4]. The use of these state-of-the-art models has proven valuable in ecological studies, for example, in general species assessments [5] or detection of endangered species [6].

While bioacoustic deep learning models are a useful asset in ecology, it is crucial to understand the models' limitations based on their training setup. The two main training strategies to develop bioacoustic deep learning models are supervised learning and self-supervised learning. Supervised learning models require large amounts of annotated data to be trained [7]. The models classify sounds based on a fixed number of predefined classes representing annotated sounds in the dataset. While supervised learning can have the benefit of instructing models to differentiate between species vocalizations, it requires annotated datasets. This limits supervised learning models to known and annotated classes and makes them sensitive to class imbalance and label quality. Alternatively, self-supervised learning can be trained without annotated data, enabling models to learn meaningful representations directly from the data. For example, in a paradigm called masked prediction, the model is trained to predict a masked portion of the audio, thus modeling bioacoustic characteristics without supervision [8]. With growing annotated databases, supervised learning models like BirdNET [9] improve in performance, yet recent developments in self-supervised learning on models like An-

imal2vec [10] indicate a promising new direction for the field requiring less manual annotation. Not requiring annotations, self-supervised learning models can be trained on far larger datasets, however there is no control of what is being learned. The model might, for instance, learn to differentiate between sounds based on characteristics very different from the species that produces them.

To evaluate bioacoustic deep learning models, a comparison of just the classifier performance obscures the fine-grained differences between models and the way they analyze input sounds. Bioacoustic deep learning models consist of artificial neural networks that can be subdivided into feature extractors and classifiers. The feature extractor creates an embedding (vector representation) of an input sound and the classifier (which corresponds to the final dense layer of the model) maps the embedding onto classes. Commonly, in bioacoustics, a suite of established benchmarks is used to compare the classifier performance of state-of-the-art models [11]. This requires the models to have been trained on the classes present in the benchmarking datasets. However, there is an alternative: using the embeddings created by the feature extractors, the embedding spaces can be analyzed with regard to their structural characteristics, irrespective of what the classifiers were trained on.

Due to their size, datasets that are used to train bioacoustic models for bird detection are often based on citizen science data (e.g., xeno-canto [12]). The majority of these recordings are focal recordings of individuals which are weakly labeled with little polyphony. When models are applied to large PAM datasets, especially outside of North America (where the majority of the training data originates), the difference in recording conditions causes performance drops [13]. To accurately evaluate the models in this study, we use a PAM bird vocalization dataset from Colombia and Costa Rica [14], as well as a dataset of frog vocalizations from Brazil [15]. Both datasets are comprised of PAM recordings in noisy environments and can therefore be considered as challenging datasets. With this, we hope to on the one hand emphasize the performance differences between the models and on the other hand produce results that will reflect in real world applications.

This study aims to showcase the potential for evaluating and especially comparing bioacoustic deep learning models with regard to their training paradigm and training data. The evaluation focuses on the structuring capabilities of each feature extractor, as measured by clustering and classification performance. Classification in this case refers to recognition of novel classes, as none of the models have been pretrained on the classes selected here. This way, classification heads are attached to each feature extractor, all of which are trained on the same evaluation sets (bird and frog vocalizations), i.e. same classes and same data, allowing us to compare their performance. Classification is done using a k-nearest neighbor (kNN) approach. This method of analysis opens up the possibilities for a fair comparison of deep learning feature extractors guiding the field to a better understanding of how training configurations affect downstream performance.

2. METHODS

To incorporate a variety of training setups, covering popular models as well as models targeted to various species groups, we compare a total of 15 pretrained bioacoustic feature extractors (Table 1). This includes both self-supervised and supervised learning feature extractors. Furthermore, large variations in input length, embedding dimension and training data provide a diverse landscape of feature extractors, allowing us to analyze performance of differently structured embedding spaces.

2.1 Dataset

The evaluation datasets that were used for this study are a bird vocalization dataset (bird dataset) recorded in coffee farms in Colombia and Costa Rica [14] and a frog vocalization dataset (frog dataset) recorded in Brazil [15]. The recordings in these datasets feature challenging soundscape recordings with overlapping vocalizers and noisy environments. Both datasets have been reduced from their original size to only include sound events corresponding to classes with more than 150 annotations. Due to the high amount of polyphony, the frog dataset has furthermore been reduced to only contain sound events with non-overlapping annotations, i.e. turning it into a single-label dataset. It is worth mentioning, that by excluding overlapping annotations, only polyphony of frog species is removed, the complex background of overlapping sounds created by insects and birds in the recordings remain.

For the bird dataset this results in 11 classes, while for the frog dataset 18 classes are included in the final dataset. We intentionally selected soundscape recordings with gradual changes of background noise and overlapping species vocalizations to amplify the differences between the feature extractors' capabilities to structure the data.

Table 1. List of feature extractors compared in this study. Columns "abbrev." shows the an abbreviated name used in Fig. 1. "training" shows the training setup chosen during training, i.e. ssl for self-supervised learning, supl for supervised learning and ft for fine-tuning. The "architecture" column more specifically describes the model architecture used. "dimension" shows the output dimension of the feature extractor. "trained on" summarizes the training data of the model. "ref." provides the respective publication.

2.2 Data pipeline

For each of the feature extractors, the respective model code base was cloned, and the model was stripped of its classifier. For both animal2vec feature extractors, outputs from the attention heads and input lengths are averaged, resulting in one embedding per input segment (as is the case with all other feature extractors). Data are imported from the sound files, resampled to the model-specific sample rate, and padded to fit the model-specific input length. All the necessary code to reproduce the computations can be found in the repository **bacpipe** [1] (**bio**acoustic **c**ollection **pipe**line).

2.3 Methods for evaluating embedding spaces

Embedding spaces are evaluated using clustering and classification. Our primary focus is the comparison of the two paradigms: supervised learning and self-supervised learning. Furthermore, we explore how the data chosen for training affects the clustering capabilities of different feature extractors.

[1] `github.com/bioacoustic-ai/bacpipe`

The clustering is computed using K-Means with the same number of clusters as classes in the ground truth. Clustering performance is evaluated using Adjusted Mutual Information (AMI) [20] to compare the K-Means clustering with the ground truth.

Performance is also evaluated by training a simple kNN classifier on each of the embedding spaces with a nearest neighbor parameter of 15. The classifier is trained on the 11 and 18 classes for the bird and frog datasets respectively. Data are split into train, validation and test set in the ratio 0.65:0.15:0.2. Performance is evaluated using a balanced macro accuracy score [21] to handle the imbalance in class sizes.

Evaluations are computed in both the original embedding spaces and an embedding space reduced to 300 dimensions. This way the embedding dimension is standardized and performance can be compared while controlling for this factor. Uniform manifold approximation projection (UMAP) [22] is selected for the dimensionality reduction to 300 dimensions. UMAP is also used to visualize the embeddings in two dimensions in Fig. 2.

Table 2. Classification (macro accuracy) and clustering (AMI) performance of the original embeddings, and UMAP embeddings reduced to 300 dimensions. Values show the mean over all ssl, supl, bird and non-bird feature extractors, corresponding to the categories and colors in Fig. 1. Best values among all categories and dimensionalities are bold.

bird data	classification		clustering	
category	original	UMAP	original	UMAP
supl	0.695	0.711	0.418	0.476
ssl	0.617	0.619	0.256	0.405
bird	0.712	**0.723**	0.426	**0.479**
non-bird	0.658	0.618	0.271	0.413
frog data				
category	original	UMAP	original	UMAP
supl	0.668	0.655	0.488	0.546
ssl	0.682	0.679	0.414	0.508
bird	**0.705**	0.698	0.5	**0.558**
non-bird	0.638	0.627	0.414	0.5

3. RESULTS

Table 2 shows the averaged performances over all feature extractors, grouped into the different categories: supervised vs. self-supervised learning, and trained on bird data vs. non-bird data. Firstly, we want to point out the performance changes following dimensionality reduction using UMAP. For evaluation with bird and frog datasets, UMAP embeddings significantly improve clustering results for each category. For the classification performance, values are very similar between original and UMAP reduced embeddings, however, when applied to the bird data, UMAP yields performance increases for most categories, whereas for the frog data, the original embeddings yield better results.

Supervised feature extractors outperform self-supervised ones by a large margin for classification and clustering on the bird dataset. For the frog dataset, due to the improved performance of the AVES models (see Fig. 1), self-supervision outperforms supervised learning measured by kNN classification. When comparing the values between all categories, the bird-trained feature extractors outperform all other categories for both bird and frog evaluation sets.

Figure 1 shows the averaged performances for each of the feature extractors. First, we will focus on the feature extractors that are applied to the bird dataset, shown in blue. When focusing on the clustering (top), the six best performing feature extractors are trained using supervised learning, while all self-supervised learning feature extractors reach clustering performances under 0.31. Performance measured by kNN classification is more mixed, however again supervised learning feature extractors reach the three highest values. Furthermore, Animal2vec_XC, the only self-supervised learning feature extractor that was not fine-tuned, performs poorly for both clustering and kNN classification. Google_Whale represents the only supervised learning feature extractor performing very poorly by clustering and kNN classification.

Comparing by training data, feature extractors trained on only or including bird datasets (supl bird and ssl bird) outperform the other feature extractors by kNN classification and even more so by clustering, with the exception of Animal2vec_XC. Aside from ProtoCLR the supervised learning models that are also trained on birds (supl bird) vastly outperform all other models by clustering and with the exception of the AVES feature extractors also by kNN classification. Perch and BirdNET lead both in clustering and kNN classification by a large margin. Biolingual, which was trained on large bird databases using a multimodal approach performs well by clustering, but comparatively poorly by kNN classification.

In green we can see the performance when the feature extractors are applied to the frog data. Among supervised learning feature extractors, changes in both clustering and kNN classification performance are varied. Especially the three best performing models by clustering for the bird data, Perch, BirdNET and Biolingual, all decrease in performance when applied to the frog dataset. The non-bird trained supervised learning feature extractors (supl non-bird) all improve their clustering performance by a large margin. All self-supervised feature extractors vastly improve in clustering performance and aside from Animal2vec_MK also in kNN classification. The self-supervised AVES feature extractors (BirdAVES, AVES and NonBioAVES) drastically improve in both clustering and kNN classification on the frog data. So much so, that all three outperform all other feature extractors by kNN classification.

All non-bird trained feature extractors improve in clustering when applied to frog data. Again, when applied to the frog dataset, all bird trained feature extractors except for Animal2vec_XC outperform the rest by clustering and the top six models are the supervised learning

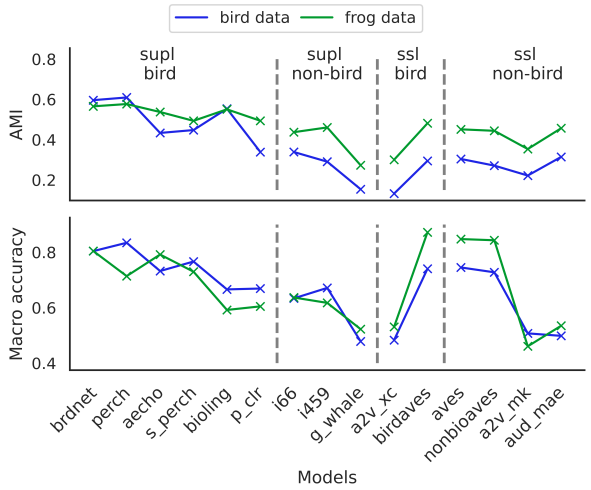

Figure 1. Comparison of feature extractor performance by learning paradigm, training data and application data. The top plot shows clustering results of AMI. The bottom plot shows macro accuracy results of kNN classification. Colors correspond to performance of the feature extractors when applied to bird data (blue) and frog data (green). The x-axis shows abbreviated model names, corresponding to "abbrev." column in Tab. 1. Models are grouped into categories along the x-axis by training paradigm (supervised learning (supl) and self-supervised learning (ssl)) and training data (bird data and non-bird data, see Table 1).

bird trained feature extractors. Among them, only AvesEcho improves in both clustering and kNN classification. However, by kNN classification, results are more mixed by both training paradigm and training domain.

For a more qualitative analysis of the different embedding spaces, two-dimensional UMAP embeddings of the feature extractors applied to the bird data are shown in Fig. 2. The worst-performing feature extractors produce large unstructured clouds of mixed color, indicating that no significant clustering is achieved. In the first and second row, feature extractors can be seen to separate the embeddings into meaningful clusters. It is noticeable that some feature extractors such as AvesEcho_PaSST and ProtoCLR seem to generate more subclusters than most other feature extractors. This, however does not reflect in their performance (Fig. 1). The seven best-performing feature extractors are all trained using supervised learning and the top three are additionally trained on bird vocalizations. All three of the AVES models (BirdAVES, AVES and NonBioAVES) reach similar performances in spite of big differences in their fine-tuning datasets [7]. Despite the embedding spaces of BirdAVES and Animal2vec_XC looking similarly cluttered, their performance varies by clustering and even more so by classification (see Fig. 1).

4. DISCUSSION

Although the self-supervised feature extractors represented in this study are trained on very large datasets, their clustering performance is inferior to most of the supervised learning feature extractors. Nonetheless, their lack of supervision benefits generalization: the majority of self-supervised feature extractors improve performance on the frog data, both for clustering and classification. Yet, as has been shown in previous studies [23], supervised learning and training data consisting of large bird song databases yield the best results, even for challenging PAM datasets. Perch and BirdNET [9], both of which are trained on thousands of classes of bird vocalizations, vastly outperform the other feature extractors by clustering and for the bird data also by classification. Despite the authors' claims [17], the multi-modal feature extractor Bilingual, which performs very well by clustering but comparably poor by classification, is outperformed by BirdNET and Perch. SurfPerch [19] and AvesEcho_PaSST [16], both of which have largely benefited from Perch or BirdNET pretraining, perform well for both clustering and classification tasks. Most notably, AvesEcho_PaSST is the only supervised learning feature extractor that demonstrates generalization by improving performance on the frog data. This could be attributed to the model's innovative transformer architecture using patchout, thereby selectively dropping patches of spectrograms during training, whilst having learned from the well-trained BirdNET embeddings through knowledge distillation [16].

As stated in the introduction, self-supervised learning models lack supervision and might therefore learn classes not meaningful to differentiate between species vocalizations. When comparing Figures 2 and 1 we observe poor clustering both in terms of AMI performance and by qualitative visual analysis of the embedding separation, which could be resulting from non-meaningful classes. However, for the three AVES feature extractors, the kNN classifier is nonetheless able to learn a meaningful differen-

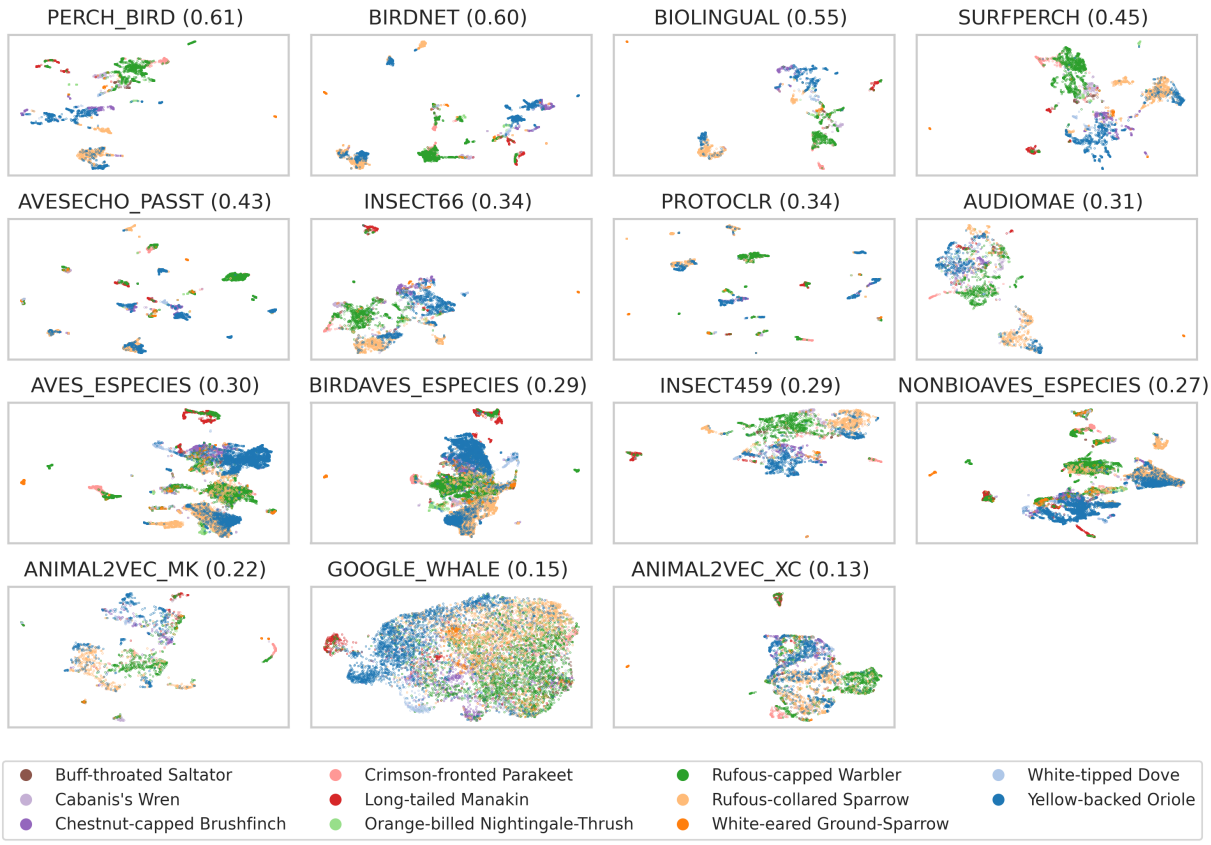

Figure 2. Two-dimensional embedding spaces of all feature extractors applied to bird data, sorted descending by their clustering performance of AMI values (indicated next to their name) from top left to bottom right. Colors correspond to the class labels, which are 11 different tropical bird species.

tiation between the classes. This could be attributed to the fact, that while they are self-supervised, the data used to train these models consisted of curated and non-sparse sound events, thereby increasing the likelihood that meaningful classes are learned. Furthermore, the HuBERT architecture used for the AVES models uses tokenization through acoustic unit discovery [7]. These acoustic units are generated during training based on 39-dimensional Mel-frequency ceptral coefficients (MFCC) features and labeled using a K-Means clustering. The transformer encoder then predicts these cluster labels. This differs fundamentally from the training procedure of the Animal2vec models and AudioMAE, both of which rely on masked prediction. In terms of classification, the results suggest that the MFCC features lead to more meaningful classes than the prediction of masked emebddings. This is supported by the drastic performance increase of all three AVES models when evaluated for the frog dataset.

For the self-supervised learning feature extractors, fine-tuning seems to only marginally improve performance. The three feature extractors based on the AVES models all share the same general audio pretraining and architecture but differ largely in fine-tuning. The similarity in performance indicates that the dominant influence on the structuring of embeddings is defined by either the pretraining or the architecture. Animal2vec_XC and Animal2vec_MK, the latter of which is fine-tuned, largely share the same architecture but were trained on very different datasets. Yet, both models reach similarly poor performance, this is especially surprising for the fine-tuned Animal2vec_MK.

While the dimensions of the feature extractors vary

greatly, performance does not correlate with dimensionality. When we used UMAP to standardize the embedding spaces, we saw performance improvements (Table 2). The observed improvements are more pronounced in clustering, likely because UMAP is an optimization algorithm that trains a neural network to find an optimized lower dimensional graph representation, which benefits K-Means.

Although the bird data were in-domain for BirdNET and Perch, the same applies for Biolingual, Animal2vec_XC and BirdAVES_ESpecies, none of which reached similar performance. The decrease in classification performance by Perch on the frog data raises the question whether this difference can be attributed to its training dataset. Perch's training data, which is comprised of solely xeno-canto recordings perhaps makes it less domain agnostic than BirdNET which was trained on selected curated bird datasets along with a large portion of xeno-canto.

This study presents a workflow for in-depth analysis of embedding spaces, which can be reproduced with the provided repository bacpipe. Evaluation through clustering and classification has shown to vary significantly when applied to the different evaluation sets, undermining the use of both metrics to better understand how training setup affects performance. While the results presented here allow for further discussion, we believe streamlining the process of evaluating and comparing such a wide variety of feature extractors can help to investigate performance differences as a function of training paradigm and training domain. By establishing a default analysis of feature extractors alongside the common classification benchmarks, bioacoustic research can accelerate towards a better understanding of what training characteristics are beneficial in this domain.

5. CONCLUSION

In this study we have compared a variety of different state-of-the-art bioacoustic deep learning models, representing different training paradigms and training domains. To compare the models, we have isolated their feature extractors and used them to generate embeddings of two curated evaluation datasets consisting of annotated bird and frog sounds. The aim of this study was to firstly present a large comparison of very different bioacoustic deep learning feature extractors and to evaluate how training setup affects performance. Performance was evaluated through clustering using an AMI score and through kNN classification using a macro accuracy score.

We have shown that bioacoustic feature extractors still struggle with polyphonic PAM datasets, especially if they are outside of the training domain. However, when comparing training paradigms, supervised learning remains a strong method to pretrain a feature extractor for general use, despite advances in self-supervised learning. This performance difference is visible in both kNN classification and even more in clustering. Furthermore, we have shown that alignment of training domain and target domain during pretraining impacts performance more than during fine-tuning. This study presents a roadmap for a more in-depth performance evaluation of bioacoustic deep learning models, allowing for a better understanding of how training setup impacts downstream performance.

6. ACKNOWLEDGMENTS

A lot of work went into developing each of the feature extractors presented here, and we highly appreciate that they are made publicly available. We would also like to acknowledge Álvaro Vega-Hidalgo as well as Juan Sebastian Cañas and their coauthors, who collected, assembled and annotated the datasets used to evaluate the feature extractors. This project is funded by the Marie Skłodowska-Curie doctoral network BioacousticAI.

ABSTRACT

In the Japanese livestock industry, while the number of pig farms is decreasing, the number of pigs raised per farm is increasing, leading to larger-scale operations. This scaling-up raises the risk of widespread damage from rapid infectious disease outbreaks. Furthermore, respiratory diseases such as pneumonia inhibit growth, delay shipments, and reduce cost-effectiveness for farmers. Consequently, there is a demand for systems that can detect illnesses early. Previous research constructed a disease diagnosis model using the cepstrum and Δ-cepstrum of body-conducted sounds from pigs as inputs, employing LSTM. However, variations among individual pigs were found to decrease the accuracy of the disease diagnosis model. Therefore, this study investigates the construction of machine learning models for individual subjects, aiming to eliminate the effects of individual differences by detecting abnormalities on a case-by-case basis.

Keywords: *Body conducted sound, Ear tag sensor, Disease detection, LSTM, Autoencoder*

1. INTRODUCTION

Porcine respiratory diseases cause significant economic damage in the livestock industry, with annual losses due to Porcine Reproductive and Respiratory Syndrome (PRRS) estimated at $664 million annually in the U.S. [1]. Hence, to prevent severe complications and widespread infections among individuals, the early detection of porkets afflicted with respiratory diseases is crucial. Furthermore, the recent trend towards large-scale porket farming has exacerbated labor shortages, highlighting the need for using technology for efficiently monitor the health status of pigs [2]. Mito et al. [3] proposed a system that utilizes a microphone array and cameras installed in pigpens to detect and locate the source of coughing and sneezing sounds, which are indicators of porcine respiratory diseases. However, environmental noise within pigpens hinders the accurate localization of these sounds. M. Guarino et al. [4] investigates the use of an intelligent alarm system for early disease detection in pigs through online monitoring of cough sounds. Initially developed in laboratory settings, the system was tested on 44 pigs in field conditions using close-range microphones. The classification accuracy was 85.5% for coughs and 86.6% for other sounds. However, the reliance on close-proximity microphones presents practical challenges for real-world application, as environmental noise impacts performance. Lagua et al. [5] discusses a commercially available AI system designed for monitoring respiratory health in swine, integrating temperature and humidity sensors with audio technologies. The system captures body-conducted sounds from individual pigs to detect respiratory diseases, employing machine learning algorithms for effective disease surveillance and management in livestock farming. However, the current system still faces limitations, particularly regarding accuracy and practical applicability in real-world settings. They suggest that further advancements in AI and sensor technology are necessary to create smarter, more reliable solutions for comprehensive health monitoring in livestock. To address this need, we are developing a system that

uses ear tag sensors to detect the body-conducted sounds of pigs, analyzes the biometric data in the cloud, and notifies farmers. Previously, models used cepstrum and Δcepstrum as inputs and employed Long Short-Term Memory (LSTM) networks for disease diagnosis [6]. However, individual differences among pigs caused a decrease in model accuracy. Therefore, this study has explored constructing individual machine learning models for each pig to mitigate the impact of these variations by detecting anomalies individually.

2. COLLECTION OF BODY-CONDUCTED SOUNDS

The animal experiment was approved by the Agricultural Research Organization's Expert Committee on Experiments. Pigs are often fitted with ear-tags for identification. In this context, our research group developed ear-tag sensors [7] that incorporated electronic circuits and miniature sensors to record body-conducted sounds. To collect data from pigs with respiratory diseases, we conducted animal experiments by intentionally infecting the animals with bacteria. Ear-tag sensors were attached to pigs at 5 w of age and data were collected during both healthy periods (2–3 d) and periods of illness (2 w).

3. CONSTRUCTION OF THE ANOMALY DETECTION MODEL

The autoencoder is a representative method for anomaly detection that compresses and reconstructs input data using an encoder and a decoder, respectively. Anomalies are detected by measuring the difference (reconstruction error) between the input and output. An LSTM model using a spectrogram of body-conducted sounds as input can accurately distinguish between pre- and post-illness states [8]. Building on these findings, the current study aimed to achieve high-precision anomaly detection using an LSTM autoencoder that used a spectrogram of body-conducted sounds as input.

3.1 LSTM Autoencoder

The LSTM autoencoder learns a vector representation of the time-series data in the encoder and reconstructs the time series in the decoder using the current hidden state and values predicted at the previous time step. The time-series data were denoted as $X = \{x^{(1)}, x^{(2)}, \ldots, x^{(L)}\}$, and the hidden state of the encoder at each time point $h_E^{(i)}$. Here, $i \in \{1, 2, \ldots, L\}$ and $h_E^{(i)} \in R^C$, where c represents the number of LSTM units in the encoder's hidden layer. In the LSTM autoencoder, the encoder compresses the data in chronological order, whereas the decoder reconstructs the data in reverse chronological order. Thus, the final state of the encoder, $h_E^{(L)}$, is used as the initial state for the decoder, $h_D^{(L)}$, and the time-series data are output in the order of $\{x^{(L)}, x^{(L-1)}, \ldots, x^{(1)}\}$[8].

3.2 Calculation of Reconstruction Error

Initially, the LSTM autoencoder model generated a 5-s output from a 5-s input. When calculating the reconstruction error, overlapping 5-s frames were used within data segments longer than 14 s. The mean and distribution differences of the reconstruction errors obtained in this manner were utilized as indicators to classify the states before and after disease onset.

3.3 Kullback-Leibler Divergence

In this study, the Kullback–Leibler (KL) divergence was used to measure the differences between probability distributions and served as a classification metric. KL divergence is a measure of how one probability distribution diverges from the second-expected probability distribution. When Q and P are discrete probability distributions, KL divergence is defined by Equation (1) [9]:

$$D(P \parallel Q) = \sum_{i=1}^{N} P(x_i) \log \frac{P(x_i)}{Q(x_i)} \quad (1)$$

For instance, if Q and P represent the probability distributions of the reconstruction errors for healthy data, the KL divergence value would be small due to the minimal difference between the distributions. However, if Q represents the reconstruction error distribution of data from healthy pigs and P represents data from diseased pigs, substantial differences in the distributions would lead to a larger KL divergence value. Therefore, by substituting reconstruction error with KL divergence, an improvement in accuracy was achieved.

3.4 Identification Results for Five Pigs

The process of training the model and detecting anomalies is described. Initially, approximately 50% of the data from a single healthy pig were used as training data and approximately 20% were used as validation data to build the model. Subsequently, the remaining data from healthy and diseased pigs were input into the built model as test data. The output results were used to calculate the

reconstruction error or KL divergence, and the anomalies in the pigs were detected based on predefined thresholds. In this study, the thresholds were set to the maximum values of the reconstruction error or KL divergence from the validation data.

To effectively implement an anomaly detection system on a real farm, it is imperative to classify all pigs with high accuracy, regardless of the presence of symptoms. Therefore, pigs A to E, showing a range of lung lesions from severe to mild, were used to validate the effectiveness of the LSTM autoencoder and KL divergence. Each pig had a machine learning model built specifically for it. The identification results for pigs A–E are shown in Figures 1–5. Except for pig D, the LSTM Autoencoder models using spectrograms as input could accurately distinguish between the pre-illness and illness states. Moreover, the use of KL divergence improved the accuracy of disease identification in pigs B –E. However, pig D showed a low identification accuracy of 0–20%. This was attributed to the presence of significant outliers in the reconstruction error or KL divergence of the 's validation data of pig D, which were set as thresholds. Consequently, the data that were actually diseased were incorrectly classified as healthy, leading to a decrease in accuracy.

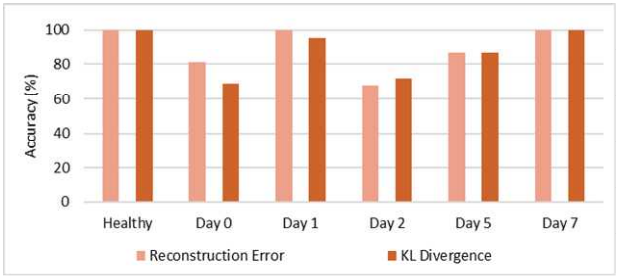

Figure 1. Results for Pig A (severe infection). The input was a spectrogram, with thresholds set for each method. 'Day' indicates the number of days post-infection.

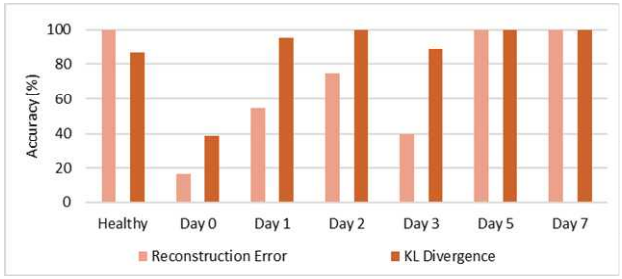

Figure 2. Results for Pig B (moderate severity infection). The input was a spectrogram with a threshold set for each method. 'Day' indicates the number of days post-infection.

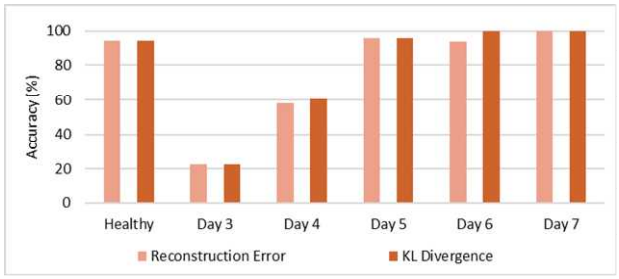

Figure 3. Results for Pig C (moderate severity infection). The input was a spectrogram with a threshold set for each method. 'Day' indicates the number of days post-infection.

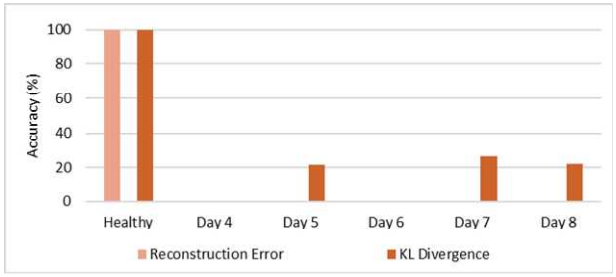

Figure 4. Results of Pig D (mild severity infection). The input was a spectrogram with a threshold set for each method. 'Day' indicates the number of days post-infection.

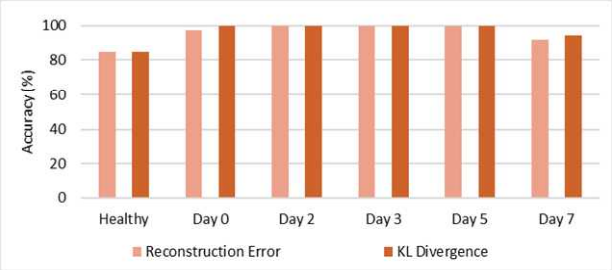

Figure 5. Results of Pig E (mild severity infection). The input was a spectrogram with a threshold set for each method. 'Day' indicates the number of days post-infection.

4. CONCLUSION

In this study, we addressed the issue of reduced identification accuracy due to individual differences by building a separate machine-learning model for each pig and detecting anomalies. Using an LSTM autoencoder with spectrogram inputs enabled highly accurate differentiation between healthy and diseased conditions, and incorporating the Kullback–Leibler divergence further improved the disease detection rates. However, for certain pigs, the classification accuracy declined substantially. Therefore, in future work, we plan to improve accuracy by using a different metric from the KL divergence and tuning the model hyperparameters through cross-validation.

ABSTRACT

The sustainability of the ocean ecosystem is threatened by increased levels of sound pollution, making monitoring crucial to understand its variability and impact. *Passive acoustic monitoring* (PAM) systems collect a large amount of underwater sound recordings, but the large volume of data makes manual analysis impossible, creating the need for automation. Although machine learning offers a potential solution, most underwater acoustic recordings are unlabeled. Self-supervised learning models have demonstrated success in learning from large-scale unlabeled data in various domains like computer vision, Natural Language Processing, and audio. However, these models require large, diverse, and balanced datasets for training in order to generalize well. To address this, a fully automated self-supervised data curation pipeline is proposed to create a diverse and balanced dataset from raw PAM data. It integrates *Automatic Identification System* (AIS) data with recordings from various hydrophones in the U.S. waters. Using hierarchical k-means clustering, the raw audio data is sampled and then combined with AIS samples to create a balanced and diverse dataset. The resulting curated dataset enables the development of self-supervised learning models, facilitating various tasks such as monitoring marine mammals and assessing sound pollution.

1. INTRODUCTION

The increasing levels of sound pollution threaten the preservation of ocean ecosystems, necessitating the monitoring of underwater sounds [1]. *Passive Acoustic Monitoring* (PAM) systems are globally deployed and collect a vast amount of diverse underwater sound recordings. The complexity of the marine environment, combined with the large volume of data, makes manual analysis impractical. As a result, annotating such data is time-consuming and expensive, leaving most PAM recordings unlabeled [1]. Although *machine learning* (ML) could potentially facilitate automatic analysis, the performance of supervised methods is limited by the scarce label availability. *Self-Supervised Learning* (SSL) has successfully handled large-scale unlabeled data in domains like computer vision, Natural Language Processing [2], and audio [3]. However, the performance of SSL models is reduced when they are optimized on uncurated data [4]. This makes balancing of the training data by data curation a key aspect for SSL models to generalize on downstream tasks. Despite the widespread availability of uncurated PAM data, no prior research has focused on curating these data to support the development of SSL-driven models for automatic underwater acoustic analysis. To address this gap, this article presents a fully automated pipeline for the curation of large-scale, freely accessible PAM recordings. This pipeline integrates *Automatic Identification System* (AIS) data with PAM data to balance both the ship distribution and the raw audio distributions. The key contributions of this paper are:

- A simple AIS curation method based on ship oc-

currence;

- An online hierarchical clustering approach for raw large-scale PAM data curation.

The curation method is evaluated by training an SSL algorithm on the curated dataset. The embedding space will be evaluated on a downstream task. The learned embeddings serve as input for the linear regression-based classification, to classify ship types from the reference datasets Deepship [5] and ShipsEar [6] containing underwater recordings of ships labeled by the type of ship.

2. RELATED WORK

2.1 SSL in underwater acoustics

Several previous studies have shown the potential of SSL in the automatic recognition of ship types [1]. With no large, curated underwater acoustic dataset publicly available yet, [7] and [8] proposed pretraining on AudioSet applying a mix-up strategy. Next, a Swin Transformer encoder is optimized with masked log-Melspectrogram, while a decoder is optimized to reconstruct the full spectrogram. A high masking rate was needed because of the limited contrast in these spectrograms. The fine-tuning on Deepship [5] yielded an accuracy of 80% - 86%. However, because of the complexity of the marine environment, tasks related to acoustics above the water may not be representative of the marine environment. To address this, [9] proposed a generative transformer model pretrained solely on underwater acoustic data. To reduce the GPU demand during training, they proposed hierarchical token-convolutions and masked these for reconstruction. Deepship model pre-training and fine-tuning on both Deepship and ShipsEar [6] improved performance over a supervised transformer baseline. However, their method is limited in real-world applications because of the lack of diversity of ocean environments in their training data. Our study overcomes this issue by representing a data curation pipeline to extract a diverse and balanced unlabeled dataset for SSL algorithms.

2.2 Data curation methods

SSL models need a balanced and diverse dataset to compete with supervised methods. The simple scraping of raw data from the web results in an unbalanced dataset, creating the need for data curation [4]. Previous research proposed an automatic data curation pipeline for data curation from images scraped from the web [10]. They suggested converting both a labeled curated dataset and an unlabeled uncurated dataset to the embedding space and performed deduplication by removing near-duplicate images in the uncurated dataset. Finally, they retrieved images from the uncurated dataset by calculating the relative distance to the curated samples. Although they state that this method is self-supervised, it still requires a large labeled dataset for matching. In a follow-up article, [11], they proposed a hierarchical KMeans algorithm to retrieve images from an uncurated dataset. Here, they overcome the problem that web-scraped big data is mostly long-tailed. Sampling from traditional KMeans does not encounter this, and therefore, hierarchical KMeans clustering and sampling are proposed. In addition, the DINOv2 algorithm was applied to text-image pairs [4]. In this paper, they performed data curation. Here, they aligned the images to the captions and sampled from the aligned captions to create the image dataset. The addition of metadata for data curation has also been proposed for audio-visual video representations in [12]. In this work, they tried to maximize the estimated mutual information between the video imagery and the corresponding audio. Both studies showed that the incorporation of metadata for data curation can improve the quality of the curated data.

3. METHODS

3.1 PAM data

The raw audio data is collected from NOAA [1], selecting hydrophones which started recording in 2023 or later. All these PAM audio recordings are combined into the resulting dataset $\mathcal{D}$. In total, this combination covers the duration of 8 years, 6 months, 9 days, 15 hours, 19 minutes, and 49 seconds from 11 individual hydrophones. These hydrophones are visualized in Figure 1.

3.2 AIS data

Track records of ships are recovered by AIS. This system captures information about ship characteristics, the location, and movements of almost all ships worldwide. The NOAA also provides freely accessible AIS data [2] covering the same regions as raw PAM data. The raw PAM data were aligned with the AIS data by drawing a 4 km

[1] https://console.cloud.google.com/storage/browser/noaa-passive-bioacoustic;tab=objects?inv=1&invt=AbnmXQ&prefix=&forceOnObjectsSortingFiltering=false

[2] https://marinecadastre.gov/accessais/

Figure 1. The locations of the hydrophones from the web scraped PAM data, indicated in red pointers.

$\times$ 4 km square with the hydrophone in the center (Figure 2). This square defines the range of the hydrophone, and therefore, every AIS pulse within this range was considered recorded. The data set containing the AIS pulses will be referred to as $\mathcal{A}$. All recordings, with AIS information, were gathered to create the dataset $\mathcal{D}_s$.

3.3 AIS data curation

The low contrast of radiated ship noise against background noise makes it difficult for simple machine learning methods to encounter ship noise in a large volume of data. To ensure a diverse representation of the acoustic profiles of the ships in the curated dataset, the AIS data $\mathcal{A}$ is also curated. A simple approach inspired by [4] is proposed. Here, they proposed to curate the aligned caption to curate an image dataset from a caption-image pair dataset. In this work, the AIS data are aligned with the PAM data, creating a dataset $\mathcal{D}_s$ holding the aligned PAM recordings and a dataset $\mathcal{A}$ holding the aligned AIS pulses. These pulses are then sampled based on the occurrence of individual ships, using a threshold value t. This threshold is defined based on the incidents of individual ships in the aligned PAM dataset $\mathcal{D}_s$. Ships with a lower incidence than t will not be sampled and kept complete in the curated dataset, while ships that exceed t are sampled according to their sample probability. This probability is inversely proportional to the occurrence of the ship in $\mathcal{D}_s$, the higher the occurrence, the lower the sampling probability and vice versa. Here, the objective is to balance the long-tailed distribution of $\mathcal{D}_s$ given $\mathcal{A}$, resulting in a more balanced dataset $\mathcal{D}_s^*$:

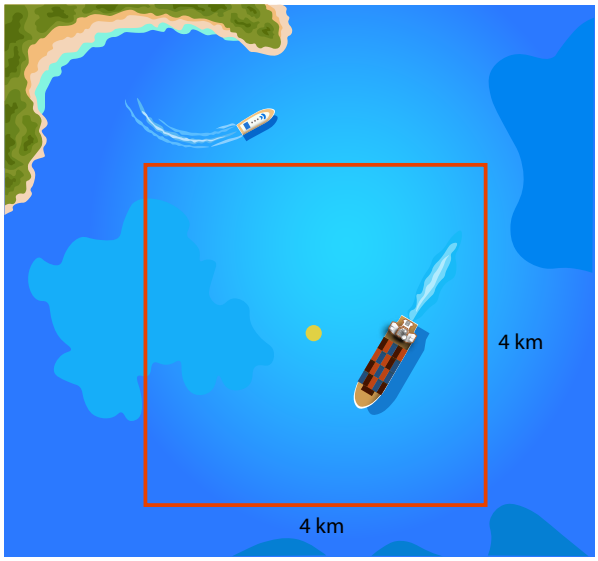

Figure 2. The defined range of the selected hydrophones to align raw PAM recordings with the AIS pulses.

$$\mathcal{D}_s^* \leftarrow f(\mathcal{D}_s; \mathcal{A}, t) \tag{1}$$

3.4 Audio preprocessing

First, the raw audio was resampled to a sample rate of 16 kHz to ensure a common sample rate for all recordings. Next, the audio was windowed using a 10-second window size without overlap. From this windowed audio, embeddings were generated using the model presented in [13]. In this research, they state that this model is optimized on a large quantity of unlabeled underwater acoustic data and generates generalized embeddings with dimension 2048.

3.5 PAM data curation

The objective of the PAM data curation method is to retrieve a dataset with the target distribution U. This distribution is defined as a uniform distribution with the support of the distribution P, where P represents the distribution of dataset $\mathcal{D}$. The data curation method is inspired by the method proposed by [11]. The entire dataset $\mathcal{D}$ is employed to optimize a hierarchical KMeans model using the resampling-clustering technique. This model consists of four levels with cluster sizes of $[6000, 400, 40, 10]$. Here, the lower cluster levels focus on detailed informa-

tion, while the upper levels capture global features. Audio samples of 10 seconds are then drawn from each hierarchical layer. Given the large size of the dataset $\mathcal{D}$, the hierarchical KMeans is optimized in a streaming manner, which approximates the optimal solution [14]. After training, the optimal HKmeans is utilized to sample the data from each cluster level. A maximum of target size N samples is selected from the first datastream based on the relative distance of the datapoints to the assigned cluster centers. As additional datastreams are processed, once the target number of N samples is exceeded, the samples with the greatest distance to the cluster center are replaced by those closer to the center.

3.6 SSL algorithm training and evaluation

The proposed method is evaluated by training the Data2vec base framework [15]. The base model pretrained on speech is completely fine-tuned using the curated dataset. This dataset is defined as:

$$\mathcal{D}^* = \mathcal{D}_a + \mathcal{D}_s^* \tag{2}$$

The model is optimized using a batch size of 64, where each input sample for the student model is masked for 15% while the teacher model receives the full audio. The teacher model weights Δ keep track of the student model weights θ by:

$$\Delta = \tau\Delta + (1-\tau)\theta \tag{3}$$

The parameter τ $(\tau_0 \leq \tau \leq \tau_e)$ is gradually increased from $\tau_0 = 0.999$ to $\tau_e = 0.9999$ over 20 updates. The performance of the model is compared by training the same framework on a randomly curated dataset of the same size. A simple logistic regression is optimized using the learned embeddings for the classification of the type of ships.

4. RESULTS

4.1 Data curation

For the AIS curation method, the optimal threshold value t is defined to correspond to the knee of the skewed distribution of $\mathcal{D}_s$ [4]. Figure 3 illustrates the number of 10-second audio windows per individual ship, revealing a skewed distribution. The optimal threshold, aligning with the knee of the distribution, is around 250. For this reason, the threshold value t was set to 250, resulting in a dataset $\mathcal{D}_s^*$ capturing 25,021 audio samples.

In addition to AIS samples, 323,532 samples were selected during PAM data curation. These samples were combined to create the dataset $\mathcal{D}^*$ holding roughly 970 hours of PAM recordings.

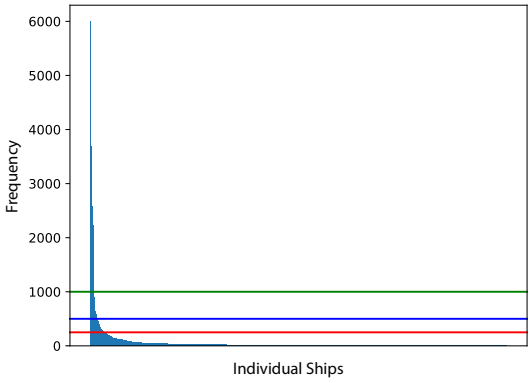

Figure 3. AIS distribution of individual ships in dataset $\mathcal{D}_s$ with threshold value $t = 250$ in red, $t = 500$ in blue, $t = 1000$ in green

4.2 SSL results curated dataset

The proposed method is evaluated using the labeled benchmark datasets Deepship [5] and ShipsEar [6]. Both datasets hold ship types recorded in two distinct regions. Table 1 presents the accuracy scores of the Data2Vec model trained on curated and random datasets. The results indicate that the curated model outperforms the random model on both benchmark datasets. However, the performance gain is smaller for ShipsEar, likely due to environmental factors. The ocean environment of ShipsEar is quite different from the environment of the hydrophones in the raw PAM data (Figure 1), making classification more challenging. In contrast, the ocean environment of Deepship is more comparable with the PAM data, leading to a performance increase of more than 7%.

Table 1. Accuracy scores ship type classification

	ShipsEar	Deepship
Random	51.98%	49.16%
Curated	53.11%	56.72%

5. CONCLUSION

This work describes the first automatic data curation pipeline to curate large web-scraped PAM data. The study demonstrates that curation is a key aspect in extracting accurate SSL model representations from unlabeled underwater recordings. Although this work focuses on data curation, more research is still required on SSL methods applied to underwater acoustics. Due to the stationarity of the data, the masking strategy may be suboptimal, and the results may benefit from a more contrastive approach. In addition to the raw web-scraped PAM data used in this study, more diverse data is publicly available. Expanding the diversity by incorporating more hydrophones from various regions would make the representations more robust for various other underwater acoustic-related tasks. This offers the possibility of training large-scale SSL models from scratch, enabling more advanced underwater acoustic applications.

ABSTRACT

Biophonies, anthropophonies and geophonies characterize and shape an environment and contribute to the human appreciation of that place. Thus, sound event classification can be a useful tool to assess its quality and detect changes affecting it. In this study, different machine-learning models for multilabel sound classification are tested to monitor the ante-opera situation of the renewed square "Piazza della Scienza" of the University of Milano-Bicocca (Italy). The one-week monitoring was performed in May 2023 using 7 Song-Meter-Micros. The recordings were equalized to correct the devices' nonlinear frequency response. The paper is structured to: (a) test two sets of features in the Piazza's polluted soundscape by constant ventilation noise and other anthropogenic sources: YAMNet embeddings and classic audio features (such as MFCCs), (b) find the best algorithm between: decision tree, random forest, k-nearest neighbor and support vector classifier and (c) evaluate their performance when filtering the background ventilation noise to increase the datasets size. Preliminary results are presented with the final aim of optimizing the detection and applying it to describe the Piazza's soundscape, investigate differences in events spatial distribution, and evaluate the effects of the urban regeneration plan on the soundscape.

1. INTRODUCTION

Noise pollution is a major environmental health concern in Europe since noise made by traffic, trains and airplanes is the second most important cause of disease, behind air pollution caused by very fine particulate matter [1]. This issue is particularly impactful in urban areas where about 60% of the European population will live by 2050 [1, 2]. In urban centers there are multiple anthropogenic sound sources often overlapping with one another (e.g., engines idling, car horns, technical installations, sirens and alarms, nightlife) [3] and with biophonic sounds (e.g., birds vocalizations, dog barking, cicada sounds) and geophonic ones (e.g. wind, rain, thunder). The noise impact on humans does not depend solely on the overall sound pressure level but also on the typology of noise sources, the individual sensitivity and the social and cultural context [3–5]. This reasoning is also valid for faunal communities which are impacted by noise depending on its typology and on species' aural sensitivity [6, 7]. For these reasons, sound event classification is a topic that gained greater importance in these years and many studies have dealt with it. This technique applied to open environments is useful in many applications, from automatically discriminating against adverse meteorological conditions in large datasets [8,9], to detect specific noises [8] and to collect events for soundscape assessments [10] and bio/eco-acoustic analyses [8, 9, 11, 12]. Linked to urban settle-

ments, many works have been performed on event classification from real in-field recordings, focusing on single events or on overlapping multiple events [10–12]. In this work, sound event classification is applied to a university square in Milan (Italy) which is heavily impacted by constant technical installation noise. The study's final aim is to develop a classifier for different sound events (i.e., road traffic, tram passages, speech, sirens) which will be used to assess the changes in the square's sound environment after an architecture requalification [13] which will improve the public space usage and increase the surface occupied by trees, bushes and lawns instead of cement. Moreover, the classification will allow a better understanding of the ecoacoustic indices behavior in urban environments and of people's acoustic environment perception already carried out in the square. In this paper, the efficacy of two sets of features on the square recordings was tested: the YAMNet embeddings and more classical features, such as the Mel-frequency cepstral coefficients (MFCCs), using different machine learning classificators: Decision tree, Random forest, K-nearest neighbor e Support vector classifier.

2. MATERIALS AND METHODS

2.1 Study Area

The area under study is the main square of the University of Milano-Bicocca called "Piazza della Scienza". It is set in the Bicocca neighborhood in the north outskirts of Milan, an area which went through a renovation process in the last fifty years, shifting from an industrial site to a university and third sector district. The Piazza covers a surface area of 8590 m^2 and is surrounded by 6-floor buildings and arranged on two levels: a fully cemented ground level and four lowered courtyards, three of them with a lawn cover. In 2024, the Piazza underwent a regeneration process thanks to the MUSA project (Multilayer Urban Sustainability Action) [13]. This project is set into the framework of the National Recovery and Resilience Plan (NRRP) and aims at proposing management strategies to face the environmental, social, and economic sustainability challenges of the metropolitan city of Milan. The Piazza renovation aims to increase its environmental sustainability in terms of reducing the heat island effect, increasing the water descent into the aquifer, reducing local air pollution, and improving the area's biodiversity. Moreover, it will allow a better use of the public space and increase students' quality of life in the Piazza. These results will be achieved through the depaving and greening of the ground level and the renewal of the lowered courts (Figure 1).

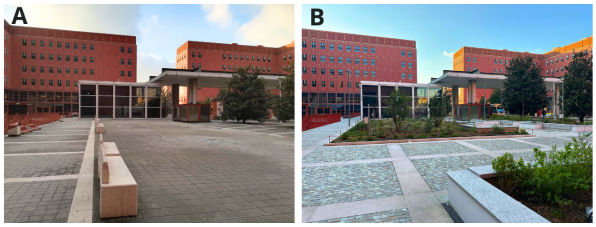

Figure 1. Piazza della Scienza before (A) and after (B) the regeneration process of MUSA.

2.2 Data collection and annotation

The monitoring campaign used to populate the database was performed in May 2023, from Monday 22th to Sunday 28th, in 7 sites of the Piazza (Figure 2). To capture the different sound sources present, 2 devices were placed at the ground level floor, 2 in the lowered courtyards and 3 at the first floor of the buildings.

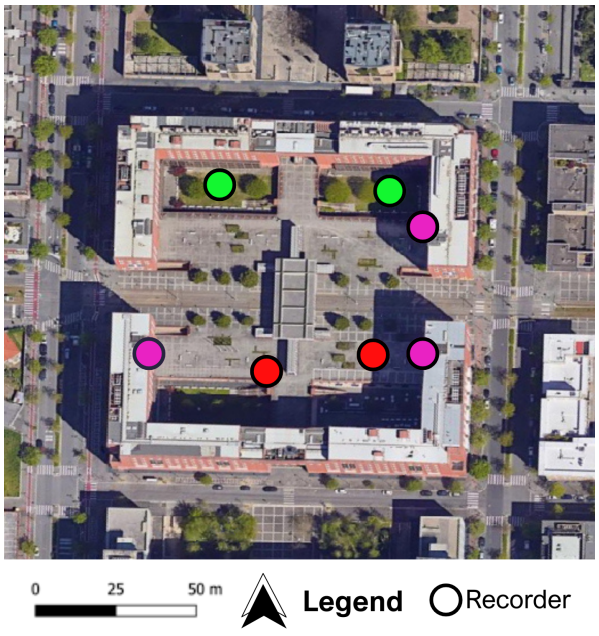

Figure 2. Piazza della Scienza (before the regeneration) and recording sites (pink: first floor, red: ground floor, green: lowered courtyards).

Table 1. Event labels present in the dataset, their description and total time duration.

Label	Description	Duration (min)
Road	Road traffic	17.55
Brake	Brake noise from vehicles and tram	5.65
Car horn	Car horn	0.24
Vpbor	Vehicle passing by on tram rails	0.89
Tram	Tram passing by, stopping and departing	12.41
Motorbike	Motorbike engine noise and passing by	3.79
Street cleaning	Street cleaning vehicles and operators	1.09
Siren	Ambulance and police sirens	6.10
SignalAlarm	Signals and Alarm noises	4.22
Construction	Noises from construction sites	3.29
TrolleyCart	Cart and trolley noises on pavimentation	5.39
Bird	Birds vocalizations	5.29
Dog	Dog barks	0.34
Insects	Insects sounds	4.33
Wind	Gusts of wind	1.66
Speech	Speech and human voices, exclamation, laughs	21.57
Ventilation	Technical installations noise	125.00
Complex	Unclassified sounds	3.23

The Song Meter Micros from Wildlife acoustic were used, set with a sampling rate of 48 kHz and an amplitude gain of +12 dB, recording for 1 minute and pausing for 1 minute. Furthermore, the recordings were equalized to correct the devices' nonlinear frequency response [14,15]. In the Supplementary Materials of [14] it is available the open source MATLAB script for equalizing the recordings and obtain linear-comparable audio files with other devices and between ecoacoustic studies. The recording campaign resulted in a total of 75 hours of acoustic data per sensor. The labelling process was performed on Audacity following previous works of coauthors [16]. Audacity is an audio recording and editing software which allows users to select part of an audio file and associate a text label with it. These labels can be exported in a text file (txt) as a list indicating the labels' name and their starting and ending time (time is expressed in seconds and calculated referencing to the audio beginning as the time zero). In this work, a single label was applied to each sound event independently of its time duration. The total labelled time is 2 hours and 5 minutes. The label taxonomy was adapted from [17] to fit the particular sound events present in the Piazza and discharge those not happening. In Table 1 are reported the 18 labels kept for this study area and their total time duration in the dataset. To be fed into the classifiers, the txt files from Audacity were converted into one-hot-encoded format.

2.3 Feature extraction

To detect the sound events in the Piazza two methods have been used to test their efficiency:

- YAMNET's embeddings.
- Features from the python package librosa.

2.3.1 YAMNet's embeddings

YAMNet is a pre-trained neural network model which has been used in many works in literature to perform sound event detection [9, 18] or to obtain features to be used as features for other algorithms [19]. The model relies on the MobileNet V1 architecture which consists of 27 convolutional layers, 1 global average pooling layer, and 1 fully connected layer; it employs ReLU activation functions, batch normalization and Softmax activation to obtain an

Complex	487	1'461	347	1'041	1'430	4'290

output feature vector of size 1024 [20, 21]. The model predicts the 521 sound event classes of the AudioSet corpus [22]. Each audio file is first downsampled at 16 kHz and normalized to fit the AudioSet requirements before calculating the features (embeddings) on a time window of 0.96 seconds with a 50% overlap. The embeddings calculation is explained here [23] but, shortly, they are logarithmic Mels calculated in the range 0.125 - 7.5 kHz and fed to the MobileNet V1 model. As the final step, the model calculates the output scores for each of the 521 AudioSet classes. In our study, YAMNet was used as a feature extractor on each labelled audio file and each 0.96 seconds time frame is characterized by 1024 features.

2.3.2 *Features from the python package librosa*

To compare YAMNet's features performances, another set of features have been calculated. In particular, the python package librosa [24] was used. In this case, downsampling and normalization were not applied. The features were calculated on a 1-second time frame and a 20-millisecond time frame without overlapping; the double timeframes are kept to understand their influence on the classification. The following spectral features were calculated following previous works [25]:

- Mel-frequency cepstral coefficients (MFCCs), using a number of coefficients of 13.
- Spectral centroid (SC).
- Roll-off frequency, with a rollpercent of 10 and 90.
- Amplitude root-mean-square (RMS).
- Zero-crossing rate (ZCR).
- Static tempo.
- Flatness.
- Spectral bandwidth.

For each feature (except MFCCs and static tempo), 7 statistical descriptors were calculated: minimum, maximum, mean, median, standard deviation, skewness and kurtosis [25]. Thus, each 1-second time frame is characterized by 1272 values (of which 1222 are MFCCs), while each 20-millisecond time frame by 297 values (of which 247 are MFCCs).

2.4 Data filtering to increase the datasets

To increase the number of recordings populating the datasets, filtration of the ventilation noise (label "Ventilation") has been carried out. This operation have been achieved using the "Noise Reduction" function of Audacity. This function elaborates the noise profile of a recording and uses it to reduce that noise in other recordings.

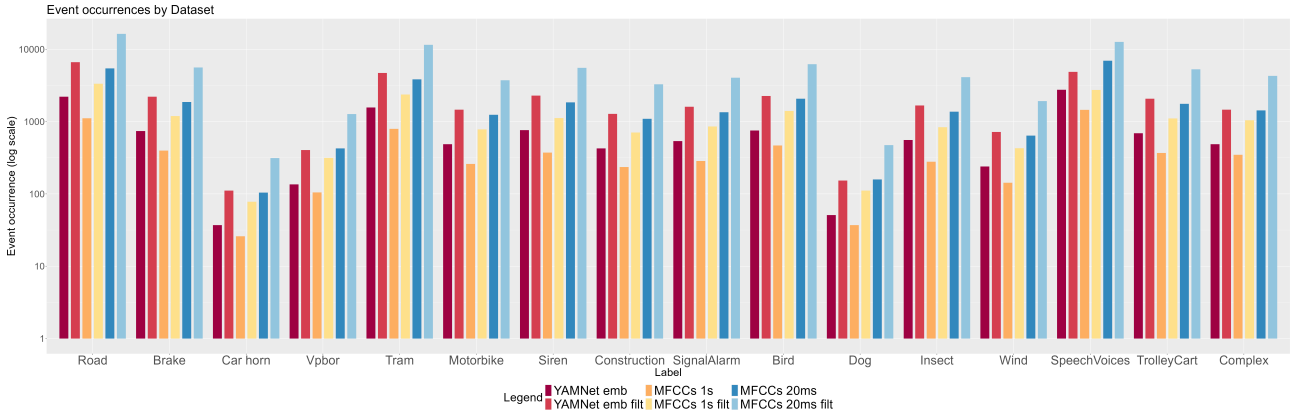

Figure 3. Labels occurrences in each dataset.

For each site, a midnight recording containing only ventilation noise was selected. Two settings were applied: T1 (Noise reduction: 6 dB, Sensitivity: 5, Frequency Smoothing = 4) and T2 (Noise reduction: 10 dB, Sensitivity: 10, Frequency Smoothing = 8). Furthermore, due to uneven occurrences of labels (see Table 2 and Figure 3), in the filtered recordings the label with the highest occurrence ("Speech") and the corresponding features were removed when the event was not overlapped with others. After these filtering and balancing processes, the datasets are shaped as reported in Table 2 and in Figure 3.

2.5 Detection

For the detection of sound events, different classification models have been implemented in the Python environment. A pipeline has been built to run the following classification models: decision tree (DT), random forest (RF), k-nearest neighbor (KNN), support vector classifier (SVC). These algorithms are executed to perform a multi-output classification to classify overlapping sound events. Different trials have been performed using three different scalers (standardscaler, minmaxscaler, robustscaler); standardscaler subtracts the mean and scales the data to unit variance, minmaxscaler uses the maximum and minimum values of the dataset to rescale the features in the range [0, 1], and robustscaler is based on the percentiles thus is less affected by outliers [26]. The datasets have been split into training (80%) and testing (20%) using the train_test_split command from sklearn. The best classifier will be chosen based on three metrics: Precision, Recall and F1-Score.

3. RESULTS AND DISCUSSION

In Table 3 and 4, the best values of Precision, Recall and F1-score are reported for each label and feature typology, indicating the relative dataset, classifier and scaler.

Looking at the "Dataset" columns of Table 3 and 4, we found that the classificators performed better with the augmented datasets (occurrences increased by filtering the Ventilation background noise). Regarding the librosa features timeframe, the 20-ms windowing allowed a better performance.

Focusing on the typology of Classifier and Scaler, the most frequent one are the Decision Tree (DT), followed by the Random Forest (RF), and the StandardScaler (Std).

In Table 3 (YAMNet embeddings), it is possible to notice that the majority of the F1-scores are above 60% with Street cleaning, Siren, Bird, Insect and Speech being over 70%. On the other hand, in Table 4 (Librosa features) events that have an F1-score higher than 70% are Street cleaning, Siren, Insect, Speech, Road, Tram, SignalAlarm, Construction and TrolleyCart. Dog barking obtained the lowest scores, probably due to its lower occurrence in the dataset (Table 2) and the masking caused by ventilation systems. Siren got the highest score, probably because of its marked distinguished spectrum.

When comparing the F1-score between the datasets, the librosa features received higher scores for the majority of labels. This trend is also visible for Precision and Recall, even if not for the same sound events.

Table 3. Best results using the YAMNet embeddings

Label	Precision	Recall	F1-score	Dataset	Classifier and scaler
Road	0.64	0.67	0.65	Filter	DT - Std

4. CONCLUSIONS

Sound classification is a rich and growing research field in various acoustic branches nowadays and has been applied to numerous case studies around the world. This paper is focused on classifying the sounds occurring in the Piazza della Scienza in Milan, Italy.

These preliminary results provide important insights which show the better performance of the models using the librosa features instead of the YAMNet embeddings and the usage of a shorter time frame. Future analyses will be implemented on the librosa features dataset. They will consist of different steps like the implementation of confusion matrices and the application of a cross validation. Moreover, the GridSearch algorithm will be applied for tuning the models' hyperparameters. Furthermore, other algorithms will be tested (i.e., CNN-models) and the effects of the time window size on the performances will be studied. Finally, transfer learning will be taken into account to increase the dataset size, alongside the addition of audios recorded outside the Piazza to bypass the ventilation background noise.

ABSTRACT

Lung Ultrasound (LUS) imaging is a valuable diagnostic technique for lung condition evaluation, due to its non-ionizing and portable nature. However, its complex interpretation can be enhanced by Machine Learning (ML) tools, yet traditional solutions often fail to meet the speed demands of real-time applications. This paper presents a Field Programmable Gate Array (FPGA)-based hardware solution for real-time segmentation of lung ultrasound images using a Convolutional Neural Network (CNN), achieving a throughput of 80 inferences per second.

Keywords: *Machine Learning (ML), Lung ultrasound (LUS), Field Programable Gate Array (FPGA), hardware acceleration, edge computing.*

1. INTRODUCTION

Artificial Intelligence (AI) has revolutionized many scientific fields. In medicine, AI tools have aided healthcare professionals in more accurate and effective patient diagnoses [1, 2].

LUS is a non-invasive imaging technique increasingly used for evaluating respiratory diseases [3]. Although its acquisition is fast, LUS interpretation requires expertise and can result challenging for less experienced clinicians [4] .

Muñoz et al. [5] developed a Machine Learning (ML) model based in the U-NET architecture [6], trained on a video dataset from 30 patients, acquired and labeled at video level by an expert physician. That manual tagging was extended to frame level by a semiautomatic labeling tool developed in the same work. The model processes the B-Scans and generates four outputs (pleura, consolidation, B-line, and A-line) representing the probability of each artifact per pixel. While achieving high performance, its GPU implementation (Mini-PC with integrated GTX-2060) limits its usability in low-power consumption portable devices and clinical enviroments.

Field Programmable Gate Arrays (FPGAs) are integrated circuits that can be reprogrammed after manufacturing, showing promising results in accelerating ML models [7], due to their versatility, low power consumption, and small size.

This work proposes a high-throughput implementation using Vitis-AI, an open source framework that provides the tools to implement AI models it a cost-effective FPGA real-time solution, demonstrating its viability for ML hardware acceleration.

2. METHODS

2.1 Neural Network

Convolutional Neural Networks (CNNs) are widely used for segmentation tasks due to their ability to identify both

local features and global patterns. The U-Net architecture has skip connections that incorporate spatial information at different scales, thus preserving structural details. In this work, attention gates, used in the skip connections of [5] were removed from the implemented model due to limitations with Vitis-AI on FPGA fabric. One of the objectives of this work is to analyze how the performace is affected by this modification.

A simplified version of the architecture is shown in Fig. 1. The 256x128 input image first goes through the encoder, where increasingly abstract information is extracted, while spatial resolution is reduced. The decoder processes and upsamples the extracted features thanks to skip-connections, which help maintain crucial spatial information. This results in four 256x128 output images, each segmenting a relevant artifact (Pleura, consolidations, B-lines and A-lines).
This model underwent the same training as the original and serves as the baseline for comparing subsequent modifications.
Python implementations of ML are typically optimized for CPU or GPU architectures, which differ significantly from the architecture of FPGAs. The original model needs to go through some transformations to make it compatible with FPGA constraints. As a consequence, both model size and inference time decrease. The processes required to implement the model in FPGA are pruning (removal of weights with values close to zero and retraining to recover accuracy) and quantization (conversion of model parameters from floating-point to fixed-point representations). For this specific implementation only quantization was required.

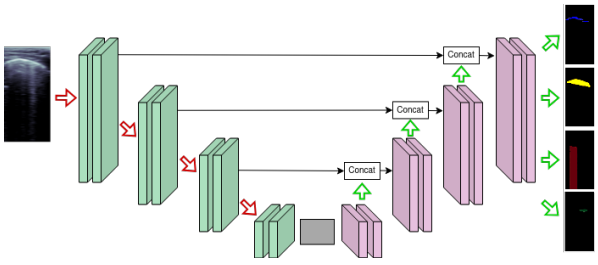

Figure 1. U-NET architecture. The first half encodes and reduces the dimensionality of the input, while the second half decodes and expands.

2.1.1 Training

The Python model was trained with 9624 images (70 % train, 30 % validation), using a learning rate of 0.0005. The loss function employed was binary cross-entropy, with a batch size of 64 images. Training was conducted for a maximum of 100 epochs, with early stopping activated if the validation loss did not decrease for 6 consecutive epochs. Upon completion of the training process, the model was prepared for quantization.

2.1.2 Quantization

FPGAs are not well-suited for the 32-bit floating-point precision commonly used in Python models. Instead, their computational capabilities are optimized for 8-bit fixed-point operations. This process, known as quantization, involves retraining the original model with a subset of the dataset, readjusting parameters and activations, and rounding decimals beyond a specific point (Fig. 2). The quantized model weighs less than a quarter of the original model.

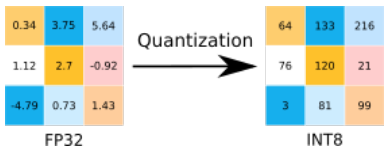

Figure 2. Quantization simple example.

2.2 FPGA architecture

The model is implemented on the Kria KV260 Vision AI Starter Kit, an FPGA particularly well-suited for real-time computer vision and edge computing applications. Its low cost and limited power consumption make it a suitable solution for a portable IA-assisted diagnosis tool.
The Deep Learning Processing Unit (DPU) is a programmable core for AMD FPGAs optimized for accelerating neural network computations through a specialized instruction set. The DPU processes the input data, provided with the correct dimensionality, performs the necessary computations (such as convolutions), and stores the segmentation results in the FPGA memory for further use.
Vitis-AI was used to retrain, modify, quantize, and tune the parameters of the model in an intuitive manner.

After successfully creating the hardware project, including the DPU and its bus connections with the embedded microprocessor and system memory, we generated a PetaLinux image configured to load the trained ML model and perform the segmentation process.
A dataset of 1358 validation images is transferred to the board. A Python script executed on the board processes the images to generate the segmentation masks. These masks are then transferred back to the host computer for analysis.

3. RESULTS

Fig. 3 and Fig. 4 show two segmentation examples. In each figure, the left image represents the tagged segmentation (ground truth) of the LUS artifacts, color-coded as follows: pleura (blue), consolidations (yellow), B-lines (red), and A-lines (green). The middle image shows the output of the original U-NET model (thresholded at 0.5), using the same color scheme. The right image shows the output of the FPGA-implemented model with the same threshold. Visually, the FPGA results are almost identical to the original model's.

Comparing the segmentations indicates that the model's performance was not significantly affected by the modifications required for FPGA implementation. Tab. 1 presents three evaluation metrics, calculated for all artifacts across the test dataset: the **Dice** coefficient (measuring the overlap between two sets), **precision** (the percentage of correctly identified positive pixels), and **recall** (the percentage of retrieved positive pixels). The FPGA-implemented model shows very similar performance to the original model in detecting all artifacts.

The model achieves a throughput of more than 80 inferences per second, compared to the the 50 per second reached in the previous GPU implementation.

4. DISCUSSION

This study successfully implemented a LUS segmentation model, originally developed in Python, onto an FPGA. The necessary modifications for FPGA compatibility were achieved with minimal impact on the model's performance. The results demonstrate that the FPGA-implemented model closely replicates the behavior of the original software model, as shown in Tab. 1.

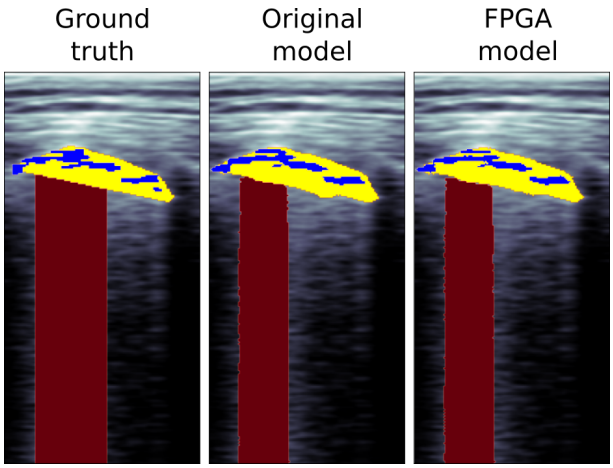

Figure 3. Pleura, B-line and Consolidation output example.

Table 1. Metrics for all artifacts and the two different models.

	Metric	Original	FPGA
Pleura	DICE	0.86	0.86
	Precision	0.85	0.88
	Recall	0.89	0.85
Consolidation	DICE	0.97	0.97
	Precision	0.97	0.98
	Recall	0.99	0.99
B-line	DICE	0.77	0.76
	Precision	0.90	0.90
	Recall	0.82	0.82
A-line	DICE	0.73	0.71
	Precision	0.78	0.77
	Recall	0.80	0.79

The achieved latency (12.5 ms), throughput, and power consumption demonstrate that FPGAs offer a viable alternative to traditional GPUs for hardware acceleration of AI-assisted LUS diagnostic tools. The compact size of the FPGA makes it particularly suitable for integration into small, portable ultrasound scanners.

The KV260 evaluation board (14cmx12cmx3.5cm) is smaller than the mini-PC with an integrated GPU

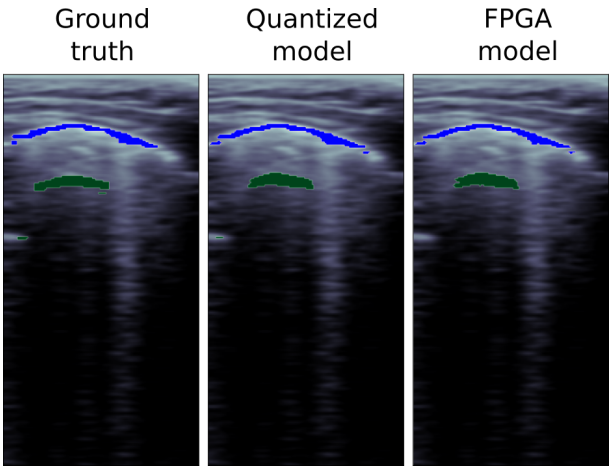

Figure 4. Pleura and A-line output example.

(21cmx19cmx5cm) employed in [5], and its use would eliminate the bottleneck caused by transferring the raw data to the PC for inference. Energy-wise, following the literature [8] FPGAs are more energy-efficient than GPUs, but a detailed study needs to be carried out to conclude that.

While the results are promising, this study was conducted using an offline test, processing all images in batch. Future work will focus on implementing frame-by-frame segmentation, integrating the neural network into the real-time data acquisition pipeline, and displaying the results to the physician on a screen.

5. CONCLUSIONS

Our findings demonstrate the suitability of FPGA acceleration for real-time LUS diagnosis due to its high inference speed, small size, and low power consumption with a cost-effective device. A key finding is that the quantization process bears almost no appreciable effect in the model performance, while reducing the size to a quarter of the original. Similarly, the removal of attention gates had neglible impact on the model's effectiveness.

The developed pipeline has been optimized for the specific characteristics of LUS segmentation. However, its core steps—model modification, quantization, and implementation—are adaptable and can be applied to other ML models and FPGA platforms. This underscores the potential of FPGAs in edge-computing by enabling rapid inference directly at the point of data acquisition.

ABSTRACT

Developing deep learning models for lung ultrasound (LUS) segmentation is hindered by limited annotated data. This study demonstrates the effectiveness of cross-domain transfer learning (TL) using ImageNet pre-trained encoders (VGG16, ResNet50, MobileNetV2) within a U-Net architecture. Compared to training from scratch, TL with ResNet50 and VGG16 significantly improved segmentation Dice score (up to 30%). Furthermore, TL allowed reducing the training dataset to 45% while achieving performance comparable to the baseline trained on full data. These findings validate cross-domain TL as a valuable and data-efficient approach for LUS analysis.

Keywords: Artificial Intelligence (AI), Transfer Learning, Fine-tuning, Segmentation, Lung Ultrasound (LUS).

1. INTRODUCTION

Artificial Intelligence (AI) has emerged as a transformative technology with significant potential in medical imaging and diagnostics. In particular, AI-based approaches hold promise for improving the accuracy and efficiency of diagnostic procedures in various medical domains, including pulmonary imaging [1, 2, 3]. Lung ultrasound imaging plays an important role in diagnosing respiratory conditions, offering real-time visualization of pulmonary lesions [4]. However, the interpretation of lung ultrasound images can be challenging, and requires expertise to identify subtle features and abnormalities accurately [5].

AI-based Semantic segmentation, is a powerful approach for assessing LUS interpretation. However, a critical challenge in applying deep learning models for segmentation is the limited availability of large, annotated datasets. The process of acquiring LUS images and obtaining accurate annotations from expert radiologists is both time-consuming and expensive. To mitigate this bottleneck, some research efforts focus on developing automatic labeling tools [6]. While promising, transfer learning offers a complementary strategy by leveraging knowledge from pre-trained models, potentially reducing the amount of labeled data and training time required to achieve high performance.

Transfer learning has the potential to address the challenges associated with acquiring and labeling large datasets for comprehensive model training, making it a promising approach for enhancing the diagnostic utility of AI-based segmentation models in pulmonary ultrasound imaging [7].

The objective of this study is to investigate the application of cross-domain transfer learning techniques for lung ultrasound image segmentation, aiming to harness the power of pre-trained convolutional neural network (CNN) models for diagnostic assistance in pulmonary imaging and, to evaluate the impact of reduced training data on accuracy. Specifically, architectures such as VGG16, ResNet50 and MobileNetV2 are studied as pre-trained encoders within an Attention U-Net architecture.

2. METHODS

2.1 CNN architectures

For semantic segmentation of LUS images, an Attention U-Net architecture [8] was employed. This network is based on the U-Net [9], which follows an autoencoder design (Figure 1). An autoencoder consists of two primary components: an encoder that progressively reduces the spatial dimensions of the input image while extracting increasingly abstract features, and a decoder that upsamples these features to reconstruct an output of the same size as the input. In U-Net based networks, skip connections between corresponding encoder and decoder layers facilitate the preservation of fine-grained details. The Attention U-Net incorporates spatial and channel attention modules [8] to further enhance feature discrimination.

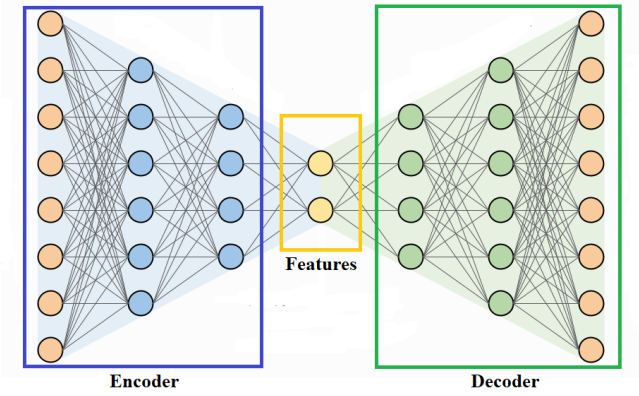

Figure 1. Schematic Autoencoder network architecture

To leverage transfer learning, the encoder portion of the Attention U-Net was replaced with pre-trained networks. Transfer learning is a technique where a model developed for a task is reused as the starting point for a model on a second task. In this case, models pre-trained on the large ImageNet dataset for image classification were utilized as encoder of the new architectures adapting them for LUS image segmentation. This study investigated three such pre-trained models: VGG16 [10], ResNet50 [11], and MobileNetV2 [12]. The classification layers of these models were removed, and feature maps were extracted from a specific layer of each encoder serving as input to the Attention U-Net decoder, which remained consistent across all configurations.

2.2 Dataset

This study utilized a dataset of 5131 lung ultrasound (LUS) images obtained from 30 patients diagnosed with COVID-19. The images were acquired as part of the clinical study described in [13]. The dataset exhibits typical LUS artifacts associated with pneumonia, including A-lines, B-lines, and consolidations.

Image annotation was performed using a semi-automatic labeling tool presented in [6]. This tool employs signal processing algorithms to generate initial segmentation masks. The results of this semiautomatic annotation tool were validated at the video level by a LUS expert physician. The annotations delineate the boundaries of artifacts such as pleura, A-lines, B-lines, and consolidations.

2.3 Methodology

This study evaluated cross-domain transfer learning for LUS image segmentation. An Attention U-Net, trained from scratch, was compared to three transfer learning configurations using pre-trained encoders (VGG16, ResNet50, MobileNetV2). Each configuration was trained four times with different random weight initializations to account for the inherent stochasticity of the training process. Performance was assessed using the mean and standard deviation of the Dice Similarity Coefficient (DSC) between the mean values on a reserved test set.

The dataset was divided into training (60%), validation (20%), and testing (20%) sets using a patient-wise split to provide a more realistic assessment of generalization performance. All models were trained with a learning rate of 3e-5, a batch size of 32, and the binary cross-entropy loss function. A two-stage transfer learning procedure was used: encoder layers were frozen for the first 60 epochs, then unfrozen for fine-tuning during the remaining 60 epochs. The reference model was trained from scratch for 120 epochs. Training was performed using TensorFlow 2.10 on two NVIDIA 2080 Ti GPUs.

The best-performing encoder (based on DSC) was then used in a data reduction experiment. Training set size was reduced 5% by 5% until the model achieved a validation DSC value below the reference model. The training procedure was repeated four times for each reduced dataset aiding consistency to the results. The model is stopped when the DSC is below the baseline model.

3. RESULTS

Table 1 shows the mean and standard deviation of the Dice Similarity Coefficient (DSC) for each model applying

Transfer learning (TL) and fine-tunning (FN) calculated on the test set.

Table 1. Segmentation performance.

Model Att-Unet	Dice (mean±std)
From Scratch	0.544 ± 0.034
VGG16 (TL+FN)	0.691 ± 0.033
MobileNetV2 (TL+FN)	0.516 ± 0.152
ResNet50 (TL+FN)	0.711 ± 0.043

Using ResNet50 as encoder with TL and FN achieved the highest mean DSC (0.71 ± 0.04), a statistically significant improvement over the baseline Attention U-Net (0.54 ± 0.03). With VGG16 as encoder (TL+FN) also significantly outperformed the baseline (0.69 ± 0.03). These results showed no statistically significant difference between Resnet50 and VGG16 encoders. MobileNetV2 (TL+FN) exhibited the lowest DSC (0.52 ± 0.15).
Figure 2 illustrates an example of the differences on segmentation performance between the Attention U-Net base model and the Resnet50-based Attention U-Net.

Figure 2. Segmentation performance comparison between the reference model (from scratch) and the Resnet50-Att. U-Net with TL and FN.

Following the initial comparison, the best-performing encoder (ResNet50) was used to investigate the impact of reduced training data. Models were trained on progressively smaller subsets of the training data, ranging from 95%. Figure 3 illustrates the mean DSC (± standard deviation) achieved modifying the percentage of training data used. The results indicate that leveraging transfer learning with the ResNet50 encoder allowed the training dataset size to be reduced to approximately 45% while still achieving a mean DSC comparable to the baseline Attention U-Net model trained from scratch on the full (100%) training dataset.

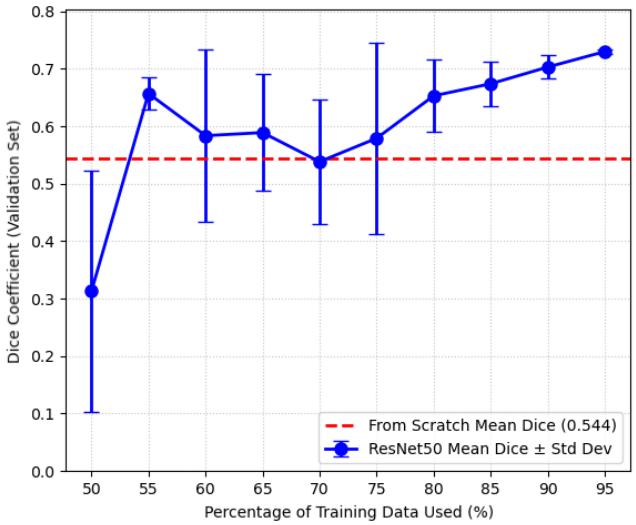

Figure 3. Data reduction results over Resnet50-based Attention U-Net fine-tuned.

4. DISCUSSION

This study investigated the effectiveness of cross-domain transfer learning for LUS image segmentation. The results demonstrate its advantages: pre-trained ResNet50 and VGG16 encoders significantly outperformed the baseline Attention U-Net trained from scratch. This suggests that, despite the significant domain difference between natural images (ImageNet) and medical ultrasound, features learned during pre-training are valuable for extracting relevant patterns in all type of images. While ResNet50 yielded the highest mean Dice score, VGG16's performance was comparable. On the contrary, MobileNetV2 performed worse, potentially because its design, focused on efficiency via parameter reduction, leads to lower representational capacity or features less transferable to this specific cross-domain task.

The data reduction study further highlights the value of transfer learning, with results quantitatively presented in Figure 3. This figure plots the validation Dice score of the ResNet50 transfer learning model against the percentage of training data used. It demonstrates that performance comparable to the baseline model (DSC ≈ 0.54) was maintained even when using only 55% of the original training data. This represents a substantial 45% reduction in the required annotated dataset, underscoring the practical benefit of cross-domain transfer learning in mitigating the need for extensive data annotation. Interestingly, the performance trend was not strictly constant; a noticeable dip

towards the baseline performance occurred around the 70% data mark where the mean performance approached or slightly fell below the baseline threshold. However, a sustained drop significantly below the baseline threshold was only observed for data levels below 55%. Furthermore, Figure 3 illustrates increased performance variability (larger standard deviations) at lower data percentages (particularly ≤75%), indicating greater training instability or sensitivity to data sampling when data becomes severely limited. Notably, while the standard deviation observed at the 55% data level appears comparatively low relative to surrounding data percentages in this experiment, this is likely to be due to the stochastic nature of training with only four runs, rather than an indication of particular stability at this specific data level.

It is important to acknowledge certain limitations of this study. Notably, exhaustive hyperparameter optimization was not performed for each encoder, potentially impacting individual model performance. Furthermore, results are based on a specific COVID-19 LUS dataset, which may limit generalizability. Future work should address these limitations by performing systematic hyperparameter tuning and evaluating performance on larger, more diverse LUS datasets encompassing various pathologies. Investigating more recent encoder architectures and comparing cross-domain pre-training with medical domain pre-training could also yield valuable insights.

Despite these limitations, this work provides evidence that cross-domain transfer learning, particularly with ResNet50 or VGG16, is a highly effective and data-efficient approach for LUS segmentation.

5. CONCLUSIONS

This study evaluated the application of cross-domain transfer learning techniques for the semantic segmentation of LUS images. The results conclusively demonstrate that using pre-trained architectures such as VGG16 and ResNet50 as encoders within an Attention U-Net network significantly improves segmentation performance compared to training from scratch. A marked increase in the Dice Similarity Coefficient (DSC) of approximately 30% was observed when employing transfer learning with the most effective encoders.

A key additional finding is the potential of transfer learning to mitigate the need for large annotated datasets. The data reduction analysis indicated that it is possible to decrease, in this specific example, the training dataset size to approximately 45% of its original size while still achieving segmentation performance comparable to the baseline model trained on the full dataset. This data efficiency considerably reduces the burden associated with manual labeling and model training, facilitating the development of AI tools in data-limited settings.

Finally, this work validates the utility of cross-domain transfer learning for medical imaging, and specifically for lung ultrasound. It confirms that features learned from large-scale natural image databases can be effectively transferred and adapted to improve analysis in specialized medical domains such as LUS, despite the inherent differences between the image types. Overall, transfer learning presents itself as a practical strategy for developing accurate and efficient LUS segmentation models.

ABSTRACT

Reinforcement learning (RL) offers a powerful approach to automate decision-making in Computational Fluid Dynamic (CFD), improving accuracy and reducing human effort, leading to more efficient solvers.

In this work, we expand our RL-based polynomial adaptation technique for high-order solvers [1, 2] to capture acoustics. We improve aeroacoustic simulations employing RL to define a high-order acoustic path in the high-order solver HORSES3D [3], allowing precise wave capture from source to observer. Offline training eliminates the need for high-fidelity solutions, making the method versatile across various meshes and PDEs. This approach effectively addresses aeroacoustic challenges, focusing computational efforts where needed and ensuring accurate results at a reduced cost.

Keywords: *reinforcement learning, high-order discontinuous Galerkin, p-adaptation, adaptive mesh refinement, acoustics*

1. INTRODUCTION

The field of computational fluid dynamics (CFD) has undergone a paradigm change through the integration of machine learning techniques with classical numerical methods [4, 5]. In particular, reinforcement learning (RL) has been adopted as a valuable tool for a variety of fields, creating high-performing autonomous agents capable of making real-time decisions in complex environments [6]. In fluid dynamics, RL has been widely used to enable dynamic flow control [7–9], surpassing traditional approaches. Other applications in the field of numerical simulations for fluid dynamics include the selection of constants in turbulence models [10, 11], optimal parameters in high-order schemes [12, 13] or mesh adaptation.

Mesh adaptation or adaptive mesh refinement (AMR) allows to refine or coarsen the computational mesh based on sensors or metrics. Traditionally, this process has relied on manual intervention, heuristics or error estimators [14, 15], which is time-consuming and limits the ability to capture complex flow phenomena. The integration of RL for mesh adaptation offers a novel approach to automate the process, minimizing user intervention while providing a flexible and general framework applicable to a wide range of problems. RL has been successfully used for AMR (h-refinement) in recent works, where agents were trained to refine or coarsen the mesh, increasing the accuracy in critical regions and minimizing the computational cost [16]. Additionally, Yang et al. [17] consider new policy architectures which are trained from numerical simulations and are agnostic to the mesh size. These approaches provide accurate solutions and a reduced computational cost, surpassing traditional mesh refinement approaches.

This work extends our research presented in [1, 2], where

we established the basis for applying reinforcement learning to p-adaptation in complex 3D turbulent problems. Furthermore, we provide an RL-based error estimator that can be used to estimate the order of magnitud of spatial errors inexpensively. Based on this original concept, we have developed a novel methodology to apply this approach to acoustic simulations. Here, we define an acoustic path, from a source to an observer, where the task of the p-adaptation algorithm is to accurately capture pressure waves; while outside of the acoustic path, the mesh is refined based on aerodynamic features. This hybrid adaptation strategy provides accurate solutions and results in a reduction of the required computational cost when running numerical simulations for acoustics.

2. METHODOLOGY

The methodology is implemented in the open source solver HORSES3D [3, 18, 19], developed at the ETSIAE-UPM School of Aeronautics in Madrid, and available on Github (`https://github.com/loganoz/horses3d`). This solver is a high-order discontinuous Galerkin (DG) tool capable of simulating compressible, incompressible, and multiphase flows with acoustics. HORSES3D allows for the use of high order polynomials in each element in the mesh, and shows exponential decay of the error when increasing the polynomial order but with only a linear increase in the cost, which results in very efficient computations.

The p-adaptation strategy [2] allows one to select the optimal polynomial order in each element of the mesh independently. As the proposed approach is anisotropic, three different polynomials are defined inside each element of the mesh. This methodology provides an automatic way of increasing the accuracy of the solver, by refining the mesh in regions with strong gradients, while keeping the computational cost down, as the polynomial order is reduced in the far field or other regions of less interest. The p-adaptation process is based on a set of *variables of interest* (e.g., momentum or pressure) that the user must provide. These variables will be used as a reference for the RL agent, resulting in an optimal adaptation for these specific variables.

When applied to acoustics, it is possible to define an *acoustic path* between a source and an observer. Within this acoustic path, the RL agent applies a pressure-based p-adaptation to accurately capture the acoustic waves; and outside the path, it applies a momentum/velocity-based adaptation to represent aerodynamic flow features. The acoustic path is defined along a straight line between the source and the observer. Then, the minimum distance from every high order Gauss node of the mesh to that line is calculated as depicted in Figure 1. All elements with at least one Gauss node whose distance d is below a threshold d_{th}, will be included inside the acoustic path. The definition of d_{th} is problem dependent and is an input provided by the user. Finally, in a real problem both the source and the observer could be defined as a surface (e.g., a boundary) instead of a single point. In this scenario, a different line is created from each node of the source to each node of the observer. Furthermore, since this step is performed only once, at the beginning of the simulation, the overhead in relation to the complete simulation time is negligible.

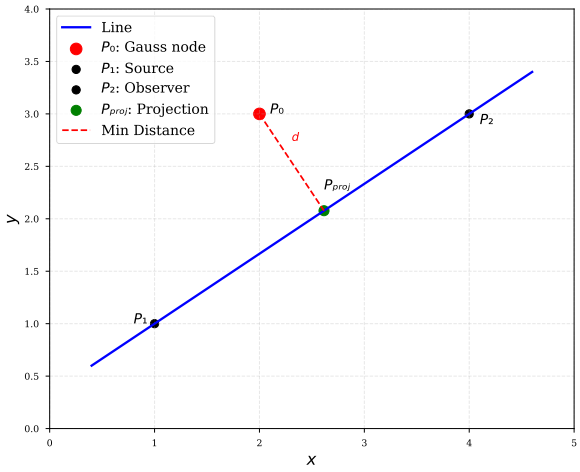

Figure 1. Example of the distance calculation from a high order Gauss node to the line that connects the acoustic source and the observer.

3. RESULTS

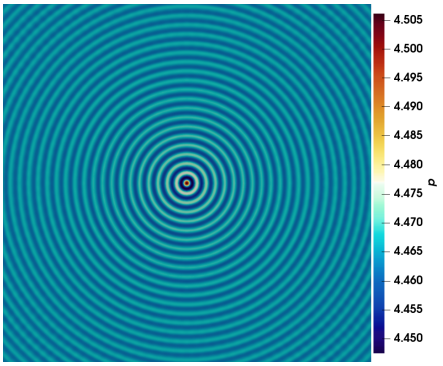
To test the proposed p-adaptation methodology for acoustics and the acoustic path, we simulate different problems, in increasing level of complexity. As the RL-based p-adaptation agent is agnostic to the computation mesh and the PDE being solved, only one agent is trained, which is used for every problem without modifications.

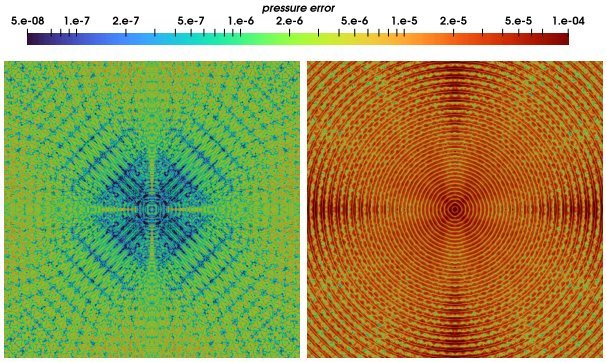
3.1 Monopole

First, to test the performance of the pressure-based p-adaptation against a momentum-based, a simple

monopole is simulated using the nonlinear Euler Equations (EE). The mesh is a square with 400×400 elements. In this test case, the acoustic path is not considered; instead, the polynomial order will be adapted by the RL agent in the whole mesh. A snapshot of the pressure field, once quasi-steady state conditions are achieved, is represented in Figure 2.

Additionally, to validate the proposed methodology, three simulations have been performed, with different p-adaptation strategies: an uniform $p = 6$ polynomial order (used as a reference), a pressure-based adaptation and a momentum-based adaptation. For the two p-adaptation strategies, the maximum polynomial order is limited to $p_{\max} = 6$; hence, the uniform $p = 6$ simulation will always be more accurate than the p-adaptation solutions, but also more costly. In Figure 3, we show the error between both p-adaptation strategies and the reference $p = 6$ solution for the pressure field. The solution computed with the pressure-based adaptation shows a significantly smaller error. Although momentum-based adaptation is appropriate to capture aerodynamic features [2], this problem highlights the importance of using pressure as the reference variable for acoustics.





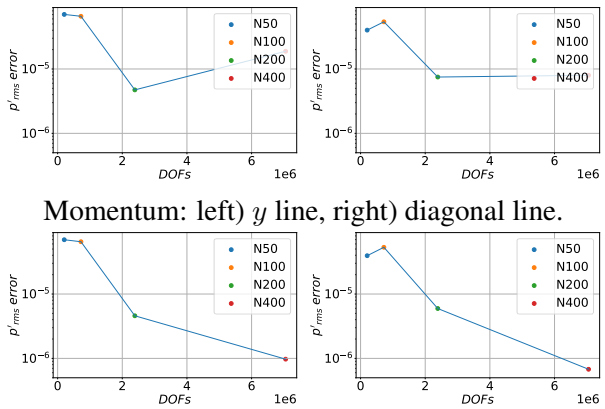


Figure 2. Snapshot of the pressure field.

Finally, in Figure 4 we show the rmse error of the pressure field, as a function of the degrees of freedom of the mesh, in a vertical line (from the source to the boundary at the top) and a diagonal line (from the source to the top-right corner) for both the momentum-based and the pressure-based simulations. As expected, the pressure-based adaptation shows a decreasing error with the number of degrees of freedom, while the momentum-based is not able to reduce the error below 10^{-5}, even if the mesh is refined. Therefore, the momentum field is not an appropriate reference variable to accurately capture acoustic waves.

a) Pressure-based. b) Momentum-based.

Figure 3. Comparison of the pressure error, in relation to the reference $p = 6$ simulation, between the pressure-based and the momentum-based adaptations.

Momentum: left) y line, right) diagonal line.

Pressure: left) y line, right) diagonal line.

Figure 4. Comparison of the pressure rmse error for four different meshes, computed in relation to the reference $p = 6$ simulation, for the pressure-based adaptation and the momentum-based adaptation.

3.2 Multiphase monopole

Once it is demonstrated that the pressure is the appropriate variable to adapt the polynomial order in acoustic problems, we simulate a multiphase problem with two fluids: air and water. In this problem, an acoustic source generates pressure waves in the air region, which are propagated to the water region through an interface. The problem is solved inside a square with a 100×100 Cartesian mesh. To avoid reflections at the boundaries, a sponge is defined near the boundaries to dampen the acoustic waves. This setup is shown schematically in Figure 5. As the wavelength of the pressure waves are different in air and water, the p-adaptation agent should be able to select the optimal polynomial order in each region accordingly. Then, as we want to focus on the propagation of the acoustic waves from the air to the water, we define the acoustic path from the source to the boundary at the bottom, as shown in Figure 6, with a threshold distance of $d_{th} = 2.5$. This way, the RL agent will adapt the polynomial order inside the acoustic path only, reducing the computational cost of the overall simulation.

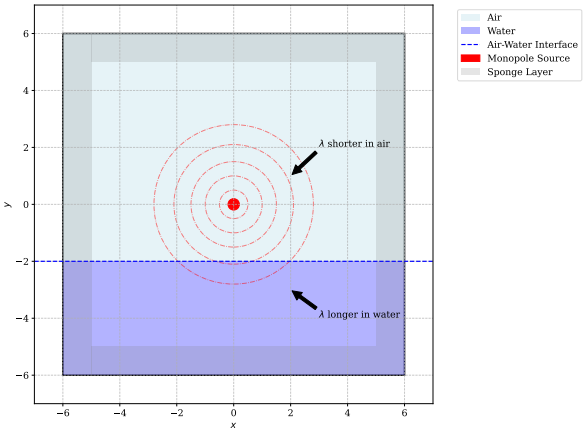

Figure 5. Setup of the multiphase problem.

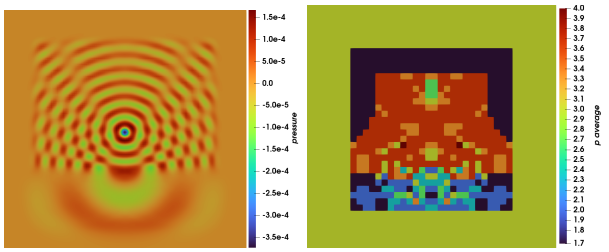

The pressure field, once the simulation is stable, is represented in Figure 7 a). As expected, the wavelength of the pressure waves is significantly longer in the water and, therefore, the polynomial order should be smaller in that region. The average polynomial order (among the three anisotropic polynomials p_x, p_y and p_z) in each element of the mesh is shown in Figure 7 b). In this figure, there are four regions of interest that should be analyzed:

1. Near the boundaries, inside the sponge layer, the polynomial order has been manually fixed to a constant value to avoid undesired reflections.
2. Above the source, in the air region, but outside the acoustic path, the polynomial order is set to the minimum to reduce the computational cost, as we are not interested in the acoustics there.
3. Inside the acoustic path, in the air region, the wavelengths are shorter, and strong pressure gradients can be found inside some elements. Hence, the RL agent selects high-order polynomials to accurately capture the pressure waves.
4. Inside the acoustic path, in the water region, the wavelengths are longer and low order polynomials are enough to represent the pressure waves.

In conclusion, the RL agent is capable of selecting the optimum polynomial order inside the acoustic path, discriminating between different regions, and adapting the polynomial order accordingly.

Figure 6. Acoustic path of the multiphase problem.

a) Pressure. b) Average polynomial.

Figure 7. Snapshot of the pressure field and the average polynomial order in each element of the mesh.

3.3 Cylinder at Reynolds 200

Finally, we propose a more challenging problem, the direct noise computation (DNC) produced by the flow around a cylinder at Reynolds 200, where the RL agent must consider two different adaptation strategies at the same time: inside the acoustic path, a pressure-based adaptation is performed to capture the acoustic waves, and outside the acoustic path, a momentum-based adaptation is used to represent aerodynamic flow features, such as vortices. For this problem we solve the full compressible Navier–Stokes (NS) equations, that accounts for both aerodynamics and acoustic physics. The acoustic path for this problem and the background mesh are depicted in Figure 8, where the acoustic source is the cylinder, the observer is defined 20 length units above the source and the threshold distance is $d_{th} = 1$. Also, it is necessary to define two tolerances to let the agent know when the fluctuations of the reference variable inside one element are negligible. In this case:

$$tol_m = 10^{-2} \qquad tol_p = 10^{-4}, \tag{1}$$

with tol_m as the momentum tolerance and tol_p as the pressure tolerance.

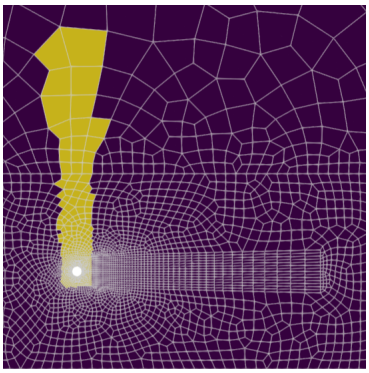

Figure 8. Acoustic path of the cylinder at $Re = 200$.

Once the flow field is stable, a snapshot of the average polynomial order in each element is represented in Figure 9, where there are three main regions:

1. The acoustic path: The polynomial order is increased to capture the pressure waves between the source and the observer.
2. The wake: The vortex shedding creates strong velocity gradients in this region, and high-order polynomials are required to accurately represent the flow field.
3. The far field: Although this region is also adapted based on momentums, the gradients are negligible, and the RL agent selects the minimum polynomial order available in each axis, as nothing of interest is happening.

Therefore, the RL agent, without additional information on this particular problem, is able to discriminate between different regions and to select the optimal polynomial order that provides an accurate solution while keeping the computational cost down.

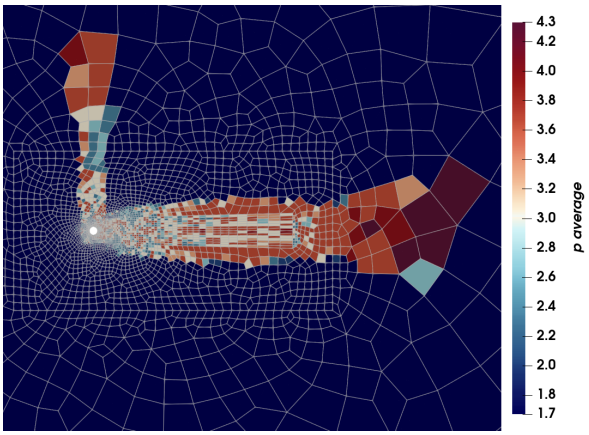

Figure 9. Snapshot of the average polynomial order of the cylinder at $Re = 200$.

Then, to check the accuracy of the proposed methodology, we compare the current results with two additional simulations with an uniform polynomial order of $p = 3$ and $p = 5$ in the whole mesh. First, in Figure 10 we show the root mean square pressure fluctuations along the acoustic path, from source to observer. Although the number of high-order elements in the p-adapted mesh is smaller, the results show a good agreement with the reference simulations. Furthermore, the reader may notice that the p-adapted solution is closer to the reference $p = 3$ simulation instead of $p = 5$, which is more accurate. The main reason behind this behavior is that, close to the cylinder, the aerodynamic pressure gradients are stronger than the acoustic fluctuations, but also very smooth. Therefore, near the cylinder a polynomial order $p = 2$ or $p = 3$ is enough to represent the pressure gradients, reducing the accuracy of the acoustic waves in that region, which are

propagated to the observer. To solve this issue, an uniform high-order polynomial order could be set around the body manually. Secondly, in Figure 11 we compare the SPL measured at the observer's location with different approaches, which highlights the accuracy of the current methodology.

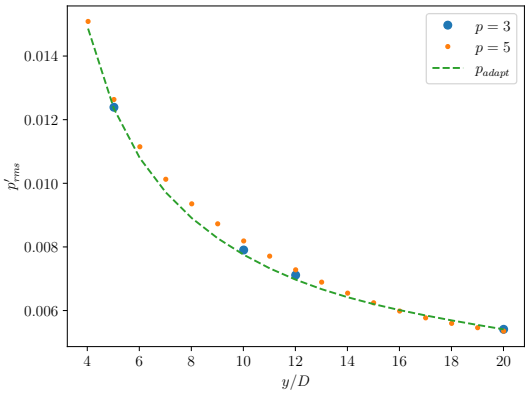

Figure 10. Comparison of the rms pressure fluctuations from the source to the observer.

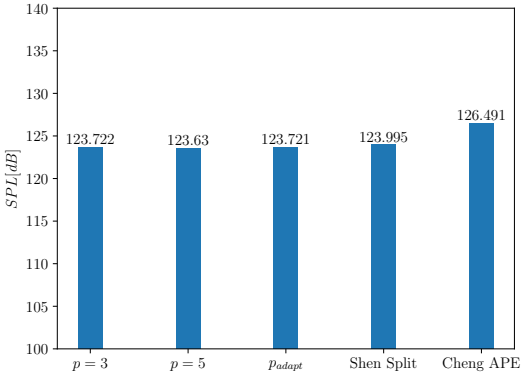

Figure 11. Comparison of the overall SPL at the observer's location.

Finally, for completeness, the u velocity field following the x axis is shown in Figure 12, where the vortex shedding is accurately represented, highlighting the effectiveness of the proposed p-adaptation strategy. In addition, this problem shows the flexibility of the p-adaptation RL agent, which can be applied in many different ways (to different problems, PDEs and meshes) and based on arbitrary reference variables, without retraining the agent. All these advantages make reinforcement learning for adaptive mesh refinement a good choice to solve aeroacoustic CFD problems, including DNC.

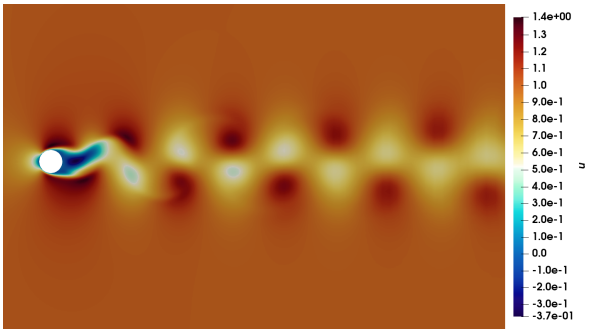

Figure 12. Snapshot of the velocity field of the cylinder at $Re = 200$.

4. CONCLUSIONS

In conclusion, this study presents a new approach to applying anisotropic p-adaptation for acoustics in high-order h/p solvers using reinforcement learning. The RL-based adaptation dynamically adjusts high-order polynomials based on the pressure field to capture acoustic fluctuations. Furthermore, it can handle different adaptation regions based on pressure, momentum, velocity, or other flow features. The proposed methodology is independent of the computational mesh and can be applied to any partial differential equation, illustrating its broad applicability and flexibility.

These findings open new avenues for further research in acoustics and other CFD applications using RL-based h/p-mesh adaptation.

ABSTRACT

When passengers of an autonomous vehicle have conversations or engage in various activities, the soundscape of the vehicle that suits the atmosphere can play an important role. This study introduces the results of developing a system that recognizes emotions and conversation states from passengers' face images in autonomous vehicles, selects music or the sounds of nature that match this atmosphere, and automatically adjusts the volume to not interfere with passengers' conversation. This study consists of the following process. First, algorithms for emotion classification and conversational state recognition using facial expressions are developed, and the program is lightened and implemented in the vehicle's deep learning control system. Second, a soundscape system is developed that matches and plays sound sources suitable for emotions and conversational states estimated in real time in vehicles. Third, the control and soundscape system are installed in an autonomous vehicle and the accuracy and satisfaction of the systems are evaluated by users. This technology is expected to provide new auditory experiences and increase satisfaction, especially for passengers of autonomous vehicles such as robotaxi.

1. INTRODUCTION

In recent years, automobiles are expanding from simple means of transportation to spaces that improve the quality of life, and at the same time, the technology to provide new experiences in accordance with the emotions of passengers in the vehicle is becoming more important. Particularly in autonomous vehicles, playing music that best suits the mood and emotions without disturbing the conversation of several passengers is expected to give high satisfaction.

Research on recognizing emotions from passengers' facial expressions using cameras in vehicles is an important technology for personalization, and many studies have been conducted so far [1-3]. For example, W. Li et al. [1] had a camera installed in a vehicle simulator and analyzed the driver's emotions into five categories: anger, happiness, sadness, fear, and surprise. Z. Chen et al. [2] developed a face recognition and emotion classification system for autonomous vehicles with a low latency of 2ms and high accuracy (F-score 96%) to enable real-time implementation in Internet of Things (IoT) systems. K.-J. Chang et al. [3] developed a new soundscape provision system that classifies emotions and provides customized driving sound using a multimodal analysis method that combines facial expressions, heart rate, and skin conductivity of vehicle drivers. These studies show that there is a growing interest in in-cabin camera utilization and emotion recognition technology to provide personalized entertainment services. However, when implemented in a vehicle controller, it is very necessary to design an efficient algorithm that can achieve high performance at a low capacity so as not to interfere with other control performance of a vehicle.

On the other hand, in terms of technology for recognizing the conversation state, only methods for measuring and analyzing users' voices have been mainly studied [4-5].

In contrast, this study introduces a technology that uses only an in-cabin camera to identify the passenger's emotions and conversation state from the passenger's facial image information and provides the most appropriate soundscape in the vehicle. In addition, an algorithm that operates with minimal capacity and calculation is produced and implemented in the AI controller of an autonomous vehicle for robotaxi.

2. AI ALGORITHMS

2.1 Emotion recognition

First, the face recognition model of this study uses Multi-task Cascaded Convolutional Neural Networks (MTCNNs) [6]. This is a cascade structure that sequentially passes through three lightweight convolutional neural networks (CNNs) called proposal network (P-Net), refinement network (R-Net), and output network (O-Net), so it is fast to process and accurate even in low-quality images. Fig. 1 shows the architecture of MTCNN. The face recognition model of this study has been designed with a small capacity of 600 KB and has achieved a high recognition rate of 98.02% for 24,111 images on the FER-2013 dataset. Next, the emotion classification model uses the Mini-Xception algorithm [7], which is a lightweight and efficient convolutional neural network (CNN) architecture. This is known for its depthwise separable convolutions that reduce computational cost while maintaining performance. In this study, the emotion classification model has been designed with a small capacity of 853 KB and has showed 74% accuracy for 10,767 images on the FER-2013 datasets. Table 1 shows the results of testing the accuracy of the emotion classification model used in this study. For use in vehicles, confidence for emotions such as Happy, Sad, and Neutral is extracted for each basic frame according to the passenger's facial expression, and the emotion with the greatest value is classified as a cumulative emotion by accumulating the confidence for 30 seconds. Here, 30 seconds is a cycle in which emotions are updated to change the soundscape, and as the emotion update time approaches, confidence is given a high weight so that the recent emotional state can be reflected more. When several passengers board, the above analysis is performed for each passenger, and the most common emotion is selected as the representative emotion.

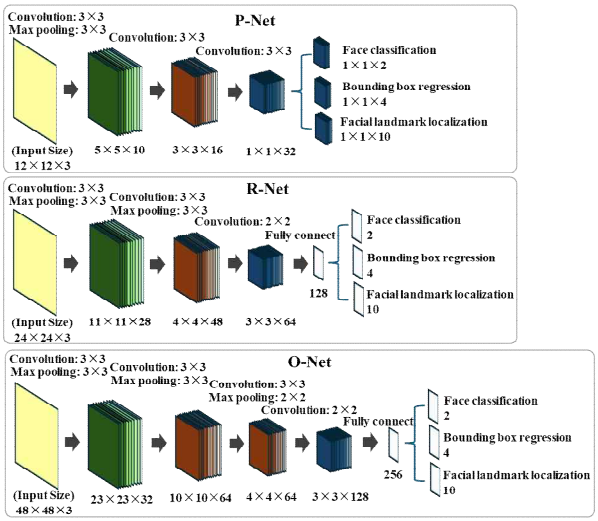

Figure 1. Architecture of MTCNN.

Table 1. Emotion classification test results using the Mini-Xception.

Predicted / Actual	Neutral	Happy	Sad
Neutral	5198	553	224
Happy	857	2257	75
Sad	912	209	482

2.2 Conversation state recognition

When several passengers talk to each other, it is important to select music suitable for the atmosphere and provide it at an appropriate volume so as not to interfere with the conversation. In this study, the conversational state of passengers is determined through CNN algorithm and calculation process from the passenger's facial image data, not the passenger's voice. This method has the advantage that it is not necessary to add a microphone and is not affected by various vehicle noises because it can be performed with an in-cabin camera. A model with 68 face landmarks from the passenger's face image is constructed, and the passenger's conversation state is determined by calculating the number of openings and the opening distance of the landmark around the mouth for a certain time. The above process is repeated for all passengers' mouths, and the conversational state is divided into three categories: No talk, Weak talk, and Strong talk from the calculation results. Fig. 2 shows an example of landmarks around the mouth estimated by facial images.

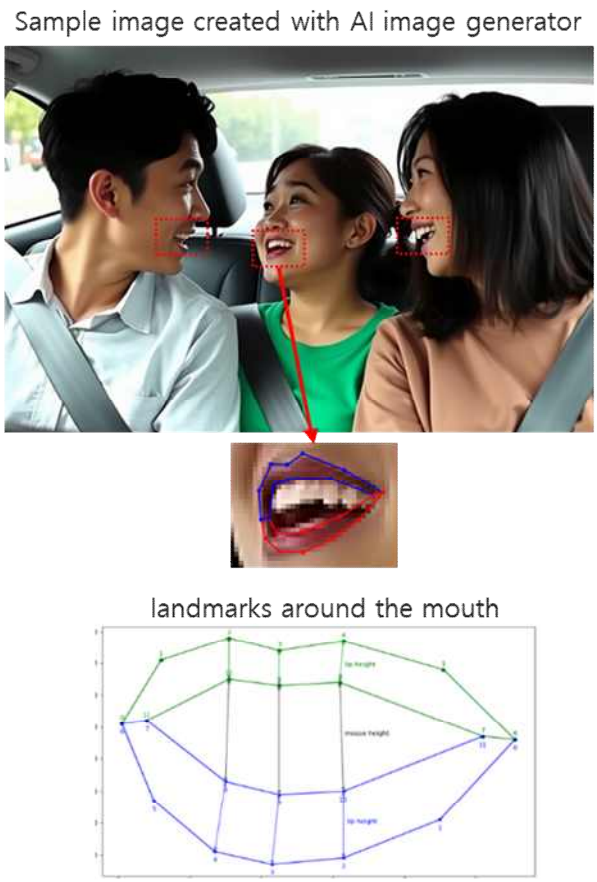

Figure 2. Examples of landmarks around the mouth for conversation state recognition.

3. SOUNDSCAPE

3.1 Soundscape library

Sound sources collected in the library of four concepts (i.e., Neutral, Happy, Sad, Talkative) are used to provide soundscape suitable for passengers' emotions and conversational states. These sound sources have been produced using an AI composition program and improved through correction by music experts. The Happy library contains bright and fast beat music, and the Sad library contains blue and melancholic music. The Neutral library contains comfortable and calm music, and the Talkative library contains simple music with the beats removed so as not to disturb the conversation.

3.2 Soundscape control logic

The Soundscape library selects the sound source that best matches the results of the passengers' representative emotions and conversational states analyzed in real-time in the vehicle. If multiple passengers show various emotions, four complex emotions can be selected as follows: Neutral + Happy (NH), Neutral + Sad (NS), Happy + Sad (HS), and Neutral + Happy + Sad (NHS). In the case of complex emotions, music that satisfies both or more emotions is matched, and if there is a dominant emotion (e.g., cumulative confidence of 80% or more), music that considers that emotion first is selected. Fig. 3 shows the distribution of sound sources matched according to the four complex emotions in this study. On the other hand, when the conversation of passengers is detected, music suitable for the conversation state is played. In addition, the automatic volume logic is applied to reduce the volume of music if it corresponds to Strong talk and increase the volume of music again if it corresponds to Weak talk by determining the stage of conversation with the method introduced in Section 2.2.

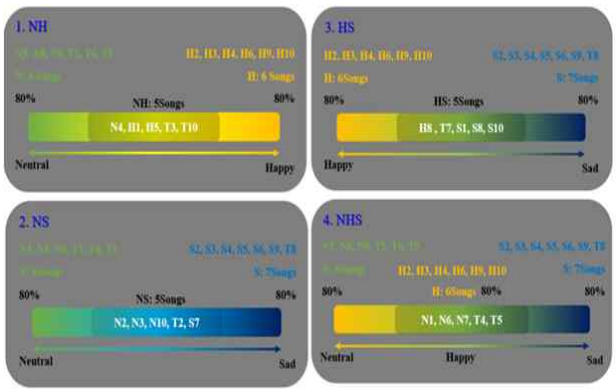

Figure 3. Distribution of sound sources according to the four complex emotions.

3.3 Jury test

Jury evaluation has been performed on 20 people with the camera, AI controller, and soundscape provision system developed in this study. The average age of the subjects is 26.3 years old, and they are organized to have various emotions while looking at various images in the listening room. At the same time, music suitable for the emotions recognized from the subjects' facial expressions is played, and the accuracy of emotion recognition, the accuracy of matching music and emotion, and auditory satisfaction are evaluated. The results of evaluating each item with a 10-

point Likert scale are shown in Fig. 4, and the average value is 7 points or more, showing relatively good results.

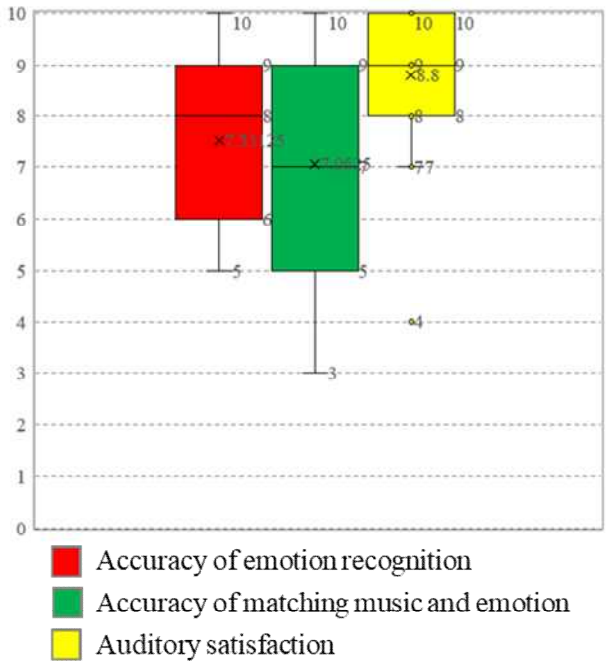

Figure 4. Jury test results for AI algorithms and soundscape.

4. IMPLEMEMTATION IN AUTONOMOUS VEHICLES

4.1 AI Controller

The AI model of this study has been programmed with TensorFlow and embedded in an Ambarella EVK board capable of AI image processing to operate in an autonomous vehicle. Fig. 5 shows the Ambarella EVK board used in this study, which is equipped with CV25, a system-on-chip that supports EasyAI libraries and provides a vector processor with instruction sets that handles a lot of data. The camera installed in the front center of the vehicle interior to capture images of passengers is the ON Semiconductor's AR0239, which is a 1/2.7-inch CMOS digital image sensor with an active-pixel array of 1936 × 1188.

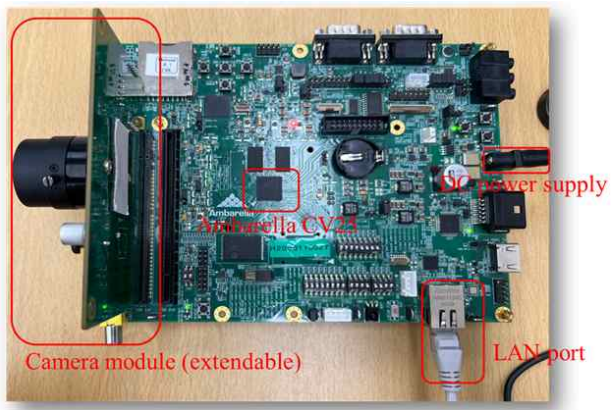

Figure 5. Ambarella EVK board.

4.2 User Interface system

An application for Microsoft Surface Pro tablets has been created to allow passengers to check the emotional and conversational status analyzed in real time, watch videos that fit well with the music determined by the proposed algorithm, and manually select an interface menu. Fig. 6 shows the screen image of this application, including the function of automatically adjusting the volume according to the conversation state. The determined music is played by the vehicle audio amplifier and speaker through the added external sound card. Fig. 7 shows a camera and tablet mounted inside the vehicle, an Ambarella controller mounted in the trunk room, and a sound card.

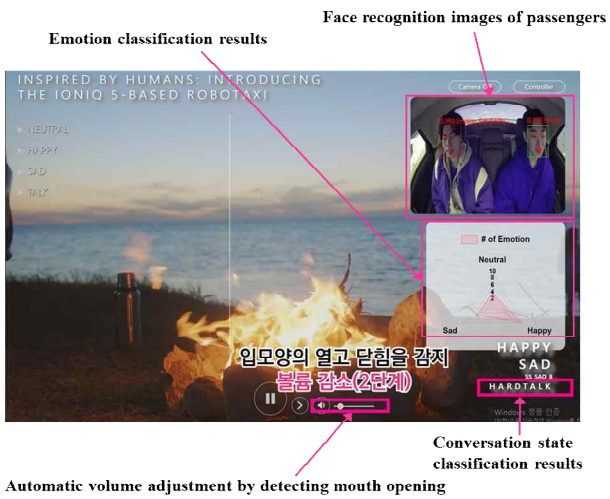

Figure 6. Screen image of an app running on a tablet.

Figure 7. AI controller and camera mounted on an autonomous vehicle.

4.3 Driving Demonstration

The control and soundscape system of this study has been mounted on an autonomous test vehicle and demonstrated while driving with several passengers on board. In the demonstration and evaluation involving a total of 16 people, the overall satisfaction score is 8.4 out of 10. Compared to Section 3.3 evaluated in the listening room, the vehicle evaluation result shows higher satisfaction. Many users are found to be satisfied with providing a soundscape suitable for customers' emotions and moods in the vehicle.

5. CONCLUSIONS

In this study, a lightweight emotion/conversation recognition and soundscape matching algorithm using face images that can be embedded in a deep learning controller of an autonomous vehicle has been proposed and implemented in a test vehicle. As a result of user evaluation, it has been confirmed that the accuracy of emotion recognition, the accuracy of matching music and emotions, auditory satisfaction, and user satisfaction in vehicles are all better than 70%. The results of this study can be used as important guidelines for designing autonomous vehicle services. That is, it is possible to provide a more personalized and immersive auditory experience to passengers through a soundscape suitable for the recognized emotion and conversation state. In addition, if the results of this study are used for self-driving taxis, it is expected to improve the service quality of self-driving taxis and secure a competitive advantage over other transportation methods by providing a personalized sound environment experience in the vehicle.

ABSTRACT

Sorting packaging waste at the source is key to effective recycling. Reverse vending machines (RVMs) can encourage recycling by offering incentives, but they rely on costly sensors like barcode scanners and computer vision, which face issues such as unreadable barcodes, high computational demands, and lighting sensitivity. This paper proposes an alternative approach using acoustic technology. The idea is to use a parametric array loudspeaker (PAL) to emit ultrasonic and audible sound waves towards the recyclable object, and by measuring its interaction, classify the item with the help of machine learning or deep learning. The exponential sine sweep method is used to measure the ultrasonic and audible impulse response of each item, creating a dataset for various containers. Classical and deep learning models are trained to classify items into categories like plastic, glass, cardboard, and metal. The system was tested in a controlled environment featuring a scaled replica of a reverberation chamber, with an omnidirectional parametric loudspeaker (OPL) serving as the sound source. Preliminary results demonstrate high classification accuracy, highlighting the potential of acoustic-based methods to improve the accessibility and efficiency of RVMs in promoting recycling initiatives.

1. INTRODUCTION

Reverse vending machines (RVM) are devices used to recover recyclable packaging waste at source. These machines receive and identify the introduced package and give a reward in return to the customer. The idea is to motivate users' participation in the recycling chain while preventing this packaging waste from reaching waste deposits, incineration plants or nature itself —places where its impact can be problematic in varying degrees of severity. This goes in hand with a global trend towards sustainability and the implementation of circular economy [1–3].

The identification of the type of packaging waste in RVMs has been done by several means. Most commonly, barcode readers, infrared sensors and vision systems are used to classify the item. These are not without their challenges. Barcode readers are useless in cases where the barcode is damaged or missing [4], and infrared and vision systems depend on external factors such as illumination, item condition and fullness [5]. Other systems, such as magnetic separators and inductive sensors [4], are dependent on the material and cannot deal with glasses or cartons. Furthermore, these devices can be expensive, which limits the spread of RVMs that employ them in certain regions. Acoustic-based systems can circumvent the above limitations. The sensors they use, such as microphones, are typically more affordable than vision cameras or barcode sensors. Moreover, acoustic data is less computationally demanding to process than images and is not affected by lighting conditions. Most of the solutions are passive, that is, they classify the item according to the sound it produces when it is returned [5–8]. However, they are sensitive to environmental noise.

This work proposes to use an acoustic technology

based on an active approach. A sound is emitted with a loudspeaker and the recyclable item is detected by analysing the variations it produces in the acoustic field. Parametric acoustic loudspeakers (PAL) are used for this purpose. Based on the Parametric Acoustic Array (PAA) phenomenon [9], they generate ultrasonic waves and, thanks to the non-linear propagation in the air, audible waves are also produced. The packaging waste is then excited with ultrasonic and audible waves at the same time, covering a wide frequency range. The impulse response of the recyclable item is obtained in the ultrasonic and audible range simultaneously, following the exponential sine sweep (ESS) methodology presented in [10] and latter applied in [11] to measure the acoustic absorption coefficient of material samples in a reverberation chamber. The ultrasonic and audible impulse responses of various recyclable items are collected and used to train and test various machine learning algorithms, like support vector machines (SVM), k-nearest neighbours (KNN), random forests (RF), and others. The developed approach is tested under laboratory conditions using an omnidirectional parametric loudspeaker (OPL) as the sound source [12], and a highly reverberant enclosure designed specifically for these experiments. The experimental setup is located inside an anechoic chamber to minimize background noise. To train and test machine learning algorithms it is necessary to apply windows to post-process the impulse responses. This work also explores the sensitivity of the method to these windows by exploring various configurations.

This paper is structured as follows. Section 2 presents the dataset, the ESS method, the experimental setup and the machine learning techniques used. Section 3 displays the classification results based on the combination of the ultrasonic and audible data. Section 4 finishes the discussion and proposes potential explorations in future works.

2. METHODOLOGY

This section first explains the experimental setup used to gather data. Then, it describes the signal processing techniques and the feature extraction process. Finally, it presents the machine learning models used for the automatic classification of packaging waste.

2.1 Measurement of the ultrasonic and audible impulse responses

The experimental setup (see Figure 1) consisted of a mini-reverberation chamber made of cellular polycarbonate,

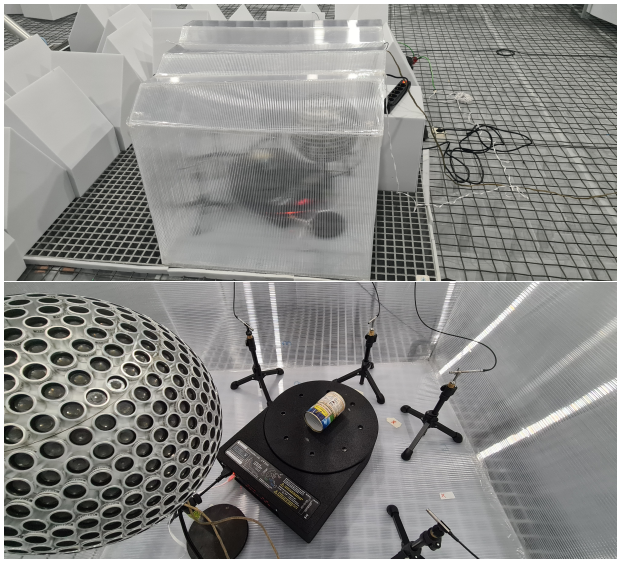

Figure 1: Experimental setup to measure the ultrasonic and audible impulse responses of packaging waste. It consists of a mini reverberation chamber located inside an anechoic chamber containing an omnidirectional parametric loudspeaker (OPL), four microphones and a turntable. An aluminium can in horizontal position is shown as an example.

following the shape of the reverberation chamber at La Salle - Universitat Ramon Llull (URL) and scaling it down by a factor of 1:70. Its irregular shape is expected to improve sound diffusion. To eliminate background noise, the mini-reverberation chamber was placed inside the anechoic chamber of La Salle - URL. Inside, we find the OPL described in [12], used to generate audible and ultrasonic waves through the PAA effect [9]. The recyclable item was put on a rotating table (Outline ET250R2-3D) that rotated every 30 degrees. Four 1/4" measurement microphones (two GRAS 40BF and two GRAS 46BF-1), located at about $0.22\,\mathrm{m}$ from the packaging waste, were used to record the generated sound field . The generation and acquisition of the signal were performed using a Brüel & Kjaer LAN-XI Type 3160-A-042 module with a UA-3102-041185 front-end. The generated signal was amplified up to $17\,\mathrm{V}$ peak-to-peak using an Ecler XPA3000 amplifier. A sampling frequency of $131\,072\,\mathrm{Hz}$ — the maximum available for the equipment — was used.

The Exponential Sine Sweep (ESS) methodology was used to measure impulse responses due to its robustness

Figure 2: Examples of items in the training dataset.

to noise and distortion [13–15]. It consists of emitting and recording a sinusoidal signal with exponentially increasing frequency. The recording is then convolved with the respective inverse filter of the sine sweep, resulting in the impulse response of the system. In the context of this work, the presence of a recyclable object inside the enclosure causes an impact on the sound field, which is reflected in the measured impulse response. This in turn is used to classify the different items. The utilisation of ESS in PALs was first proposed in [16] and extended in [10] to simultaneously measure audible and ultrasonic impulse responses. It requires that the sweep goes through an upper side-band amplitude modulation (USBAM) with a transmitted carrier component [17]. This strategy is adopted in this work, setting the carrier frequency for the OPL to 44.1 kHz [10].

The dataset comprises items that could potentially be introduced into a reverse vending machine. Fifty-one different containers were selected. In terms of material, we used 16 glass bottles, 11 metallic cans, 15 plastic bottles and 9 cardboard cartons. Figure 2 shows a representative

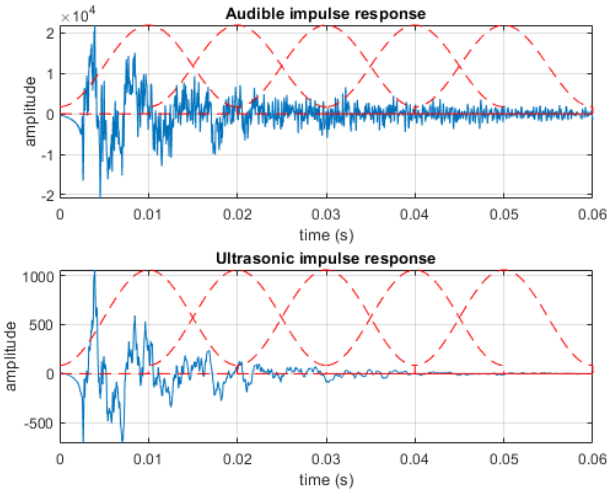

Figure 3: Audible and ultrasonic impulse response of a glass bottle. The red dashed lines indicate the five short windows used to extract the features.

item from each category. Each item was measured in horizontal and vertical position and rotated every 30 degrees. The sound field in the enclosure is measured at 4 different positions. This results in 96 different measurements per item, yielding a total of 4896 measurements that will be analysed by the machine learning algorithms.

2.2 Extraction of features

To evaluate the best way to characterize the impulse responses, a set of features was extracted from both audible and ultrasonic impulse responses. This set includes classical acoustic features such as 13 Mel Frequency Cepstral Coefficients (MFCC) and 13 GammaTone Cepstral Coefficients (GTCC), the spectral centroid, spectral entropy, spectral crest, spectral flatness, spectral flux, spectral kurtosis, spectral skewness, spectral spread and spectral rolloff point.

For each measurement, these features were first obtained from the audible impulse response and a post-processed version of the ultrasonic impulse response obtained by translating its frequency content to the audible range. Then, the features were merged to obtain a single vector of characteristics for each measurement.

The features were extracted from five separate windows of the original impulse response, using a window duration of 20 ms and 50% of overlap. From each of these windows, a set of the 35 aforementioned features were ex-

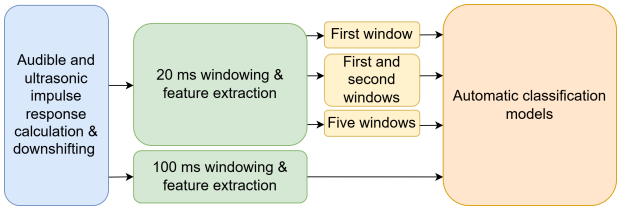

Figure 4: Block Diagram of the 4 different windowing modalities.

tracted, effectively multiplying the amount of total available features for both training and testing by five.

Figure 3 shows an example of audible and ultrasonic impulse responses from a glass bottle measurement, where the 5 windows are superimposed using red dashed lines. It can be observed that the audible impulse response has a slower decay compared to the ultrasonic one, and that both responses (audible and ultrasonic) show an exponential decrease over time. This typical behaviour, confirmed also in the whole set of measurements, suggested to us that the discriminative information between packaging waste is not equally distributed along the time axis. For this reason, four types of feature vector configurations have been explored in this work: i) using only the first window (first 20 ms); ii) using the first two windows (first 30 ms); iii) using all five windows (up to 60 ms); iv) using a single but wider time window that encompasses the same length that 5 windows (also 60 ms). The first and the fourth configurations use the same number of features (35) while the second option doubles this number (70) and the third compiles a total of $35 \times 5 = 175$ features.

In order to validate the amount of windows to be used, the training and testing of the models has been done separately for each of the four feature configurations, as shown in Figure 4.

2.3 Machine learning and deep learning models

The extracted features have been used to train and test six different models of both more traditional machine learning and deep learning models. Regarding machine learning, they can be categorized between those that make use of Decision Trees and those that are not. Specifically, Decision Trees (DT) were utilized directly, while Random Forest (RF) and Gradient Boosting (GB) were included to assess ensemble learning variations of Decision Trees for this task. Additionally, K-Nearest Neighbour (KNN) and Support Vector Machine (SVM) algorithms were employed to evaluate their performance on this type of data. For the deep learning models, a Multi-Layer Perceptron (MLP) was tested as the simplest deep learning approach to determine the viability of such algorithms for classification in this task. All models were evaluated using accuracy and F1-Score as performance metrics. To ensure result stability, a 5-fold cross-validation process was applied.

3. RESULTS

Table 1 presents the results for each experimental setting, incorporating the six machine learning and deep learning algorithms along with the four window configurations described in the previous section. The results bring a series of interesting insights to light. First, the best-performing model across all settings is the SVM, with a peak of 89% in both evaluation metrics. Ensemble models (RF and GB) have achieved a good score on both metrics (accuracy and F1), but they still fall short compared to the performance of both the KNN and SVM models. The same applies to the MLP model, which is the only one to benefit from the increased input feature size. Second, the use of five windows does not provide a significant increase in any of the evaluation metrics, despite this configuration is the one that uses the largest number of features. In fact, this configuration generally leads to a decline in performance. Notably, the best results are achieved when only the first two windows are used, indicating that the most relevant information from the impulse response is concentrated within the first 30 milliseconds. Looking at Figure 3, it can be confirmed that most of the energy is concentrated in this region, and beyond 30 ms we have almost no information. The use of a single window across the entire impulse response yields the lowest score. The features extracted from this large window fail to provide enough information for the models to effectively differentiate between classes. The number of features used in this setting is the same as in the first one, where only the first of the five windows is used. However, the latter contains much richer information, resulting in an accuracy increase of 4-19% depending on the model.

Table 2 shows the confusion matrix for the SVM model, using only the first two of the the five possible windows. This matrix presents the aggregated results of the five cross-validation folds. There is little confusion between classes, with the highest misclassification occurring between plastic and glass, the two most represented classes in our samples. These samples primarily consist

Table 1: Classification metrics obtained through cross-validation using the 4 different windowing modalities of impulse responses. The tested algorithms include classical machine learning techniques (DT, RF, GB, KNN, and SVM) and a deep neural network (MLP)

Algorithm	1st Window (of 5 of 20 ms)		1st-2nd Windows (of 5 of 20 ms)		1st-5th Windows (of 5 of 20 ms)		1 Window (of 60 ms)	
	Accuracy	F1	Accuracy	F1	Accuracy	F1	Accuracy	F1
DT	52%±2%	52%±2%	51%±2%	50%±2%	48%±1%	48%±1%	48%±2%	44%±2%
RF	79%±2%	78%±2%	81%±2%	81%±2%	76%±2%	76%±2%	69%±2%	66%±2%

KNN	82%±1%	82%±1%	88%±1%	87%±1%	86%±1%	86%±1%	70%±1%	68%±1%
SVM	83%±1%	83%±1%	89%±1%	89%±1%	89%±0%	89%±0%	74%±1%	74%±1%
MLP	67%±1%	67%±1%	73%±0%	73%±0%	75%±1%	75%±1%	48%±1%	40%±1%

Table 2: Confusion matrix for the first two windows aggregating the results of all the cross-validation folds. The model used for the classification is the Support Vector Machine.

Metal	**974**	17	46	19
Cardboard	29	**735**	78	22
Plastic	38	66	**1244**	92
Glass	21	23	90	**1402**
	Metal	Cardboard	Plastic	Glass

of different types of bottles, jars, and similar containers. It is possible that the size and shape of the container influence on the classification and the ability of the model to differentiate between samples. However, this confusion accounts for only 6% of the total predictions, which is not a concerning amount of misclassified samples.

4. CONCLUSIONS

This work has proposed to use acoustic technology and machine learning to classify packaging waste in reverse vending machines (RVMs). The idea is to use a parametric array loudspeaker (PAL) to emit ultrasonic and audible sound waves towards the recyclable item, and by measuring the sound field, detect the recyclable item introduced with the help of machine learning or deep learning models. The exponential sine sweep method has been used to obtain the acoustic impulse response of the recyclable items in both the ultrasonic and audible range. Results have shown that the technology is viable, achieving a top evaluation metric of 89% in both Accuracy and F1-Score with a Support Vector Machine. Four window configurations were tested to extract the features, but the one that worked best used two windows for the first 30 ms. Incorporating more time generally led to a decrease in classifier performance.

The experimental setup used in this work was performed in a controlled environment using high-end measurement equipment, ensuring optimal input data conditions for the models. While this data does not fully replicate the environmental conditions of an RVM, it serves as a foundational testbed for future research. Future work will focus on conducting measurements in enclosures that more closely resemble an RVM, as well as developing new PALs designed to fit within these machines. It is worth mentioning that the best-performing model, the SVM, is lightweight enough to be deployed on lower-end hardware, enabling on-device processing and classification. This, in turn, will makes RVMs more stable and cost-effective to produce.

5. ACKNOWLEDGMENTS

DEEP LEARNING-AIDED DESIGN OF A BROADBAND LOW-FREQUENCY META-ABSORBER FOR ROOM ACOUSTIC APPLICATIONS

Oluwaseyi Ogun[1] **John Kennedy**[1*]
[1] School of Engineering, Trinity College Dublin, Ireland, D02 PN40

ABSTRACT

Designing acoustic metamaterials (AMMs) capable of achieving broadband low-frequency absorption remains a considerable challenge due to the physical limitations imposed by long wavelengths, which typically necessitate thick, voluminous structures. This paper introduces a data-driven approach that employs a pretrained deep learning (DL) model to generate optimized AMM geometries based on targeted absorption spectra, which are tailored to room-specific modal behavior and layout. The resulting designs aim to maximize absorption efficiency within the 100–250 [Hz] range while minimizing structural footprint and material usage. The proposed AMM absorbers are evaluated through finite element simulations and validated against experimental reverberation time (RT60) measurements in a partially evacuated office environment. Performance is benchmarked against a commercial 10 [cm] thick Spektra A10 absorber. Results reveal that the AMM, with only 3 [cm] thickness, achieves competitive performance in the targeted low-frequency range, offering moderate RT60 reduction. While the Spektra A10 exhibits better performance above 200 [Hz], the AMM's compact form factor and design flexibility provide compelling advantages for low-frequency room treatment. These results highlight the potential of integrating machine learning with acoustic design to develop lightweight, application-specific absorption solutions for modern architectural acoustics.

1. INTRODUCTION

The way sound is perceived within a room results from both direct sound—traveling straight from the source to the listener—and reflected sound, which bounces off various surfaces. Key contributors to these reflections include architectural features such as walls, floors, and ceilings, but other objects, including furniture and even people, can also influence sound propagation. How sound interacts with a surface depends on factors such as the material composition and the angle at which the sound wave strikes it. The acoustical analysis of a room is essential for understanding and optimizing the behavior of sound within enclosed spaces for optimal sound experience. The interaction of sound waves with surfaces, objects, and air affects how sound is perceived, making room acoustics a critical factor in designing environments such as concert halls, theaters, recording studios, classrooms, offices, and residential spaces [1]. Poor acoustic design can lead to issues such as excessive reverberation, speech intelligibility problems, and unwanted echoes, which degrade the quality of auditory experiences.

However, achieving a universally ideal acoustic environment for concerts and theaters for instance, is an idealization, as musical perception is influenced not only by objective sound characteristics, but also by individual perceptions and requirements. This inherent diversity in acoustic preferences leads to a wide range of successful concert hall designs, making room acoustics a continuously evolving field [2]. To navigate these complexities, acoustic modeling provides a structured approach to evaluate key sound characteristics within a space, and enables

auralization [3].

The two primary methods for modeling room acoustics are based either on solving the Helmholtz wave equation or its variants, or on the principles of geometrical acoustics which form the foundation of ray acoustics. Geometrical acoustics, a commonly used approach for room acoustic modeling [1, 4–6], treats sound propagation as rays and disregards its wave nature. This assumption is accurate at high frequencies where the sound wavelength is much smaller than the objects and room features (e.g., walls, furniture). However, at low frequencies, wave phenomena such as diffraction and interference become more pronounced, leading to significant small-scale effects that geometrical acoustics cannot account for, thus necessitating wave-based methods such as the finite element modeling (FEM) or a hybrid approach [7].

Konrad et al. [8] explores simulating room acoustics using the finite-difference time-domain (FDTD) method, focusing on boundary and medium modeling. Their findings suggest that the proposed 3D schemes outperform traditional methods like Yee's staggered grid [9], and the digital waveguide mesh while maintaining desirable boundary properties. Elzbieta et al. [10] explores the theoretical and practical approaches to optimizing the sound field through architectural design. The study provides guidelines for acoustic planning, focusing on sound absorption strategies, spatial and material solutions, aiding systems, and proper device implementation. Noting a gap between acoustics and architecture, the paper bridges these fields by highlighting their mutual influence on sound absorption and propagation in office spaces.

Noise control in open offices can be achieved through high room absorption, tall screens, bookcases, and sufficient masking sound. However, the interaction of these elements is complex, particularly at varying distances from a speaker. Jukka et al. [11] conducted room acoustic measurements in 15 open offices and developed a model using multivariable regression analysis of the measurement data. Their model predicts two key descriptors of open office acoustics: the A-weighted speech level per distance doubling and the radius of distraction. These predictions are then used for decision making, to improve speech privacy and overall acoustic conditions.

An optimization model to help office space designers select cost-effective noise control materials while meeting acoustic quality requirements was presented in Abdullah et al. [12]. The model follows five key stages: identifying designer decisions affecting cost, formulating an optimization function, defining constraints related to acoustic quality and material selection, implementing the model using genetic algorithms (GA), and evaluating its performance in a real-world office space. Their model determines the optimal type and area of acoustic materials for each surface in the room, ensuring both cost efficiency and acoustic performance.

Low-frequency noise is still a challenge that is practically difficult to deal with especially in communication spaces where sound quality is non-trivial. Fuchs et al. [13] highlights the often-overlooked issue of low-frequency noise (below 100–125 [Hz]) in communication spaces such as offices, conference rooms, and restaurants. Traditional building and room acoustic standards fail to address this frequency range, which significantly impacts speech intelligibility and sound quality. To tackle this, the development and consulting institute, IBP, developed slender compound panel absorbers (CPA), which can be mounted on walls or ceilings to dampen dominant room eigenfrequencies. Through extensive real-world testing, the study demonstrates substantial improvements in acoustic comfort. The paper serves as a call to recognize the limitations of conventional acoustic ratings and proactively address low-frequency issues rather than waiting for updated standards.

Artificial intelligence (AI) has emerged as a transformative tool in the field of acoustics, revolutionizing acoustic design by enabling advanced noise control solutions. With its ability to analyze vast amounts of data and predict sound behavior with high precision, AI allows for the creation of customized acoustic environments tailored to specific needs, empowering designers to achieve targeted sound control with greater efficiency, and achieving optimized acoustics in spaces ranging from open offices to concert halls, while reducing time and resources spent on traditional trial-and-error approaches. A machine learning-based approach to estimate room acoustic parameters using only geometrical information as input was employed in [14]. The work demonstrates that traditional methods often rely on geometrical models (which approximate high-frequency sound as rays but lack accuracy for wave effects) or wave-based models (which are more precise but computationally expensive). The study builds a dataset from real-world acoustical measurements, using microphone array encoding to extract room impulse responses and absorption area in multiple directions. A neural network model is then trained to predict key acoustic parameters like reverberation time (T60) and early decay time (EDT). Compared to the traditional Sabine method, the model achieves higher accuracy, particularly at low

frequencies.

In Ciaburro et al. [15], an automatic procedure for estimating the reverberation time of a room using artificial neural networks (ANNs) was developed. Traditionally, reverberation time measurement requires specialized equipment and exclusive access to the space. In contrast, their work proposed a method that uses simple audio recordings, from which acoustic features are extracted and labeled with corresponding reverberation time values in octave bands. The labeled dataset is then used to train an ANN model, enabling it to predict reverberation time in any closed space without the need for complex measurements or calculations. The approach simplifies and streamlines the process of estimating reverberation time, making it more accessible and efficient.

Low-frequency broadband noise is a common phenomenon in room acoustics, which is a challenge for traditional acoustic panels as they would need to be impractically bulky to absorb such frequencies. In this paper, a partially empty office space is considered for acoustic treatment. A wave-based numerical method based in COMSOL® Multiphysics is used to simulate the behavior of the room to sound, and the reverberation time measurements are compared with those from experiment. Next, a previously trained deep learning model of an acoustic metamaterial (AMM) absorber is used to predict broadband absorber geometries, with a user-specified subwavelength thickness, according to the experimentally determined room modes. This paper is structured as follows. Section 2 outlines the methodology, including the numerical modeling procedure, experimental setup, and the measurement metrics employed. Section 3 presents the results of the study, covering the validation of the numerical model and the performance comparison between the proposed AMM and a commercial-grade absorber based on RT60. Finally, Section 4 provides the conclusions and discusses key findings and potential improvements.

2. METHODOLOGY

2.1 Room description and numerical modeling

The considered office space is a rectangular room of dimensions 580 [cm] × 266 [cm] × 280 [cm], with a window of dimensions 130 [cm] × 54 [cm] × 180 [cm] as depicted in Fig. 1(a). The office is constructed with solid concrete and brick surfaces with reflective acoustic characteristics. The walls are made of exposed bricks, offering high mass and rigidity. This results in strong sound reflection, with minimal sound absorption at lower frequencies. The surface texture of the brick may introduce some diffusion at mid-to-high frequencies. The ceiling consists of a solid reinforced concrete slab, providing a highly reflective surface that contributes to sound reverberation within the room. The lack of absorption may lead to longer decay times for higher frequencies unless treated with acoustic materials. The floor is a polished concrete surface, which is both acoustically reflective and structurally robust. The smooth finish enhances high-frequency reflections, potentially increasing room brightness. The window is a rectangular opening with a shallow cavity ending in the glass backing. The glass pane, set at the rear of the cavity, influences both sound reflection and absorption characteristics.

The acoustic response of the room is modeled using the lossless Helmholtz wave equation within the Pressure Acoustics Module of COMSOL® Multiphysics. The medium is excited with a monopole domain source, applied through a spherical volumetric source. This configuration approximates an omnidirectional point source, which is representative of a typical loudspeaker or sound source in enclosed spaces. The spherical region ensures uniform radiation of acoustic energy in all directions, minimizing directional bias and better simulating diffuse field conditions assumed in statistical models such as the Sabine and Eyring formulas.

Boundary conditions are assigned to the room surfaces and furniture based on their respective material properties, as detailed in Tab. 1, and their absorptivities across octave band center frequencies are obtained from the literature [16, 17]. The computational domain is discretized using a tetrahedral mesh, with a maximum element size of $\lambda/7$, where λ represents the wavelength corresponding to the highest frequency of interest.

2.2 Reverberation time

Reverberation is a key acoustic parameter that defines how sound persists in a room after the source has stopped [18]. It significantly impacts both speech intelligibility and musical quality. Excessive reverberation can blur speech by masking short consonant sounds, while insufficient reverberation can make music sound lifeless and lacking in richness. The reverberation time, $RT60$, is the duration required for the sound level to decay by 60 dB after the source ceases. This metric provides insight into the room's acoustic properties and can be measured empirically by analyzing the sound pressure level over time. The RT60 in frequency domain is commonly computed

Table 1: Absorption coefficients of the surface materials in the investigated office space.

Surface		Absorptivities in Octave Bands					
Type	Material	125 [Hz]	250 [Hz]	500 [Hz]	1000 [Hz]	2000 [Hz]	4000 [Hz]

according to the Sabine formula [19] in Eqn. (1)

$$RT60 = \frac{0.161V}{A}, \tag{1}$$

where V is the volume of the room, and A is the total equivalent absorption area given by

$$A = \sum(S_i.\alpha_i), \tag{2}$$

where S_i is the effective surface area of each material in the room, and α_i is the absorption coefficient of the material. The Sabine formula assumes that sound energy is uniformly distributed within the room, with minimal influence from objects and furniture on the overall acoustic response. However, in practice, perfect sound diffusion is rarely achieved, requiring adjustments in some cases to account for furniture or surfaces not accounted for due to the assumption.

2.3 Measurement setup

Reverberation time measurements are conducted in accordance with the ISO 3382-2:2008 standard. Two microphone positions, M_1 and M_2 are marked within the room, spaced at least 1 [m] from the nearest reflecting wall, and avoids symmetric positions. Three sound source positions are utilized: two located at opposite corners of the room (S_1 and S_3) and one at the center, S_2 (see schematic in Fig. 1(b). The excitation signal is a time-domain logarithmic sine sweep, providing a high signal-to-noise ratio and enabling deconvolution to extract the room impulse response from which RT60 is estimated via Schroeder integration. The sweep is generated at –12 [dBFS] with a sampling rate of 44.1 [kHz].

A total of ${}^3P_2$ (= 6) source-microphone combinations were measured, and the results were averaged to obtain a single representative reverberation time curve. The of-

fice measurement setup comprises a Genelec 8020B active monitoring loudspeaker and an omnidirectional microphone, connected to the output and input channels, respectively, of a Focusrite Scarlett 2i4 audio interface. The measurement signals are generated and analyzed using Room EQ Wizard (REW) V5.31.3, allowing for precise estimation of the decay characteristics of the room impulse response.

3. RESULTS AND DISCUSSION

3.1 Model validation

Fig. 2 shows the one-third octave RT60 of the office space without any acoustic treatment. The measurements at each speaker-microphone position are shown in gray, while the average response is indicated in red (refer to Fig. 1(b) for speaker-microphone positioning). It is noteworthy that the office space was already in use, meaning some items could not be removed during measurements, which may have impacted the room's response. Subsequently, the numerical RT60 is compared to the experimental results. Initial simulation shows that the numerical model tends to overestimate the reverberation time. This discrepancy is likely due to the presence of surfaces, crevices, cavities, and other elements within the office space that are not fully accounted for in the numerical model. To correct for this, the unknown absorption characteristics are estimated by calculating the absorption area required to match the difference between the numerical and experimental RT60 responses. This "deficit" in absorption area is used to generate frequency-dependent absorption data, which are subsequently applied to a section of the room's wall in the numerical model. The required absorption area is computed using Sabine's equation as

$$\Delta A(f) = A_{exp}(f) - A_{num}(f) = \frac{0.161.V}{RT_{60}^{exp}} - \frac{0.161.V}{RT_{60}^{num}}, \tag{3}$$

So that the correction absorption coefficient, $\Delta\alpha(f)$, is then obtained according to Eqn. (4)

$$\Delta\alpha(f) = \frac{\Delta A(f)}{A_{corr}}, \tag{4}$$

where A_{corr} is the correction absorption area. The result of this correction is shown in Fig. 3 which validates the numerical for subsequent analysis.

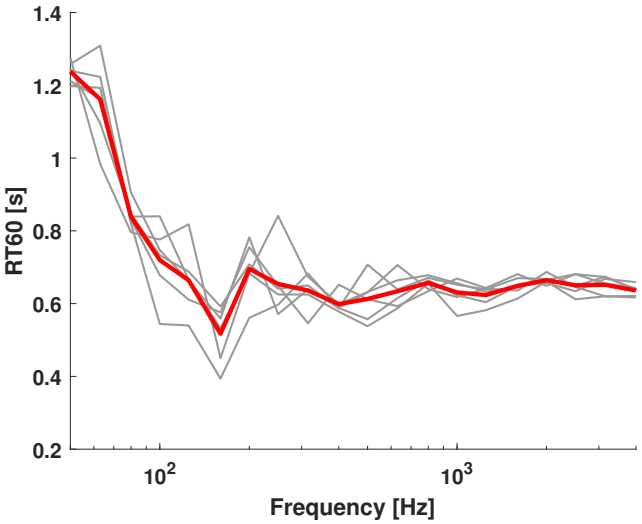

Figure 2: Acoustic response of the space measured using a logarithmic sine sweep excitation showing the reverberation time (RT60) and decay characteristics of the space.

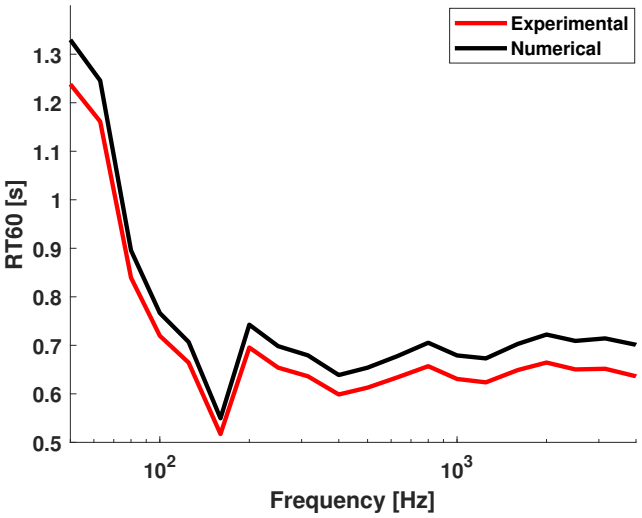

Figure 3: Comparison between experimental and numerical reverberation times after correcting for the unknown absorption area in the space.

3.2 AMM Application to Room Acoustics

Having validated the numerical room model against experimental measurements, a simulation study is conducted

to evaluate the performance of a deep learning-based AMM absorber in comparison to a conventional industrial absorber, the Spektrum A10, which consists of a fabric cover and mineral wool core, with dimensions 60[cm] $\times$ 60 [cm] $\times$ 10 [cm]. A pre-trained autoencoder model is employed for inference, enabling the prediction of AMM geometrical parameters based on a desired target absorption spectrum. Here, the target spectrum is informed from the room's reverberation response in Fig. 2. The decoder component of the network is used to reconstruct the original input spectrum, which is subsequently applied to the AMM panels in the numerical room model. A unit structure of the designed AMM absorber is shown in Fig. 4. Each unit is a supercell composed of four inhomogeneous cells, each tuned to a different target frequency. The supercells are periodically arranged in a 60 [cm] $\times$ 60 [cm] rectangular panel, which is then applied to the room surfaces and ceiling. Four panels each of 60 [cm] $\times$ 60 [cm] cross-section are used in the simulation. On the other hand, the industry-grade Spektrum A10, shown in Fig. 5 is of similar cross-section, but witha thickness of 10 [cm]

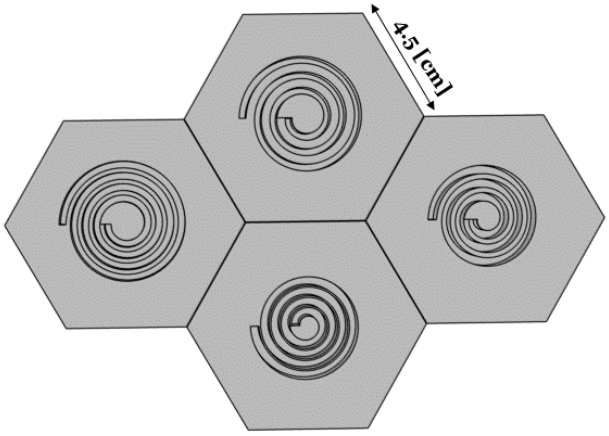

Figure 4: A unit structure of the designed broadband AMM absorber composed of a hexagonal cavity, a spiral inclusion and a top perforated plate.

For the private office space under consideration, it is desired to have RT60 between say $0.4 \leq \text{RT60} \leq 0.6$ [s] at low frequencies (< 200 [Hz]) to improve speech intelligibility and reduce listener fatigue from reflected noise. Thus, a broad range of 100 to 200 [Hz] with absorptivities higher than 0.8 is presented to the encoder for which the corresponding geometry is predicted, and the reconstructed absorption spectrum, $\alpha(f)$, is then applied to the

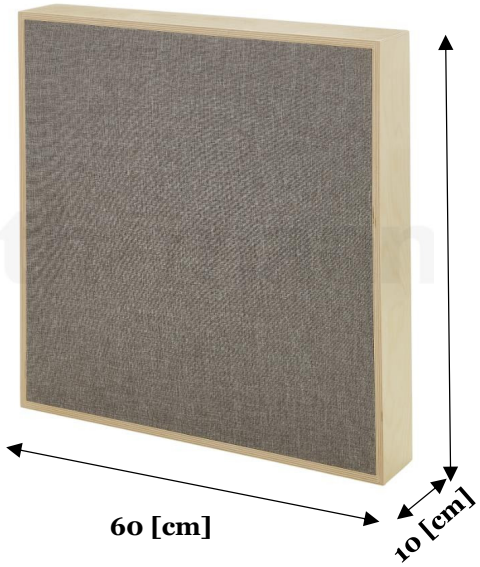

Figure 5: A 60 [cm] $\times$ 60 [cm] Spektrum A10 industrail panel used as a benchmark in this study

absorber surfaces in the room model. For fair comparison, the AMM absorber is also designed with the same 60[cm] $\times$ 60 [cm] cross-section, but with a thickness of 3 [cm]. Fig. 6 shows the performance comparisons of both absorbers. It can be observd that the AMM slighly improves the RT60 relative to the baseline in the range between 100 and 200 [Hz], but the effect at higher frequencies are very minimal. This is because the absorber is targeted for the low frequencies (≤ 200 [Hz]) and more so, the range of influence of the aborber can be increased by increasing the number of inhomogeneous unit that makes up each broadband absorber, as low frequencies are characterized by sharp narrow peaks. The Spektrum A10 on the other hand performs better at higher frequencies ($>$ 200 [Hz]) with lower RT60. Fig. 7 shows a bar plot of the reduction in RT60 relative to the baseline. It is clear that the AMM provides a superior performance in the targeted low-frequency range, and beyond this range, the Spektrum A10 provides the better performance.

4. CONCLUSIONS

This paper presents a deep learning-driven acoustic metamaterial (AMM) absorber aimed at mitigating low-frequency room acoustic issues, and compares its performance with a conventional industry-grade absorber. The

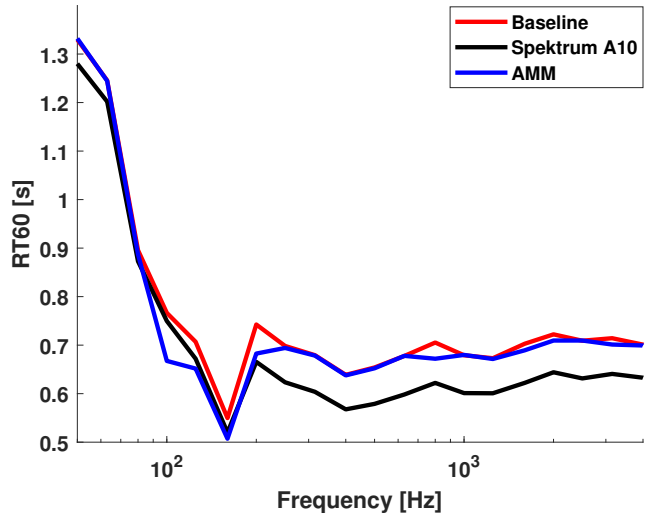

Figure 6: Performance comparison of RT60 curves from both absorbers relative to the baseline.

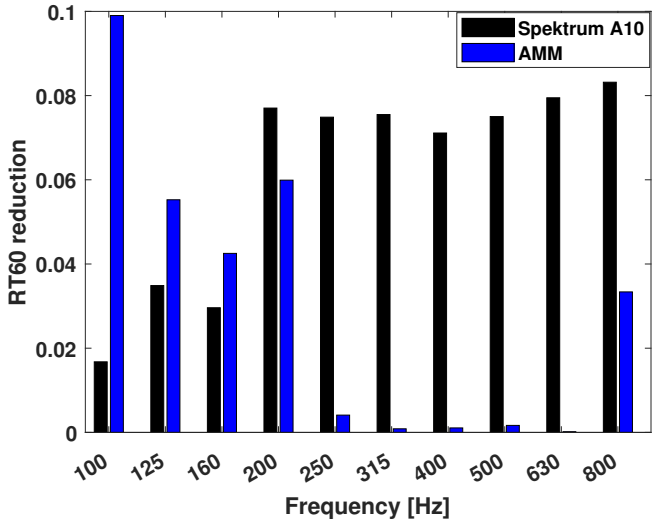

Figure 7: Relative difference in RT60 from the baseline from both absorbers in the targeted frequency range.

target environment is an existing office space that was partially evacuated and acoustically characterized using the RT60 metric.

To establish a baseline and validate the simulation framework, numerical modeling was carried out using the finite element method in COMSOL Multiphysics. Following validation, a pretrained autoencoder was employed to predict an optimal absorption spectrum in the 100–250 [Hz] frequency range. These frequency-dependent absorption coefficients were then applied to panel surfaces in the FEM model to simulate the corresponding reverberation times.

Simulation results demonstrate that the proposed AMM absorber shows promising performance within the targeted low-frequency range, with a modest reduction in RT60 compared to the untreated baseline response. However, the commercial Spektra A10 panel, with a thickness of 10 [cm], slightly outperforms the 3 [cm] thick AMM at higher frequencies above 200 [Hz]. This performance gap is primarily attributed to the limited number (four) of inhomogeneous unit cells used in constructing the broadband AMM absorber. It is anticipated that increasing the number of such units would broaden the effective bandwidth and enhance overall absorption performance over a wider operational range.

DETECTION OF OPERATIONAL REGIMERELATED FAULTS IN AIR COMPRESSOR SYSTEMS USING ACOUSTIC ANALYSIS AND MACHINE LEARNING

Andrej Hvastja **Jurij prezelj**
Faculty of Mechanical Engineering, University of Ljubljana, Slovenia

ABSTRACT

Compressed air systems are critical yet energy-intensive in industrial operations, making operational reliability essential for efficiency and safety. This study presents a novel approach using acoustic monitoring and machine learning to detect and classify operational regime-related faults in air compressor stations. Signal-processing and psychoacoustic features extracted from audio recordings enabled distinct regime identification through dimensionality reduction (autoencoders) and clustering (Gaussian Mixture Models). Regime duration analysis facilitated anomaly detection linked to operational inefficiencies. The proposed method effectively distinguished normal from abnormal patterns, highlighting regimes tied to compressed air consumption variability and equipment cycling, offering valuable improvements for predictive maintenance and reliability.

Keywords: *compressor station, acoustic monitoring, regime classification, anomaly detection*

1. INTRODUCTION

1.1 Compressed Air Systems in Industry

Compressed air is a versatile energy carrier widely used in various industrial sectors due to its applicability in numerous operational processes [1,2]. However, compressed air systems represent significant energy consumers within industrial facilities. According to [3], air compressors account for approximately 10% of industrial electricity consumption in the European Union and the USA, and up to 9.4% in China. According to [4], use of compressed air should be limited to scenarios involving safety improvements, substantial productivity improvements, or considerable labor reductions.

1.2 Economic and Operational Challenges

The operating costs of compressed air systems are predominantly due to their electricity consumption, which frequently exceeds the initial investment cost of the equipment [3, 4]. Furthermore, air compressor systems are prone to frequent faults and anomalies, making them expensive and inefficient, especially as the equipment ages [5]. Older compressors are notably susceptible to faults arising from wear and aging, highlighting the necessity for robust fault detection and diagnostic approaches [6]. In industries such as manufacturing, where machinery operates under extreme conditions and at high speeds, undetected faults can significantly disrupt production and compromise employee safety [7].

1.3 Fault Detection and Maintenance Strategies

Traditional preventive maintenance strategies, which rely on scheduled intervals, often result in premature component replacement, incurring unnecessary expenses [8].

Condition-Based Maintenance (CBM) addresses this inefficiency by monitoring the actual condition of the equipment to determine precise maintenance actions before failures occur. CBM involves tracking parameters such as vibration, acoustics, temperature, and pressure to detect early fault indicators [9].

1.4 Advantages of Acoustic Monitoring

Among various monitoring methods, acoustic sensors offer distinct advantages, including their non-contact nature, non-destructive implementation, and ease of integration into existing systems due to their compact size. The relatively low installation cost of microphones has encouraged widespread adoption for acoustic data collection in industrial environments. Despite these benefits, distinguishing

fault-related acoustic signals from background noise remains a challenge due to noisy industrial conditions [10]. Machine learning (ML) has emerged as an effective tool to address this challenge, enabling efficient analysis and interpretation of acoustic data.

1.5 Operational Regime Classification

While conventional fault detection techniques primarily address abnormalities linked to fluctuating loads and environmental factors [10], much less attention has been paid to systematically classifying operational regimes. Yet industrial performance depends not only on mechanical reliability, but also on precise scheduling and evaluation of task durations. By comparing expected task timelines with actual operational performance, discrepancies become evident, revealing potential workflow anomalies or inefficiencies. This paper tackles that gap by emphasizing the necessity of classifying operational regimes, particularly those underscored by deviations between standard task durations and real-world operational times.

2. MATERIALS AND METHODS

2.1 Data Acquisition and Preprocessing

An operating compressor station, responsible for supplying compressed air to the Faculty of Mechanical Engineering in Ljubljana, was monitored using a microphone. The sound was recorded in WAV format over several days, including both weekdays and weekends. To accurately capture continuous operating conditions, a custom Python script segmented the audio into 2-second intervals with a 50% overlap.

2.2 Feature Extraction

For each sound segment the folowing signal-processing features were computed: Root Mean Square (RMS), Zero Crossing Rate (ZCR), Crest Factor, Short-Time Energy (STE), Variance, Skewness, Kurtosis and Arc length of the signal and its derivative, effectively capturing dynamic variations in the acoustic signals.

In addition to signal-processing features, the following psychoacoustic features were also computed on the sound signal: Sharpness, roughness, tonality, loudness, fluctuation strength, as they have been shown to be effective in machine fault detection [11].

2.3 Data filtering

To ensure data quality for the unsupervised clustering of operating regimes, outlier detection was performed using Isolation Forest on the aggregated feature set. Detected outliers, representing atypical data, were removed, preserving only normal operational data for subsequent analysis.

2.4 Dimensionality Reduction with Autoencoder

A deep autoencoder neural network was used for feature set dimensionality reduction [12]. The autoencoder architecture consisted of 4 dense layers with progressively reduced dimensions leading to a latent space dimension of 3 neurons. The model was trained with mean squared error (MSE) loss, using early stopping to avoid overfitting.

2.5 Operational Regime Classification

Latent features obtained from the autoencoder were clustered using a Gaussian Mixture Model (GMM). This unsupervised clustering approach grouped similar compressor operating states based on their latent representations, effectively classifying distinct operating regimes. Model selection criteria (AIC and BIC) were used to determine the optimal number of clusters. An illustration of the GMM clustering is provided in Figure 1 below, clustering latent features into 6 classes.

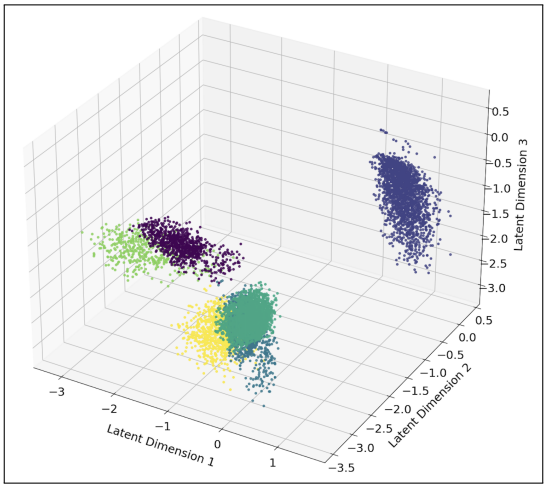

Figure 1. 6 clusters of operating regimes, based on GMM clustering.

2.6 Sequential Data Classification

The autoencoder and GMM were trained on randomly shuffled data to reduce overfitting and improve overall generality. In the second step, the same dataset was classified into identified operational regimes using the trained models. Whenever multiple consecutive sound recordings were assigned the same class, the event duration increased accordingly. However, to accurately evaluate the class or event duration, it is essential to process the recordings in their original sequence. This approach yields a feature that closely reflects the true duration of each event, and any deviation from this duration is flagged as an anomaly in the working regime.

3. RESULTS

This study examined a dataset of compressor station sound recordings spanning various operating regimes. Signal-processing features and psychoacoustic features, which capture human auditory perceptions and have been effective in machinery fault detection were derived from the sound recordings. The latent representation of the features was acquired using an autoencoder neural network and clustered using the Gaussian Mixture Model where the number of regime classes was selected using the AIC and BIC criteria.

Out of the six identified operating regimes, not all event durations are repeatable. As shown in Figure 2, the blue classes represent normal weekend operation and its typical duration range. Weekends serve as the baseline for "normal behavior" because of minimal compressed air usage. Through auditory inspection, Class 1—with its wider spread—was identified as the "working regime," as its duration varies with compressed air consumption. In contrast, Classes 0, 2, 3, 4, and 5 remain similar across weekend (normal) and weekday (test) datasets, suggesting they correspond to more repeatable operations (e.g., turning compressors on/off or switching between them). Their durations should therefore remain relatively constant, given that these transient events (start-up, shutdown, etc.) are not driven by air consumption. Consequently, any deviation from expected durations in these transient regimes may indicate abnormal behavior and signal changes in compressor station operation.

Meanwhile, the purple set of regimes was recorded when a series of tests were conducted following compressor station maintenance. These regimes, labeled "overloading" and "rest," demonstrated notably different durations, underscoring that the anomaly detection method successfully captured these unusual events.

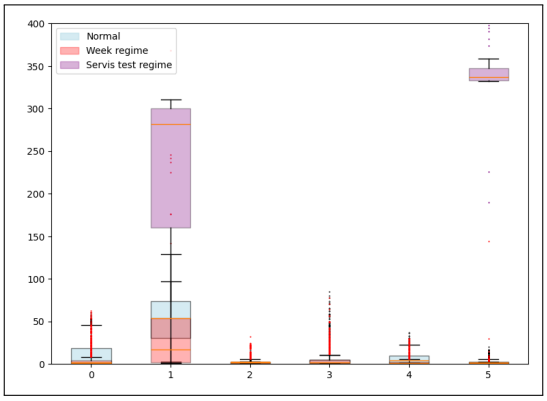

Figure 2. Event duration distribution of train (blue) and test (red) dataset.

The criteria for marking an event as an anomaly required its duration to fall below the 0.01 percentile or exceed the 0.99 percentile of the test dataset's event durations. This approach proved most effective, as it flags events that are significantly shorter or longer than expected.

Figure 3 highlights these anomalous events using golden rectangles with thin red outlines. Several anomalies occurred in Class 1, which corresponds to compressor operation tied directly to compressed air consumption, and is therefore naturally more variable. Additional anomalies appeared in Class 2, typically representing regimes expected to have consistent durations. Notably, anomalies in Class 1 diminished over time as the operational durations became shorter and returned to expected ranges.

As expected, Figure 4 illustrates that all events from the unusual "overloading" testing regime following compressor maintenance were marked as anomalies. This confirms the method's sensitivity and effectiveness in accurately detecting operational deviations.

4. CONCLUSION

This study demonstrated the effectiveness of acoustic monitoring combined with machine learning for detecting operational regime-related faults in air compressor systems. By extracting and analyzing signal-processing and psychoacoustic features from compressor sound recordings, distinct operational regimes were successfully iden-

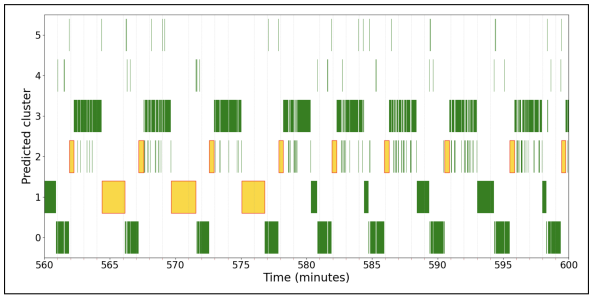

Figure 3. Work regime classes with corresponding durations.

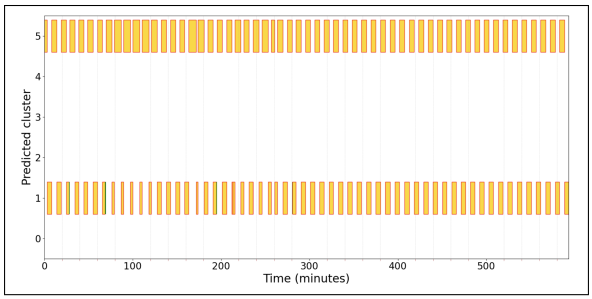

Figure 4. Overloading testing regime classes with corresponding durations.

tified using dimensionality reduction with autoencoders and clustering via Gaussian Mixture Models (GMM). The approach enabled the detection of anomalies based on deviations in regime durations, which were shown to correspond closely to actual operational events. Particularly, it was found that regimes associated with variable compressed air consumption exhibited significant variability in duration, whereas regimes related to equipment cycling and switching were highly consistent. Future work may focus on integrating this method into real-time monitoring systems to further enhance predictive maintenance and operational reliability in industrial compressor stations.

MONITORING OF MANUFACTURING PROCESS USING UNSUPERVISED SOUND EVENT CLASSIFICATION WITH APPLICATION OF SOUND DIRECTIVITY

Jurij Prezelj[1*] **Andrej Hvastja**[1] **Tomaž Berlec**[1]
[1] University of Ljubljana, Faculty of Mechanical Engineering, Slovenia

ABSTRACT

This study explores the use of sound directionality (DOA) as a key feature for unsupervised classification of acoustic events in industrial environments. A novel methodology was developed, combining a custom microphone array with SubWindowing to extract directional, spectral, and statistical features from production noise. Acoustic events were clustered using the k-means algorithm, with the optimal number of clusters determined via the elbow and silhouette methods. Feature importance was evaluated using Principal Component Analysis (PCA), which consistently identified sound directionality as the most influential feature. The results showed that integrating DOA significantly improved clustering performance and enabled accurate identification of machine states. The detected clusters aligned well with manually recorded operational states, confirming the method's effectiveness. This approach offers a robust and interpretable framework for real-time monitoring and fault detection in industrial settings. Future work will focus on extending this method to predictive maintenance systems and broader manufacturing environments.

Keywords: *acoustic event classification, sound directionality, unsupervised learning, k-means clustering, industrial monitoring*

1. INTRODUCTION

Current machine learning approaches for acoustic event classification in industrial environments typically rely on spectral, statistical, and temporal features. Traditional supervised methods have been widely applied, but unsupervised techniques, such as k-means clustering, are gaining traction due to their ability to classify unlabeled data and reduce dimensionality in high-dimensional datasets [4]. For instance, Ding and Li [4] proposed a feature selection framework for k-means, while Sun and Wang [5] introduced improvements via an ADMM algorithm to enhance clustering performance. Coates and Ng [6] also emphasized the role of k-means in feature learning, particularly due to its simplicity and effectiveness.
In audio classification specifically, deep learning methods have been reviewed by Mesaros et al. [7], highlighting the importance of robust feature representation. However, these methods largely overlook spatial acoustic features, such as sound directionality, also known as Direction of Arrival (DOA). Despite its well-known role in human perception, evident in the "cocktail party effect", DOA remains underexplored in unsupervised learning pipelines for acoustic event classification [2]. Base on literature review and our expertise we identified a research gap, placed a hypothesis, detect challenges and placed objectives of this study.
Research Gap: Current machine learning approaches for acoustic event classification typically rely on spectral, statistical, and temporal features. However, the role of sound directionality has been underexplored as a key feature for classification. Despite the relevance of directionality in distinguishing sound sources, it remains inadequately studied within unsupervised learning models, such as k-means clustering, for acoustic event classification [2].

Hypothesis: Incorporating DOA as a core feature can significantly improve clustering performance and enable more accurate detection of machine states and process deviations in industrial environments.
Challenges: Accurate measurement of DOA requires precise sensor arrays and fast-response algorithms (<50 ms). Another challenge lies in combining DOA with time–frequency features into a unified feature set and validating its impact using robust dimensionality reduction methods such as Principal Component Analysis (PCA).
Objective:
This study aims to investigate the role of DOA in the classification of acoustic events using unsupervised learning, specifically focusing on k-means clustering.

2. METHODOLOGICAL OVERVIEW

The classification system developed in this study consists of three main stages: (1) data acquisition using a custom-designed differential microphone array, (2) feature extraction incorporating both time–frequency and directionaly DOA, and (3) unsupervised classification using the k-means algorithm. To enhance temporal resolution, a SubWindowing technique was used to segment the acoustic data. Features were extracted from both time and frequency domains, including Direction of Arrival (DOA) information computed via beamforming algorithms. Dimensionality reduction techniques such as Principal Component Analysis (PCA) was employed to assess feature importance and ensure model interpretability. The proposed system enables precise spatial classification of acoustic events and supports real-time monitoring in industrial environments.

2.1 Feature Extraction

The feature extraction process is a critical step in the overall methodology, converting raw sound signals into meaningful descriptors that can be used for clustering and classification. Key features are extracted from both the time and frequency domains. Spectral features such as spectral centroid, spectral bandwidth, spectral flatness, and spectral roll-off are calculated for each SubWindow segment. Temporal features, including Zero-Crossing Rate (ZCR), Root Mean Square (RMS) energy, and Sound Pressure Level (SPL), are also extracted. Additionally, statistical features like skewness, kurtosis, and entropy are computed to capture distributional properties of the signal. A unique contribution of this study is the inclusion of sound directionality as a feature, which is derived from the microphone array's spatial configuration. This information is combined into a feature vector representing each time segment, enabling a comprehensive representation of the acoustic event.
The feature set is subsequently refined using dimensionality reduction techniques, including Principal Component Analysis (PCA), to identify and retain only the most influential features for clustering

2.2 Time Intervals of feature extraction and their integration

In industrial acoustic environments, sound signals are inherently complex. They are composed of a combination of impulsive, transient events, such as impacts, cutter engagements, or part drops, and longer lasting background or cyclical machine operations. Capturing this full acoustic landscape using a single fixed time resolution would either miss rapid changes or smooth over important long-term patterns. To address this, we implemented a dual-time-constant segmentation strategy, which enables the extraction of both fast-evolving and slowly varying features from the signal.

2.2.1 Motivation for the Approach

The main rationale behind this two-level segmentation was to construct a feature representation that simultaneously captures the detail of transient events and the consistency of long-term operational patterns. Many machine learning models fail to distinguish between these layers of acoustic behavior when using a single time scale, which leads to suboptimal clustering or misclassification of machine states. By layering feature extraction over both short and long intervals, we aimed to provide the unsupervised algorithm with richer and more distinguishable patterns for clustering.
This approach mirrors human auditory perception, where the brain reacts to sudden sounds immediately while also tracking longer sequences and rhythms over time. The short segments allow us to detect quick, local fluctuations in sound energy or frequency, while the longer segments offer context highlighting how those fluctuations develop over time.

2.2.2 Short-Term Segmentation (τ_z)

The sound signal was initially divided into short overlapping windows of duration τ_z. These segments were small enough to preserve detail on the time scale of tens of milliseconds, suitable for detecting tool strikes or abrupt machine transitions. For each τ_z segment, we applied a Short-Time Fourier Transform (STFT) to compute sound pressure level (SPL) values across multiple frequency bands. This frequency-domain representation was essential for identifying spectral structures linked to different

machine behaviors. The use of overlapping windows ensured smoother transitions between adjacent segments, preventing the loss of critical information at boundary points and improving temporal continuity in the feature space.

2.2.3 2.2.3 Long-Term Aggregation (τ_k)

To build a higher-level representation, we grouped i consecutive τ_z segments into a longer interval $\tau_k = i \cdot \tau_z$. Within each τ_k block, a set of statistical metrics was computed for every frequency band and acoustic feature:

- Mean: representing the average energy or behavior in the interval,
- Range: capturing variation or dynamics,
- Standard deviation and variance: indicating spread or instability,
- First-order temporal derivatives: highlighting changes and slopes.

This allowed us to extract a macro level picture of the evolving sound environment, revealing whether the machine operation was stable, variable, cyclic, or anomalous.

2.2.4 2.2.4 Temporal Derivatives and Spectral Dynamics

To further enrich the feature set, we computed temporal derivatives (differences between adjacent τz segments) for each SPL value, capturing short-term dynamics like rising or falling spectral power. These were aggregated in the same way as raw SPL values, maintaining the temporal structure of the sound while enabling detection of directional changes in signal characteristics.

We also calculated the spectral length for each frequency band, defined as the cumulative distance (or variation) between successive SPL values. This served as a descriptor of spectral "activity" or instability, providing a useful contrast between steady and fluctuating sounds.

2.2.5 2.2.5 Feature Matrix Construction

The final step involved concatenating all extracted descriptors—spectral, temporal, statistical, and derivative-based—within each τk interval into a composite feature vector. These vectors formed the rows of the feature matrix used for unsupervised clustering with the k-means algorithm. Importantly, we later appended the direction of arrival (DOA) features (see Section 2.3) to this same matrix, enabling the clustering to incorporate both spectral content and spatial origin.

This dual-time approach, illustrated in Figures 1 and 2, ensured that the model could effectively group acoustic events that were similar not only in sound quality, but also in time structure and directional behavior—essential for robust classification in complex industrial soundscapes.

$$L = \sum_{j=1}^{N-1} \sqrt{(\Delta f)^2 + (Lp_{j+1} - Lp_j)^2} \quad (1)$$

By using this methodology for the analysis of acoustic data, numerous features of the sound can be extracted from the frequency domain. Furthermore, by transforming the data into a new time constant, it is possible to derive features that also describe changes in the time domain. This dual-domain approach ensures that both rapid and gradual changes in sound are effectively captured, thereby improving the clustering and classification of acoustic events.

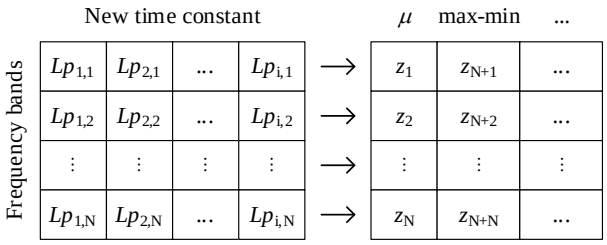

Figure 1: Grouping i[th] time steps into a time constant τk for each frequency band.

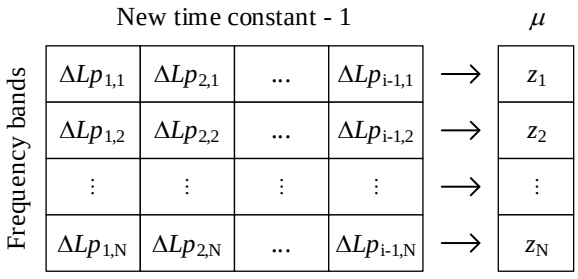

Figure 2: Grouping (i-1)[th] derivatives into a time constant τ_k for each frequency band.

2.3 Directionality (DOA) Estimation with SubWindow Beamforming

The process of measuring immission directivity necessitates the use of a microphone array and a beamforming algorithm, tools that aid in localizing sound sources or determining the Direction Of Arrival (DOA) of sound. Differential Microphone Arrays (DMAs), a distinct subset in sound localization, have emerged as the most appropriate beamforming method for a variety of applications that require speech recognition over the past decade. These applications include hands-free systems, mobile phones, and hearing aids. Circular DMAs have undergone extensive

examination for speech and audio applications, primarily due to their adaptability in control, the capacity to establish frequency-invariant directivity patterns, and superior directivity factor [8] Their inherent benefits include significant beam alignment, frequency independence, and a compact geometrical configuration Several models have been constructed where all the first-order DMA computations are conducted in the time domain. This approach offers a crucial advantage - the computations exhibit minimal latency. This feature is particularly vital and advantageous in real-time applications [9, 10, 11]. The principle of merging microphone signals from a circular array [12] sparked the development of our unique algorithm [13, 14, 15, 16, 17]. This algorithm, designed to compute the DOA, utilizes a simplified method based on timed delay cascading pairs, as depicted in figure 3 and given by Eq. (2). to form a DMA.

$$argminj = \|\sum_{i=0}^{D}\left[x_{\mathrm{mic1}}(n) - x_{\mathrm{mic2}}\left(n - \frac{D}{2} + i\right)\right]^2\|_{j=1}^{N} \quad (2)$$

The differential beamforming algorithm based on sub-windowing (SubW-DBA), is developed for this application and is described in our previous work [13] SubW-DBA has an advantage in that it is not limited to the low-frequency range, at least theoretically. In practice, the low-frequency limit is defined by the phase matching of the microphone pairs. The high-frequency limit depends on the nature of the sound. If the sound is random, there is no frequency limit. If the sound is harmonic, the boundary is at the distance between the microphone pairs, like the usage of sound intensity probes.

The algorithm defined in Eq. (2) was used to compute the instantaneous DOA to experimentally verify the hypothesis that the 2D immission directivity pattern can be obtained by associating the instantaneous total sound level (SPL) with the instantaneous dominant direction (DOA) during sub-windowing. The objective is to compile a collection of immission vectors from which an immission directivity pattern can be derived through consistent integration/averaging of the immission vectors. $x_{mic,1}(n)$ and $x_{mic,2}(n)$ in Eq. (2) represents the signals from microphone 1 and microphone 2 respectively. N denotes the number of directions. D is the number of samples in the observed window. The minimum value of D is defined by the speed of sound c, the sampling frequency f_s and the distance between two microphones, which determine the time resolution of direction detection. Index i represents the steering value, i.e., Δn, which is proportional to the time delay $\Delta\tau$.

$$D_{min} = \frac{X_{mic} f_s}{c} \quad (3)$$

For the fastest possible response of detecting the direction of arrival M = N.

$$\Delta t_{min} = \frac{D_{min}}{f_s} \quad (4)$$

Using a differential array with four microphones and a diameter/side length of 0.04 m, it is possible to shorten the length of the direction detection subwindow to 0.232 ms. Shortening the subwindow to 0.232 ms provides 44 signal values for calculating the DOA of the dominant sound source. If the signals from two microphones placed 40 mm apart are recorded at a sampling rate of 192 kHz, then 22 samples are needed to arrange the signals for the maximum delay for each direction, and thus the time resolution of detecting the dominant direction is 0.232 ms.

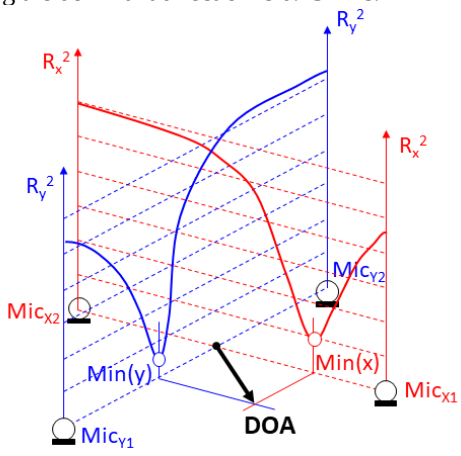

Figure 3: Differential microphone array of the first order, used during the experiment. Two pairs were used for the calculation of DOA on the immission plane.

2.4 Experimental setup

To optimize the quality of the acoustic data, a specific part of the production facility was selected, focusing primarily on the area where aluminum profiles are cut and processed using CNC (Computer Numerical Control) machinery. This decision assumed that these processes would produce distinguishable and characteristic sound signatures suitable for efficient clustering using the k-means algorithm.

The recording site was strategically positioned among seven cutting machines where incoming aluminum profiles are cut and mechanically processed before being automatically stacked into metal containers by handling robots. This location was chosen because it provided a rich source of distinctive mechanical sounds while being sufficiently

distant from the cluster of CNC machines, thereby reducing potential background noise interference.

To further minimize sound reflections and possible echo effects that could distort the acoustic data, the array of microphones was placed in an open area, as far away from wall surfaces as possible. The arrangement of microphones was carefully planned to avoid obstructing factory operations while ensuring the placement did not interfere with worker movement or the transit of forklifts. The selected recording site is depicted in figure. 5, where the observed machines are labeled from 1 to 7. The microphone array was oriented according to the layout shown in the figure.

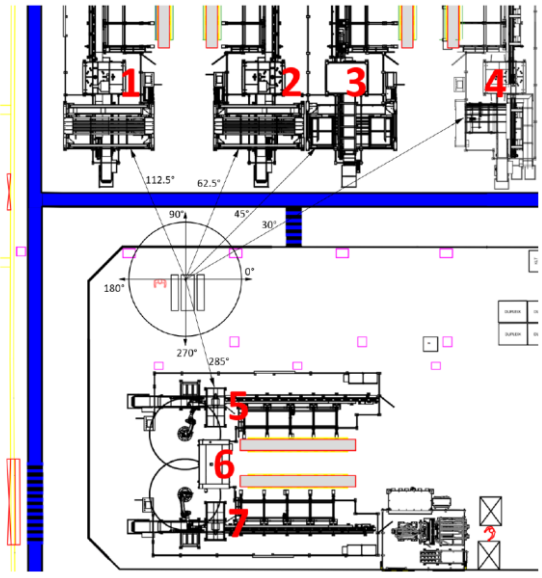

Figure 5: Recording site layout

Based on the microphone configuration, the expected orientation of the dominant sound during the operation of each machine was calculated. For machine 1, the sound direction was expected to be between 110° and 120°, for machine 2 it was estimated between 60° and 65°, and for machine 3, around 45°. Machine 4 was expected to have a dominant sound direction of around 30°, while machines 5, 6, and 7 had dominant sound directions expected to fall between 270° and 290°.

The machines being observed were expected to produce sharp, steady-frequency sounds caused by the milling cutter, as well as loud impulsive sounds generated when aluminum pieces were dropped into metal containers. To capture these sound events effectively, four omnidirectional microphones with polarized 6.35 mm condenser capsules were utilized. These microphones had a frequency range of 20 Hz to 20 kHz and a maximum sound pressure level (SPL) of 132 dB. The microphones were mechanically linked at equal distances to facilitate the calculation of the dominant sound direction.

The system also included a Behringer soundboard for initial pre-amplification and signal merging. For data storage, a simple signal acquisition program was developed using the LabVIEW software environment. This comprehensive setup ensured high-quality data acquisition, enabling the accurate capture of essential sound properties for subsequent feature extraction and clustering analysis.

3. RESULTS

Figure 6 presents a typical 30-second sound recording from the production environment. The upper panel shows the spectrogram, illustrating the spectral energy distribution over time. Several high-energy broadband events are visible, especially between seconds 4–6, 10–12, 17–18, and 23–25, which correspond to distinct mechanical actions such as cutting or part ejection.

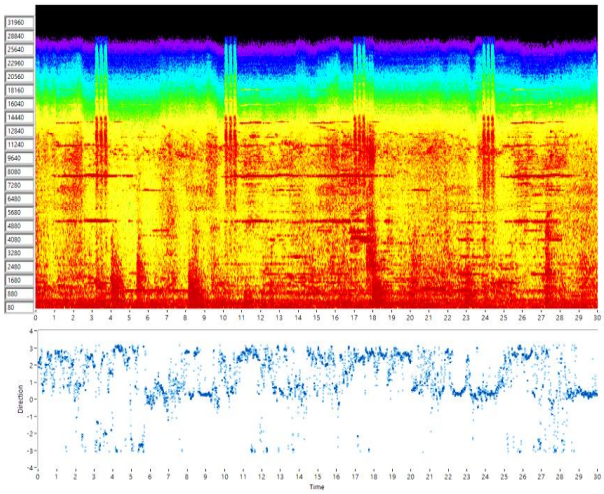

Figure 6. Spectrogram of a typical 30-second recording segment from the manufacturing process (top), with extracted dominant sound directions plotted below (bottom). The spectrogram displays energy distribution across frequencies, while the blue dots in the lower plot represent the instantaneous direction of arrival (DOA) of the sound.

The lower panel of the figure displays the corresponding instantaneous direction of arrival (DOA) of the dominant sound source, extracted using the SubWindow-DBA algorithm. The DOA estimates exhibit clustered patterns in both time and angular space, indicating repeated events

with consistent spatial origin, likely associated with recurring machine actions. Notably, transitions in DOA correspond well with changes in spectral content, affirming the relevance of including directionality as a classification feature.

This visualization supports the hypothesis that directionality provides an orthogonal, highly discriminative feature not captured by traditional spectral descriptors. The events clustered in the spectrogram are reinforced by clear directional patterns in the lower plot, validating the importance of sound directionality for distinguishing machine states. This correlation is consistent with the PCA results (Fig. 7), where DOA was identified as the most influential feature.

3.1 Identification of the Most Influential Features Using PCA

Typica spectrogram, together with extracted direction of Arival (DOA) in blue dots is presented in figure 6 above. To identify the most influential features in the dataset, a PCA analysis was employed. This process provided an assessment of the importance of each feature, which were then ranked according to their significance and the fifteen most important are displayed in Figure 7.

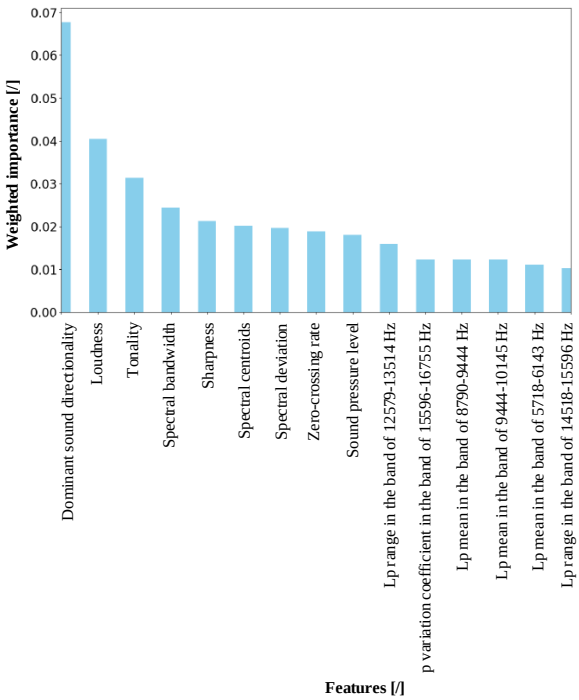

Figure 7: Weighted importance of the 15 most influential features below.

The graph reveals a decline in the weighted importance of features after the first few. This visualization serves as a useful tool for selecting and recognizing features. It helps to assess whether certain features contribute meaningfully to the quality of the data input or if they represent unnecessary noise. Figure 7 further allows for a clear understanding of which features contribute most significantly to the diversity of the data.

The analysis shows that the dominant feature is sound directionality. It has by far the highest weighted importance. This result is expected, as it is the only feature not directly derived from the sound signal itself and the only one that does not describe the characteristics or quality of the sound. Consequently, it has the lowest correlation with the other features, thereby contributing the most to the diversity of the data - a key aspect for successful classification. Following the dominant sound directionality, other key features calculated at the time constant τk=1 second, such as loudness, tonality, and spectral characteristics, also rank highly.

Next, a set of features derived from the frequency domain at a shorter time constant τ_z=50 milliseconds follow in terms of importance. Among these features, those describing higher frequency bands have the most significant influence. While these individual features do not possess high weighted importance on their own, together they still contribute significantly to the diversity of the data. This contribution underlines the relevance of combining features from different time scales and frequency ranges, ensuring the model captures both short-term and long-term acoustic patterns crucial for effective classification.

The optimal number of clusters for the k-means method can be determined in several ways. One common approach is an iterative trial-and-error method, where clustering begins with two clusters and gradually increases the number of clusters, observing changes in the classification results. The process continues until adding more clusters and no longer provides new information about the dataset. Another widely used approach involves the use of formal methods, such as the elbow method and the silhouette coefficient method, to identify the optimal number of clusters.

3.1.1 Elbow Method

The elbow method is visualized through a graph, as shown in Figure 8, which plots the sum of squared distances within each cluster as a function of the number of clusters *k*. The "elbow" of the curve is the point where the rate of decrease in the sum of squared distances slows down significantly, indicating that adding more clusters provides diminishing returns in reducing within-cluster variability. For this

particular study, the elbow can be observed around k=3 or k=4, as the addition of clusters beyond this point results in only marginal reductions in the total within-cluster sum of squares. This observation suggests that selecting 3 or 4 clusters would provide an optimal balance between simplicity and classification performance.

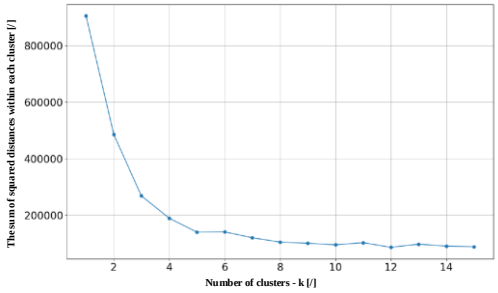

Figure 8. Elbow method graph for finding the optimal number of clusters - *k*.

3.1.2 Silhouette Coefficient Method

The silhouette coefficient method offers another perspective on selecting the optimal number of clusters. The silhouette coefficient measures how similar an object is to its own cluster compared to other clusters. A higher silhouette score indicates well-defined clusters. The silhouette graph for the data used in this study is presented in Figure 9. The peak of the graph is observed at k=2, indicating that, at this point, the clustering achieves the highest coherence of points within clusters. However, dividing the data into only two clusters limits the classification utility, as it would only distinguish between operational and non-operational states of the production process. This segmentation could still be useful for monitoring downtime, including pauses, breaks, and shift changes.

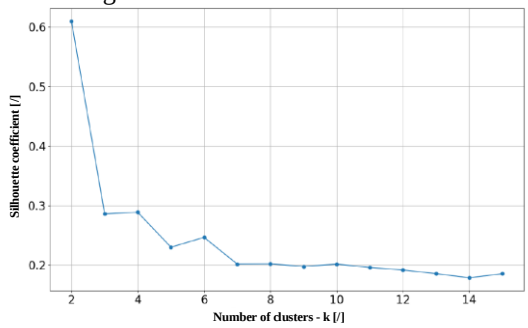

Figure 9. Silhouette coefficient graph for finding the optimal number of clusters - *k*.

As the number of clusters increases, the silhouette score gradually decreases, but it remains above zero, indicating that the cluster structure is still meaningful even with a larger number of clusters. Notably, local peaks are observed at k=4 and k=6, which correspond to improved clustering results relative to other values of k. Given that the elbow method also indicated a clear break at k=4, it can be inferred that selecting k=4 would provide the most interpretable and effective clustering solution for this dataset. This selection ensures a balance between model simplicity and classification accuracy, offering meaningful segmentation of acoustic events within the production process.

4. CONCLUSIONS

Based on the conducted research and the obtained results , the main findings can be summarized as follows:

1. We successfully classified acoustic signals using the k-means algorithm, effectively grouping the data into meaningful clusters based on their features. Initial classification was performed with k=4 clusters, followed by a refined analysis with k=6 clusters.
2. The feature extraction process was based on a methodology where frequency domain characteristics were derived at a lower time constant τ_0=50 ms. These features were then aggregated using various merging methods to form a higher time constant τ_k=1 second, thereby capturing time-domain properties as well.
3. Principal Component Analysis (PCA) was employed. A dimensionality reduction technique facilitated better organization of the data in a multidimensional space, ultimately improving the classification efficiency of the *k*-means algorithm.
4. It was found that the k-means algorithm was unable to capture all anticipated acoustic patterns, which can be attributed to the algorithm's limited generalization capabilities. Certain specific acoustic patterns, which are critical for a comprehensive understanding of machine operation, remain undetected.
5. The results indicate that the choice of the number of clusters *k* plays a crucial role in classification quality, but at the same time, it is challenging to determine objectively. The application of PCA to identify the most influential features revealed that the directionality of the dominant sound is the most important feature. This finding was expected since this is the only feature not directly derived from the sound signal and the only one that does not describe the sound's properties or quality. Consequently, it has the lowest correlation with other features and contributes the most to data variability, which is essential for successful classification. By implementing the PCA on the extracted features, we confirmed the hypothesis that the direction of the sound event is a significant feature that

should be included in classification algorithms for acoustic event detection.

The study demonstrated that the k-means algorithm is suitable for basic classification of acoustic signals in production environments, but it has limitations that require further investigation to achieve a more comprehensive capture of all acoustic patterns. Our study contributes to a better understanding of the applicability of classification algorithms in real-world industrial environments.

4.1 Suggestions for Future Work

Based on the findings of this study, it would be beneficial to explore the use of other unsupervised learning methods that were not considered in this research. While this study focused on the classification of specific acoustic patterns, future research could investigate longer periods of production operation and place greater emphasis on macro-level events. Additionally, efforts could be made to quantitatively assess the relative productivity of the production process over time. This broader perspective would provide a more comprehensive understanding of operational efficiency and help identify potential areas for optimization.

ABSTRACT

The Column Type Electric Power Steering (C-EPS) system consists of a motor, a reduction gear, and bearings that ensure structural stability and minimize friction. Noise in rotating systems mainly arises from motor noise, component defects, and frictional sounds caused by rotational dynamics.

Operational noise defects are typically managed within regulatory thresholds. Recently, machine learning-based anomaly detection models have gained popularity, often relying on labeled datasets for training. However, this process demands substantial human and time resources for labeling, and distinguishing between noise types remains a significant challenge.

In response to these challenges, this study introduces a method that preprocesses noise input data using Short-Time Fourier Transform (STFT), utilizes unsupervised learning for data encoding, and applies clustering to generate labels. The effectiveness of the proposed approach is demonstrated through a validation process.

Commonly Mel-spectrogram and MFCC transformations are used for AI noise input, but bearing noise often exhibits distinct high-frequency features. STFT was chosen to preserve high-frequency characteristic without attenuation. Various unsupervised learning techniques were utilized to encode the noise data effectively. As the goal was clustering rather than generation, and C-EPS noise shows limited temporal variation, experiments identified Convolutional Autoencoder as the effective unsupervised learning method for mapping noise.

1. INTRODUCTION

As shown Fig. 1, the steering system required to steer in a vehicle is divided into three main parts: the steering gear system that changes the rotational force into linear force, the Column Type Electric Power Steering system (C-EPS) [1] that helps the driver to steer with the power of motor [2] and the universal joint that connects the steering gear system and C-EPS. Among them, as shown Fig. 2, the C-EPS which consist of motor and the reducing gear system causes a lot of noise problems. In general, these noises cause emotional quality degradation to customers who drive the vehicle, which incurs steady field claim costs to companies. [3] One of the consistently problematic noise issues in C-EPS originates from the bearings in the worm shaft system. This bearing-induced noise can be broadly classified into frictional noise and rotational noise. However, there are limitations in detecting it using conventional quantitative noise indicators such as overall level and order noise level. Recently, supervised learning-based machine learning models have been introduced for anomaly detection. However, these methods still rely on subjective human evaluations, and there are ambiguous cases where classification based on subjective assessment is challenging. As a result, the accuracy of labeling inherently suffers, and a significant human resource is required. In addition, conventional quantification methods such as overall level

and order-based filtering are limited in effectively analyzing bearing noise in C-EPS systems.

Consequently, this study aims to identify an optimized model for detecting bearing noise defects in C-EPS using an unsupervised learning approach. In addition, the labeling of bearing noise based on unsupervised learning can be further utilized in combination with supervised learning and explainable AI (XAI) to establish new criteria. In other words, it enables the development of an end-to-end model capable of generating noise specifications even in the absence of prior knowledge about the noise characteristics.

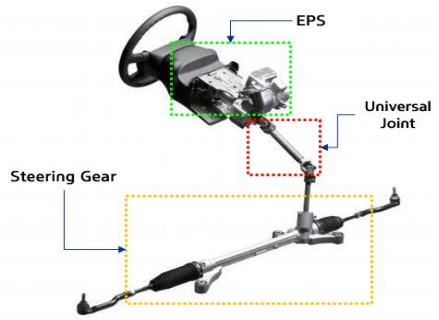

Figure 1. Composition of steering system of vehicle

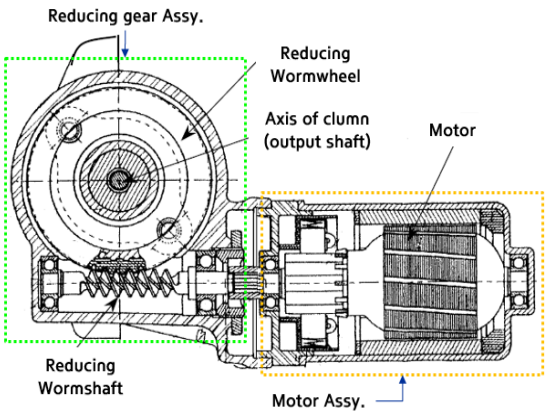

Figure 2. C-EPS Structure Diagram

2. EVALUATION OF NOISE AND VIBRATION

2.1 Evaluation Method

To measure the operational noise of the C-EPS, tests are conducted under constant velocity or constant acceleration conditions using equipment that controls the torque while considering the real vehicle conditions of the input and output, as shown in Fig. 3. As shown in the STFT colormap of the C-EPS operational noise in Fig.4, the advantage of constant acceleration evaluation is that it enables the identification of frequency characteristics across a range of rotational speeds in a single test. Reflecting this advantage, constant acceleration evaluation is commonly selected for assessing abnormal noise in rotating systems.

For the evaluation, both a microphone and multiple accelerometers were used to capture noise and vibration signals. The accelerometers were attached to the motor center, the motor lower area near the defective bearing, and the worm shaft. The reason for including accelerometer measurements was to ensure the applicability of the model not only during development but also in the production stage, where microphone-based measurements are often not feasible in End-of-Line environments.

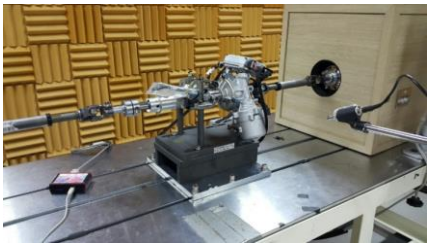

Figure 3. Evaluation setup for operational noise

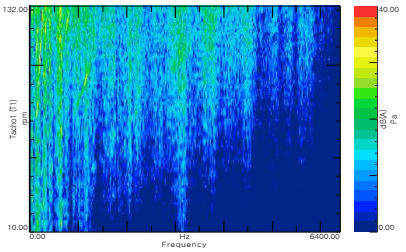

Figure 4. Colormap of the STFT Spectrogram

2.2 Description and analysis of noise

The bearing located at the upper end of the worm shaft, which is in contact with the motor, is subjected to a high load. Therefore, even minor defects can cause noise issues, which are generally classified into friction noise and rotational noise. Friction noise typically occurs when foreign substances such as aluminum particles or grease enter the bearing, whereas rotational noise is generated when there is damage to the raceway surface. Friction noise is characterized by broad-band frequency components that

are independent of rotational speed. In contrast, rotational noise exhibits prominent order components that vary with speed.

In general, noise regulation is based on problematic order components and overall level, and the operational noise of C-EPS systems is also quantified using these two criteria. As shown in Table 1, the detection performance based on the overall level indicates that the microphone sensor failed to capture more than 50% of the bearing noise cases. The accelerometer attached to the motor lower section detected rotational noise with an accuracy of 61%, but was less effective for frictional noise, detecting only around 34%. Notably, the accelerometer placed at the motor center detected less than 15%, which is likely due to strong reflections of motor-specific characteristics. Theses results suggest that proper sensor placement is critical for effectively detecting bearing noise. Additionally, detection rates based solely on order components were extremely low and therefore not included in the table.

Table 1. Detection performance according to Noise type based on overall RMS thresholding (O/A)

	detection rate [%]	
Sensor type and Location	Rotation	Friction
MIC O/A	54.3	33.1
Motor Center Acc O/A	20.4	9.2
Motor Lower Acc O/A	67.7	44.2
Worm Shaft Acc O/A	59.1	39.9

2.3 Data preprocessing

Although the STFT is commonly used for preprocessing bearing operational noise, various preprocessing techniques including Mel spectrogram, Mel Frequency Cepstral Coefficients (MFCC), and Continuous Wavelet Transform (CWT) were applied in this study to prepare the data as input for machine learning models.

Mel Spectrograms and MFCC are widely used feature representations in audio signal processing, particularly in machine learning-based approaches. Mel spectrograms provide a time-frequency representation based on Mel scale, which reflects the non-linear perception of pitch.[4] MFCC, in contrast, captures perceptually relevant characteristics by modelling the human auditory system and is effective for extracting timbral features.[5] Both techniques have been extensively applied in speech recognition, acoustic scene analysis, and environmental noise classification, serving as standard input features for various learning models.[6] As shown in Figure 5, the average colormaps of MFCC and Mel spectrogram for each noise type indicate that MFCC fails to reflect the timbral differences of bearing noise, and the Mel spectrogram similarly does not sufficiently highlight distinctive frequency characteristics compared to STFT. This is likely because both preprocessing methods apply scaling in the high-frequency range, resulting in dimensionality reduction that diminishes the high-frequency characteristics of bearing noise. Therefore, it was concluded that these methods offer no clear advantage over STFT in preserving the high-frequency characteristics of bearing noise.

And CWT is effective for preprocessing impulsive or transient signals due to its ability to capture localized time-frequency characteristics with high resolution. This makes it a suitable choice for fault detection tasks where short-duration, high-frequency components are critical.[7] As shown in the CWT colormaps for each noise type in Figure 5, the characteristic order components of rotational noise appear too be suppressed by the CWT representation. Considering these characteristics of CWT, it was concluded that STFT is more effective in capturing the features of both rotational and frictional noise.

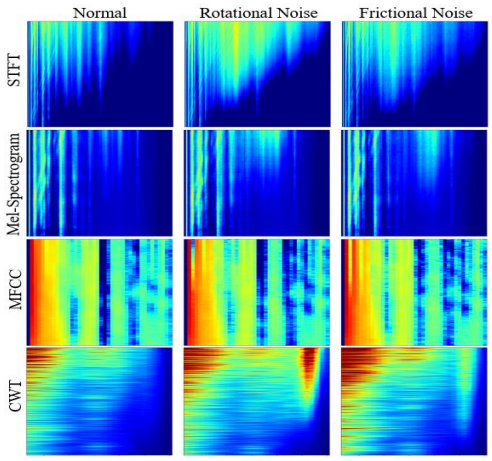

Figure 5. Average colormaps of each preprocessing method according to bearing noise defect types

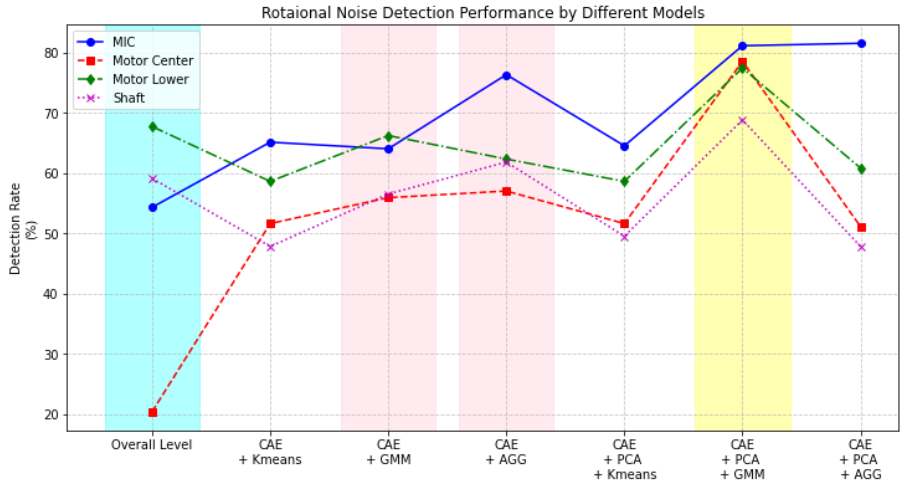
3. UNSUPERVISED LEARNING

3.1 Unsupervised Learning

To embed the input data preprocessed using STFT through unsupervised learning, several models were employed, including Convolutional Autoencoder (CAE), Cluster GANs, Variational Autoencoder (VAE), ResNet-18 and LSTM-CNN Autoencoder. Since the primary objective of



this study is clustering rather than generation, and the rotational noise signals exhibit minimal temporal variation, the experimental results suggest that the CAE is the most suitable architecture for unsupervised mapping of operational noise in C-EPS bearing.[8]

3.2 Clustering

For clustering the latent features extracted by the convolutional autoencoder (CAE), we utilized Gaussian Mixture Models (GMM), K-means, and Agglomerative Clustering (AGG). Among the clustering methods applied to the CAE-extracted embeddings, as shown Fig.6, the GMM and AGG achieved notably better separation of frictional and rotational anomalies compared to K-means. The improved performance of GMM and AGG can be attributed to their flexibility in modeling non-spherical clusters, robustness to boundary ambiguities, and ability to capture complex structure in high-dimensional acoustic feature spaces.[9] Furthermore, it was observed that applying Principal Component Analysis (PCA) to the latent representations extracted by the CAE further improved the detection performance when combined with GMM clustering.[10] These results are considered to stem from PCA's ability to reduce noise and redundancy in the CAE-derived embeddings, thereby improving the separability of clusters in the GMM process. In conclusion, the results in Table 2 demonstrate that GMM clustering, when applied after sequential embedding via CAE and PCA, substantially improves the detection rate compared to the baseline approach based on overall level. The calculated value represents the proportion assigned to the two clusters classified as defective products through clustering, rather than as normal ones. Although the detection performance of unsupervised learning does not surpass that of supervised approaches, it offers greater potential in capturing previously unseen frictional or rotational noise. This is particularly important in real-world applications, where ambiguous acoustic anomalies often lack clear boundaries, and the initial labeling process is prone to subjectivity. Therefore, the level of detection performance achieved in this study is considered highly meaningful and practically valuable. Accordingly, in situations where no alternative indicators beyond overall level or order level are available, the proposed model can be recommended for detecting bearing-related noise.

Table 2. Detection performance by noise type based on overall RMS thresholding (O/A) versus CAE-PCA-GMM (C.P.M)

		Detection rate [%]	
Sensor	Method	Rotation	Friction
MIC	O/A	54.3	33.1
	C.P.M	81.1	76.1
M. Center (Acc)	O/A	20.4	9.2
	C.P.M	78.5	54.6
M. Lower (Acc)	O/A	67.7	44.2
	C.P.M	77.4	63.8
Worm Shaft (Acc)	O/A	59.1	39.9
	C.P.M	68.8	52.8

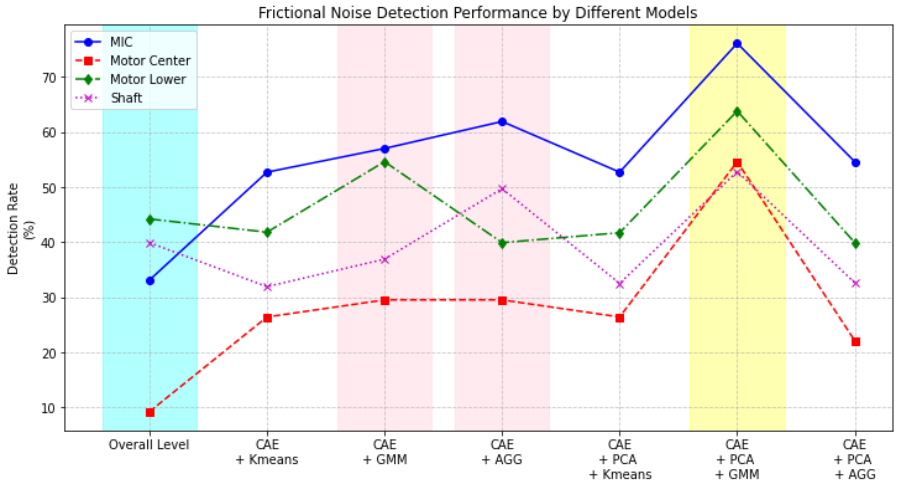


Figure 6. Detection rates for rotational and frictional noises using unsupervised learning with different clustering

3.3 End-to-End model for feature extraction

In addition to performing anomaly detection using unsupervised learning and clustering, the label sets obtained through these unsupervised approaches can further be utilized to enable supervised learning and XAI. This allows for the extraction of class-specific feature maps corresponding to different types of bearing noise. The overall framework can thus be the end-to-end model for extracting discriminative feature maps of bearing noise. As shown in Fig. 7, the process begins with STFT-based time frequency transformation, followed by dimensionality reduction through CAE and PCA. Unsupervised learning with GMM clustering yields label sets, which are then utilized to train a supervised classification model. Finally, XAI methods are applied to interpret the learned representations and extract feature maps associated with each noise type. Initially, both the ResNet18 and ResNet18 with Self-Attention models were applied for supervised learning. [11-12] Due to the lack of significant differences between the two, a classification model was developed using ResNet18. Subsequently, XAI tools such as Smooth Grad, Gradient-weighted Class Activation Mapping (Grad CAM), Score-Weighted Visual Explanations for Convolutional Neural Networks (Score CAM), and Local Interpretable Model-agnostic Explanations (LIME) were utilized to obtain the average heatmap of feature maps for each noise type. [13-15]

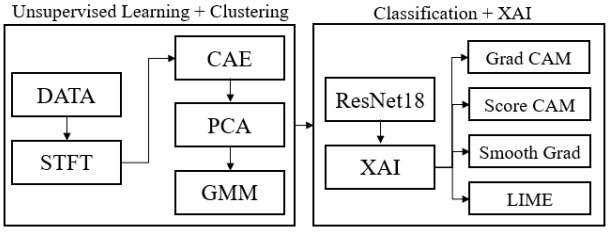

Figure 7. Diagram of end-to-end model

As shown Fig.8, the heatmaps generated by each XAI tool revealed that rotational noise primarily identifies the diagonal components of the order elements as key factors, while frictional noise is characterized by broad bands regardless of speed. In conclusion, an end-to-end process is established where labeling is performed through unsupervised learning and clustering. Subsequently, a classification model is developed based on the labeled data using unsupervised learning. Finally, XAI tools are employed to automatically extract features according to the characteristics of each noise type. If additional noise types are anticipated, unsupervised learning can be employed to add new classes. These feature maps can then be utilized as weighted filters for the specifications of noise and vibration. We believe that recalculating the noise using such feature maps and managing it through thresholding is significantly more effective than conventional overall-level-based approaches.

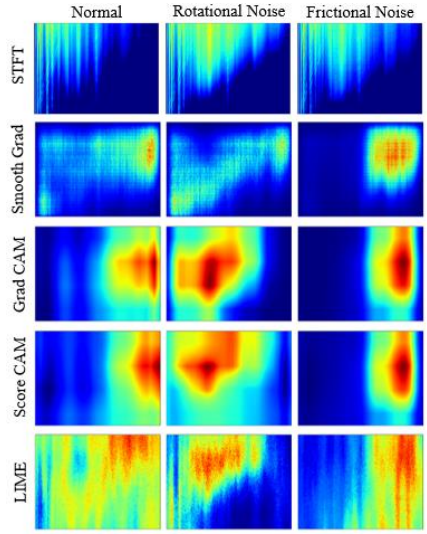

Figure 8. Average heatmaps of each XAI method according to bearing noise defect types

4. CONCLUSIONS

This study demonstrates the effectiveness of anomaly detection in diagnosing bearing defects in C-EPS systems by optimizing unsupervised learning and clustering methodologies. To preprocess the input data, STFT was employed to retain the high-frequency characteristics of bearing noise.

Unsupervised learning was conducted using CAE, with PCA applied to improve performance. The embedded features were clustered using GMM, resulting in superior detection capabilities compared to the traditional overall level metric for noise and vibration. Although both noise and vibration were analyzed, vibration was prioritized due to limitations of noise measurement in EOL environments.

Additionally, a classification model was developed using supervised learning based on noise-type labels derived from optimized unsupervised learning and clustering. This model integrates XAI to extract feature maps for each noise type, enabling identification of the speed and frequency at which anomalies occur. While the end-to-end model does not guarantee perfect detection, it offers a fast and practical auxiliary tool for EOL and early-stage development.

ABSTRACT

In Non-Destructive Testing (NDT), imaging with array probes is frequently performed in a two propagation medium scenario, where the first acts as a coupling medium, and the second is the object under test. Therefore, the position and shape of the refracting interface between the two mediums must be known in order to compute the imaging focal laws. This geometrical information can be inferred from the arrival times of echoes reflected on the object's surface, which must be identified within the signals. A common approach for detecting these surface echoes is the first-threshold crossing method; however, it is susceptible to outliers, and more robust alternatives are needed. In a recent work, we developed and trained a 3D Convolutional Neural Network (DeepEcho3D) using an 11x11 matrix array to accurately and reliably detect surface echoes. While effective, the model is tailored to the specific array used. In this study, we explore extending DeepEcho3D to other matrix arrays with varying shapes and frequencies. Our findings demonstrate that it is unnecessary to start from scratch for each new array; instead, we can leverage transfer learning from the initial model.

1. INTRODUCTION

Ultrasonic Testing (UT) is a widely used Non-Destructive Testing (NDT) technique for internal imaging of industrial and structural components. It relies on proper coupling between the transducer and the test component, often achieved through immersion tests, that is, using water as coupling media.

The use of array probes [1] allows various imaging modes, including conventional Phased Array (PA), as well as more advanced techniques such as TFM (Total Focusing Method) [2] and PWI (Plane Wave Imaging) [3, 4], which offer improved resolution and versatility.

Inspection using the immersion technique presents difficulties in accurately calculating focal laws due to refracted rays. This, in turn, requires in-depth knowledge of both the test component surface and the probe location and orientation (PLO) relative to it.

The mentioned challenge has been addressed by adaptive imaging algorithms, which utilize ultrasonic signals to estimate the geometry before generating the final image, also referred to as auto-focusing techniques [5–7]. Among the various proposed algorithms for computing surface points, a subset of them relies on accurately detecting the time of flight (TOF) of surface echoes, making a robust TOF measurement method essential.

There are various methods for TOF detection [8, 9], being the simplest one the threshold crossing technique. Nevertheless, despite its efficiency, spurious echoes, as

those from water bubbles or probe surface waves, can cause measurement errors. Improving these methods is essential, as TOF measurements is widely used not only in UT but also in numerous other acoustic signals applications.

Given the strong capabilities of machine learning and deep learning for data classification and image segmentation, as well as their successful application in NDT research [10, 11], we leveraged this potential in a recent study to address the aforementioned measurement issues. The designed network (DeepEcho3D) was trained using data acquired from a 3 MHz, 1 mm pitch, 11×11 matrix array and a set of simple yet diverse surfaces [12]. The model demonstrated strong performance in detecting surface echoes across a sufficiently distinct set of test geometries, evaluated using two customized metrics: the percentage of outliers and a magnitude of error relative to the ground truth for the acquired data.

This study explores the adaptation of the DeepEcho3D model to a different array configuration using transfer learning and fine-tuning techniques. The model was adapted to a 5 MHz, 0.9 mm, 8×16 matrix array. The adaptation process consisted of three key stages: **(a)** transferring the pre-trained model to the new array dimensions, **(b)** fine-tuning selected layers to improve performance, and **(c)** evaluating the model's stability across multiple training runs.

2. METHODS

The adaptation process involved loading the pre-trained DeepEcho3D model, modifying its architecture to accommodate the new input shape (8×16), and transferring the original model's weights to the corresponding layers in the new network. To fine-tuning the transferred network, the dataset was obtained from a plane surface. The purpose is to use a single component instead of a set of different shapes, as in [12]. And finally, performance evaluation was conducted using customized metrics originally defined for the original net.

2.1 Data Acquisition

Data was generated through the Full Matrix Capture (FMC) [1] technique across 178 PLOs. For each PLO, a partial FMC was obtained using 9 elements as emitters, and all 128 elements as echo receivers, resulting in a total of 1602 (178 × 9) images. These images were then randomly divided into training (60%), testing (20%), and validation (20%) subsets

Essential for the network retraining stage, image labeling was automated during the post-processing of the acquired data. The Ground Truth (GT) is a binary mask, $GT(i,j)$, being i the time index and j the array element index. The theoretical TOF of the surface echo has time index $Idx_{true}(j)$, such that:

$$GT(i,j) = \begin{cases} 0, & i > Idx_{true}(j) \\ 1, & i < Idx_{true}(j) \end{cases} \quad (1)$$

$Idx_{true(j)}$ is computed using the law of specular reflection, as described in [13]. Fig. 1 shows an example of Idx_{true} in its upper graph (green line).

Three extra sets of data, two convex cylindrical surfaces (35 and 12 mm diameter), and one concave-shaped cylinder (40 mm diameter), were further acquired to assess the fine-tuned models performance under different geometries.

2.2 Experimental Setup

2.2.1 Preliminary Testing

The first dataset came from a plane surface, providing an initial test for the transferred model. The initial assessment revealed that, although the model generalized well, certain segmentation inaccuracies persisted. Fig. 1 and Fig. 2, illustrate, respectively, **1)** an example of satisfactory performance, where the model correctly segmented the image (lower plot) based on the ground truth shown in the upper graph; and **2)** a challenging case for the new model, with imprecise segmentation. Both images correspond to a single emitter element, and what is seen is the 2D representation of the 3D array acquisition (upper plot), and the transferred model segmentation output (lower plot). Now, to mitigate these segmentation inaccuracies, a fine-tuning strategy was implemented, retraining specific layers on the new dataset.

2.2.2 Section-Wise Exploration

DeepEcho3D consists of an *autoencoder* architecture, which can be divided into three main sections: (1) the encoder, which extracts hierarchical features and compresses input data into a lower-dimensional representation. It consists of two internal blocks, each containing

[1] FMC: Technique where each element in an ultrasound array transmits a pulse one at a time while all elements in the array record the returning echoes. This process is repeated for each element in the array.

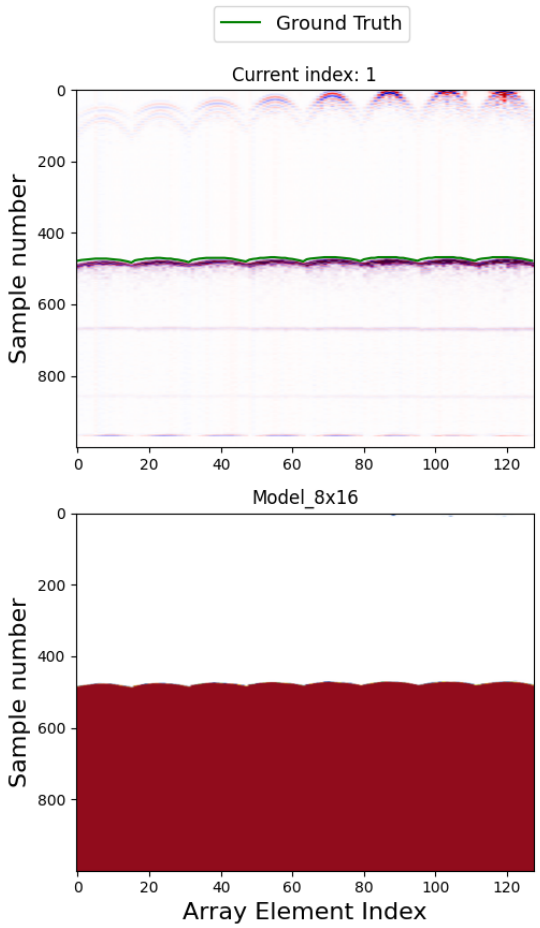

Figure 1: Instance of acceptable performance for initial model adaptation

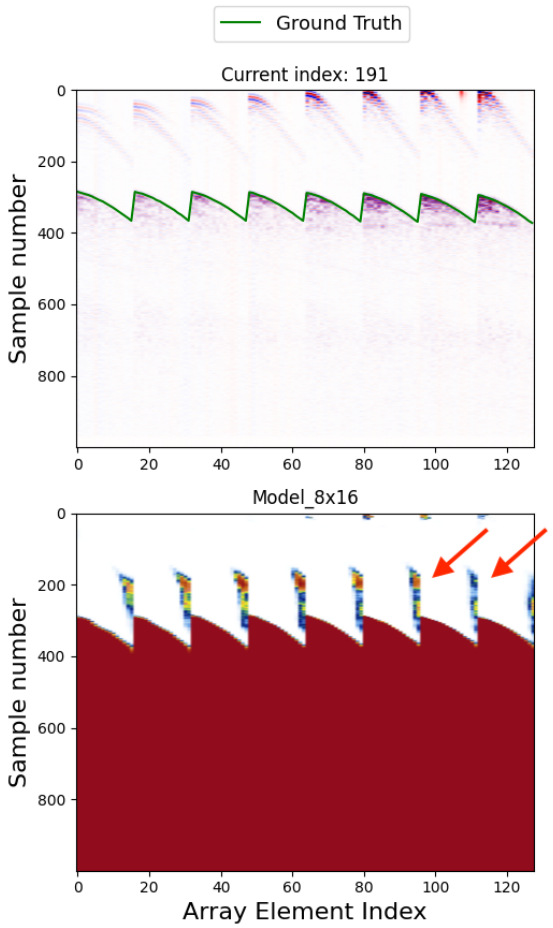

Figure 2: Instance of challenging case for initial model adaptation. Red arrows highlight the regions where the network's segmentation is inaccurate.

two convolutional layers. (2) The bottleneck, which incorporates a reduced set of features representing the most important information from the input; and (3) the decoder, that reconstructs the original data from the latent space, aiming to preserve essential spatial and feature details.

The exploration was structured into the network's three main sections: encoder, bottleneck, and decoder, with fine-tuning applied only to convolutional layers, excluding batch normalization and other layers. Additionally, the two internal encoder blocks were added as supplementary configurations to be explored. This led to five different fine-tuning setups. **1)** Encoder (4 convolutional layers); **2)** Bottleneck (2 convolutional layers); **3)** Decoder (5 convolutional layers); **4)** Encoder 1st block (2 convolutional layers); and **5)** Encoder 2nd block (2 convolutional layers)

Convolutional layers are primarily responsible for feature extraction and generalization across different datasets [14–16], which motivated the chosen approach.

2.2.3 *Fine-Tuning Implementation*

During the fine-tuning process, the following optimized hyperparameters were used (see Table 2), originally se-

lected as the best-performing ones for the 11×11 model [12]. This approach aimed to retain the effectiveness of the original model while allowing it to generalize to different array configurations.

Table 1: DeepEcho3D optimized hyperparameters.

Hyperparameter	**Value**
Number of filters	16
Number of layers	12
Convolutional kernel size	(3, 3, 12)
Pooling size	(1, 1, 8)
Epochs	10
Batch size	16
Learning rate	0.001
Steps per epoch	61
Loss function	Binary cross-entropy

2.3 Evaluation

Regarding the metrics used to assess the performance of the resulting models, two customized evaluation metrics were employed, defined as follows.

Index Error: This metric is defined as the maximum of the absolute value of the numerical difference between the predicted indexes and the true indexes, over the entire set of array elements [2], see Eqn. (2). Thus, for each A-scan within an FMC acquisition, a theoretical TOF index is determined and compared against the index predicted by the model.

$$Idx_{MaxError} = \max(|Idx_{pred} - Idx_{true}|) \quad (2)$$

Outlier Rate: This metric is particularly important for evaluating models reliability in practical applications. It is based on the computed error of indexes ((3))

$$Idx_{err} = |Idx_{pred} - Idx_{true}| \quad (3)$$

It measures how frequently the Idx_{err} exceeds a predefined threshold. The total count of such occurrences, relative to the dataset size (N), defines the outlier percentage.

[2] For instance, with 989 test images, this would correspond to $N = 989 \times 128 = 126592$ index-error values

Finally, given the stochastic nature of deep learning optimization, a stability assessment was carried out on each of the fine-tuned configurations, via multiple runs. Specifically, 10 runs per model were performed, and both evaluation metrics were computed for each, aiming to identify the configuration with the least deviation from its previous results. Therefore, the ideal models are those that exhibit minimal dispersion and remain close to the origin in the metric space.

Performance was assessed using data acquired from the three previously mentioned cylindrical components. These geometries were previously included in the test set for the original 11×11 model, making them suitable benchmarks to evaluate fine-tuned models. In particular, the concave-shaped 40 mm cylinder posed the greatest challenge, as it represents a complex case for the segmentation process.

3. RESULTS

Fig. 3 presents a comprehensive comparative analysis, not only between the fine-tuned models and the transferred network (Model_8x16) but also among themselves. It shows that the selective retraining of each set of convolutional layers enhances the capabilities, to a greater or lesser extent, of the transferred model, which has 14.43% outliers.

The most significant improvement correspond to the first block of the encoder section, highlighted in Fig. 3 (with 2.33% of outliers), followed by the full encoder (5.53 %); the bottleneck (6.56 %); the decoder (8.13 %); and finally the second block of the encoder (8.37 %).

Fig. 4 illustrates how fine-tuning enhances performance in a challenging case where the initial model encounters difficulties with image segmentation, where the test image exhibits low-amplitude surface echoes.

With the model using only the transferred weights, it fails to accurately identify and segment these surface echoes (Fig. 4a). However, in the encoder's first-block fine-tuned version, the model demonstrates a notable ability to capture very low-amplitude surface echoes while effectively suppressing superficial waves generated by the transducer (Fig. 4b). This highlights the efficacy of fine-tuning in improving the model's image segmentation performance.

Fig. 5 represents the results of the stability analysis described earlier. As observed, this analysis confirms that the first block of the encoder is the most consistent and stable configuration, exhibiting the least dispersion and

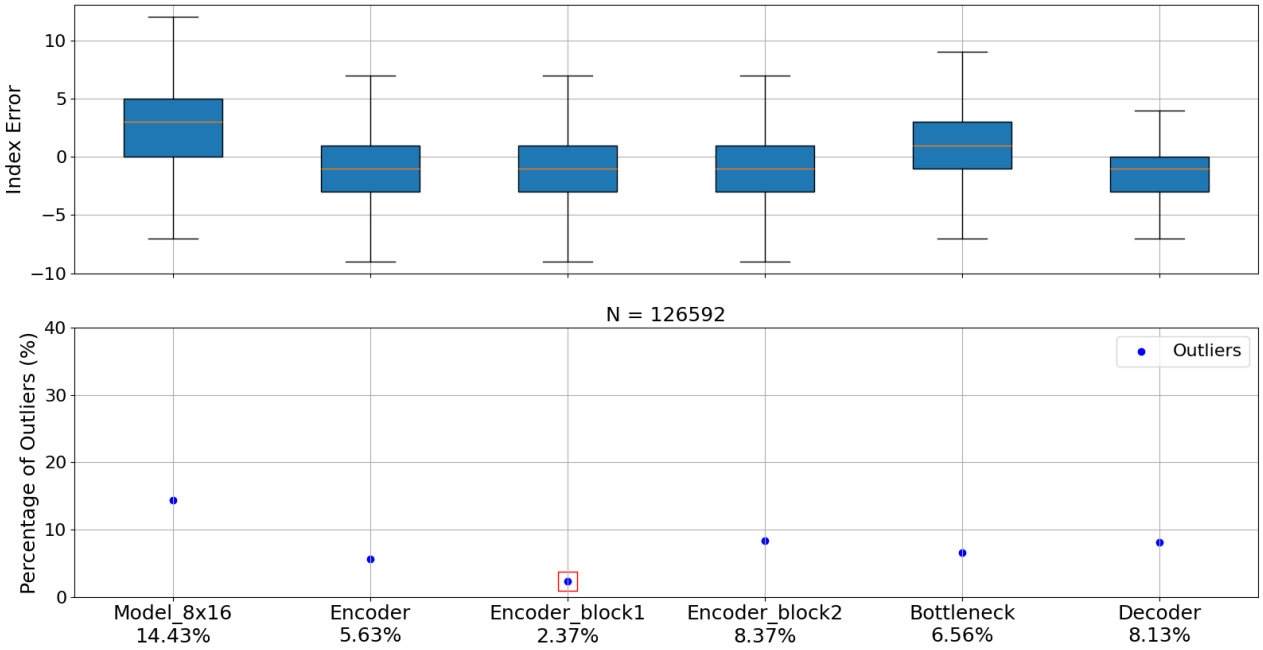

Figure 3: Comparison of Model Performance by customized metrics

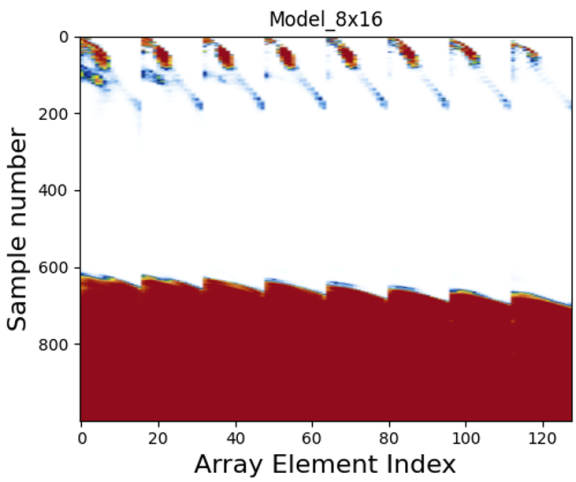
the best performance in the metric space (with an average outlier rate of 2.6%, and an average $Idx_{MaxError}$ of 6.4%).

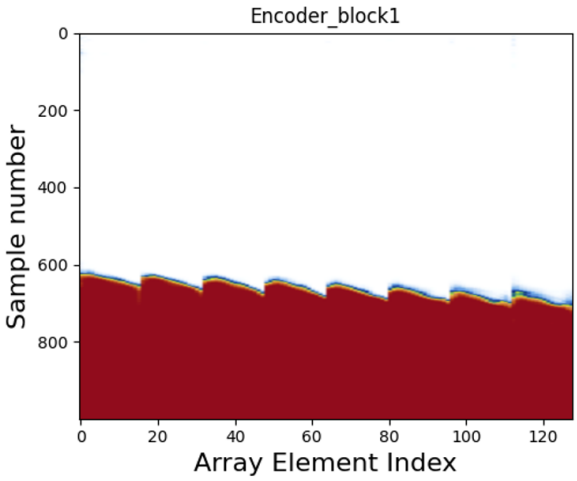
4. DISCUSSION

This study confirmed that knowledge learned from one array setup can be successfully leveraged for another, with fine-tuning improving segmentation accuracy. However, several aspects of this adaptation approach call for further discussion.



One of the key challenges in transfer learning is determining which layers should be fine-tuned to maximize performance while maintaining computational efficiency. This study evaluated various fine-tuning configurations, with results indicating that retraining the first encoder block yielded the most stable and accurate outcomes. However, the success of the first encoder block in this specific setting does not necessarily generalize to all ultrasound imaging problems, and a more thorough analysis could reveal alternative fine-tuning strategies with even better results. For instance, investigating the impact of fine-tuning different types of layers, beyond just convolutional ones, or employing techniques such as progressive fine-tuning [17], may further refine model adaptation.

While the study successfully adapted the model to an 8x16 array, the performance of this transfer learning approach could be explore further across different ultrasound imaging conditions, such as variations in material properties, noise levels, or different probe manufacturers.



To enhance model adaptation even more, future research could explore adaptive fine-tuning strategies that automatically determines the optimal layer to update based on the dataset and task complexity [18]. Additionally, conducting experiments with a wider variety of geometries and different acquisitions conditions would help validate the robustness of the approach.

5. CONCLUSIONS

The results demonstrate that transfer learning plus fine-tuning was a viable approach for adapting the DeepEcho3D model for a different array configuration, without requiring a complete retraining process, and by utilizing only a single training component. The initial transferred model already showed promising performance, confirming that knowledge learned from one array setup can be effectively leveraged for another. Despite this, fine-tuning

(a) Segmentation for initial transferred model without fine-tuning

(b) Segmentation after fine-tuning the first block of the encoder

Figure 4: Comparison between Transfer learning vs Transfer learning + Fine-tuning

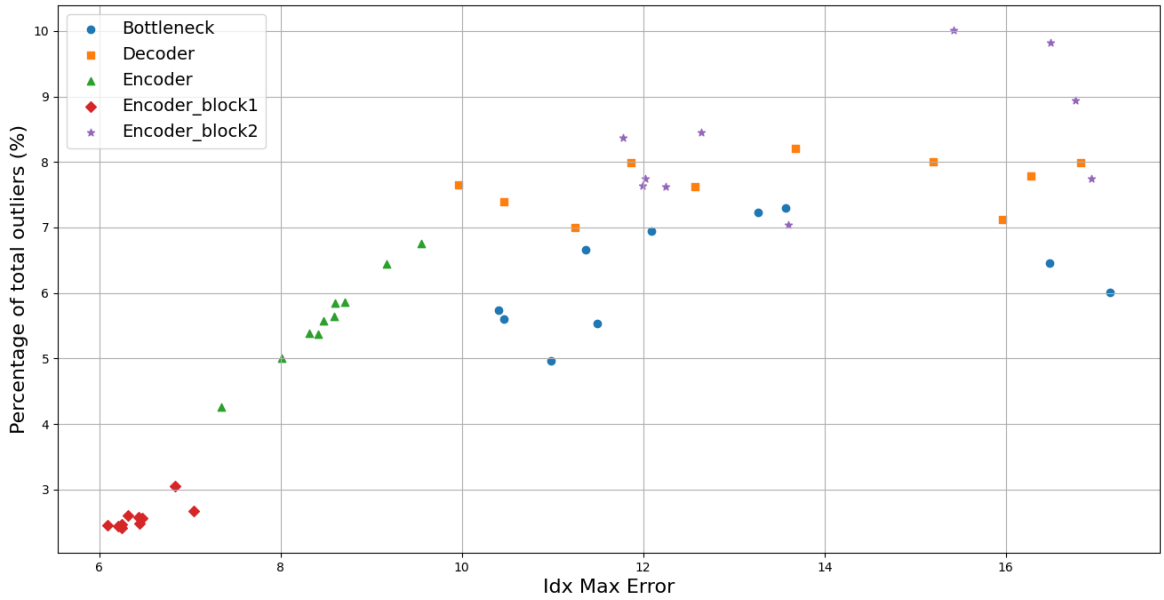


Figure 5: Stability Analysis

specific network sections enhanced segmentation accuracy.

The exploration of different fine-tuning strategies revealed that focusing on the first block of the encoder pro-

vides the most significant improvements, offering the best performance and greatest stability within the metric space. This suggests that early layers of the encoder, which capture more fundamental features, may be particularly critical for adapting the model to new array configurations.

DOES SOURCE DIRECTIVITY INFLUENCE NEURAL NETWORK-BASED SPEECH POSITION ESTIMATION?

Rhoddy Viveros-Muñoz[1*] **Sebastián Guajardo**[1]
[1] Department of Electronics and Computer Sciences, Universidad Técnica Federico Santa María, Concepción, Chile

ABSTRACT

This study explores the ability of an artificial neural network (ANN) to estimate the position of speech sources—comprising both direction of arrival (DOA) and distance—by addressing the question: "Does the directivity of a speech source influence an ANN's position estimation?"
A comparative analysis was performed between omnidirectional and directional speech sources, with the latter simulating the natural directivity pattern of a human voice. Stimuli were generated using an acoustic virtual reality framework (RAVEN), encompassing multiple conditions: four reverberation times (0.1, 0.3, 0.6, and 0.9 seconds), 12 DOA angles (spaced at 30-degree intervals in azimuth), and two source types (omnidirectional vs. directional).
Findings from this analysis aim to shed light on the role of source directivity in shaping the performance of machine learning models for spatial audio tasks, such as sound source localization and enhancement in complex acoustic environments. The outcomes have promising implications for applications in spatial audio systems, hearing aids, and autonomous systems that rely on auditory information for navigation and interaction.

Keywords: *artificial neural network, direction of arrival, source directivity, acoustic virtual reality, source position estimation.*

1. INTRODUCTION

Sound source localization (SSL) refers to the process of estimating the spatial origin of an acoustic signal, specifically described in terms of direction of arrival (DoA) and distance relative to a listener or sensor array. Accurate SSL is critical for various applications, including surveillance, human-computer interaction, robotics, and auditory scene analysis [1-2]. In recent years, increasing attention has been paid to data-driven and learning-based approaches for solving SSL tasks, as traditional signal processing techniques such as time difference of arrival (TDOA), interaural level and time differences (ILD/ITD), and beamforming; often struggle in reverberant or noisy environments [3-4].
Machine learning (ML) methods, particularly deep neural networks (DNNs), have demonstrated considerable promise in overcoming the limitations of classical approaches by learning robust representations from complex acoustic scenes [5]. Interestingly, many of these models draw inspiration from human auditory processing mechanisms. For example, the use of mel-frequency cepstral coefficients (MFCCs) or mel-spectrograms as feature representations mimics the frequency selectivity of the human cochlea [6-7], embedding perceptual priors into the computational models.
Among the broad category of SSL tasks, the localization of speech sources is of particular importance, especially in the context of assistive hearing technologies. For hard-of-hearing individuals or users of hearing aids, the ability to spatially segregate and localize speech sources plays a critical role in auditory scene understanding and effective communication [8-10]. One key but often overlooked property of speech is its acoustic directivity, the way the voice radiates differently across directions depending on frequency and articulation. While traditional SSL models usually assume omnidirectional sources, human speech

exhibits strong directional patterns that can influence spatial cues, particularly under realistic reverberant conditions [11-12]. Despite its potential importance, the influence of source directivity on neural network-based SSL systems remains underexplored.

Therefore, the primary objective of this study is to investigate whether the directivity of speech sources has a measurable effect on the performance of deep neural network-based models for speech position estimation using binaural recordings. We aim to compare two types of spectral feature representations: (i) a Fourier-based spectrogram, which provides a general, physics-driven decomposition of the signal, and (ii) a mel-spectrogram, which mimics the frequency analysis performed by the human auditory system.

By training similar neural network architectures on both representations, we seek to isolate the role of biologically inspired features in learning to resolve spatial information, particularly under conditions that include speech signals with varying directivity patterns.

Understanding the interaction between acoustic directivity and feature representation is expected to provide theoretical insights into the interpretability of ML models for speech localization and inform future designs of assistive hearing technologies that operate in real-world acoustic environments.

2. METHOD

2.1 Dataset and Acoustic Simulation

To investigate the effect of speech source directivity on the performance of neural network-based position estimation, we used a dataset of speech recordings using a controlled simulation framework. The speech material consisted of 700 phonetically balanced sentences adapted from the SHARVARD corpus [13] into Chilean Spanish. These sentences were recorded by 20 native speakers (10 female), all of whom participated in a supervised recording session. The recordings were made in a sound-attenuated booth using a high-quality microphone at a sampling rate of 44.1 kHz.

Spatialization of the speech recordings was performed using the Room Acoustics for Virtual Environments (RAVEN) simulation framework [14], which allowed precise control over source characteristics, spatial configuration, and room acoustics. Two types of source directivity were modeled: an omnidirectional source, radiating energy uniformly in all directions, and a directional speech source, simulating the typical radiation pattern of the human voice. For the directional condition, two speaker orientations were simulated to reflect contrasting spatial alignments relative to the listener: (i) facing the listener, and (ii) facing directly away from the listener (i.e., 180° rotation). This manipulation aimed to capture the acoustic variability introduced by speech directivity and head orientation.

The directional speech source was modeled using a voice directivity pattern available in the RAVEN directivity database. Each selected utterance was rendered in multiple acoustic scenes, varying systematically across:

- Four reverberation times (T30): 0.1 s, 0.3 s, 0.6 s, and 0.9 s.
- Twelve DoA: 0°, 30°, 60°, 90°, 120°, 150°, 180°, 210°, 240°, 270°, 300°, and 330°.
- Three source conditions: omnidirectional, directional-facing, and directional-reversed.

Binaural renderings were generated using head-related transfer functions (HRTFs) obtained from the IHTA-indHARTF database, which contains high-resolution acoustic measurements from 30 adult participants recorded [15]. Their use ensured that the binaural stimuli reflected perceptually valid spatial information suitable for human-oriented localization models.

The final dataset comprised 144,000 binaural audio samples. The data were split into training (80%), validation (10%), and test (10%) sets.

2.2 Feature Extraction

To investigate the role of feature representation in speech source position estimation, we extracted two types of time-frequency features from the binaural audio signals: Short-Time Fourier Transform (STFT) spectrograms and mel-spectrograms.

For the STFT spectrograms, each audio signal was segmented using a Hamming window of 512 samples and a hop size of 256 samples. The STFT was independently applied to the left and right channels, yielding complex-valued spectrograms that were converted to magnitude representations. These were subsequently concatenated along the channel axis to form a two-channel input capturing the interaural spectral differences.

For the mel-spectrograms, a Hamming window of 1024 samples and a hop size of 512 samples were used to better align with perceptual frequency resolution. The resulting magnitude spectra were passed through a mel filterbank composed of 64 filters spaced according to the mel scale, approximating cochlear frequency selectivity. The resulting mel-spectrograms were log-compressed

(log-mel) to enhance dynamic range compression and facilitate neural network training.
Both representations were stored as input tensors of shape [C × F × T], where C = 2 (left and right channels), F corresponds to the number of frequency bins (129 for STFT, 64 for mel), and T denotes the number of time frames. This formulation allows for a consistent comparison of biologically inspired and physics-based spectral front-ends within the same deep learning framework.

2.3 Neural Network Architecture

We implemented a convolutional neural network (CNN) designed to estimate the position of speech sources—specifically, the DoA and distance—from binaural time-frequency representations. The network accepts as input either STFT spectrograms or mel-spectrograms, both formatted as two-channel tensors that encode spectral features from the left and right ears.
The architecture consists of the following components:

- **Input layer**: Accepts input tensors of shape [2×F×T], where F is the number of frequency bins, and T is the number of time frames, depending on the duration of the audio segment and the hop size used.
- **Convolutional blocks**: The feature extractor comprises four convolutional layers with increasing filter depths (64, 128, 256, 512), each followed by ReLU activation, 2D max-pooling, and dropout (rate = 0.1). These layers are responsible for learning hierarchical patterns across time and frequency.
- **Flattening and fully connected layers**: The output of the final convolutional block is flattened and passed through a series of dense layers with 64 and 32 hidden units, respectively. This stage maps the high-level feature representations to a compact encoding suitable for regression.
- **Output layer**: The final dense layer contains two units, corresponding to the predicted azimuth angle (in degrees) and distance (in meters).

The total number of trainable parameters was approximately 2 million, and the model was implemented using PyTorch version 2.4.1. To ensure a controlled comparison, both models were trained using the same neural network architecture and optimization procedure, although the input representations differed not only in perceptual scaling (mel vs. linear) but also in time-frequency resolution due to distinct window and hop size configurations.

2.4 Evaluation Metrics

The performance of the neural network models was evaluated using regression-based metrics for both spatial dimensions: DoA and distance. Given the continuous nature of these output variables, the Mean Absolute Error (MAE) was used as the evaluation metric on the test set. For both DoA and distance, MAE was computed as the average absolute difference between the predicted values and the ground truth. MAE in DoA was expressed in degrees, while MAE in distance was expressed in meters. This metric provides an intuitive measure of average estimation accuracy and is robust to outliers.
All metrics were computed independently for the STFT-based and mel-based models under each experimental condition. Performance was further analyzed by grouping the results according to source directivity (omnidirectional, directional-facing, directional-reversed) to assess whether speech radiation patterns affected localization accuracy.

3. RESULTS AND DISCUSSION

3.1 Effect of Source Directivity on Direction of Arrival (DoA) Estimation

The impact of source directivity on DoA estimation was analyzed for both STFT-based and mel-based models across the 12 tested azimuth angles. Figures 1 and 2 show polar plots of the Mean Absolute Error (MAE) in azimuth estimation as a function of angle, grouped by directivity condition (omnidirectional, directional-facing, and directional-reversed). Figure 1 corresponds to the mel-spectrogram-based model, while Figure 2 displays results from the STFT-based model.

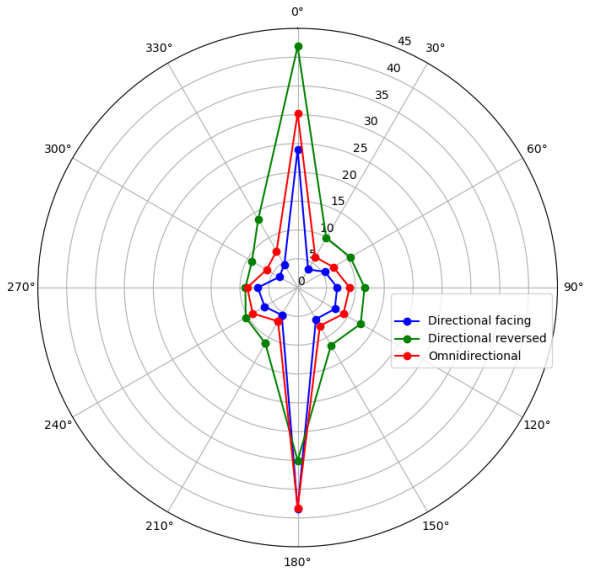

Figure 1: Mean Absolute Error (MAE) in DoA estimation for the mel-spectrogram-based model, plotted as a function of source azimuth angle. The polar plot shows results for three source directivity conditions: omnidirectional (red), directional-facing (blue), and directional-reversed (green).

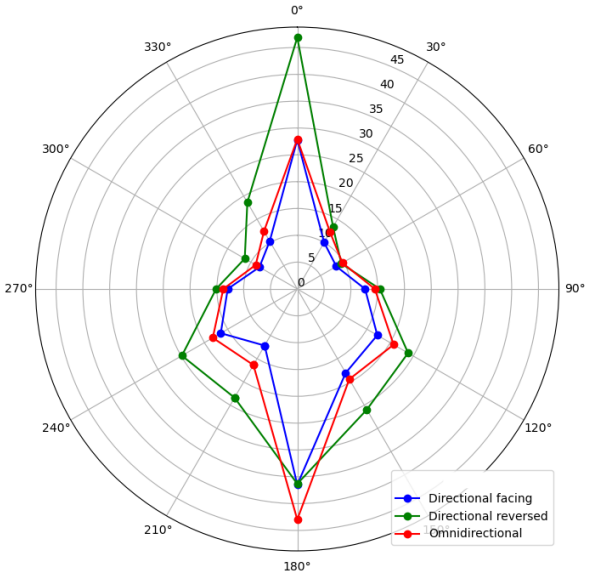

Figure 2: Mean Absolute Error (MAE) in DoA estimation for the STFT-based model, plotted as a function of source azimuth angle. The polar plot includes results for omnidirectional (red), directional-facing (blue), and directional-reversed (green) conditions.

For both feature types, source directivity strongly influenced DoA estimation accuracy. The lowest errors were consistently observed for the directional-facing condition, followed by the omnidirectional condition. In contrast, the directional-reversed configuration yielded the highest errors, especially at frontal (0°) and rear (180°) angles, suggesting a prominent front-back confusion effect.

When comparing the two feature representations, the mel-based model exhibited a more robust DoA estimation across all azimuth degrees and source directivity conditions. Specifically, mel features reduced angular MAE by up to 10 degrees in the most challenging reversed condition at 0° and 180°, relative to the STFT model. This suggests that the perceptually motivated mel scale better captures direction-dependent spectral variations, particularly under conditions of direct-path cues.

Overall, these results confirm that speech directivity patterns, especially when facing away from the listener, can impair azimuth estimation, and that mel-based models are more resilient to such degradations.

3.2 Effect of Source Directivity on Distance Estimation

Figures 3 and 4 show the Mean Absolute Error (MAE) in distance estimation as a function of distance bins (ranging from 1.0 to 4.0 meters), grouped by source directivity condition. Figure 3 presents results for the mel-spectrogram-based model, while Figure 4 displays results for the STFT-based model.

Both the STFT-based and mel-based models demonstrated clear performance degradation with increasing distance, consistent with the expected weakening of spatial cues at longer ranges.

In terms of directivity effects, the directional-facing condition yielded the most consistent and lowest distance errors across all bins, for both models. The omnidirectional source, in contrast, showed increasing error with distance, particularly above 2.5 meters, likely due to more uniform spatial energy distribution and reduced spectral asymmetries. The directional-reversed condition exhibited variable performance: at close distances, its error was relatively low, but it increased sharply beyond 3 meters, especially for the STFT model.

Again, mel-spectrograms provided superior distance estimation, with lower overall MAE in all distance bins and for all directivity types. The advantage of mel features was particularly pronounced for far-field estimation (>3 m), where STFT-based predictions showed significantly larger variance and error, especially for omnidirectional sources.

These findings reinforce the idea that biologically inspired spectral representations enhance robustness in challenging

acoustic conditions, especially when direct-path information is weak or distorted by reverberation and source radiation patterns.

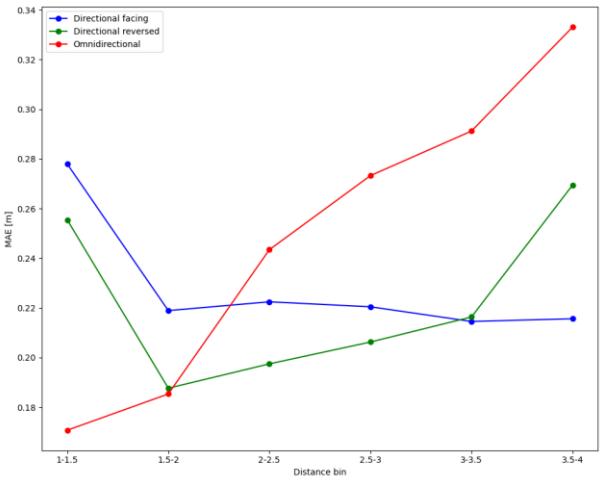

Figure 3: Mean Absolute Error (MAE) in distance estimation for the mel-spectrogram-based model, shown across distance bins from 1.0 to 4.0 meters. Each curve represents a different source directivity condition: omnidirectional (red), directional-facing (blue), and directional-reversed (green).

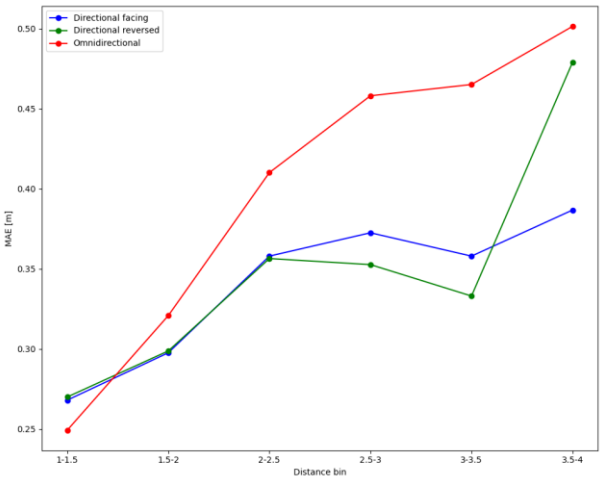

Figure 4: Mean Absolute Error (MAE) in distance estimation for the STFT-based model, plotted across distance bins from 1.0 to 4.0 meters. Results are shown for three source directivity conditions: omnidirectional (red), directional-facing (blue), and directional-reversed (green).

4. CONCLUSION

This study investigated whether the directivity of speech sources affects the performance of a deep neural network in estimating source position from binaural audio. The findings provide a clear affirmative answer to the central question: yes, source directivity significantly influences neural network-based speech position estimation.

Across both spatial dimensions, DoA and distance, models trained on signals from directional sources yielded different levels of accuracy depending on the orientation of the speaker. The directional-reversed condition, in which the source was facing away from the listener, consistently led to higher estimation errors, especially under reverberant conditions. This demonstrates that the directionality of speech radiation alters the availability and quality of spatial cues, which are crucial for both angular and distance localization.

Furthermore, models trained with mel-spectrogram features showed greater robustness to variations in source directivity and acoustic conditions compared to those using STFT-based representations. This suggests that biologically inspired, perceptually motivated features may better capture the spatial information encoded in directional speech signals.

Overall, the results emphasize that source directivity should not be neglected in the development and evaluation of spatial hearing models. Accounting for realistic radiation patterns is essential for building deep learning systems capable of generalizing complex and ecologically valid environments. These insights are particularly relevant for applications such as assistive hearing devices, speech enhancement systems, and auditory scene analysis in autonomous agents.

While the use of simulated environments allowed precise control over acoustic and spatial parameters, future work should explore real-world recordings and dynamic source behaviors—such as head movements—to further enhance model generalizability and ecological validity.

SPEECH POSITION ESTIMATION USING NEURAL NETWORKS FROM ACOUSTIC SIGNALS OF HEARING AIDS

Sebastián Guajardo-Herrera[1*] **Rhoddy Viveros-Muñoz**[1]

[1] Department of Electronics and Computer Sciences, Universidad Técnica Federico Santa María, Concepción 4030000, Chile.

ABSTRACT

The localization of sound events, including speech, has evolved with the use of deep learning algorithms. The inclusion of distance in the task of estimating the direction of arrival allows us to obtain the spatial position of the sound source, which is a variable of interest for the improvement of auditory perception. This study addresses speech direction of arrival and distance estimation using signals generated by simulated hearing aid microphones in acoustic virtual reality environments.

The approach involves the collection of a dataset designed to represent various scenarios, with 96,000 samples distributed at 24 angular positions, varying distances between the source and the listener (ranging from 1 to 3 meters) and 4 reverberation times (0.1, 0.3, 0.6, and 0.9). These data are then used to evaluate the performance of a deep learning algorithm in simulated scenarios that replicate real conditions. The objective of this work is to contribute to the development of techniques that integrate direction of arrival and distance estimation in applications related to hearing aid systems and other acoustic support devices.

Keywords: Direction of Arribal Estimation, Distance Estimation, Deep Learning, Neural Networks, Hearing Aids

1. INTRODUCTION

The perception of the position of a sound event can be decomposed in the estimation of the direction of arrival (DoA), that refers to the angular direction of the event with respect to the listener, and the sound distance estimation (SDE) that is the relative distance between the source and the listener. These parameters allow to characterize spatially one or more sources, allowing to use them in different systems and applications. These parameters have been previously studied using different signal processing and deep learning (DL) techniques [1, 2].

Generally, implemented models for these tasks has been: convolutional neural networks (CNN) [3, 4], residuals networks (ResNet) [5], recurrent convolutional networks (CRNN) [6], Conformers [5, 7], and Transformers [8]. Among the input features used we can find magnitude and phase spectrograms, mel spectrograms, intensity vectors in the case of ambisonic microphones, interaural phase difference, generalized cross-correlation and Spatial Cue-Augmented Log-Spectrogram (SALSA) [9, 10] being particularly prevalent. These features have proven to be effective in obtaining spatial characteristics of sound sources.

A sound source of interest is the voice, which is crucial in communication processes, knowing the spatial position can improve the assistance systems as well as robotic applications [11].

In the case of hearing aids, they have been applied for the estimation of DoA [12], but distance estimation has not been incorporated. In this study we seek to test the effectiveness of deep learning algorithms for the estimation of both: DoA and distance.

The data used in this study have been generated in acoustic virtual reality [13], which enables faster data acquisition and fully accurate labels, avoiding the need for fully measured and controlled environments.

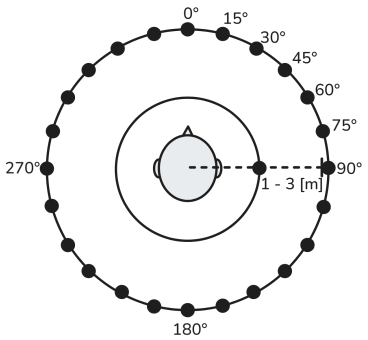

Figure 1. The positions of the simulated sources were configured in azimuth every 15°, elevation 0°, and distance between 1 and 3 meters.

2. METHODOLOGY

2.1 Dataset and Acoustic Simulation

Using a dataset of recorded speech and a controlled simulation framework, we investigated whether a neural network can learn the position of speech using hearing aid signals. The speech signals consisted of 700 sentences adapted to Chilean Spanish from the SHARVARD corpus [14]. These sentences were recorded with high quality microphones at a sampling rate of 44.1 kHz.

The speech signal was positioned at different distances and DoAs, varying in intensity, reverberation and source directivity using the simulation framework Room Acoustic for Virtual Environments (RAVEN) [15]. The listener was simulated as a 4 channel hearing aid. Hearing aid transfer functions (HATF) were obtained from the IHTA-indHARTF dataset [16]. This variability allows the models to generalize to different head shapes and sizes, avoiding the limitation of training to a single type.

The generated data contains the following spatial characteristics: 24 different azimuth angles between 0-360° every 15°, random distance between listener and event in the range of 1-3[m], random directivity of the source between 0-360° (see Figure 1).

The total data was generated is 96,000 samples of 4 channel audio, with a uniform distribution for both DoA and distance. For training the network, this was divided into training and validation sets with an 80-20 ratio.

2.2 Feature Extraction

The feature used for training and inference was a Mel Spectrogram obtained using Torchaudio library, to extract frequency and time features from the 4 microphones channels. We used a Hanning window with 1024 samples with a hop size of 512 samples, to get a magnitude spectrogram and applied a mel filterbank with 64 filters. The resulting input tensor has the shape [C x F x T], where C = 4 (left/right front and rear microphones), F corresponds the frequency bins (64) and T denotes the number of time frames.

2.3 Neural Network Model

The model used was a CNN designed to estimate the position (DoA + Distance) of a sound source, in this case speech, from a 4-channel time-frequency representation of the hearing aid. The architecture consists of:

1. **Input Layer**: Mel spectrogram per channel with shape [4 x F x T].
2. **Convs Layers**: Extract features from time-frequency representation, increasing filter depths (64, 128, 256, 512), each layer followed by ReLU activation function and 2D Max-Pooling. In the training process we used a Dropout (rate = 0.1).
3. **Flattening and Fully Connected Layer**: Flattened features passed through a dense layers with 64 and 32 hidden units.
4. **Output Layer**: Use a two neurons output, corresponding to azimuth angle (in scaled degree) and distance (in scaled meters).

The size of the network was approximately 2 million of parameters, and the model was implemented using PyTorch version 2.4.1.

3. RESULTS AND DISCUSSIONS

The overall results of the network for all validation data can be seen in Table 1, where we can observe the errors of the predictions in terms of DoA (in degrees) and Distance (in meters), measured in Mean Absolute Error (MAE) and Root Mean Square Error (RMSE).

The effect of the different reverberation times can be seen for DoA in Figure 2 and for Distance in Figure 3, in both cases we can observe an exponential increase of the error.

Table 1. MAE and RMSE calculated using the validation data set. Azimuth DoA is displayed in degrees and distance between listener and event is displayed in meters.

	MAE	RMSE
Distance [m]	0.40	0.49
DoA [°]	24.91	35.1

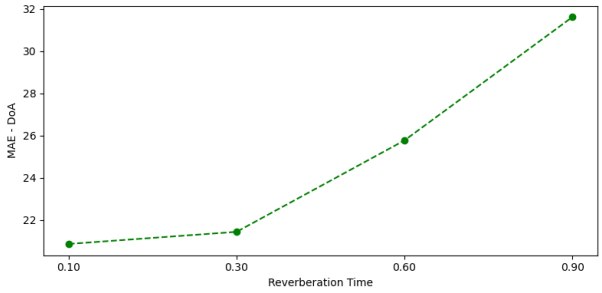

Figure 2. MAE of DoA estimation plotted as a function of reverberation time.

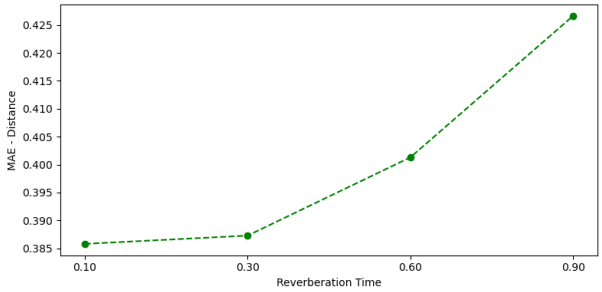

Figure 3. MAE of Distance estimation plotted as a function of reverberation time.

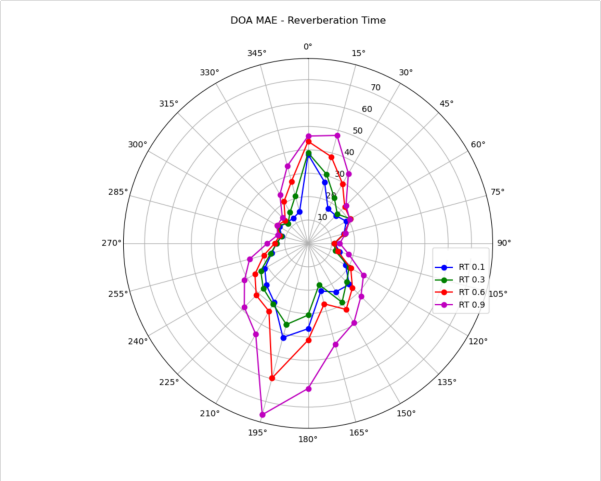

Figure 4. MAE of DoA plotted as a function of source azimuth angle. The polar plot includes the result for 4 reverberation times: 0.1(blue), 0.3(green), 0.6(red), 0.9(magenta).

Finally, the results of the error by DoA are presented in Figure 4 we can see an increase of the error in the rear zone of the listener, since the best estimation angles are the lateral ones.

4. CONCLUSIONS

This work investigate whether DL architectures, such as CNN, are capable of estimating the position of a speech sound source from signals coming from hearing aids. In this work, it is possible to demonstrate the architecture capability to perform this work from using only spectrograms of Mel as feature extraction, as well as characterize how the estimation varies according to the reverberation and position of the source.

Given the results, as future work we will analyze the possibility of incorporating more features and measure the impact that these have on improving the results, as well as incorporate improvements to the proposed model, thinking about applications in hearing aid systems or other acoustic support systems.

ABSTRACT

Smart vehicles are experiencing increasing adoption, driven by a growing demand for their applications. To facilitate widespread deployment, it is important to improve the security and trust of these vehicles. This paper focuses on improving smart car safety by developing an audio-based system for detecting important sound events, including emergency vehicle sirens, tire skidding, car crashes, horn types, drifting, and others. Our methodology involves a multifaceted approach to classifying a diverse range of driving-related audio events. We begin with a Convolutional Recurrent Neural Network (CRNN) as a baseline. Subsequently, we investigate the performance of pre-trained foundational models (e.g., BEATs, Audio Spectrogram Transformers) followed by a Recurrent Neural Network layer, aiming to leverage the pre-trained representations for improved event classification. Additionally, we explore the potential benefits of combining these approaches, considering as well the effect of introducing augmented data. We propose novel hybrid models that integrate features extracted by the convolutional layers of the CRNN with those directly obtained from the pre-trained models. Our experimental results demonstrate significant performance gains when combining these distinct approaches into a unified architecture.

1. INTRODUCTION

Human senses, especially sight and hearing, play a major role in our perception, communication, and safety. Although sight is undoubtedly the most important sense, hearing helps humans absorb and analyze surrounding information and may even be the only reliable source in certain situations. Due to the importance of auditory information, integrating auditory sensing into smart devices and autonomous systems, which are increasingly prevalent, has become essential [1]. These systems, including smart cars, are now equipped with various sensors such as cameras, long and short-range radars, Light Detection and Ranging (LiDAR), ultrasonic transducers, and GPS receivers. However, these sensors have limitations [1]. For instance, cameras have blind spots and are sensitive to lighting and scene structure, making visual information unreliable. According to the National Highway Traffic Safety Administration, approximately 840,000 blind spot incidents occur annually in the United States, resulting in 300 fatalities [2]. Similarly, lasers are ineffective in extreme weather conditions.

To handle these challenges, researchers are increasingly focusing on the ability of devices to automatically detect and classify sound events through technological means known as sound event detection (SED) [3]. SED is the automatic process that detects and classifies events in audio streams and estimates the onset and offset of these events [4]. SED has many applications, including audio/video surveillance [5,6], healthcare monitoring, environmental monitoring [7], industrial machine fault mon-

itoring [8], human-computer interaction, and smart cars. By accurately detecting and timestamping sound events, SED systems can enhance the capability, security, and trust in smart devices and autonomous systems.

However, SED is still an evolving research topic due to several challenges, such as having enough data for training, ensuring performance in noisy environments, real-time processing, and modeling overlapping sounds [9]. Additionally, the development of robust SED systems is complicated by the need for sufficiently labeled datasets with accurate annotations for training purposes, making them more applicable in real-world scenarios [10]. Traditional SED methods relied on manual feature extraction (e.g., MFCC [11], Mel spectrograms) and classical machine learning techniques such as SVM [11], KNN, and HMM/GMM [12]. While these approaches provided initial insights, they often required extensive experimentation and struggled in complex, noisy environments. These limitations spurred the transition to deep learning, which has revolutionized sound event detection. Recent works have shown that through deep learning models, specifically Convolutional Neural Networks (CNNs) [13,14] and Recurrent Neural Networks (RNNs) [15], state-of-the-art performance is achieved on numerous tasks involving pattern recognition and learning data representations. These models reduce the dependency on manual feature extraction. This gave deep learning models the potential to handle the complexities of multiple concurrent and overlapped sound events; hence deep learning has become the state-of-the-art approach for SED with better accuracy and robustness.

More recently, pre-trained foundational audio models, such as BEATs [16] and the Audio Spectrogram Transformer (AST) [17], have emerged as powerful tools for capturing universal audio representations from large-scale datasets. These models offer enhanced feature extraction capabilities and have shown promise in various audio analysis tasks, making them particularly well-suited for addressing the challenges of SED in dynamic environments like driving scenarios.

There are, however, a few remaining research gaps. Despite many advances, current models still need to better consider temporal dependencies, contextual complexities, and rich feature extraction. Moreover, more generalized models that perform well under diverse acoustic environments [15] are needed, and the issue of computational efficiency—especially for deployment in resource-constrained setups—remains a challenge. The main objective of this paper is to address these gaps by investigating novel deep learning architectures and training strategies aimed at developing more robust, general, and efficient SED systems for driving scenarios. In particular, this paper promotes the sound event detection field by developing and evaluating novel deep learning models that combine the strengths of traditional CNN and RNN architectures with the enhanced representations obtained from pre-trained embedding models. The critical contributions from this work include presenting a novel hybrid model that integrates convolutional and recurrent layers with pre-trained audio representations to improve both performance and generalization. Comprehensive experimental results on data collected in driving environments, demonstrate the effectiveness and superior performance of the proposed methods.

Section 2 provides an overview of the data used in our study. Section 3 outlines a baseline system and different proposed SED models. Section 4 describes the experimental setup, including the preprocessing step, training details, and evaluation metrics. Section 5 provides the experimental results and discusses their implications, and Section 6 concludes the paper with suggestions for future research.

2. DATASET

The dataset used in this study was collected by [18], specifically designed to support the training and evaluation of sound event detection systems in driving environments. This dataset has sounds that originated from both internal sources within the vehicle, such as vehicle components, devices, and human interactions, as well as external sources like traffic, road conditions, and environmental factors (see Fig. 1).

2.1 Dataset overview and Sources

The dataset comprises 19,000 audio files, each with a duration of 10 seconds, resulting in a total duration of approximately 53 hours. To ensure a balanced representation of events, the dataset was split into training, validation, and test subsets: 15,000 audio samples for training, 2,000 for validation, and 2,000 for testing [18]. The sound events were sourced from various publicly available datasets with unrestricted usage rights, including: Musical Genre Classification of Audio Signals [19], UrbanSound [20], AudioSet [21], Old Phone Ringtones as MIDI [22], ASR-CabNois (Cabin Noise Dataset) [23], Freesound [24], A Singing Voice Dataset [25], DCASE

Figure 1. Internal (e.g. ring tone) and external (e.g. horn, siren) sounds while driving.

2020 Task 4 Dataset [26], Donate-A-Cry Corpus Features Dataset [27].

2.2 Synthetic Data Generation and Labeling

To simulate realistic driving conditions, the dataset was created using **Scaper** [28] with augmentation techniques such as time stretching and pitch shifting applied to improve diversity and model generalization. Table 1 provides a concise overview of our dataset, which comprises 41 classes. In our classification framework, we explicitly consider a problem with 41 distinct classes. These events are organized into nine primary distractor categories- horns, Sirens, Speech, Physiological, Pets, Notifications, Vibrating, RingTone, and Cry- each of which represents sounds most likely to divert a driver's attention. All other environmental sounds, such as rain, thunder, or microphone noise, are grouped under "Other", thus completing the broader driving environment. Each event was assigned **hard labels**, providing precise onset and offset timestamps within the 10-second clips. The event annotations followed a standardized format: The audio file name, the event type, the event onset and offset times. This structured labeling approach ensured the dataset was compatible with multiple machine learning frameworks and facilitated accurate model training. The dataset is openly accessible via `https://www.kaggle.com/datasets/ccastorena/sound-event-detection-for-driver-safety` and can be utilized by researchers and practitioners for benchmarking and further development in sound event detection [18].

Table 1. Dataset Summary

Class Groups	Classes	Appearances
Horns	4	11,693
Sirens	3	8,858
Speech	1	3,020
Physiological	3	8,639
Pets	2	5,843
Notifications	1	2,862
Vibrating	1	2,988
RingTone	1	2,835
Cry	1	2,950
Other	24	16,597
Total	**41**	**66,285**

3. SED MODELS

Sound Event Detection (SED) involves identifying and localizing sound events by capturing both their spectral details and temporal dynamics. We begin with a popular CRNN baseline from the DCASE framework, which uses convolutional layers to extract features from Log-Mel spectrograms and recurrent layers to model how these features evolve over time. To further enhance our model's performance, we also combine additional feature extraction from pretrained models like the Audio Spectrogram Transformer (AST) and BEATs, creating a richer representation of the audio signals for more robust detection.

3.1 CRNN model as a baseline

We employ the DCASE baseline architecture [29] based on Convolutional Recurrent Neural Networks (CRNNs), which are widely used in sound event detection. This architecture is used to detect patterns in complex audio signals (via convolutional layers) and interpret how those patterns evolve over time (via recurrent layers). We use the standardized CRNN architecture defined by the DCASE framework, ensuring compatibility with other studies. As illustrated in Figure 2, the CRNN starts by converting audio into a Log-Mel spectrogram. This spectrogram, sized [1, 626, 128] (1 is the channel dimension, 626 is the time dimension, and 128 is the number of Mel frequency bands), is processed through seven convolutional blocks.

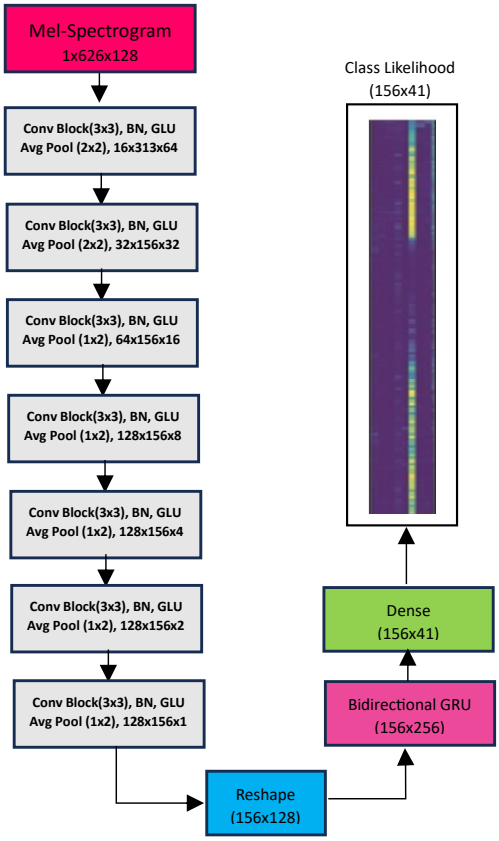

Figure 2. Baseline CRNN Architecture.

Each block uses a 2D convolution with a kernel size of 3×3, batch normalization, GLU activations, and average pooling. The number of filters in each layer is: 16, 32, 64, 128, 128, 128, 128, and the pooling operations has the specific dimensions of 2×2, 2×2, 1×2, 1×2, 1×2, 1×2, 1×2, respectively. This results in the convolutional output shape of [128, 156, 1]. To integrate with the bidirectional recurrent layers, the filter dimensions are transposed, and the extra dimension is removed. The bidirectional GRU layer produces an output of [156, 256], with 128 hidden units in both directions. Finally, a dense layer with softmax activation generates the final output with 156 frames and 41 distinct events.

3.2 Proposed models

Our proposed framework explores three distinct feature-extraction pathways for each audio clip, as illustrated in Figure 3. The first pathway, termed the *Baseline CNN Path*, uses Log-Mel spectrograms of size 1×626×128 as input to a convolutional neural network. This CNN processes the spectrograms to generate initial feature tensors with dimensions of [128, 156, 1].

The second pathway, referred to as the *AST Path*, leverages the frame-level version of the Audio Spectrogram Transformer (AST), specifically the ATST-Frame variant with a Base384 configuration. This model processes 10-second audio segments to produce a feature tensor of size 768×496 (representing the embedding dimension and time steps). An average pooling stage is applied to reduce the time dimension from 496 to match the CRNN's temporal resolution of 156, resulting in a pooled output of size [768, 156]. Features from this path are stored in HDF5 format for efficient loading.

The third pathway, known as the *BEATs Path*, utilizes BEATS_iter3_plus_AS2M.pt, a model pre-trained on AudioSet. Operating at a 16 kHz sampling rate with a 25 ms window (and a 10 ms hop length), this approach also outputs embeddings of size 768×496, which are similarly reduced via average pooling to produce a tensor of dimensions [768, 156]. Again, the features are stored in HDF5 format.

To harness the complementary strengths of these pathways, our framework investigates several fusion strategies. The simplest strategy is the CNN+RNN baseline, which relies solely on features extracted by the CNN. Alternatively, pretrained features from the BEATs and AST paths can be fed directly into recurrent layers (BEATs/AST Path + RNN). Another approach involves concatenating the CNN-extracted features with those from the AST or BEATs paths (CRNN + AST/BEATs), before inputting the combined representation into recurrent layers. Finally, a full integration strategy (CRNN + BEATs + AST) is proposed, combining all feature streams into a unified architecture. This multi-path fusion is designed to exploit the diverse and rich representations provided by each pathway, ultimately enhancing the robustness and accuracy of sound event detection in dynamic driving scenarios.

4. EXPERIMENTAL SETUP

4.1 Audio Pre-processing and Augmentation

All audio clips are first resampled to a 16 kHz sampling rate (mono) using Librosa. To ensure consistent input lengths, clips longer than 10 seconds are truncated, and those shorter than 10 seconds are zero-padded to reach

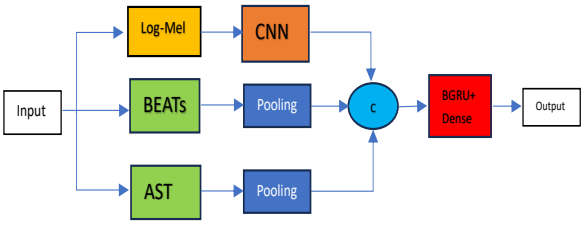

Figure 3. Proposed models.

the 10-second duration. For labeling, a frame-wise hard label format is used, where each frame corresponds to a discrete timestamp. Each frame has a value of 1 when an event is present and 0 otherwise. The output must predict 156 frames, corresponding to the chosen number of events. The model uses log-mel spectrograms as input features for the CNN model, using 128 mel-filters with a window length and FFT size of 2048, a Hamming windowing function, and a hope size of 256. The frequency range for the Mel spectrogram is from 0 Hz to 8000 Hz. The resulting Mel spectrogram has dimensions of 626 frames, 128 Mel bands, and a single channel. During training, we apply a combination of data augmentation techniques to enhance the robustness and generalization of our models. Specifically, we use the mixup technique and specaugment. Mixup is a widely adopted augmentation method in both machine listening and computer vision [30]. It creates synthetic training samples by linearly interpolating pairs of input spectrograms and their corresponding labels, thereby increasing the diversity of the training data and smoothing the decision boundaries. In addition, specaugment [31] is applied to the Log-Mel spectrograms, which involves randomly masking blocks of time and frequency bins. This perturbation forces the model to learn more invariant features and reduces sensitivity to noise, ultimately contributing to improved performance in dynamic and challenging driving scenarios.

4.2 Training Schedule

All experiments (CRNN-only, CRNN+AST, CRNN+BEATs, etc.) use the same overall training procedure: training continues for up to 200 epochs with early stopping triggered if no improvement is observed for 100 consecutive epochs, a dropout rate of 0.5 is applied, and the batch size is set to 48 for both training and validation. Additionally, the Adam optimizer is employed with a learning rate of 0.001 and a warm-up phase during the first 50 epochs.

4.3 Metrics

To comprehensively evaluate sound event detection systems, we employ a range of complementary metrics. While Accuracy is a common measure, relying on it exclusively can be misleading, especially for frame-by-frame detection and rare events. Thus, we complement it with more detailed metrics, such as the F1 score and the Polyphonic Sound Detection Score (PSDS).

The F1 score is widely used because it effectively balances Precision and Recall, thereby measuring the system's accuracy in detecting events without over- or under-detection. Meanwhile, the PSDS is computed using the `psds_eval` toolbox [32], which is a recognized standard within the DCASE community. PSDS values are derived from 50 operating points (linearly distributed from 0.01 to 0.99) and refer to the normalized area under the PSD-ROC (Receiver Operating Characteristic) curve up to a specified maximum effective false positive rate (eFPR).

In our experiments, we use PSDS1, where $DT_C = GT_C = 0.7$, in accordance with common practices in general SED tasks.

5. RESULTS AND DISCUSSION

Models	Augmentation	Accuracy	PSDS	F1
CRNN+ReLU	None	92	22.1	55.6
CRNN+ ReLU	Mixup+specaugment	94	23.5	56.3
CRNN+GLU(baseline)	Mixup+specaugment	95	28.1	58.1
AST+RNN	Non	96	30.1	59.9
BEATs+RNN	Non	98	31.5	60.6
CRNN+AST	Mixup+specaugment	97	37.4	61.2
CRNN+BEATs	Mixup+specaugment	97	39.7	61.6
BEATs+AST+RNN	Non	97	43.6	63.1
CRNN+BEATs+AST	Mixup+specaugment	97	44.3	63.4

Table 2. Comparison of models, augmentations, and their performance metrics.

Table 2 summarizes the performance of various sound event detection models. We begin with a CRNN+ReLU model without augmentation that achieved an accuracy of 92%, a PSDS of 22.1, and an F1 score of 55.6. When augmented with Mixup and specaugment, the CRNN+ReLU configuration improved slightly to 94% accuracy, 23.5 PSDS, and 56.3 F1. Replacing ReLU with GLU in the

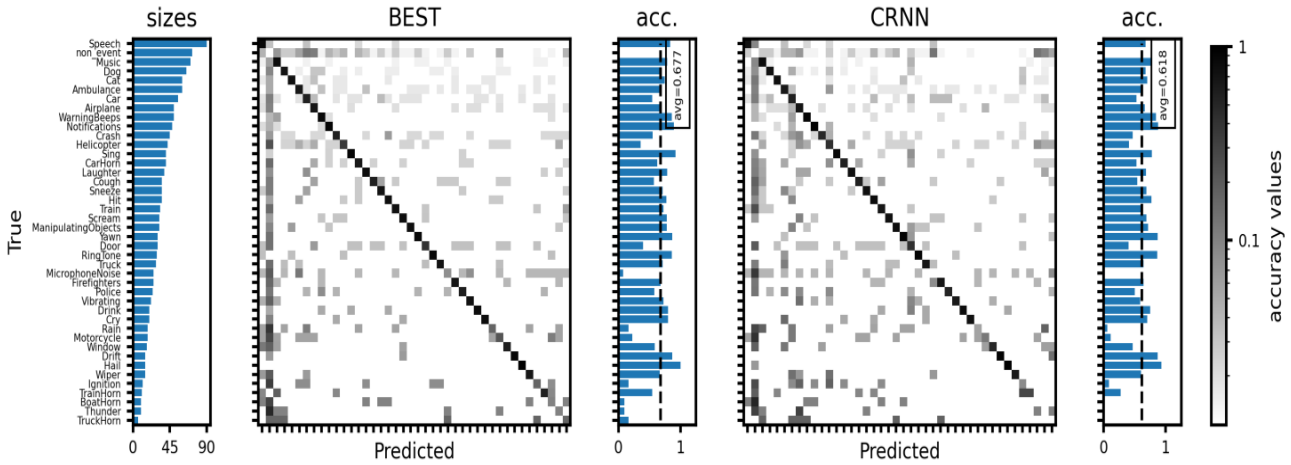

Figure 4. Confusion matrices comparing the best proposed model (left) and the CRNN+GLU baseline(right)

CRNN, while using the same augmentation, further enhanced performance to 95% accuracy, 28.1 PSDS, and 58.1 F1. This enhanced model not only serves as the baseline for the DCASE 2021-2023 editions [29], but it also becomes our reference point for comparing the performance of our proposed models, and forming the backbone of our hybrid approaches.

Models that integrate pre-trained audio features also showed notable improvements. The AST+RNN model, which does not use data augmentation, reached 96% accuracy, 30.1 PSDS, and 59.9 F1, while the Beats+RNN model outperformed it with 98% accuracy, 31.5 PSDS, and 60.6 F1.

The benefits of fusion strategies become even more evident in the hybrid models. The CRNN+AST and CRNN+Beats models, CNN employing Mixup and specaugment, achieved 97% accuracy with PSDS scores of 37.4 and 39.7, and F1 scores of 61.2 and 61.6, respectively. The Beats+AST+RNN configuration, without augmentation, reached 97% accuracy, 43.6 PSDS, and 63.1 F1. Finally, the fully integrated model CRNN+Beats+AST with Mixup and specaugment maintained 97% accuracy while achieving the highest PSDS (44.3) and F1 (63.4) scores.

To illustrate the behavior of the best model and the CRNN+GLU baseline on different classes, frame-based confusion matrices and associated accuracies are shown in Figure 4. The confusion matrices demonstrate that the BEST model has a stronger diagonal, reflecting a higher number of correct predictions, whereas the baseline shows more off-diagonal misclassifications. In Figure 4, we use a support-weighted per-class accuracy metric that differs from the frame-based accuracy presented in Table 2. The Table 2 metric is computed online using `torchmetrics`, evaluating the model's ability to correctly detect the presence or absence of sound events within fixed-length segments and capturing both active and inactive portions. By contrast, the metric in Figure 4 is derived post-hoc from a confusion matrix (often excluding the non-event class) by normalizing each class's counts and computing a weighted average based on class frequencies, effectively treating each class as a separate binary classification (one-vs-rest). These differences in aggregation, class inclusion, and weighting account for the observed discrepancies between the two accuracy values. Notably, for Figure 4, the BEST model achieves an average accuracy of 67.7% compared to the CRNN baseline's 61.8%, highlighting the benefits of integrating pre-trained audio features in driving scenarios.

These results indicate that leveraging pre-trained audio models substantially enhances the detection of complex, overlapping sound events in dynamic driving environments, with data augmentation further improving generalization. The superior performance of the hybrid models over the CRNN approaches underscores their potential for robust real-world sound event detection in challenging driving scenarios.

6. CONCLUSION

In this study, the integration of pre-trained models, specifically AST and BEATs, into a CRNN-based framework represents a significant breakthrough in sound event detection for driving scenarios. By leveraging the advanced feature extraction capabilities of models like AST and BEATs alongside the proven temporal modeling of CRNNs, our hybrid approach achieves superior performance—demonstrated by higher accuracy, PSDS, and F1 scores—compared to traditional methods. Data augmentation techniques such as mixup and specaugment further enhance model robustness in noisy, real-world environments, making the approach well-suited for the complex auditory landscapes encountered in smart vehicle applications.

Looking ahead, these findings open up promising avenues for future research, including real-time deployment optimizations, exploration of additional fusion strategies, and training on more diverse datasets. Overall, our work marks a significant step toward developing safer, more reliable autonomous systems by providing a robust framework for detecting critical sound events in dynamic driving conditions.

ABSTRACT

Machine Learning (ML) techniques are gaining interest in many scientific applications, including analysing and forecasting road traffic noise. Many alternatives to the classic Road Traffic Noise Models (RTNMs) are then opened: ML provides ways for studying the traffic noise in urban and non-urban environments straightforwardly, using the same input data of the RTNMs. In this work, an analysis of road traffic noise equivalent levels by using ML regressors is described. Those regressors are calibrated on real data (coming from an experimental long-term monitoring station) using the well-known 80%/20% calibration/validation split rule. Splitting of data for calibration and validation is coupled with shuffling of the data themselves to evaluate possible output variations. Even with some differences, regressors exhibit promising potentialities in the simulation of the road traffic noise levels in the case under study. The mean error is very low and comparable with other models available in Literature. The comparison between the distribution of the measured data and the simulated one shows a general good agreement, and also underlines peculiarities of the single regressors.

Keywords: *machine learning, regression analysis, road traffic noise, modelling, computed data.*

1. INTRODUCTION

Noise has a severe impact on urban environments since it is ubiquitous and its gravity is generally not perceived as other pollutants. People subjected to high noise levels, anyway, experience equal or even worse effects. Consequences of prolonged exposure to high noise levels are numerous: tiredness, lack of sleep, irritability and irascibility, problems in concentration, scarce intelligibility during conversations, tinnitus, and difficulty in conducting daily tasks like study or work [1]. Worse consequences may be related to transient or permanent hearing loss and, even if rarely, to hypertension and/or cardiovascular diseases [2]. Road traffic is responsible for the main part of the impact of noise in a given urban environment, and for this reason, governments are constantly trying to implement noise control and reduction strategies [3]. European Union, for example, aims at a 30% reduction in the number of people subjected to high noise levels before 2030 [4]. Due to this, the importance of monitoring and controlling noise in urban areas is clear, and the implementation of valid measuring strategies is decisive for a successful assessment of the problem. Noise can be directly measured, but when such a direct approach is not possible, modelling is an appropriate alternative. Many models, commonly known as Road Traffic Noise Models (RTNMs), exist since long time, and different RTNMs have been adopted in the past by different national institutions: the CoRTN model, used in the United Kingdom [5], the SonRoad model, used in Switzerland [6]; the NMBP model in France [7]; the ASJ in Japan [8]; the RLS90 in Germany [9] and the Harmonoise model [10]. A comprehensive review of the evolution of RTNMs can be found in [11]. Recently the European Union (EU) has realized and recommended the CNOSSOS-EU model, which is a common procedure for the evaluation and simulation of transportation and industrial noise levels in all European countries [12-13]. CNOSSOS-EU framework is

also used for the final development of noise maps. Together with the aforementioned methods, anyway, recently new procedures have recently been investigated and implemented for the assessment of noise. In particular, Machine Learning (ML) techniques have been more and more used for this scope. While RTNMs investigate the direct physical cause-effect relationships between noise emitters characteristics (number of vehicles running, vehicle category, speed) and noise levels at a sensible receiver, ML approaches evaluate such relationship from a statistical point otrof view. In such a way they open to their usability in the same contexts where traditional RTNMs are commonly applied, but also in unusual traffic conditions (presence of roundabouts and/or stops and traffic lights). This is very important considering that RTNMs typically presuppose free-flow conditions. Many examples can be found in the literature. In [14], as an example, Support Vector Machine and Multilinear Regression have been used to evaluate noise in relation to its annoyance to people, generating a final model that correlates noise perception, noise exposure levels, and demographics; in [15] a similar approach is reported, but with more details on the type and number of inputs to be used. An Extreme Gradient Boosting (XGB) approach has been used in [16] to properly relate the performances of the most common traffic noise models and validate them. A wide comparison of the efficiency of several ML approaches can be found in [17]. In the work of Singh et al. [18], a ML approach is used together with a Monte Carlo Simulation for the assessment of noise impact in India. In [19], together with the classic input road traffic parameters, the honking occurrences have been used as input for ML approaches, namely Decision Tree and Random Forest. In [20] the very same regressors have been calibrated by using pass-by noise. All these literature experiences, together with the high potentiality of such approaches, have led the authors to dedicate efforts to the production of a large and comprehensive study on three different ML regressors - Multilinear Regressor (MLR), Decision Tree (DT) and Random Forest (RF) to predict Road traffic noise equivalent levels. After a detailed hyperparameter tuning and calibration approach such models have been validated on a set of road traffic collected data. Specifically, data have been collected by French researchers in a specific extra-urban viaduct in Saint Berthevin, France, during an experimental campaign that lasted several years called "Long Term Monitoring Station" (LTMS). Such data are freely available for research use.

The here presented study stands out for the important aspects of the ML application to road traffic noise simulation. The experimental procedures have been developed using Python programming language. Outputs of the here presented models are provided as hourly continuous equivalent sound level $L_{eq,h}$. The result is a study on the potentiality of the application of such ML approaches on noise assessment and its impact on the environment of urban and extra-urban contexts.

2. MATERIALS AND METHODS

2.1 Workflow of the experimental procedure and used programming environment

Jupyter notebook, a Python environment, has been used to implement the Machine Learning analysis on a DELL personal computer (Intel® Xeon® CPU E3-1245 v5 @3.50 GHz) with 16 GB of RAM installed, 64-bit. The main packages used were: pandas, numpy, scikitlearn, matplotlib and seaborn. The whole experimental procedure consisted of three parts: a first part in which the three chosen regressors have been tuned with the best hyperparameters combination; a second part consisting in the calibration of the regressors, and a final part of validation of the regressor themselves. Figure 1 visually resumes the steps of the process.

2.2 Dataset used for calibration and validation of the regressors

The data used in this experiment to calibrate and validate the regressors come from a large road traffic noise dataset available in the literature, obtained from a large campaign of data collection pursued by the *Unité Mixte de Recherche en Acoustique Environnementale* (UMRAE), within Université Gustave Eiffel, Nantes. In this study, both meteorological and acoustic data were collected by different masts installed in the city of Saint-Berthevin (France) for a period of six years, from 2002 to 2007 [21]. Within this large dataset, the following data were used in this paper: sound equivalent levels, number of light and heavy vehicles, and average speeds for both vehicle categories. Specifically, all the above parameters were recorded in 15-minute intervals, but for this study, they were converted to 60-minute time ranges. To do this, equivalent levels based on 15 minutes were logarithmically summed to calculate the equivalent hourly level. When performing this procedure, authors removed the entries where, for some reasons, equivalent levels were missing. A detailed report of this procedure can be found in [22]. As a result, the dataset used for this contribution was reduced from the original 30347 entries (based on 15 minutes) to a filtered one of 3404 entries (based on 1 hour).

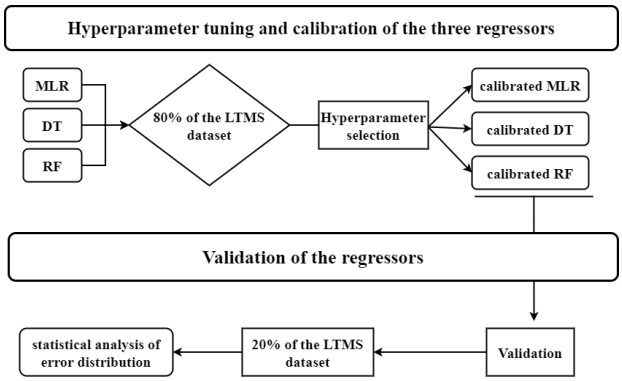

Figure 1: Workflow of the experimental procedure.

2.3 Hyperparameters tuning of the regressors

Hyperparameters tuning is a procedure aiming at finding the best combination possible of the hyperparameters of each regressor to get the best simulation results taking as input a given set of data. In this application, the tuning test has been performed on the same dataset used in the calibration described in subsection 2.4. Different nested cycles have been implemented to check the progressive advances of each test and to save the results. Please note that an in-built function for hyperparameter testing is present in the Scikit-learn package, but the authors preferred to build a personalized one, to have more control over the phases of each iteration. A description of the hyperparameters involved in the tuning procedure is reported below.

For Decision Tree (DT), the hyperparameters are: the criterion to measure the quality of the split, the strategy used to choose the split at each node, the maximum depth of the tree, the minimum number of samples required to split an internal node, the minimum number of samples required to be at a leaf node, the minimum weighted fraction of the sum of weights, the number of features to consider when looking for the best split, the function considering the randomness of the estimator, a maximum number of nodes for each leaf, the value inducing a decrease of the impurity at each node split, the hyperparameter used for Minimal Cost-Complexity Pruning and the monotonicity constraint to enforce on each feature.

For Random Forest (RF), the hyperparameters are: the number of trees in the forest, the function to measure the quality of a split, the maximum depth of the tree, the minimum number of samples required to split an internal node, the minimum number of samples required to be at a leaf node, the minimum weighted fraction of the sum total of weights, the number of features to consider when looking for the best split, a hyperparameter to grow trees with a maximum number of leaves in best-first fashion, the value inducing a decrease of the impurity at each node split, a hyperparameter to establish whether bootstrap samples are used when building trees, a hyperparameter to establish whether to use out-of-bag samples to estimate the generalization score, the number of jobs to run in parallel, a hyperparameter controlling both the randomness of the bootstrapping of the samples used when building trees, the hyperparameter controlling the verbosity when fitting and predicting, a hyperparameter establishing to reuse the solution of the previous call to fit and add more estimators to the ensemble, a complexity hyperparameter used for Minimal Cost-Complexity Pruning, the number of samples to draw to train each base estimator the monotonicity constraint to enforce on each feature.

Finally, for MultiLinear Regressor (MLR), the hyperparameters are: the hyperparameter controlling whether to calculate the intercept or not, the number of jobs to use for the computation, a hyperparameter forcing the coefficients to be all positive.

2.4 Calibration of the regressors

The calibration of the regressors is the process by which every single regressor involved in this experimental study has been trained with a section of the calibration dataset and then has been evaluated in a subsequent validation (test) phase. This process has been carried out following a standard procedure where a section of the data has been devoted to the training of the regressors and the remaining section to their validation. For this specific application 80% of the whole dataset has been used for training, and the remaining 20% for the validation. The train/test split of the dataset is randomly performed by an in-built method of the scikit-learn package that assigns a seed to assure the repeatability of the process. All the analyses reported in Section 3 have been pursued using the same seed, thus fixing the calibration and validation datasets.

2.5 Validation of the regressors

After the calibration of the model, the validation step has been performed by comparing the values simulated by each single regressor with the real one. The validation of the regressors took accounts of statistical analysis of the distribution of the simulated values and of the real ones (mean, standard deviation, skewness, kurtosis) and also a statistical evaluation of the distribution of the errors, where errors have been calculated as the difference of real data and the corresponding simulated ones.

3. RESULTS

3.1 Hyperparameters tuning and calibration results

The first step of evaluation of the work focused on the hyperparameters tuning of the four regressors. As described in subsection 2.3, MLR has been tuned by testing 4 hyperparameters, DT has been tuned by testing 11 hyperparameters and RF has been tuned by testing 17 hyperparameters. In Figure 2 the authors report the boxplots of the distributions of the MAE for the three regressors considered. MLR has a very narrow distribution of MAE values: the minimum value is 1.37 dBA, and the maximum one is 1.39 dBA. DT has a value of MAE ranging from 1.17 dBA to 1.49 dBA. RF has a minimum MAE value of 1.01 dBA and a maximum of 1.32 dBA.

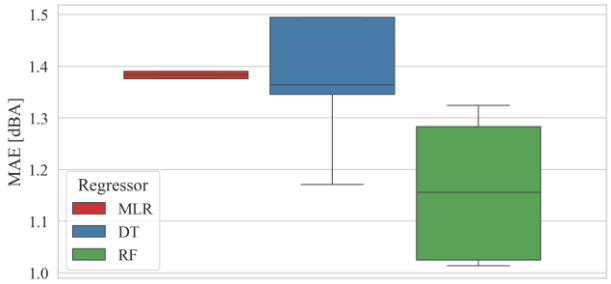

Figure 2: Boxplots of the MAE distributions of all the tested hyperparameters combinations, for all regressors. The solid line is the median of the distribution.

Figure 2 implies an important consideration to be done when calibrating a model since it clarifies how the accuracy of the regressors cannot be considered as a single value coming from a single procedure, but it must be interpreted after taking account of the hyperparameters' tuning. If working on RF, as an example, an output having MAE of 1.3 dBA could be considered as a good value since both MLR and DT have higher average values, but carefully analysing the results of hyperparameters' tuning, it's observed that the final result could be furtherly improved with a better hyperparameters' combination, having an even lower MAE value.

Table 1 reports the best hyperparameters' combination for each regressor as a function of the MAE and mean residuals. The residual is computed as the difference between the measured and the simulated noise levels in the tuning/calibration phase. Consequently, the negative values of the mean residuals found in Table 1 show a slight overestimation of all the models.

Since the tuning has been performed by testing the various hyperparameters' combinations on the same 80% of the overall dataset selected for the calibration, the results of this process provided the final calibration of each regressor.

Table 1: Results of the best hyperparameters' tuning combination for each regressor, in terms of mean error and MAE

Regressor	Mean Error [dBA]	MAE [dBA]
MLR	-0.05	1.38
DT	-0.04	1.17
RF	-0.08	1.01

3.2 Simulation outputs: validation and error analysis

After the regressors tuning and calibration phase, the validation step of the regressors themselves has been made. A due premise to this subsection is that until now authors used the MAE metric as the main indicator for the tuning and calibration phase. The strategy of using MAE as an indicator of the calibration phase has been used to drive the choice of the best hyperparameters setting for each calibration since it is a concise and easy-to-use indicator. In contrast, the validation process has been pursued more in detail, comparing the distributions of real and simulated data, and performing on them statistical investigations. Specifications of such analysis are presented below.

After the hyperparameters selection has been done, the regressors have been fed with input validation data and the final outputs have been collected and compared with the measured levels. Table 2 reports the main statistical descriptors of the measured and simulated equivalent sound level distributions for each regressor, which are plotted in Figure 3.

Table 2. Main statistical descriptors of measured and simulated levels distributions.

	Mean [dBA]	Median [dBA]	St.dev. [dBA]	Skew	Kurt
Measured	72.04	72.52	2.16	-2.13	4.87
MLR	72.09	72.03	0.88	0.49	0.06
DT	72.09	72.41	1.89	-1.50	4.42
RF	72.13	72.38	1.40	-1.79	5.09

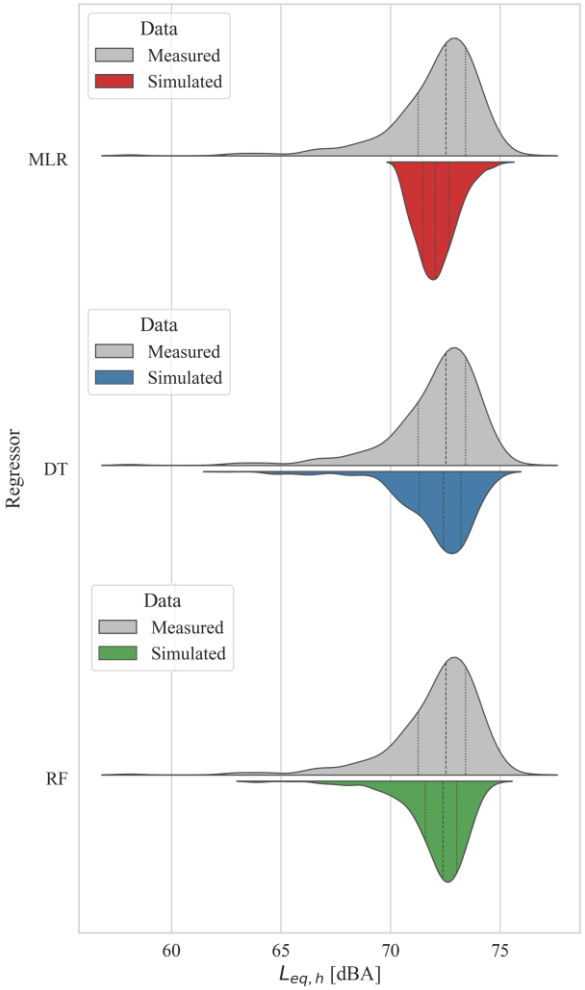

Figure 3. Distributions of measured and simulated equivalent sound levels, calculated by each regressor. The dashed line is the median and the dotted lines are the 1st and 3rd quartile.

At first glance, all the regressors give as output simulated data close to the measured ones, meaning that the hyperparameters' tuning process performed before the calibration indeed selected a good combination for each regressor. Validation data present a mean value of 72.04 dBA, a median of 72.52 dBA, a standard deviation of 2.16 dBA, a skewness of -2.13 (due to the equivalent levels on the left tail of the distribution), and a kurtosis index of 4.87. As for the central tendency metrics, all the regressors perform well, especially with the mean values of the distributions being very close to the measured ones. Median values show a small underestimation of MLR compared to the other regressors.

As for the standard deviations, it is interesting to note how the three regressors' distributions present a value lower than the measured levels one, meaning that no regressor can fully and properly simulate the dispersion of the real data, especially in the tails of the distribution. This behaviour reflects also on the skewness and kurtosis indexes for MLR, which are significantly different from those related to the distribution of the measured levels. More specifically, MLR tends to stabilize around zero skewness and kurtosis indexes. In contrast, DT and RF have higher values (in absolute) for both indexes, close to those of the distribution of the measured levels. MLR, then, can simulate data whose mean value is very close to the real one but misses the shape information of the simulated data distribution. DT and RF also catch the central tendency of the distribution but, in addition, they can also depict the left tail of the distribution, even if not perfectly.

A deeper analysis of the results comes from the investigations of the errors, defined as measured minus simulated equivalent levels in each entry of the dataset (each 1-hour slot), whose distributions are reported in Figure 4. The main statistical descriptors of error distributions for each regressor are resumed in Table 3.

Shapes of the error's distributions are very similar for the three regressors and all have mean values very close to zero (see Table 3). This aspect means that all the chosen regressors can simulate the equivalent noise levels in a good way and that the models aren't affected by any systematic underestimation or overestimation error. From Table 3 it also appears the Gaussian shape of the errors' distribution, since the Shapiro-Wilk index [23], measuring the normality of the distribution, is very high (0.91 for all the regressors).

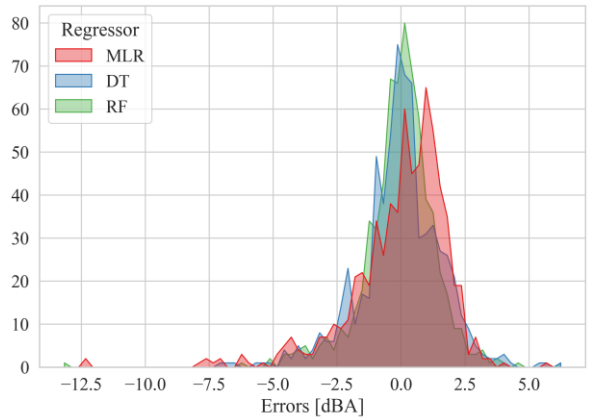

Figure 4. Distributions of the errors according to the regressor used for simulation.

Table 3. Main statistical descriptors of the error distributions for all the regressors.

	MLR	DT	RF
Mean [dBA]	-0.05	-0.04	-0.08
Median[dBA]	0.32	0.02	0.06
St. deviation [dBA]	1.92	1.62	1.48
Kurtosis index	6.32	2.10	10.72
Skewness index	-1.75	-0.42	-1.46
Shapiro-Wilk index	0.89	0.97	0.91
Bowley-Youle index	-0.15	0.00	-0.09

The Bowley-Yule test [24], used to estimate the symmetry of the distributions, is also good since it is very close to zero for all three regressors. Errors of the regressors, then, are peaked to zero and are symmetrically distributed on both negative and positive values, ensuring the stochastic nature of the errors themselves.

A final investigation comes from the visualization of Figure 5, where the scatterplots of measured (on *x*-axis) versus simulated (on *y*-axis) values of $L_{eq,h}$ for all the regressors are reported. The solid red diagonal line represents the ideal 1:1 agreement, whereas the red dashed lines indicate a ±2 dBA deviation, which does not have any statistical validity but it's a commonly accepted range in environmental noise modelling.

As for MLR (top plot), one of the most striking aspects of the model's behaviour is that it does not predict values lower than approximately 70 dBA. The same aspect was observed also in Figure 3, looking at the missing left tail. This result suggests a limitation in its ability to capture the full range of noise levels, possibly due to the linear nature of the model. If the dataset includes lower measured values, the model might be constrained by the way predictor variables interact, leading to an artificial threshold effect. Additionally, the data points are tightly clustered, with a tendency to underestimate higher values, as confirmed by the median simulated level in Table 2 and median error in Table 3, reinforcing the idea that MLR struggles with nonlinear relationships in the data.

The DT model (centre plot) exhibits a much wider scatter, with significant deviation from the 1:1 line. Unlike MLR, it does predict lower values but does so with higher dispersion. The large spread outside the ±2 dBA range reinforces the known tendency of decision trees to create rigid, locally optimized models that may not perform well on new data [25].

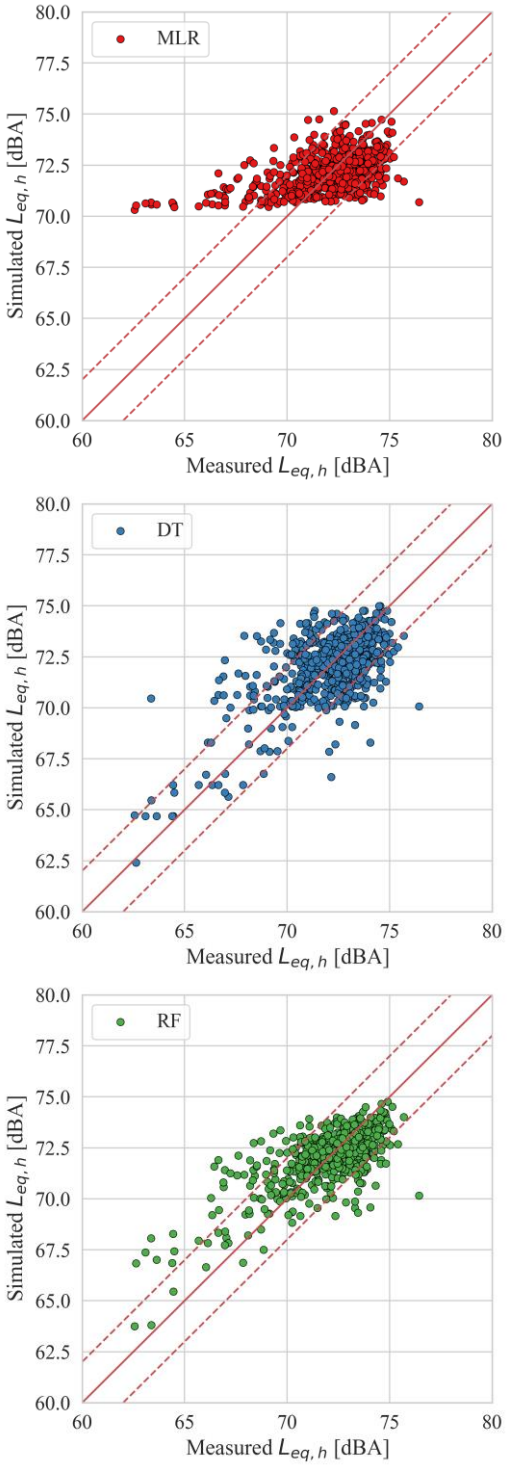

Figure 5. Scatterplots of simulated vs measured data for each regressor

As for the RF model (bottom plot), it provides a more balanced spread of predictions across the range of measured values, without the artificial cut-off seen in MLR. The alignment with the 1:1 line is generally better, although some dispersion is still evident, particularly at the extreme ends of the scale. This suggests that while RF effectively captures nonlinear dependencies, it may still struggle with rare or extreme cases. However, the lower variance compared to DT and the statistics resumed in Table 3 indicate a better ability to generalize.

From a comparative standpoint, the RF model appears to be the most robust, showing good predictive capability across the measured range while maintaining relatively low variability. The MLR model, despite being a simpler approach, fails to predict values below 70 dBA, which raises concerns about its suitability for datasets with a wider dynamic range. Meanwhile, the DT model, though flexible, introduces higher variability.

For a better understanding of such results, the authors calculated the amount of data lying between the ±2 dBA diagonal dashed lines. Table 4 resumes the percentage of data falling within and outside the mentioned interval. RF has the greater amount of data within the ±2 dBA interval, confirming the above comments about its performances.

Table 4. Percentage of data within the ± 2 dB area for each regressor.

	MLR	**DT**	**RF**
Data within ± 2 dBA lines	81.06%	80.91%	87.96%

4. CONCLUSIONS

In this paper three different regressors have been tuned, calibrated and validated on a measured dataset of equivalent continuous sound levels available in literature, to simulate the road traffic noise levels of an extra-urban road. The calibration approach of the regressor is a classical one, where a section of the whole dataset (80%) has been dedicated to the calibration and the remaining part (20%) to the validation of the models. Before the calibration, the regressors were tuned with fine hyperparameter tuning, which revealed the best combination of each regressor to get the lower MAE.

When validating on the dedicated portion of the dataset, outputs show how the simulated values with all regressors fall in a reasonable range of validity. The three regressors seem to get equivalent results when considering central tendency metrics. Anyway, differences exist and can be highlighted by looking at the shape of the distributions of the simulated data, which are slightly different from the measurements' distribution.

MLR is not able to depict the data on the tails, completely missing then noise situations far from the average ones and exhibiting an artificial threshold effect around 70 dBA. For this reason, concerns have been raised regarding its suitability for datasets exhibiting a broader dynamic range, even if the MLR model respects the parsimony principle, with a low number of parameters. DT, while sufficiently accurate, introduces slightly higher variability in the error. The RF model appears to be the most precise, exhibiting good performances in the entire range of measurements and keeping relatively low error mean and dispersion.

In conclusion, machine learning regressors seem to provide a valid option, besides the already existing models, to simulate noise traffic values, starting from the very same input parameters. The future steps of this work will be surely focused on improving the analyses performed on the regressors and including additional models, as well as testing all the regressors on new datasets, possibly related not only to highway road traffic noise data but also urban levels. This will shed light on the usability of such an approach in more complex scenarios, in which several sources may contribute to the environmental noise levels.

URBAN SOUND CLASSIFICATION ON THE EDGE: EXPLORING THE ACCURACY-EFFICIENCY TRADE-OFF

Lion Cassens[1*] **Maarten Kroesen**[1] **Simeon Calvert**[2]

ABSTRACT

Sound source classification is a valuable addition to noise monitoring, providing `further insights into local soundscapes. For privacy preservation, this classification often must be conducted on the edge, i.e., in real time on noise sensors. This puts constraints on the size and complexity of the classification models that can be used. Furthermore, there is a trade-off between accuracy and efficiency, which needs to be balanced on battery or solar powered sensors. However, little is known about this trade-off under consideration of constraints imposed by such sensors. In this paper, we explore the scope of sound classification models that can run efficiently on low-cost sound sensors. Specifically, we investigate the Pareto frontiers between model accuracy and computational complexity, providing insights into the trade-off necessary for deploying such models on very constrained hardware. Building on these findings, we train new classification models optimized for edge devices. The models are trained on publicly available audio samples and a new Dutch Urban Sounds dataset specifically collected to enhance the accuracy of sound source classification in urban environments. The models and implementation are open source, enabling researchers and practitioners to adopt, adapt, and build upon our work.

1. INTRODUCTION

Various studies have shown the importance of perception to explain the human response to the urban soundscape[1]. Annoyance, as well as recreational effects of the sound environment, depend not only on loudness but also on various other indicators. One important factor is the presence or absence of different sound sources. Bird song may be perceived by most as pleasant, while traffic noise is more likely to create a negative stress response. Machine learning models can be used to predict the presence of such sources. For privacy purposes, it is often necessary to run such models on a sensor, which requires small and efficient models.

While various papers propose such small models, few consider the end-to-end performance on edge devices (e.g., execution time including preprocessing), and practical constraints of microprocessors (such as limited for certain deep learning architectures).

In this paper, we define various models and analyze the trade-off between predictive performance and on-device efficiency. This trade-off is very important for battery or solar-powered sensors, as more efficient models result in lower energy consumption. Lastly, three Pareto optimal models along this trade-off are identified.

2. METHODS

The study follows the following steps: potential model candidates are created based on constraints imposed by microcontrollers. Then, these models are pretrained on public datasets and finetuned to a new dataset on Urban

Dutch Sounds. This dataset is then used to measure the predictive performance of all models. The on-device execution time of all models is measured as a proxy for energy efficiency. Lastly, Pareto optimal models are identified along the trade-off of predictive performance and efficiency.

2.1 Microcontroller constraints

Microcontrollers are energy and cost-efficient and, therefore, well-suited for low-cost or energy-constraint noise sensors. Yet, these low-memory devices impose several hardware and software limitations for machine learning models on the edge.

One difference compared to a desktop computer is the limited memory. Microcontrollers typically have less than 8MB RAM, which needs to be shared between sound source classification and all other tasks. Therefore, the model weights and any intermediate results and variables must not occupy more than a few MB of memory. Another difference is the limited processing speed, which is important because edge AI requires sound to be processed in real time. Thus, the classification time for a 3-second audio sample must not exceed 3 seconds.

Besides hardware constraints, there are further limitations in the support and optimization of certain ML operations. While it is theoretically possible to implement and optimize all required operations from scratch, this requires extensive knowledge and effort, which is often ignored in literature proposing very small ESC models. For this analysis, we constrain the choice of machine learning models to those that are supported and optimized for microcontrollers by TensorFlow Lite Micro. This excludes Transformer models and Long Short-Term Memory models.

Lastly, resampling audio is computationally expensive on most microcontrollers. We assume that the proposed models will run alongside a dB(A) calculation, which benefits greatly from a high sample rate. Therefore, all proposed models process audio sampled at 48 kHz.

2.2 Model candidates

Based on the constraints imposed by hardware and software, a total of nine convolutional neural network (CNN) candidates are evaluated. Specifically, three CNN architectures with varying numbers of parameters are combined with three Mel spectrogram sizes: 32, 64, and 104 Mels. All Mel spectrogram sizes are computed from short-time furrier transforms (STFT) with a 1024 sample window and hop rate. Table 1 lists the three CNN architectures.

Table 1. Layers and number of filters for all three model architectures. MaxPooling2D (2x2) follow each Conv2D but were omitted. Flatten and Dropout layers were also omitted from the table.

	Number of filters in Conv2D and units in dense layer		
Layer	**Small**	**Medium**	**Large**
Conv2D (3x3)	16	32	64
Conv2D (3x3)	16	48	64
Conv2D (3x3)	32	64	64
Conv2D (3x3)	32	64	96
Conv2D (3x3)	48	64	128
Dense	64	128	128
Dense (output)	11	11	11

2.3 Datasets

All models were pretrained on public datasets and then finetuned and evaluated on recently collected sound samples from the Netherlands.

To cover a variety of sounds, samples from the following datasets have been combined for the pretraining of all models: Google's AudioSet[2], ESC-50[3], UrbanSound8K[4], SONYC-UST[5] and Amsterdam Sounds Serval[6].

Some samples do not contain any of the selected sound classes but have been included to ensure that other audio sources are not mistaken for the sources considered here (i.e., to reduce false positives).

2.3.1 Dutch Urban Sounds

In addition to the existing datasets, a novel dataset has been collected to improve the prediction performance of sound source classification in an urban context. These 3-second samples have been collected in the Dutch cities Amsterdam and Leiden. Ideally, the microphone used for training data collection should be the same microphone that will be used in a noise sensor running the model. Otherwise, differences in microphones might bias the model predictions. This dataset has been recorded with a TDK ICS-434 MEMS microphone, which is well-suited for noise sensors.

Finetuning the candidate models to these samples is expected to improve real world accuracy, as publicly available datasets such as Google AudioSet can have poor data quality and do not necessarily reflect real world conditions. Other datasets such as SONY-UST are collected in a realistic setting, but specific to the American context.

Table 2. Audio datasets and occurrences of relevant sound classes per dataset.

	AudioSet	SONY-UST	Urban Sound 8K	ESC-50	Amsterdam Serval	Dutch Urban Sounds	Total
Samples	33,220	18,509	8,730	2,000	1,629	1,727	65,815
Vehicle	7,790	10,025	1,000	40	863	405	20,123
Honking	2,043	2,382	428	40	132	18	5,043
Aircraft	2,811	-	-	80	-	40	2,931
Siren	2,443	1,502	929	40	-	190	5,104
Human	10,310	7,254	1,000	40	634	585	19,823
Bark	843	1,114	999	40	-	61	3,057
Bird song	2,485	-	-	40	-	271	2,796
Church Bell	1,089	-	-	40	-	52	1,181
Music	6,886	1,627	1,000	-	-	133	9,646
Wind	2,322	-	-	40	-	457	2,819
Rain	1,145	-	-	40	-	104	1,289

Table 2 shows the number of samples per sound class for each dataset. AudioSet, SONY-UST, and Dutch Urban Sounds are multilabel datasets, meaning each sound class can occur more than once per sample.

2.4 Evaluation procedure

All models are pretrained on the mentioned public datasets. Then, each model is finetuned with 5-fold cross-validation on our Dutch Urban Sounds dataset. This dataset is imbalanced (i.e., some sound classes are sparser than others). Therefore, we evaluate the prediction performance using macro precision, recall, and F1. Micro metrics consider all samples equally, while macro metrics consider all sound classes equally. The latter is more suitable for this imbalanced dataset because the real-world class distribution likely differs from the dataset's distribution. To balance precision and recall, the macro F1 score is used as the final indicator of model performance.

An optimal model not only needs to be accurate but also computationally efficient. Slower models with longer execution times require stronger hardware and lead to an increased energy consumption. Therefore, an optimal model is always a trade-off between prediction performance (e.g., accuracy or F1 score) and efficiency. We measure efficiency as the total time to run the prediction pipeline on the sensor (execution time). The pipeline contains preprocessing and the ML inference itself. The on-device execution time is also a good proxy for energy consumption.

Measuring both prediction performance and efficiency allows us to find models that are Pareto optimal. A model is considered Pareto optimal if no other model performs better in one metric (e.g., F1 score or efficiency) without performing worse in the other, meaning it offers an optimal trade-off between the two.

3. RESULTS AND DISCUSSION

Table 3 lists macro precision, recall and F1 scores over all classes. As discussed, the macro F1 scores are used to determine the best predicting model.

The medium and large 104 Mel models achieve the same macro F1 scores. This may be caused by the imbalanced and relatively small finetuning dataset, which may lead to overfitting of large models. The worst model based on macro F1 is the small 32 Mel model.

Table 3. Macro precision, recall, and F1 scores for all model candidates.

Model		Macro		
Architecture	**Mels**	**Precision**	**Recall**	**F1**
Small	**32**	74.41%	52.38%	59.96%
Small	**64**	76.89%	55.80%	63.41%
Small	**104**	73.34%	54.30%	61.38%
Medium	**32**	70.38%	55.82%	61.90%
Medium	**64**	73.30%	56.17%	62.52%
Medium	**104**	76.27%	58.46%	65.69%
Large	**32**	70.33%	55.99%	61.97%
Large	**64**	75.04%	58.23%	64.77%
Large	**104**	76.07%	59.05%	65.69%

Prediction performance alone, however, is not sufficient to identify an optimal model for resource constraint edge AI. Therefore, we now discuss the on-device speed of each model.

The execution time refers to the overall time required to make a sound source prediction on the sensor. In this case, time was measured on an ESP32-S3 running at 240 MHz. Continuous monitoring of soundscapes requires the execution time for processing of n-seconds audio to not surpass n-seconds. In this case, each audio sample is 3 seconds long. Table 4 shows that all but the Large 104 Mel models fulfill the real-time requirement. The table further shows that architecture size is more important than input size (which depends on the number of Mels) for the execution time of the candidate models. Preprocessing (creation of Mel spectrograms) poses a significant overhead for smaller models but less so for larger models. This is due to the computational expense of short-term furrier transforms (STFT), which is independent of the number of Mels. Only the conversion to Mels varies but is less computationally demanding than STFT.

Table 4. Execution time (including preprocessing and ML inference) for the model candidates.

Model		Execution time (ms)		
Architecture	**Mels**	**Preprocessing**	**Inference**	**Total**
Small	**32**	107	79	186
Small	**64**	113	155	268
Small	**104**	118	250	368
Medium	**32**	107	239	346
Medium	**64**	113	476	589
Medium	**104**	118	759	877
Large	**32**	107	1,040	1,147
Large	**64**	113	2,069	2,182
Large	**104**	118	3,844	3,962

After considering predictive performance and efficiency (represented by execution time) individually, we now discuss the trade-offs between both metrics.

The ideal trade-off depends on the specific use case and design requirements. Therefore, there is no universally best trade-off. Instead, we look at multiple Pareto optimal models along this trade-off, which form the Pareto front.

Figure 1 compares the total execution time and Macro F1 scores of all models. Three models are Pareto optimal, namely the small architecture with 32 Mels, the small architecture with 64 Mels, and the medium architecture with 104 Mels. The large architecture with 104 Mels does not fulfill the requirements of a Pareto optimal model because the medium architecture with 104 Mels has a better execution time for the same Macro F1 score. The remaining models are also inferior to at least one of the Pareto optimal models and can be rejected.

The three Pareto optimal models contain between 46,379 and 281,147 model weights and occupy between 58 and 296 KB of memory after quantization.

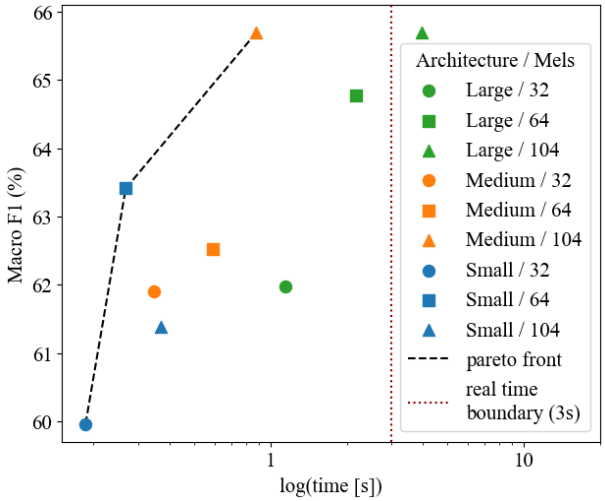

Figure 1. Total execution time and Macro F1 scores of all models and their Pareto front.

For training similar models on other datasets, it is recommended to repeat the Pareto analysis as the model candidates may perform differently depending on the dataset characteristics.

To provide a reference point for model performance, we compare the models with the state-of-the-art Audio Spectrogram Transformer[7] (AST) after also finetuning it on our Dutch Urban Sounds dataset. The AST reached a Macro F1 score of 74.87%. While this surpasses the best-performing model of this paper, the AST is also significantly larger (86,197,259 parameters). The finetuned AST is more than 300 times bigger than our largest Pareto optimal model and unsuitable for microprocessors.

Further research is necessary to compare our Pareto optimal models with other approaches, such as a training pipeline proposed by Mohaimenuzzaman[8].

4. CONCLUSION

Microprocessors impose various practical constraints on the choice of machine learning models due to hardware limitations or missing support and optimization for various deep learning architectures. This currently prohibits the use of Transformer and LSTM models with ML libraries such as TensorFlow Lite Micro.

Therefore, nine convolutional neural networks were compared regarding the trade-off between model performance (measured via Macro F1 scores) and efficiency (measured as total execution time). The most complex model did not fulfill real-time requirements but was also not found to be optimal. Instead, three Pareto-optimal models have been identified, each representing a different optimal trade-off between F1 score and efficiency.

The analysis shows the importance of considering efficiency in addition to model performance, as all six non-optimal models would lead to either more computational cost or less accurate sound source predictions. All three Pareto optimal models are openly available on GitHub[1] and can be used on microcontrollers supported by TensorFlow Lite Micro.

5. ACKNOWLEDGEMENTS

The research was funded by the TU Delft AI Initiative. The sound sample collection in Amsterdam was supported by the Responsible Sensing Lab of the Amsterdam Institute for Advanced Metropolitan Solutions.

ABSTRACT

Noise management has become a major public health issue over several decades. To initiate protective measures against noise overexposure, it is essential to accurately evaluate annoyance. This involves detecting sound sources, their emission durations and associated sound levels. Among commonly encountered sources, road traffic is a prominent contributor to noise pollution, according to health organisation reports. This paper presents an automatic roadway noise detection system. The proposed method combines event detection and classification through a multi-layer approach. Sound event detection is ensured by distinct units. First, a sliding window enables signal preclassification by identifying specific patterns on its mel-spectrogram. Simultaneously, sound level features are used to detect prominent periods, often marking off sound events. Both units combined and sharpened provide detection of the most relevant sound events over the acoustic signal. Precise classification is issued by an additional AI model, dedicated to recognising roadway noise among various vehicle types. Our system operates in diverse soundscapes while maintaining a high level of roadway noise detection accuracy. It permits an automatic estimation of roadway noise contribution, which corresponds to equivalent sound level when roadway noise prevails. This estimation closely aligns with manual assessments from experts, validating the proposed system relevance.

1. INTRODUCTION

Over the past decades, noise from transportation has emerged as a significant public health issue. Several World Health Organization reports point at induced health issues [1]. The European Union indicates that "approximately 1 in 5 people [...] are exposed to unhealthy levels of road traffic noise" among European citizens [2]. In such context, it is essential to provide adequate solutions to reduce noise overexposure. This involves first, a precise diagnosis of the impacted areas, by estimating roadway noise contribution. Roadway noise contribution corresponds to the equivalent sound level during periods of roadway noise prevalence over other sound sources. It is often evaluated thanks to a manual detection of roadway noise over acoustic signals. However, this is a tedious and time-consuming task. With the advent of Machine Learning and automatic Sound Event Detection models, a new perspective appears to automate this process. In that context, an automatic approach is proposed in this paper, through a three-staged method designed to handle long-term acoustic signals and separate roadway from non-roadway noise periods. Its detailed functioning is presented (Section 2) before discussing its performances in several contexts (Section 3) and concluding on various development perspectives.

2. METHODOLOGY

The presented process addresses the issue of automatic roadway noise contribution estimation, which requires the identification of roadway noise prevalence periods over other sound sources. The proposed method relies on successive units, presented in Fig. 1. *YAMNet sound ensemble preclassification* and *Final classification* operate at different levels to classify sounds. They are enhanced by two processing units, refining event detection and boundary definition thanks to the evolution of sound level.

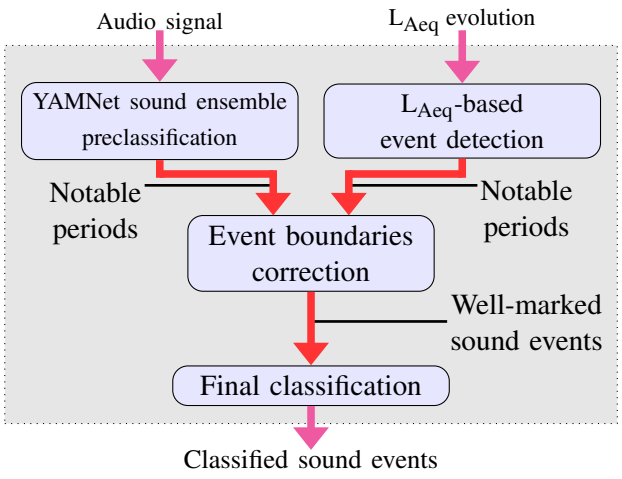

Figure 1. Description of the proposed automatic roadway noise detection method.

The first stage involves a coarse detection process, which utilizes two parallel analyses: one classification over the raw audio signal and another event detection system relying on sound level evolution. In the second stage, the *Event boundaries correction* algorithm processes the detected "Notable periods" from both units. This step provides a clear delimitation of each detected event, defining accurate start and end points, and identifying the monophonic or polyphonic nature of the event. In the last stage, a classifier processes each refined event to accurately classify the prominent sound source, determining whether it corresponds to roadway noise or not. These stages are now discussed in three dedicated subsections (2.1 to 2.3).

2.1 Long-term signal preclassification

This subsection details the two upper units of Fig. 1. The outcome of the open source environmental acoustic classifier YAMNet is exploited (section 2.1.1). In parallel, another algorithm uses A-weighted equivalent sound level (L_{Aeq}) evolution to detect singular events (section 2.1.2).

2.1.1 YAMNet sound ensemble preclassification

After the recording of a long-term acoustic signal, a broad preclassification stage helps understanding the various elements that form the complete soundscape. This analysis is carried out with a sliding window (0.96 s, 50%-overlap) over the full audio signal, to get an objective first view of the prevalent sources. Open-source environmental acoustic classifier YAMNet [3], developed by Google in 2020, was trained on more than 2 millions of audio segments, split into 521 labels [4]. As a CNN replicating MobileNet v1 architecture, it relies on mel-spectrogram representation of the audio signal [3]. Thus, characteristic spectral patterns are identified over the signal and associated with sound sources. However, data imbalance and label imprecision make the classifier unreliable in complex soundscapes. It is better to interpret its prediction as a hint on the involved sounds. Thus, several sound ensembles are defined: *Vehicles, Animals, Music or Speech, Alarms, Loud construction sounds* and *Background noise*. Each initial YAMNet class is associated with one of our sound ensembles. We look into the predicted sound ensembles instead of the YAMNet class, to prevent most misclassifications. This helps defining notable periods over the signal, where detected sounds clearly differ from background noise.

2.1.2 L_{Aeq}-based event detection

To complement sound ensemble preclassification, the equivalent sound level (L_{Aeq}, Eq. (1)) evolution is used to detect notable periods on the long-term signal. In this context, "notable periods" refer to energetic parts of the signal, having the most impact on the perceived nuisances.

$$L_{Aeq,T} = 10\log_{10}\left[\frac{1}{T}\int_0^T \frac{p_A^2(t)}{p_{ref}^2}\,dt\right] \qquad (1)$$

Two different properties or patterns are sought in the L_{Aeq} signal to detect these notable periods. Medium or long-term L_{Aeq} leaps signify the appearance of a loud sound source. Also, a high L_{Aeq} degree of variance is often inconsistent with roadway noise, and rather caused by speech, construction or animal sounds.

Two criteria are introduced to detect these two phenomena. For detecting medium and long-term L_{Aeq} leaps, we compare short-term $L_{Aeq,T=2\ min}$ to long-term $L_{Aeq,T=3\ hrs}$ (Eq. (1)) along the signal. Each time short-term exceeds long-term levels, a notable period is defined. On the other hand, detection of periods with a high degree of variance is performed with a threshold on $L_{Aeq,1s}$ standard deviation over a 20s-long sliding window.

2.2 Event boundaries correction

The stage role is to gather information from the initial preclassification and event detection stages (Notable periods in Fig. 1). Outcomes of both units are subject to sound emergence and duration criteria before they get merged. Thus, each event is defined with its starting time, ending time and one or several prevalent sound ensemble(s). These information are transmitted to the final classifier, aimed at improving the sound sources classifications.

2.3 Final classification

At this stage, a complete overview of the major sounds that prevail over the long-term acoustic recording is available. Nonetheless, numerous use cases require more precision than the defined sound ensembles (section 2.1.1).

For example, the *Vehicles* ensemble may refer to roadway noise as well as aircraft or railway noise. Therefore, we choose to use another classifier to bring in-depth sound source prediction. With such expectations, close attention should be paid to the chosen dataset and classifier model.

2.3.1 *Training dataset*

In order to build a performing supervised classifier, an appropriate training dataset is essential. It should cover most environmental sounds with few classes, while keeping consistency in defined classes. Our dataset architecture is inspired from other major environmental sounds datasets (AudioSet [4] and ESC-50 [5]). 13 classes are used, split into 4 categories, as depicted in Tab. 1.

Table 1. Categorisation of the classifier training dataset.

Roadway sounds	Human sounds, Animal & Music	Other vehicles sounds	Natural sounds
Dense road traffic noise	Human Voice	Airplanes & Helicopters	Wind
Cars	Music & Alarms	Railway	Rain
Motorcycles	Animals (Birds)	Construction machines	
Trucks & Buses	Animals (Insects)		

Internally collected signals, completed with few samples from ESC-50 [5] and Urbansound8k [6] make up for a total of 3500 files and around 10h of labelled data.

2.3.2 *Classifier model*

Regarding the classification model, the goal is to maximize the separation between roadway-related sounds and non-roadway noise. To build it, we drew inspiration from Contrastive Language-Audio Pretraining (CLAP) model, recently proposed in [7]. This model has already shown its effectiveness to encode audio waveforms and text signals. The same audio encoder architecture is trained on our data and used as input to a two-layer deep neural network. These last layers provide a 1D-classification vector corresponding to our dataset classes (Tab. 1).

3. DATASET AND RESULTS

3.1 Step-by-step application on a custom example

To ease the evaluation, a synthetic audio signal is built in mixing sound events from various sites over 30 minutes. Added sound events include train pass-bys, construction sounds, music, alarms, birds, insects and human voice, from 3 dB(A) to 30 dB(A) above residual sound level. L_{Aeq} evolution, reference labels and mel-spectrogram of this signal are shown in the three upper subplots of Fig. 2.

The detection part (2 preclassification stages and event boundaries correction) is first evaluated on its own. A 99 % recall and a 73 % precision are reached when comparing frames from reference and automatically detected events. This means that almost the entirety of reference events have been detected with proper boundaries. Meanwhile, some frames belonging to background noise were detected as sound events, explaining the 73 % precision.

Once the events are properly detected, the final classification unit is called. For each event, it predicts whether it belongs to roadway noise or not. This prediction is depicted in the last subplot of Fig. 2. To evaluate it, Average Precision (AP) [4] is computed regarding the *Roadway sounds* category. On this short example, a 0.92 AP is obtained. It shows that the detector recognizes various environmental sources emerging from background roadway noise. However, this small synthetic test sample is not large enough to conclude on the system performances.

3.2 Application on a large dataset

To carry on with the evaluation, real acoustic signals from 3 different locations were recorded and strongly labelled. Along each 24-hour long signal, roadway noise is manually detected and established as a reference. It permits the estimation of roadway noise contribution : equivalent sound level over all roadway noise-labelled periods. For each site, roadway noise contribution (denoted here as $L_{road,ref}$) is given in Tab. 2. It can be compared to $L_{glob,ref}$, equivalent sound level over the whole signal. The closer both indicators are, the more prevalent roadway noise is.

Table 2. Soundscapes and noise contribution of the 3 evaluation dataset sites.

Site	Major non-roadway source	$L_{road,ref}$	$L_{glob,ref}$
1	Construction machines	53.3 dB(A)	55.9 dB(A)
2	Birds	51.3 dB(A)	51.8 dB(A)
3	Railway	45.8 dB(A)	56.0 dB(A)

Chosen sites cover various use cases: prevalent roadway noise in sites 1 & 2, with disturbance from construction machines or birds. On site 3, railway noise prevails and road traffic is the secondary noise disturbance source.

Audio recordings from each site are supplied to our automatic detector, whose outcome is used to compute AP (Tab. 3). Also, automatic roadway noise contribution estimation ($L_{road,auto}$) is compared to the manual one ($L_{road,ref}$). This second comparison focuses on noisier periods, that matter most for noise contribution estimations.

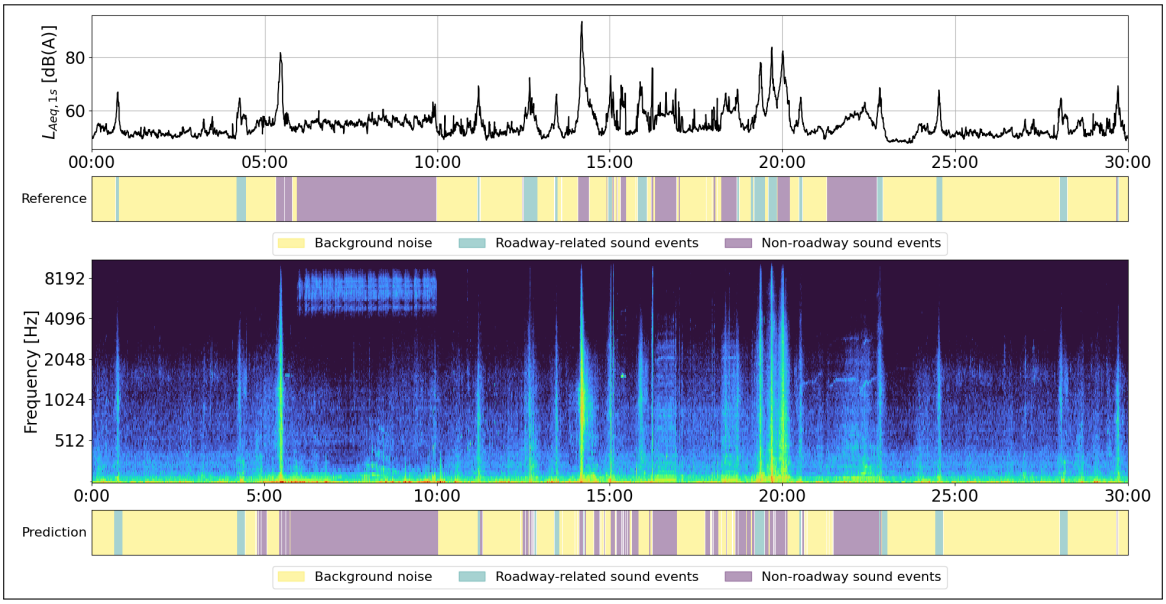

Figure 2. $L_{Aeq,1s}$ evolution, manually detected events, mel-spectrogram and predicted events for a 30-minute signal.

Table 3. Average Precision (AP) of the automated roadway noise detection and comparison between automated and manual roadway noise contributions.

Site	AP	$\lvert L_{\mathbf{road,auto}} - L_{\mathbf{road,ref}} \rvert$
1	0.88	0.1 dB(A)
2	0.91	0.1 dB(A)
3	0.96	0.7 dB(A)

On each site, AP stands above 0.88 and even reaches 0.96 for Site 3. Regarding automatic roadway noise contribution estimations, it also stands within a 0.7 dB(A) margin compared to the one obtained with manual labelling. Therefore, in three various contexts, our automatic achieves a high roadway noise detection rate, especially for noisier periods, allowing an accurate roadway noise contribution estimation.

4. CONCLUSION

In this paper, an automatic roadway noise detection method is proposed. With two classifiers enhanced by sound level analysis units, a robust sound event detection method is provided for road-impacted soundscapes. On 3 long-term signals from various recording sites, a minimum 0.88 Average Precision is reached. Above all, the proposed method aims at automating roadway noise contribution estimations. To this matter, it achieves satisfactory results on each site, with predictions standing within a 0.7 dB(A) margin compared to manual estimation. Future work on dataset or final model may improve accuracy. Still, this method already efficiently handles the automatic roadway noise detection tasks in various contexts.

ABSTRACT

Long-term noise monitoring is essential to ensure compliance with regulations. This process requires the removal of spurious sounds unrelated to the target source or to the typical soundscape of the monitored area. Traditionally, such tasks relied on manual labelling by operators, but recent advancements in data-driven methodologies highlight that it is time to automate the process using cutting-edge machine learning techniques. Pre-trained models, widely available in literature, are trained on extensive datasets covering numerous classes and serve as a foundation for developing specialized machine learning models fine-tuned for specific tasks or subsets of classes. This study presents a Transfer Learning approach to leverage the knowledge of the Contrastive Language-Audio Pre-training (CLAP) model for a classification task focused on a subset of its original classes. Although the CLAP model has demonstrated adaptability across a broad range of classes with good results, the findings of this study suggest that the application of Transfer Learning can enhance classification accuracy for the selected subset of environmental sound classes.

1. INTRODUCTION

The evaluation of noise sources is essential for monitoring and mitigation of environmental noise levels in order to protect public health [1]. The primary contributors to environmental noise typically include road traffic [2–4], railways [5,6], airports [7], and industrial activities [8]. In real monitoring scenarios, however, in addition to the noise originating from the target source, a substantial number of unintended or anomalous events, referred to as spurious sounds, is also collected. In this context, accurately attributing the correct amount of responsibility to each source is crucial. Consequently, the identification and subsequent exclusion of spurious events from measurements becomes a key task. At present, this process is generally performed by acoustic experts through visual inspection of time histories and spectral representations. While effective in some cases, this method is highly time-consuming and susceptible to human error. These limitations are particularly evident in the case of wind turbine noise, where long-term measurements are necessary. To address these challenges, it can be useful to adopt new data-driven methodologies, capable of efficiently processing large volumes of data. In this regard, machine learning and deep learning offer promising potential to enhance and accelerate the detection of spurious events. The specific name of the task just described is Sound Event Detection (SED), which aims not only to identify the class of the event but also to determine its onset and offset within a longer audio recording. In this article, we address a preliminary step to this task, commonly referred to as Sound Event Classification (SEC), where audio segments are pre-

trimmed to contain only the sound event to be classified. This classification step serves as a foundation for building a model capable of accurately recognizing sound classes, which can then be integrated into a more complex pipeline to perform event detection.

One of the main difficulties related to this task lies in the highly heterogeneous nature of these anomalous occurrences, which makes their identification very complex. The principal categories of identifiable sources include anthropogenic sounds, transportation infrastructure noise, natural and animal-generated sounds, agricultural machinery, and industrial operations. Nevertheless, even this macro-level classification does not fully capture the variability found within individual categories, highlighting the need for adaptable classification approaches. The traditional strategy for addressing these tasks involves designing a neural network architecture and training it from scratch to differentiate among a fixed set of predefined target classes. While this method is effective in scenarios with a limited scope, it lacks generalization capability. Specifically, if the initial set of target classes were to be extended, the model would require complete retraining to accommodate the new classes. Moreover, in order to achieve good classification performance, especially on heterogeneous and complex datasets such as in this case, it is necessary to train the neural network on a very large amount of data. This ensures that the model can learn a comprehensive representation of the wide variability in data and scenarios it will be required to recognize. To address the need for a solution that is both adaptable to diverse contexts and trained on sufficiently varied data, the use of pre-trained models has recently become widespread. Pre-trained models already possess knowledge of the general features typical of the task they were designed for, such as image recognition, natural language processing, or audio classification. They can be used either directly or as a starting point to develop specialized models tailored to a specific set of classes or more targeted tasks. In this context, the Contrastive Language-Audio Pretraining (CLAP) [9, 10] model has been developed. It is a deep learning model designed to learn joint representations of audio and text. In order to achieve this, CLAP transforms both an audio measurements and its corresponding textual description into vectors of the same dimension, called embeddings. During training, the model pulls the embeddings of matching audio-text pairs closer together, while pushing apart those of unrelated pairs. This contrastive learning enables the model to capture semantic relationships, organizing the embedding space so that similar sounds and descriptions are near each other. To reinforce the selection of this model, it is worth mentioning that in [11] it has been demonstrated that, on a subset of five classes extracted from the ESC-50 dataset [12], the performances achieved using embeddings extracted by CLAP overcome the performances obtained using the classic features Mel-Frequency Cepstral Coefficients and Gammatone Frequency Cepstral Coefficients, both in clustering and classification task.

A more detailed description of the CLAP model will be provided in Section 2, along with an explanation of the transfer learning approach adopted in this study. Subsequently, in Section 3 the preliminary outcomes obtained with the fine-tuned model will be presented and compared with the results of the original CLAP model on the same dataset. Finally, Section 4 will briefly analyze these results and outline the main conclusions.

2. METHODOLOGY

2.1 CLAP model

The CLAP model consists of an audio encoder and a text encoder, designed to extract two embeddings of equal dimensionality d from the audio measurement and its corresponding textual description, respectively. The audio encoder is based on a Transformer architecture named Hierarchical Token-Semantic Audio Transformer (HTS-AT), introduced in [13]. The goal of CLAP is to compare these embeddings and optimize the representation space such that audio and text embeddings with similar semantic content are pulled closer together, while those with differing semantics are pushed farther apart. Analyzing the structure of the model in detail, the input of the audio encoder is the Mel-Spectrogram of the audio, that is the spectrogram computed using the Mel scale, designed to mimic human auditory perception, which is nonlinear. This scale converts frequencies so that equal distances on the scale correspond to equally perceived differences in sound, with greater sensitivity to lower frequencies and less to higher ones. The structure of CLAP model is depicted in Figures 1 and 2.

The Mel-Spectrogram of dimensions (T, F), where T is the temporal dimension and F is the number of frequency bins, is cut into different patches of dimensions $(P \times P)$, as it can be seen in Figure 1. Each element of the sequence is then passed to a module composed by a Convolutional Neural Network (CNN), to be transformed transformed in a so-called token of dimen-

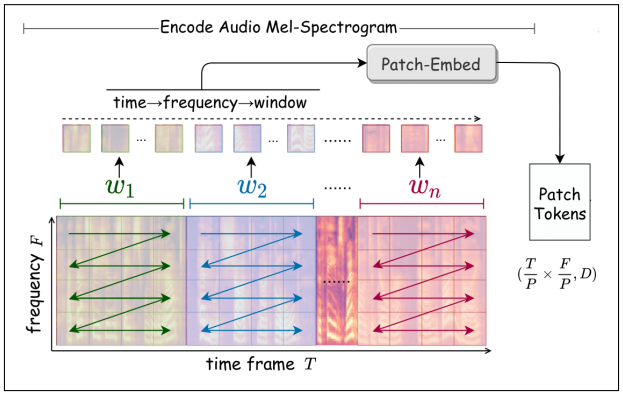

Figure 1. Mel-spectrogram encoding as input for HTS-AT. Architecture and Figure have been presented in [13].

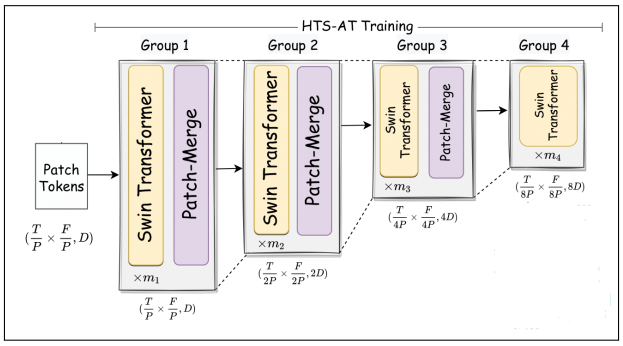

Figure 2. Sequence of SWIN Transformers and Patch-Merge in HTS-AT. Architecture and Figure have been presented in [13].

sions $(1, D)$. Then, all the tokens are arranged in a single structure of dimensions $\left(\frac{T}{P} \times \frac{F}{P}, D\right)$ where $\frac{T}{P} \times \frac{F}{P}$ is the number of tokens. The tokens are then fed into a sequence of transformer-encoder groups, as shown in Figure 2. The transformer architecture differs from previous models used in sequence analysis, like recurrent neural networks (RNNs) and long short-term memory networks (LSTMs), as it doesn't rely on recurrent structures. Instead, it uses a self-attention mechanism to dynamically adjust the relevance of different tokens based on their contextual dependencies, allowing the model to focus on the most relevant parts of the sequence and capture complex relationships within the data. After the Transformer, the patch-merge module is applied to decrease the number of patches and increase the dimension in the latent space, combining adjacent patches. This procedure is repeated sequentially for other groups of transformer-merger, until the i^{th} audio is transformed into the embedding E_a^i of dimension $d = 1024$. By means of an encoder also every textual descriptions is transformed into a d-dimensional embedding E_t^i. Assuming to have N pairs of audio and text, it is possible to arrange the embeddings into two matrices E_a and $E_t \in R^{N \times d}$. The audio and text embeddings obtained through this procedure are then used to compute a similarity measurement, namely a scalar product between the vectors as an estimate of their distance in the hyperspace created by the model. The similarity matrix is equal to

$$\text{SIM} = \tau(E_t \cdot E_a^\top) \,, \tag{1}$$

where τ is a scaling factor. The matrix contains the similarity between N matching pairs in the diagonal and between $N^2 - N$ non-matching pairs off-diagonal. The goal of the training stage is to bring closer matching pairs and separate non-matching ones. The loss function is therefore designed so that, by minimizing it, the similarity between matching pairs (i.e., along the diagonal) is increased, while the similarity between non-matching pairs (i.e., off-diagonal elements) is decreased. The two loss functions ℓ_{text} and ℓ_{audio} are equal to

$$\ell = -\frac{1}{N} \sum_{i=0}^{N} \log \text{diag}(\text{softmax}(\text{SIM})) \,. \tag{2}$$

The terms of the matrix softmax(SIM) can be interpreted as the probability of matching between the corresponding audio-text pairs. The total loss is equal to:

$$\mathcal{L} = 0.5(\ell_{text} + \ell_{audio}) \,. \tag{3}$$

In the latent hyperspace of the model, minimizing this loss function results in bringing closer audio and text embeddings concerning the same semantic area.

2.2 Transfer learning

The CLAP model, once trained, generates a latent space where elements are arranged based on their semantic relationships. This structure allows the model to be used for classification tasks without additional training. To classify a new sound using the original model, a set of candidate class labels must be provided. Since the pre-training

objective was to align audio and text embeddings that refer to the same concept, the model performs classification by evaluating the similarity between these embeddings. Specifically, it computes the similarity score between the audio embedding and each of the class label embeddings, selecting the class with the highest score as the predicted output. Directly employing the pre-trained model for classification offers clear advantages, including its ability to recognize a vast range of classes. However, performance on an arbitrary set of classes is not guaranteed to be optimal. Since the goal of this work is not to ensure applicability to an unlimited set of categories, but rather to achieve high performance on a well-defined subset, a transfer learning strategy was adopted. The idea is to leverage the robust foundational knowledge of the CLAP model and fine-tune it to specialize in the selected subset of classes. The goal is to enhance accuracy within a limited set of sound classes, compared to the broader but less specialized performance of the original model. To achieve this, only the initial portion of the CLAP architecture, specifically the component responsible for embedding extraction, was retained. A new linear layer was then trained to project the resulting embeddings of dimension $d = 1024$ into a lower-dimensional space corresponding to the number of target classes of dimension $n_{\text{classes}} = 21$. Each output value from this layer represents the predicted likelihood that the input sound belongs to one of the predefined categories. The linear transformation applied by the layer to map the input x into the output y is equal to:

$$y = xW^{\top} + b \,, \tag{4}$$

where W and b are the learnable weights and bias of the layer, of dimension (n_{classes}, d) and (n_{classes}) respectively.

2.3 Dataset

The dataset was constructed using both measurements collected online, primarily from the website freesound.org [14], and those recorded by the authors. The classes were selected based on the authors' experience with monitoring measurements, primarily conducted in non-urban or sparsely populated areas with some human presence. The classes belong to five main categories: anthropogenic sounds, transportation infrastructure noise, natural and animal-generated sounds, agricultural machinery, and industrial operations. The chosen classes are 21, and they are reported in Table 1. It has been observed that varying the segment lengths within the same dataset during classification can result in different accuracy outcomes. Consequently, multiple versions of the dataset were created, with measurements segmented into durations ranging from 1 to 10 seconds in 1-second increments. For each dataset version, four distinct sets were constructed: the training set, the validation set, the early stopping set, and the test set. The early stopping set is essential to prevent overfitting, as training is stopped when the accuracy on the early stopping set does not improve for 10 consecutive epochs. Each dataset version consisted of 500, 100, 100, and 100 measurements for the training, validation, early stopping, and test sets, respectively. In cases where the total duration of the dataset for a given segment length was insufficient to meet these numbers, data augmentation was applied through the addition of gaussian noise.

Table 1. Classes of sounds chosen for the dataset.

Classes of Sounds	
Airplane	Bells
Birds	Cats
Chicken coop	Cicadas and crickets
Clacson	Crows and seagulls
Dogs	Glass breaking
Helicopter	Lawn mower and brush cutter
Music	Sirens and alarms
Thunder, fireworks and gunshot	Train
Vacuum cleaner, fan and hairdryer	Vehicle idling
Vehicle pass-by	Voices

3. RESULTS

In this Section the results obtained using directly the pre-trained model are compared with the results obtained with the fine-tuned model. The length of the measurement in seconds plays a crucial role in classification performance. It has been observed that varying the lengths of the segments from the same dataset during classification can lead to different accuracy results. This variation is likely due to the structural differences in the spectrograms. To accurately capture recurring patterns in a sound's spectrogram,

a minimum duration may be required. Hyperparameters were tested with lengths ranging from 1 to 10 seconds, in 1-second increments. Table 2 shows the accuracy and loss of the original pre-trained model on the validation set, depending on the length of the input audio. Various experiments were then conducted using the fine-tuned model, with different hyperparameters adjusted during training. The best result is reported in Table 3.

Table 2. Accuracy and Loss results of the original CLAP model on the validation set at varying of the audio length hyperparameter.

Audio length	Accuracy	Loss
4 s	72.93 %	2.83
7 s	72.89 %	2.82
8 s	70.55 %	2.83
3 s	70.23 %	2.82

2 s	64.02 %	2.84
1 s	60.42 %	2.86

Table 3. Accuracy and Loss result of the fine-tuned model.

Audio length	Accuracy	Loss
4 s	91.83 %	0.28

4. DISCUSSION AND CONCLUSIONS

This study presents the Contrastive Language-Audio Pretraining (CLAP) model, which integrates inputs from different domains into a shared space where their vector representations can be compared and manipulated. The model was fine-tuned using a Transfer Learning approach to perform Sound Event Classification (SEC) on a specific dataset, focusing on key environmental sources relevant to noise monitoring. A linear layer was applied to the sound embeddings generated by the original model to adapt it for the classification task. The results demonstrate a significant improvement in accuracy, increasing from 72.93 % (the best performance achieved by the original model) to 91.83 % (the best performance achieved by the fine-tuned model) on the validation set. These findings highlight the effectiveness of the fine-tuned model in the classification task, showing a substantial performance gain over the original model. Further analysis and exploration of additional fine-tuning strategies are warranted to continue improving these results. The next step in this research will involve incorporating the fine-tuned model into a detection pipeline for Sound Event Detection (SED), which is the ultimate objective in real-world scenarios.

ABSTRACT

Safe driving depends on both internal and external factors of the vehicle, including those manifested as acoustic signals. Sounds, whether external, such as sirens or horns, or internal, such as conversations between passengers or the sound system, provide critical information to identify events that could compromise safety. The placement of microphones used for monitoring and feeding into an artificial intelligence-based detection system plays a crucial role. Microphones placed externally are essential for capturing sounds like sirens or horns, but they face challenges such as wind noise and vibrations caused by the movement of the vehicle. On the other hand, detecting these external events from the interior presents difficulties due to attenuation or distortion caused by the acoustic insulation of the body of the vehicle. This work explores the relevance of microphone placement by comparing the performance of models when processing data captured separately from the interior and exterior of vehicles. The challenges associated with capture are also discussed.

Keywords: *sound detection, mic placement, road safety*

1. INTRODUCTION

Audio-based event detection systems offer distinct advantages over vision-based systems in vehicle safety and driver assistance, particularly in scenarios where a direct line of sight to the event source is obstructed [1]. The ability to recognize critical acoustic cues, such as emergency vehicle sirens or horn sounds, enhances situational awareness and supports timely decision-making while driving [2, 3]. However, the performance of such systems is highly sensitive to microphone placement and their robustness in dynamic, noisy environments.

Microphone positioning plays a critical role in determining the accuracy and reliability of audio-based detection systems. External microphones, mounted outside the vehicle, are well-suited to capturing environmental sounds, such as approaching emergency vehicles or honking cars. However, they are vulnerable to various interferences, including wind noise, road noise, and other environmental disturbances. To mitigate these issues, approaches such as physical filters [4], digital signal processing techniques [5], and deep learning-based noise reduction methods [6] have been proposed. While these methods enhance detection performance, they require careful optimization to remain effective under diverse real-world conditions.

In contrast, placing microphones inside the vehicle provides a more controlled acoustic environment, thereby reducing exposure to external noise. Nonetheless, this setup introduces its own challenges, such as sound attenuation caused by the vehicle's structure and interference from internal noise sources like conversations, infotainment systems, and engine vibrations. Additionally, capturing external acoustic events from within the cabin is complicated by the sound-insulating properties of modern vehicle designs. To address these challenges, advanced

deep learning models capable of processing polyphonic sound events [7, 8]—where multiple overlapping sounds occur simultaneously—are increasingly employed. These models improve the system's ability to differentiate between relevant and irrelevant auditory signals within the complex acoustic environment of a vehicle interior.

Recent research has also explored multimodal approaches [9] that integrate both audio and visual data to improve event detection capabilities. By combining acoustic signals with visual cues, these systems can compensate for limitations in either modality, leading to improved overall detection accuracy. However, multimodal systems introduce additional complexities, including higher computational demands, synchronization requirements between audio and video streams, and sensitivity to adverse environmental conditions (e.g., poor lighting or occlusions) that may impair one or both modalities. These limitations highlight the need for thoughtful design and implementation when considering multimodal solutions.

This study evaluates the impact of microphone placement—inside versus outside the vehicle—on the performance of three state-of-the-art deep learning models: the Audio Spectrogram Transformer (AST) [4, 10], Convolutional Recurrent Neural Networks (CRNN) [11, 12], and a version of YOLO adapted for audio spectrogram inputs [8, 13]. Rather than focusing solely on performance comparisons, the primary objective is to investigate how microphone placement, ambient noise conditions, and overlapping sound events influence the ability of each model to detect key auditory events, such as sirens and horn sounds, under realistic driving scenarios. By examining detection accuracy across different microphone configurations, this work sheds light on the trade-offs inherent in each setup and contributes to the development of more robust and context-aware audio-based detection systems for intelligent vehicle applications.

2. METHODOLOGY

2.1 Data Collection

To evaluate model performance under different acoustic conditions, two distinct sets of audio recordings were collected. Recordings were made using WM-61A DIY and XYH-6 microphones connected to a Zoom H6 recorder to ensure synchronized multi-channel capture. Two channels were placed inside the vehicle, centrally positioned, while four were mounted externally—two on each side. The external microphones were installed on a stable base and fitted with physical wind filters, which have been shown in prior studies to effectively reduce wind interference. The microphone layout is shown in Figure 1.

In Scenario 1, recordings were conducted both inside and outside the vehicle under low-noise conditions . No additional sound sources from the inside—such as radio, mobile phones, or conversations—were present . This scenario represents an idealized environment with minimal internal interference. A total of 1245 seconds were recorded, which were segmented into 4-second clips using a 1-second sliding window, resulting in 23 horn and 94 siren events.

Scenario 2 was designed to simulate a realistic and noisy in-cabin environment. In this case, background sounds including conversations, radio playback, and mobile phone usage were deliberately introduced. The total duration of this recording was 877 seconds, yielding 29 horn and 179 siren events after segmentation using the same process as in Scenario 1.

Both datasets were segmented into overlapping 4-second clips using a 1-second stride to construct a continuous and structured dataset. Rather than adopting a traditional sound event detection (SED) framework, each segment was assigned a single label—*Horn*, *Siren*, or *No Event*—based on the presence of a target sound within the

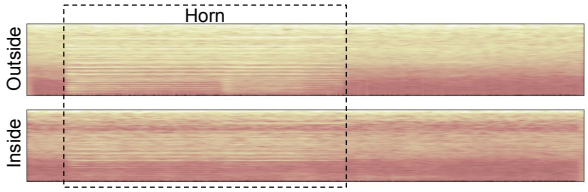

Figure 1: Microphone placement in the vehicle. Microphones M1–M4 (WM-61A DIY) are positioned externally, while microphone M5 (XYH-6, two channels) is located inside.

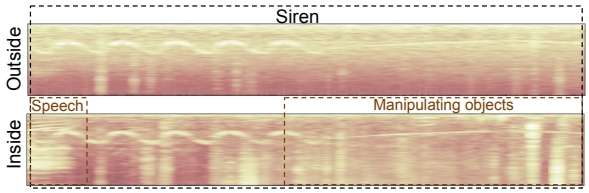

clip. This simplified labeling strategy was chosen to facilitate a direct and controlled comparison of model performance across different microphone placements, focusing on the detectability of key acoustic events rather than precise time event localization or boundary detection. While this approach does not capture the full temporal dynamics of sound events, it provides a practical and interpretable means of evaluating classification accuracy under varying acoustic conditions.

All recordings were conducted with the vehicle in a stationary state to minimize wind-induced noise, whose limited impact has been demonstrated in [4]. The recording site was selected to ensure consistent exposure to traffic-related sounds, resulting in a naturally high frequency of siren and horn events.

To illustrate the acoustic differences between scenarios, Figure 2 shows representative 4-second audio segments from both conditions: (a) a clean sample from Scenario 1, and (b) a more complex recording from Scenario 2, where overlapping internal sounds such as speech and object interaction are present.

(a) Scenario 1: 4-second audio segment with minimal background noise.

(b) Scenario 2: 4-second audio segment with overlapping in-cabin events (e.g., speech, object handling).

Figure 2: Representative audio samples from the two recording scenarios. Scenario 1 provides a low-noise baseline, while Scenario 2 reflects more realistic in-vehicle acoustic conditions.

2.2 Detection Models

To investigate how microphone placement affects the detection of relevant acoustic events in vehicular contexts, we implemented three deep learning-based models with distinct architectural characteristics: the Audio Spectrogram Transformer (AST), a Convolutional Recurrent Neural Network (CRNN), and a fully convolutional architecture based on YOLO. While the primary goal is not to compare absolute model performance, these architectures offer complementary perspectives on how different microphone configurations influence the perception and classification of acoustic signals. Each model was adapted to produce standardized outputs—three class probabilities for *Siren*, *Horn*, and *No Event*—to enable a consistent evaluation framework.

The AST model [14] leverages a Multihead Self-Attention mechanism to learn long-range dependencies within audio sequences. This capacity to capture global contextual information makes it particularly effective for identifying complex acoustic patterns, even in the presence of noise or temporal distortion. In this study, AST was trained using 4-second Mel spectrograms with 128 Mel bands, a 32 ms analysis window, and a 10 ms hop size. Unlike the other models, AST processes stereo audio by jointly analyzing two input channels. For in-cabin detection, the two interior microphones were used as stereo input; for exterior detection, the two side-mounted microphones were combined. To adapt the model for three-class classification, the pre-trained attention layers were frozen, and a dense layer with 768 neurons and PReLU activation was added, followed by a softmax output layer with three units [4].

The CRNN model [11,12] combines two-dimensional convolutional layers for spectral feature extraction with a bidirectional GRU layer to model the temporal evolution of sound events. Its frame-wise output allows for temporal localization of events within each segment. In contrast, the YOLO-based model [8] follows a fully convolutional approach adapted from object detection in computer vision. It produces predictions at multiple temporal resolutions using bounding-box-like structures, without relying on sequential modeling. Both CRNN and YOLO operate on single-channel audio, and were thus trained and tested on individual microphone signals. Input Mel spectrograms for these models were computed with 128 Mel bands, a 32 ms window, a 16 ms hop, a Hamming window function, and a 2048-point FFT, all sampled at 16 kHz.

The models were trained on a curated subset of open-

source datasets, primarily based on AudioSet [15], augmented with additional publicly available recordings of sirens, horns, and urban noise. Training procedures were customized for each architecture, ensuring that learned features aligned with the goal of robust acoustic event detection under real-world conditions.

While AST was trained using 4-second monophonic labels, both CRNN and YOLO were originally designed for polyphonic event detection across 10-second clips. For evaluation, however, all models were tested using 4-second segments to ensure consistency. Although AST does not support polyphony, this limitation had minimal impact in our experimental setting, where overlapping events were rare. Nevertheless, this distinction remains an important consideration when interpreting the models' capabilities in more complex acoustic environments.

2.3 Performance Metrics and Evaluation

The performance of each model was evaluated using standard classification metrics: precision (P), recall (R), and F1-score (F1), which are commonly used in classification tasks. These metrics provide a comprehensive assessment of model performance, particularly in scenarios with imbalanced class distributions. In such cases, it is essential to evaluate not only the quantity of correct predictions but also their relevance and consistency. This is especially important in the context of acoustic event detection, where the goal is to identify specific sounds (e.g., horns and sirens) amidst varying levels of background noise.

The recordings used in this study were segmented into 4-second clips with a 1-second sliding window. Each segment was assigned a single label—*Horn*, *Siren*, or *Nothing*—with events outside these categories discarded, particularly for the CRNN and YOLO models. These models generate hard predictions, meaning they provide precise timestamps for detected events within each 4-second segment. For consistency across all models, these timestamps were converted into weak labels, simplifying the task to a binary classification problem, i.e., determining whether an event was present or absent in each segment, without considering its exact duration or temporal position.

Each model was evaluated using both interior and exterior microphones, under two distinct recording conditions. Scenario 1, with minimal background noise, represents a controlled environment, allowing us to assess model performance in an ideal setting. In contrast, Scenario 2 introduces background noise from conversations, radio playback, and mobile phone use, simulating a more realistic in-vehicle environment. By analyzing the performance of the models in these scenarios, we can assess how the placement of the microphone affects the detection accuracy and robustness of the models under varying acoustic conditions.

3. RESULTS

The results presented in Table 1 highlight the impact of microphone placement and background noise on the performance of the three deep learning models—AST, YOLO, and CRNN—in detecting acoustic events. Overall, all models performed better with external microphones compared to internal ones. This effect was observed in both scenarios, but it was especially pronounced in Scenario 2, where background noise from conversations, radio playback, and mobile phone use inside the vehicle further degraded performance.

In Scenario 1, where external microphones captured clearer signals, AST achieved the highest F1-score (0.77), followed closely by YOLO (0.72) and CRNN (0.51). AST's superior performance in this controlled environment is largely attributed to its high recall values, particularly for horn detection (0.96). However, when evaluated inside the vehicle, all models experienced performance drops. AST, despite maintaining the highest F1-score (0.69), showed a notable decline in recall (0.63), while YOLO and CRNN also decreased to 0.50 and 0.34, respectively.

The performance degradation is even more evident in Scenario 2, where additional noise sources such as conversations, radio, and mobile phone sounds were present. AST exhibited the most pronounced decline, particularly for horn detection inside the vehicle, where its precision, recall, and F1-score dropped to zero. This suggests that AST, which assigns a single label per segment, struggles in polyphonic scenarios where multiple sound events overlap, leading to a total drop in performance for horn detection when other, more dominant sources are present. In contrast, while YOLO and CRNN also showed a considerable drop in performance, they retained some detection capability for horns, with F1-scores of 0.15 and 0.17, respectively. However, AST maintained a similar average F1-score inside the vehicle due to its stronger performance in siren detection, despite its inability to detect horns in this scenario.

Although the results of the experiment suggest that external microphone placement might be more effective for detecting sirens and horns, it is important to note that

this study has excluded certain variables that could influence monitoring effectiveness in real-world conditions. These variables include background noise from the external environment, weather conditions, microphone wear, among others. Additionally, for comprehensive monitoring of the vehicular environment, it is crucial to consider that monitoring the interior may be more complex from the outside due to the vehicle's inherent acoustic insulation, compared to detecting external events from the inside. This suggests that future research could explore the feasibility of implementing two microphone sources, each focused on detecting specific events from the interior and exterior, which could improve the accuracy and reliability of the system in more complex scenarios.

4. CONCLUSIONS

This study evaluated the performance of three deep learning models—AST, YOLO, and CRNN—for detecting external acoustic events (such as sirens and horns) in vehicular environments under various conditions. The results highlight the significant impact of microphone placement and background noise on detection accuracy. External microphones generally provided clearer signals, leading to better performance, while internal microphones were more susceptible to degradation, particularly in noisy conditions.

AST achieved the highest F1-score in controlled environments but struggled with overlapping sounds, resulting in a complete failure in horn detection inside the vehicle. In contrast, YOLO and CRNN maintained some detection ability in these challenging scenarios, although with lower overall accuracy.

Future work should explore the models' performance in more complex tasks, such as detecting the precise onset and duration of events, rather than merely classifying their presence within fixed segments. Additionally, investigating multi-microphone fusion strategies could help mitigate the limitations observed with single-channel inputs.

HIGH BULK MODULUS PENTAMODES: THE THREE-DIMENSIONAL METAL WATER

ABSTRACT

Pentamode metamaterials (PMs) mimic the acoustic properties of liquids and offer a powerful means of controlling sound propagation. However, their design and realisation remains an open challenge, especially in three dimensions. Existing PMs rely on thin junctions to simultaneously achieve high bulk modulus, low shear modulus and adequate density. This is successful in 2D but not in 3D, where an upper bound on the bulk modulus prevents efficient interaction with underwater sound waves. Hence, a fundamentally different geometry is needed.

We first apply topology optimisation to find different geometries and test it against the design of a two-dimensional Lüneburg lens. We show that it offers greater flexibility than conventional parametric optimisation approaches and the usual geometry based on effective pins is recovered. However, extending this method to three dimensions leads to geometries that are extremely difficult to manufacture. We show that simple pin-like kinematics are no longer sufficient in 3D, but that slider-like joints are required. Applying this paradigm, we propose the first 3D periodic lattice that successfully mimics the acoustic behaviour of water at low frequencies.

Keywords: *pentamode, underwater acoustics, cloaking, phononic crystal.*

1. INTRODUCTION

Pentamode metamaterials (PMs) have attracted considerable attention for their potential in underwater acoustics, enabling applications such as acoustic lenses, waveguides and invisibility cloaks [1]. PMs are solids in which the propagation of shear waves is prevented by a low shear-to-bulk modulus ratio, allowing them to behave like artificial fluids. It is common in the literature to present the concept in a two-dimensional approximation, where the so-called bimode metamaterials (BMs) are typically designed by parametric optimisation. All current designs are based on thin junctions that act as kinematic pins, making it possible to achieve a material with the same quasi-static properties as water. The same concept has been applied to the design of three-dimensional PMs [2, 3], and materials with the same sound speed as water and tunable anisotropy have been proposed to build acoustic devices [4]. However, the acoustic impedance of such materials is two orders of magnitude lower than that of water, preventing effective implementation. In this work, we first rely on topology optimisation to look for a new geometry of BMs. A unit cell shape similar to those existing in the literature is recovered, with the advantage of being a more efficient and versatile approach than the usual parametric optimisation. When aiming for a 3D PM, topology optimisation provides a geometry that is extremely difficult to realise [5], so we take a step back and focus on the kinematics of a PM. We show that the pin-like junctions are no longer sufficient to achieve the high bulk modulus of water and that a more complex topology is required [6]. We therefore propose slide-like junctions and design the first material whose mechanical properties are truly indistinguishable from water in the quasi-static limit.

2. TOPOLOGY OPTIMIZATION FOR BIMODE METAMATERIALS

To design a BM with a desired acoustic behaviour, we apply a density-based topology optimisation strategy to a

square unit cell. For simplicity, we focus on the design of an isotropic material, targeting only the effective bulk modulus and mass density, along with a low shear modulus. We define the inverse problem for a unit cell as:

$$\begin{aligned} &\min_{\rho} \mathbb{C}^{\mathrm{H}}_{33} + \alpha_T C_T \\ &\text{subject to :} \\ &\quad \mathbb{C}^{\mathrm{H}}_{11} < \kappa_L \\ &\quad \mathbb{C}^{\mathrm{H}}_{12} > 0.99\,\kappa_L \\ &\quad 0.99\,V_L < V < V_L \\ &\quad 0 \le \rho_k \le 1 \quad \forall k = 1, \dots, N \\ &\quad \text{Cell problem} \\ &\quad \text{Thermal problem} \end{aligned} \tag{1}$$

where the tensor $\mathbb{C}^{\mathrm{H}}$ is the homogenised elasticity tensor [7]. The objective function minimises a combination of the shear stiffness $\mathbb{C}^{\mathrm{H}}_{33}$ and the thermal compliance C_T, scaled by a weight factor α_T. The thermal compliance acts as a proxy for joint thickness, introduced following the virtual temperature method so that overly thin or disconnected regions are penalised [8]. The constraints enforce that the effective moduli $\mathbb{C}^{\mathrm{H}}_{11}$ and $\mathbb{C}^{\mathrm{H}}_{12}$ match the target bulk modulus κ_L, while a volume constraint ensures that the amount of solid material remains within bounds (V close to a prescribed value V_L). The design field $\rho \in [0, 1]$ describes the solid and void regions inside the cell. We apply this topology optimisation framework to design the unit cells of a 2D Lüneburg lens [9] for underwater acoustics. A circular Lüneburg lens is discretised into square unit cells that are optimised independently. The target properties for each cell are given by the local bulk modulus κ_L and density ρ_L, derived from the analytical profile of an impedance matched lens. The results demonstrate that the optimised structures provide accurate refractive index control, preserve constant impedance, and enable fluid-like wave propagation, making them ideal candidates for underwater metamaterial applications. Figure 1 shows that the effective properties of the cells are very close to the desired ones.

3. TRANSITION TO 3D: A NEW KINEMATIC APPROACH

The inverse design of a 3D PM can be solved by topology optimisation as before, but the solution is generally hard to realise, see for example [5]. In fact, while thin joints are sufficient for 2D metaliquids, applying this approach

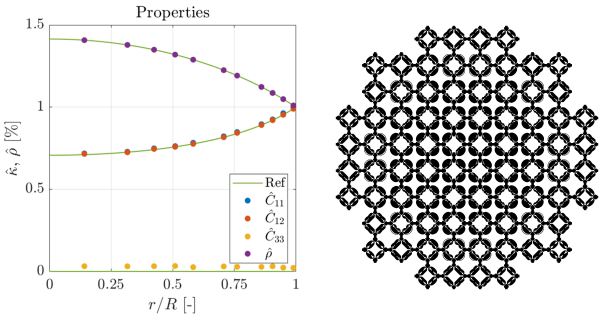

Figure 1: Left, properties of the optimised cells compared to the target; right, microstructure of the lens.

to three dimensions limits the bulk modulus to two orders of magnitude less than a liquid [6]. The effective stress tensor $\mathbb{C}^{\mathrm{H}}$ of an elastic network is computed as the summation over the boundary nodes of a cell as [10]

$$\mathbb{C}^{\mathrm{H}} = V^{-1} \sum_i \mathbf{r}_i \otimes \mathbf{f}_i, \tag{2}$$

where $\otimes$ is the outer product, $\mathbf{r}_i$ the position of the i^{th} node, and $\mathbf{f}_i$ the force applied to it. Note that the moments acting on the nodes have no effect. Therefore, we relax the hinge-hinge kinematics and instead design a link that acts as a slider, transferring not only axial forces but also momenta from one node to another. To address this, we propose a novel 3D pentamode metamaterial (PM) geometry inspired by the kinematics of ropes. Instead of relying on traditional pin-like junctions, our structure uses thin fibre links that behave like slider joints. This design enables the PM to replicate the acoustic properties of water in the low-frequency regime, achieving a near-perfect pentamode response. The proposed design is illustrated in Figure 2, where each titanium unit cell consists of massive nodes connected by multiple thin fibres acting as sliders. Repeating this unit cell results in a face-centred cubic lattice whose effective elastic tensor is:

$$\frac{\mathbb{C}^{\mathrm{H}}}{\kappa_{\mathrm{H_2O}}} = \begin{bmatrix} 1.04 & 1.01 & 1.01 & 1.4\times10^{-5} & -2.9\times10^{-5} & -2.1\times10^{-5} \\ & 1.04 & 1.01 & 1.9\times10^{-5} & -2.2\times10^{-5} & -1.9\times10^{-5} \\ & & 1.04 & 1.2\times10^{-5} & -2.3\times10^{-5} & -1.8\times10^{-5} \\ & & & 0.039 & -5.2\times10^{-6} & -5.8\times10^{-6} \\ & \text{sym} & & & 0.039 & 5.7\times10^{-6} \\ & & & & & 0.039 \end{bmatrix}, \tag{3}$$

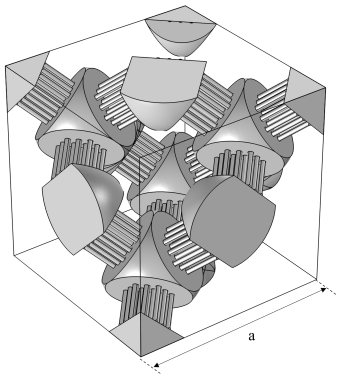

Figure 2: The PM lattice of the metal water.

where $\kappa_{H_20} = 2.2\,\mathrm{MPa}$ is the bulk modulus of water. The tensor $\mathbb{C}^{\mathrm{H}}$ is very close to that of water, with the terms in the upper left 3×3 matrix close to 1 and the remaining terms very small.

4. CONCLUSION AND FUTURE PERSPECTIVES

In this work, we propose two different approaches to the design of pentamode metamaterials aimed at replicating the acoustic properties of liquids. Topology optimisation has proven to be a flexible strategy for designing bimode materials for underwater applications, ensuring both manufacturability and precise control over the acoustic parameters.

When extending the design to three dimensions, a more complex topology is required. To address this, we introduce fibre-based slider-like connections that overcome the limitations of traditional pin-junction designs, achieving a nearly ideal pentamode material with a bulk modulus comparable to that of water. The proposed 3D structure exhibits a low shear modulus and impedance matching with water, making it a promising candidate for underwater acoustic applications such as invisibility cloaking. As a next step, we are preparing for experimental validation, which will include the fabrication of the proposed structures and their acoustic characterisation.

INCREASING HELMHOLTZ RESONATOR STABILITY AGAINST NON-LINEAR RESISTANCE INCREMENTS USING CHAMFERS

David Jun[1*] **Josef Plasek**[1] **Monika Rychtarikova**[2]
Zuzana Fisarova[1] **Christ Glorieux**[3]

ABSTRACT

Weakly damped Helmholtz resonators (WDHRs) are resonant devices with their surface resistance near resonance being substantially lower than the one of air and therefore the sound reflection at their resonance is out-of-phase. They are known for their absorption to increase with increasing in-neck velocities. This nonlinear effect is a consequence of turbulence and jets forming at the interfaces between the neck and the inner cavity and the exterior environment, causing increased acoustic resistance. In many cases, the level dependence of the behavior can be partially overcome by increasing the cavity or neck damping by enhanced increased level-independent resistance of an incorporated porous material, which leads to lower in-neck velocity magnitudes, but leads to at least partial loss of the WDHR-specific reflection characteristics. A WDHR with level-independent reflection characteristics would be beneficial for narrow-band room acoustic corrections such as damping of modes or their redistribution over the spectrum. In this work, chamfering of the resonator neck edges is used as a strategy to obtain a weakly damped resonator with sound pressure level independent behavior.

1. INTRODUCTION

Helmholtz resonators (HRs) are devices that can be used for acoustic applications by utilizing a compressible cavity with an open aperture (neck) in order to achieve subwavelength resonance. A weakly damped Helmholtz resonator (WDHR) is a variant of an HR, having its surface resistance near resonance substantially lower than that of air so that the sound reflection at its resonance is out-of-phase. Such behavior can be exploited for selective mode damping or manipulation [1–3] or scattering [4]. WDHRs are generally known for their characteristics being dependent on the in-neck velocity, which is also part of the focus of this contribution.

Ingard and Labate [5] studied the formation of vortices and jets on perforated boards and modeled the structure by defining four distinct regimes of nonlinear behavior in terms of the average particle velocity in the orifice. In the first region, vortices start to form around the orifice edges; in the fourth one, the turbulent jet is fully developed at least at one side of the orifice. It is worth noting that the authors pointed out that at resonance "nonlinear effects become of importance for sound pressure levels of about 65 dB for the incoming wave". The occurrence of nonlinear effects at this moderate sound pressure level makes the phenomenon relevant also for room acoustics. A few years later, Ingard [6] published his major work on Helmholtz resonator design, covering also the non-linear behavior. Ingard here introduced the following term for resonator resistance using neck end correction lengths:

$$\rho_0 c_0 \theta_{\text{total}} = \rho c(\theta_{\text{l}} + \theta_{\text{nl}}) = \frac{2R_s}{r_0}\left(t + \Delta_{\text{l}} + \Delta_{\text{nl}}\right) \quad (1)$$

where $\rho_0 c_0$ is the characteristic specific impedance

of air, ρ_0 the density, and c_0 the speed of sound in air. The dimensionless correction θ_{total} [-] accounts for both the linear θ_{l} [-] and non-linear θ_{nl} [-] end correction effects related to the apparent neck length in terms of losses. The surface resistance R_s is given by $R_s = 0.5\sqrt{2\mu\rho\omega}$ [kg·m^{-1}·s^{-1}], where μ is the dynamic viscosity, r_0 is the neck radius, and t is the plate thickness. Δ_{l} and Δ_{nl} are the linear and non-linear end correction lengths for the neck length. According to his work, the linear end correction is given by $\Delta_{\text{l}} = 2r_0 = d$, and the non-linear end correction Δ_{nl} can be expressed for sufficiently thick plates using the empirical equation:

$$\frac{\Delta_{\text{nl}}}{d} = C u_0^n \tag{2}$$

where C and n are parameters that might show some frequency dependence and u_0 [m/s] is the particle velocity magnitude in the aperture. The work of Blackman [7], however, reported experimental results that aligned rather poorly with the above model. Later, Ingard and Ising [8] further refined his findings, showing that at high pressure levels (in the 4th regime), the resistance of the orifice is approximately given by

$$R \approx \rho_0 u_0 \tag{3}$$

Melling [9] further extended this relation by invoking the particle velocity-dependent "orifice discharge coefficient", C_D [-], as part of the proportionality factor between R and ru_0. The discharge coefficient was known from fluid dynamics and had been studied already in a steady-state situation with constant flow by Johansen and Southwell [10]. While Melling [9] was mainly interested in the highest nonlinear regime, where C_D asymptotically reaches a constant value, the earlier steady flow-focused work of Johansen and Southwell [10] showed the potential of this parameter to identify and describe also the remaining regimes. Despite that, no model has been proposed for these lower regimes by any of the authors mentioned above.

More recently, the non-linear behavior in the orifice was exploited in micro-perforated panels (MPP) and was characterized via a non-linear impedance [11–14]. Investigations of non-linear HR behavior (or more generally, perforated plates) are still ongoing, mainly at high sound pressure levels [15] or for measurement applications [16].

In room acoustics-related applications, sound pressure level (SPL)-dependent damping characteristics are typically not considered or generally unwanted, since the most common room acoustic measures rely on linear acoustics assumptions. The objective of the current work is to reduce nonlinearities by shifting the transition from the first most weakly nonlinear regime to the other ones towards higher SPL levels. This approach is followed by chamfering the neck edges.

2. METHODS

The insight on the effect of chamfering was gained by analyzing the in-neck velocity, the in-neck Reynolds number, and the incident pressure, which were extracted from impedance tube measurements. The two-microphone impedance tube method was used according to ISO 10534-2 [17]. In this method, the pressure reflection factor of the WDHR resonator, r, is retrieved from the transfer function measured between two microphone positions, $H_{12} = \frac{p_2}{p_1}$, where p_1 and p_2 are the acoustic pressures measured at the respective microphone positions. The surface acoustic impedance was then obtained from the pressure reflection coefficient via

$$Z_s = R + jX = \frac{1+r}{1-r} \cdot Z_0, \tag{4}$$

where R, the real part of Z_s, is the surface resistance, X is the surface reactance, and $Z_0 = \rho_0 c_0$ is the characteristic impedance of air. The impedance tube used in this study was a next-generation version of the one used and validated in [18]. The tube in this study was made out of steel and had a square cross-section. The lateral dimensions were 102×102 mm^2, the steel wall thickness was 4 mm, and the rigid termination was 30 mm deep. The tube corners were rounded with a radius of 4 mm. The tube frequency range, given by its geometry, was 40 Hz to 1680 Hz. The acquisition chain consisted of two Behringer ECM8000 microphones, a Focusrite Scarlett 18i20 Gen3 sound card, and a Fedora Linux-powered mini PC running Python-based "imptube" software [18]. On the sound source side, a logarithmic sweep was played through a t.amp S75 MKII power amplifier and a low to medium frequency range 6.5" loudspeaker with a working frequency range of 40 to 4500 Hz.

At first, in the analysis phase, the instantaneous sound pressure $p_{m,\text{norm}}(f)$ in the tube was obtained according to Figure 1. The input sweep $y_{\text{in}}(t)$ was normalized to the full-scale range of -1 to 1, and its spectrum was used as a reference $y_{\text{in,norm}}(f)$ for calculating the instantaneous values relative to full scale $y_{m,\text{norm}}(f)$.

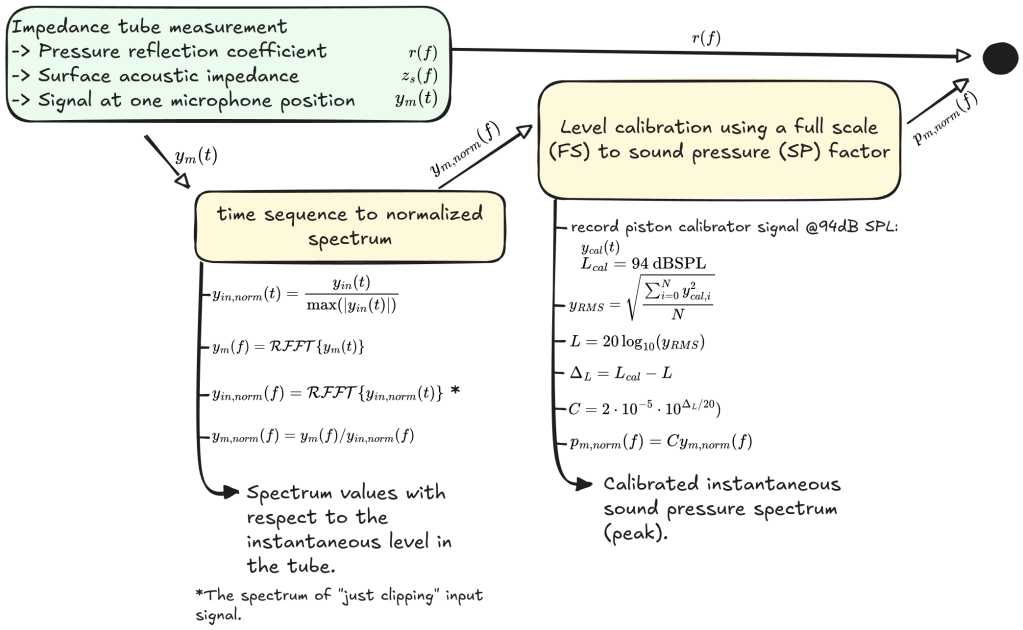

Figure 1. Procedure for obtaining the instantaneous sound pressure from an impedance tube measurement. The measured time sequence was first transformed to frequency domain and then divided by the "just-clipping" input sweep spectrum. That led to a spectrum expressing for each frequency its headroom towards clipping. Level calibration was based on a piston calibrator measurement, its RMS level and the subtraction of the calibrator level value (94 dB) and the recorded signal value. The latter was converted to a factor applied to the instantaneous pressure spectrum.

$$y_{m,\text{norm}}(f) = \frac{y_m(f)}{y_{\text{in,norm}}(f)} \tag{5}$$

This representation yields the spectrum with respect to the instantaneous level in the tube for each frequency bin. These values were converted to the physical pressure $p_{m,\text{norm}}(f)$ using a piston calibrator of known RMS SPL level.

Assuming plane wave propagation normal to the test specimen, the sound field can be decomposed into two opposing waves, and the homogeneous particle velocity can be obtained as a function of the acoustic pressure at a microphone position, $p(x_m)$, and the pressure reflection factor at the specimen surface r.

$$u(x=0) = \frac{p(x_m)\cdot(1-r)}{Z_0\left(e^{-jkx_m} + re^{jkx_m}\right)} \tag{6}$$

The average particle velocity in the neck of a plate perforation can be expressed as

$$u_0 = \frac{u(x=0)}{\phi} \tag{7}$$

where $\phi = \frac{A_n}{A}$ is the open plate porosity, i.e., the ratio between the neck cross-section surface A_0 and the total specimen surface A. The velocity can be used for calculating the in-neck Reynolds number Re:

$$\text{Re} = \frac{\rho_0 u_0 L}{\mu} \tag{8}$$

where L is the characteristic length (in this case, the perforation diameter d), $\mu = 1.84 \times 10^{-5}$ Pa·s is the dynamic viscosity of air, and u_0 is the particle velocity magnitude. Similarly, the in-neck displacement ξ [m] can be obtained:

$$\xi = \frac{u_0(f)}{i\omega} \tag{9}$$

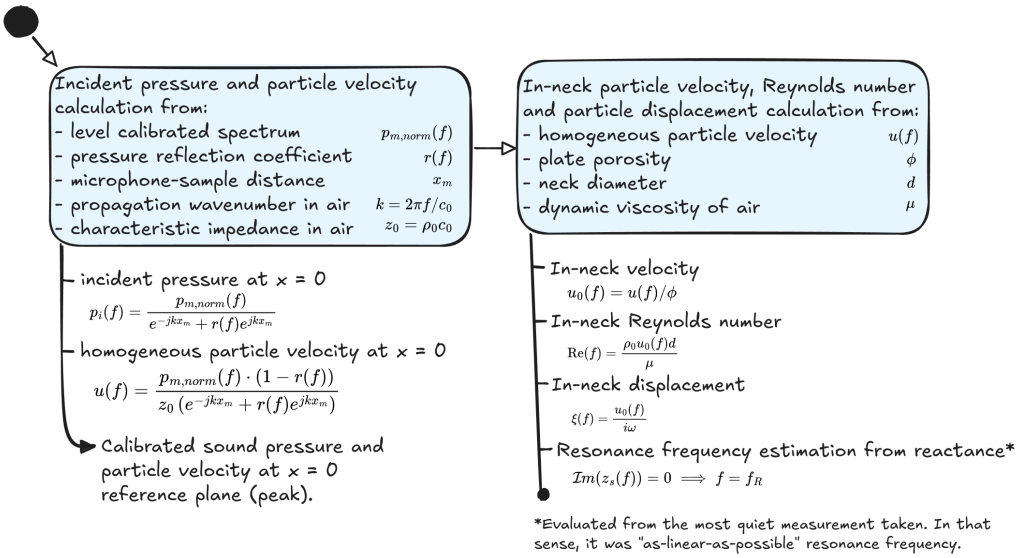

Figure 2. Calculation summary for the incident pressure, in-neck particle velocity, Reynolds number and displacement.

Similarly to the homogeneous velocity, also the incident pressure can be obtained from a plane wave reflection measurement as

$$p_i = \frac{p(x_m)}{e^{-jkx_m} + re^{jkx_m}}. \tag{10}$$

The calculation overview is shown in Figure 2.

3. RESULTS AND DISCUSSION

Two perforated plate variants were measured under different pressure levels in the tube. Both shared most of the geometrical parameters: the neck diameter $d = 12\,\mathrm{mm}$, the virtual neck spacing (the lateral dimension of the tube) $D = 102\,\mathrm{mm}$, the plate thickness $t = 9\,\mathrm{mm}$, and the cavity depth behind the plate $d_c = 200\,\mathrm{mm}$. The only changing parameter was the presence/absence of a 1 mm deep chamfer cut at 45° from both sides of the neck.

In the following, the quantities are presented only at the resonance frequency obtained from the acoustic reactance of the most quiet measurement. In that sense, it was the as-linear-as-possible resonant frequency obtained through measurements. This choice was done for two reasons, which appeared during the analysis: (a) At the resonance frequency, HRs show a rather simple behavior of either completely in- or out-of-phase response, leading to a pressure maximum or minimum directly in the neck. (b) The response at the resonance frequency seems to drive also the response in its vicinity. More precisely, a similar degree of nonlinearity is observed near the resonance, even though the calculated in-neck velocities differ.

Figure 3 shows the normal incidence absorption coefficient with respect to the incident pressure level. In both cases, the values started at about 0.5 for lower levels, reach a maximum, and start to decrease again. The decrease happens when the acoustic resistance crosses the characteristic impedance of air. Maximum absorption is reached for both cases at different levels, which are approximately 3.5 dB apart in incident SPL. The average difference for $0.5 < \alpha < 0.9$ between the two cases is $\Delta L_p = 10.6 \pm 3.2\,\mathrm{dB}$. Since the analysis does not account for the resonance frequency shift at high levels, the chamfered variant does not reach the $\alpha = 1$ point.

Figure 4 puts the findings in the context of in-neck velocity and Reynolds number. These results can be qualitatively compared to the previous studies. Johansen and Southwell [10] reported for low porosity plates that the transition between the weakly velocity-dependent regime 1 and the strongly velocity-dependent regime 4 happens at $10 < \sqrt{\mathrm{Re}_0} < 40$, which seems to align rather well with the presented results. For the chamfered variant, this transition is shifted towards higher Reynolds num-

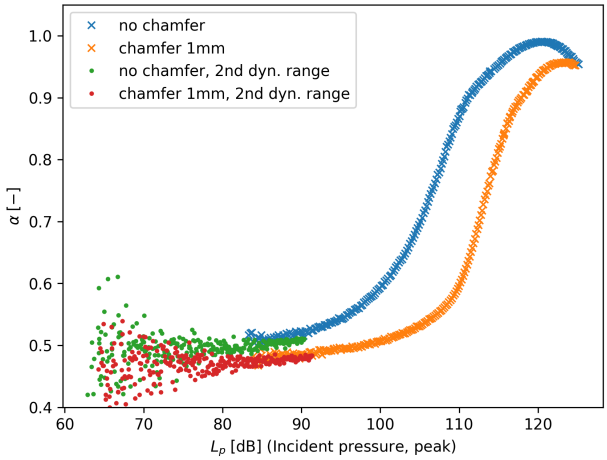

Figure 3. Normal incidence absorption coefficient at the resonance frequency as a function of incident SPL level (peak). Two dynamic ranges of measurements were tested for both orifice variants. In the first one (blue and orange), there is a minor offset between the levels of approx. 0.2 dB, in the second one 0.1 dB (green and red).

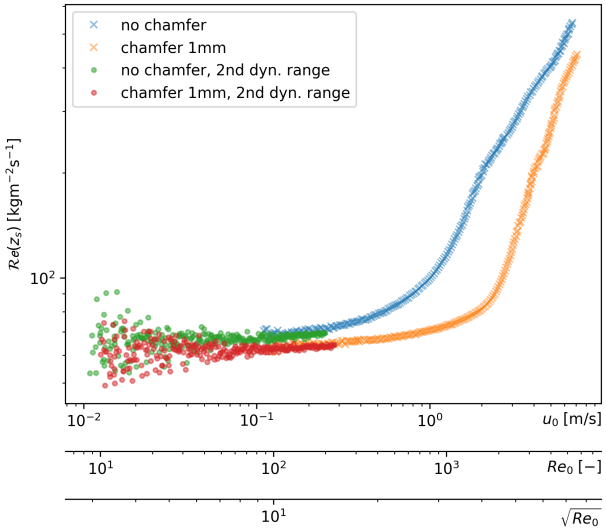

Figure 4. Normal incidence surface resistance as a function of in-neck velocity amplitude, Reynolds number and its square root. Two dynamic ranges of measurements were tested for both orifice variants. In the first one (blue and orange), input sweep level spacing is approx. 0.2 dB, in the second one 0.1 dB (green and red).

bers. When comparing to Ingard and Labate [5], we need to extrapolate their findings. At 224 Hz and for a plate thickness of 9 mm, they located the transition between $0.5 < u_0 < 2$ m/s. Based on their experiments and assumptions, both values of this range should decrease towards lower frequencies. In the present case, the transition roughly happens in the range originally assigned to $f = 224$ Hz.

It is important to note that it is not feasible to strictly connect the definitions of the different regimes between different authors, such as Ingard and Labate, Johansen, or Melling. For Labate and Ingard, regime 4 started when the turbulent jet appears at least on one side of the plate. In the view of Johansen's and Melling's discussions, no strict transition boundaries were mentioned, but a full turbulent jet was assumed as the limit at which the discharge coefficient stabilizes and which could be seen as the boundary of the final regime.

4. CONCLUSIONS

The objective of this study was to extend the weakly non-linear regime of a Helmholtz resonator reflection response towards higher incident sound pressures. The effect of neck chamfering was studied under normal incidence conditions in an impedance tube. The instantaneous sound pressure amplitude was used to calculate the in-neck velocity and the Reynolds number in order to allow for a more in-depth view of the problem. The results for the sharp-edge variant were found to be in good qualitative agreement with previous studies [5, 6, 10]. The chamfered variant showed an uplift of $\Delta L_p = 10.6 \pm 3.2$ dB in terms of the level difference at which the transition to more strongly non-linear regimes happens.

Future research should focus on a more parameter-rich and in-depth description of the different non-linear regimes as well as on the neck shape influence on them. For the sake of comparison, steady flow measurements should be conducted in a flow resistivity setup to further verify the discharge coefficients obtained acoustically and under steady flow.

ABSTRACT

Acoustic metamaterials offer unique capabilities for achieving exceptional performance at low frequencies with compact designs. However, many existing designs focus on single-function applications, leaving a need for multi-functional solutions. To address this, we propose a Dual-Function Passive Acoustic Metamaterial (DFPAM) that integrates sound absorption and diffusion within the same structure by applying principles of causality and passivity. The DFPAM delivers broadband performance with excellent sound absorption ($< \alpha >= 0.85$) and diffusion ($< \delta >= 0.8$) over 1 octave and a half each, i.e., 400-1100 Hz for absorption and 1000-2500 Hz for diffusion. With a compact thickness of 12 cm-nearly half the size of traditional treatments-it efficiently uses space (1/3 for absorption, 2/3 for diffusion) while optimizing the performance of each state. Importantly, it mitigates the trade-offs often associated with combining these two acoustic mechanisms. This solution offers significant potential for room acoustics and environments where space is at a premium. By addressing multi-functional requirements with dual efficiency, The DFPAM offers transformative possibilities for room acoustics and can be adapted to diverse environments where multi-functional acoustic solutions are in increasing demand.

Keywords: *absorption, diffusion, hybrid materials, metamaterial, passivity*

1. INTRODUCTION

Most existing acoustic metamaterial solutions remain configuration-dependent, addressing either sound absorption or diffusion, but rarely both. Hybrid solutions attempting to integrate these functions have often been constrained by physical and spatial trade-offs, leading to suboptimal performance.

In this work, we adopt a causality-driven approach to design a Dual-Function Passive Acoustic Metamaterial (DFPAM) that optimizes both absorption and diffusion within a single structure.

2. DESIGN PRINCIPLE

Absorption and diffusion of acoustic waves are contrastive effects as the former needs to dissipate the acoustic energy and the latter needs to scatter the waves with minimal dissipation. In the present case, we intend to use a strategy based on rigidly-backed slits loaded by an array of Helmholtz resonators as shown in Fig. 1(a).

By analyzing the sum rule given by the passivity/causality conditions of the acoustic system accounted for in this work, it is possible to evaluate the optimal value of the absorption-to-diffusion surface area ratio, $\phi_{\alpha|\delta}$, with a given target absorption spectrum. A depth of 12 cm is chosen in order to provide a solution that fits within dimensions similar to other metamaterial designs reported in the literature. It follows that $\min\left(\phi_{\alpha|\delta}\right) \approx 0.33$. Starting from a 3×3 square grid for the quarter of unit-cell with a combinatorial ratio of absorption cells to overall cells $\phi_\alpha = 1/3$, there are a total of 84 possible combinations. Due to mirror symmetries and further physical considerations regarding the choice of tesselation pattern and diffusion optimality, the rhombus depicted in Fig. 1(a) happens to be one of the best candidates available for sound diffusion. We finally make use of non-linear constrained minimization algorithms for maximizing both absorption and diffusion as well as determining their respective geometries. Figures 1(b-c) display the analytical, numerical and experimental sound diffusion and absorption coefficients obtained throughout this study. The DFPAM achieves high broadband sound absorption ($<\alpha>\approx 0.85$) and diffusion ($<\delta>\approx 0.8$), covering more than one octave in each configuration. For more details, the reader can refer to [1].

3. CONCLUSION

In this work, we present a dual-function metasurface capable of achieving high values of absorption, $<\alpha>= 0.85$, and diffusion, $<\delta>= 0.8$, for different broadband frequency ranges covering more than one octave in each configuration, i.e., $\Delta\alpha = [400, 1100]$ Hz, and $\Delta\delta = [1000, 2500]$ Hz, while still maintaining compact dimensions.

ABSTRACT

This study presents an acoustic switch based on a sonic crystal (SC) with multiresonant scatterers arranged in a square 2D lattice. The scatterers feature Helmholtz resonators (HRs) tuned to different frequencies. A 90° rotation of all scatterers enables switching the interaction between Bragg bandgaps (Bragg- BGs) and Helmholtz resonator (HR) bandgaps, creating selective frequency filtering and wave propagation control. The research targets low to mid frequencies (500-2500 Hz), an underexplored range in current studies. The structure, made via cost-effective 3D printing without infill to reduce absorption, is both simple and practical. Tests in an anechoic chamber reveal a notable 20 dB contrast in acoustic insulation. This design offers potential applications in noise reduction for urban and industrial settings, adaptive acoustic systems, sensors, and acoustic energy harvesting.

1. INTRODUCTION

Phononic crystals are periodic structures composed of rigid scatterers embedded in a fluid. A particular case of phononic crystals is the so-called Sonic Crystals (SCs), where the fluid is air. They allow fluid and light passage while blocking specific acoustic frequencies due to multiple scattering effects [1]. These frequency gaps, known as Bragg Bandgaps (Bragg-BGs) [2], depend on the lattice periodicity. The first Bragg-BG for a square lattice under normal incidence occurs at $f_{\text{Bragg}} = c/2a$, where c is the sound speed in air and a is the lattice parameter [3].

SCs have been extensively studied since Kock and Harvey's pioneering work [1], enabling applications in waveguides [4], diffusers [5], noise barriers [6, 7], and switches [8]. Beyond Bragg scattering, local resonances, particularly from Helmholtz resonators (HRs) [9], create additional bandgaps (HRs-BGs). Their frequencies depend on the internal cavity and mouth orientation, offering enhanced wave control [10, 11].

Most acoustic metamaterials operate passively within fixed frequency ranges, limiting adaptability [12]. Phononic crystals with asymmetric scatterers have demonstrated switching capabilities in high-frequency regimes (around 300 kHz) by independently varying scatterer angles [13].

This study introduces a multiresonant SC-based acoustic switch. Each scatterer consists of two perpen-

dicular HRs, enabling two distinct configurations: 0° and 90°, relative to the incident wave. These orientations determine selective frequency filtering by tuning Bragg- and HRs-BGs. The switch functionality requires mechanical adjustment of all scatterers.

The paper is structured as follows: Section Fig. 2 details the methodology, covering numerical modeling (II.A), 3D printing (II.B), and experimental validation (II.C). Section Fig. 3 presents numerical and experimental comparisons, assessing the device's performance. Finally, Section Fig. 4 summarizes key findings and practical applications.

2. MATERIALS AND METHODS

We analyze a 2D sonic crystal (SC) composed of scatterers with Helmholtz resonators (HRs) arranged in an infinite periodic square lattice. The unit cell, illustrated in Fig. 1a, consists of a scatterer with an outer radius R and two apertures forming HRs with distinct resonant frequencies. Periodic boundary conditions are applied along the X and Y boundaries to model the infinite SC, characterized by a constant square lattice parameter a and the unit cell of the irreducible Brillouin zone in reciprocal space [14]. The HRs are defined by the neck length L (thickness and difference between outer and inner radii), mouth width w, and inner surface area S. The first resonant frequencies of the HRs oriented at 0° and 90° are given by [15]:

$$f_{HR}^{0°/90°} = \frac{c}{2\pi}\sqrt{\frac{w}{(L+\delta\frac{w}{2})S_{0°/90°}}} \tag{1}$$

where δ is the correction factor for the effective neck length, accounting for the neck-cavity junction effects due to sudden changes in circular cross-sections (typically between 1.6 and 1.8).

The first resonances of the HRs ($f_{\text{HR}}^{0°}$ and $f_{\text{HR}}^{90°}$) relative to the central frequency of the Bragg bandgap (f_{Bragg}) are critical in determining their interaction with the periodic structure. Notably, the inclusion of HRs in an SC does not inherently reduce transmission through the structure [11]. Therefore, careful attention must be given to the alignment of the HR mouths and their fundamental frequencies. Fig. 1a depicts a scatterer with two HRs aligned at 0° and 90°, with coupled surfaces and a 110° angle between the separation walls. The central frequency of the Bragg bandgap is $f_{\text{Bragg}} = 1400$ Hz, with the HRs' fundamental frequencies at the extremes of the first Bragg bandgap. The larger cavity (90°) has $f_{\text{HR}} = 760$ Hz $> f_{\text{Bragg}}$, while the smaller cavity (0°) has $f_{\text{HR}} = 1800$ Hz $< f_{\text{Bragg}}$. Both HRs share identical mouth dimensions ($w = 0.025$ m) and neck length ($L = 0.006$ m).

Thermoviscous losses in the medium are negligible in this study due to the dimensions of the multiresonant scatterers and the low frequency range of interest (see Appendix A in ref [11]). At a measurement temperature of 293 K and the lowest operational frequency of 500 Hz, the viscous and thermal boundary layers in air are calculated to be 116 μm and 97.8 μm, respectively. These values are 1.56% and 1.85% of the neck length $L = 0.006$ m, well below the 5% threshold known to affect acoustic performance in small cavities [16].

The band structure is calculated for different propagation directions (ΓX, XM, MX', $X'\Gamma$), as shown in the inset of Fig. 1a. These directions correspond to the unit cell of the SC and the irreducible Brillouin zone of the square lattice, based on Bloch-Floquet theory [14]. Numerical simulations evaluate transmission in two configurations: ΓX for the 0° orientation and $X'\Gamma$ for the 90° orientation. Periodic boundary conditions (PBC) are applied along the Y-direction to emulate an infinite SC, while the X-direction is limited to three rows of scatterers for practical modeling (see Fig. 1b and Fig. 1c).

Both transmission models use a lattice parameter $a = 0.12$ m. The geometric model of the SC and the unit cell represent the same periodic structure, a 2D square lattice. However, while the unit cell represents an infinite system, the transmission models consist of three-layer systems with infinite lateral extension. A harmonic plane wave with frequency f and acoustic pressure P_i propagates along the X-axis, aligned with the mouth of the higher-frequency HR in Fig. 1b and the lower-frequency HR in Fig. 1c (referred to as 0° and 90° alignments). Perfectly matched layers (PML) are placed at the ends of the X-axis to absorb outgoing waves.

Transmission is determined using pressure fields (P_t) evaluated at specific points (shown in Fig. 1b and Fig. 1c), positioned 1 m from the SC. Fig. 1d shows a numerical model simulating the experimental setup described in Section 2.2. This 2D simulation replicates expected experimental conditions, enabling direct comparison between numerical predictions and experimental results. The evaluation region is defined by a grid with points spaced at intervals of $a/4 = 0.03$ m, allowing accurate analysis of the transmitted pressure field in the frequency range of interest.

In Fig. 1d, the source is represented by a vertical line emitting an acoustic pressure of 1 Pa, located 0.5 m from the nearest scatterers. The evaluation region spans 0.5 m

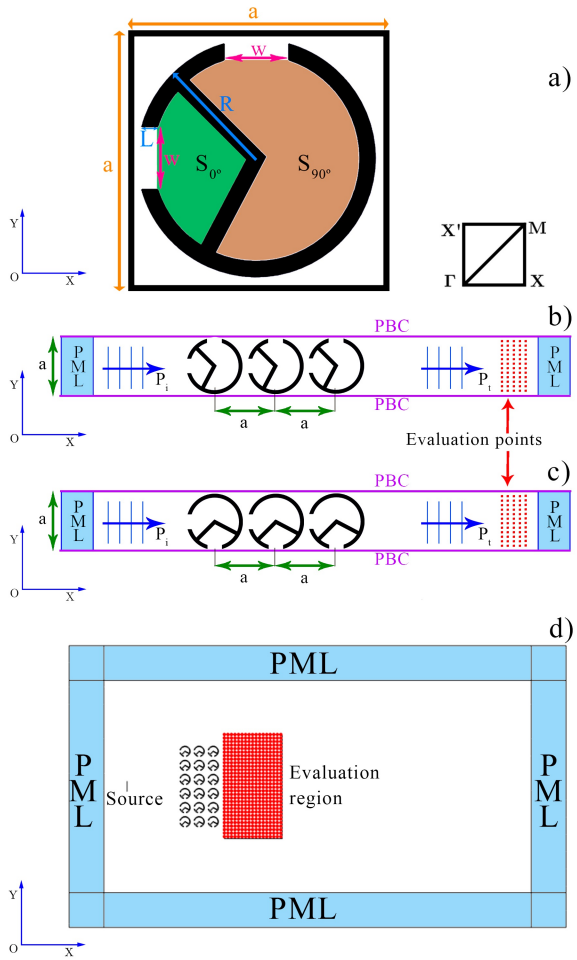

Figure 1. (a) Unit cell with two Helmholtz resonators; inset shows paths in the irreducible Brillouin zone. (b) and (c) Transmission models for 0° and 90° orientations. (d) Full numerical model corresponding to the experimental setup.

along the x-axis and 1.1 m along the y-axis, with the closest measurement points 0.05 m from the last scatterer row and the furthest points 0.55 m away. The y-axis evaluation region is centered relative to the SC array (3 columns by 6 rows), leaving 0.09 m between the evaluation region and the top and bottom edges of the SC structure.

Transmittance ($\mathbb{T}$) is defined as:

$$\mathbb{T} = \frac{\langle P_{t,with}^2 \rangle}{\langle P_{t,without}^2 \rangle} \tag{2}$$

where $\langle\rangle$ denotes the average over all evaluation points, $P_{t,without}$ is the acoustic pressure without the SC, and $P_{t,with}$ is the transmitted acoustic pressure with the SC. Insertion loss (IL) in decibels is derived from Eq. 2:

$$\text{IL} = -10 * \log_{10}(\mathbb{T}), \text{ [dB]} \tag{3}$$

This equation quantifies the change in sound pressure level (SPL) at the evaluation points when the SC is placed in the path of the incident acoustic wave.

The transmission coefficient $\mathbb{T}$ is used to compare the performance of the SC configurations across different frequency ranges. Asymmetric transmission, quantified by the Contrast Ratio (CR) [17, 18], measures the difference in transmission for waves incident from opposite directions. In this study, CR is evaluated based on the comparison of two scatterer orientations, with wave incidence from left to right along the x-axis. The 0° orientation corresponds to the ΓX direction in reciprocal space, while the 90° orientation corresponds to the $X'\Gamma$ direction. The CR is given by:

$$CR = \frac{|\mathbb{T}_{0^\circ} - \mathbb{T}_{90^\circ}|}{|\mathbb{T}_{0^\circ} + \mathbb{T}_{90^\circ}|}, \tag{4}$$

where $\mathbb{T}_{0^\circ}$ and $\mathbb{T}_{90^\circ}$ represent the transmission coefficients for the ΓX and $X'\Gamma$ directions, respectively. The CR quantifies the contrast in wave propagation between the two perpendicular orientations of the multiresonant scatterers, with a maximum value of 1 indicating complete suppression of transmission in one orientation and a minimum value of 0 indicating identical transmission in both orientations.

2.1 Numerical Analysis

This section explores the simulation results based on the geometry described in Section 2, focusing on the band structure and transmission of an incident plane wave. The interaction between the Bragg bandgap and HRs yields increased transmission, particularly due to the alignment of the resonators' mouths. The band structure, calculated using finite element analysis with Floquet periodicity conditions, is shown in Fig. 2. The complete Bragg bandgaps for all propagation directions (ΓX, XM, MX', $X'\Gamma$) are shown in gray, while partial bandgaps for 0° (ΓX) and 90° ($X'\Gamma$) are shown in blue and red, respectively.

The transmission ($\mathbb{T}$) is shown adjacent to the band structure. Transmission values close to zero occur at frequencies corresponding to the partial bandgaps for each orientation, highlighting the acoustic switching function

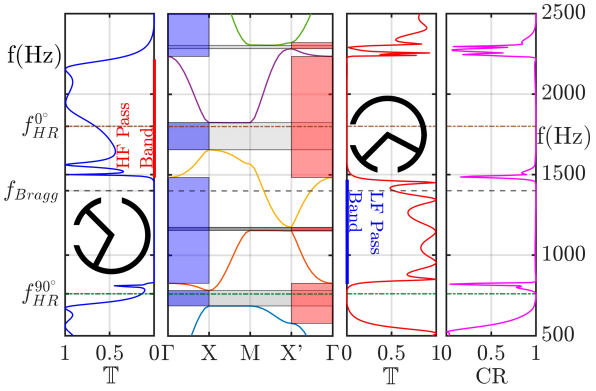

Figure 2. Band structure diagram and perpendicular transmission spectra.

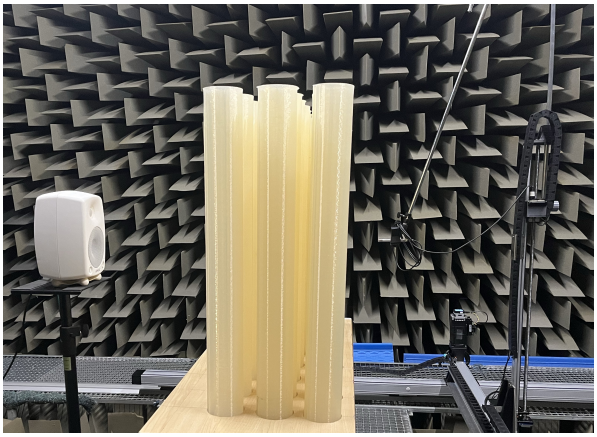

Figure 3. Side view of the experimental setup.

of the structure. The Low Frequency Pass Band (LFPB) spans 830-1500 Hz for the 0° orientation, while the High Frequency Pass Band (HFPB) spans 1500-2250 Hz for the 90° orientation. The first resonant frequencies of the HRs and the central Bragg bandgap frequency (f_{Bragg}) follow the order $f_{\text{HR}}^{90^\circ} < f_{\text{Bragg}} < f_{\text{HR}}^{0^\circ}$, enabling interactions that support the acoustic switch function.

Complete bandgaps, shown in gray, occur at frequencies close to the first resonant frequencies of the HRs ($f_{\text{HR}}^{90^\circ} = 760$ Hz and $f_{\text{HR}}^{0^\circ} = 1800$ Hz) and the Bragg frequency ($f_{\text{Bragg}} = 1400$ Hz). Despite their presence, the SC maintains effective transmission in both the LFPB and HFPB.

2.2 Experimental Assessment

A prototype SC device was manufactured using 3D printing and tested in the anechoic chamber of the Higher Polytechnic School of Gandia (Valencia, Spain). The experimental setup, shown in Fig. 3, included a Genelec 8030A loudspeaker as the sound source and a B&K Type 4189 microphone for acoustic field measurements. The SC was placed on a rigid wooden base, and measurements were taken using a 3D Robotised Acoustic Measurement System.

The frequency range of interest was 500-2500 Hz, with the source placed 0.5 m from the SC. Measurements were taken over a 1.1 m × 0.5 m grid with a spacing of $a/4 = 0.03$ m, resulting in 576 measurement points. The microphone was calibrated using a B&K Sound Calibrator Type 4231, and the robotized system ensured precise acoustic field mapping.

3. RESULTS

The experimental results are compared with numerical simulations in Fig. 4, which shows the transmittance ($\mathbb{T}$) and contrast ratio (CR) as functions of frequency. The top plot illustrates $\mathbb{T}$ for both 0° and 90° orientations, with numerical and experimental data showing strong agreement. The bottom plot depicts CR, highlighting the difference in transmittance between the two orientations. High CR values in the LFPB (830-1500 Hz) and HFPB (1500-2250 Hz) indicate effective acoustic switching behavior.

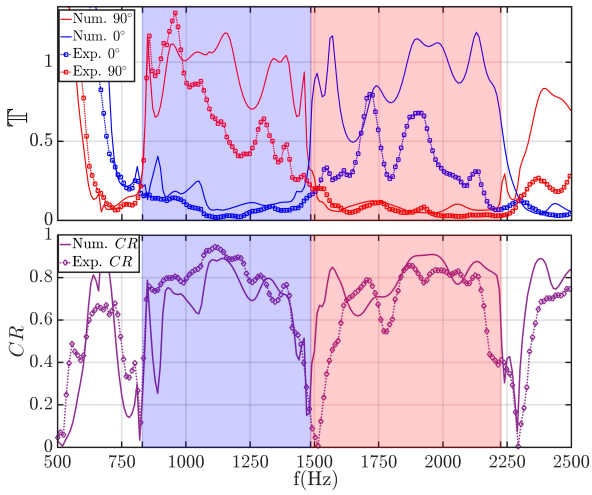

Figure 4. Transmittance, numerical and experimental (top); contrast ratio (CR), numerical and experimental (bottom).

The design functions as an effective acoustic filter, with the ability to control transmission based on scatterer orientation. The strong agreement between numerical and experimental results underscores the robustness of the design and experimental methodology. Fig. 5 shows insertion loss (IL) maps and CR maps for representative frequencies in the LFPB and HFPB, further illustrating the acoustic switching performance of the SC.

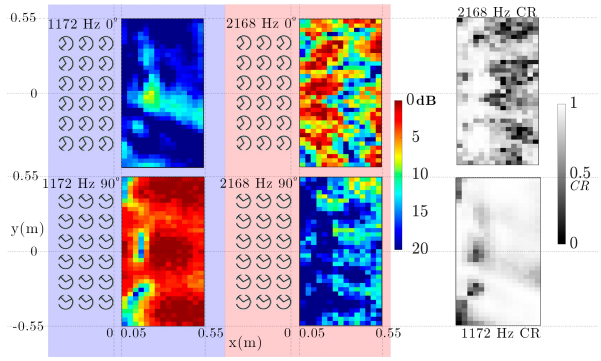

Figure 5. Experimental insertion loss maps with CR maps for two representative frequencies at 0° and 90°.

The results demonstrate the SC's potential as an effective acoustic switch, with tunable transmission properties based on scatterer orientation. This capability is promising for applications in acoustic control, passive filtering, and reconfigurable acoustic devices.

4. CONCLUSION

In conclusion, this paper introduces a novel multiresonant SC device that leverages the interaction between Bragg and Helmholtz resonator-based bandgaps in a simple 3D-printed structure. By varying the scatterer orientation, the device effectively switches between two distinct frequency passbands (830–1500 Hz and 1500–2250 Hz), overcoming limitations of existing acoustic switches that rely on complex geometries or operate at higher frequencies.

The device's performance was validated through numerical and experimental studies, demonstrating strong agreement. Transmission characteristics, contrast ratio (CR), and insertion loss (IL) confirmed its ability to control acoustic response based on scatterer orientation, achieving high contrast and effective attenuation.

Potential applications include urban and industrial noise reduction and adaptive acoustic environments in buildings and vehicles. This versatile and easy-to-implement design opens new possibilities for wave manipulation and acoustic metamaterials.

ADDITIVE MANUFACTURE OF FLEXIBLE LATTICE ABSORBERS FOR ENHANCED LOW FREQUENCY PERFORMANCE

Conor Neill[1*] **John Kennedy**[1]

[1] Department of Mechanical, Manufacturing and Biomedical Engineering, Trinity College Dublin, Dublin, Ireland

ABSTRACT

Traditionally porous materials have been used to mitigate a range of noise problems with excellent performance in the mid to high-frequency range, but these materials struggle to attenuate low frequencies. Recently, additive manufacturing (AM), including stereolithography (SLA), has enabled the fabrication of engineered porous structures that can create tuneable acoustic materials. This research focuses on the further development of flexible lattice structures, with inclusions that can add local resonances as an additional dissipation mechanism. This study systematically designs, manufactures, and tests flexible lattice absorbers for low-frequency noise control. By controlling the print parameters and lattice geometry, the acoustic properties can be varied and evaluated through impedance tube testing. Numerical modelling is utilised to iteratively manufacture an optimised flexible lattice structure for low-frequency sound absorption. This study focuses on refining the relationship between printing parameters and acoustic properties to enhance sound absorption while also maintaining structural integrity. These flexible lattice structures provide a tuneable lightweight solution for low-frequency sound absorption while also progressing the fabrication process of engineered porous materials. This offers a novel solution that helps to broaden the scope of engineered porous materials, benefiting the field of noise control.

1. INTRODUCTION

Noise pollution is a growing concern in urban and industrial environments, as exposure to excessive levels can lead to hearing impairment, psychophysiological distress, and cardiovascular diseases [1]. While mid to high-frequency noise is well addressed by conventional materials, low-frequency noise has remained difficult to attenuate [2]. This highlights the need for new engineered noise control solutions to innovate and solve these low-frequency issues. Engineered porous materials are a new area of study, made possible by the significant improvements in computing power and manufacturing techniques, which allow these complex shapes to be fabricated more easily [3]. Lattice structures have demonstrated potential for sound absorption similar to that of traditional materials but can allow increased tuneability by controlling their geometric parameters [4, 5]. The lattice structure attenuates the noise through viscous and thermal dissipation. This has been shown to be similar to traditional foam materials, with higher broadband absorption and shallow resonance peaks [3]. Tuned Helmholtz resonators (HR) can provide low-frequency noise absorption and can have high attenuation peaks, but they suffer from a narrow frequency range [6].

This work combines lattices for acoustic absorption with embedded resonators using a flexible material and demonstrates a new potential for noise control materials. This complex geometry has been enabled through increases to computational power required for both design and modelling. Additionally due to the introduction of

low-cost commercial 3D printers, such a structure is becoming more readily manufacturable at industrial scales. With the use of SLA, the two designs are merged to enable a single-step manufacturing process that incorporates tunable broadband and peak absorption, utilising local resonances through the embedded HR's. This combination allows for low-frequency noise absorption, while also maintaining broadband absorption at the mid and high frequencies of traditional materials. The use of a flexible material can allow for these lattices to be contoured and bent to fit a chosen profile under space constraints. The use of SLA allows for the flexible and precise lattice-Helmholtz resonators to be fabricated in a single step, and subsequently tested using ISO 10543-2 standard impedance tube testing to examine the noise absorption performance.

2. METHODOLOGY

The lattice structure's design was based on a Kelvin cell geometry for its isotropic and energy-absorbing qualities while remaining relatively simple to fabricate [5, 7]. The lattice parameters were determined using LattSAC, which is a software for the acoustic modelling of lattice sound absorbers [8]. The final design parameters included a cell size of 4.25 mm and a strut width of 0.66 mm. These values provided a good balance between what the LattSAC software could simulate, manufacturability, and testable acoustic properties. The HR design was based on Eqn. (1) [9]. The correction factor δ_R is $0.849r$, where r is the neck radius, and is based on the Rayleigh equation for the resonance frequency of a HR.

$$f = \frac{c}{2\pi}\sqrt{\frac{A_0}{V\left(l_0 + 2\,\delta_R\right)}}. \tag{1}$$

This was used to design both embedded HR's. The parameters used and the resulting resonance frequency can be seen in Tab. 1. The three final designs can be seen in figure Fig. 1 below, with a section view to show the embedded HR. The design features, (a) Bare Lattice, (b) Helmholtz resonator set at the middle for a low resonant frequency (LHL), and (c) Helmholtz resonator lowered to the bottom for a mid-resonant frequency (MHL).

The hexagonal shape of the unit structures was chosen for space-saving reasons and it allowed units to be easily combined in different arrangements. The dimensions for the individual hexagons were 50.95 mm tall and 33.43 mm from flat side to flat side. The included partition that created the HR was 1 mm with the neck wall thickness being 0.75 mm, this is highlighted in red in figure Fig. 1. Both experimental tests included a PLA holder that fit tightly around the hexagonal design and into the respective impedance tube. The large holder could accommodate seven hexagons and the smaller could fit a single unit.

Res. frequency (Hz)	**601**	**2480**

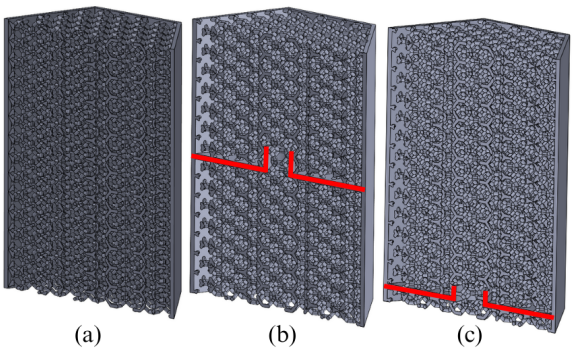

Figure 1: CAD designs, (a) Bare Lattice, (b) Low-Frequency Helmholtz-Lattice (LHL), (c) Mid-Frequency Helmholtz-Lattice (MHL)

The samples were made from Prusa Flex 80A and printed on a Prusa SL1S Speed. The relevant printing parameters for reliable fabrication can be seen in Tab. 2. These were the necessary changes from the default Prusa print settings. In total, 17 samples were made, seven Bare Lattices, seven LHL's, and three MHL's. This was to allow a mixture of the Bare Lattice and LHL designs to be tested in the larger impedance tube.

Absorption measurements were conducted in accordance with ISO 10534-2 using two impedance tubes, one low-frequency (50-1500 Hz), and one high-frequency (300-4500 Hz). The two tubes had respective internal diameters of 127 mm and 40 mm, where the schematic can be seen in Fig. 2. Acoustic measurements were taken using GRAS 40PH microphones (50 Hz - 5 kHz, ± 1.5

Table 2: Print Parameters

Parameter	Value

dB). A National instruments DAQ, amplifier, and MATLAB GUI controlled the system. For sample testing in the high-frequency tube, each sample design was fabricated three times and tested three times, totalling to nine results per design. This ensured repeatability and reproducibility within the designs. The low-frequency tube tests, because they consisted of seven single samples, were tested three times to obtain an average.

3. RESULTS AND DISCUSSION

Fig. 3 shows the predicted absorption coefficients from the LattSAC model. The Bare Lattice (black line) shows 2 peaks at 1500 Hz and 4100 Hz, with absorption coefficients of 0.44 and 0.61 respectively. Once a HR is embedded in the lattice the effective thickness is reduced to the distance from the resonator division to the top of the sample. The two coloured dashed lines are calculated based on this reduced lattice thickness from Fig. 1. These thicknesses are 50% and 94% thickness of the LHL and MHL designs. As expected, the 94% lattice (MHL) is very similar to the bare design, with a small lowering and shift to

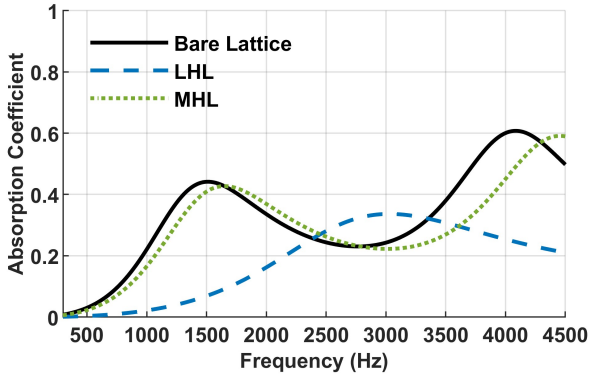

Figure 3: LattSAC numerical absorption coefficient tests

the right, due to the small decrease in available lattice. The 50% lattice (LHL) has its peak lowered to 0.34 and shifted considerably to the right at 3000 Hz.

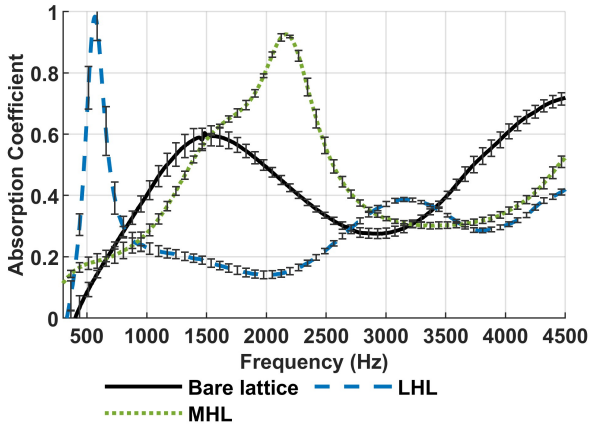

Figure 4: High-frequency impedance tube tests

Fig. 4 shows experimental results from the designs in Fig. 1. The bare lattice matched the LattSAC model with a peak absorption at 1500 Hz but has increased the absorption coefficient to 0.6. This is likely due to LattSAC's inability to take into account surface roughness which will increase the peak absorption [10, 11]. The MHL (green dotted) curve showed a similar peak shift to the right at the beginning. Then the peak from the HR occurs at 2170 Hz with an absorption coefficient of 0.92. This is lower than analytically expected due to the reduced accuracy of the Helmholtz model at higher frequencies. The LHL (dashed blue) curve showed an excellent absorption at 570 Hz with a peak absorption of 0.98. This aligned well with both the analytical and LattSAC models, with its lattice-only portion showing a peak at 3150 Hz and an absorption of 0.39.

Fig. 5 presents four tests where seven individual samples were configured as an array in a PLA holder. An example design of 4 LHL - 3 Bare Lattice can be seen within the figure. The Bare Lattice design (black line) matched well with the single test and LattSac by showing a rising peak up to around 1400 Hz. The LHL (blue dashed) curve agreed with the individual tests and had a peak of absorption of 0.91 at 570 Hz. The other two tests consisted of a blended array of the Bare lattice and LHL designs. The 4 LHL - 3 Bare Lattice array showed a lower peak at 560 Hz but maintained absorption above 0.43 over the 800 Hz to 1400 Hz range due to the increased lattice content. The standalone LHL design did not exceed 0.2 in the same range. To confirm this, the 3 LHL - 4 Bare Lattice array was also tested, which had a lower Helmholtz peak, as expected.

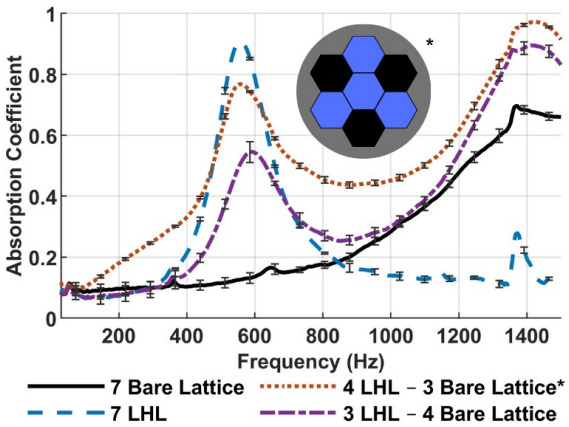

Figure 5: Low-frequency impedance tube tests

4. CONCLUSION

To summarise, an acoustic modelling software was used to design a lattice structure with enhanced performance through the inclusion of embedded Helmholtz resonators. The resonant frequencies were controlled through simple geometric modifications to the unit cells. The samples were manufactured in a flexible material with high precision. Repeatable and reproducible designs were successfully manufactured with the acoustic properties and printing parameters being optimised for enhanced mid and low-frequency sound absorption. The performance was validated through impedance tube testing of individual and grouped sample combination designs that demonstrated how a variety of unit cells can be combined to achieve a target performance. This work demonstrates that a tuneable, lightweight, and flexible material for low-frequency absorption can be designed and fabricated successfully. Future work on further design optimisation and the ability to fabricate larger-scale samples could see applications to real-world noise control.

TUNABLE ENVELOPE SOLITONS IN A PIEZOELECTRIC METAMATERIAL OBEYING THE NONLINEAR SCHRÖDINGER EQUATION

Chongan Wang[1] **Alper Erturk**[1*]

[1] G. W. Woodruff School of Mechanical Engineering, Georgia Institute of Technology, USA

ABSTRACT

Nonlinear shunt circuits can substantially alter the dynamic response of piezoelectric structures, offering a great potential to use in metamaterials and metastructures for wave manipulation. These circuits, implemented as analog or digital shunts, offer tunable and programmable nonlinear characteristics. In this work, we investigate the solitary wave dynamics in a metamaterial beam with a periodic array of piezoelectric patches shunted to Duffing circuits. Our focus is placed on the tunability of the solitary wave propagation by varying the linear and nonlinear inductance values. The wave evolution in the proposed piezoelectric metamaterial beam follows the nonlinear Schrödinger equation (NLSE), where the dispersion and nonlinear coefficients are dependent on the inductance parameters. By adjusting the linear inductance, the dispersion curve can be tuned, enabling the generation of solitary waves with either softening nonlinearity or hardening nonlinearity. The amplitude and shape of the solitary wave can also be controlled through the variation of inductance values. These findings may open new avenues for programmable elastic/acoustic metamaterials, with potential applications in elastic wave control, targeted energy transfer, and physical intelligence.

1. INTRODUCTION

Shape-invariant solitary waves in nonlinear mechanical metamaterials attracted significant attention due to its ability to propagate without dispersion, making them valuable for energy and information transmission. While previous research on solitons in mechanical metamaterials have mainly focused on the structural design with geometric nonlinearity, recent advances in piezoelectric structures [1] highlight the potential for controlling structural responses by introducing the source of nonlinearity through cubic inductive shunts. Such nonlinear shunt circuits can be implemented using either analog circuits or digital signal processing-based synthetic impedance circuits. Compared to purely structural nonlinearity, these nonlinear circuits offer a great flexibility of wave manipulation by controlling mechanical responses through electric signals. In this work, we investigate the tunability of solitary wave motion in a piezoelectric metamaterial beam [2] with an array of piezoelectric patch pairs shunted to linear and cubic inductive circuits. We exclusively focus on how variations in linear and cubic nonlinear inductance influence soliton formation and propagation.

2. SYSTEM DESCRIPTION

We consider a piezoelectric metamaterial beam with unit cells made of two piezoelectric layers sandwiching a central substrate layer (i.e. bimorph setting) as shown in Fig. 1. The piezoelectric layers are oppositely poled in different directions and segmented periodically. The surface electrodes of each unit cell are connected to a nonlinear shunt circuit with a linear inductance and a cubic nonlinear inductance (Fig. 1). Based on the Euler-Bernoulli

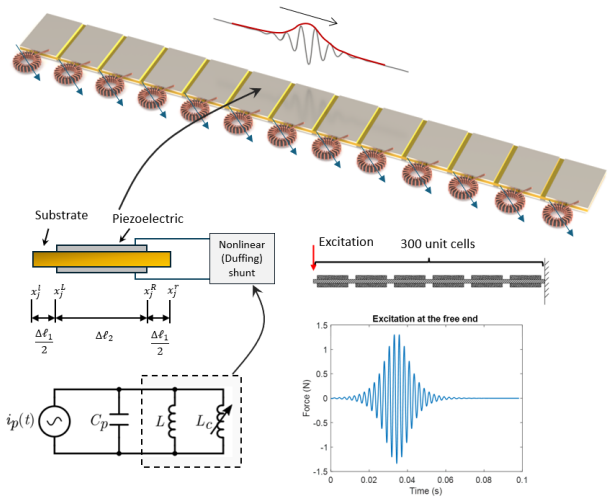

Figure 1. System overview depicting the metamaterial beam, unit cell detail, the excitation and its location on the beam with free-fixed boundary conditions.

beam theory, the undamped flexural wave equation of the beam with electromechanical coupling and circuit current balance equations are:

$$\frac{\partial^2}{\partial x^2}\left(EI(x)\frac{\partial^2 w}{\partial x^2}\right)+m(x)\frac{\partial^2 w}{\partial t^2} -\vartheta\frac{\partial^2}{\partial x^2}\sum_{j=1}^{N} v_j\left(t\right)\left[H\left(x-x_j^L\right)-H\left(x-x_j^R\right)\right]=0 \tag{1a}$$

$$C_{p,j}\dot{v}_j+\frac{1}{L_j}\int_0^t v_j\left(\tau\right)d\tau +\frac{1}{L_{cj}}\left(\int_0^t v_j\left(\tau\right)d\tau\right)^3+\vartheta\int_{x_j^L}^{x_j^R}\frac{\partial^3 w}{\partial x^2\partial t}dx=0 \tag{1b}$$

where the $j-$ th pair of piezoelectric patch spans the spatial positions x_j^L to x_j^R. The transverse deflection $w(x,t)$ and the voltage in the $j-th$ shunt circuit v_j are the unknown variables in Eq. (1). The distribution of mass $m(x)$, flexural rigidity $EI(x)$, electromechanical coupling ϑ and capacitance $C_{p,j}$ are dependent on the material and structural properties of the beam, while the linear and nonlinear inductance L_j and L_{cj}, can be independently designed on the circuit side, allowing tunability of the system's response.

Previous analysis in [2] has shown that a continuous and homogeneous approximation can be applied to the foregoing integro-differential equations, converting the governing equations to a simpler nonlinear partial differential equation in the long wavelength limit:

$$\bar{m}\frac{\partial^2\bar{w}}{\partial t^2}+\bar{EI}\frac{\partial^4\bar{w}}{\partial x^4}-\bar{\vartheta}\frac{\partial^3\bar{\lambda}}{\partial x^2\partial t}=0 \tag{2a}$$

$$\bar{C}_p\frac{\partial^2\bar{\lambda}}{\partial t^2}+\frac{1}{\bar{L}}\bar{\lambda}+\frac{1}{\bar{L}_c}\bar{\lambda}^3+\bar{\vartheta}\frac{\partial^3\bar{w}}{\partial x^2\partial t}=0 \tag{2b}$$

where an overbar represents homogenized variables, and $\bar{\lambda}$ denotes the flux linkage, defined as the time integral of voltage over time. $\bar{L}$ and $\bar{L}_c$ are the linear and cubic nonlinear inductance scaled over an entire piezoelectric patch given by:

$$\begin{aligned}\bar{L}=L_j\Delta\ell;\ \ \bar{L}_c=L_c\Delta\ell\\ \Delta\ell=x_j^R-x_{j-1}^R=x_j^L-x_{j-1}^L\end{aligned} \tag{3}$$

Under weakly nonlinear assumption, the method of multiple scales is introduced to solve the nonlinear partial differential equations given by Eq. (2):

$$t_i=\varepsilon^i t; x_i=\varepsilon^i x, i=0,1,2,... \tag{4}$$

where ε is a small bookkeeping parameter. The leading-order solution of Eq. (2) is the linearized plane wave solution:

$$\begin{pmatrix}\bar{w}\\ \bar{\lambda}\end{pmatrix}\approx\varepsilon A_1\left(x_1,t_1,x_2,t_2\right)\begin{pmatrix}C_{w1}\\ C_{\lambda1}\end{pmatrix}e^{i(kx_0-\omega t_0)}+c.c. \tag{5}$$

where $(C_{w1},C_{\lambda1})^T$ denote the mode shape, and c.c. denotes the complex conjugate. ω and k denote the frequency and wavenumber of the plane wave that obeys the dispersion relation. Past research [3] reveals that the linearized dispersion relation of the piezoelectric metamaterial exhibits a frequency bandgap near the resonant frequency of the shunt circuit.

The modulation equation of the envelope A_1 can be solved by substituting Eq. (5) back into Eq. (2). Perturbation analysis in [2] shows that the modulation of A_1 follows the nonlinear Schrödinger equation (NLSE) that is well known to support solitary wave solutions [4]:

$$i\frac{\partial A_1}{\partial\tau_2}+P\frac{\partial^2 A_1}{\partial\xi_1^2}+QA_1^2A_1^*=0 \tag{6}$$

where ξ_i and τ_i are coordinate variables in the frame moving at the group velocity v_g,

$$\xi_i=x_i-v_g t_i;\ \tau_i=t_i, \tag{7}$$

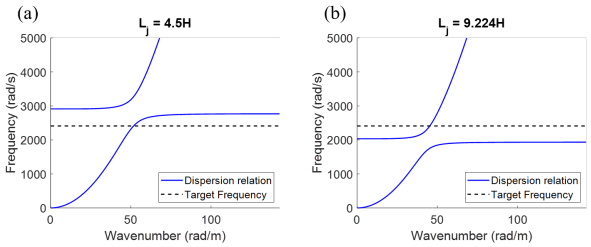

Figure 2. Linearized dispersion relation for different linear inductance values (a) $L_j = 4.5\text{H}$ where the excitation frequency hits the acoustic band and (c) $L_j = 9.224\text{H}$ where the excitation frequency hits the optical band.

Furthermore, P and Q quantify the effect of dispersion and nonlinearity:

$$P = \frac{1}{2}\frac{\mathrm{d}^2\omega}{\mathrm{d}k^2} \tag{8a}$$

$$Q = -\frac{3\left|C_{\lambda 1}\right|^4}{L_{\mathrm{c}}\begin{pmatrix} C_{w1}^* & C_{\lambda 1}^* \end{pmatrix}\begin{pmatrix} 2\bar{m}\omega & i\bar{\vartheta}k^2 \\ -i\bar{\vartheta}k^2 & 2\bar{C}_p\omega \end{pmatrix}\begin{pmatrix} C_{w1} \\ C_{\lambda 1} \end{pmatrix}}, \tag{8b}$$

where the superscript $*$ denotes the complex conjugate.

3. RESULTS AND DISCUSSIONS

We investigate the tunability of solitons by numerically simulating a cantilever beam with 300 pairs of piezoelectric patches as shown in Fig. 1 inset. The excitation is applied at the free end of the cantilever beam with the profile shown in Fig. 1. The pulse has a sech-shaped envelope, characteristic of NLSE soliton solutions, and oscillates at a frequency close to 2500 $\mathrm{rad/s}$.

We first examine the dispersion curves for different values of linear inductance, which influence the frequencies of the LC (inductive-capacitive) circuit dynamics. Since the frequency bandgap of the metamaterial beam is close to the circuit resonant frequency, varying the linear inductance shifts the bandgap accordingly. In Fig. 2, we present the linearized dispersion curves of the metamaterial beam, as developed in [5], for linear inductance values of 4.5H and 9.224H. The figure illustrates the tunability of the frequency bandgap, which can be shifted by varying the inductance—allowing the excitation frequency to lie within either the acoustic or the optical band.

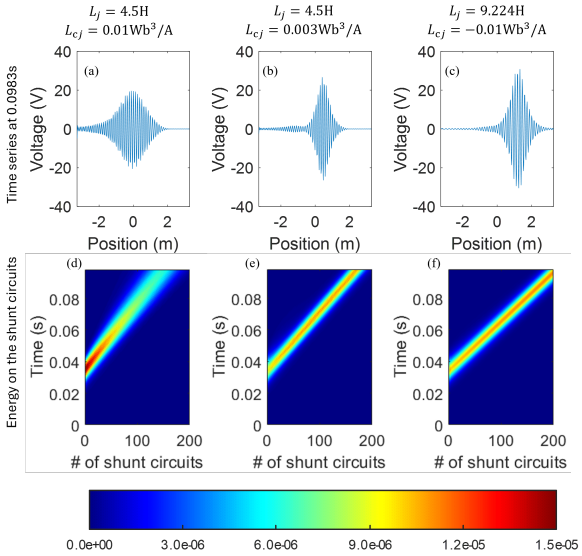

Figure 3. Distribution of the voltage across the metamaterial beam: (a,b,c) Time series of voltage across all entire shunt circuits at $t = 0.0983\text{s}$ and (d,e,f) Spatio-temporal variation of the energy in each shunt circuits. The linear and nonlinear inductances are given by, (a,d) $L_j = 4.5\text{H}$ and $L_{cj} = 0.01\text{Wb}^3/\text{A}$, (b,e) $L_j = 4.5\text{H}$ and $L_{cj} = 0.003\text{Wb}^3/\text{A}$ and (c,f) $L_j = 9.224\text{H}$ and $L_{cj} = -0.01\text{Wb}^3/\text{A}$.

The excitation frequency falls in different branches of the dispersion curve, resulting in distinct solitary wave solutions. As shown in [4], the NLSE supports solitary wave solution only with the focusing nonlinearity condition $PQ > 0$, where the nonlinearity counterbalance the effect of dispersion. Eq. (8) shows that P is proportional to the second derivative of the dispersion curve, while Q always has the opposite sign of the cubic inductance L_{cj}. To initiate a solitary wave, a softening nonlinear inductance is required in the acoustic band where the dispersion relation is concave upwards, whereas hardening nonlinear inductance is required in the optical band where the dispersion relation is concave downward.

To confirm our analysis, we present finite-element simulation results of the entire metamaterial beam, considering the linear inductances 4.5H, and 9.224H, combined with various nonlinear inductance values $L_{cj} = \pm 0.01\text{Wb}^3/\text{A}$, and $0.003\text{Wb}^3/\text{A}$. The voltage and energy distributions across the shunt circuits of the entire

metamaterial beam are presented in Fig. 3.

The simulation results confirm the theoretical analysis on soliton's tunability. Fig. 3a and 3d present the simulation results of $L_j = 4.5\text{H}$ and $L_{cj} = 0.01\text{Wb}^3/\text{A}$. With an excitation frequency in the acoustic branch and a hardening nonlinearity, the wavepacket maintains a solitary-like bell shape. However, from Fig. 3d, we note that the energy gradually disperses as the wavepacket propagates along the metamaterial beam. A stronger nonlinear focusing effect is observed with a larger nonlinear coefficient. As shown in Fig. 3e, reducing the nonlinear inductance to $L_{cj} = 0.003\text{Wb}^3/\text{A}$ enhances the nonlinearity, resulting in reduced energy dispersion during propagation. In Fig. 3b, the wavepacket is much narrower compared with the one in Fig. 3a as the nonlinear coefficients are increased.

In addition, Figs. 3c and 3f present simulation results for $L_j = 9.224\text{H}$ and a softening nonlinear inductance of $L_{cj} = -0.01\text{Wb}^3/\text{A}$. These results confirm the initiation of a solitary-like wavepacket when the excitation frequency lies within the optical branch and the system exhibits softening nonlinearity. Overall, the simulations highlight the high tunability of solitary wave responses—demonstrating that by varying the linear and nonlinear inductance, the frequency bandgap can be shifted and the nonlinearity can switch between hardening and softening, enabling the effective generation of solitons in both the acoustic and optical bands.

4. CONCLUDING REMARKS

To summarize, we propose a piezoelectric metamaterial beam coupled with nonlinear shunt Duffing circuits consisting of both linear and cubic nonlinear inductance. We investigate the effects of these inductance values on the solitary wave propagation within the metamaterial beam, demonstrating strong tunability of solitary waves. Specifically, varying the linear inductance shifts the linearized frequency bandgap, allowing excitation of either the acoustic band, optical band, or bandgap under identical external excitation. Since the dispersive effect is dependent on the second derivative of the dispersion curve, different types of nonlinearity supports distinct soliton solutions. In particular, hardening nonlinearity supports solitons in the acoustical band, whereas softening nonlinearity supports solitons in the optical band. Furthermore, since the soliton is formed due to the counterbalance of nonlinearity, we demonstrate that the steady-state profile of the soliton can be tuned by varying nonlinear inductance. With identical excitation, a larger nonlinear coefficient leads to stronger focusing effect, resulting in a narrower wavepacket. By tuning the linear and nonlinear inductance, solitons with varying amplitudes and widths can be achieved under the same excitation profile.

OPTIMIZING LOCALLY RESONANT ELEMENTS DISTRIBUTION ON ISOTROPIC PLATE FOR INCREASED SOUND INSULATION AND MASS REDUCTION

Klara Chojnacka[1*]

[1] AGH University of Krakow, Poland

Department of Mechanics and Vibroacoustics, al. Adama Mickiewicza 30, 30-059 Cracow

ABSTRACT

Locally resonant metamaterials enhance sound and vibration reduction within specific frequency ranges when attached to a base plate. Typically, these metamaterials are designed with periodically distributed elements across the surface, maintaining subwavelength spacing. Using periodic boundary conditions simplifies calculations and reduces the computational power needed compared to finite-sized models. However, no other practical background states that the elements should be distributed evenly in the whole available space for maximum metamaterial effectiveness. The effectiveness of each resonant element depends on the displacement amplitude of the base plate, making elements placed in areas with lower vibration amplitude less effective than those in higher vibration regions. This work presents a topological optimization of the distribution of locally resonant elements. The Method of Moving Asymptotes is employed to minimize the number of resonant elements while preserving the initial sound reduction achieved by periodic metamaterials. Calculations were conducted in COMSOL Multiphysics with MATLAB, using a combined analytical and numerical approach for sound insulation simulation. The results confirm that the number of resonant elements, and therefore the additional mass of the metamaterial on the base plate, can be reduced while maintaining the initial effectiveness of the solution.

1. INTRODUCTION

Locally resonant structures (LRS) are widely exploited in the literature in noise and vibration suppression problems. Resonant elements are based on a mass-spring-damper system and when attached to a base plate create a stopband effect. In the stopband frequency range, flexural waves cannot propagate in the base plate, causing vibration and noise mitigation. Typically, LRS consists of a periodical mesh of resonant elements distributed equally over the plate surface at sub-wavelength distances [1]. The periodic distribution is beneficial due to the simplification of manufacturing and the lower computational costs. In the literature, most of the LRS simulation examples are based on unit cell simulations with periodic boundary conditions, as a simplified model that gives information about the whole structure [2]. However, the periodicity is a proper solution in model simplification, and gives a good approximation of how the finite system will behave, it also narrows the possibility of creating quasi-periodic or non-periodic solution. It can be stated that the effectiveness of the resonant elements distributed on the plate depends on the displacement of the base plate at the attachment point [3, 4]. Therefore, in places where the base plate has lower displacement amplitude, resonant elements may have lower effectiveness.
In this paper a topological optimization procedure is pre-

sented, which allows for resonant element number minimization, while preserving the metamaterial effectiveness in noise and vibration reduction at specified level. This gives the possibility to create quasi-periodic element distribution on the base plate, by removing unnecessary mesh elements, which leads to mass reduction.

2. SOUND INSULATION FOR PLATE WITH RESONANT ELEMENTS

Sound reduction index is a logarithmic variable dependent on transmission coefficient τ_d and is given as

$$R = 10 \log_{10} \frac{1}{\tau_d}. \tag{1}$$

Coefficient τ_d for a diffuse field can be described in approximate form as

$$\tau_d \approx 8\rho_0 c_0 \int_0^{\pi/2} \frac{\Re(\overline{z}_{f,\text{fin}})}{|Z_{\text{eff}} + 2\rho_0 c_0 \overline{z}_{f,\text{fin}}|^2} \sin\theta \mathrm{d}\theta, \tag{2}$$

where ρ_0 is air density, c_0 is wave speed in the air, θ stands for elevation incident wave angle, $\overline{z}_{\text{fin}}$ is radiation impedance, and Z_{eff} is mechanical impedance of the structure [3]. In the analyzed case, the radiation impedance is calculated for a finite-size rectangular plate according to the equations given in [5] and [3]. The effectiveness of resonant elements can be determined based on the effective modal mass [6], calculated for the natural frequencies of the single resonant element. The effective modal mass can be used to calculate the effective parameters of the plate with LRS. One of the parameters is effective mechanical impedance Z_{eff} which can be calculated according to equation

$$Z_{\text{eff}} = \frac{B'}{i\omega}\left(k_x^2 + k_y^2\right)^2 + i\omega\left(m_p'' + \frac{m_z'' s_z''(1+i\eta_z)}{i m_z''(\omega_0^2 - \omega^2) + i\eta_z s_z''}\right). \tag{3}$$

In Eq. (3) B' stands for plate bending stiffness, m_p'' is the surface mass of the plate, m_z'', s_z'' and η_z are the surface mass, stiffness and damping of the resonant element with a resonant frequency ω_0. The variables k_x, k_y are wavenumber components, and ω is frequency. Based on these equations the effectiveness of the plate with LRS can be determined.

3. OPTIMIZATION OF THE RESONANT ELEMENTS DISTRIBUTION

The Method of Moving Asymptotes algorithm was selected for the topological optimization of the LRS distribution [7]. The problem solved in this chapter was defined as a constrained cost function. The cost function minimizes the number of resonant elements while constraining the mechanical impedance of the base plate. In this case, the constraint was defined as the smallest possible difference between the effective mechanical impedance of the optimized solution and the effective mechanical impedance of the reference solution with uniformly distributed resonant elements.

The contribution of each resonator in the model is determined by the variable ζ^e, which is assigned individually to each resonator. The variable ζ^e can be defined by the following equation

$$\zeta^e = \begin{cases} 0, \text{ dla } e \in P_r \\ 1, \text{ dla } e \notin P_r, \end{cases} \tag{4}$$

where P_r is a vector of resonant elements included in the model. When a resonant element is absent in the P_r vector, $\zeta^e = 0$. The optimization problem is meant to find the values of ζ^e through cost function f_c minimization, while fulfilling the constraint g at the same time, which can be described as [8]

$$\begin{aligned} \min_{\zeta} \quad & f_c(\zeta) \\ \text{s.t.} \quad & g \leq 0, \\ & 0 \leq \zeta_{min} \leq \zeta^e \leq 1. \end{aligned} \tag{5}$$

To minimize the number of resonant elements, the cost function was defined as follows

$$f_c(\zeta) = \frac{1}{N_{\text{rezo}}}\left(\sum_{\zeta=0}^{N_{\text{rezo}}} \zeta^e + \alpha \sum_{\zeta=0}^{N_{\text{rezo}}} \zeta^e(1-\zeta^e)\right), \tag{6}$$

where N_{rezo} is the overall number of resonant elements, and α is weighting factor forcing ζ^e to achieve values 0 or 1. The constraint function can be written as

$$g(\zeta, \Delta, P, f) = \frac{1}{\Delta}||\delta_Z||_P - 1, \tag{7}$$

where Δ is the target difference between the mechanical impedance level of the basic and optimized case, and δ_Z is the level difference in the current iteration.

4. HYBRID SIMULATION MODEL

In order to perform topological optimization of resonant elements distribution, a hybrid analytical-numerical model was created. Hybrid modeling allowed for a finite-size plate with resonant elements implementation with reduced time needed for a single calculation. Simulations were conducted using COMSOL Multiphysics with

MATLAB LiveLink. The numerical model created in COMSOL is shown in Fig. 1. 3D model consisted of a shell plate with finite dimensions $x_{\text{plate}} = 0.55$ [m], $y_{\text{plate}} = 0.45$ [m], and thickness 0.001 [m]. The plate material was steel with the material parameters: density $\rho = 7850$ [kg/m^3], Young's modulus $E = 205$ [GPa], and Poisson ratio $\nu = 0.33$ [−]. For the base plate, an excitation was defined in the form of a force per unit area, expressed in [N/m^2].

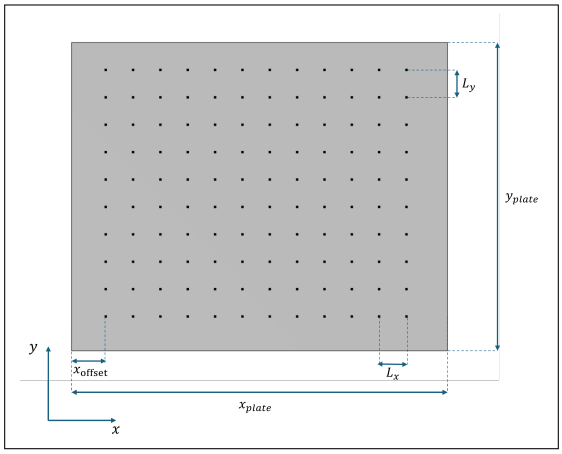

Figure 1. Base plate model with periodically distributed resonant elements, with dimensions.

On the surface of the base plate, a grid of points was created, in which resonant elements modeled as mass-spring-damper systems were placed. The distance between consecutive points is defined along the y axis as L_y and $L_y = L_x$. To model the resonant element, the *Lumped Parameter Modelling* module was used, which allows the parameters of a mass-spring-damper system to be expressed through mechanical parameters, without the need to model the geometry of the element. The effective parameters of the resonant element were determined using a hybrid model based on modal mass calculations [6].

For the developed base plate model, it was possible to determine the vibration velocity of the base plate and, on this basis, the mechanical impedance Z_{eff} of the plate with metamaterial. The mechanical impedance of the plate can subsequently be used to calculate the acoustic insulation of a plate with LRS according to equations presented in Sec. 2.

5. RESULTS

To determine the frequency range of interest, calculations were performed for frequencies in the range $100-300$ Hz. Resonant elements were tuned to one of the base plate resonant frequencies $f = 153$ Hz. The calculations were limited to the implementation of a resonant element with a natural frequency of $\omega_0 = 153$ Hz and effective mass in the z axis. For these elements, the effective mass was $m_r = 0.00051$. The loss factor was assumed to be $\eta = 0.05$ (as for polycarbonate).

For the optimization of the resonator distribution, the frequency range was narrowed to $f = \langle 140, 170 \rangle$ Hz with a step of 3 Hz to reduce the computation time per iteration. In optimization, a target error $\Delta = 3$ dB was assumed. The optimization was run for 600 iterations and the solution was obtained after 225 iterations. The error δ_Z achieved after optimization was 2.8 dB, which met the constraints defined by the constraint function.

In Fig. 2 optimized distribution of resonant elements is presented. In color, the base plate displacement amplitude for 153 Hz is presented. The positions of the resonant elements resulting from the optimization procedure are correlated with areas with larger displacement amplitudes. The acoustic insulation characteristics obtained from the simulation for an empty steel plate, a plate with a uniform distribution of resonant elements, and a plate with an optimized distribution of elements are shown in Fig.3. Despite a 35 % reduction in the number of resonant elements, the differences in the acoustic insulation values for individual frequencies do not exceed 1 dB.

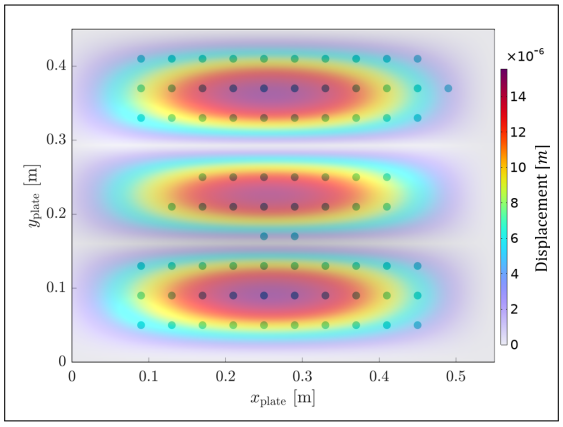

Figure 2. Displacement of the base plate at the frequency $f = 153$ Hz with the optimized distribution of resonant elements on the surface of the base plate.

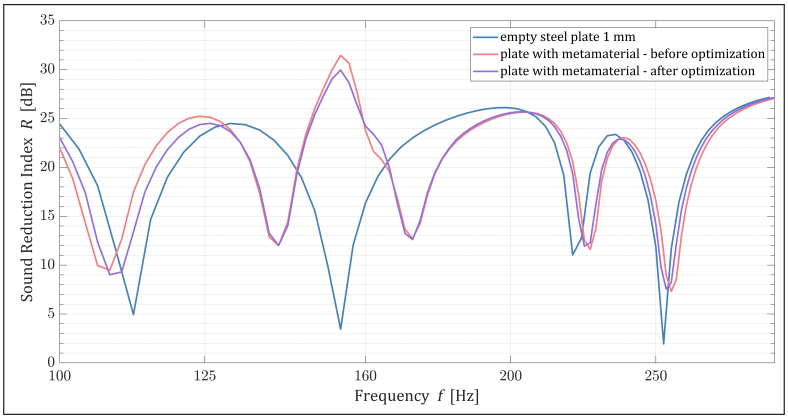

Figure 3. Comparison of the acoustic insulation simulation results for the empty steel plate, the plate with uniformly distributed resonant elements over the entire available surface, and the plate with the optimized distribution of resonant elements.

6. CONCLUSION

In this paper, an optimization procedure is presented, which allows for resonant elements number minimization while preserving the effectiveness of the solution in noise and vibration mitigation in specified frequency range. Thanks to the conducted optimization, the possibility of optimizing the distribution of resonant elements on the base plate in order to minimize the number of resonant elements was confirmed. The effectiveness of the optimization algorithm was validated for the case of a rectangular plate with fixed edges and excitation by a plane wave. The method of optimizing the distribution of elements can be extended, for example, by optimizing the distribution of elements in a three-dimensional machine casing. The developed optimization procedure, combined with algorithms based on hybrid models for LRS simulation, constitutes a solution that enables the improvement and extension of computational capabilities for vibroacoustic metamaterials.

ABSTRACT

This research presents a novel geometric configuration for acoustic metamaterials designed to optimize sound absorption, particularly at low frequencies. The design introduces a segmented pathway composed of two sections, creating an effective acoustic path longer than the linear distance between the sound wave entry point and the cavity access. This configuration maximizes absorption while maintaining a constant overall thickness.
The study explores various geometric configurations by adjusting the angles of the segmented pathway to enhance absorption at specific frequencies. The research integrates analytical analyses based on the transfer matrix method implemented in MATLAB. A prototype fabricated through 3D printing provides experimental validation of the findings. Preliminary results indicate that tuning the angles of the segmented pathway significantly improves acoustic absorption, offering new possibilities for applications in noise control and architectural acoustics.

1. INTRODUCTION

Acoustic metamaterials (AMMs) are designed to optimize sound absorption, particularly at low frequencies. Traditional configurations consist of a flat rigid surface with circular holes or slits, where the neck is typically a single, linear, and straight segment [1]. Sound attenuation primarily occurs due to viscous friction within the pores, while the combination of the neck and the cavity allows for resonance phenomena to enhance absorption. For this reason, resonant absorbers are widely used in architectural acoustics. However, optimizing absorption at low frequencies remains a complex challenge, as the effectiveness of passive absorbers is constrained by the size required to interact with long acoustic wavelengths. Various strategies have been proposed to lower the resonance frequency, such as increasing panel thickness, reducing the diameter of the perforations, or decreasing the overall porosity [2,3]. Although these solutions are effective, they present limitations related to bulkiness, manufacturing costs, and compatibility with compact spaces.
Recent studies have demonstrated that tilting the perforations can shift the resonance frequency to lower values and increase the acoustic absorption coefficient [4,5]. To this end, this research investigates two different

approaches to predict the acoustic properties of materials with segmented pores divided into two inclined sections, contributing to the design of more efficient devices.
This study is structured as follows: Section 2.1 presents the modeling approach and discusses the geometric description of the acoustic metamaterial's unit cell. Section 2.2 describes the analytical method based on the transfer matrix method implemented in MATLAB. Section 2.3 details the experimental procedure, following ISO 10534-2 [6], to characterize the sound absorption properties of the proposed metamaterial. Subsequently, Section 3 presents a comparison of the preliminary results obtained. Finally, Section 4 discusses the main conclusions.

2. GENERAL DESCRIPTION

2.1 Unit Cell Description

The alternative studied in this article introduces a single neck, but divided into two inclined segments, creating a structured geometric configuration. In this design, the first segment forms an entry angle with the external surface, while the second segment, connected to the first, generates a transition angle that alters its direction. Finally, the neck terminates with an exit angle inside the resonant cavity. This configuration extends the effective length of the neck without increasing the overall system thickness, thereby optimizing absorption at low frequencies.
Figure 1 illustrates the geometric dimensions of the resonator in cross-section. Here, r and R_w represent the perforation radius and the impedance tube radius, respectively; L is the resonator thickness; D and R_c denote the cavity depth and radius, respectively; while θ_1 and θ_2 correspond to the inclination of the first segment relative to the incidence surface and the inclination of the second segment relative to the cavity surface. The linear lengths of the first and second segments, L_1 and L_2, are:

$$L_1 = \frac{L}{\frac{\cot(\theta_2)}{\cot(\theta_1)}+1}\frac{\cot(\theta_2)}{\cot(\theta_1)} \quad (1)$$

$$L_2 = \frac{L}{\frac{\cot(\theta_1)}{\cot(\theta_2)}+1}\frac{\cot(\theta_1)}{\cot(\theta_2)} \quad (2)$$

While the effective lengths of the first and second segments, d_1 and d_2, are:

$$d_1 = \frac{L\cos(\theta_2)}{\sin(\theta_1+\theta_2)} \quad (3)$$

$$d_2 = \frac{L\cos(\theta_1)}{\sin(\theta_1+\theta_2)} \quad (4)$$

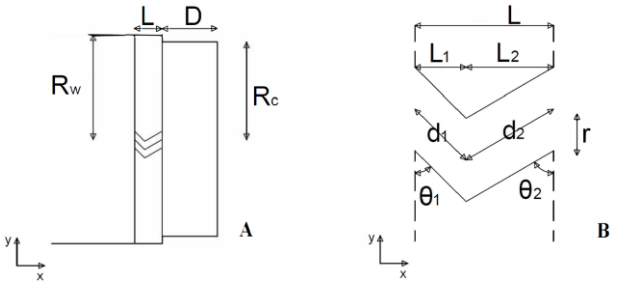

Figure 1. Schematic cross-sectional representation of the proposed resonator with the indication of the main geometric parameters. Figure 1a (left) illustrates the overall configuration of the resonator, highlighting the general geometry, the resonant cavity, and the impedance tube. Figure 1b (right) provides a detailed view of the resonator structure alone, emphasizing the configuration of the neck, which is divided into two inclined segments. Additionally, the total thickness (L), the perforation radius (r), and the angles (θ_1, θ_2) of the two neck segments are indicated.

2.2 Analytical model

The analytical model formulated in this study for characterizing the sound wave propagation in the acoustic metamaterial (AMM) employs the transfer matrix method [7] and the equivalent fluid approach of Johnson-Champoux-Allard (JCA) [8], with the analytical estimation of transport parameters adapted from Atalla and Sgard [3]. To investigate the acoustic properties of the proposed absorber, a theoretical model based on the equivalent fluid theory was developed, treating the perforated resonator as a homogeneous medium with fluid equivalent acoustic properties. This approach enables the characterization of the absorber's acoustic impedance and its behavior in terms of sound absorption.
The absorption coefficient is calculated as:

$$\alpha = 1 - \left|\frac{T(1,1) - Z_0\,T(2,1)/S_w}{T(1,1) + Z_0\,T(2,1)/S_w}\right|^2 \quad (5)$$

where $T=M_1M_2M_c$ is the transfer matrix, $Z_0=c_0\rho_0$ is the characteristic impedance of air, c_0 is the speed of sound propagation, ρ_0 is the air density, and $S_w=\pi R_w^2$ is the cross-section of the impedance tube.
M_1 and M_2 are the matrices describing the acoustic wave propagation through the first and second inclined segment of the resonator neck:

$$M_i = \begin{bmatrix} \cos(k_i L_i) & jZ_i \sin(k_i L_i) \\ \frac{j}{Z_i} \sin(k_i L_i) & \cos(k_i L_i) \end{bmatrix} \quad (6)$$

with $i=1,2$ where the characteristic impedance of the first and second segment of the neck is $z_i = \sqrt{\rho_i B_i}/\pi r^2$. The matrix describing the acoustic wave propagation through the air cavity of the resonator is:

$$M_c = \begin{bmatrix} \cos(k_0 D) & j\frac{Z_0}{S_c} \sin(k_0 D) \\ \frac{jS_c}{Z_0} \sin(k_0 D) & \cos(k_0 D) \end{bmatrix} \quad (7)$$

$S_c = \pi R_c^2$ is the cross-section of the cavity, the wavenumber of air is $k_0 = \omega/c_0$ and the wavenumber of the first and second segment is $k_i = \omega(\rho_i/B_i)^{\frac{1}{2}}$ where ω is the frequency. Initially, in the model herein developed, each region can be homogenized as function of equivalent density ρ_i [8]:

$$\rho_i = \rho_0 \alpha_{\infty i} \left(1 + \frac{\sigma_i \phi_i}{j\omega\rho_0 \alpha_{\infty i}} G_i\right) \quad (8)$$

$$G_i = \sqrt{1 + \frac{4j{\alpha_{\infty i}}^2 \rho_0 \omega}{\lambda^2 {\sigma_i}^2 {\phi_i}^2}} \quad (9)$$

with viscous and thermal characteristic length $\lambda = r/2$. The subscript i describe the effective density in the first and second perforation segments, respectively.

The geometric tortuosity $\alpha_{\infty,i}$ of the first and second neck segments [3]:

$$\alpha_{\infty i} = \frac{1}{\sin^2(\theta_i)} + 2\frac{\varepsilon_{ei}}{d_i} \quad (10)$$

with $\varepsilon_{ei} = 0.85 r F_{ei}$ and $F_{ei} = 1 - 1.4092\xi_i + 0.33818\xi_i^3 + 0.06793\xi_i^5 - 0.02287\xi_i^6 + 0.03015\xi_i^7 - 0.01641\xi_i^8$ with $\xi_i = (\Phi_i)^{1/2}$ is the Fork function [9]. The flow resistance of the first and second neck segments is described as [3]:

$$\sigma_i = \frac{(2d_i/r)sin^2(\theta_i)+4}{d_i \Phi_i} Rs + \frac{8\eta}{\phi_i \left(\frac{r}{2}\right)^2 \cos^2(\theta_i)} \quad (11)$$

where η is the dynamic viscosity of air and $Rs = \frac{\sqrt{2\eta\rho_0\omega}}{2}$. $\Phi_1 = S/S_w$ is the open porosity of the first segment of the neck, where $S = \pi r^2$ and the open porosity of the second segment is $\Phi_2 = 1$, since the radii of the first and second perforation are equal.

The effective compressibility in the first and second segments is [8]:

$$B_i = \frac{\gamma P_0}{\Phi_i} [\gamma - (\gamma - 1)(1 - HG')^{-1}]^{-1} \quad (12)$$

$$H = \frac{8\eta}{j\lambda^2 Pr\omega\rho_n} \quad (13)$$

$$G' = \sqrt{1 + \frac{jPr\omega\rho_0\lambda^2}{16\eta}} \quad (14)$$

where γ is the ratio of specific heats of air, P_0 is the static air pressure, and $Pr = 0.71$ is the Prandtl number for air.

2.3 Experimental Model

To validate the theoretical model introduced in this research, experimental tests were conducted in the laboratory using an impedance tube. The samples were manufactured through an additive manufacturing process at the *Institute for Sustainability and Innovation in Structural Engineering (ISISE)*, within the Department of Civil Engineering at the University of Coimbra. Considering recent advancements in 3D printing techniques for acoustic metamaterials (AMMs) [10], these acoustic metamaterials were designed using advanced computer-aided design (CAD) software and fabricated through a *Fused Deposition Modelling (FDM)* process. The 3D printing process was carried out using a *Blocks One MK2* printer. The *Fused Deposition Modelling (FDM)* method involves melting a thermoplastic filament composed of polylactic acid (PLA), with a diameter of 1.75 mm, at a temperature of 210°C. The molten filament is extruded through a heated 0.4 mm nozzle and systematically deposited layer by layer onto a print platform maintained at 50°C. The 3D-printed samples, shown in Fig. 2, feature a circular configuration with a nominal outer radius R_w of 18.75 mm (Fig. 2a), precisely designed to fit perfectly within a 37,5 mm impedance tube. The actual thicknesses of the specimens, with nominal values (L) of 5 mm and 10 mm, are shown in Fig. 2b and Fig. 2c, respectively.

Figure 2. Sample of the proposed AMM.

Table 1 summarizes the actual thickness (L) dimensions of the six tested samples.

Table 1. Thickness (L) measurements of the printed samples expressed in millimeters.

Sample	L
45°-45°	5,16
60°-45°	5,30
30°-60°	5,28
45°-45°	10,22
60°-45°	10,23
30°-60°	10,28

For this evaluation, the measurement procedure was carried out using the previously described small-scale samples under controlled conditions. The sound absorption and reflection coefficients were measured using the two-microphone technique, employing the transfer function method, in accordance with ISO 10534-2 [6]. The measurement apparatus consists of a closed tube with a sound source that emits a sine-sweep signal generated by a loudspeaker, thereby exciting the system within its operational frequency range. Specifically, for a circular tube with an internal radius of R_w = 18,75 mm, the operational frequency range is between 200 Hz and 4800 Hz. The measurement process of the acoustic pressure measured by microphones p_1 and p_2, positioned at points x_1 and x_2 inside the tube, can be described as follows:

$$P_1 = |p_i|e^{jkx_1} + |p_r|e^{-jkx_1} \quad (15)$$

$$P_2 = |p_i|e^{jkx_2} + |p_r|e^{-jkx_2} \quad (16)$$

where $|p_i|$ and $|p_r|$ represent the amplitudes of the incident and reflected wave pressures on the sample surface, respectively. The transfer functions H_i and H_r, considering each component of the total pressure, can be expressed as follows:

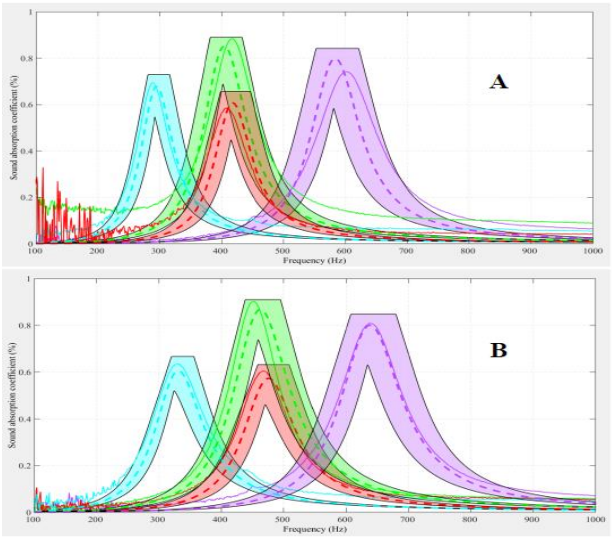
$$H_i = \frac{p_i e^{jkx_2}}{p_i e^{-jkx_1}} = e^{jks} \quad (17)$$

$$H_r = \frac{p_r e^{jkx_2}}{p_r e^{-jkx_1}} = e^{-jks} \quad (18)$$

where $s = x_2 - x_1$. Consequently, the transfer function between the two microphones, H_{12}, is defined as:

$$H_{12} = \frac{p_2}{p_1} = \frac{e^{jkx_2} + Re^{-jkx_2}}{e^{jkx_1} + Re^{-jkx_1}} \quad (19)$$

where R is the complex reflection coefficient, which, as a function of H_{12}, can be expressed as:



$$R = \frac{H_{12} + H_i}{H_r - H_{12}} e^{2jkx_1} \quad (20)$$

The sound absorption coefficient can then be calculated for normal incidence using the following relation: $\alpha = 1 - |R|^2$. This formulation allows for the determination of the sample's acoustic absorption based on the measurement of the transfer function between the two microphones, following the standardized method outlined in ISO 10534-2 [6].

3. PRELIMANARY RESULTS

In the experimental tests, three different unit cell geometries were analyzed, characterized by angles (θ_1 and θ_2) of 45°-45°, 60°-45°, and 30°-60°, respectively. For each configuration, two different variants of nominal thickness (L), 5 mm and 10 mm, and two nominal cavity depth (D) configurations, also 5 mm and 10 mm, were tested. The experimental results obtained in the laboratory were compared and validated using the analytical model. The latter was implemented using the (L) values measured directly from the samples, as reported in Table 1.

Figure 3 shows the comparison between the analytical predictions and the experimental data for the absorption coefficient as a function of frequency. The envelope observed in the analytical graphs is attributed to the uncertainty in the exact measurement of the sample neck radius r. To account for potential inaccuracies due to the printing process, an error margin of 0.05% of the nominal radius of 3 mm was introduced, allowing for possible variations in the actual radius.

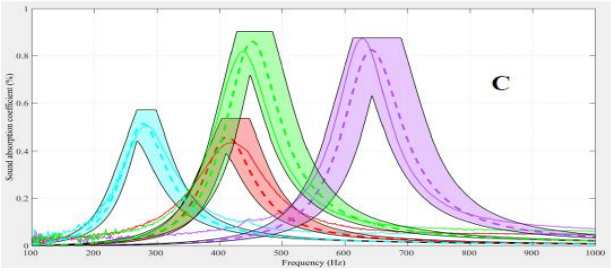


Figure 3. Comparison between experimental and analytical results for the acoustic absorption coefficient as a function of frequency with different geometric configurations of AMMs. Graph (A) corresponds to the configuration with angles 45°-45°, (B) to the 60°-45° configuration, and (C) to the 30°-60° configuration. The colored curves represent different combinations of thickness (L) and cavity depth (D): blue indicates L = 10 mm, D = 10 mm; red L = 10 mm, D = 5 mm; green L = 5 mm, D = 10 mm; and purple L = 5mm, D = 5 mm. Solid lines represent the experimental results, while dashed lines indicate the analytical results obtained for a perforation radius of r = 3 mm. The envelope accounts for a ±5% variation in the perforation radius.

4. CONCLUSIONS

The article explored the study of different unit cell geometries for an acoustic metamaterial resonator (AMM), examining the influence of variations in thickness (L), cavity depth (D), and angles (θ_1 and θ_2) on the geometric configuration of individual cells. The absorption values of the unit cells were validated both through an analytical model using the transfer matrix method [7] and the Johnson-Champoux-Allard (JCA) equivalent fluid approach [8] and through experimental measurements conducted according to the guidelines of ISO 10534-2 [6] on 3D-printed samples. The results demonstrated a significative agreement between the experimental data and analytical predictions, highlighting how variations in geometric characteristics influence both the resonance frequencies and the absorption coefficient amplitudes. This opens space to future investigations about optimised panels handling the segmented necks.

ABSTRACT

Acoustic metamaterials that consist of multiple folded quarter-wavelength resonators in parallel have the potential to realise high and broadband low-frequency sound absorption while maintaining a compact volume. In a previous study, it was shown that folding can alter the acoustic behaviour of a quarter-wavelength resonator significantly and a length correction factor was proposed to account for the effect of a single 90° bend in analytical models. In this paper, a transfer matrix approach to model quarter-wavelength resonators with multiple 90° bends is proposed. Firstly, the different steps of the transfer matrix method are discussed and the two-port matrix of a 90° bend is predicted as a function of the resonator width by applying a passive two-port characterisation technique to the result of numerical simulations. Then, the transfer matrix method is applied to determine the resonance frequency of a set of single-bend and two-bend quarter-wavelength resonators. Lastly, these results are verified against other modelling approaches and finite element simulations in COMSOL Multiphysics.

1. INTRODUCTION

Sound absorbing panels made of porous material (e.g. mineral wool) offer a broadband solution to indoor noise problems, but since the needed layer thickness scales with the wavelength, issues might arise when targeting low-frequency sound in confined spaces. In such case, resonant acoustic metamaterials can be used instead, offering a compact and broadband solution to low-frequency sound problems [1–3].

This work focusses on quarter-wavelength ($\lambda/4$) acoustic metamaterials, which consist of multiple folded or coiled $\lambda/4$ resonators in parallel and/or series. In a previous study, it was shown that folding can affect the resonance frequency of a $\lambda/4$ resonator significantly [4]. Hence, an empirical length correction factor was derived to account for the effect of a 90° bend [5]. Although the proposed correction factor was successfully verified and validated [6], its use is limited to $\lambda/4$ resonators with a single 90° bend, whereas real-life resonators are often folded multiple times.

Hence, this paper investigates the use of a transfer matrix approach to determine the absorption coefficient and resonance frequency of a $\lambda/4$ resonator with multiple 90° bends. The remainder of this paper is structured as follows. In Section 2, the different steps of the proposed transfer matrix method are discussed and transfer matrices for straight and 90° corner elements are defined. Section 3 covers the numerical verification of the transfer matrix method against various single-bend and two-bend resonator configurations. Finally, the main conclusions are given in Section 4.

2. TRANSFER MATRIX METHOD

The transfer matrix method (TMM) is a well-established approach to determine the acoustic properties (e.g. the absorption coefficient) of a complex, multi-element structure [7]. In this work, the structure is a folded $\lambda/4$ resonator, which can be seen as a series arrangement of straight and 90° corner elements, embedded in a baffle. The different steps of the TMM are discussed in the following subsections.

2.1 Transfer matrix of an acoustic element

In order to apply the TMM, the transfer matrix $\underline{T}$ of each element must be known. This matrix relates the total pressure p and axial particle velocity v at the inlet and outlet of the element, as given by Eqn. (1) [7]:

$$\begin{Bmatrix} p \\ v \end{Bmatrix}_{out} = \underline{T} \begin{Bmatrix} p \\ v \end{Bmatrix}_{in}. \tag{1}$$

Depending on the type of element, $\underline{T}$ is calculated directly or derived from the scatter matrix $\underline{S}$, which relates the complex amplitudes of the left and right propagating pressure wave at the inlet and outlet of the element, as given by Eqn. (2) [8]:

$$\begin{Bmatrix} p^+_{out} \\ p^-_{in} \end{Bmatrix} = \underline{S} \begin{Bmatrix} p^+_{in} \\ p^-_{out} \end{Bmatrix}. \tag{2}$$

2.1.1 *Straight element*

For a straight element, $\underline{T}$ is given by Eqn. (3):

$$\underline{T} = \begin{bmatrix} \cos(kL) & -\mathrm{j}Z\sin(kL) \\ -\mathrm{j}\frac{1}{Z}\sin(kL) & \cos(kL) \end{bmatrix}, \tag{3}$$

with j the imaginary unit, L the length of the element, and k the wavenumber and Z the characteristic impedance of the equivalent fluid inside the element, respectively [7, 9].

2.1.2 *90° corner element*

For a 90° corner element, a direct representation of $\underline{T}$ like Eqn. (3) is not available in literature. Hence, $\underline{T}$ is calculated from $\underline{S}$ using Eqn. (4):

$$\underline{T} = \begin{bmatrix} \frac{1-S_{12}}{2} & \frac{Z(1+S_{12})}{2} \\ \frac{-S_{22}}{2} & \frac{ZS_{22}}{2} \end{bmatrix}^{-1} \begin{bmatrix} \frac{S_{11}}{2} & \frac{ZS_{11}}{2} \\ \frac{S_{21}-1}{2} & \frac{Z(1+S_{21})}{2} \end{bmatrix}. \tag{4}$$

The scatter matrix of a 90° corner element is derived by applying a passive two-port characterisation technique to the results of 2D finite element simulations in COMSOL Multiphysics [10]. In this work, only 90° corners with a square cross-section with side length b ranging from 1 to 6 mm are considered. It is found that, for each corner, $\underline{S}$ is symmetric (i.e. $S_{11} = S_{22}$ and $S_{12} = S_{21}$) and can be obtained using Eqn. (5)-(8):

$$\Re(S_{11}) = -0.287(k_0b)^2 - 0.013(k_0b) + 0.999, \tag{5}$$

$$\Im(S_{11}) = -0.783(k_0b) - 0.001, \tag{6}$$

$$\Re(S_{12}) = -0.161(k_0b)^2 - 0.004(k_0b) - 0.0002, \tag{7}$$

$$\Im(S_{12}) = -0.221(k_0b) - 0.0003. \tag{8}$$

The coefficients in the above equations are rounded to enhance readability. Eqn. (5)-(8) are valid for $k_0b \leq 0.16$, with k_0 the wavenumber of the lossless medium. The R^2-value of each fit is greater than 0.98.

2.2 Transfer matrix of the entire structure

Once the transfer matrix of each element is defined, the total transfer matrix $\underline{T}'$ of the $\lambda/4$ resonator can be calculated using Eqn. (9):

$$\underline{T}' = \left(\prod_{i=m}^{i=1} \underline{T}_i \right) \underline{T}_{EC} \underline{T}_{\phi}, \tag{9}$$

with $\underline{T}_i$ the transfer matrix of the i-th element, $\underline{T}_{EC}$ the end correction matrix and $\underline{T}_{\phi}$ the porosity matrix [11].

2.3 Absorption coefficient and resonance frequency

From $\underline{T}'$, the absorption coefficient α of the $\lambda/4$ resonator can be calculated using Eqn. (10):

$$\alpha = 1 - \left| \frac{T'_{21} + \frac{T'_{22}}{Z_0}}{\frac{T'_{22}}{Z_0} - T'_{21}} \right|^2, \tag{10}$$

with Z_0 the characteristic impedance of the lossless medium [7]. The resonance frequency f_R of the resonator is the frequency at which α reaches its maximum value.

3. NUMERICAL VERIFICATION

The use of Eqn. (3)-(10) is verified by comparing the results of the TMM to the results of 3D finite element simulations for a wide variety of folded $\lambda/4$ resonators.

3.1 Approach

To verify the formulas presented in Section 2, various single-bend and two-bend $\lambda/4$ resonators are modelled in 3D in COMSOL Multiphysics. Each resonator has a square cross-section and is embedded in a square baffle, as shown in Fig. 1.

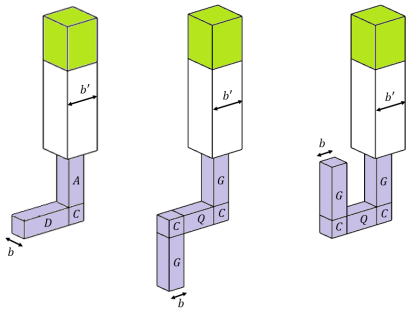

Figure 1. 3D model of a single-bend (left), Z-shaped two-bend (middle) and U-shaped two-bend (right) $\lambda/4$ resonator. Each capital letter indicates an acoustic element.

An overview of the modelled resonators is given in Tab. 1. In total, 54 unique single-bend and 192 unique two-bend resonators are modelled.

Table 1. Overview of the modelled $\lambda/4$ resonators. The porosity ϕ equals $(b/b')^2$.

Resonators with one 90° bend	
Porosity ϕ [-]	0.072
Centreline length L_{CL} [m]	0.06; 0.15; 0.35
Side length b [mm]	1; 2; 3; 4; 5; 6
L_A/L_{CL} [-]	0.1; 0.5; 0.75
L_D [m]	L_{CL} - b - L_A
Resonators with two 90° bends	
Folding shape [-]	U; Z
Porosity ϕ [-]	0.072
Centreline length L_{CL} [m]	0.06; 0.1; 0.25; 0.4
Side length b [mm]	1; 2; 3; 4; 5; 6
L_Q/b [-]	0.2; 0.6; 1; 5
L_G [m]	(L_{CL} - 2b - L_Q) / 2

For each resonator, the absolute relative error in predicted resonance frequency $|\Delta f_R|$ is calculated using Eqn. (11):

$$|\Delta f_R| = \left| \frac{f_R(T) - f_R(C)}{f_R(C)} \right| .100\%, \qquad (11)$$

with $f_R(C)$ the resonance frequency extracted from the finite element simulations and $f_R(T)$ the resonance frequency obtained using the TMM. For the single-bend resonators, the accuracy of the TMM is verified against the accuracy of two other modelling approaches: the length correction factor (LCF) and the model used to model unfolded resonators, which is from now on referred to as the basic analytical model (BAM) [4,6]. For the two-bend resonators, the accuracy of the TMM is only verified against the accuracy of the BAM since the LCF is not applicable.

3.2 Single-bend resonators

The results for the single-bend resonators are visualised in Fig. 2. In this figure, it is seen that the TMM yields similar accuracy values as the LCF. Since the latter was successfully validated in earlier work [6], the use of the formulas presented in Section 2 is justified. It can also be seen that both methods yield significantly higher accuracies than the BAM. The maximum value of $|\Delta f_R|$ when applying the TMM is 0.18%.

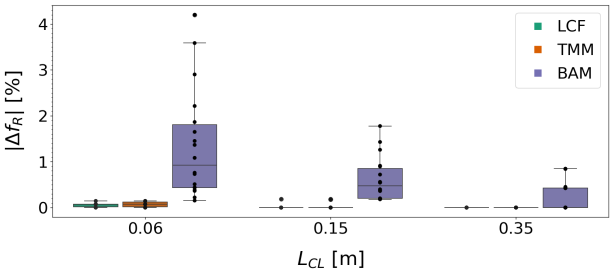

Figure 2. Results for the 54 single-bend resonators.

3.3 Two-bend resonators

The results for the two-bend resonators are visualised in Fig. 3. In this figure, it is seen that (i) the TMM yields significantly higher accuracies than the BAM and (ii) similar accuracy values are achieved for U- and Z-shaped resonators. The maximum value of $|\Delta f_R|$ when applying the TMM is 0.56%.

When looking into the values of $|\Delta f_R|$ in more detail, it is found that, for fixed values of b and L_{CL}, $|\Delta f_R|$ increases when the distance between the bends decreases. This holds for both U- and Z-shaped resonators and implies that interaction effects occur between closely spaced bends. However, since the TMM still yields accurate results, no additional correction is included to account for these effects.

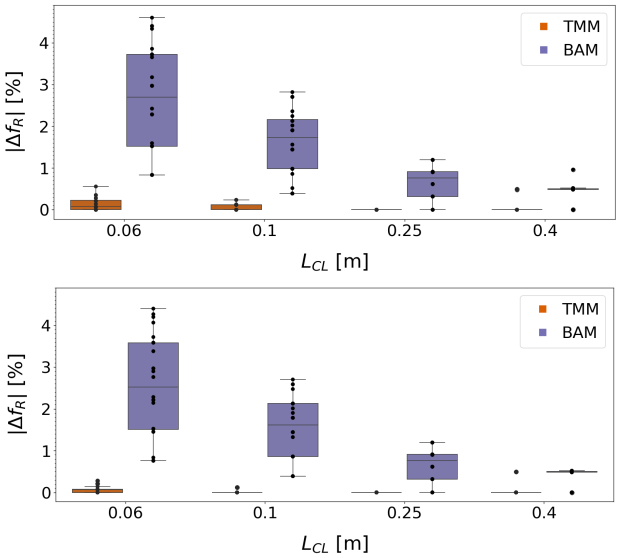

Figure 3. Results for the U-shaped (top) and Z-shaped (bottom) resonators.

4. CONCLUSIONS AND OUTLOOK

In this work, the TMM is applied to determine the resonance frequency of various square $\lambda/4$ resonators with one or two 90° bends and the results are verified against other modelling approaches and 3D finite element simulations in COMSOL Multiphysics. It is found that the TMM yields accurate results: the maximum absolute relative error in predicted resonance frequency is 0.18% and 0.56% for single-bend and two-bend resonators, respectively. In a next step, the use of the TMM will be verified for square $\lambda/4$ resonators with more than two 90° bends and experimental validation will be performed on 3D-printed samples.

ABSTRACT

As metamaterials are coming closer and closer to becoming a mature industrial solution, the question of manufacturing has started to gain importance. Indeed, variability related to industrial processes can cause geometric variability which might degrade the attenuation performance of manufactured samples. Hence, there is a strong need to quantify the impact of uncertainty on the behavior of vibroacoustic metamaterials. However, full-scale metamaterial models can require a relatively high computational time to solve. This makes uncertainty quantification methods like Monte-Carlo simulations either computationally intensive or infeasible due to the high number of model solves required. Hence, this paper proposes a parametric reduced-order model based on the Krylov subspace to predict the vibroacoustic response of a metamaterial structure due to geometric changes without requiring another solve of the full system. Derivation of the response statistics is then achieved by applying a Monte-Carlo simulation on the obtained reduced-order model.

1. INTRODUCTION

When it comes to lightweight solutions for sound and vibration attenuation, metamaterials are showing more and more potential for noise and vibration harnessing in different areas of the industry [1, 2]. The locally resonant nature of metamaterials allows them to create stopbands in which the vibration response is attenuated. However, the problem of variability in metamaterials and the prediction of its effects on their performance is currently a topic of interest. As metamaterials often rely on either in tune resonators or periodicity, imperfect manufacturing of metamaterial structures could lead to underperforming solutions. This is why, the impact of such uncertainty needs to be assessed.

Currently, few design procedures for metamaterials take into account the impact of uncertainties. At present, metamaterials are typically designed by Unit-Cell (UC) modeling [3]. This method takes advantage of the metamaterial translational symmetry to reduce the size of the problem, as only the smallest repeating period of the material is modeled. Some authors used this method to characterize the impact of uncertainty at the UC level [4, 5]. However, as this representation assumes perfect periodicity of the material between the UCs, it is not able to describe the random imperfections that occur when the material is actually manufactured. Still, to take into account these imperfections, different approaches were already proposed in current literature. Some authors suggest to take into account the impact of variability in a finite metamaterial model. Some references [6, 7] present studies of

metamaterial structures through uncertainty quantification techniques such as Gaussian process modeling to characterize e.g. the uncertainty bounds on its response metrics. In [8], a model-order reduction strategy is presented to improve the solving time of nearly periodic structure, based on periodic structure theory, which allows to partially overcome the computational limitations of statistical analysis for large metamaterial structures.

However, the study of uncertainty in metamaterials has been mostly limited to point scatterers or idealized resonators [9], and the study of geometric deviations in such structures has received less attention. Indeed, geometric perturbations of a structure leads to nonlinear changes in the finite element matrices, making model-order reduction more complex. Additionally, parametric model-order reduction schemes need to be developed for efficient sampling and uncertainty quantification of the system as the number of solves needed for convergence of the statistics under consideration might be high in some cases.

In this paper, a parametric model-order reduction scheme based on [9] is developed for finite-size metamaterials. The method is applied to a phononic crystal beam to obtain the statistics of its vibration response to a point excitation. The accuracy of the method is assessed by comparison with the full-order model for individual simulations, but also for the statistics of the system's response.

The rest of the paper is structured as follows: section 2 provides a description of the problem under consideration. Then, section 3 gives an overview of the parametric model-order reduction approach. A statistical analysis of the structure as well as a comparison with the full-order model are given in section 4. An extension of the proposed method by projection basis enrichment is proposed in 5. Finally, the results are summarized in section 6.

2. PROBLEM DEFINITION

In this paper, the phononic Euler-Bernoulli beam of [10] is considered as case study. A one-dimensional structure is considered, for which geometric changes are straightforwardly defined and have a direct effect on the stopband behavior of the metamaterial. The system also has the advantage of being practically manufacturable, allowing for possible experimental validation of the numerical study in future work.

The beam is composed of 9 UCs with subsequent thickness variations (Fig. 1). The UC has a length $L_{UC} = 40$ mm and is composed of two equal-sized parts with different heights $h_1 = 10$ mm and $h_2 = 3$ mm respectively. The material properties of the beam are described in table Tab. 1. Free-free boundary conditions are considered and a unit transverse point force is applied on the first node on the left side of the beam.

Table 1. Properties of the phononic beam.

Property	Symbol	Value
Width	b	10 mm
Mass density	ρ	1135 kg/m^3
Young's modulus	E	1.9 GPa
Structural damping	η	5 %

Due to the presence of variability, the position of each UC center is assumed to randomly deviate from its nominal value and is described by the parameters l_n. This choice is motivated by the fact that this phononic beam relies on periodicity to produce a stopband. Therefore, modifying l_n directly impacts the periodicity but also preserves its total length as well as the location of the forcing and response nodes. The length deviation of l_n is assumed to follow a uniform distribution with limits at $\pm 3\%$ of the nominal length. There is currently no justification for this choice as data in the metamaterial literature on such variation is rather limited. However, the statistical distribution of the l_n could be determined by production of a large enough series and statistical analysis of the dimensions of the system.

To conduct the numerical study, the beam is discretized using the Finite Element Method (FEM). Euler-Bernoulli beam elements are used to obtain a small, one-dimensional problem instead of a full elastodynamic model. 8 elements per UC are used, ensuring a minimum of 10 elements per wavelength in either of the sections of the beam. The FE-discretized, l_n-dependent equations of motion then write as

$$\mathrm{D}(l_n)\mathbf{u}(l_n) = \mathbf{F}, \tag{1}$$

where $\mathrm{D}(l_n)$ is the dynamic stiffness matrix, $\mathbf{u}(l_n)$ is the displacement vector and $\mathbf{F}$ is the force vector. The dependency with respect to the l_n is accounted for by moving the nodes of the structure in space such that the elements of the beam are either contracted or dilated by a small percentage compared to the case $l_n = 0$ to match the desired geometric variation. In general, metamaterial UCs can become quite intricate, and UC meshes rather large, making full structure models of the UC assembly even

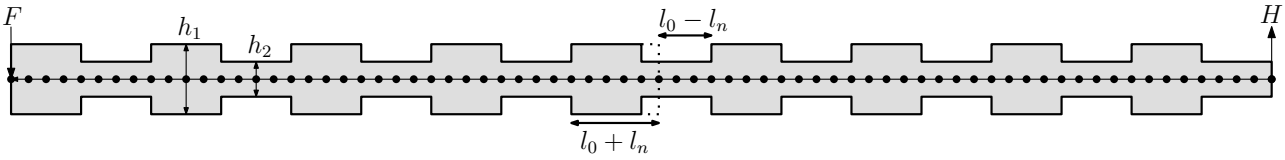

Figure 1. Phononic beam structure under consideration. F represents the forcing point, while H represent the velocity response point.

larger. Solving equation Eqn. (1) might then be too computationally expensive for full-order uncertainty propagation simulations requiring high amount of samples as the computational cost for one solve is already high. In the following section, a parametric model-order reduction scheme is developed to take into account the impact of geometrical uncertainties. The model under consideration is rather small and does not need to be reduced to perform uncertainty quantification. In principle, the method proposed is however generally valid, and in this paper it will be applied to this simple case as a first validation. The goal of the method is to obtain a parametric reduced-order model to quickly evaluate the response of a structure subject to geometric variations.

3. METHODOLOGY

3.1 Parametric Model-Order Reduction Scheme

As a first approach, one might consider expanding $\mathbf{u}$ as a first order perturbation series around $\mathbf{u}_0$:

$$\mathbf{u} \simeq \mathbf{u}_0 + \sum_{n=1}^{N_p} l_n \mathbf{u}_1^{(n)}, \tag{2}$$

with N_p the number of random parameters, equal to the number of UCs in this study, $\mathbf{u}_0 = \mathbf{u}(l_n = 0)$ and $\mathbf{u}_1^{(n)} = \mathrm{D}^{-1}(0)\frac{\partial \mathrm{D}}{\partial l_n}|_{l_n=0}\mathbf{F}$. The matrices $\frac{\partial \mathrm{D}}{\partial l_n}$ can be straightforwardly evaluated using the analytical expression of the Euler-Bernouilli beam element matrices

$$K_e^p = \frac{EI_p}{l_e^3}\begin{pmatrix} 12 & 6l_e & -12 & 6l_e \\ 6l_e & 4l_e^2 & -6l_e & 2l_e^2 \\ -12 & -6l_e & 12 & -6l_e \\ 6l_e & 2l_e^2 & -6l_e & 4l_e^2 \end{pmatrix}, \tag{3}$$

$$M_e^p = \frac{\rho S_p l_e}{420}\begin{pmatrix} 156 & 22l_e & 54 & -13l_e \\ 22l_e & 4l_e^2 & 13l_e & -3l_e^2 \\ 54 & 13l_e & 156 & -22l_e \\ -13l_e & -3l_e & -22l_e & 4l_e^2 \end{pmatrix}, \tag{4}$$

where K_e^p and M_e^p are respectively the Euler-Bernoulli beam element stiffness and mass matrices of the p-th cross section of the beam with $p = 1, 2$, S_p and I_p are the surface and quadratic moment of inertia of the p-th cross section of the beam and l_e is the element length.

Eqn. (2) usually suffers from accuracy and instability, especially in the presence of resonances, making it unsuitable for accurate computation of the frequency response of a vibrating structure in which many resonances are present [11].

This is why an alternative moment-matching approach [9, 12] is used instead in this paper. The moments of the first-order perturbation series $\mathbf{u}_0$ and $\mathbf{u}_1^{(n)}$ are multiplied by a set of coefficients for the chosen set of parameters by multiplying them by a correction contribution amplitude w_n.

$$\mathbf{u} \simeq w_0\mathbf{u}_0 + \sum_{n=1}^{N_p} w_n l_n \mathbf{u}_1^{(n)}. \tag{5}$$

These additional degrees of freedom will later allow for an optimal correction of the displacement vector. This is equivalent to taking the assumption that the solution $\mathbf{u}$ lies in the subspace

$$\mathrm{Q} = orth\left(\left[\mathbf{u}_0, \mathbf{u}_1^{(1)}, ..., \mathbf{u}_1^{(N_p)}\right]\right). \tag{6}$$

Projecting Eqn. (1) onto the basis Q, the following reduced-order problem is obtained

$$\tilde{\mathrm{D}}(l_n)\mathbf{w}(l_n) = \tilde{\mathbf{F}}, \tag{7}$$

with $\tilde{\mathrm{D}}(l_n) = \mathrm{Q}^*\mathrm{D}(l_n)\mathrm{Q}$, and $\tilde{\mathbf{F}} = \mathrm{Q}^*\mathbf{F}$. Eqn. (7) can then be used to quickly evaluate the changes of $\mathbf{u}$ to parametric variations, without the need to solve for the full-order problem once again, and only requiring a reassembly of the system matrices with a transformed mesh according to the l_n.

3.2 Monte-Carlo simulations

To quantify the random changes in the structure's response, Monte-Carlo simulations are used to propagate the uncertainty. For a sufficiently large number of samples $N_{samples}$, the set of l_n is drawn from a uniform distribution using a random number generator. In this study, the Python function from the *Numpy* library `numpy.random.uniform` is used.

For each set of l_n, and at each frequency the matrix $\mathrm{D}(l_n)$ is assembled. Then the system Eqn. (7) is derived and solved. Equation Eqn. (5) is finally used to obtain the displacement vector and the response. Once the procedure is repeated for the full set of l_n, statistical analysis can be run on the obtained set of responses.

In the following section, the previously derived reduction scheme and the Monte-Carlo simulation approach are used for statistical analysis of the phononic beam structure.

4. STATISTICAL ANALYSIS OF THE PHONONIC BEAM

In this section, the method of section 3 is validated on the structure from section 2. Then an error analysis is performed to verify the accuracy of the method.

4.1 Response analysis

In (Fig. 2), the endpoint velocity response of the beam is displayed in dashed lines for the nominal case, where $l_n = 0$. The nominal periodic phononic beam shows a frequency range of strong vibration reduction around 1050 Hz. As shown in [10], this is due to the presence of a Bragg stopband around this frequency. Destructive interference occurs, which prevents waves from propagating to the probing location at the other side of the beam. As this effect is linked to the periodicity of the structure, including disorder in the UC geometry through the l_n, and therefore breaking the periodicity of the systems is expected to have an impact on the stopband effect.

The median of the response (blue) as well as the confidence interval between its 5-th and the 95-th percentiles (light blue region) are also displayed. A total of 1000 Monte-Carlo sample are computed using the reduced-order model from Eqn. (7) method and used to obtain the statistics of the response. After 1000 samples, it was observed that the relative variation in the statistical indicators under consideration is less than 3% over the frequency range $50 - 2500$ Hz when increasing the number of iterations.

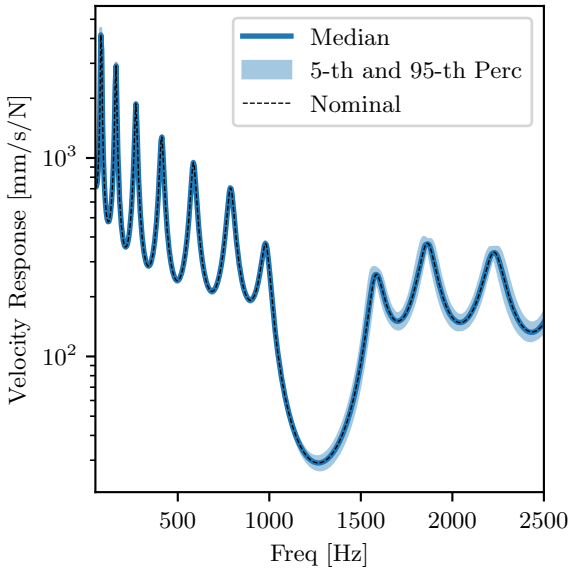

Figure 2. Endpoint velocity response of the phononic response in the nominal case, median, 5-th and the 95-th percentiles of the response.

Thanks to these response statistics, the effect of geometric variations on the vibration attenuation performance of the beam can be assessed. In the higher frequency part of the stopband region, as well as above it, the difference between the 95-th and 5-th percentile responses is seen to be bigger than in the lower part of the frequency range, meaning that the magnitude of the response is more uncertain in this frequency region. For the geometrical changes considered, small variations affect the response in the band gap. However, a clear attenuation region still persists for the disorder strength considered. This was also observed for locally resonant disordered beam metamaterial structures in the literature [6, 13, 14].

4.2 Error Analysis

Following computation of the response statistics, an analysis is conducted to compare how representative the reduced-order model is of the full-order model. After performing statistical computations with the reduced-order model, a Monte-Carlo simulation is run for the full-order model Eqn. (1) for the same set of l_n to conduct an error analysis. This is feasible since the model considered

here has a small number of degrees of freedom. To verify the accuracy of the reduced-order model, the maximum of the relative error between the reduced and full-order models across all realizations of the structure is evaluated. This error metric can serve as an estimate of the minimum degree of accuracy attained by the method in the desired frequency range.

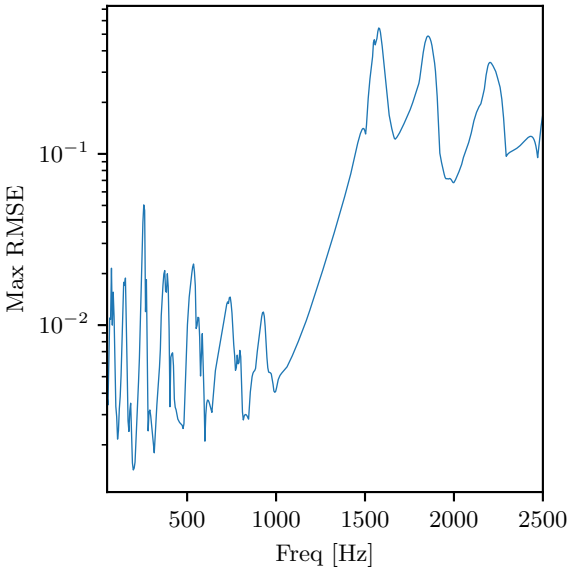

Figure 3. Maximum relative root mean square error between the reduced and full-order models observed across realizations of the system.

The results of this first analysis are displayed in Fig. 3. From the error curve across the frequency range, we can observe that the reduced-order model performs best up to 1000Hz, before the stopband region, with under 5% relative error. At higher this frequencies, the maximum error between the two models is higher, and can get as high as 40% near some resonances. Indeed, past the stopband, the dynamics of the phononic beam are different and could explain the difference in accuracy. Additionally, error peaks occur near resonances of the system.

To verify the accuracy of the method, the error on the statistical indicators is computed for this system, namely, the median, 5th and 95th percentiles of the response is computed compared to the full-order system in (Fig. 4).

The error does not exceed 15% for either of the statistical quantities over the frequency range of interest. How-

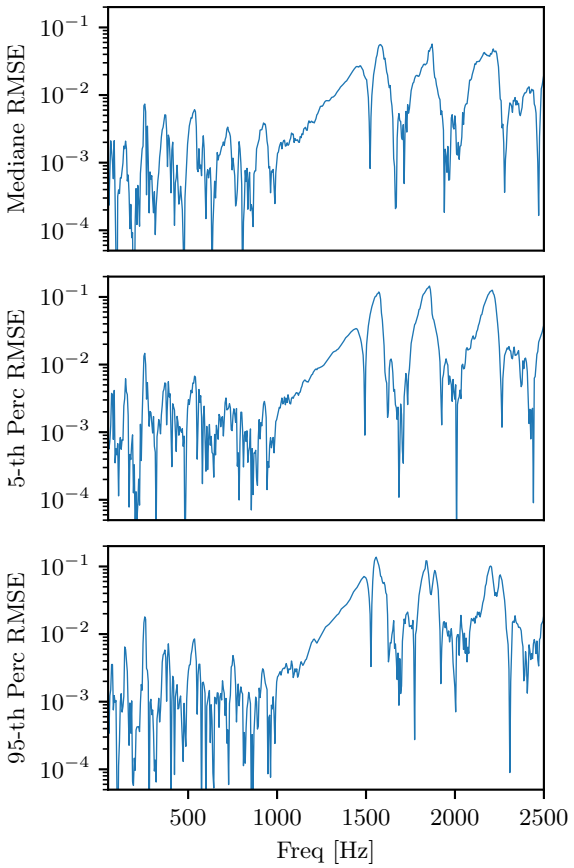

Figure 4. Relative root mean square error between the reduced and full-order models on the median, 5-th and 95-th percentiles of the endpoint velocity response.

ever, similarly to (Fig. 3), a much lower accuracy is obtained above the stopband region and error peaks are again notified near resonances of the system, confirming the inaccuracy problem notified earlier. The relative error on the statistics is seen to be much lower than the maximum error across realizations of the system. This is to be expected since the first error metric serves as a measure of the maximal error and single realizations of the system will have an error profile either lower or equal to the one of (Fig. 3).

If the desired accuracy of the reduced-order model is not acceptable for certain use cases. The origin for the error between the two models is that the subspace Q is not

of sufficient rank to describe effect of geometric variations with sufficient accuracy, especially in the regions of high error. A higher accuracy could be attained by enriching the projection basis with higher order moments of $\mathbf{u}$ and is the object of the following section.

5. SECOND ORDER PROJECTION SCHEME

To obtain additional accuracy, one may consider adding the second order terms of the perturbation series to the reduced-order basis. The subspace Q then becomes,

$$\mathrm{Q}_2 = orth\left(\left[\mathrm{Q}, \mathbf{u}_2^{(1,1)}, \mathbf{u}_2^{(1,2)}, ..., \mathbf{u}_2^{(N_p,N_p)}\right]\right), \quad (8)$$

where the $\mathbf{u}_2^{(m,n)}$ are defined as

$$\mathbf{u}_2^{(m,n)} = \mathrm{D}^{-1}(0)\left[2\frac{\partial \mathrm{D}}{\partial l_m}\mathbf{u}_1^{(n)} + \frac{\partial^2 \mathrm{D}}{\partial l_m \partial l_n}\mathbf{u}_0\right]_{l_m=0}. \quad (9)$$

The procedure from section 3 is then followed using Q_2 instead of Q. Monte-Carlo simulations are run on this enriched reduced-order model. The maximum error across realizations of the system is computed again and displayed in Fig. 5.

An increase of accuracy of about one to two orders of magnitude is observed compared to Fig. 3 for the whole frequency range. Error peaks are still observed but their magnitude is lower. However, this gain of accuracy comes at the cost of a higher need in computational resources as the size of the reduced-order model might increase significantly from $1 + N_p$ to $1 + N_p + N_p^2$ at most due to the number of correction vectors to be computed increasing.

6. CONCLUSION

In this paper, a parametric model-order reduction scheme was derived to analyze the effect of random geometric variations on the behavior of a phononic crystal beam. A comparison of the reduced-order model with the full-order model response and statistics was performed, verifying the accuracy of the method.

Statistical analysis of the structure was conducted through Monte-Carlo simulation of the reduced-order model. A statistical analysis of the metamaterial structure allowed for quantification of the effect of geometrical variations stopband behavior of the structure. The attenuation performance of the structure was observed to be impacted by the random length changes in some cases,

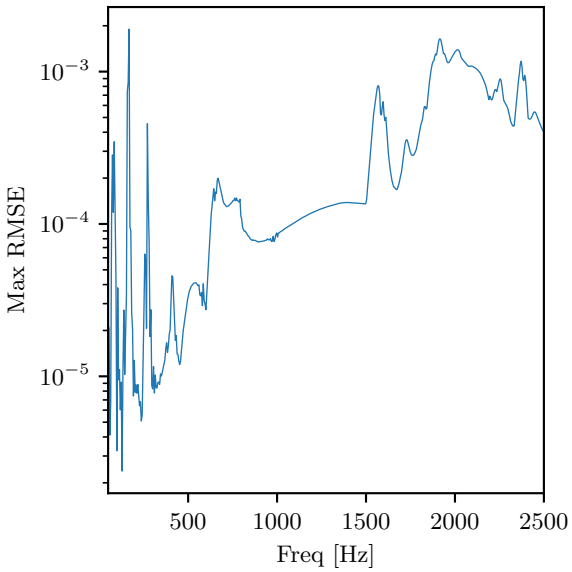

Figure 5. Maximum relative root mean square error between the reduced and second order full-order models observed across realizations of the system.

meaning that some samples of the beam might underperform compared to its target performance, which was observed in the literature for different structures. In this situation, the vibration attenuation region stays relatively close to the nominal case for the considered geometric perturbations.

In the specific case study of this paper, the full and reduced-order models take similar time to run. In the upcoming works, larger structures will to be analyzed as the computational cost reduction is expected and needs to be quantified. The impact of the number basis of correction vectors used in the model needs as well to be assessed in terms of accuracy gain and computational cost increase for a wider range metamaterial structures and problems, as it is important to verify that the accuracy is sufficient for the study under consideration. To do so in a different, specific case study, the analysis from (Fig. 3), using only a few realizations (say 10 to 50) of the system could serve as a benchmark.

ABSTRACT

A well-known solution for suppressing undesired resonances in a vibrating structure is to place a tuned mass damper tuned to the frequency of the targeted mode. When a range of frequencies needs to be attenuated, vibroacoustic metamaterials are known as an effective solution. However, the periodic placement of resonators increases the added mass significantly, limiting its implementation in industrial applications. To address this, recent works have developed a methodology for optimizing the location and modal properties of a small number of resonators to achieve broadband attenuation in a desired frequency range. The aim of this study is to propose a practical implementation of this method for different mountings of a steel rectangular plate. Applying rotational inertia amplification for the local resonators offers a high dynamic to static mass ratio. The modal properties – mass and frequency - of the resonators are achieved by shape optimization to suit the target frequency range of a specific mounting case. This multi-objective optimization uses a practical data-driven generic design tool to avoid computationally heavy finite element models. The attenuation achieved by the rotational inertia amplifiers is then compared to the one achieved by mass-spring systems with equivalent modal properties.

1. INTRODUCTION

Periodic placement of resonators on a host structure to mitigate vibrations, a solution known as locally resonant metamaterials, results in the attenuation of not a single frequency, but a range of frequencies known as a bandgap. This solution poses limitations for industrial applications, as it involves adding a significant amount of mass to the system. For this reason, methods for locally treating the host structure have been investigated [1, 2]. In [3], Dedoncker et al. propose to apply two algorithms, gradient based and simulated annealing, in order to simultaneously optimize the placement and modal properties of a finite number of tuned mass dampers on a plate to achieve broadband attenuation. Based on a defined frequency range to be attenuated, the algorithm converges on a solution that maximizes the vibration attenuation of the host plate and returns the position and mass, frequency and damping of the desired number of tuned mass dampers (TMDs). However, this method is based on the strong assumption that TMDs are ideal mass-spring-damper systems and can exhibit any combination of modal properties. The design of realistic resonators, on the other hand, limits the practical application of the method. Machine learning approaches have been investigated to relate design parameters to physical parameters [4–6]. In [7], the modal properties of a spiral-shaped resonator are tuned by optimizing the spiral's design parameters. This approach provides a rapid way of designing resonators according to required modal properties, both frequency and mass, using a conditional variational auto-encoder (cVAE). In this

work, we propose a practical implementation of these two methods to present an optimization routine for plate vibration treatment under different mounting scenarios. A gradient-based optimization routine calculates the optimal positions and modal properties of the resonators to be placed. These modal properties will be used by the cVAE-optimizer to design a series of complex-shaped mechanical resonators, a specific design which includes rotational inertia amplification. The vibration attenuation obtained by the set of rotational amplifier resonators, optimally placed on the plate, will be compared with the attenuation predicted by the gradient-based method using the set of ideal TMDs.

2. GRADIENT BASED METHOD FOR RESONATOR PLACEMENT AND MODAL PROPERTIES OPTIMIZATION

The following study considers a steel plate with a thickness of 3 mm and dimensions of 1,6 m (x-direction) by 1,2 m (y-direction). Two mounting conditions, shown in Figure 1, are investigated. In the first mounting scenario the plate is clamped on its left and right edges and excited by a force of 1 N (z-direction) at the center of the top edge. The second mounting scenario supposes that the plate is clamped on its bottom edge and excited by a force of 1 N (z-direction) on the top-right corner. The gradient based algorithm is used to optimize the placement and modal properties of 3 TMDs to maximize plate attenuation over the frequency range 150 Hz-200 Hz for these two mounting scenarios. The modal properties of the optimized TMDs are bounded by the distribution of the modal properties of the resonator dataset used to train the cVAE. Here, TMDs can take any frequency between 10 and 300 Hz, although their effective mass is constrained between 148 and 152 g. This high constraint on the effective mass is due to a narrow distribution of the modal properties of the resonator dataset considered. The modal properties of the 6 TMDs proposed by the algorithm are presented in Table 1. Figure 2 shows the average plate deformation with (blue) and without (black) TMDs. In both scenarios, we observe that 3 resonators are sufficient to achieve broadband attenuation over the frequency range specified: all resonance peaks are suppressed within this range.

3. SHAPE OPTIMIZATION OF ROTATIONAL AMPLIFIERS USING CONDITIONAL VARIATIONAL AUTOENCODERS

The geometry of the resonator is chosen as follows: an hourglass shaped soft core is connected to two identical heavy disks at the bottom and top. The disks are connected by tilted struts with spherical joints as in [8]. The tilted struts allow the translation of the disks to be coupled to their rotation thereby inducing inertia amplification to the system as described in [9, 10]. As a consequence, the rotational amplifier achieves a high static-to-dynamic mass ratio, further minimizing the mass added to the host structure. The torsional and axial stiffnesses connecting the disks together are defined by the design of the hourglass-shaped core, which therefore influences the amplifier's modal properties. Realistic resonators are designed using the cVAE developed in [7] to achieve the modal properties given in Table 1. The geometry of the ro-

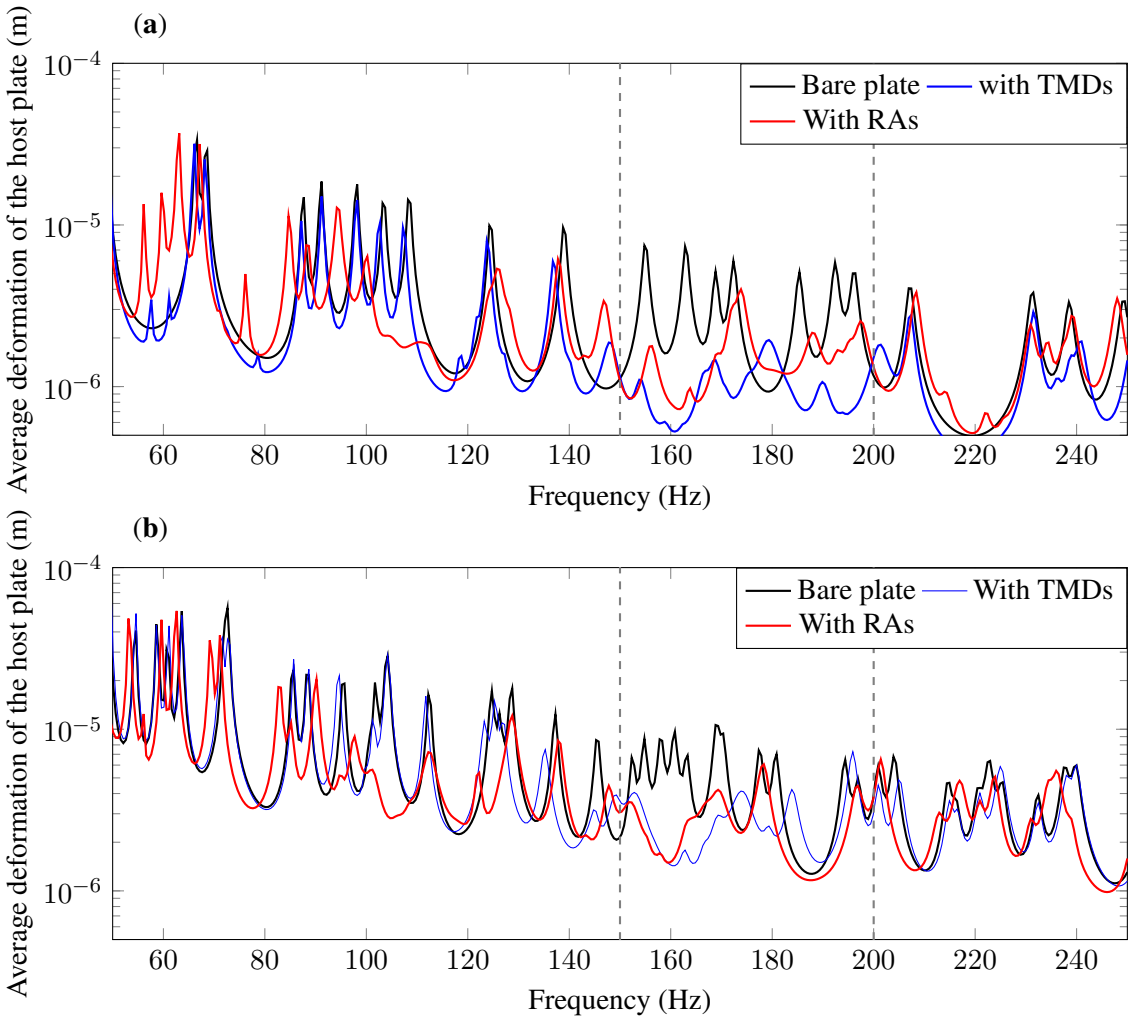

Figure 2. Average deformation of the mounted plate under mounting scenarios 1 (a) and 2 (b): bare plate in black, with ideal TMDs in blue and with RAs in red.

tational amplifier (RA) is parameterized according to the dimensions d1, d2, d3, d4 and angles a1 and a2 shown in Figure 3(a). 1100 designs are generated by Latin Hypercube sampling (LHS) of the resonator's geometrical parameters. The frequency and effective mass of the predominant axial vibration mode of each design, shown in Figure 3(b), are calculated performing a modal analysis in AnsysR2024V2. The conditional variational auto-encoder is then trained on the dataset created and finds the best designs to reach desired modal properties. The modal properties predicted for the best design given by the cVAE are compared with those required by the gradient-based algorithm. These latter modal properties are then compared to those observed on a FEM model of the suggested design. The geometric parameters of the 6 RAs best fitting the modal properties of the 6 TMDs required by the gradient based optimization are shown in Table 2. For the 6 ideal TMDs, Table 3 shows an error of less than 5% for all frequencies and effective masses.

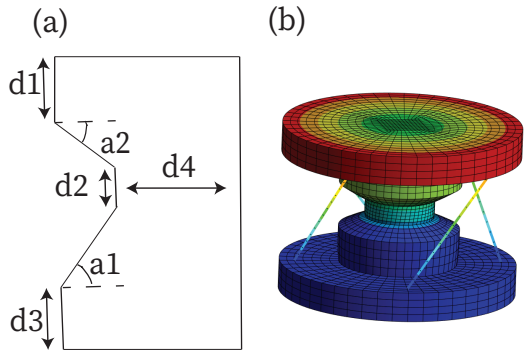

Figure 3. (a) Parametrized shape of the soft core. (b) First torsional mode of the rotational amplifier.

4. PRACTICAL IMPLEMENTATION OF THE DESIGNED ROTATIONAL AMPLIFIERS

An explicit FEM model created in ANSYS2024R2 couples the resonators designed with the cVAE to a plate with dimensions defined above at their optimized position as shown in Figure 4. The rotational amplifiers for the two considered mounting scenarios attenuate the targeted resonance peaks between 150 and 200 Hz. As an interesting side effect, the chosen resonators also attenuate the plate over unforeseen frequency ranges. A clear vibration reduction is noticeable near 100 Hz for both configurations: the resonators undergo a bending mode in this frequency range, and attenuate the motion of the plate. The approach presented in [3] allows the accurate placement of realistic resonators. However, the attenuation level achieved by the realistic resonators is lower than that achieved by ideally tuned mass dampers, as observed at 170 Hz for both mounting scenarios. This difference can be explained by two assumptions made by the gradient based optimization method. The optimized TMDs feature a single vibration mode, allowing only the predominant axial mode of the resonator to be modeled, and thus ignoring the more complex resonator dynamics. Moreover, this method assumes a point-wise contact between the resonator and the host plate, thus neglecting the local stiffening that can be observed at attachment points.

5. CONCLUSION

In this study, two optimization methods are combined to enable a fast routine for positioning and designing a small number of resonators to attenuate a mounted plate. This method allows the resonator design to be adapted to the different mountings and excitation points of the plate. Coupling the two methods results in a clear attenuation over the desired frequency range containing multiple resonance peaks. However, the fast optimization methods use simplifying assumptions, such as ideal, point-like mass-spring systems and the omission of multiple resonances of the resonators. The more complex dynamics of realistic resonators should be considered explicitly, by full harmonic simulations of the final setup.

ABSTRACT

Resonant metamaterials are a promising approach to achieve vibroacoustic attenuation in partition panels. By adding subwavelength resonators to a host plate, free-travelling elastic waves in specific frequency bands, called bandgaps, are prohibited. While conventional resonant metamaterials typically exploit single-mode translational resonators resulting in narrowband attenuation, recent advancements have theoretically indicated that broader attenuation bands can be achieved by resonators with multiple translational and rotational modes. However, the effectiveness of this concept has not yet been experimentally demonstrated. In this study, we address this gap by designing, manufacturing and experimentally validating a multi-modal metamaterial panel aimed at mitigating broadband coincidence effects in orthotropic host plates. The proposed metamaterial panel integrates medium-density fiberboard resonators attached to an orthotropic cross-laminated timber plate. The resonator geometry is optimized to maximize the effect of two distinct directional bandgaps induced by two rotational resonator modes. Extensive vibroacoustic testing is performed to characterize the metamaterial performance. Laser vibrometry measurements under shaker-based excitation confirm the presence of these two resonance-based bandgaps. Sound transmission and radiation tests demonstrate significant attenuation within the bandgaps (by around 8-10 dB) compared to the host plate, as well as the suppression of the broad sound transmission loss dip due to coincidence effects.

Keywords: *locally resonant metamaterial panels, multi-modal resonators, sound transmission loss, sound radiation, experimental characterization*

1. INTRODUCTION

In the search for compact and lightweight solutions for vibroacoustic attenuation, locally resonant metamaterials have been introduced to achieve exceptional properties beyond those of conventional materials [1]. These metamaterials achieve enhanced wave control by small, local resonators added to a host structure on a subwavelength scale. As a result, an effective mass that varies with frequency is achieved, which shows a peak around the local resonance [2]. Around this frequency, the effective mass of the metamaterial structure surpasses its static mass, significantly improving sound insulation [3, 4]. Additionally, in the frequency range immediately above the peak, the effective mass becomes negative and a wave propagation bandgap emerges, which inhibits free-traveling mechanical waves [5].

Metamaterials have been successfully employed to enhance vibration attenuation and sound insulation in partition panels [6]. Conventional designs only utilize a single mode of the local resonators, typically associ-

ated with a transversal vibration to the host plate, therefore limiting the attenuation bandwidth. To achieve attenuation in a broader band, multiple mechanical resonators can be attached in series [7, 8] or in parallel [9, 10] to the host plate. More recently, theoretical studies have indicated that multi-modal metamaterial panels—featuring multiple local resonances within each resonating unit, and including both transversal and rotational modes—can generate a sequence of adjacent attenuation bands, which collectively span a broader frequency range [11, 12]. However, despite their potential, the experimental validation of metamaterial panels incorporating multi-modal and particularly rotational resonators remains an open challenge.

This study addresses this gap by designing, manufacturing and experimentally validating a metamaterial panel with multi-modal rotational resonators. The proposed metamaterial panel is specifically tailored to mitigate broadband coincidence effects in orthotropic host plates. It consists of a host orthotropic plate made of cross-laminated timber (CLT) to which local resonators made of medium-density fiberboard (MDF) are attached. The resonator geometry is optimized to suppress the broad sound transmission loss (STL) dip due to coincidence effects in the host panel, by leveraging two distinct directional bandgaps induced by two rotational resonator modes. Extensive vibroacoustic testing is conducted to assess the performance of the metamaterial panel, in terms of sound transmission loss, structural wave propagation, and sound radiation.

The paper is structured as follows. Section 2 describes the design of the proposed multi-modal metamaterial CLT panel. The experimental validation is presented in the following Sections, in terms of sound transmission loss (Section 3), flexural wave propagation (Section 4), and sound radiation (Section 5). Finally, Section 6 concludes the paper.

2. DESIGN OF THE MULTI-MODAL METAMATERIAL CLT PANEL

The proposed metamaterial panel, shown in Fig. 1, consists of an orthotropic CLT host plate with periodically attached multi-modal rotational resonators made of MDF. The orthotropic host CLT panel is composed of 3 spruce wood layers, crosswise glued together with alternating fiber directions [13], following a 0°/90°/0° stacking sequence relative to the global x-axis. The host CLT panel has an overall thickness of $t_{\mathrm{CLT}} = 0.027$ m

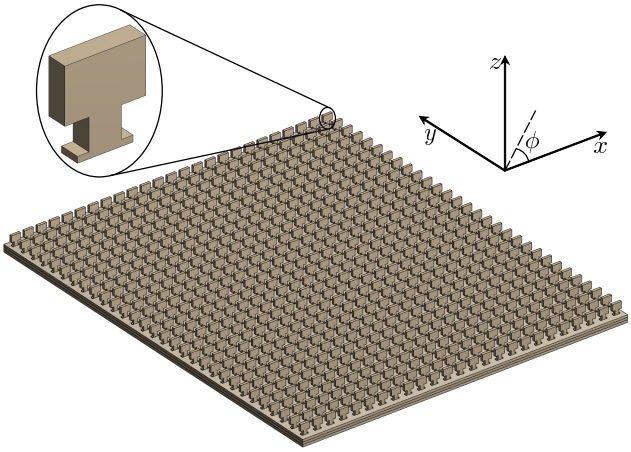

Figure 1: Designed metamaterial CLT panel with MDF multi-modal rotational resonators.

(each layer being 0.009 m thick), and has in-plane dimensions 1.235×1.485 m^2.

Due to its high degree of orthotropy, the host CLT panel exhibits broadband coincidence effects, leading to a broad dip in its diffuse STL curve. In orthotropic panels, the critical frequency f_{cr}, at which the flexural wave speed matches the speed of sound waves in the surrounding fluid, varies with the in-plane propagation direction defined by the azimuthal angle ϕ (see Fig. 1). Under diffuse sound incidence, this results in a broad coincidence STL dip spanning the range $\left[\min\left(f_{\mathrm{cr}}(\phi)\right), \max\left(f_{\mathrm{cr}}(\phi)\right)\right]$. To mitigate broadband coincidence effects, the metamaterial panel integrates multi-modal local resonators made of MDF. The resonators are laser-cut and periodically attached to the host panel using adhesive, with subwavelength unit cell dimensions 0.05×0.05 m^2. Each resonator includes a vertical cantilever beam, a mass at the top of the beam, and a broadened base for attachment to the host panel.

The material properties of the CLT layers and the MDF resonators are experimentally identified through dynamic testing [14] and summarized in Tab. 1. Both materials are modelled as orthotropic and characterized by the Young's moduli E_{x}, E_{y}, E_{z}, the shear moduli G_{xy}, G_{yz}, G_{xz}, the Poisson's ratios ν_{yx}, ν_{zy}, ν_{zx}, the mass density ρ, and the damping loss factor η.

The multi-modal local resonators are designed to suppress the broad STL dip of the host structure. This is performed by leveraging the first two bending modes of the vertical cantilever beam-mass structure (Fig. 2),

Table 1: Estimated material properties for CLT layers and MDF. CLT properties refer to the local reference system, with x-axis along the wood fibers, oriented at 0°/90°/0° to the global x-axis. MDF properties refer to the global reference system.

in which the end mass rotates around the x and the y axis respectively. These rotational modes generate two directional bandgaps that inhibit flexural wave propagation in the directions perpendicular to the rotation axes, and are exploited to suppress coincidence effects along the two principal axes of the orthotropic host plate.

The resonator layout is numerically optimized by using the dimensions of its geometrical features as design variables. A genetic algorithm is employed to maximize the broadband diffuse STL in the frequency range 100-3150 Hz, while ensuring that the resonator mass does not exceed 20% of the host panel's mass [11]. The final optimized configuration exhibits local resonance frequencies at 1085 Hz and 1640 Hz (Fig. 2), strategically positioned to suppress the broad STL dip, and maximized participating mass in the modes of interest.

Figure 3: Fabricated multi-modal metamaterial panel, mounted in the transmission opening of the Laboratory of Acoustics of KU Leuven.

3. EXPERIMENTAL EVALUATION OF THE SOUND TRANSMISSION LOSS

The STL of both the bare CLT host panel and the metamaterial panel is experimentally measured in the transmission suite of the Laboratory of Acoustics of KU Leuven. The facility consists of two reverberation chambers, each with a volume of 87 m^3, and a transmission opening with dimensions 1.25 × 1.5 m^2, inside which the tested panel is installed (Fig. 3). The sound transmission loss R is measured according to the ISO 10140-2 standard [15].

The STL curves of the bare CLT panel (without resonators) and the metamaterial CLT panel are displayed in 1/48-octave bands in Fig. 4, along with numerical predictions obtained through an infinitely periodic finite element model [16, 17]. In this model, one single unit cell is discretized by solid finite elements, including a segment of the laminated CLT panel and one attached resonator. The STL is computed by analyzing the interaction between the panel and the surrounding diffuse acoustic fields, under appropriate periodicity boundary conditions. The numerical predictions are reported for the bare panel, for a bare panel with an equivalent

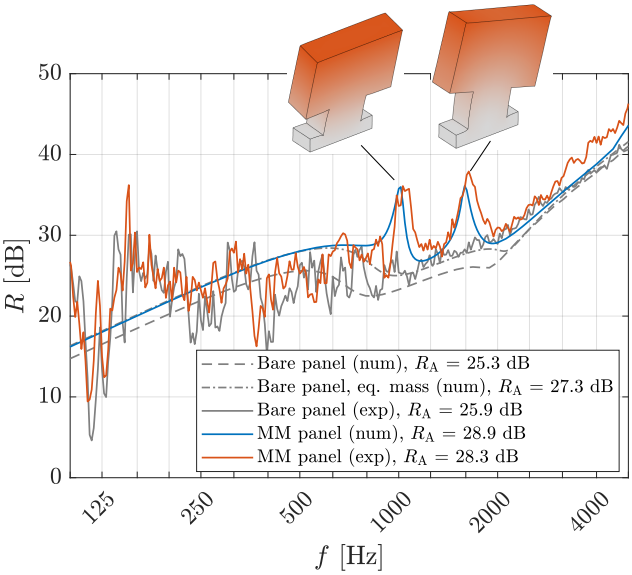

Figure 4: Comparison between the experimentally measured and numerically predicted diffuse STL of the bare and the metamaterial panel.

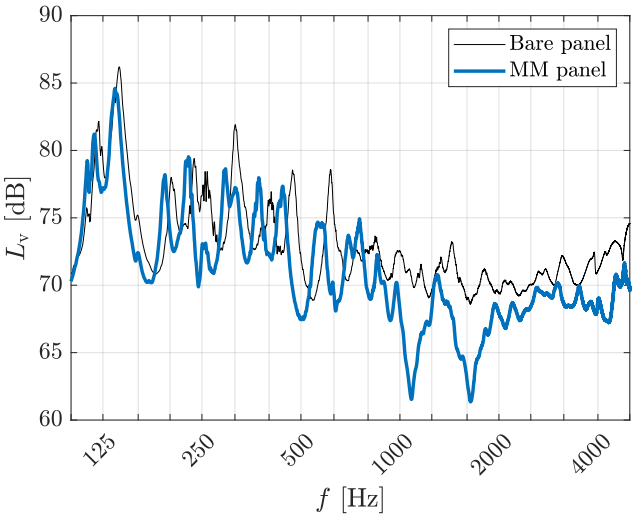

Figure 5: Comparison between the experimentally measured surface-averaged vibration velocity levels of the bare and the metamaterial panel under shaker-based excitation.

mass to the metamaterial panel, and for the metamaterial panel.

At low frequencies, the 20% added mass of the resonators shifts the numerical STL curve upwards by around 1.6 dB. In this range, besides mass effects, the measured STL is mainly dominated by the global modal behaviour of the panel, which is particularly prominent given its relatively compact dimensions. Since the periodic finite element model does not account for boundary effects and global panel resonances, some deviations between numerical and experimental results are observed.

Above 250 Hz, the influence of the individual panel modes becomes less significant, progressively leading to a good alignment between numerical predictions and experimental results. Within the broad coincidence range (760-1950 Hz), the STL dip observed in the bare panel is effectively suppressed by two distinct STL peaks, achieving STL improvements of about 8-10 dB around the local resonance frequencies. Interestingly, no STL dip is observed in the frequency ranges immediately above the resonance peaks, which constrasts with the usual behaviour seen when the local resonances are tuned below coincidence. By tuning the local resonances within the coincidence range, here no additional range of increased radiation efficiency is introduced, and the overall zone of efficient acoustic radiation is reduced [18].

To provide a standardized evaluation of the sound insulation performance, the single number rating R_A from ISO 717 [19] is also computed. This metric represents the A-weighted broadband diffuse sound insulation for pink noise excitation over the frequency range 100-3150 Hz, and is found as $R_A = R_w + C$, where R_w and C are defined by the ISO standard. Both numerical predictions and experimental results indicate that the metamaterial panel achieves an increase of R_A by around 3 dB compared to the bare CLT panel, while the R_A improvement with respect to the bare panel with equivalent mass is 1.6 dB. This confirms the effectiveness of the proposed multi-modal rotational resonator design in enhancing broadband sound insulation.

4. EXPERIMENTAL EVALUATION OF FLEXURAL WAVE PROPAGATION

To evaluate the impact of the metamaterial design on flexural wave dispersion, the vibration fields in both the bare CLT panel and the metamaterial panel are measured under shaker excitation. The shaker is attached to the panel (mounted in the transmission opening) via

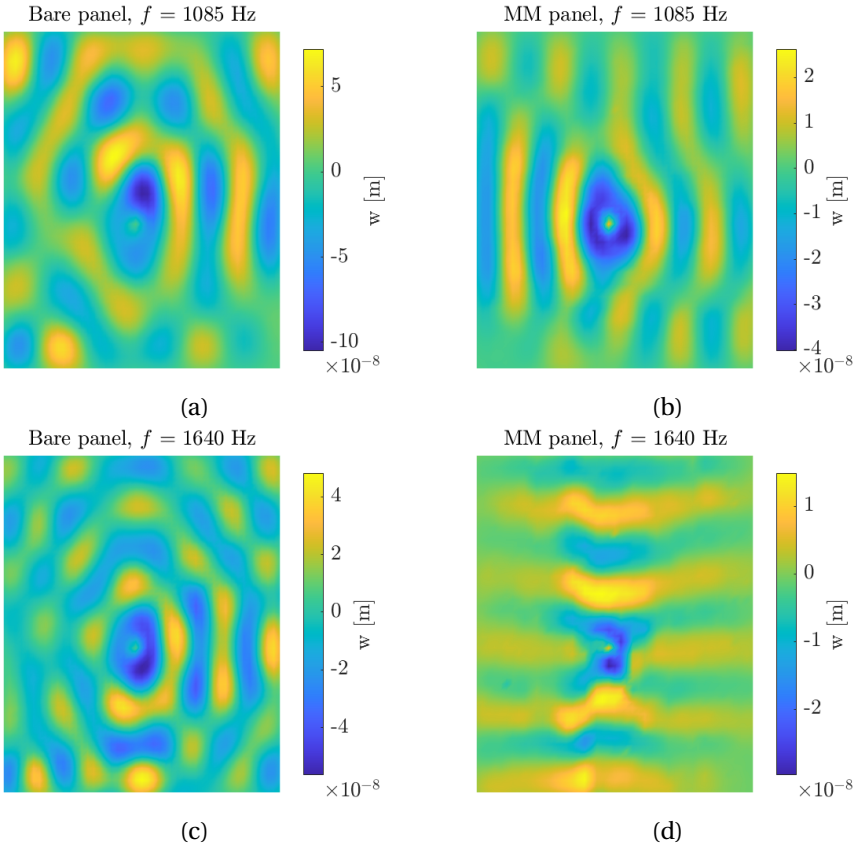

Figure 6: Measured vibration fields for (a, c) the bare and (b,d) the metamaterial panel at (a,b) 1085 Hz and (c,d) 1640 Hz, in terms of the out-of-plane displacement w.

an impedance head, which measures the input force. The shaker is positioned slightly off-centered with respect to the panel, and a white noise excitation signal is applied as input. The resulting out-of-plane vibration field is measured by a scanning laser Doppler vibrometer (SLDV), by evaluating the frequency response function (FRF) between the input force and the displacement responses. A Polytec PSV-Qtec Scanning Vibrometer is used to capture the vibration field at 2769 points on a rectangular grid, with a spatial resolution of 2.5 cm. Measurements are taken across the frequency range 0-6400 Hz with a frequency resolution of 0.5 Hz.

The measured vibration data are used to compute the surface-averaged velocity level L_v at each frequency, considering a reference velocity value of $5 \cdot 10^{-8}$ m/s. Fig. 5 compares the L_v curves for the bare panel and the metamaterial panel, in 1/48-octave bands. Across the entire frequency range, the added mass of the resonators causes a slight shift downwards in the L_v curve of the metamaterial panel compared to the bare CLT panel, along with a slight reduction of the resonance frequencies associated with the global panel modes. Most notably, two pronounced dips appear at 1085 Hz and 1640 Hz, corresponding to the directional bandgaps introduced by the local resonators. Around these frequencies, the vibration levels are effectively reduced by approximately 8 dB compared to the bare panel.

The impact of the directional bandgaps is further analyzed by comparing the measured vibration fields of the metamaterial panel against those of the bare panel. In the bare panel, flexural waves radiate uniformly in all directions from the excitation point (Figs. 6a and 6c). In the metamaterial panel, wave propagation is inhibited in specific directions due to the introduced directional

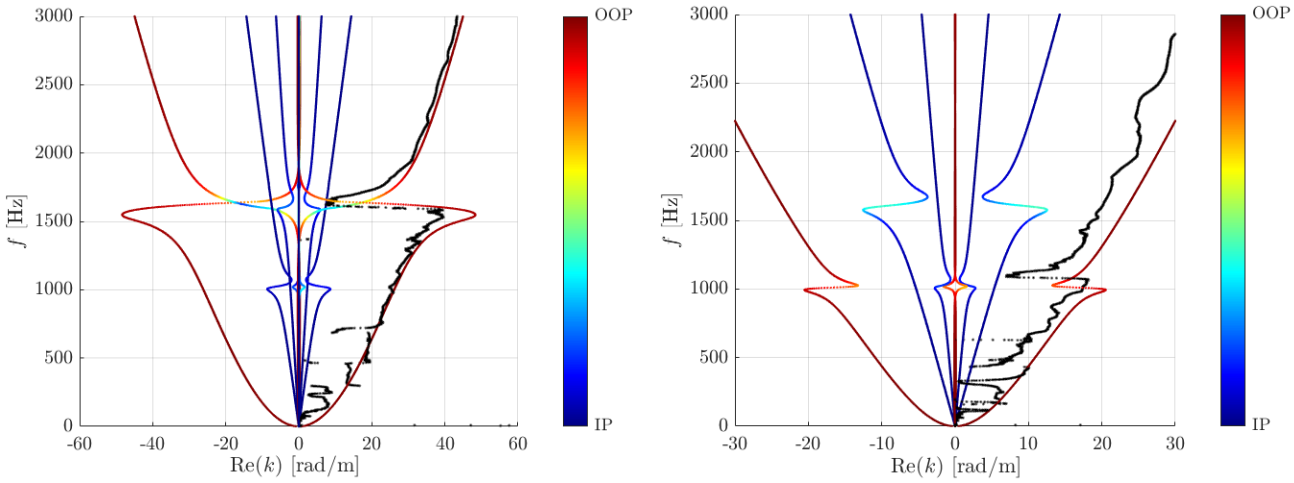

Figure 7: Experimental (black) and numerical (coloured) dispersion curves of the metamaterial panel for propagation along (a) the x axis and (b) the y axis. The numerical dispersion curves are coloured according to the out-of-plane (OOP) vs. in-plane (IP) nature of the wave modes.

bandgaps: at 1085 Hz, flexural wave propagation is suppressed along the vertical direction (Fig. 6b), while at 1640 Hz, flexural wave propagation is suppressed along the horizontal direction (Fig. 6d).

To further characterize the wave behaviour, the experimental dispersion curves are extracted using the Extended Inhomogeneous Wave Correlation approach [5], which correlates the measured vibration fields with analytical functions representing inhomogeneous plane waves. Fig. 7 presents the experimental dispersion curves (for real wavenumbers), along with numerical predictions through periodic finite element modelling. The numerical dispersion curves are coloured according to the out-of-plane nature of the wave modes, which is calculated using the ratio of surface-averaged out-of-plane to in-plane nodal displacements at the mid-plane of the plate: red indicates out-of-plane flexural waves and blue indicates in-plane waves. Both in-plane and out-of-plane (flexural) dispersion branches are numerically predicted, but since only out-of-plane displacement fields are measured, only the flexural wave dispersion is experimentally retrieved.

In the lower frequency range, the experimental estimation of the dispersion curves is strongly influenced by the global modal behaviour of the panel. Above 800 Hz, the modal behaviour of the panel becomes less pronounced, and a good agreement is observed between experimental and numerical results. A minor discrepancy is present in the slope of the dispersion curve for propagation along y, where the experimental panel appears slightly stiffer than predicted.

For both numerical and experimental results, two regions of significant flexural wave dispersion are identified: one around the first directional bandgap for propagation along y and another around the second directional bandgap for propagation along x. The observed bandgap behavior shows strong agreement between experimental measurements and numerical simulations.

Interestingly, the numerical model further predicts that the directional bandgaps also affect in-plane wave propagation, despite this effect not being captured by experiments. This highlights that the designed vertical cantilever beam-mass resonators transfer both bending moments and in-plane forces to the host structure, impacting both flexural and in-plane wave behavior.

5. EXPERIMENTAL ASSESSMENT OF SOUND RADIATION

To experimentally assess the reduction of acoustic radiation in the bandgap regions, the spatially averaged sound pressure in the receiver room of the transmission

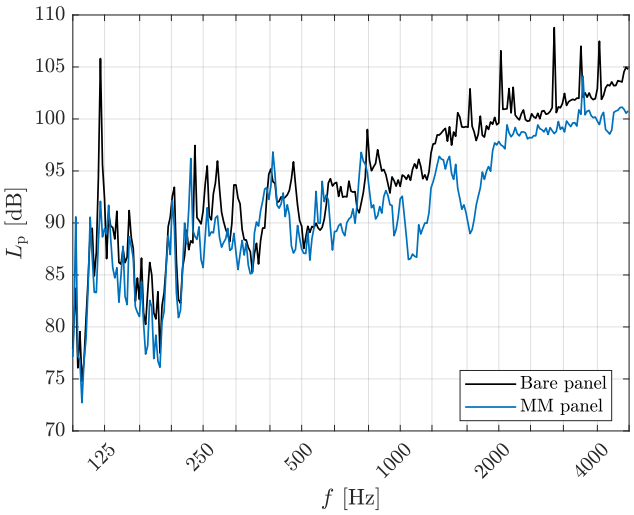

Figure 8: Comparison between the experimentally measured sound pressure levels in the receiver room when the bare and the metamaterial panel are subjected to structure-borne (point) excitation.

suite is measured, when the panel is mounted in the transmission opening and subjected to structure-borne (point) shaker excitation. The FRF between the input shaker force and the harmonic sound pressure in the receiver room is measured for 4 different excitation locations and 8 microphone locations. The sound pressure level L_p per unit of excitation force is then computed by energetically averaging the FRFs obtained for all excitation and measurement positions.

Fig. 8 compares the resulting sound pressure levels for the bare panel and the metamaterial panel, in 1/48-octave bands. In general, the metamaterial panel exhibits a slight reduction in overall sound radiation due to the additional mass of the resonators. More significantly, two distinct dips are observed around the local resonance frequencies (1085 Hz and 1640 Hz), where the metamaterial treatment achieves an 8–10 dB reduction in radiated sound pressure compared to the bare CLT panel.

6. CONCLUSIONS

In this work, we have experimentally demonstrated the effectiveness of multi-modal metamaterial panels in achieving broad attenuation bands. Specifically, a multi-modal metamaterial panel has been designed, manufactured and experimentally validated to mitigate broadband coincidence effects in orthotropic host plates. The proposed metamaterial panel integrates medium-density fiberboard resonators attached to an orthotropic cross-laminated timber plate. The resonators consist of a vertical cantilever beam-mass structure and their layout has been geometrically optimized to maximize the effect of two distinct directional bandgaps induced by two rotational modes.

The performance of the metamaterial panel has been characterized by extensive vibroacoustic testing. Laser vibrometry measurements under shaker-based excitation have confirmed the presence of two resonance-based bandgaps. Diffuse sound transmission and radiation tests have demonstrated significant attenuation within the bandgaps (by around 8-10 dB) compared to the host plate, as well as the suppression of the broad sound transmission loss dip caused by coincidence effects.

The results of the work represent a significant advancement towards lightweight insulating partitions with broadband enhanced vibroacoustic performance through metamaterials.

ABSTRACT

While acoustic metamaterials have shown promising noise reduction capabilities, their design optimization has traditionally focused on physical acoustic properties rather than perceived sound quality. This research introduces a design methodology that integrates psychoacoustic metrics into the optimization of metamaterial architectures. The methodology uses a previously developed Global Sensitivity Analysis scheme as a basis for an optimization framework that specifically targets desired psychoacoustic outcomes while maintaining practical design constraints. Micro-perforated panels are used as a preliminary case study. The design optimization is validated with multiple prototypes and measured in an impedance tube, with results analyzed for both traditional acoustic measurements and psychoacoustic metrics including loudness and sharpness. The experimental validation demonstrates how optimized designs can achieve specific sound quality targets while remaining practically manufacturable.

Keywords: *sound quality, acoustic metamaterial, sensitivity analysis, micro perforated panel*

1. INTRODUCTION

Acoustic metamaterials have revolutionized the field of noise control with their ability to manipulate sound waves beyond conventional materials. Their unique structures enable exceptional sound absorption, transmission loss, and wavefront manipulation capabilities [1]. Traditionally, metamaterial design has been guided by physical acoustic properties such as absorption coefficients and transmission loss. However, these objective parameters do not fully correlate with human perception of sound quality. Previous research revealed that acoustic metamaterials can significantly alter psychoacoustic metrics, sometimes in directions contrary to what traditional acoustic measurements might suggest [2]. This potential disconnect between objective measurements and subjective perception creates a design challenge when optimizing metamaterials for human-centered acoustic environments.

This paper builds upon a recently developed sensitivity analysis approach for micro-perforated panels (MPPs) [3], extending the methodology into a full optimization workflow, and including an experimental validation of the psychoacoustic metrics. The research objective is to develop a framework for designing acoustic metamaterials with desired psychoacoustic features as targets, while maintaining practical design constraints. The focus is specifically on a simplified single-panel MPP configuration to establish the foundation for more complex systems.

The rest of the paper is structured as follows: Section 2 described the MPP model, design optimization and validation methodologies. In Section 3 the results are shown. Discussion of the results and a summary can be found in Section 4.

2. METHODS

2.1 Micro-Perforated Panel Modeling

The analysis is simplified to focus on a single MPP, 1-D transmission configuration, as shown in Figure 1, to establish a clear relationship between design parameters and sound quality metrics. For the MPP analysis, 3 key parameters are determined, with parameter bounds carefully defined by balancing theoretical acoustic principles, manufacturing feasibility constraints, and the desired transmission loss (TL) performance targets [4]:

- Perforation diameter (d): 0.03 to 3 mm,
- Porosity (ϕ): 0.2% to 3.14%,
- Panel thickness (t): 1.5 to 2.0 mm.

The acoustic behavior of the MPP was modeled using Atalla and Sgard's approach [5], where the surface impedance for transmission is calculated as:

$$Z_t = \left(\frac{4t}{d} + 4\right)\frac{R_s}{\phi} + \frac{1}{\phi}(2\epsilon + t)j\omega\rho_0 + \rho_0 c, \qquad (1)$$

where ω is the angular frequency, $\epsilon = 0.24\sqrt{\pi d^2}(1 - 1.14\sqrt{\phi})$ represents the end correction factor, R_s is the surface resistivity, ρ_0 is the air density, and c is the speed of sound. Then, with the characteristic acoustic impedance $Z_0 = \rho_0 c$, the transmission coefficient can be derived as:

$$\tau = \frac{1 + R_s}{Z_t/Z_0} = \frac{2\rho_0 c}{Z_t + \rho_0 c}. \qquad (2)$$

TL values in decibels (dB) can then be calculated as $\mathrm{TL} = 10\log(1/\tau)$.

2.2 Global Sensitivity Analysis Framework

The global sensitivity analysis (GSA) approach used in this study follows the Sobol method [6], which quantifies the contributions of individual parameters and their interactions to the variance in model outputs. This approach is particularly valuable for complex systems like metamaterials where multiple parameters may exhibit nonlinear and interdependent effects on acoustic performance. The GSA process preserves the quasi-random properties of Sobol sequences while ensuring that each parameter's individual and interactive effects can be isolated through variance decomposition.

In order to sufficiently explore the design space, a sampling method is needed. A sampling procedure was implemented through the SALib library's `saltelli.sample` function [7–10], resulting in 4096 distinct parameter combinations for the 3-parameter MPP system. With each parameter combination, a unique acoustic transmission coefficient is computed and documented, preparing for the sound quality metrics prediction.

2.3 Sound Quality Prediction and Design Optimization

For the design optimization phase, conventionally, MPP parameters are directly calculated from objective acoustic (sound absorption or transmission loss) behaviors. However, in this research, the general goal is to predict MPP parameters using psychoacoustic metrics (loudness and sharpness) as targets. The motivation for using these psychoacoustic metrics comes from their direct relation with human perception, offering an intuitive approach to acoustic design than traditional physical metrics alone. Loudness quantifies the subjective intensity of sound perceived by listeners, while sharpness characterizes the high-frequency content often contributing to annoyance. Hence, the sound quality prediction process follows this systematic workflow:

1. Generation of acoustic filters (impulse responses) based on transmission coefficients from MPP parameters;
2. Convolution with pre-recorded noise stimuli;
3. Calculation of psychoacoustic metrics: loudness from ISO 532-1:2017 C code [11] and sharpness using Python library MosQiTo [12].

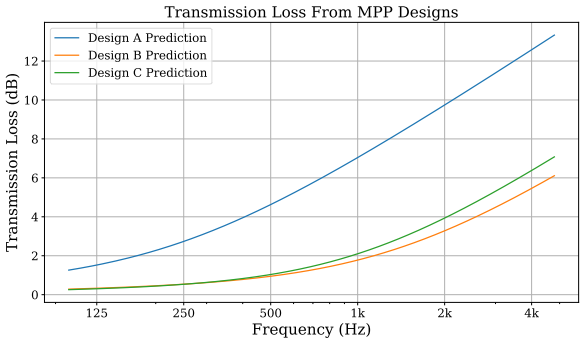

Figure 2. Predicted transmission loss curves for the MPP design A, B, and C.

Key parameters were predicted based on earlier GSA results and targeted toward specific sound quality goals:

- Design 1: Minimize loudness and sharpness.
- Design 2: Maximize loudness and sharpness.

2.4 Prototype Designs and Acoustic Performance

Based on the 4096 Satelli samples from GSA, three distinct MPP designs: Panel labels A, B, and C were manufactured with parameters shown in Table 1, and Figure 2 shows their predicted transmission loss performances. Panel A is designed to have in overall lowest loudness and sharpness metrics, panel B and C are designed to have high loudess and sharpness, but having parameters that differ enough. Hereby, panel samples are manufactured using a photomask laser cutter with a precision of 5 µm. With this tolarance, the TL deviation is maximally 0.04%, ensuring minimal impact from engineering errors.

Table 1. MPP design parameters for the three prototype configurations.

Design	Diameter (mm)	Porosity (%)	Thickness (mm)
A	0.94	0.594	2
B	0.47	2.99	2
C	0.73	1.94	1.5

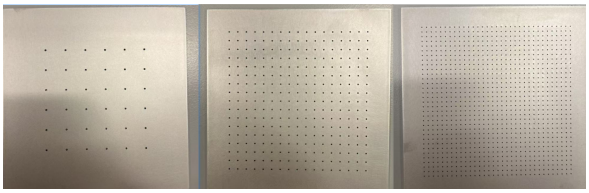

Figure 3. Stainless steel panels A, B, and C, laser cut with 0.005 mm precision.

2.5 Experimental Setup for Micro-Perforated Panel Measurements

The acoustic transmission characteristics of micro-perforated panels (MPPs) were experimentally investigated using an impedance tube configuration corresponding to the modeled 1-D setting described in Figure 1. The experimental apparatus consists of a Mecanum impedance tube, Siemens SCADAS Mobile data acquisition frontend with Simcenter Testlab 2406.0002 "Sound transmission loss using impedance tube," six G.R.A.S. 46BD quarter inch microphones, following the procedure in ASTM standard [13]. The manufactured panels are shown in Figure 3. The frequency range of this measurement is between 100 Hz and 5000Hz, with a resolusion of 5 Hz. Considering that the sharpness metric is greatly impacted by the contrast between high and low frequency content, sound stimuli in this research is designed not to contain much frequency information above 5000 Hz, minimizing potential impact when validating in the impedance tube.

3. RESULTS

Figure 4 shows the measured transmission loss (TL) curves for each design: Design A, B, and C from Table 1. Design A demonstrates higher TL values across all frequencies, especially in the mid to high-frequency range, while Design B and Design C offer moderate TL performance. The impulse responses corresponding to the simulation are then calculated from the transmission coefficients, shown in Figure 5.

The simulated and measured impulse responses are compared with normalized mean square error (NMSE) and normalized rood mean square error (NRMSE) over dynamic range. Panel B has the best overall match, with an NMSE of 0.176 and an NRMSE over the dynamic range of 0.016. Panel A has an NMSE of 0.457 and an NRMSE of 0.025, while Panel C has an NMSE of 0.425 and an NRMSE of 0.0212. These higher NMSE

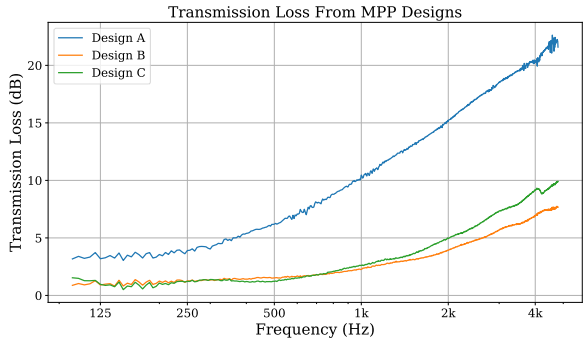

Figure 4. Measured transmission loss curves for the MPP design A, B, and C.

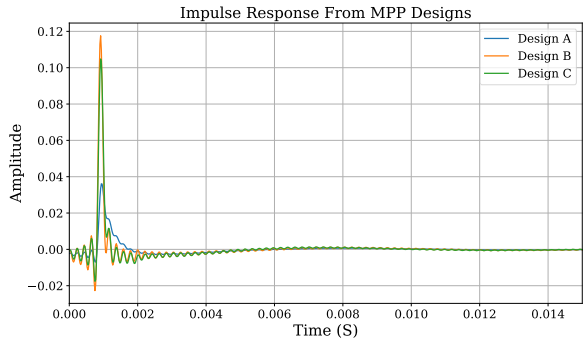

Figure 5. Impulse responses derived from the MPP design A, B, and C.

and NRMSE values for panel A and C indicate a moderate match between the simulated and measured impulse responses for these MPPs.

3.1 Psychoacoustic Performance

The predicted and measured psychoacoustic metrics for the three designs are presented in Table 2.

The results show agreement between predicted and measured psychoacoustic metrics, with deviations less than 6% for loudness and sharpness. Design A, with its smaller perforation rate and larger diameter, achieved the lowest loudness (22.2 sone) and sharpness (0.82 acum), aligning with our optimization target. Design B, featuring the average perforation diameter and perforation rate, resulted in the highest loudness (26.4 sone) and sharpness (0.97 acum), as expected from GSA predictions.

Table 2. Predicted vs. measured psychoacoustic metrics for the three designs.

Design	Loudness (sone)		Sharpness (acum)	
	Predicted	Measured	Predicted	Measured
A	23.5	22.2 (-5.5%)	0.87	0.82 (-2.0%)
B	27.0	26.4 (-5.7%)	0.99	0.97 (-4.5%)
C	26.8	25.6 (-2.2%)	0.99	0.94 (-5.1%)

4. DISCUSSION AND CONCLUSION

This study demonstrates the effectiveness of using global sensitivity analysis (GSA) as a framework for optimizing acoustic metamaterials based on psychoacoustic metrics. The findings confirm that this computational model can accurately predict complex relationships between psychoacoustic metrics such as loudness and sharpness, and the design parameters of the micro-perforated panels (MPP) such as thickness, hole diameter, and perforation rate.

The experimental validation of the theoretical predictions has yielded several important insights:

First, the disagreements between predicted and measured values are within 6% for both loudness and sharpness metrics. Considering the loudness parameter sone is on a relative scale, this deviation on loudness can be considered negligible. For instance, Design A has a loudness deviation from 23.5 sones predicted to 22.2 sones measured, which are correspondingly converted to 73.5 dB and 72.7 dB. This difference (0.8 dB) is within the just-noticeable difference (1 dB) of human hearing. This finding suggests the reliability of the prediction.

Second, this research provided a basis for design optimization. By establishing quantitative relationships between design parameters of MPP and sound quality metrics, it becomes possible to navigate the design space to achieve specific sound quality targets. Design B and C have distinct design parameters but share the same sharpness (0.99 acum predicted). This confirms that GSA-based design optimizations can be trusted for practical design applications.

Third, the workflow presented bridges the gap between objective acoustic properties to subjective auditory perception. It allows acousticians directly compare the

sound quality metrics derived from material parameters. These metrics represent perceptually relevant features that correlate with subjective impressions, providing a more intuitively valid assessment of acoustic performance compared to abstract measurements of TL numbers and IR curves across the spectral and temporal domains. This approach extends the material design range by incorporating human perception into the design process, which is valuable for applications where sound quality, rather than mere noise reduction, is the primary design goal.

While this study focused on a simplified MPP configuration to establish methodologies, the workflow can be extended to more complex setups. Future work may explore periodic media exhibiting metamaterial behavior, starting with periodic arrangements of MPPs.

In conclusion, this study validates the use of GSA as an effective tool for sound quality driven metamaterial design. The agreement between predicted and measured psychoacoustic metrics suggests that this approach can guide the design optimization using sound quality as targets. By integrating acoustic modeling with sound quality metrics, this methodology provides a framework for designing materials that address not only physical performance requirements but also human perceptual preferences.

ABSTRACT

Phononic crystal-based noise barriers offer promising solutions for urban noise mitigation, particularly concerning traffic and highway noise, due to their capacity to efficiently attenuate sound while maintaining ventilation. This study advances the state of the art through two key contributions: first, by developing an experimental setup to analyze stopband frequencies and, second, by creating a numerical model that replicates real-world conditions for further validation. Unlike previous studies, which primarily assessed phononic crystal barriers in semi-anechoic chambers with single noise sources, this work introduces a more realistic experimental approach. The setup utilizes an Alpha cabin with a diffuse sound field, where a 4×6 array of cylindrical scatterers is mounted on the cabin door. Insertion Loss (IL) is measured using an external microphone array, capturing the barrier's performance in practical conditions. To account for production and assembly tolerances, slight variations in the scatterers' x and y coordinates are introduced into the numerical model. Results show peak attenuation values between 1 and 2 kHz, aligning with critical urban noise frequencies. This study presents a methodology for evaluating ventilated phononic crystals in real-world scenarios, providing valuable insights for designing efficient noise barriers tailored to traffic and highway applications.

1. INTRODUCTION

Noise pollution is a growing concern in urban environments, impacting public health and well-being. Prolonged exposure to excessive noise levels can result in hearing loss, cardiovascular issues, sleep disturbances, and cognitive impairments, particularly in children. Conventional noise barriers, while effective in reducing sound transmission, tend to be bulky and visually intrusive, blocking natural airflow. These limitations have spurred the search for alternative solutions, with phononic crystal-based noise barriers emerging as a promising innovation.

Phononic crystals (PCs), a type of acoustic metamaterial, utilize periodic structures to control wave propagation, providing enhanced noise reduction while still allowing for ventilation. Recent studies have explored their ability to reduce traffic noise, but practical applications remain limited. PCs can create stopbands, which are frequency ranges where sound transmission is blocked, making them particularly effective for targeted noise reduction. However, further research is necessary to optimize their design for real-world applications.

Traffic noise is one of the primary sources of urban noise pollution, affecting large populations in cities due to the high volume of vehicles and continuous road traffic. Figure 1 illustrates the spectral energy contribution rate of traffic noise at various vehicle speeds, ranging from approximately 34 km/h to 93 km/h. Figure 2 displays the sound pressure levels (SPL), in dB(A), at ground level as a function of frequency. Both figures emphasize that traffic noise is most prominent between 500 Hz and 2 kHz, with a peak between 1 kHz and 1.6 kHz. This observation aligns with typical noise sources, including engine vibrations, tire-road interactions, and aerodynamic effects. The energy distribution increases significantly within this frequency

range, indicating that any effective noise mitigation strategy must focus on these frequency bands.

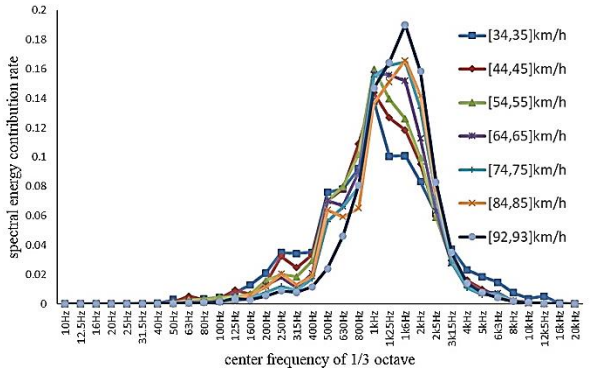

Figure 1. Traffic Noise Spectrum showing dominant frequencies [1]

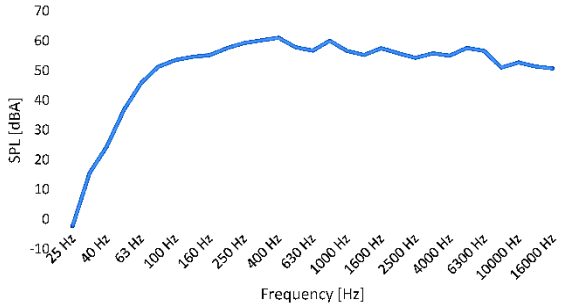

Figure 2. SPL versus frequency recorded in traffic-generated noise measurements [2]

In recent years, acoustic metamaterials have been increasingly utilized to mitigate traffic noise, capitalizing on their unique ability to manipulate sound waves. Sonic crystals and phononic crystals have garnered attention for their ability to control sound propagation, especially at frequencies where traffic noise is typically present. Sonic crystals use periodic arrays of scatterers to create band gaps that block specific frequencies of sound [3]. Phononic crystals, on the other hand, utilize periodic structures at the scale of acoustic wavelengths to prevent the transmission of sound, making them highly effective for controlling low-frequency noise [4]. Their tunable properties enable the precise targeting of problematic noise frequencies, making them highly adaptable for various applications in traffic noise control.

This study presents an integrated approach that combines numerical modeling with experimental validation to evaluate the performance of an array of phononic crystal-based noise barriers. A 4×6 array of cylindrical scatterers was tested in a diffuse sound field within an Alpha cabin, with Insertion Loss (IL) measurements taken externally. By incorporating production tolerances into numerical analysis, this research provides a more realistic evaluation of PC barriers. The findings demonstrate peak attenuation between 1 and 2 kHz, which aligns with the dominant frequencies of urban noise pollution. This work contributes to the advancement of sustainable, high-performance noise control solutions suitable for traffic and highway applications.

2. THEORY AND DESIGN

Phononic crystals (PCs) are artificially engineered periodic structures that manipulate the propagation of elastic and acoustic waves. These structures achieve sound attenuation by introducing bandgap frequency ranges where wave transmission is significantly suppressed. The attenuation mechanism primarily relies on Bragg scattering and local resonance effects [5].

The concept of sonic crystals was first introduced by Martinez [6] in 1995. They conducted sound attenuation experiments on a sculpture by Eusebio Sempere, which was displayed at the Juan March Foundation in Madrid. The team measured sound attenuation under outdoor conditions, focusing on sound wave vectors that were aligned perpendicularly to the vertical axis of the cylinder. They identified a sound attenuation peak at 1670 Hz, marking the emergence of the first band gap.

Figure 3: Different types of Sonic Crystals, also known as periodic structures

According to Bragg's law [7], the mechanism of sound attenuation involves the destructive interference of reflected sound waves with incident sound waves within the band gaps. If the interference is constructive, then the energy of the original wave gets transmitted through the sonic crystal, which forms the propagation bands. In Bragg scattering,

destructive interference occurs when the wavelength of an incident wave matches the periodicity of the structure. The Bragg condition for a 1D periodic structure is given by:

$$m\lambda = 2dsin\theta \quad (1)$$

Where m is the diffraction order (usually m = 1 for the first Bragg condition), λ is the wavelength of the incident wave, d is the lattice constant (the periodic spacing of the scatterers), θ is the angle of incidence of the wave relative to the structure. For a 2D phononic crystal, where periodicity is in two dimensions, the formation of a stopband is governed by the Bloch wave condition using the dispersion relation:

$$k = k0 + G \quad (2)$$

Where k is the wavevector in the phononic crystal, k_0 is the incident wavevector, and G is the reciprocal lattice vector. This equation describes the multiple scattering effect, where waves interfere constructively and destructively, leading to bandgap formation [8]. For periodic scatterers with a lattice constant a, the Bragg Bandgap frequency can be approximated as:

$$f_b = \frac{c}{2a} \quad (3)$$

Where c is the speed of sound in the background medium, this relation shows that the stopband shifts to lower frequencies as the lattice spacing increases, making it a crucial design parameter in phononic crystal barriers. In theory, band gaps should be at multiples of the above fundamental frequency.

Similarly, the filling fraction, a crucial property, influences the width of the band gap. It indicates the proportion of the structure filled by the cylinders [4]. For a square lattice arrangement with scatterers of radius r, the filling fraction is defined as

$$F = \frac{\pi r^2}{a^2} \quad (4)$$

The fundamental component of a phononic crystal is its unit cell, which can be a scatterer or multiple scatterers and can have shapes such as cylindrical, square, or spherical, organized in a periodic pattern. The selection of lattice configuration, whether square, hexagonal, or triangular, greatly influences wave propagation characteristics. A square lattice featuring cylindrical scatterers is frequently used in phononic crystal barriers due to its simplicity in production and the reliable creation of bandgaps.

In this study, we have modeled and tested a unit cell with a lattice constant of 15 cm, a scatterer diameter of 10 cm, and a height of 100 cm to investigate the effectiveness of sonic crystal-based noise barriers in attenuating traffic noise. Figure 4 illustrates the dimensions and geometry of a single unit cell. For the array configuration, we opted for four rows and six columns of scatterers, which was determined to provide an optimal trade-off between acoustic performance and structural efficiency. This array configuration ensures sufficient coverage of the target frequencies while minimizing material usage and production complexity.

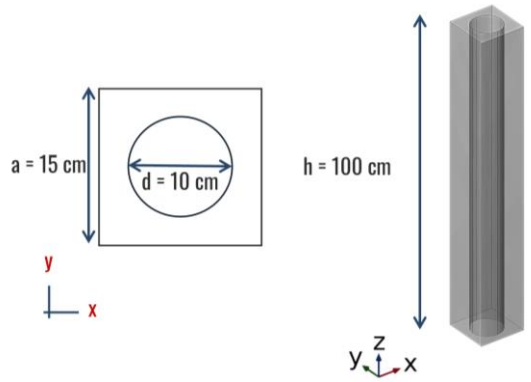

Figure 4: Unit Cell representing one barrier with a=lattice constant, d=diameter of scatterer, and h=height of scatterer

Using the designed unit cell, a numerical model was developed in COMSOL Multiphysics, complemented by an experimental setup, to study the acoustic performance of the unit cell and the array of barriers. The numerical simulations allowed for a detailed analysis of sound wave interactions with the scatterers, while the experimental setup provided empirical data for validation. This methodology enabled a comprehensive evaluation of the noise attenuation capabilities of the barriers, as detailed in Section 4, and the results are discussed in Section 5.

3. METHODOLOGY

3.1 Stopband Analysis

An eigenfrequency study is conducted on the unit cell shown in Figure 6 to determine its band structure and eigenmodes by analyzing the first five eigenfrequencies. A parametric sweep is performed for the wave vector kx along the wave propagation direction over the range $0 \leq kx \leq \pi/a$, which corresponds to the irreducible part of the Brillouin zone.

This analysis helps identify phononic bandgap frequency ranges where wave propagation is prohibited by observing gaps in the computed eigenfrequencies. The resulting dispersion curve provides insights into the wave propagation characteristics of the phononic crystal, enabling the optimization of its design for effective noise attenuation, particularly within the 500 Hz–2 kHz range, which is relevant to traffic noise.

3.2 Numerical Model

To evaluate the acoustic performance of a periodic sonic crystal array in a realistic setting, a comprehensive 3D finite element model was developed using COMSOL Multiphysics. The simulation focused on predicting the insertion loss (IL) and identifying the acoustic stopband behavior of a 4 × 6 array of scatterers, tailored to replicate a real-world prototype under diffuse field conditions. A conceptual diagram is illustrated in Figure 5.

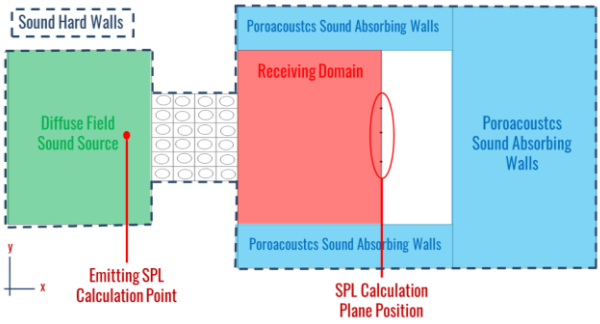

Figure 5: 2D Graphical representation of numerical model used in COMSOL to compute Insertion Loss

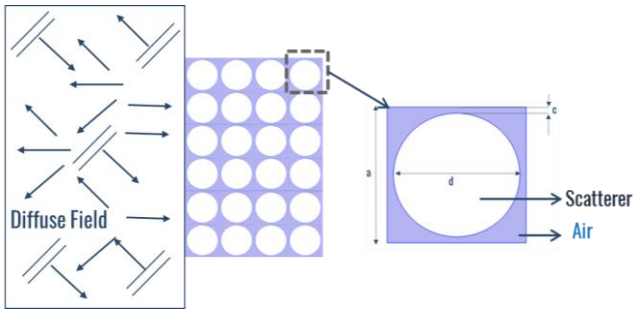

Figure 6: Air applied on surrounding domain of scatterer and random pressure in emitting domain

Table 1. Geometric Parameters of Unit Cell.

Parameter	Description	Value
a	Lattice Constant	15 cm
d	Diameter	10 cm
c	Gap	5 cm

The simulated geometry represents a 3D array of 24 cylindrical scatterers (4 rows × 6 columns) positioned in air, as illustrated in Figures 5 and 6. Scatterers are infinitely rigid and, on the source side, random pressure input diffuse field effects.
In the absence of flow and thermal effects, the Helmholtz equation governs the acoustic pressure field in the frequency domain:

$$\nabla \cdot \left(\frac{1}{\rho_0}\nabla p\right) + \frac{\omega^2}{\rho_0 c_0^2} p = 0 \qquad (6)$$

where:

- p is the complex acoustic pressure [Pa],
- ρ_0 is the air density [kg/m^3],
- c_0 is the speed of sound in air [m/s],
- $\omega = 2\pi f$ is the angular frequency [rad/s].

To replicate realistic boundary absorption (instead of using perfectly matched layers, PML), porous absorbing materials were modeled using the Johnson-Champoux-Allard (JCA) framework, valid for rigid-frame porous media. To replicate environmental excitation such as traffic noise, a diffuse acoustic field was approximated numerically by summing multiple

incident plane waves over an emitting domain. This mimics a random incidence angle distribution:

$$p_{\text{inc.}}(\mathbf{r}) = \sum_{n=1}^{N} A_n e^{-j\mathbf{k}_n \cdot \mathbf{r}} \quad (8)$$

where:

- r: position vector,
- k_n: incident wave vector for angle θ_n and ϕ_n
- A_n: complex amplitude (random phase),
- N: number of plane waves.

Considering geometric variations for realism, this model simulates prototype inaccuracies and production tolerances, precisely scatterer position offsets.

Insertion Loss (IL) measures the reduction in sound transmission that occurs when a barrier is inserted into the acoustic path. In the model, IL is calculated as the difference in Transmission Loss (TL) between the reference case (an empty domain) and the case with the present barrier. Sound pressure levels (SPL) were measured inside and outside the array, and the IL of the variety was computed in dB using TL with and without barriers as explained in the following relations:

$$TL_{empty} = SPL_{inside} - SPL_{outside}$$

$$TL_{barriers} = SPL_{inside} - SPL_{outside}$$

$$IL\ (dB) = TL_{barriers} - TL_{empty}$$

$$= SPL_{outside\ (Empty)} - SPL_{outside\ (Barriers)}$$

The difference in TL values isolates the acoustic effect of the barrier, effectively accounting for diffraction and scattering. This method ensures a reliable and realistic evaluation of the barrier's performance, consistent with established acoustic standards.

3.3 Experimental Setup

To experimentally validate the stop-band effect of the sonic crystal array due to Bragg scattering, measurements were conducted by installing a sonic crystal (SC) array on the door of an Alpha Cabin reverberant cabin, which serves as a diffuse-field sound source. Sound excitation was generated using six high-power loudspeakers capable of producing a sound power of up to 115 dB, thereby creating a diffuse sound field that simulates real-world noise conditions, as shown in Figures 7 and 8.

A 4×6 array of rigid PVC pipes, acting as sonic crystals, was installed on the door of the measurement cabin. Each scatterer has a diameter of 10 cm and is arranged in a square lattice with a 15 cm periodicity, resulting in an array with a width of 90 cm, a depth of 60 cm, and a height of 100 cm.

The pipes were filled to avoid any resonances and precisely arranged to maintain the desired periodicity required for Bragg scattering. To prevent unwanted sound leakage, the array was fully sealed with wooden panels on all four sides- top, bottom, left, and right- except for the side facing the microphone array.

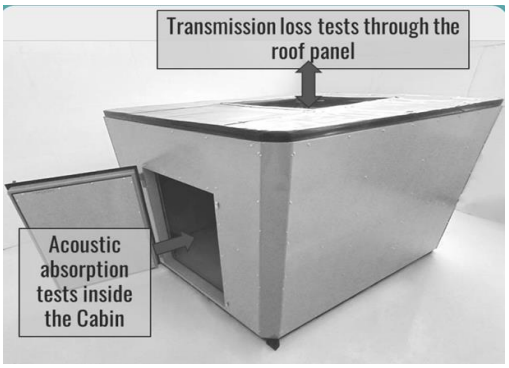

Figure 7: Phononic Vibes 9m^3 Alpha Cabin

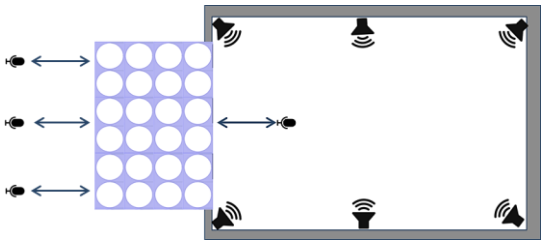

Figure 8: Schematics showing how source and receiving domain look in experimental setup

This configuration ensures that sound waves existing in the cabin must pass through the periodic structure, facilitating selective frequency attenuation via the bandgap effect.

A 2D array of seven microphones is positioned 60 cm from the last row of the SC array to capture transmitted sound levels. To accurately capture sound pressure levels (SPL), seven microphones were placed in front of the array,

and one microphone was positioned inside the cabin. This multi-point measurement approach enabled spatial logarithmic averaging, reducing position-dependent variations and providing a more representative assessment of the overall sound attenuation caused by the barrier.

Table 2. Description of Microphones and their distances.

Microphone no.	Position	Distance from Array
Mic1	Receiving	60 cm
Mic2	Receiving	60 cm
Mic3	Receiving	60 cm
Mic4	Receiving	60 cm
Mic5	Receiving	60 cm
Mic6	Receiving	60 cm
Mic7	Receiving	60 cm
Mic8	Emitting	60 cm

Sound pressure levels (SPL) were measured at multiple positions inside and outside the phononic crystal array to evaluate its noise attenuation performance. The microphone-facing walls of the Alpha cabin were covered with sound-absorbing material to minimize unwanted reflections and prevent any unnecessary resonances that could interfere with the accuracy of the measurements. Additionally, the wall behind the microphone array was also treated with absorbent material to eliminate back reflections, ensuring that the recorded sound levels accurately represent the transmitted sound without contamination from secondary reflections, as shown in Figures 9 and 10.

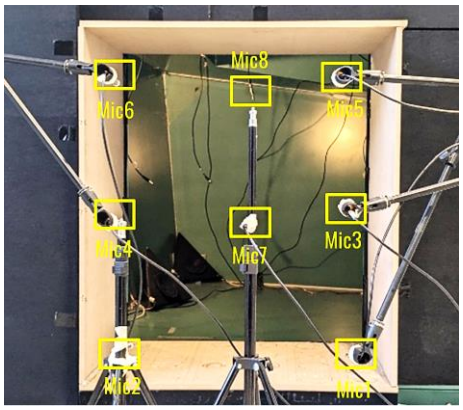

Figure 9: Baseline: No barriers installed and SPL_{empty} measured inside (Mic8) and outside (Mic1-7) to computed TL_{empty}

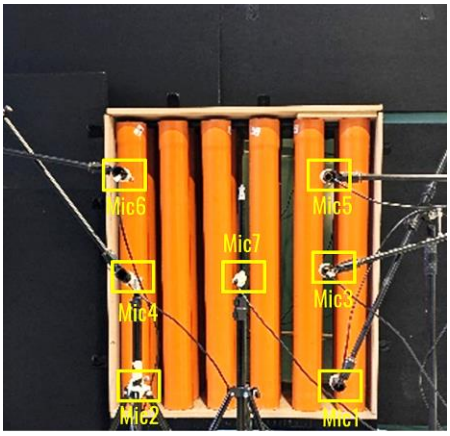

Figure 10: Barriers installed and $SPL_{barriers}$ measured inside (Mic8) and outside (Mic1-7) to computed $TL_{barriers}$

Given the periodic arrangement of the SC array, Bragg scattering effects are expected to cause significant attenuation in the 500–2 kHz range, which corresponds to the dominant frequencies of traffic noise. The measured IL data will validate the formation of a bandgap and assess the overall effectiveness of the SC array in noise mitigation applications.

4. RESULTS AND DISCUSSION

The numerical and experimental results indicate that the phononic crystal (PC) array exhibits strong attenuation characteristics within the designed frequency range. The dispersion analysis of the unit cell (Figure 11) confirms the presence of a complete stopband between 1300 Hz

and 1400 Hz, demonstrating the periodic arrangement's potential to suppress wave propagation effectively. This range aligns well with the observed peak insertion loss (IL) in the numerical simulations (Figure 13).

Figure 13 illustrates the insertion loss obtained for the 4x6 array of scatterers, comparing the ideal periodic arrangement with a structure incorporating random variations in scatterer positioning along the x- and y-coordinates. The results show that the perfectly periodic PC configuration achieves a maximum IL of approximately 16 dB at 1250 Hz, validating its effectiveness in mitigating noise in the mid-to-high-frequency range, with a grey-shaded envelope representing the range between maximum and minimum values.

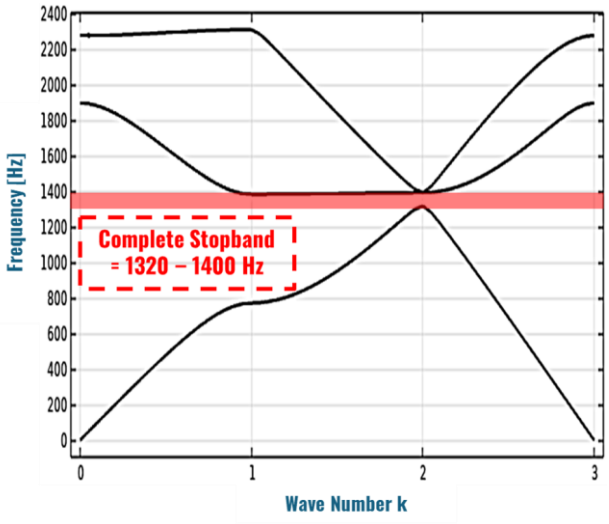

Figure 11: Dispersion Curve showing a complete stop band of designed unit cell between 1300-1400 Hz

The application of random variation along scatterers introduces some fluctuation in the insertion loss response yet maintains a strong attenuation band centered around 1250 Hz. The broadening of the attenuation peak suggests improved robustness and potential for practical deployment, where production imperfections and environmental conditions would otherwise degrade performance.

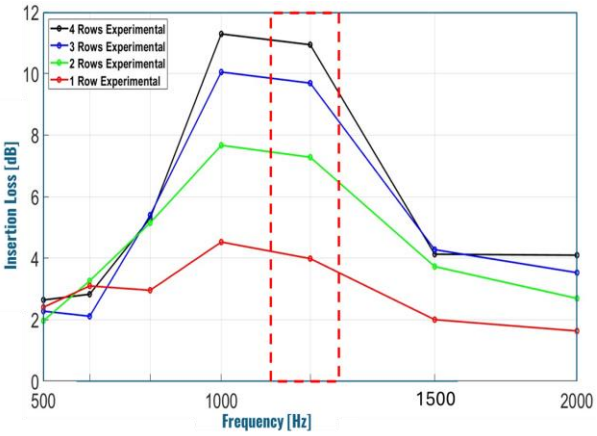

Figure 12: Experimentally measured IL showing the stopband between 1000-1500 Hz in 1/3 Octave bands

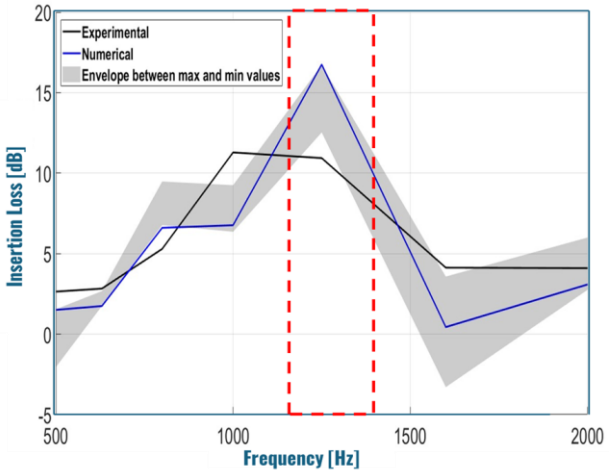

Figure 13: Experimental vs Numerical IL of 4x6 Array of Barriers

Figure 12 shows the experimentally computed IL with different numbers of rows of the barriers. The incremental increase in IL with additional rows suggests that multiple scattering and destructive interference significantly contribute to noise reduction. The experimental results demonstrate the effectiveness of the sonic crystal noise barrier in reducing sound transmission, particularly in the 1000–1400 Hz range, where the insertion loss (IL) reaches a peak of approximately 12 dB for the 4-row configuration.

Figure 13 shows a comparison between experimental and numerical IL for a 4x6 array of barriers, considering variation, and confirms the presence of a stopband between the desired frequencies. The deviations between experimental and numerical data could stem from imperfect boundary conditions (such as wooden panels), production tolerances, or edge diffraction effects.

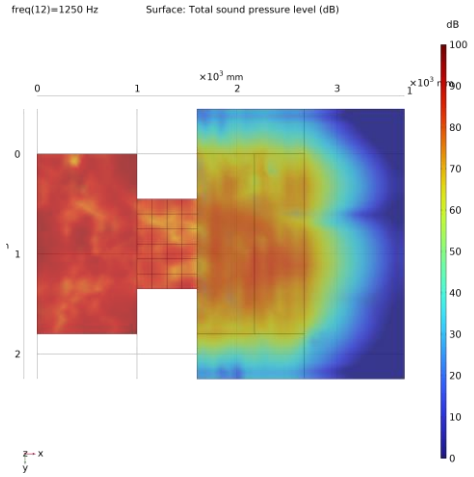

Figure 14: With no barriers, no apparent reduction in SPL

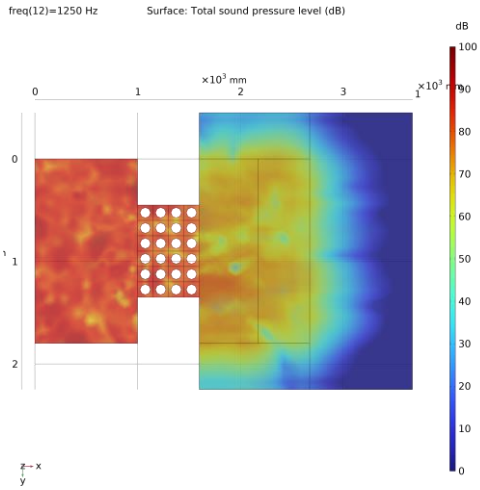

Figure 15: SPL reduced in receiving domain with barriers

Figure 14 shows the scenario without barriers, where SPL remains high and widespread, indicating minimal noise reduction. In contrast, Figure 15 presents the sound pressure level (SPL) distribution, demonstrating reduced SPL in the receiving domain when barriers are present, confirming their noise mitigation capability. These results highlight the effectiveness of the barrier array in controlling noise propagation within stopband frequencies.

ABSTRACT

Vibroacoustic and acoustic metamaterials are promising technologies for noise and vibration reduction. However, their adoption in the industry is limited due to several factors, including a complex design process, industrialization challenges, and costly solutions that constrain their cost-benefit in real applications.
The present work focuses on the design and experimental validation of two types of metamaterials designed to address specific acoustic challenges in train interior noise. The first solution is a vibroacoustic metamaterial (VAMM) based on local resonance effect, designed to reduce the transmission of vibrations on a train panel around 160 Hz. The second solution is a ventilated acoustic metamaterial (AMM) for rectangular open ducts, conceived to reduce airborne noise at frequencies around 170 Hz without reducing the airflow. For both cases, a numerical model was developed and a prototype was built using additive manufacturing technologies.
Experimental validations showed vibration reductions greater than 30 dB in narrow-band and 17 dB in 1/3rd octave bands at the frequencies of interest for the VAMM. In addition, sound pressure level reductions up to 6 dB in narrow-band and 3 dB in 1/3rd octave bands were achieved for the AMM. These results demonstrate the potential of metamaterials for industrial and railways applications.

1. INTRODUCTION

Developing low frequency and broadband sound insulation solutions has always been a significant challenge in noise control engineering. In many sectors like aircraft and railways, solutions based on porous materials for low-frequency sound absorption are limited to the available space for their installation, as these require a significant thickness to be efficient. This challenge becomes even more critical when low frequency airborne sound attenuation is needed with minimal reduction of the air flow. To address this, acoustic metamaterials (AMMs) offer promising solutions.
AMMs are engineered materials that have unique properties, such as negative mass or negative bulk modulus, which arise from their periodic structure. The study of AMMs originated with research on phononic crystals in 1993. In recent decades, its use has expanded significantly, driven by advancements in additive manufacturing technologies that enable the fabrication complex geometries. One of the most compelling aspects of AMMs is their ability to manipulate sound, enabling the creation of barriers that selectively attenuate specific frequencies [1].
Recently considerable effort has been dedicated to developing AMM for low frequency broadband insulation. Some proposed solutions include the use of periodically aligned acoustic black holes [2], honeycomb sandwich structures with attached membranes [3]. Additionally, significant advances have been made to enhance the broadband attenuation capabilities of vibracoustic metamaterials (VAMM) [4] and ventilated acoustic

metamaterials [5], offering solutions that are both effective and easy to manufacture. In the railways sector, innovative solutions for interior noise reduction in trains, including AMMs, were explored in the TRANSIT project with promising results from simulation point of view [6] [7].

2. RESEARCH CONTEXT AND OBJECTIVES

The aim of this work is to propose innovative solutions, based on metamaterials, for potential application cases in railways and industry. Noise reduction based on conventional solutions faces limitations related to weight and space, particularly when dealing with low frequency. Train interior noise is a combination of airborne and structure-borne noise. The structure-borne part is low frequency, and it is transmitted from the main noise sources such as the bogie and auxiliary equipment through the train carbody to the interior. Vibroacoustic metamaterials can help to reduce vibration and thus the structure-borne noise contribution in this frequency range. In this context, a VAMM based on local resonance effect to cancel bending waves in a plate structure is proposed.

Besides, there are several acoustic sources related to ventilation systems, such as cooler fans of auxiliary equipment, or the HVAC supply fan. The latter might be a relevant noise source for train interior noise, especially at train low speeds and for certain passenger positions. The duct's system has often limitations in terms of space, so solutions based on AMM can be a smart alternative to reduce the fan's blade passing frequency. In this context a ventilated AMM is proposed, tuned at a typical frequency for this kind of fan.

The objective of this research is, based on previous works found on literature as a starting point, to adapt specific designs to the above-mentioned applications.

The VAMM solution and its validation are described in chapter 3. The ventilated AMM solution and its validation are described in chapter 4.

3. CASE STUDY 1: VIBROACOUSTIC METAMATERIAL

3.1 Proposed solution

The first solution proposed in this study is a resonator, based on the VAMM approach proposed in [4] but redesigned to achieve its eigenmode at lower frequencies (around 150 Hz). Additionally, the requirements for the solution included ease of manufacturing, the ability to be mounted vertically and the affordability of use in terms of cost. For this reason, a beam-like resonator made with polypropylene with a metallic tip mass was designed and simulated.

The resonator was attached to a 3mm thick aluminum 2024 T3 plate, which served as the base structure. A 3.6 g steel tip mass, representing 26% of the bare plate's mass, was used. According to the framework described in [4], this configuration is expected to produce a bandgap width of 15 Hz. COMSOL Multiphysics was used to fine-tune the resonator's geometry in order to achieve the desired eigenfrequency of around 160 Hz (Figure 1). The chosen material, Innovatefil© polypropylene used has a very low young modulus (390 MPa), making it suitable for this application. The VAMM was manufactured using Bambu X1 Carbon 3D printing machine and glued directly to the aluminum plate. To facilitate the placement of the samples, a 0.8 mm thick tape was also printed

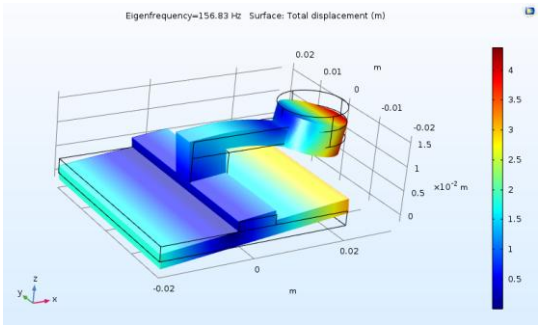

Figure 1. Modal analysis simulation of the beam-type VAMM resonator.

3.2 Experimental validation

The validation of the VAMM material performance was done by measuring averaged frequency response functions through impact testing. Results have been compared between 2 cases:

- The reference plate (bare plate)
- The reference plate + add-on VAMM

Validation has been done for two different configurations: a case where the VAMM has been installed over the whole plate area and a case where it has been installed only in the central part of the plate, occupying 22% of the total area.

Acceleration frequency response functions have been measured by averaging 5 impacts, performed at the lower edge of the plate. The response was measured at 4 different positions, at the upper edge of the plate. The impacts were performed with an instrumented hammer (PCB, model

086D05) with a nylon tip, and a set of piezoelectric accelerometers of 100mV/g.
The experiment performed with the solution added on the whole surface was done in free boundary conditions, by suspending the plates on an elastic rope, and in supported condition, with the plates supported on a table by means of foam pads (Figure 2). The evaluation of the partially applied solution has only been done in the supported condition.

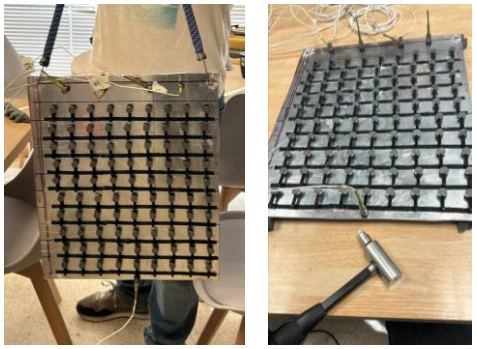

Figure 2. Experimental validation of the beam-like VAMM in free and supported boundary conditions.

3.3 Results

The comparison of the averaged frequency response functions of the bare plate and the bare plate with the VAMM are shown in Figure 3 and Figure 4 for free and supported boundary conditions respectively.

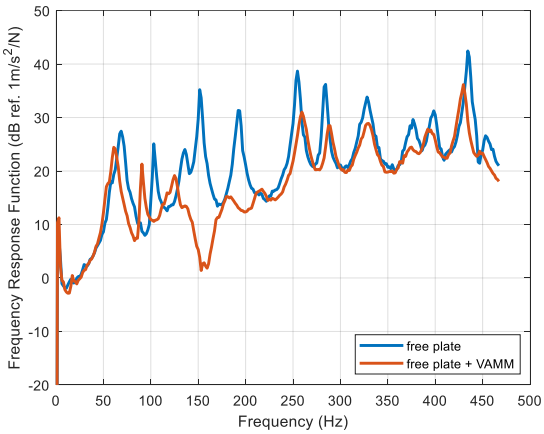

Figure 3. Magnitude of the averaged acceleration frequency response function with the VAMM solution applied in the whole plate surface (free boundary conditions).

Some differences are observed in the magnitude of the peaks between the free and supported cases. Despite the different boundary conditions, the same stop band is observed in both cases, in the range between 130 and 180 Hz, with a strong dip at 155 Hz (33 dB of reduction). Furthermore, a suppression of the peaks is observed up to 210 Hz. Besides, probably due to a significant amount of damping, peaks above 210 Hz are partially damped.

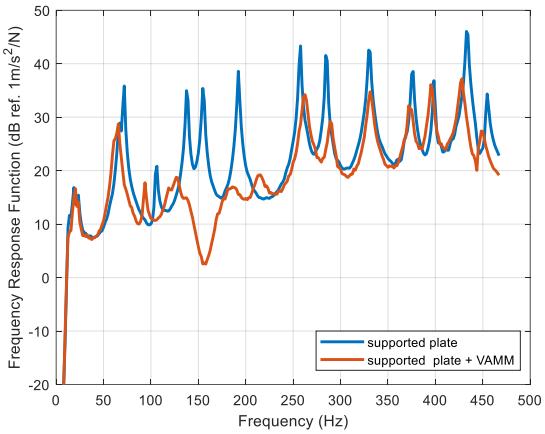

Figure 4. Magnitude of the averaged acceleration frequency response function with the VAMM solution applied in the whole plate surface (supported boundary conditions).

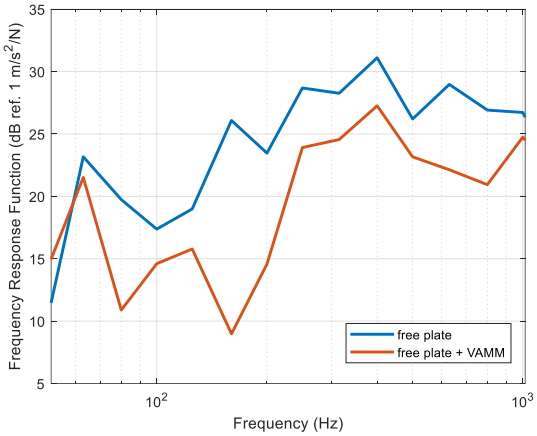

Figure 5. Averaged acceleration frequency response function in 1/3rd octave bands with the VAMM solution applied in the whole surface.

It is worth reading these results in one-third octave bands, as they are commonly used in noise control in industry. Reductions of 17 dB at 160 Hz band, and 9 dB at 200 Hz are achieved (Figure 5).
Results for the VAMM installed in 22% of the surface are shown in Figure 6. The stop-band behaviour is not observed in this case. A reduction in the amplitude of the peaks is achieved between 140 and 200 Hz. Above this frequency, only a very slight reduction in the amplitude of the peaks is observed. In one-third octave bands, the maximum reduction achieved is 11 dB at 160 Hz.

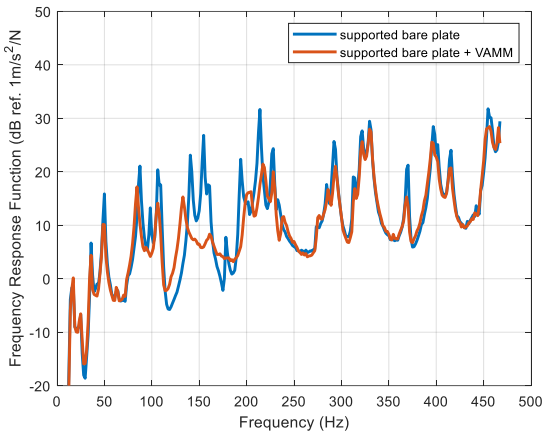

Figure 6. Magnitude of the averaged acceleration frequency response function with the VAMM solution applied in 22% of the plate surface.

4. CASE STUDY 2: VENTILATED ACOUSTIC METAMATERIAL

4.1 Proposed solution

The solution proposed to increase the absorption in an open-duct is a ventilated acoustic metamaterial, composed of multiple monopolar resonators arranged the same plane parallel to the section of the tube. The design features several Helmholtz resonators placed in a rectangular ring configuration. This design was based on the methodology proposed by Meng et al. [5], adapted to match the typical dimensions of a train's HVAC ducts (270 x 210 mm). A frequency domain analysis was performed using COMSOL Multiphysics to achieve an eigenfrequency at lower frequencies. The analysis involved creating a plane wave excitation in a Navier-Stokes linearized domain with perfect matching layers applied at the end of the ducts. The results show that the sound pressure levels (SPL) at Helmholtz resonator cavities are highest around 170 Hz (Figure 7).

The ventilated acoustic metamaterial was fabricated using PLA on a Prusa XL 3D printer. Due to the large sample size, the structure was subdivided into multiple sections and assembled using screws. To avoid the use of support materiel, the Helmholtz cavities were printed without the rear wall, which was glued in place after printing.

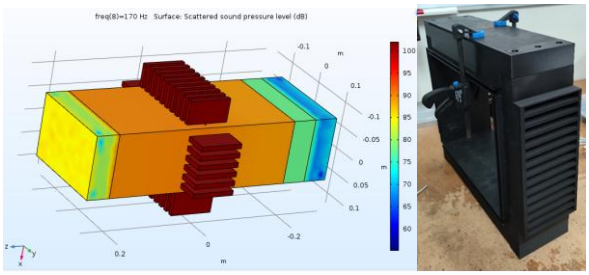

Figure 7. Scattered SPL obtained with finite element simulation of ventilated acoustic metamaterial (left), and process of assembling the metamaterial (right)

4.2 Experimental validation

Experimental validation has been done in a semi-anechoic chamber. A rectangular duct made of 4 mm thick PMMA material has been mounted and assembled, at one end, to a box containing a loudspeaker. To test the solution, the AMM has been assembled at the other end of the rectangular duct (Figure 8).
The validation has consisted in the comparison of the sound pressure level at a set of receiver positions between the case with the AMM installed and a reference case, where the duct has been assembled to a sample with the same dimensions than the ventilated AMM but without the Helmholtz resonators. Pink noise has been used as acoustic excitation.
The set of 15 receivers has been placed at 80 cm from the end of the sample, covering an area of 100 x 50 cm. Results have been calculated by averaging the sound pressure level at all positions.

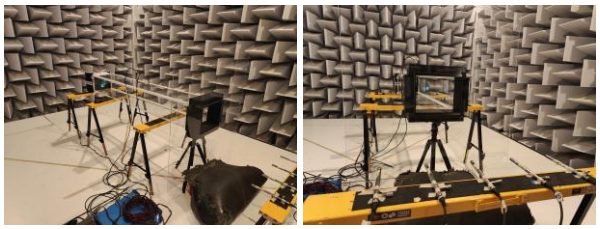

Figure 8. Images of the set-up in the semi-anechoic chamber.

4.3 Results

The comparison of the averaged sound pressure level results with and without the AMM solution is shown in Figure 9. In narrow band, a maximum reduction of 6 dB is found at 178 Hz and at 202 Hz. In one-third octave bands, this translates into a reduction of 3 dB at the band of 200 Hz and 1.4 dB at 160 Hz.

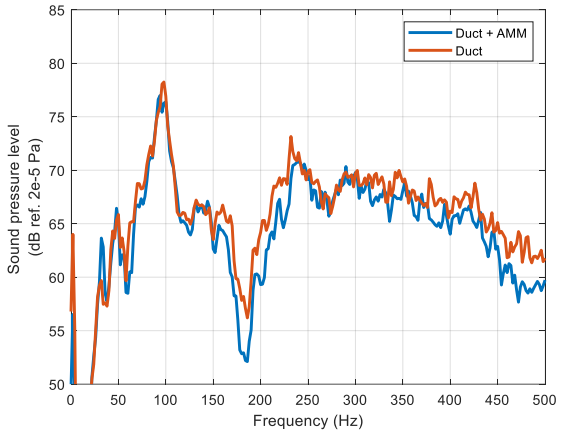

Figure 9. Comparison of the average sound pressure level results with and without the AMM solution installed.

5. CONCLUSIONS

In this work, two metamaterials have been designed, prototyped and experimentally evaluated for potential applications in the railway industry, based on the requirements and specifications of possible real-world cases. The proposed solutions are lightweight, easily manufacturable and easy to mount, with low production cost.

After the experimental evaluation of the beam-resonator based VAMM, a stop band has been clearly observed, with reductions up to 33 dB at 155 Hz. This corresponds to a reduction of 17 dB at 160 Hz one-third octave band. Thanks to these results, the solution appears promising. It has been observed that the total amount of resonators in the plate is relevant for the stop band performance. The next step to further develop this material would be, on the one hand, to move forward toward the industrialization phase. On the other hand, modifications could be explored to increase the stop-band frequency range without adding extra weight to the solution.

The results of the ventilated AMM solution have shown reductions of 6 dB in narrow band at frequencies near the target frequency, 170 Hz, which leads to a reduction of 3 dB at 200 Hz third-octave band. Discrepancies with the results of the literature may arise from defects in the design of the AMM, which is not completely optimized, or issues related to the assembly of its components. Further research is needed to improve the performance of the proposed solution.

ABSTRACT

In order to obtain a strong absorption over a large range of incidence angle, the reflection of an incident acoustic plane wave by a rigidly backed lossy architectured layer is studied numerically and theoretically. This layer is composed of a periodic arrangement of inclined resistive wiremeshes. Impedance matching is achieved when the angle of the incident wave corresponds to the angle of inclination of the wiremesh as well as its exact opposite angle, thanks to the reciprocity principle. The structure exhibits either large absorption over a broad frequency band for medium inclination angles or almost omnidirectional large absorption over a subwavelength frequency band for large inclination angles. This peculiar acoustic behavior provides another perspective for the design of perfect omnidirectional subwavelength sound absorbing devices.

Keywords: *wiremesh, effective medium, broadband absorption, omni-directional absorption.*

1. INTRODUCTION

Low frequency noise absorption is a challenging task which has been addressed in numerous studies this last decade [1–3]. The main difficulties to confront this problem are related with the large acoustic wavelength and the required space and amount of material for passive noise control solutions [4]. As an alternative, acoustic metamaterials developed under the slow sound propagation concept have been used to design broadband acoustic perfect absorbers leading to deep-subwavelength structure thicknesses [5]. The performance of these solutions is limited when the acoustic wave arrives from angles that are different from normal incidence or from grazing angles.
Among other metamaterials, layered metasurfaces based on the extraordinary reciprocity property [6, 7] exhibit a symmetric reflection coefficient providing very interesting absorption characteristics. From this property, the reflection coefficient of a structure with ultra thin resistive sheets, in a transmission problem, is zero when the incident field arrives with the same angle as the orientation of the layers. On the other hand, when the incident field arrives with the exact opposite angle, the reflection is again zero and the transmission is different to one. In consequence, impedance matching is produced at this exact opposite angle and the absorption coefficient is close to the unity.

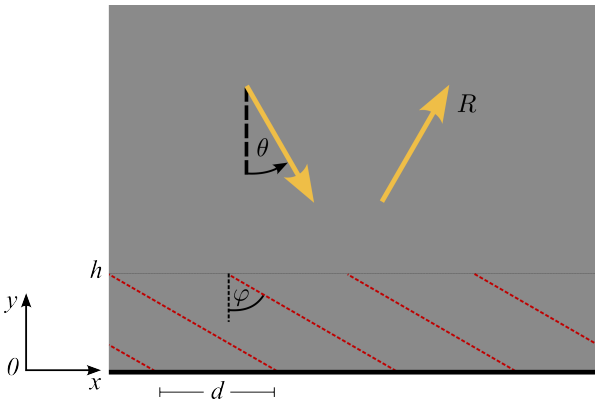

Figure 1. Reflection problem of a wiremesh (red dashed) grating with rigid backing.

Inspired by this reciprocity principle, we explore the reflection of an incident acoustic plane wave by a rigidly

backed lossy architectured layer composed of resistive wiremesh material. In this study, we compute the absorption coefficient numerically and theoretically. In addition, we show that the structure exhibits either large absorption over a broad frequency band for medium inclination angles or almost omni-directional large absorption over a subwavelength frequency band for large inclination angles. This document is organized as follows. Sec. 2 describes the wiremesh grating structure in a reflection problem. Sec. 3 presents the structure effective medium formulation and an explicit expression for the reflection coefficient. Finally, comparisons between the numerical computations with analytical results are shown in Sec. 4.

2. WIREMESH GRATING

Fig. 1 depicts a reflection problem of a rigid backing wiremesh grating. This problem is described by the Helmholtz equation, $(\Delta + k^2)p = 0$, using the time-harmonic convention $e^{-i\omega t}$. The structure is composed of inclined thin wiremesh units horizontally arranged with a periodicity d, a layer inclination angle φ and a height h. The boundary conditions that define the wiremesh, assuming that the layers does not vibrate, are a normal particle velocity continuous through the wiremesh and a pressure jump around the layer [8,9], as

$$[\![\partial_n p]\!] = 0 \;\; and \;\; [\![p]\!] = \frac{i\zeta}{k}\partial_n p. \tag{1}$$

In Eqn. (1), ζ is the purely resistive wiremesh impedance normalized by the characteristic impedance of the medium ρc. As the structure is d-periodic along the x-axis, the present study is focused only on the propagation of the fundamental mode, i.e. $kh/\pi \leq 1$ [10].

3. EFFECTIVE MEDIUM FORMULATION

According to the effective medium theory ($kd \ll 1$), a lossy wiremesh layered structure can be represented using an artificial homogeneous anisotropic medium slab, with principal directions of anisotropy (X, Y) [11], as it is represented in Fig. 2. This problem is described by the wave equation

$$\nabla \cdot [\mathbf{a}\nabla p(x,y)] + bk^2 p(x,y) = 0. \tag{2}$$

In this equation, $\mathbf{a}$ and b are the effective parameters related with the density and bulk modulus of the slab relative to a reference medium (where $a = 1$ and $b = 1$). The boundary conditions for the reflection problem are

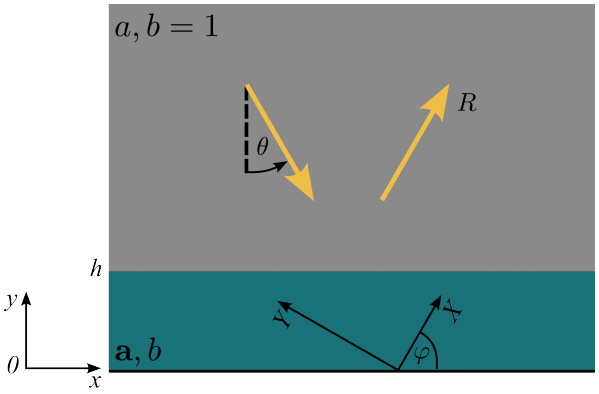

Figure 2. Reflection problem of a rigid backing wiremesh grating.

$$\begin{aligned} [\![p]\!] = 0 \quad and \quad [\![\mathbf{n}\cdot(\mathbf{a}\nabla p)]\!] = 0 \quad at \;\; y = h, \\ \mathbf{n}\cdot(\mathbf{a}\nabla p) = 0 \quad at \;\; y = 0. \end{aligned} \tag{3}$$

Considering that the principal directions of anisotropy (X, Y) coincides with the directions of the unit cell, the effective parameter $\mathbf{a}$ is a diagonal matrix defined as

$$\mathbf{a} = \begin{pmatrix} 1/\rho_{eff} & 0 \\ 0 & 1 \end{pmatrix}, \tag{4}$$

with an effective density [12]

$$\rho_{eff} = 1 + \frac{i}{kh}\left(\frac{\zeta h}{d\cos\varphi}\right). \tag{5}$$

Applying a rotation of the homogenized medium by an angle φ, the $\mathbf{a}$ matrix is mapped to the global components (x, y) in the form

$$\mathbf{a} = \begin{pmatrix} a_x & a_{xy} \\ a_{xy} & a_y \end{pmatrix}. \tag{6}$$

The reflection problem is solved using the wave fields solutions

$$\begin{aligned} p(x, y \geq h) &= e^{ik_x x}\left(e^{-ik_y(y-h)} + Re^{ik_y(y-h)}\right), \\ p(x, 0 \leq y \leq h) &= e^{ik_x x}\left(Ae^{i\kappa^+ y} + Be^{i\kappa^- y}\right), \end{aligned} \tag{7}$$

with $k_x = k\sin\theta$, $k_y = k\cos\theta$ and k the wave number in the reference medium. In Eqn. (7), $\kappa^{\pm}$ is the wave number of the anisotropic slab in the normal direction

$$\kappa^{\pm} = -\frac{a_{xy}k_x}{a_y} \pm \frac{k}{a_y}m', \tag{8}$$

with

$$m' = \sqrt{ba_y - (a_x a_y - a_{xy}^2)\sin^2\theta}.$$

Applying the boundary conditions of Eqn. (3), the reflection coefficient of the homogenized slab at $y = h$ is

$$R = \frac{\frac{\cos\theta}{m'} + i\tan\frac{kh}{a_y}m'}{\frac{\cos\theta}{m'} - i\tan\frac{kh}{a_y}m'}, \tag{9}$$

and the absorption coefficient is computed as

$$\alpha = 1 - |R|^2. \tag{10}$$

4. RESULTS

In order to compare the effective medium formulation, the absorption coefficient is calculated numerically using COMSOL Multiphysics and used as reference. In Fig. 3, the absorption coefficient is depicted. On the left-hand side numerical results using input parameters $\zeta = 2$ and $h = 2$ and on the right-hand side the effective medium results for dimensionless parameters $\varphi = 60$ and $\zeta h = 4$. In this figure, the effective medium results exhibit absorption deviations compared with numerical computation when kh/π increases. Furthermore, large absorption is obtained in both cases when the incident angle is exact the inclination angle of the layered structure ($\theta = \pm 60$), for frequencies above 0.4.

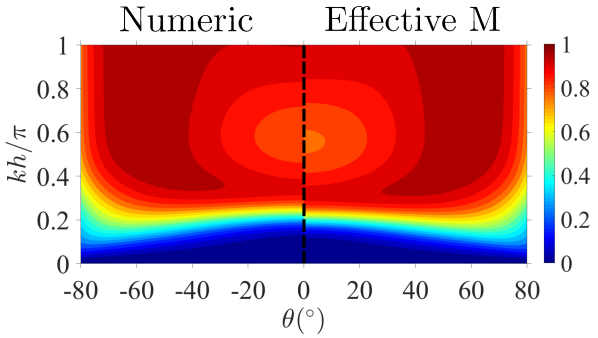

Figure 3. Absorption coefficient of the metasurface for $\varphi = 60$ and $\zeta h = 4$. Left side, numerical result using $\zeta = 2$ and $h = 2$, and at the right side the effective medium formulation.

The effect of varying φ for a fixed ζh value is presented in Fig. 4, for numeric ($\zeta = 2$ and $h = 2$) and effective medium computations. These results show that increasing the inclination angle of the layer structure larger absorption is achieved. A remarkable result is noticed for $\varphi = 75$, where impedance matching is achieved at the exact the inclination angle of the layered structure and broadband absorption is appreciable starting from low frequency ($kh/\pi \leq 0.2$). Furthermore, almost omnidirectional large absorption over a subwavelength frequency band is obtained for $\varphi = 75$ at a $kh/\pi = 0.14$. From the effective medium results, deviations appear as the frequency increase. Despite this, effective medium retains the subwavelength absorption and broadband at the same inclination angle of the structure.

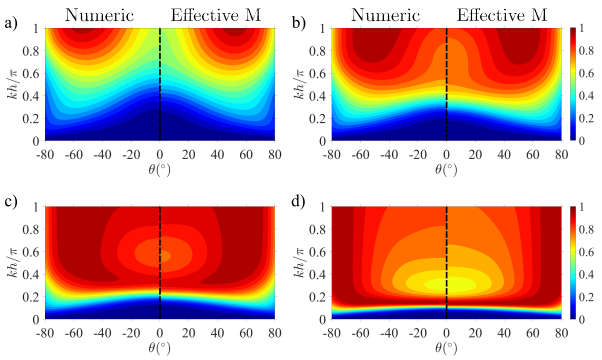

Figure 4. Effect of varying φ for $\zeta h = 4$ value. a) $\varphi = 30$, b) $\varphi = 45$, c) $\varphi = 60$ and d) $\varphi = 75$.

5. CONCLUSIONS

In this work, we studied the reflection problem of a rigidly backed lossy architectured layer composed of resistive wiremesh material. The understanding of the structure was performed using the effective medium formulation. From this procedure, we observed the dependency of the reflection coefficient on the dimensionless parameters kh and ζh. To compare the effective medium formulation, we used numerical computations as reference. We showed good correlation between numerical and effective medium results, and deviations where addressed at high frequencies. We observe good agreement between effective medium theory and full numerical solutions for a given ζh, as long as ζ is not large and h not too small. Additionally, we showed that the structure exhibits either large absorption over a broad frequency band for medium

inclination angles or almost omni-directional large absorption over a subwavelength frequency band for large inclination angles. This peculiar acoustic behavior provides another perspective for the design of perfect omni-directional subwavelength sound absorbing devices.

ABSTRACT

Sonic crystals (SC) have emerged as a promising alternative to solid noise barriers, offering comparable attenuation properties with improved design flexibility. This study presents the design and analysis of a sonic crystal noise barrier covered with absorbing material to reduce urban traffic noise. The scatterers are designed to meet urban aesthetic requirements, with a maximum height of 1 m and a diameter of 8 cm.

Numerical simulations and experimental work were conducted to evaluate the sound absorption and insertion loss of the barrier. The results highlight the distinct roles of the rigid core and absorbing material layer, showing significant noise attenuation across a wide frequency range.

This research demonstrates the potential of combining absorbing material with rigid structures to develop effective noise barriers for urban environments. Furthermore, it details nonstandard methods to test the attenuation of the barrier. The findings contribute to advancing the practical application of sonic crystals in addressing traffic noise challenges while maintaining aesthetic and functional considerations

1. INTRODUCTION

Acoustic waves have been the focus of research for decades. Brillouin's classical work opened the field's possibilities with concepts like band gaps or the Brillouin zone, which can also be used in electromagnetic waves [1]. In 1987, the photonic crystal concept was first proposed to evaluate light's propagation inside a periodic structure [2]. Taking that work as inspiration, the concept of phononic crystal (PC) was born, with acoustic waves propagating inside periodic structures as well.

Phononic crystals are man-made composite materials consisting of periodically distributed scatterers in a matrix (fluid) with a high impedance, mass, and elastic moduli contrast to the host fluid, which can give rise to acoustic dispersions and band structures due to Bragg scattering [3]. Phononic crystals are mainly organized in three different distributions: one, two, and three dimensions (1D, 2D, 3D). The dimensions refer to the number of directions in which the crystal is periodic. Each of these tackles either pure or mixed transversal and longitudinal waves. [4]

The infinite repetition of the same unit cell or pattern constitutes a periodic system. This means that, at any location or portion of the system, the behavior is the same and is independent of its vicinity. The specific pattern that will be infinitely repeated is called a lattice. The space between individual unit cells in a lattice is called the *lattice constant* and is generally abbreviated with the symbol a. This is one of the most important things to consider when designing the SC. a will, in theory, determine the first Bragg band gap (BG) [5]. This means that the spacing between unit cells in rigid sonic crystals will establish the frequency range where acoustic waves are not able to propagate. a and the frequency relate to each other in the

equation:

$$f_c = \frac{c}{2a} \tag{1}$$

where f_c is the central frequency of the first Bragg-BG, and c is the speed of sound in the propagating medium.

Another important geometric parameter is the *filling fraction*, abbreviated with ff. This value is the amount of volume the scatterers occupy relative to the total volume of the sonic crystal. For a 2D sonic crystal with a rectangular lattice pattern, it can be calculated as:

$$ff = \frac{\pi r^2}{a^2} \tag{2}$$

where r is the radius of the scatterers, with a constant lattice constant a. If the filling fraction increases, it means that the scatterers occupy more of the total volume. As shown in equations 1 and 2, the effective frequency range that the noise barrier (NB) will attenuate is governed by the geometric parameters. Bevilacqua and her team [6] performed a study campaign to see the change in the insertion loss of a wooden SC when the radius and spacing of the unit cells are changed. They demonstrated that thinner scatterers shift the sound attenuation to higher frequencies. If the aim is to attenuate low frequencies in the unit cells, a larger diameter size should be considered.

While rigid sonic crystals offer promising noise reduction capabilities, further advancements can be achieved by incorporating additional functionalities into their design. There have been works that focus on changing the shape of the scatterer, like the one made by [7]. They found that by doing this, they have more versatility in changing the band gap without having to modify a or ff. Another option to enhance the acoustic response of the scatterers is to take advantage of its resonance. This means not only improving the spacing or the geometry of the inclusions but also taking advantage of another property. [8, 9] used a split ring resonator to enhance the properties of the sonic crystal. When the opening is carefully selected to have a resonance under or over the Bragg BG, the barrier in theory will have a wider bandgap. Another approach is to coat the scatterer with a porous material. Umnova et al. [10] Their findings show that covering the cylinders with a porous material makes the array insertion loss more uniform in frequency.

What these researchers can tell is that SC is an effective technique to combat railway and traffic noises. They are more aesthetically pleasing than solid NB and require less material to build. However, to have good attenuation properties in a wide frequency range using rigid scatterers is not enough. Early improvements to SC focused on geometric parameters, that are effective in some applications. For traffic use, it is necessary to combine multiple strategies in one inclusion in a way that guarantees the necessary properties.

This study focuses on the design and evaluation of a sonic crystal (SC) enhanced with an absorbing material to improve its performance against traffic noise. Given the intended outdoor application, porous concrete was selected as the preferred material due to its sound absorption properties and durability. To assess the effectiveness of the proposed configuration, a nonstandard experimental approach was employed. The methodology utilizes an alpha cabin as a controlled noise source, with the SC noise barrier mounted at the cabin door. An array of microphones is used to measure the attenuation induced by the scatterers, with focus on insertion loss. In addition to the experimental campaign, numerical models of the SC array are developed to compare with the measured results, providing further insight into the barrier's acoustic performance and the impact of the hybrid material composition.

The paper from this point forward is distributed as: Sec. 2 introduces the dimensions of the SC, materials used, and how they were characterized numerically and experimentally. Sec. 3 explains the experimental method to test the SC with the alpha cabin. Sec. 4 details the how the array was modeled using FEM. The experimental and numerical results are presented in sec. 5. Finally, sec.6 discusses the results.

2. SONIC CRYSTAL DESIGN AND MATERIAL CHARACTERIZATION

2.1 Sonic crystal unit cell and array dimensions

In this study, a square lattice sonic crystal (SC) was designed with scatterers consisting of a PVC pipe core (6 cm diameter) surrounded by a 1 cm thick polyester fiber absorbing layer, resulting in a total scatterer diameter of 8 cm. While the final SC design will use rigid and porous concrete, the polyester fiber layer was chosen for experimental testing in the alpha cabin as a proof of concept. Numerical simulations compare the acoustic behavior of both materials to assess their performance. In Fig. 1 the diagram of the scatterer is represented. In Tab. 1 the acoustic parameters of the configuration are given. The chosen lattice constant is because for traffic noise the most critical frequencies are close to 1000 [Hz], and to the ge-

ometric constraints of the experimental setup.

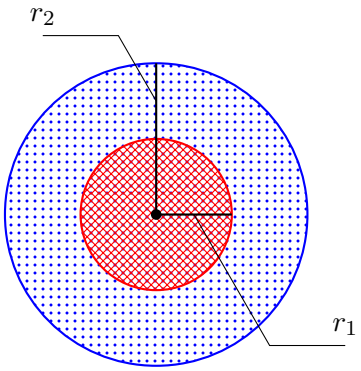

Figure 1: Top view of the scatterer

Table 1: Array geometric and acoustic parameters

Parameter	Value	Description
r_1	3 [cm]	radius rigid inner core
r_2	4 [cm]	radius complete scatterer (core + absorbing layer)
a	15 [cm]	lattice constant
f_c	1143 [Hz]	central Bragg frequency
ff	1.4	filling factor

2.2 Experimental material characterization

The characterization of the absorbing material was conducted in the Alpha cabin following ISO 354:2003 [11]. This standard specifies the use of a reverberation room and a 12 m² sample to determine a material's sound absorption coefficient (α) based on its reverberation time. Although the standard requires a large test sample, the polyester fiber layer was characterized inside the Alpha cabin, which also generates a diffuse sound field, ensuring the validity of the method. In this case, the sample size was reduced to 1.2 [m^2].

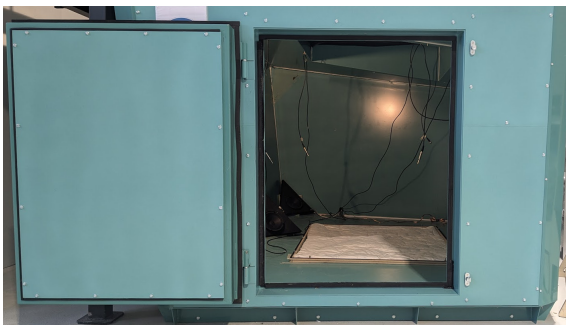

Figure 2: Polyester fiber sound absorption coefficient measures in an Alpha cabin using ISO 354:2003 standard.

To calculate α, two measurements were performed. First, the reverberation time was measured inside the empty Alpha cabin. Then, the test was repeated with the material inside. By comparing the reverberation times from both cases and applying Sabine's formula (Eq. 3), the absorption coefficient was determined.

$$TR_{60} = \frac{0.161 \times V}{S \times \alpha}. \tag{3}$$

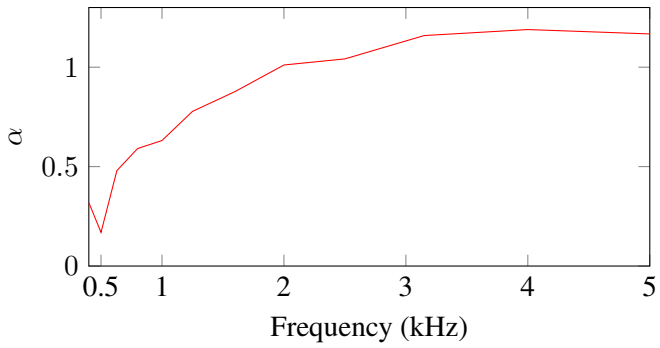

Figure 3: Polyester fiber sound absorption coefficient results obtained in an Alpha cabin using ISO 354:2003 standard.

2.3 Miki Equivalent fluid models

Miki's equivalent fluid model [12] are empirical relationships that estimate the characteristic impedance and propagation constant of porous materials. Those depend on porosity, tortuosity, and a pore shape factor.

Miki proposes to use the following expressions for the wave number (k) and characteristic impedance (Z_c):

$$Z_c = \rho_0 c_0 \left(1 + 5.5(\times 3\left(\frac{f}{\sigma}\right)^{-0.632} - i8.43(\times 3\left(\frac{f}{\sigma}\right)^{-0.632}\right) \tag{4}$$

$$k = \frac{\omega}{c_0}\left(1 + 7.81(\times 10^3\left(\frac{f}{\sigma}\right)^{-0.618} - i11.41(\times 10^3\left(\frac{f}{\sigma}\right)^{-0.618}\right) \tag{5}$$

The selected absorbing material can be accurately represented using this model.

3. EXPERIMENTAL METHOD

Noise barriers are typically tested *in situ* following the ISO 10847:1997 standard. However, since the current design is still under development, performing full-scale tests for every iteration would be impractical. Instead, a non-conventional method is proposed to obtain reliable data on noise attenuation rapidly. The key component, besides the sonic crystal (SC), is an Alpha cabin, whose characteristics are summarized in the following table and visible in Fig. 4.

Table 2: Alpha cabin characteristics

Parameter	Value
Internal volume	9 m^3
Maximum SPL	115 dB
Frequency range	400–10,000 Hz

To assess the effectiveness of the sonic crystal, insertion loss (IL) is selected as the performance metric, defined by:

$$IL = SPL_{\text{without}} - SPL_{\text{with}} \quad \text{[dB]} \tag{6}$$

This requires measuring the sound pressure level (SPL) in two configurations: (i) with the SC mounted on the Alpha cabin door and (ii) without it. The SPL is recorded using an array of seven PCB Piezotronics 130F20 microphones, positioned 60 cm from the outermost scatterer of the SC.

The system is controlled via a DEWESoft Sirius XHS LV, which generates a white noise signal for the speakers and processes input from the microphone array.

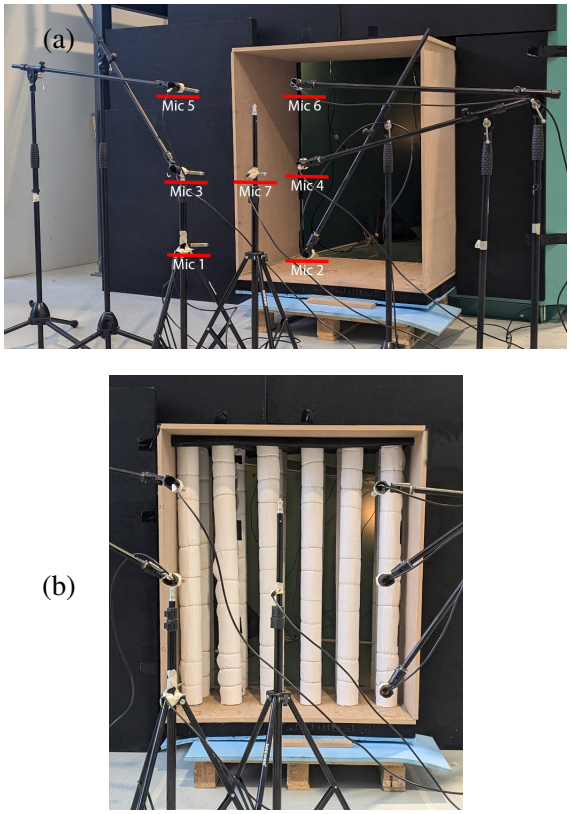

Figure 4: IL experimental setup: (a) Empty Alpha cabin with SC frame; (b) SC covered with polyester fiber absorbing material.

4. NUMERICAL MODELING

To validate and understand the behavior of 2D sonic crystals two-dimensional FEM simulations were employed. By using this technique, it is possible to test parameter changes quickly. The simulation setting for this section is relatively simple and is used with some adaptions for the studied cases.

Fig. 1 shows the geometries for the simulation. r_1 is the radius of the rigid cavity inside the scatterer, and r_2 is the radius of the full scatterer (core + absorbing material). Likewise, as with the experimental method, the analysis parameter to assess the barrier's performance is Insertion Loss (IL).

The modeled geometry is three scatterers in a row with infinite periodic conditions to the sides. The system is excited by a plane wave coming from the bottom edge of the model.

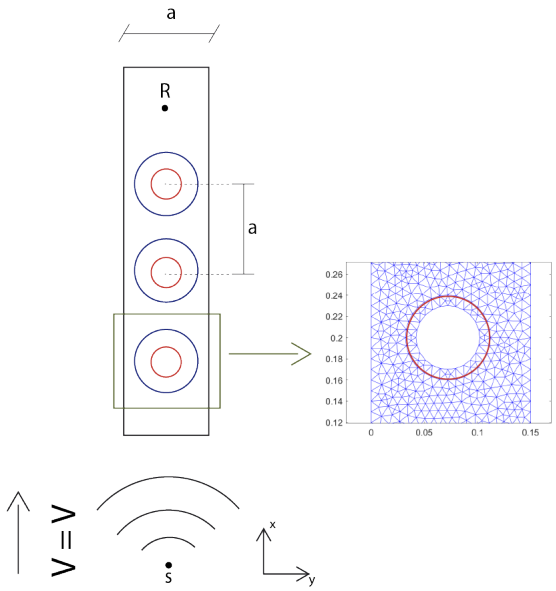

Figure 5: FEM model example for the numerical analysis.

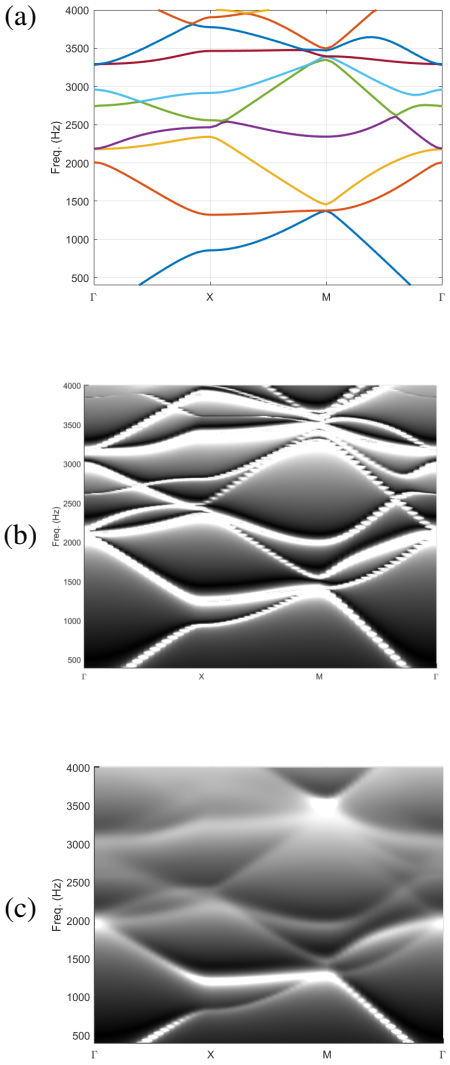

Figure 6: Dispersion relation curves for the different configurations: (a) normal eigen frequency analysis for a 8 cm rigid scatterer SC; (b) fine band analysis of a 8 cm rigid scatterer SC; (c) fine band analysis of a 6 cm rigid scatterer SC covered with 1 cm thick polyester layer.

5. RESULTS

Dispersion relation curves were obtained for both the rigid and porous cases to understand the wave propagation characteristics of the sonic crystal (SC) and identify the expected frequency range of the band gap. The rigid case was analyzed using eigenfrequency analysis, providing a direct calculation of the dispersion curves. In contrast, the porous case required a frequency-dependent approach, where each frequency was evaluated separately, and the contribution of the modes was analyzed independently.

Figure 6 presents the dispersion relation curves for both configurations. The results highlight differences in wave propagation characteristics between the two cases, with the introduction of porous material influencing the modal contributions, making them weaker. By this behavior, it is possible to expect a considerable energy reduction

starting around 600-700 Hz. These findings provide insight into the type of acoustic response expected from the SC and indicate the frequency range where attenuation effects should be most pronounced.

Experimental tests were conducted to measure the SC's acoustic attenuation performance. Figure 7 presents an overview of the microphone measurements collected during the experimental setup.

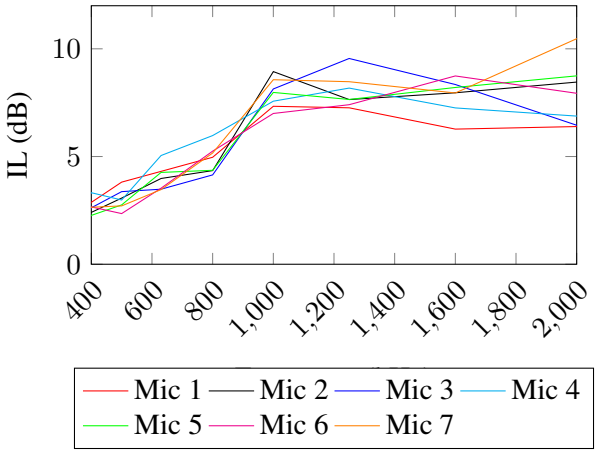

Figure 7: IL results per microphone for the absorbing layer configuration SC.

With these results, it is possible to see the contribution from both the Bragg scattering and the absorbing layer. As predicted, there is a peak of absorption between the 1000 to 1200 Hz 1/3 octave band, this is thanks to the interference caused by the rigid core. After the bandgap, the attenuation stagnates with a high value, which is approximately the same behavior as the experimental sound absorption coefficient curve visible in Fig. 3.

The IL experiments are then correlated with a FEM analysis. The results of the comparison are visible in Fig. 8

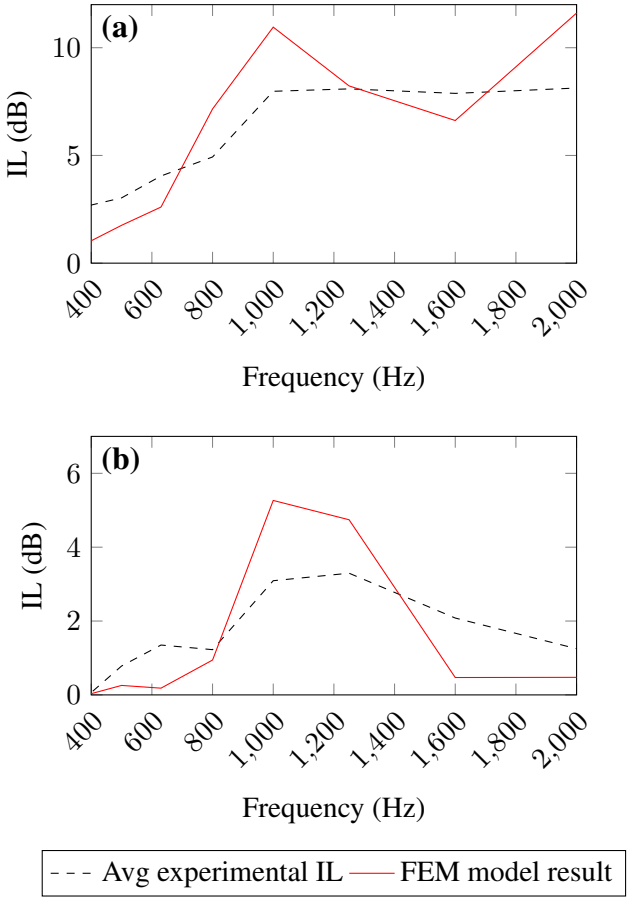

Figure 8: Average experimental IL results compared with numerical FEM results for the configurations: (a) 6 cm rigid core scatterer covered with 1 cm polyester fiber, and (b) 6 cm rigid scatterer.

The numerical results align with the experimental findings and the dispersion relation predictions, confirming the role of the porous material in enhancing sound attenuation. The simulations provide a detailed understanding of the SC's acoustic behavior, reinforcing the observed improvements in noise reduction.

The experimental results reveal key differences in insertion loss between the two cases, demonstrating the impact of the porous material on acoustic attenuation. The presence of the absorbing layer enhances attenuation, shifting and broadening the band gap, as anticipated from the dispersion analysis. These observations provide strong experimental support for the effectiveness of integrating

porous materials into the SC design.

6. FINAL REMARKS

The numerical results align closely with both the experimental findings and the dispersion relation predictions, confirming the role of the porous material in enhancing sound attenuation. The consistency of these results underscores the potential of combining porous materials with sonic crystal structures for effective noise control solutions. The simulations contribute to a detailed understanding of the SC's acoustic behavior, suggesting that this design approach could be a viable strategy for mitigating urban noise pollution, particularly from traffic sources.

ABSTRACT

Locally resonant acoustic metamaterials have shown significant potential to enhance acoustic insulation in lightweight partitions, though typically only within narrow bands. We previously developed a highly efficient numerical model of a metamaterial partition to address the coincidence dip of a single panel using equally tuned resonators. This study introduces multiresonant configurations, optimized via a genetic multi-objective algorithm, to broaden the resonators' impact on diffuse transmission loss near the critical frequency while minimizing the added mass. Comparative analyses between equally tuned and multiresonant systems are performed, evaluating both acoustic and psychoacoustic metrics to investigate the relationship between varying mass ratios and perceptual features. The findings aim to inform the design of lightweight, high-performance acoustic partitions for diverse environments.

Keywords: *acoustic metamaterials, sound transmission loss, optimization, building acoustics, sound quality*

1. INTRODUCTION

Locally resonant metamaterials have emerged as a cutting-edge solution for lightweight, high-performance sound insulation, addressing challenges where traditional methods struggle to meet environmental and mass constraints [1]. Their unique ability to manipulate wave propagation through tailored resonant structures has drawn increasing attention from both academia and industry, leading to diverse applications across multiple sectors.

Multiresonant structures have been explored as a means to enhance sound transmission loss by extending the bandwidth of attenuation. This can be achieved through the incorporation of multiple resonators within a unit cell (UC) [2] or through multimodal optimized resonators [3]. Both approaches enable the formation of multiple band gaps within a target frequency range, effectively reducing structural vibrations and noise transmission. Given the complexity of designing such systems, advanced optimization techniques —particularly topology optimization and generative inverse methods— represent some of the most promising approaches for developing realizable multimodal metamaterials [4].

This study aims to compare the acoustic performance of metamaterial-based building partitions configured with either equally-tuned or multiresonant systems, represented as independent mechanical resonators. Leveraging an efficient hybrid modeling approach, we implement a genetic algorithm for multi-objective optimization, enabling to obtain a Pareto front or set of optimal solutions. Evaluation is then conducted using both objective acoustic metrics, such as the weighted sound reduction index, and psychoacoustic metrics to assess perceptual annoyance. For this case study, we focus on single-leaf building partitions and specifically target the critical frequency dip under diffuse sound incidence.

2. MODELING AND OPTIMIZATION

To enable the optimization and psychoacoustic study of the metamaterial partition, a computationally efficient model is required. This section outlines the hybrid numerical-analytical modeling approach used to evaluate the sound transmission loss of the partition wall.

2.1 Sound Transmission Loss

The partition wall is modeled with beam elements using an efficient Finite Element (FE) model in 1D, as detailed in [5]. The host-structure consists of standard 1/2" Gypsum board panels with density $\rho = 820$ kgm^{-3}, Young's modulus $E = 3.2$GPa, Poisson's ratio $\nu = 0.262$ and loss factor $\eta = 0.1$.

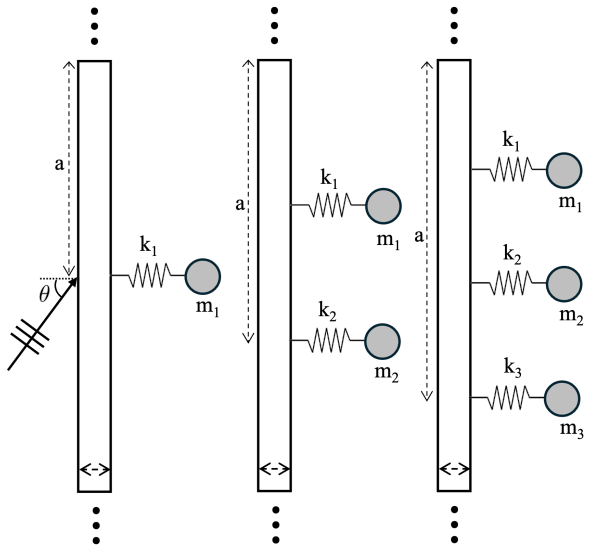

Figure 1. Representative scheme of modeled UCs.

A single unit cell (UC) is modeled using periodic Bloch-Floquet boundary conditions, which significantly reduce computational costs by limiting the domain to a representative repeating unit. Figure 1 presents a representation of the UC, illustrating three configurations: single, double, and triple resonator systems. Each resonator is represented as a vibrating spring-mass element with a single translational degree of freedom and massless attachment point.

The transmission coefficient of the periodic infinite structure, τ_∞, is determined as the ratio of radiated to incident sound pressure. The radiated pressure is approximated using the computed velocity of the vibrating panel, given by $|p_{\text{rad}}| = Z_0|v|$, where Z_0 is the air characteristic impedance and v is the velocity derived from nodal displacements. For a given plane wave incidence angle θ, the corresponding sound reduction index or sound transmission loss is obtained as $R_\theta = -10\log_{10}(\tau_\infty)$.

Although computationally efficient, R_θ is limited by its assumption of a single incidence angle and an infinitely extended structure, which does not accurately represent real-world conditions. In practical scenarios, sound waves arrive from multiple angles, interacting with a finite panel. To address this, additional analytical computations are performed to approximate a more realistic transmission loss, integrating the transmission coefficient over all incident angles

$$\tau_{\text{d}}(\omega) = \frac{\int_{\theta=0}^{\pi/2} \tau_f(\omega,\theta)\cos(\theta)\sin(\theta)\,\text{d}\theta}{\int_{\theta=0}^{\pi/2} \cos(\theta)\sin(\theta)\,\text{d}\theta}, \tag{1}$$

where $\tau_f = \tau_\infty(\sigma_R \cos\theta)$ is the transmission coefficient of the finite structure [6]. The acoustic domain is taken into account through the radiation efficiency σ_R, obtained from the real part of the normalized radiation impedance averaged over the azimuth angle [7]. A panel measuring 1.5 × 1.25 m is assumed for all computations, following ISO 10140 [8], which defines this size for laboratory measurements of sound insulation of building elements with a small test opening. Finally, the diffuse incidence sound transmission loss of the finite structure can be obtained by $R = -10\log_{10}(\tau_{\text{d}})$.

2.2 Multiobjective Optimization

Optimization is performed using a genetic algorithm with two cost functions: one aimed at maximizing the sound transmission loss R_θ around the critical frequency and another minimizing the added mass ratio M_{r}, given by the ratio between the added resonators m_r and the host structure's UC mass m_p, which can be defined as:

$$\varphi_1 = \frac{1}{\left(\int_{f_l}^{f_u} R_{\theta,\text{meta}}(f, f_{res}, M_{\text{r}}, \eta_{\text{r}}) - R_{\theta,\text{bare}}(f)\,\text{d}f\right)^2}, \tag{2}$$

$$\varphi_2 = M_{\text{r}} = m_r/m_p. \tag{3}$$

To prevent resonators from being tuned to the same resonance frequency f_{res}, constraints are imposed on the frequency range assigned to each resonator. This range is evenly subdivided based on the number of resonators in a given configuration. The optimization bounds for frequency, f_l and f_u, are set to 1500 Hz and 3500 Hz, respectively, corresponding to the typical coincidence range for gypsum board panels [5]. Additionally, the mass ratio is constrained between 0.01 and 0.5 to ensure lightweight solutions. A structural damping factor η_r of 5% is assumed for all resonators, implemented as a complex stiffness term. This value is chosen based on typical values obtained in realizable resonant elements [2].

To enhance the genetic algorithm's ability to explore the solution space thoroughly and avoid convergence to local minima, a population size of 500 is used in MATLAB's `gamultiobj` function. Optimization is performed at grazing incidence, as this approach has been shown to yield equivalent results with significantly reduced computation time in comparison to diffuse incidence optimization [5]. On average, a single run takes 45 seconds on a 10-core M1 Pro CPU. The resulting Pareto front consists of 175 solutions, as shown in Figure 2.

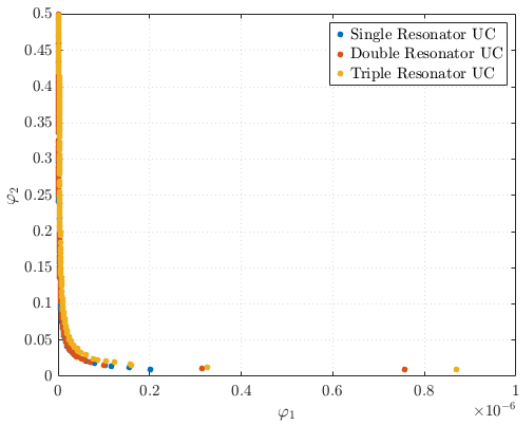

Figure 2. Pareto front of modeled UCs.

By computing the diffuse sound transmission loss for each solution point using Equation 1, the single-value rating R_w can be determined according to ISO 717-1 [9]. The resulting ratings can be then plotted as a function of the mass ratio (Figure 3) for each resonator configuration.

In terms of the weighted sound reduction index, sound insulation improves steadily with increasing mass ratio.

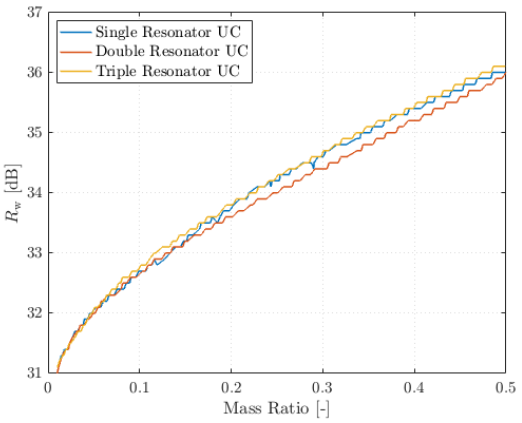

Figure 3. Weighted sound reduction index in function of mass ratio.

However, for the critical dip in gypsum board panels, the improvements achieved with multi-resonant configurations appear too small to be significant. This is because R_w accounts for the overall increase in sound insulation across one-third-octave frequency bands from 100 Hz to 3150 Hz and is not designed to capture narrowband improvements in R, such as those introduced by metamaterials. Taking the pareto optimal solution (i.e. the points of each pareto front closer to the origin) we can plot the optimal solution found for each resonator configuration (Figure 4).

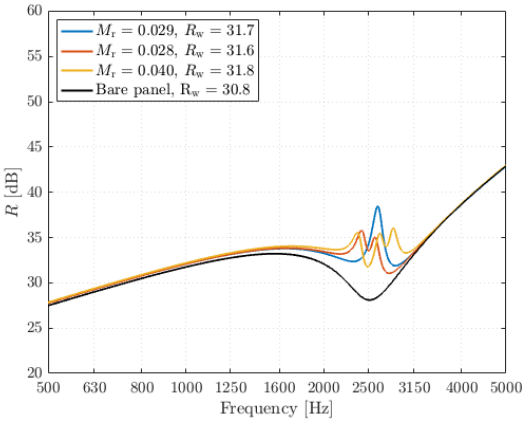

Figure 4. Sound reduction curves for pareto optimal solutions.

2.3 Sound quality evaluation

A sound quality evaluation, incorporating psychoacoustic metrics, was conducted to explore additional assessment criteria for the metamaterial partitions. The optimized Pareto front solutions were analyzed using their random incidence curves, computed across the complete audible range with a 10 Hz frequency resolution.

The impulse response for each solution point was obtained by applying an inverse Fourier transform to the transmission magnitude. A random phase spectrum, generated from precomputed values between 0 and 2π, was added to the transmission spectrum to ensure a more accurate translation of the signal into the time domain [10]. Finally, the impulse response was convolved with a pink noise signal.

For this study, the Psychoacoustic Annoyance (PA) metric was employed, as it integrates multiple perceptual attributes —including loudness, tonal characteristics, and temporal structure— into a single measure [11]. It is calculated as:

$$\mathrm{PA} = N_5 \left(1 + \sqrt{w_S^2 + w_{FR}^2}\right) \tag{4}$$

$$w_S = \begin{cases} (S - 1.75) \cdot 0.25 \log(N_5 + 10) & S > 1.75 \\ 0 & S \leq 1.75 \end{cases} \tag{5}$$

$$w_{FR} = \frac{2.18}{N_5^{0.4}}(0.4F + 0.6R) \tag{6}$$

where N_5 is the percentile loudness in sones, S is the sharpness metric, F the fluctuation ratio, and R the roughness metric. These psychoacoustic metrics were computed using MATLAB according to ISO 532-1 [12], and a virtual calibrated microphone with a 1 kHz reference signal assuming a SPL meter reading of 84 dB.

The computed annoyance values plotted against the mass ratio, are shown in Figure 5. Across all configurations, annoyance levels were lower than those of the bare panel. For mass ratios below 5%, the configurations exhibited similar annoyance values. However, as the mass ratio increased, differences became more pronounced. Notably, the triple-resonator configuration achieved the greatest reduction in annoyance, with its advantage becoming increasingly significant at higher mass ratios.

Beyond a 20% added mass ratio, perceived annoyance plateaued —unlike the single-value rating, which suggested a steady improvement in sound insulation with increasing M_r. This discrepancy can be attributed to the trend in loudness (Figure 6), as loudness carries the highest perceptual weighting in annoyance calculations. Additionally, higher M_r values lead to a more pronounced dip in insulation following the resonators' peak performance. This trend is reflected in the Sharpness metric, which consistently increases with M_r across all configurations.

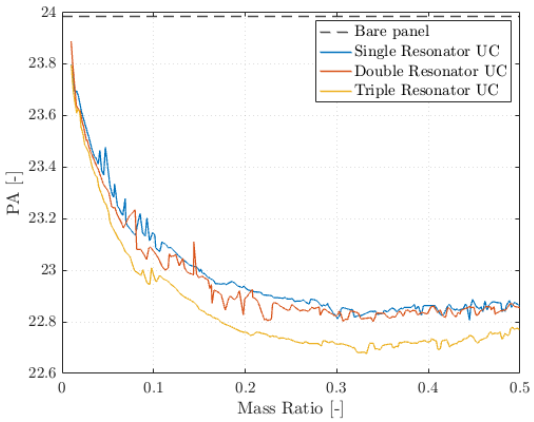

Figure 5. Zwicker's Annoyance metric of the optimized metamaterial panels.

3. CONCLUSION

This work presents an efficient modeling and optimization approach for a partition wall with multiple local resonators, designed to enhance sound insulation around the critical frequency while minimizing the added mass ratio. Additionally, psychoacoustic metrics are introduced as an evaluation tool, complementing traditional single-value ratings by providing deeper insights into specific configurations. This holistic approach is particularly relevant for applications where human acoustic comfort is a priority. Future research could explore additional psychoacoustic metrics and their integration into the optimization process.

ABSTRACT

We present a proof-of-concept experiment demonstrating the efficient noise absorption of a 3-D printed metamaterial panel. The panel consists of an arrangement of unit cells designed using a fractal-inspired geometry from which a relation between the level of iteration and resonance frequency is derived. An analytical model and numerical simulations are used to study the absorption characteristics of the single labyrinthine units, and optimization methods derived from the causality principle are employed to find the optimal arrangement of unit cells to enhance the absorption performance in the low frequency range ($\sim$ 300 Hz). The performance of the panel is experimentally validated in fully anechoic room, using an impulsive sound source separation technique. Results show close to ideal values of absorption at the desired frequency of operation in a subwavelength regime with a wavelength to thickness ratio of 27.5 for a panel 50 mm thick. This work suggests a design procedure for noise-mitigation panel solutions and provides experimental evidence of the versatility and effectiveness of hierarchical coiled-up metamaterials in providing tunable low-frequency sound attenuation with relatively thin structures.

1. INTRODUCTION

Acoustic metamaterials (AMs) have gained growing attention because of their exotic properties, which are not found in naturally occurring materials. AMs design parameters offer the possibility of developing a new generation of acoustic absorbers and diffusers tailored for a desired frequency spectrum and with sub-wavelength sizes [1] and low-frequency absorption [2]. AMs are thus able to achieve high performance in terms of noise reduction, and simultaneously reduce the size and weight of structures [3], going beyond the limitations of conventional technologies based on porous absorbers or resonant structures coupled with air [4]. AMs are employed as acoustic sound absorbers with which perfect absorption can be obtained at their resonance frequency, by design. This occurs for a critical coupling condition: thermo-viscous losses are exactly balanced by energy leakage [5]. Thus, to extend the effect on a broader frequency range, the design concept of 'rainbow trapping' is exploited combining acoustic resonators with variable parameters, and hence working frequencies [6] or systems with asymmetric porous absorbers [7].

With the aim of reducing the volume occupied by these AM absorbers, 'labyrinthine' or 'coiled' structures were brought up [8, 9]. These are based on exploiting acoustic wave propagation in curved channels of sub-wavelength cross-section, giving rise to an extremely high effective refractive index (and thus to a decrease of the effective wave speed). Fractal inspired design with the aim of tuning the resonance frequency range, reducing the volume encumbrance have been investigated and experimentally characterized [9–11]. Thus, labyrinthine and space-filling AMs have provided a very

convenient and efficient way to achieve sound control in large frequency ranges, especially in the subwavelength regime, by tuning geometrical design parameters (e.g. channel tortuosity or elongation and cavity size). This kind of adaptability could largely benefit noise absorption applications at small to medium scale, in comparison with thick conventional acoustic absorbing materials. At present, few studies in the literature have presented detailed acoustic characterization studies on large structures such as metamaterial-based panels, and none on labyrinthine ones, to the best of our knowledge. Further, the need emerges to investigate labyrinthine AM performance on structures that are closer to potential operating conditions, i.e. in free field.

2. METHODS

2.1 Unit cell design

The design of the Unit Cell (UC) shown in fig. 1a corresponds to the second iteration of the Wunderlich curve. This system can be simplified to two connected waveguides of different cross section for the orifice and the coiled-up channel. While the orifice acts as a pore, the channel works as a quarter wavelength resonator and its resonance frequency can be computed as $f_0 = 4c/L_{eff}$, where $c = 343$ m/s is the speed of sound in air, and L_{eff} is the effective length of the tube. With the same design principle of [9], a 3D UC is designed (fig. 1b). Due to the narrower size of both the orifice and the channel compared to the wavelength, thermoviscous losses have to be taken into account. These physical dissipation mechanisms effectively absorb sound energy, leading to perfect absorption when they are balanced by the acoustic energy leakage by radiation from the UC: the matching of the two correponds to the critical coupling condition [5]. Thus combining the Stinson's and Johnson-Champoux-Allard models for the coiled-up channel and the orifice, respectively, we can compute the impedance Z_s at the aperture of the UC, from we which we can compute the absorption spectrum:

$$\alpha = 1 - \left| \frac{Z_s - Z_0}{Z_s + Z_0} \right|^2, \qquad (1)$$

where Z_0 is the characteristic impedance of air. A parametric study of the analytical model is carried out (fig.1c) to study the dependence of maximum sound absorption on the edge size a, ranging from $20-60$ mm, and the aperture cross section t from approximately $10-50$ mm. From this four-parameter map a UC of size $a = 20$ mm and $t = 15$ mm is selected and numerically characterized, showing good agreement with the analytical prediction (fig.1d).

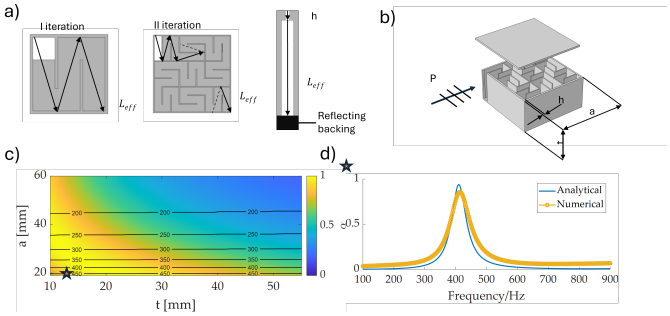

Figure 1. (a) Exploded view of the UC and its lid. (b, left) Top view of the coiled up structure and effective length path with (right) schematic of its equivalent model. (c) Four parameter map of absorption peak as a function of the UC cell size a and thickness t

2.2 Panel design and fabrication

Establishing the target frequency for sound absorption around 300 Hz, we use analytical data to design the sound absorption panel. This can be achieved by exploiting various UCs of different effective length, corresponding to different resonance frequencies arranged in a exponential progression, to maximize the absorption spectrum over the target frequency range [3]. An AM panel is thus designed, consisting of differently sized UCs. The internal wall thickness of each UC is 2 mm and their height of 20 mm. 6 UCs have been selected with edge size a ranging from 38.5 to 40.2 mm and assembled together in a row, as shown in fig. 2a. The complete panel consists of the combination of 87 macro-cells arranged in the plane (2b), to total size of $775 \times 640 \times 43$ mm. The UCs are selected so as to provide different absorption peaks, whose superposition provides a wider working frequency spectrum in the chosen target frequency range. The overall impedance of the panel can be calculated as the combination in parallel of the impedances of the single UCs. The polyamide panel is then manufactured through selective laser sintering (SLS), a technique where each level is sintered by a laser beam, directed by a scanning system. The process is repeated, and the prototype is built layer by layer.

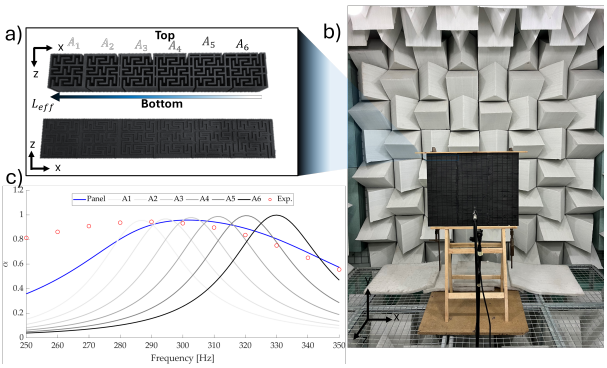

Figure 2. (a) Top and bottom view of the macrocell featured by 6 UCs of different edge size, i.e. L_{eff}. (b) Experimental setup in anechoic chamber. (c) Absorption spectra analytical prediction compared with the experimental result.

2.3 Experimental determination of sound reflection characteristics

In order to measure the performance of the hierarchical panel in a free field condition, all measurements were performed in a fully anechoic room. The setup consisted in placing the panel and the loudspeaker in front of each other and fixing their respective position. Then, between the panel and the loudspeaker, a grid of microphones should be placed, in order to measure the scattered field from different positions and take account of the boundary effects such as the diffraction by the edge of the panel. In our case, repeated measurements with a single microphone were made, placing it at each respective point of the grid, in order to have an equivalent system. The position of the panel and the microphone in the anechoic room can be seen in figure 2b. The measurement grid points were chosen along the horizontal and vertical middle line of the panel. The input signal sent to the loudspeaker consisted of three consecutive exponential sweeps, each generated according the the following function:

$$x(t) = \sin\left[2\pi f_1 \exp\left(\frac{N f_s \ln(f_2/f_1)}{T} t\right)\right] / f_s \,, \quad (2)$$

where f_s is the sampling rate, f_1 and f_2 are the start and end frequencies of the sweep, N is the length of the signal and T is the sweep duration.

2.4 Signal processing

Once the output signal $y(t)$ is measured, some processing must be done to get the reflection index of the panel.

First, for each microphone placement, three consecutive sweeps were sent. By performing a cross-correlation with the input signal, we could synchronize and cut the sweeps in order to perform an average, removing a significant amount of noise. The signal was then deconvoluted to obtain the impulse response $h(t)$ by means of a convolution with the inverse sweep defined as:

$$x_{\text{inv}} = x(-t) \exp\left[-\frac{t}{T} \ln\left(\frac{f_2}{f_1}\right)\right]. \quad (3)$$

For obtaining the reflected field without the contribution of the incident field, we used the signal subtraction technique. It consists in subtracting the free field impulse response to which an appropriate amplitude correction has been applied, to the scattered field impulse response.

In order to avoid unwanted reflections, an Adrienne window composed of a leading edge having a left Blackman-Harris shape, followed by a flat portion and closing with a trailing edge having a right Blackman-Harris shape was applied to the impulse response. With that, we were able to compute the Fast Fourier Transform (FFT) of both the incident and the reflected fields in order to get the Frequency Response Functions (FRF) $H_{i,k}(f)$ and $H_{r,k}(f)$ for each measurement point k of the incident and reflected fields respectively.

The reflection index is calculated as follows:

$$R(f) = \frac{1}{n} \sum_{k=1}^{n} \left[\frac{|H_{r,k}(f)|^2}{|H_{i,k}(f)|^2} C_{\text{geo},k}\right] \quad (4)$$

where the correction factor for geometrical divergence $C_{\text{geo},k}$ is:

$$C_{\text{geo},k} = \left(\frac{d_{r,k}}{d_{i,k}}\right)^2, \quad (5)$$

and $d_{i,k}$ is the distance from the front panel of the loudspeaker to the k-th measurement point and $d_{r,k}$ is the distance from the front panel of the loudspeaker to the source and microphone reference plane and back to the k-th measurement point following specular reflection.

Finally, he absorption coefficient of the panel is simply:

$$\alpha = 1 - |R|^2. \quad (6)$$

3. RESULTS

The absorption coefficient has been calculated analytically and measured experimentally in the range of frequencies where the largest absorption was expected. The length of the unit cells were tuned for the absorption peaks of the quarter-wavelength resonators to cover a the interval of 280 to 330 Hz as shown in figure 2c. Experimentally, the panel has a wide peak at the same interval with perfect absorption close to 290 Hz, shown by the red dots in figure 2c.

Indeed, the panel has a thickness of the order of 50 mm, and it can absorb acoustic waves of wavelength $\lambda = c/f$ of the order of one meter. With a wavelength to thickness ratio of ≈ 27.5 at the frequency for perfect absorption, the resonator shows sub-wavelength absorption properties, covering a range of about 50 Hz around the perfect absorption frequency before the absorption decays.

4. CONCLUSIONS

The present work shows the effectiveness of the designed panel in terms of broadband, low frequency, subwavelength absorption. The conception based in labyrinthine quarter-wavelength resonators optimizes their length to a limited surface area, allowing for low-frequency absorption capabilities in a limited space. The arranged design broadens the absorption spectrum while maintaining the width of the panel. Analytically, the design features of the panel were determined and tuned to achieve perfect absorption in the wanted frequency range. A polyamide panel was built, and, using a microphone measurement grid in an anechoic room and proper signal processing, we observed how the panel exhibits perfect absorption close to the analytical target frequency range, with a high wavelength to thickness ratio of about 27.5 confirming the subwavelength quality of the design.

THE INFLUENCE OF SAMPLE SIZE ON THE RESULTS OF SOUND INSULATION MEASUREMENT CONDUCTED IN SMALL COUPLED REVERBERATION ROOMS

Dorota Młynarczyk[1*] **Katarzyna Baruch-Mazur**[1] **Agata Szeląg**[1]
[1] Cracow University of Technology, Poland

ABSTRACT

The paper presents the results of acoustic insulation measurements conducted in a unique small size coupled reverberation rooms. The volumes of the rooms are approximately 1.36 m³ each, which imply a lower measurement range limit of 400 Hz for the actual dimensions of the samples (and 50 Hz for 1:8 scale testing). Aim of the research was to evaluate the measurement setup and assess its suitability for studying the properties of various types of material including metamaterials. The influence of sample size and geometry on measurement outcomes was analyzed by comparing four square windows of side lengths equal 8.5, 17.5 cm, 35 cm and round 65 cm, and two rectangular windows of dimensions equal 12.5 × 25 cm and 25 × 50 cm. Five samples of different materials with various thicknesses selected to have diverse properties affecting wave propagation were studied: steel 0.6 and 1 mm thick, PMMA 3.8 mm thick, MDF 3.2 mm thick, Sylomer (HD 100) 12.5 mm thick and gypsum board 12.5 mm thick were measured. The analysis showed that the influence of the size and shape of the window on the obtained insulation coefficient dependent on the test frequency and the stiffness of the sample material.

1. INTRODUCTION

In laboratory acoustic testing of the sound insulation properties of materials and structures, three standardized methods can be used [1]. The first involves measuring the sound reduction index (R) of a sample placed between two reverberation rooms. The second method also uses the sound reduction index (R), where the sample separates a source room with a free-field condition from a receiving room with a reverberant field. The third approach is based on the measurement of transmission loss (TL) in an impedance tube. The article focuses on the research of the sound reduction index (R) using coupled reverberation rooms.

The measurement of the sound reduction index (R) using coupled reverberation rooms is described in the ISO 10140 series of standards, from part 1 to part 5. For material testing in full size reverberation rooms, the standard requires the use of a sample with a surface area of 10 m^2. Various methods of mounting the sample and sealing are also recommended [2]. In the literature, there is little information on the influence of sample size and shape on the results obtained. Wareing et al. demonstrated that sample size can significantly affect sound transmission loss, depending on the construction of the tested element [3]. In a subsequent study, the authors observed that smaller samples exhibited higher sound transmission loss at frequencies below the coincidence frequency [4]. On the other hand, study made by Mleczko remarked that small baffles have lower sound insulation compared to the large baffle [5]. The differences noted are more significant in the case of the square-shaped baffle. However, the author himself points out that the study should be expanded with more samples and repetitions. Therefore, the aim of this study is to address the gap in the literature by examining how different sample sizes and shapes affect the sound

reduction index measured in small size coupled reverberation rooms.

2. METHODS

The tests were performed on a unique small size coupled reverberation room [6, 7]. The stand consists of two reverberation rooms, each with a volume of 1.36 m³, designed as irregular hexagonal enclosures constructed from 20 mm thick plexiglass panels. The stand is a 1:8 scale of the coupled reverberation rooms located at AGH University of Science and Technology [8]. The rooms are connected by a shared wall that includes measurement windows for mounting test samples. The dimensions of the windows and corresponding measurement samples are summarized in Table 1.

Table 1. Measurement windows and samples shape and size.

Sample No.	Sample Shape	Sample Size [cm]
1	square	8.5 x 8.5
2	square	17.5 x 17.5
3	square	35.0 x 35.0
4	square	65.0 x 65.0
5	rectangular	12.5 × 25.0
6	rectangular	25.0 × 50.0

For investigating the influence of sample size on sound insulation measurement results in smallcoupled reverberation rooms, a selection of materials was made to encompass a wide range of thicknesses, internal structures, and, most importantly, diverse properties affecting wave propagation. The tested materials included:

- Steel – thicknesses: 0.6 mm;
- Steel – thicknesses: 1.0 mm;
- PMMA (Polymethyl methacrylate) – thickness: 3.8 mm;
- MDF (Medium-density fibreboard) – thickness: 3.2 mm;
- Sylomer (HD 100) – thickness: 12.5 mm;
- Gypsum board – thickness: 12.5 mm.

The sound reduction index (R) was measured in accordance with ISO 10140-4 [2] within the frequency range of 400–20,000 Hz. The test sample was mounted in the measurement window, securely pressed against the frame, and sealed with putty to prevent leakage.

3. RESULTS

This section presents the results of sound reduction index (R) measurements conducted for samples of various sizes and shapes. The aim was to evaluate how these parameters influence the measured acoustic insulation performance. Selected data sets are shown to illustrate the observed trends and differences. The full dataset was analyzed for consistency and repeatability across repeated measurements.

Each sample was measured three times. For each repetition, the sample was removed and reinserted into the measurement opening, then carefully resealed with putty. As part of the study, all results were compiled for each measurement opening and for each sample material across different opening sizes.

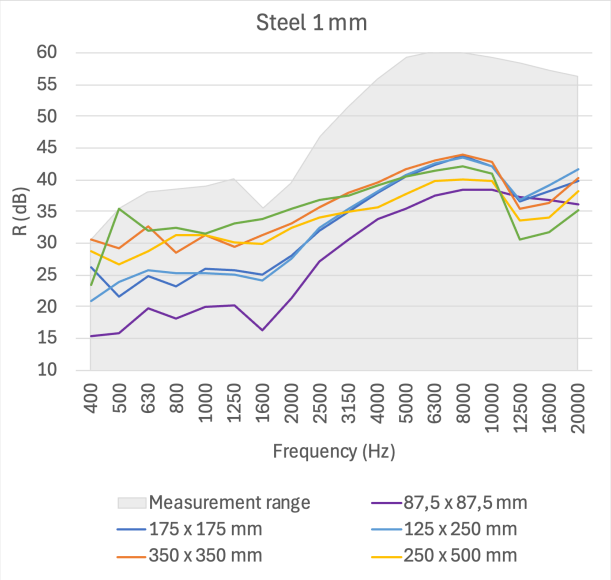

Figure 1. Sound reduction index (R) measured for a 1 mm thick steel sample of various shapes and sizes: 8.5 cm × 8.5 cm, 17.5 cm × 17.5 cm, 35cm × 35 cm, 65 cm × 65 cm, 12.5 cm × 25 cm and 25 cm × 50 cm.

This article presents selected sets of the test results. Figure 1 shows sound reduction index (R) measured for a 1 mm thick steel sample of various shapes and size.

The analysis of the sound reduction index (R) for steel samples with a thickness of 1 mm, tested in openings of varying sizes, revealed a significant influence of sample size on the measurement results. Above the coincidence frequency, an increase in sample size corresponds to a decrease in R, whereas below this frequency, larger samples exhibit higher R values. A similar trend was observed for the other tested materials, including steel samples with a thickness of 0.6 mm, PMMA with a thickness of 3.8 mm, MDF with a thickness of 3.2 mm, Sylomer HD 100 with a thickness of 12.5 mm, and gypsum board with a thickness of 12.5 mm. For clarity and conciseness, the results and analysis presented here are based on the 1 mm steel samples as a representative example.

4. CONCLUSIONS

The study demonstrated that the influence of window size and shape on the measured sound reduction index depends both on the test frequency and the stiffness of the sample material. In the case of the steel samples, a clear correlation was observed between sample size and R values, with the direction of this effect varying depending on whether the frequency was above or below the coincidence frequency.

These findings are more consistent with the observations made by Mleczko [5], who reported lower sound insulation for smaller baffles, particularly in square configurations. In contrast, the results diverge from those reported by Wareing et al. [4], especially in the context of frequencies below the coincidence frequency. This suggests that the relationship between sample size and sound insulation may be more complex than theoretical assumptions typically indicate and is likely influenced by factors such as boundary conditions and panel stiffness.

ABSTRACT

Locally resonant metamaterials (LRMs) are promising lightweight solutions for targeted vibration attenuation, achieved by incorporating resonant elements on a sub-wavelength scale into a host structure. However, manufacturability limitations form a major hurdle in their industrial adoption. Additive manufacturing offers design versatility but lacks industrial-scale throughput, while high-throughput techniques such as laser cutting or punching of resonators often require labor-intensive assembly steps to create the LRM. Furthermore, manufacturing-induced deviations in geometry and material properties can significantly impact the vibro-acoustic LRM performance, often necessitating multiple design iterations. This study addresses these challenges by proposing the high-throughput injection moulding process while accounting for process-induced influences on the LRM performance using a process simulation-informed design workflow. Injection moulding enables robust and large-scale manufacturing, whereas dedicated process simulations allow incorporating manufacturing process influences in the vibro-acoustic performance predictions. This work therefore presents the design, manufacturing and experimental validation of an injection moulded LRM demonstrator to treat a noise radiation problem around a targeted vibration mode of an aluminum pipe. The achieved vibration reduction and good agreement with the model-based predictions demonstrate the strong potential of injection moulding for the mass-manufacturing of LRMs with targeted performance.

1. INTRODUCTION

The machine and transportation industries are increasingly adopting lightweight design to reduce material use, energy consumption and environmental impact. However, the resulting lightweight structures often come with deteriorated noise and vibration characteristics, impacting our health and well-being. As

[*] ***Corresponding author***: kristof.steijvers@kuleuven.be

a solution, locally resonant metamaterials (LRMs) are currently investigated [1]. They allow for targeted frequency zones with strong vibration attenuation, so-called stop bands. These resonance-based stop bands result from the addition of resonant elements on or into a flexible host structure on a sub-wavelength scale [2].

LRMs are typically composed of periodic assemblies of identical unit cells (UC). Although periodicity is not strictly necessary for resonance-based stop bands, this facilitates the use of periodic structure modelling to predict wave propagation and stop bands early in the design stage. Dispersion curves are typically calculated from a finite element (FE) model of the representative periodic UC, combined with Bloch-Floquet periodicity boundary conditions [2].

Building upon these prediction tools, the potential of LRMs has been widely explored and demonstrated through many conceptual LRM realizations. Nevertheless, the manufacturing of LRMs is found to be challenging since the integration of resonant elements often leads to geometrically intricate geometries. Consequently, additive manufacturing (AM) has become a strong enabler in the manufacturing of LRMs. However, additive manufacturing techniques currently do not reach the throughput for commercial applications [3]. In attempts to transition towards more mass-manufacturing suited processes, laser cutting and milling have been used to produce separate resonators. Moreover, LRM structures have been manufactured using thermoforming and punching [4], requiring a post-production milling or bending step to realize the resonators. Recently, the injection moulding (IM) has been proposed for the manufacturing of resonators [5] [6]. This process comes with low costs when used for mass-manufacturing and allows achieving lower process variability in terms of dynamic LRM response compared to AM [5].

Besides the difficulties to manufacture LRM geometries, manufacturing processes also affect their geometry and material properties. Consequently, the final LRM geometry and material properties often deviate from the initial design, leading to off-design LRM performance. In case of AM, large deviations in the material properties together with anisotropy and geometric inaccuracies have led to off-design LRM stop bands [4]. In forming and bending processes, the stiffness and local density of the sheets is strongly affected by the difficult to control local thinning during forming. These effects significantly affect the resonator eigenfrequencies and, consequently, the resulting stop band. To achieve the desired LRM performance after manufacturing, design and material property updating is currently performed in iterative design steps. In case of the IM process, dedicated IM process simulations have been proposed to predict and account for process influences during the LRM design phase [7]. It is shown that for three different resonator geometries, manufactured in two materials, incorporating IM process simulations in the LRM design flow significantly improves the eigenfrequency predictions.

In view of practice-oriented solutions, LRMs have been often demonstrated as add-on resonators or resonator patches which can be applied to existing host structures. This is often more appealing to industry since it allows for LRM demonstration of existing products and machinery. For example, laser-cut resonators have been manufactured and manually glued to plates, and pipes [8] in academic demonstrators. Similar approaches have been reported to attach resonators manufactured with IM in [5].

Although successful IM mass-manufacturing of resonators with reduced off-design performance has been demonstrated, prior work has focused mainly on basic resonator geometries. This study advances the state-of-the-art by leveraging IM together with process simulation-informed LRM performance predictions to realize and validate a mass-manufacturable ready-to-use LRM solution for vibration mitigation in pipes. This allows to align the envisaged performance during LRM design and the as-manufactured performance and so reduces possible design iterations. As a demonstrator case, a aluminum tube similar to the one used in [8] is selected for targeted vibration attenuation around a dominant radiating mode. To facilitate LRM assembly, a snap-fit connection is integrated.

2. PROBLEM DESCRIPTION

The demonstrator targets an acoustically relevant ovalling mode in an aluminum pipe, inspired by [8]. An experimental modal analysis (EMA) is performed for modal identification and FE-model updating.

2.1 Experimental modal analysis

An impact hammer test is conducted to experimentally characterize the modal behavior of the pipe. To this end, the pipe is divided into a regular grid of 88 measurement points. The grid consists of 11 measurement points along the pipe's length, which are axially patterned 8 times around the circumference leading to a 45 degree shift between each measurement array. The pipe is suspended

in a free-free configuration and excited at each point using a PCB 086C03 modal hammer in a roving hammer sequence. The radial acceleration response is captured in measurement point 1 (0°, 0 mm length) and 29 (45°, 600 mm length) using two PCB ICP lightweight accelerometers. The point-to-point FRFs are calculated over 5 averages in Siemens Simcenter Testlab using the H_v approach. To avoid leakage, an exponential decaying window is applied to the excitation signal while a Hanning window is applied to the response signal.

2.2 Numerical eigenmode calculations

In order to accurately predict the LRM performance, a representative numerical host structure model is desired. To this end, a structural dynamic FE model of the host structure is created in Siemens Simcenter to calculate both the undamped eigenfrequencies and the acceleration response under force excitation. Specifically, a quadratic CQUAD8 shell mesh with an element size of 10 mm is applied to the pipe's midsurface. The pipe dimensions and mass are measured and listed Table 1. The pipe's real eigenfrequencies and forced response are calculated over a frequency range of 50-1200 Hz. For the latter, a normal unit force is applied at the first measurement point location, and the acceleration response is measured at all other measurement points. The predicted eigenfrequencies and forced response are compared to the experimentally determined modal frequencies and FRFs, whereafter the Young's modulus of the aluminum (69 GPa) is updated to the value of Table 1 to obtain good agreement between the numerical eigenfrequency of the first ovalling mode and the corresponding experimental value.

Table 1: Main dimensions and material properties of the targeted pipe host structure.

Length [mm]	1002	Young's Modulus [GPa]	81.8
Outer diameter [mm]	100.25	Density [kg/m^3]	2711
Wall thickness [mm]	2	Poisson ratio [/]	0.33
Mass [g]	1742.4		

Comparing the experimentally and numerically obtained FRFs (Figure 1a), three eigenfrequencies are identified in the frequency range under 1000 Hz. Figure *1*b, presents an overview of the FE-based real eigenmodes and the modal displacements obtained through the EMA at the peak frequencies. For the first frequency of 582 Hz, the ovalling and torsional mode are present, both of which were also identified from the EMA deformation pattern around 581 Hz. At 627 Hz, an ovalling pattern is observed, varying along the axial direction, in superposition with the first pipe bending mode. A similar modal deformation is observed in the EMA at approximately 620 Hz. Around 825 Hz, both the simulation and EMA show a similar out-of-plane behavior of higher order.

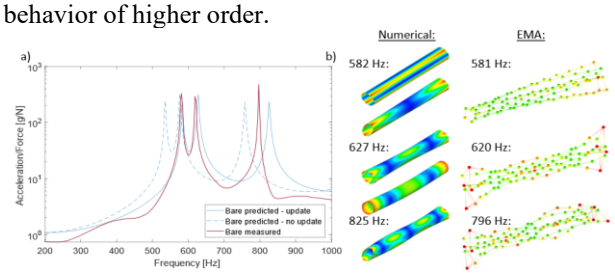

Figure 1: a) Comparison of the experimentally obtained and numerically predicted FRF of the bare pipe, b) numerically obtained real eigenfrequencies and experimentally obtained model displacement patterns at the determined resonance frequencies.

3. IDEALIZED METMAMATERIAL DESIGN

To design an LRM for targeting the first ovalling tube mode, both the LRM's vibro-acoustic performance and the IM manufacturability must be taken into account. Therefore, an idealized LRM design is optimized for a suitable eigenfrequency and hence stopband location, together with a maximized Modal Effective Mass (MEM) to increase the stop band width [2]. For three different designs resulting from the optimization, the IM manufacturability is assessed separately in Section 4.

3.1 Snap-fit ring concept

For the LRM design, eight resonant elements will be used, placed over each 45 degrees of the pipe circumference, in accordance with [8]. Whereas in this work the resonators have been manually glued to the host structure, a punched out add-on ring shaped concept has been shown in [4]. These rings allow to assemble multiple resonators simultaneously which reduces the risk op resonator misalignments, which potentially influence the final LRM performance. However, the resonator masses were still glued manually, hindering cost-effective series production. Building upon these studies, the proposed LRM in this work consists of two

identical ring sections with each four evenly distributed integrated resonators as illustrated in Fig. 2a. The ring sections can be assembled around the pipe using a snap-fit mechanism to form a closed ring. This simplifies LRM assembly by eliminating additional components. Furthermore, by moulding only half a ring at a time, the required mould size, melt volume and clamping force can be reduced, reducing the overall cost. As a result, the moulded product is ready-to-use, requiring no additional components for LRM assembly.

3.2 Resonator tuning and optimization

To create the resonance based stop band, an often-used cantilever beam type resonator is selected and adapted for integration on the ring base, targeting the first out-of-plane eigenmode. Fig. 2a,b show the design dimensions and the targeted first flexural eigenmode for a clamped ring circumference. The parameterized resonator dimensions are optimized towards a maximum MEM for the targeted eigenmode. The frequency tuning range was set around the ovalling frequency of the tube between 560-600 Hz, still allowing for a small misalignment to increase the design freedom. An exact tuning is in this stage redundant since the design will later still be tailored for IM manufacturing. Parameter ranges are set for the eight main resonator dimensions (Table 2). For these ranges, specific IM design rules are already accounted for. For example, wall thicknesses are kept under 4 mm to prevent voids caused by high shrinkage. Moreover, X_{Mass} is already set equal to X_{Leg} to facilitate filling during IM manufacturing. Lastly, the thickness of added ribs should not exceed 60% of the base structure thickness. In case the resonator is seen as a pure rib, the Y_{Leg} parameter would be highly restricted. However, the resonator is not a typical rib which is attached to the base structure over the entire rib length, therefore, this rule is not already incorporated. The selected material is ABS NOVODUR P2H-AT from INEOS (E = 2240 MPa, ρ = 1050 kg/m^3 , ν = 0.4). The optimization is performed using the hybrid adaptive SHERPA algorithm in Siemens Simcenter HEEDS across 400 designs. The objective function is formulated as follows:

Maximize MEM,

Subjected to:

$$560\ \text{Hz} \leq F_1 \leq 600\ \text{Hz}$$

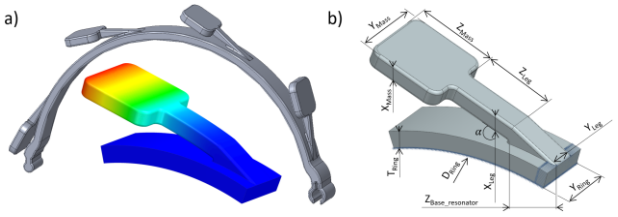

Figure 2: a) Conceptual LRM ring section with snap-fit mechanism, b) main dimensions of the LRM ring and resonator, c) targeted first out-of-plane eigenmode.

Three designs with high MEM are selected and will be evaluated for manufacturability in the following section. Table 2 lists the obtained dimensions, eigenfrequency and MEM for these designs. For all three designs, the resonator dimensions Y_{Mass} and Z_{mass} are maximized, as expected from the objective. The main differences between the designs relate to the resonator angle α, the cantilever beam length Z_{Leg} and the cantilever beam width Y_{Leg}. For design 2, the high MEM is obtained due to the high value of Y_{Leg}, whereas both the MEM and Y_{Leg} are smaller in design 3. Comparing design 2 to design 1, the steeper resonator angle in design 1 leads to only a minor difference in performance. Although design 2 offers the best MEM, it is the further away from the targeted ovalling eigenfrequency at 582 Hz.

Table 2: Baseline, min and max value of the design parameters for the optimization, followed by the obtained dimensions, eigenfrequency and MEM for the three selected designs.

Parameter	Baseline	Min	Max	Design 1	Design 2	Design 3
Y_{Ring}	8	4	10	10	10	10
$Z_{Base_resonator}$	7	3	10	7	10	8
α	95	85	100	95	85	95
Z_{Leg}	18	10	25	17	17	14
X_{Leg}	3	2	3.5	3	3	3
Y_{Leg}	6	3	Y_{Ring}-1	8	8	5
X_{Mass}	X_{Leg}	-	-	3	3	3
Y_{Mass}	9	Y_{Leg}+3	14	14	14	14
Z_{Mass}	8	8	14	14	14	14
D_{Ring}	100.5	-	-	100.5	100.5	100.5
T_{Ring}	3	-	-	3	3	3
			Mode 1 [Hz]	570.1	568.5	575.6
			MEM [g]	0.69	0.7	0.62

4. LRM MANUFACTURABILITY AND MOULD

In this section, the idealized design is further assessed and tailored for IM manufacturing by taking into account

IM related process effects such as the volumetric shrinkage. The optimal resonator design is selected and the mould design and LRM manufacturing are explained.

4.1 Manufacturability assessment of the resonator

The IM process requires specific design guidelines to enhance mouldability and avoid defects such as sink holes, part warpage and internal stresses. These effects relate to the filling, packing and cooling steps of the IM process. During the filling stage, a speed controlled forward motion of the screw ensures precise injection. When the mould cavity is almost filled, the process transitions from speed to pressure regulation at the switch-over point. From this point, a defined packing pressure is maintained at the back of the screw to fill the remainder of the cavity and compensate for material shrinkage during part solidification. Here, the available packing time strongly depends on the part solidification, thin sections like the resonator leg might solidify rapidly, hindering material entrance in thicker part sections such as the resonator mass. When the packing is finalized, the screw retracts, preparing the next shot of material while the part continues to cool.
To predict the filling, solidification and shrinkage of the resonator, commercial IM simulations are used [7]. The process settings are set to rule of thumb starting values. More specifically, the injection speed is set to 40 cm^3/s and a packing pressure is held for 10 seconds at a level of 80% of the maximum filling pressure. The melt and mould temperature are set to 240 °C and 60 °C, respectively, in accordance with the material datasheet. The resulting volumetric shrinkage and solidification time are assessed for the three resonator geometries. The volumetric shrinkage is used to compare the designs' sensitivity for sink marks, while the solidification time provides an estimate of the available packing time.

4.2 Resonator mouldability

Fig. 3 illustrates the maximum volumetric shrinkage and molten core at the time step that the first design has a fully solidified cross section, after 17 seconds of cooling. Design 1 and 2 exhibit higher volumetric shrinkage at the resonator base compared to design 3, which is attributed to the larger Y_{Leg}. This indicates a higher risk of sink marks after manufacturing. In design 3, the risk of sink marks is reduced at the expense of a lower MEM due to the lower $Y_{Resonator}$ parameter. From the molten core values, the resonator arm of design 3 freezes around 17 seconds, while design 1 and 2 still have a molten connection between the ring and the resonator mass. Therefore, design 1 and 2 allow for longer packing time, as compared to design 3. However, 17 seconds is already longer than the value used in practical moulding given the typical small gates used for the overall part melt entrance, causing the gate freezing time to be the main bottleneck for the packing phase. As a result, the difference in $Y_{Resonator}$ will not impact the filling of the resonator mass significantly, which can also be concluded from the similar shrinkage values in the resonator mass. Based on these considerations and outcomes, design 3 is selected as the final resonator geometry.

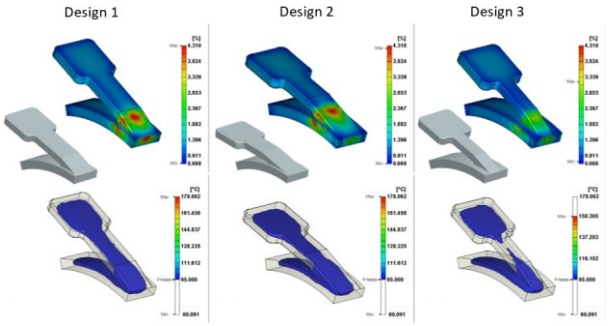

Figure 3: Volumetric shrinkage [%] (top) and molten core [°C] (bottom) after 17 seconds for the three selected designs.

4.3 Final LRM product and mould design

From the above ring filling calculations, the warpage after cooling resulted in 0.65 %, therefore, the entire design was scaled with this value to ensure a proper fit to the tube. With the resonator and ring dimensions in place, the design is further tailored for IM manufacturing. To this end, draft angles are incorporated in the entire design except for the inner diameter to facilitate demoulding while maintaining a large contact area with the pipe. Furthermore, all sharp corners are rounded to reduce internal stresses. Lastly, a cantilever-snap fit with a plug diameter of 4 mm is added and the LRM part design is further tailored for IM. These changes lead to the LRM design shown in Fig. 4a, for which a final resonator eigenfrequency of 571 Hz is obtained. To facilitate the moulding process, a 5 mm diameter runner is designed, and a submarine gate is selected. This gate type enables automatic part-gate separation during demoulding caused by the undercut which is present. The mould design includes two part

cavities, with the parting plane positioned at the product's center (Fig. 4b).

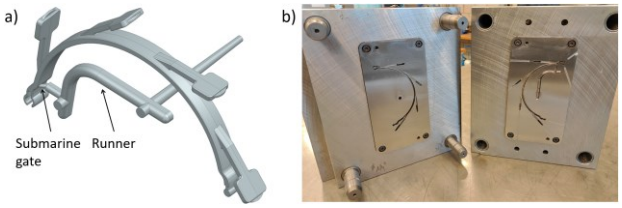

Figure 4: a) Final LRM and runner design, b) both cavity inserts positioned in the mould.

4.4 LRM manufacturing

The moulding is performed using a single screw electrical DEMAG ERGOTECH IntElect 50/330-100 IM machine. The maximal mould clamping force is 500 kN, while a 22 mm horizontal screw with a L/D ratio of 20 is used. The mould temperature is regulated using a EURO CHILLER 3FLOWS P 612/90 controller. The primary process parameters are listed in Table 3. During manufacturing, a cycle time of 21 seconds is maintained. To assemble the LRM, sixteen ring sections (Fig. 5a) are added to the tube (Fig. 5b), leading to 8 full ring additions with a intermediate spacing of 25 mm.

Table 3: Main IM process parameters.

Dosing volume [cm3]	16.3
Switch over point [cm3]	4.4
Melt temperature [°C]	240
Mould temperature [°C]	70
Packing pressure [MPa]	60
Packing time [s]	5
Cooling time [s]	20
Volumetric injection rate [cm3/s]	26.6

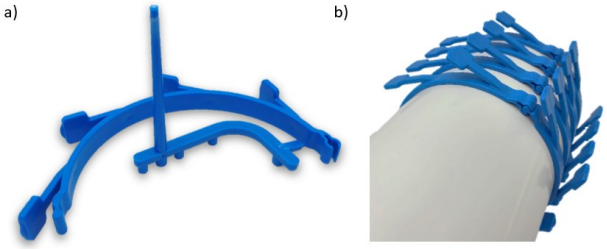

Figure 5: a) Manufactured LRM ring with runner, b) LRM rings assembled to the aluminium pipe.

5. RESONATOR AND LRM PERFORMANCE PREDICTIONS

The resonator eigenfrequencies and the LRM stop bands are predicted using the corresponding resonator and 25 mm UC FE-models. To this end, the manufacturing process-informed toolchain as proposed in [7] is used. This allows to account for process induced shrinkage and density during the predictions by transferring the deformed Boundary Layer Mesh (BLM) with distributed material density obtained from the IM simulation to structural FE. Therefore, an in-house material property mapping routine is used, in which the Scattered Interpolation [9] method is implemented in MATLAB. This method employs Delaunay triangulation to construct an interpolation function over the IM mesh. The material properties on the FE mesh are then computed using linear interpolation, ensuring smooth transitions. From the resonator FE model, the eigenfrequencies are calculated. Next, the resonator mesh is mated to host-structure for stop band calculation.

5.1 Deformed geometry and density distribution

With the final LRM, runner and gate design in place, a filling, packing and warpage simulation is conducted. Fig. 6 shows the resulting displacement of the base ring and resonators, along with the density distribution. The total displacement due to shrinkage and warpage consists of the displacement in the base ring and the displacement of the individual resonators. The ring inner diameter decreases which was already accounted for in the design to ensure a proper fit to the pipe. The resonator shrinkage is expected to lead to an increased eigenfrequency. Additionally, differences in shrinkage between the different resonators (res. 1-4) also result from the non-uniform shrinkage. The density distribution shows a decreased density at the resonator feet, in line with the shrinkage results from the manufacturability assessment in section 4.2. This density decrease at the

feet becomes more pronounced with increasing distance from the gate, as the extended flow length makes the shrinkage compensation during the packing phase more difficult. Overall, the resulting net density is 1030 kg/m^3, compared to the datasheet value of 1050 kg/m^3. The total predicted part mass is calculated to be 7.953 g.

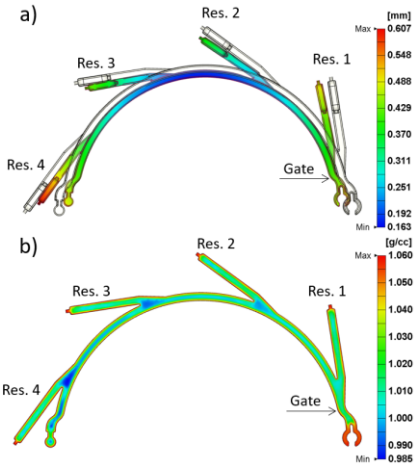

Figure 6: a) Displacement [mm] (deformation x10) and b) density distribution [g/cc] within the LRM ring obtained from IM simulation.

5.2 Eigenfrequency and stop band predictions

The resonator eigenfrequencies for an entire ring section are predicted in Siemens Simcenter using solution 103. A fixed boundary condition is applied on the inner and outer surfaces of the ring. Tab. 4 lists the predicted resonator eigenfrequencies in accordance with the numbering of Fig. 6.

Table 4: Resonator eigenfrequencies obtained form manufacturing-informed predictions.

Resonator 1 [Hz]	579.71
Resonator 2 [Hz]	579.71
Resonator 3 [Hz]	579.73
Resonator 4 [Hz]	580.60

As expected from the calculated model shrinkage and density distribution, all eigenfrequencies increase with respect to the original 571 Hz obtained after drafting. Again, only small differences appear among the resonators individually. This is expected, as the overall displacement and density distribution in the resonator cross-sections are uniform. Since the lower density of resonator 4 occurs in the resonator base, it does not significantly influence the resonator eigenfrequency.

Figure 2 compares the calculated dispersion curves for the bare and LRM case. For the bare tube, the cut-off frequency of the ovalling mode is at 582Hz. Due to the addition of the resonators and their interaction with the ovalling and bending wave, two new cut-on frequencies appear at 499.8 Hz and 665.9 Hz. The obtained stopband for the ovalling mode is (indicated in red) situated between 562.3 Hz and 665.9 Hz. A second bandgap is obtained in the bending wave branch between 562.3 Hz and 579.8 Hz result.

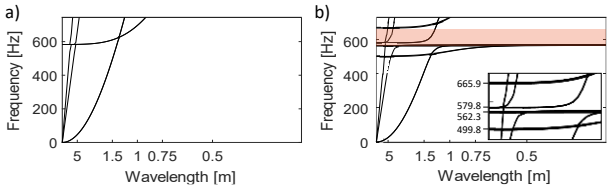

Figure 2: Obtained dispersion diagrams for the a) bare and b) LRM pipe.

6. LRM VALIDATION

For the LRM pipe with 8 fully assembled rings, the forced response is measured. The impact locations are chosen around the circumference, in front of the LRM rings while the response is captured behind the resonator ring additions (Fig. 13). To evaluate the influence of both the clamping and the mass of the rings on the pipe's response, both required to fasten the resonators to the pipe, an non-resonant ring case is created using the rings but removing the resonators, called the non-resonant ring case.

For the non-resonant ring case, the addition of the rings to the pipe clearly lowers the frequency of the first mode (ovalling) while only slightly influencing the second mode (bending). When adding the LRM rings, a clear decrease in the response between 553 Hz and 655 Hz is caused by the resonant effect of the LRM. This is in fair agreement with the predicted stop band between 562.3 Hz and 665.9 Hz. Furthermore, the first peak in the LRM curve around 500 Hz corresponds to the cut-on frequency of the ovalling mode in the LRM dispersion curve. Here the tube's and resonators' motion are in phase. After the stop band, a peak is observed in the FRF

around 655 Hz, which corresponds to the ovalling cut-on frequency after the stop band in the dispersion curve.

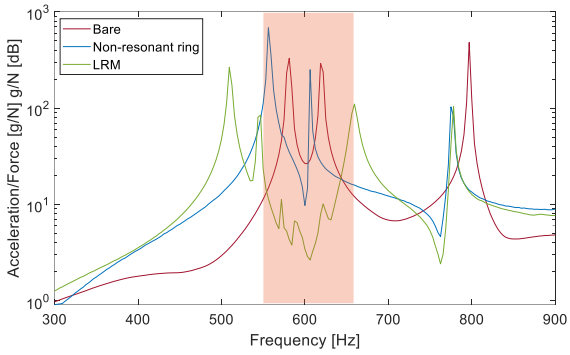

Figure 3: Measured vibration response of the bare, equivalent mass and LRM pipe.

7. CONCLUSION

IM allows for mass-manufacturing of LRM resonators whereas the incorporation of IM process simulation outcomes in the LRM performance predictions has been shown to reduce the off-design performance of resonators. This work builds upon these findings and demonstrates the design and manufacturing of a ready-to-use LRM solution. More specifically, the first ovalling mode of an aluminium pipe is experimentally determined, based on which an LRM ring with four resonators is designed for vibration treatment. To this end, three different resonator designs are found using parameter optimization, whereafter the manufacturability of the designs has been assessed using IM simulations. The final LRM is manufactured and experimentally characterized. The final LRM stop band is predicted using manufacturing-informed predictions, and good agreement is found with experimental pipe response measurements. The successful mass-manufacturing of a ready-to-use LRM with targeted as-manufactured performance facilitates the integration of LRMs in larger-scale designs and paves the way for mass-manufacturable lightweight products with superior NHV performance by design.

ABSTRACT

Selective Laser Sintering (SLS) enables the production of complex structures, but ensuring their geometrical accuracy and material properties remains challenging due to many parameters that influence the final print quality. This study investigates the vibrational properties of PA-12 beams manufactured using SLS, focusing on the relationships between the manufacturing parameters, geometrical accuracy, and natural frequencies. The beams are evenly distributed across the build volume to investigate spatial and thermal effects on the quality of the part. Dimensional measurements are used to calculate the expected natural frequencies of the cantilever beams, which are then compared with the experimental results obtained using an automated impact hammer setup. The collected data visualizes the relationships between beam dimensions, resonant frequencies, and temperature of the printer bed. This data can further be used to optimize SLS manufacturing parameters for improved precision and mechanical performance of printed components, especially important in the design and reliable performance of produced metamaterials, where small deviations can significantly alter functional behavior.

1. INTRODUCTION

Selective Laser Sintering (SLS) is a powder bed additive manufacturing (AM) process that uses one or more lasers to selectively fuse polymer powder layer by layer, enabling the fabrication of complex self-supporting geometries without the need for molds or support structures [1, 2]. Polyamide-12 (PA-12) is a common SLS material valued for its mechanical properties. Achieving high dimensional accuracy in SLS parts is critical, as deviations can negatively impact both mechanical and functional performance [2].

However, maintaining this accuracy is challenging because of shrinkage and warping effects. These occur when the sintered layers cool and crystallize, resulting in geometric distortions [3]. Effective thermal management is therefore essential to mitigate these effects and ensure consistent replication of the intended design dimensions [3, 4]. Such precision becomes even more important in acoustically sensitive designs, where geometric inaccuracies can degrade performance. For example, a study of 3D printed air diffusers found that differences in surface quality and dimensional precision across AM methods significantly influenced acoustic performance [5]. Accurate part fabrication is therefore essential in acoustic applications that rely on tightly controlled geometries. An explicit link is made between the production accuracy of

SLS and the resulting vibro-acoustic properties in a study of a lightweight vibro-acoustic metamaterial demonstrator [6]. In another investigation focused on acoustic resonators, it is suggested that the deviation of the experimental results from the predicted peaks (theory and FEA) might have been caused by geometrical inaccuracies of the 3D-printing machine [7]. Additionally, surface roughness introduced during additive manufacturing has been shown to significantly affect acoustic performance [8]. There is also growing interest in using 3D printed structures for vibration and modal analysis [9].

This study investigates the vibrational performance of PA-12 cantilever beams fabricated across the SLS build volume. Specifically, it examines how dimensional variations and thermal history correlate with the natural frequencies of the beams. The objective is to determine whether certain process parameters significantly influence resonance behavior. This information could accelerate quality control processes in the future.

2. METHODS

2.1 Part Fabriction

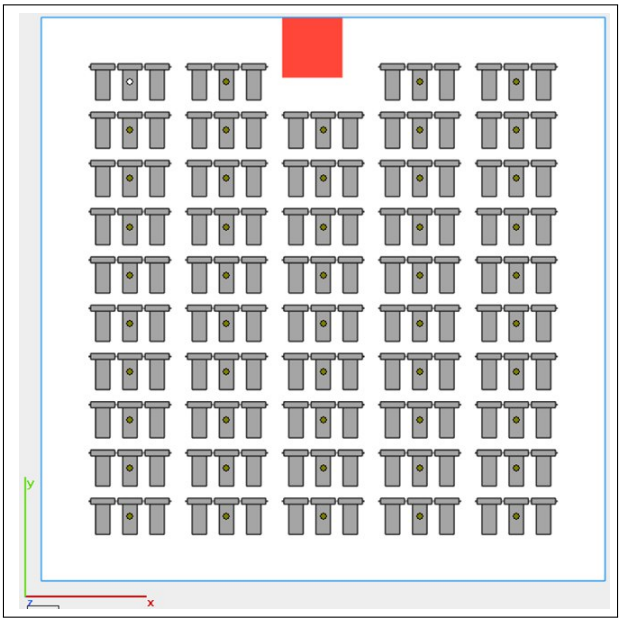

Figure 1. Top view of the printer bed beam layout.

The cantilever beam parts were manufactured using SLS on a Sindoh S100 laser sintering system. Each printed unit consists of three beam segments connected by a thin cylindrical bridge with a diameter of 1.5 mm. The base section of each beam is designed as a 5 × 5 × 20 mm³ block, while the beam portion extends 25 mm in length, 12 mm in width, and 2.5 mm in thickness. These dimensions are shown in millimeters in Figure 2.

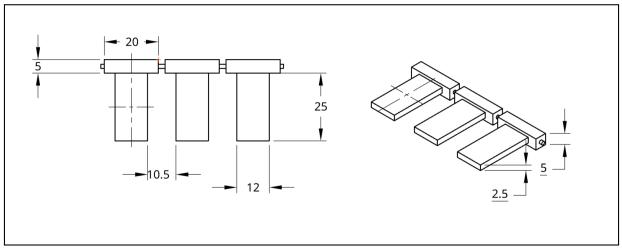

Figure 2. Dimensions of the beam set (mm).

To investigate spatial effects on part quality, the beam units were distributed evenly across the build volume. Individually, the beams form a 15 × 10 grid, which is stacked vertically for a total of 10 layers along the Z-axis. A margin of approximately 40 mm was maintained on all four sides of the print bed. Additionally, a 10 mm vertical offset was introduced below the first printed layer to help record thermal history. The spacing between adjacent parts was 12.5 mm in the X-direction, 10 mm in the Y-direction, and 20 mm in the Z-direction. Figure 1 illustrates the layout of the beam units on the printer bed. The red square in the rear region of the bed denotes a "no-build zone", designated for pyrometer temperature measurements.

All parts were printed in a single job using the same process parameters. A 1:1 mix of new and recycled PA-12 powder was used, with the bed preheat temperature maintained at 173°C. Although the print order reflects the digital label of a part, the actual scan pattern generally proceeded from the front-left to the back-right corner of the print bed, with the back row typically completed last within each layer. Upon completion, the build was allowed to cool gradually inside the chamber for four days.

All beams were labeled at the base, corresponding to their location. All three beam parts in one unit have the same X,Y, and Z label, and are distinguished by an additional number, i.e, X1Y2Z3B1, X1Y2Z3B2 and X1Y2Z3B3 with XYZ referring to the position of the unit in the build.

2.2 Geometrical Measurements

Only beams located in the odd-numbered Z-layers were measured. The primary dimensions — length, width, and thickness — were recorded using digital calipers. All measurements were taken at consistent locations across the parts. Length was measured once along the centerline of the beam (Figure 2, from base to tip. Additional measurements from the base to the left and right sides of the tip were also taken, however, only the central full-length measurement was used in the data analysis due to its greater reliability.

Width and thickness were each measured at three positions along the beam: near the base, at the midpoint, and near the tip. The centerline is shown as a dashed line in Figure 2. For data processing, the average of the midpoint and near-tip measurements was used. Measurements taken near the base were excluded from the average due to greater potential for deviation, as that region is influenced by proximity to the part's base feature.

2.3 Thermal Monitoring

The printer bed temperature was recorded using two instruments located inside the printer: the Optris CT LT pyrometer and the FLIR A655sc infrared (IR) camera. A custom script logged temperature data twice per layer: once before scanning and once before recoating the new layer. The pyrometer readings were used to correct the IR images, as the IR camera is more susceptible to heat deviations and artifacts. Each IR image was subsequently processed to determine the average temperature in the area surrounding each beam. Each beam had a square region positioned at its center, encompassing both the beam itself and the surrounding area on either side. The average temperature was then determined by averaging the pixel values within this selected square region. Certain spots were excluded from the analysis due to obstructions or dead pixels in the IR camera.

2.4 Vibrational Testing

Natural frequencies were extracted using the Grindosonic MK7 automatic impact hammer testing setup. Each beam was positioned on a piece of soft foam, placed directly above the microphone of the device. The impact hammer delivered a consistent tap to the part of the beam corresponding to the expected location of maximum displacement in the first natural frequency mode. The test was repeated three times per beam to ensure repeatability. Only the beams from the first printed layer were measured.

3. RESULTS

The SLS process yielded relatively small dimensional deviations in the length and width of the beams. However, thickness exhibited significantly larger deviations, primarily due to the small design value of 2.5 mm and the influence of shrinkage and warpage effects, as discussed in Section 1. This comparison is illustrated in Figure 3. While length and width deviations were generally centered around 0%, thickness deviations were consistently positive, ranging from approximately 9% to 20%.

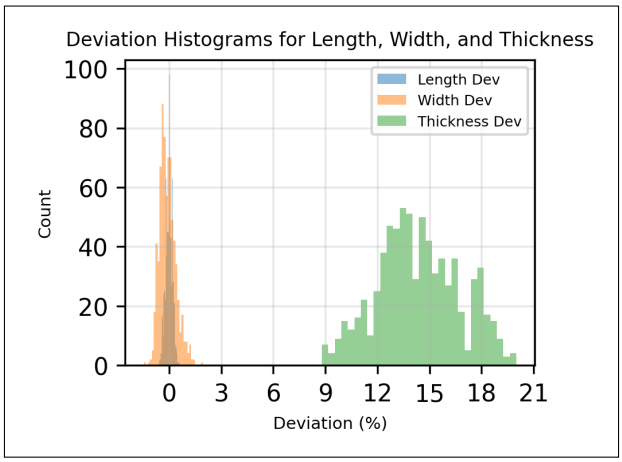

Figure 3. Percent deviation from the design values of beams' dimensions.

A closer look at the thickness distribution at layer Z3, shown in Figure 4, reveals that the thicker beams are concentrated on the right side, particularly near the back-right corner of the printer bed. This trend is also observable, to varying degrees, across the other measured layers.

Figure 5 shows the average temperature measured at each beam location. Uneven thermal distribution across the print bed is evident, with cooler temperatures concentrated near the center. In contrast, the highest recorded temperatures are observed near the back-right corner of the printer bed.

To compare thickness variations, Figures 6 and 7 display all thickness measurements plotted against their corresponding positions. Each data point is colored according to its print order. The front view in Figure 6 reveals an increase in thickness values from left to right, particularly noticeable in X indices 4 and 5. Figure 7 confirms

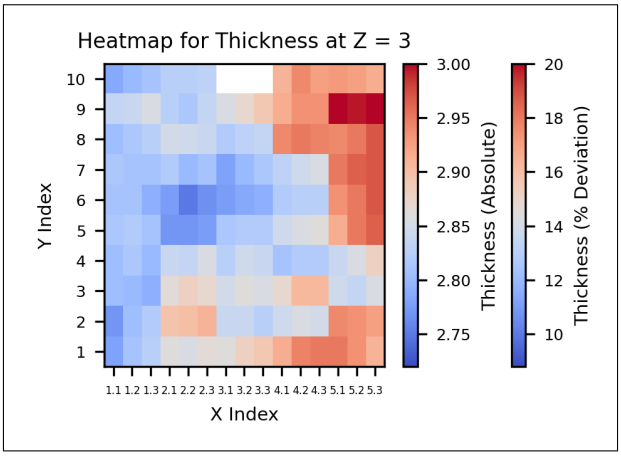

Figure 4. Heatmap of thickness measurements in layer Z3.

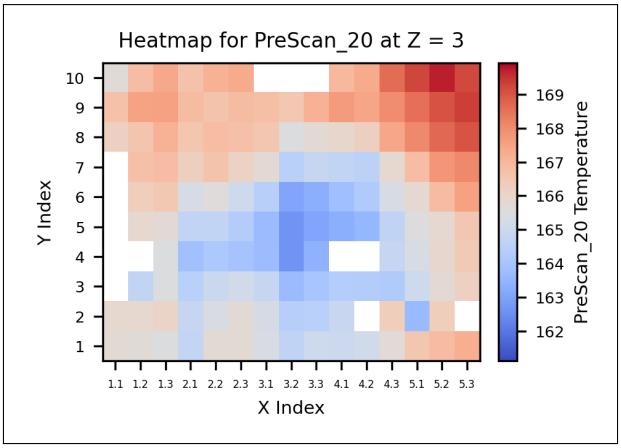

Figure 5. Heatmap of prescan temperature at the twentieth layer of parts at layer Z3 (obstructions and dead pixel measurements excluded).

that parts were generally printed from the front to the back of the bed and highlights a noticeable dip in thickness between Y indices 4 and 7.

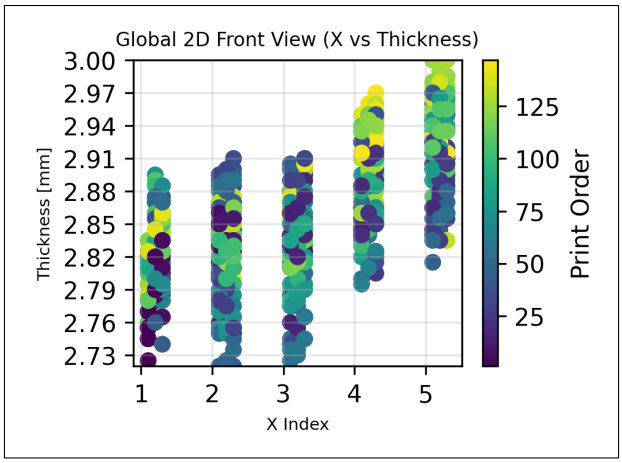

Figure 6. Front view of thickness measurements with print order in all measured layers.

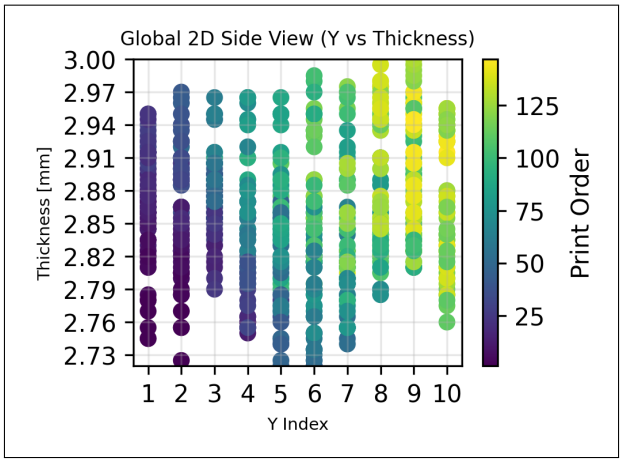

Figure 7. Side view of thickness measurements with print order in all measured layers.

Figure 8 presents the correlation matrix for all measured variables at layer Z1. In this figure, Interlayer T and Part T refer to the temperature measurements taken between layers and at the part layers, respectively. PR and PS denote the PreRecoat and PreScan processes. The numerical suffix indicates the layer number at the specific location: -1 corresponds to the layer just before the part is printed, while 20 indicates the twentieth layer of the

part. Strong correlations are observed between the different temperature measurements, as well as between frequency and both width and thickness. Moderate correlations are also evident between temperature variables and beam dimensions, as well as with the print order.

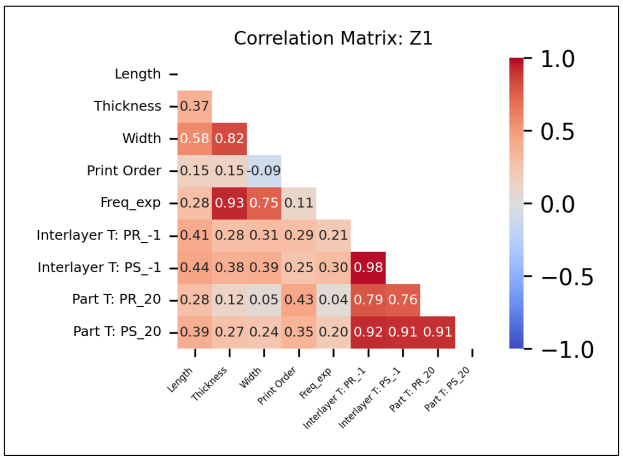

Figure 8. Correlation matrix of measurements in Z1.

The correlation matrix across all layers is shown in Figure 9, which excludes the frequency measurements. Compared to Figure 8, the correlations between the temperature variables, beam dimensions, and print order appear stronger when considering the full dataset. This suggests that the overall thermal history and printing sequence have a more pronounced effect on the geometry of the parts when aggregated across all layers.

4. DISCUSSION

The results of this study provide insights into the complex relationship between SLS manufacturing parameters, dimensional accuracy, and the vibrational properties of PA-12 parts.

4.1 Printer Bed Temperature

Goodridge et al. identified thermal management as one of the primary challenges in achieving consistent part quality in SLS processes [1]. The heatmap of the temperature distribution in Figure 5 shows a distinct thermal variation across the build platform: lower temperatures are observed near the center of the bed, while higher temperatures appear around this region, with the highest values recorded near the back-right corner. This uneven

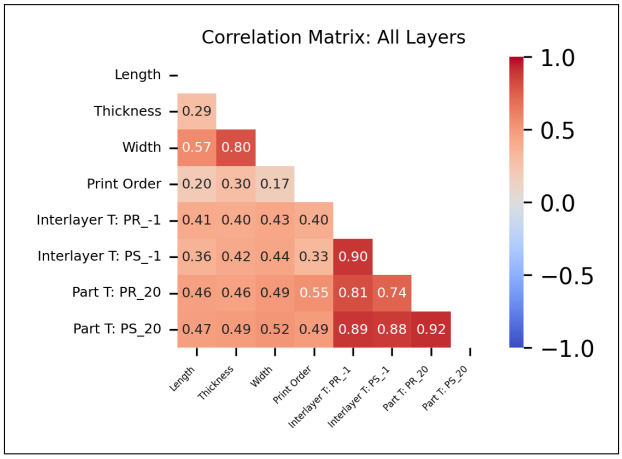

Figure 9. Correlation matrix of measurements in all measured layers.

heating correlates with observed variations in part dimensions. For instance, Figure 7 shows that beams located in the middle of the bed (Y5–Y7) tend to be thinner than those printed in surrounding regions. Likewise, Figure 4 indicates that the beams located in the back-right corner—where the temperatures are highest—are among the thickest in the build.

Despite this spatial trend, the correlation matrix in Figure 9 shows only moderate correlations between recorded temperatures and beam thickness. One explanation is that beams near the left edge of the build are also thinner, yet they experience similar temperature levels to those on the right. This suggests that additional factors, such as print order or local cooldown conditions, may play a role. As described in Section 2, the print order generally progresses from the front-left to the back-right corner, meaning the last-printed parts (often thicker) also correspond to areas with higher recorded temperatures. This may indicate a cumulative thermal effect, where successive laser passes raise the local bed temperature, influencing not only the printed layers but also the interlayers preceding them. However, if temperature were driven only by this effect, a stronger correlation with thickness would be expected. The moderate correlation observed likely arises because temperature is affected by both space and time factors. For instance, thin parts situated near the center of the bed may lie in regions with higher temperatures, but those parts are printed earlier within the layer sequence. As a result, the influence of geometry on temperature becomes entangled with location and print sequence,

weakening the direct correlation between thickness and recorded temperature.

Additionally, the absolute temperature values in Figure 5 are notably lower than the target preheat temperature of 173°C. While the powder bed reaches this temperature during the interlayer heating phase, it drops rapidly during the printing of each layer due to the time required for sintering. The internal heaters cannot compensate quickly enough, resulting in lower effective temperatures at the printed layers. This drop appears to be specific to the part layout of this particular print job and setup – too many small parts were evenly distributed throughout the printer bed, which is not common in typical builds.

4.2 Parameter Correlations

The global correlation matrix in Figure 9 reveals several key relationships between print parameters and part quality. As discussed in Section 1, shrinkage and warpage are known to affect dimensional accuracy. In this design, the width and thickness were more sensitive to these effects and thus exhibited a strong correlation with one another.

Moderate correlations were observed between all temperature variables and both the geometric dimensions and print order. These findings are consistent with the analysis presented in Section 4.1, which suggests that localized temperature changes and thermal history contribute to dimensional variability.

In the Z1 correlation matrix shown in Figure 8, the natural frequency variable was included and, as expected, showed strong correlations with both thickness and width. This is in line with theoretical predictions: the first mode of vibration in beams is a bending mode, which strongly depends on the beam's moment of inertia I, defined for a rectangular cross-section as shown in Equation 1. Here, w is the beam width and t is the beam thickness (height in the bending direction). Dimensional deviations in these parameters therefore have a direct and significant effect on the measured vibrational behavior.

$$I = \frac{wt^3}{12} \tag{1}$$

The strong correlation between natural frequency and thickness and width suggests that frequency testing can serve as an effective quality control method on its own. Rather than relying on multiple dimensional measurements, a streamlined quality control process could use automated frequency testing to flag parts that deviate from expected resonant behavior. Since the natural frequency is highly sensitive to small geometric variations, setting specific frequency thresholds would allow rapid identification of parts that may not meet the required geometrical criteria. This non-destructive testing approach could substantially reduce inspection time and costs, ensuring that only components with the proper vibrational characteristics proceed to final assembly or application in acoustically sensitive systems.

5. CONCLUSION

This study has investigated the relationships between SLS manufacturing parameters, dimensional accuracy, and vibrational properties of PA-12 cantilever beams. The findings reveal variations in thickness throughout the build volume that moderately correlate with temperature in the powder bed. Correlation analysis of the first layer of printed beams demonstrated consistent relationships between thermal conditions, dimensional deviations, print order, and natural frequencies. A strong correlation between natural frequency and part dimensions suggests the possibility of a faster, geometry-based quality control process for SLS-manufactured PA-12 parts. While only moderate correlations were found between frequency and temperature data in the first layer, measuring additional layers may reveal stronger associations.

Several areas for improvement and further investigation have emerged. First, the part design should be revised. A revised design could improve the reliability of frequency measurements and potentially reduce scan times — an important factor, as prolonged scanning was observed to lower the bed temperature during printing.

Additionally, increasing the preheating duration may help stabilize the thermal environment. Uncorrected IR camera data showed that the machine was still accumulating heat during the first two part layers of the build. A longer preheating phase could allow the system to reach thermal equilibrium before the actual printing begins. Furthermore, re-evaluating the heater orientation within the machine may help achieve a more uniform temperature distribution across the build surface.

Future work should focus on a more comprehensive analysis of the interactions between process parameters, dimensional accuracy, and vibrational response. This includes collecting data across all build layers, improving thermal management, and optimizing beam geometry. The application of compensation factors to address predictable dimensional deviations could lead to improved part consistency and performance.

ABSTRACT

Locally resonant metamaterials (LRMs) have recently emerged as a promising solution which can combine lightweight design with effective noise and vibration control. These LRMs, typically consisting of a host structure with sub-wavelength added resonators, are often manufactured using additive manufacturing, which is unsuitable for mass production. Moreover, the manufacturing process can significantly affect the performance of LRMs, leading to differences between their intended design and actual results. Injection molding (IM) has been recently explored as an alternative that is suitable for mass manufacturing of LRMs though it still may affect performance.

This study focuses on how IM process parameters such as injection and packing pressure, mold and melt temperature, cooling and packing time, and injection speed influence the vibration attenuation in LRMs by investigating their impact on the effective modal parameters of the resonator and on the predicted stop band. A framework is proposed which iteratively calculates these objectives and uses single and multi-objective Bayesian approaches to determine its upper and lower bounds with respect to variation in the process parameters. These process parameters are found to have a significant impact on the vibroacoustic behavior of the LRMs, which may also be leveraged further in view of broadband vibration attenuation.

1. INTRODUCTION

Industry has a clear trend toward lightweight designs mainly due to economic and ecological reasons; however, traditional noise and vibration mitigation strategies typically rely on adding mass or volume, which leads to heavy and bulky solutions. This not only increases emissions during transport but also contradicts the trend towards lightweight design. In contrast, LRMs offer a lightweight and targeted approach to addressing noise and vibration issues.

In literature, LRMs have been manufactured using additive manufacturing [1–3], which has advantages like rapid prototyping but is not suitable for mass production. For metals, manufacturing techniques such as punching and bending [4], milling [5], and waterjet cutting [6] are utilized. Additionally, laser cutting [7] and thermoforming [8] are other alternatives. Some recent studies [9, 10] also investigated injection molding (IM) for LRM production, which is one of the most common techniques for mass manufacturing plastics. Manufacturing variability is inherent due to real-world engineering conditions [11], which may affect robustness.

In a previous study, it was shown that incorporating IM simulations during the design of an injection-molded metamaterial can improve the predicted performance [10]. It is also well known that the machine process variables in the IM process significantly impact product quality, particularly in terms of warpage and shrinkage deformations

[12], as well as part weight [13]. In particular, process parameters influence warpage, shrinkage, and material variability. In this study, we propose an approach to evaluate the potential influence of operational parameter ranges by combining a numerical prediction workflow [10] for the as-produced metamaterial performance with an interval uncertainty quantification approach.

In what follows, first in Sec. 2 a brief description of the metamaterial design is given. Sec. 3 outlines the approaches used to calculate the performance metrics and bounds. Sec. 4 introduces the model and presents the results. Finally, Sec. 5 discusses the main findings and gives the future perspectives.

2. THE METAMATERIAL DESIGN

An LRM plate is investigated, which consists of a 50 mm square aluminum (aluminum 6061) plate with a 1.5 mm thickness as the unit cell host structure and periodically added dual-cantilever polypropylene (PP) resonators. The resonator C [10] is chosen for analysis using the same geometric parameters employed in the study, with a first combined bending eigenfrequency tuned nominally around 1154 Hz.

3. METHODOLOGY

In this section, the numerical performance prediction flow is explained, the performance metrics to be used in this study are introduced, and approaches to find the performance bounds are briefly discussed.

3.1 Injection Molding Simulations

The machine process parameters to be varied are injection and packing pressure, mold and melt temperature, cooling and packing time, and injection speed. For the specific parameters, filling, packing, and warpage processes are simulated with MOLDEX3D 2023 using a boundary layer mesh (BLM) of the part. Then, this BLM mesh is exported, including the material cards that may differ in density across the elements in the mesh.

Two approaches have been studied for performance predictions: Approach 1 for modal parameter estimation and Approach 2 for stop-band predictions. These two approaches are summarized in Fig. 1.

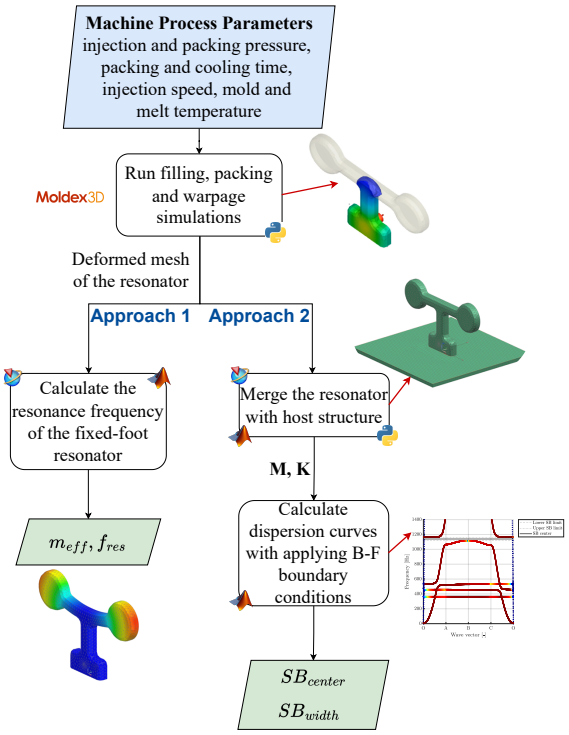

Figure 1: The flowchart of the performance prediction calculations for modal parameters (Approach 1) and stop-band predictions (Approach 2).

3.2 Approach 1: Modal Parameter Estimation

Two key modal parameters for LRM design are chosen as performance metrics: the resonator's eigenfrequency (f_{res}) and its modal effective mass (m_{eff}). The eigenfrequency of the resonator directly affects the stop-band center. On the other hand, as the m_{eff} of the resonator increases, larger stop-band widths can be achieved [14]. Hence, it is crucial to know how these metrics vary if the performance of LRMs is to be assessed.

These metrics will be computed for the resonator with clamped boundary conditions on its foot elements. The nodes corresponding to the resonator foot bottom are automatically selected and fixed for the deformed resonator mesh with variable density information exported from the injection molding simulations. Then, the f_{res} and m_{eff} are calculated by solving the corresponding eigenvalue problem. The automatization of this resonator performance prediction, Approach 1, was implemented using NX open scripts created in Python.

3.3 Approach 2: Stop-band Predictions

Ultimately, to evaluate the performance of the LRMs, m_{eff} and f_{res} may not provide the full story. Therefore, Approach 2 is employed for the stop-band predictions.

First, the deformed resonator is merged with the host structure using conformal meshes by projecting foot elements of the resonator to the unit cell of the plate host structure. Automation for this task is again done using an NX-open script created in Python. Then, applying Bloch-Floquet boundary conditions to the boundaries of the unit cell, the dispersion curves of the infinite periodic structure are calculated along the irreducible Brillouin contour (IBC). A reduced unit cell model technique known as Generalized Bloch Mode Synthesis (GBMS) [15] is used to save computational time. Finally, stop-band characteristics (SB_{center} and SB_{width}) are extracted using the resulting dispersion curves. For a more in-depth explanation of the stop-band calculation procedure, the reader is referred to [16].

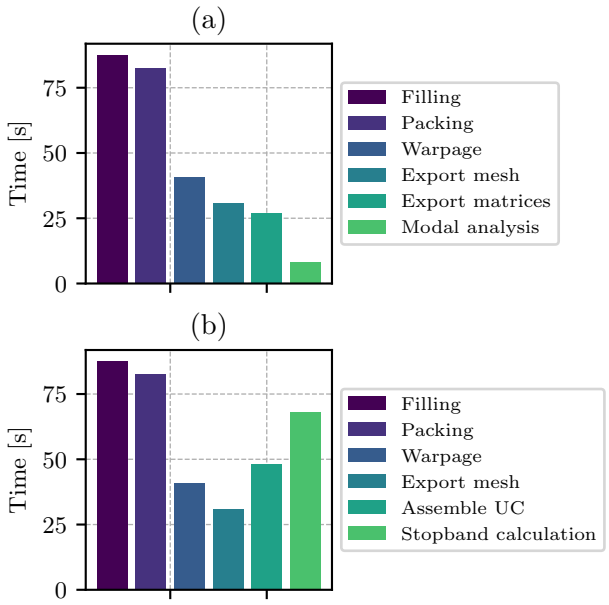

Figure 2: Overview of the time taken for (a) Approach 1, (b) Approach 2.

The steps in Sec. 3.1 and Sec. 3.2 for Approach 1, and Sec. 3.1 and Sec. 3.3 for Approach 2, are sequentially connected to formulate the objective (black-box) function that is to be iterated throughout the optimization step.

3.4 Calculating the Performance Bounds

Recently, Van Belle et al. [17] used interval descriptions of the uncertain resonator parameters to investigate the interval description of the performance metrics. A similar approach is applied here, but this time, instead of the resonator design parameters, the defined seven machine process parameters of IM are used as the bounded input parameters, which would lead to bounds to be found on the performance metrics. This has the advantage of not requiring knowledge of input distributions, allowing one to rely on ranges, tolerances, common sense, or physical constraints; however, the disadvantage is that this method results in only bounds on the performance metrics as output. Nevertheless, this method offers a useful first approximation of how significantly the process parameters influence the performance of LRMs. The objective function for this problem is defined as the calculation of the minimum and maximum values of the performance parameters (minimum and maximum of Approaches 1 and 2) according to the uncertain input interval.

The computation costs for one full evaluation using Approach 1 and Approach 2 are shown in Fig. 2. Due to these computational costs, performing a large number of evaluations for the 7-dimensional parameter space would rapidly become time-consuming. A sampling-based approach, such as quasi-random sampling, typically requires many samples, leading to numerous full simulations. Additionally, it may fail to effectively identify the performance bounds, as it may not cover the entire input space. On the other hand, given the small number of parameters, a similar surrogate modeling technique from the aforementioned study, based on Gaussian processes (GP) and Bayesian optimization (BO), can be leveraged, as it offers an efficient framework for propagating interval-uncertain parameters when there is limited number of uncertain parameters while effectively decreasing the number of simulations to be run.

The methodology of this combined BO and GP approach can be summarized as follows [18]: For a training set, based on a limited number of full simulations, a GP model of the objective function is created. This GP model acts as a hypersurface that approximates the objective function across the entire parameter space. Using this GP model, an acquisition function (AF) can be efficiently minimized to find the likely optimum, which is the potential minimum of the objective function. Depending on the AF used, the likely optimum might be based on local GP mean, uncertainty, or confidence bounds. After the most

promising parameter combination is identified with this AF, a new full simulation is run at that parameter combination. This new data point is then added to the training set, and the GP model is updated accordingly. The process then reiterates, with the updated GP model potentially suggesting even better optimals, until a stopping criterion is met, which is the maximum number of evaluations in this case.

3.4.1 Single Objective Bayesian Approach

For Approach 1, the bounds on the resulting performance metrics at the resonator level, f_{res} and m_{eff} can be computed by the following four optimization problems:

$$\begin{aligned} m_{eff,LB} &= \min\{m_{eff}(\mathbf{p}) \mid \mathbf{p}_{\min} \leq \mathbf{p} \leq \mathbf{p}_{\max}\} \\ m_{eff,UB} &= \max\{m_{eff}(\mathbf{p}) \mid \mathbf{p}_{\min} \leq \mathbf{p} \leq \mathbf{p}_{\max}\} \\ f_{res,LB} &= \min\{f_{res}(\mathbf{p}) \mid \mathbf{p}_{\min} \leq \mathbf{p} \leq \mathbf{p}_{\max}\} \\ f_{res,UB} &= \max\{f_{res}(\mathbf{p}) \mid \mathbf{p}_{\min} \leq \mathbf{p} \leq \mathbf{p}_{\max}\} \end{aligned} \tag{1}$$

where $\mathbf{p}_{\min} \leq \mathbf{p} \leq \mathbf{p}_{\max}$ denotes a vector inequality, i.e., $(p_{\min})_i \leq p_i \leq (p_{\max})_i$ for every $i = 1, 2, \ldots, 7$ defined for the input space for process parameters.

Single-objective BO with GP is applied separately to each objective function to determine the bounds for each modal performance parameter. The acquisition function is selected as the lower confidence bound. This is implemented using the *bayesopt* function in MATLAB, and a *bounding box* is created for the model performance metrics, which demarks the bounded region in the m_{eff}-f_{res} space. An initial training set of 27 full simulations is run, with the corresponding 27 parameter combinations generated through the Halton sequence using the MATLAB function *haltonset*. The stopping criterion is set at a total of 108 model evaluations for each corner of the *bounding box*.

3.4.2 Multi Objective Bayesian Approach

Instead of calculating the *bounding box*, the *bounding envelope* can be calculated if multiobjective optimization is used to calculate the Pareto optimal. Assuming a convex bounding envelope, the f_{res} and m_{eff} space is divided into four quadrants, and the Pareto front for each of these quadrants is sought by the following optimization problems:

$$\begin{aligned} f_{Q1} &= \min\{\begin{matrix}-m_{eff}(\mathbf{p}) \\ f_{res}(\mathbf{p})\end{matrix} \mid \mathbf{p}_{\min} \leq \mathbf{p} \leq \mathbf{p}_{\max}\} \\ f_{Q2} &= \min\{\begin{matrix}-m_{eff}(\mathbf{p}) \\ -f_{res}(\mathbf{p})\end{matrix} \mid \mathbf{p}_{\min} \leq \mathbf{p} \leq \mathbf{p}_{\max}\} \\ f_{Q3} &= \min\{\begin{matrix}m_{eff}(\mathbf{p}) \\ -f_{res}(\mathbf{p})\end{matrix} \mid \mathbf{p}_{\min} \leq \mathbf{p} \leq \mathbf{p}_{\max}\} \\ f_{Q4} &= \min\{\begin{matrix}m_{eff}(\mathbf{p}) \\ f_{res}(\mathbf{p})\end{matrix} \mid \mathbf{p}_{\min} \leq \mathbf{p} \leq \mathbf{p}_{\max}\} \end{aligned} \tag{2}$$

For this, a multiobjective Bayesian algorithm called TSEMO [19] is used. The stopping criteria is set to a total of 120 model evaluations per quarter, with a different set of 27 initial random data points generated through Latin hypercube sampling (LHS) for each quarter.

4. CASE STUDY

A BLM with 5 boundary layers with 1 mm node seed is used, resulting in 33949 elements. After the injection molding simulations, the mesh with variable material cards is exported using the dedicated finite element export option in MOLDEX3D. Similar to [10], density is reduced so that a minimum of 30 different material cards are exported to reduce computational time. The mesh of the resonator is given in Fig. 3.

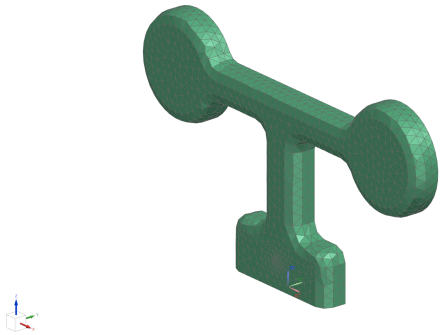

Figure 3: The resonator mesh

The machine process parameter ranges to be examined are listed in Tab. 1.

4.1 Resonator Performance Bounds

A prestudy is conducted using a random Halton dataset and an orthogonal Taguchi array with 14 levels. The total number of model evaluations is set to 196 for the Halton

Table 1: Machine process parameter ranges

Parameter	Low Bound	High Bound
Injection pressure [MPa]	100	180
Packing pressure [MPa]	100	170
Packing time [s]	1	20
Cooling time [s]	1	20
Injection speed [cm^3/s]	10	40
Mold temperature [°C]	40	70
Melt temperature [°C]	220	270

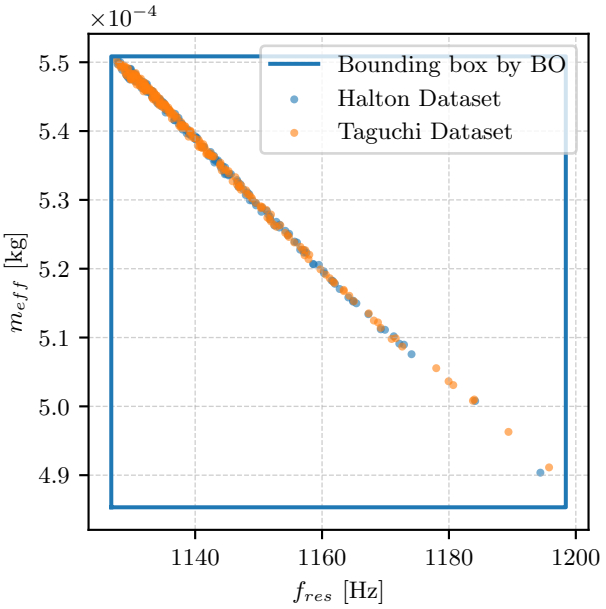

Figure 4: The bounding box calculated by single objective Bayesian optimization, together with 197 different data points calculated by Taguchi array and Halton Sequence.

dataset, based on the corresponding Taguchi array with 7 levels.

Fig. 4 gives the overview of single objective optimization and sampling results. The relationship between the resonator's eigenfrequency and modal effective mass appears to be quite linear, based on sampling. Finding the separate individual bounds shows that the samples are all within these bounds. However, the bounding box, which is now necessarily a rectangle, loses that clear trend. Thus, although interesting and promising, the multiobjective approach could give more insights.

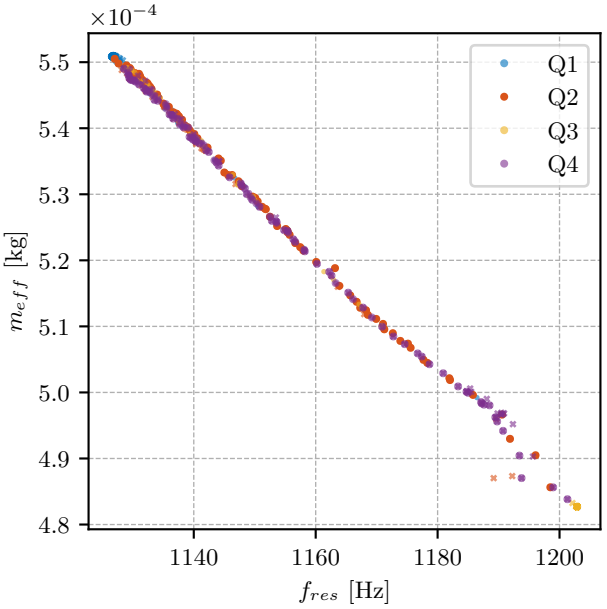

Figure 5: The bounding envelope calculated by multi-objective Bayesian optimization.

Fig. 5 gives an overview of the multi-objective optimization results. In comparison with Fig. 4, it shows that only a few samples are in the bottom-right corner, while most are clustered in the middle to top-left regions. This suggests that the parameter range leading to the bottom-right region is potentially narrow or scattered, making it harder to capture. While the BO algorithm performs well in the middle and top-left, refining the acquisition function, kernel, or objective function may help improve results in the bottom-right.

4.2 Stop-band Performance Bounds

A Taguchi sampling-based approach is done on the stop-band performance to present an initial impression in this paper. Fig. 6 shows an overview of the stop-band predictions. As is well-known from metamaterial design, the SB_{center} is highly correlated with f_{res}, which is also seen on Fig. 6, while the SB_{width} depends on the (effective) mass of the resonator. Moreover, a broader stop-band with increasing frequency is typically expected. However, in this case, the increasing frequency corresponds to, and may even be caused by, a reduced resonator ef-

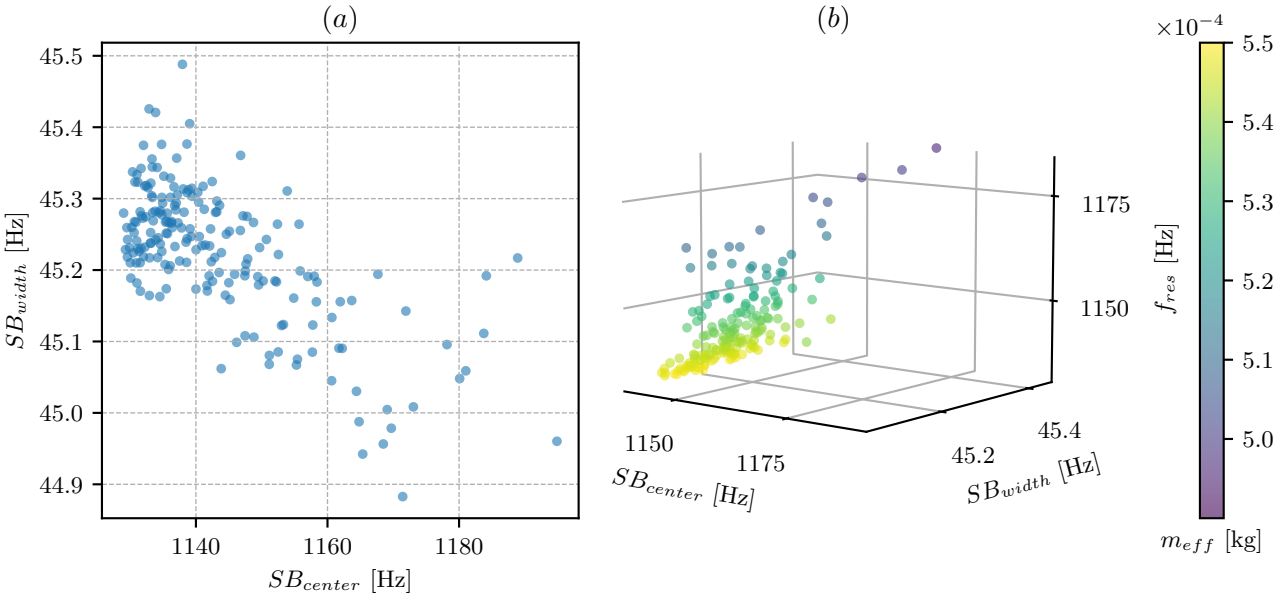

Figure 6: (a) Approach 2 metrics calculated with the Taguchi sample (b) combined resonator (Approach 1) and stop band (Approach 2) metrics plotted together.

fective mass. In Fig. 6, the stop-band width slightly decreases (yet remains almost constant), suggesting that, at the LRM level, both of these effects may, to some extent, counterbalance each other for this example.

5. CONCLUSIONS

In this paper, two approaches for assessing the IM variability are proposed for LRMs. These approaches iteratively calculate the LRM performance, either at the resonator level or at the unit cell level, to investigate the influence of manufacturing variability effects of IM.

The machine operation parameters of the IM process are shown to have a clear effect on the vibroacoustic performance of the LRMs and the targeted frequency range of the resonator. For the given case study, with the variation in process parameters shown in Tab. 1, an approximately 3% variation in frequency and 6% variation in effective mass of the resonator can be observed from Fig. 5. This variation could be utilized further for broadband attenuation.

Although the bounding box indicates bounds on individual performance metrics well, trends that may exist between dependent performance metrics are lost. Using a Pareto multi-objective BO optimization showed great potential in more accurately capturing the performance bounds in LRMs.

Further investigation is required for more definitive conclusions, as the results for Approach 1 need more analysis, and the results for Approach 2 are still very preliminary and indicative. However, this framework shows promising potential for investigating manufacturing variability. In future work,

- a qualitative study will be conducted on each parameter to assess the contribution and importance of individual machine parameters versus their combined impact.
- the analysis of resonator metrics will be further expanded, including stiffness, to explain frequency variation better.
- the scope will be extended to include material property variation besides purely manufacturing process settings.

ABSTRACT

The development of acoustic materials with broad-spectrum efficiency remains a critical challenge, particularly for achieving effective low-frequency absorption. This study presents a composite sound absorber that combines a dense, conventional felt matrix with additively manufactured 3D printed inclusions designed to enhance low-frequency attenuation. These inclusions, fabricated using cost-effective Fused Filament Fabrication (FFF) technology, feature labyrinthine geometries with high tortuosity, designed to achieve subwavelength resonances. The combination of these elements results in a thin, lightweight, and scalable solution for sound attenuation. The design procedure developed for such composites is based on complex but fully analytical modelling. The composite material exhibits exceptional performance, achieving high levels of absorption at the designed low frequency due to inclusions, while maintaining efficient broadband characteristics of the matrix. The analytical predictions are confirmed experimentally by impedance tube measurements. By leveraging the advantages of additive manufacturing and conventional materials, this work paves the way for economically viable, tailored acoustic solutions.

1. INTRODUCTION

Low-frequency sound absorption remains a major challenge in acoustic material design. Traditional porous absorbers, such as fibrous or foam-based materials, rely on viscous and thermal losses to dissipate acoustic energy [1]. While effective at mid-to-high frequencies, these materials require considerable thickness to achieve meaningful absorption at lower frequencies due to the inherent limitations of quarter-wavelength resonance. This constraint often conflicts with the practical need for thin, lightweight, and efficient sound absorbers, particularly in applications such as automotive interiors and aircraft structures.

To overcome this limitation, researchers have explored various approaches to enhance low-frequency sound absorption without excessively increasing material thickness. Acoustic metamaterials [2] have been developed to manipulate wave propagation in unconventional ways, enabling sub-wavelength sound absorption through engineered periodicity and resonance effects.

Many of these solutions are based on the use of resonant structures, such as Helmholtz resonators [3–5] of unconventional geometry, often in parallel arrangements, or micro-perforated panels [6, 7] backed by air cavities of various shapes. The aim is to exploit resonance effects in order to improve acoustic absorption in specific low-frequency bands. Impedance-matching techniques [8–10] are used for graded or hierarchical structures to help transfer sound energy more effectively into dissipative regions. Another way to approach the problem is to extend the effective propagation path of sound waves in the volume of the material, thereby improving the energy dissipation mechanisms without a substantial increase in the material thickness. Solutions based on this idea include coiled-

up cavities and labyrinthine channels [11–14]. In parallel to the aforementioned strategies, the integration of engineered materials and metamaterials within composite absorbers [12, 15–17] has gained increasing attention. By embedding carefully tailored acoustic structures into conventional porous materials, it is possible to enhance energy dissipation mechanisms and extend the absorption to lower frequencies.

This study presents an experimentally validated analytical modelling of an acoustic composite to demonstrate how inexpensive and easy-to-3D-print inclusions can enhance the low-frequency sound absorption of conventional felt-based materials. The work addresses the above-mentioned critical limitation of traditional porous absorbers, which require significant thickness to achieve effective performance in the low frequency range.

The paper is structured as follows. Section 2 describes the composite material design and its components, including their fabrication and assembly. An acoustic modelling for predicting the performance of the composite absorber is discussed in Section 3. Section 4 discusses sound absorption results and provides experimental validation obtained through impedance tube measurements of a composite sample under normal incidence conditions. The key findings and conclusions are summarised in Section 5.

2. COMPOSITE PANEL

2.1 Design and components

Conventional polyester acoustic felt is known for its excellent sound absorption capacity in the mid- and high-frequency range. However, its relatively low tortuosity and high porosity limit its effectiveness at lower frequencies. To overcome this limitation, a composite structure is proposed in which labyrinthine metamaterial inclusions are embedded in a felt matrix.

Figure 1 (a) shows an example design of such a composite panel with a simple, periodic arrangement of identical inclusions. These inclusions have the shape of a cuboid with a square base and dimensions $W \times W \times H$, see Figure 2 (b) and Table 1 for the actual values of these and other dimensions. The inclusion thickness H is greater than the thickness H_F of the felt matrix, so an air gap is created behind the felt layer, which increases its absorption capacity. The proposed acoustic composite panel consists therefore of three materials: a conventional polyester felt, 3D-printed inclusions with labyrinthine channels, and air. The air fills the gap behind the felt layer, but also saturates the pores in the felt and the labyrinthine channels of the inclusions, thus acting as a medium for the propagation of sound waves.

Table 1. Useful dimensions (mm).

D	W	H	H_F	H_G	w	a	b
63.5	40	18	9	9	1.05	0.8	6.35

An important aspect of designing the composite panel is determining the appropriate ratio of the inclusion surface area to the surface area of the felt matrix. This ratio plays an important role in the composite modelling, as discussed in Section 3. In this study, this proportion was adopted so that a composite sample that is representative of the entire composite panel could be tested in a circular impedance tube with an internal diameter of $D = 63.5$ mm, see Figure 1 (b).

2.2 Composite sample

Figure 2 shows two components, i.e. (a) the felt matrix and (b) the metamaterial inclusion, of a circular sample of the composite panel, as well as (c) the assembled sample ready for testing in a circular impedance tube. The component manufacturing and sample assembly procedure are described below.

A circular matrix sample of diameter D, see Figure 2 (b), was cut from the felt panel of thickness H_F, using an optical laser cutter (Sculpfun S30 Pro Max). The cutting diameter was increased by the laser beam width of 0.3 mm. This dimensional compensation was applied to ensure precise fit of the sample inside the impedance tube. A similar compensation was applied when cutting the square hole with dimensions $W \times W$ for the inclusion.

The labyrinthine inclusion shown in Figure 2 (b) was designed to contain three identical labyrinthine slits (channels) characterised by very high tortuosity, see Figure 3, and optimised for low-frequency sound absorption. It was additively manufactured from the thermoplastic polymer acrylonitrile-butadiene-styrene (ABS), which was selected for its reliability, quality and good mechanical properties. The two-dimensional inclusion design (see Figure 3) was optimised to facilitate efficient 3D-printing via Fused Filament Fabrication, taking into account in particular the size of the printing nozzle.

To ensure proper integration within the polyester felt matrix and eliminate acoustic leakage, aluminium tape was glued to the back and side surfaces of the inclusion as shown in Figure 2 (b). The taped inclusion was tightly fitted into the square hole of the felt matrix during assembly of the composite sample, Figure 2 (c).

3. ACOUSTIC MODELLING

3.1 Equivalent fluid approach

Acoustic modelling of the composite is based on the equivalent-fluid approach [1]. This means that both com-

Table 2. JCAL parameters for the composite panel components.

Material	ϕ (%)	α_∞ (–)	Λ_v (10^{-6}m)	Λ_th (10^{-6}m)	$\mathcal{K}_0$ (10^{-10}m^2)	Θ_0 (10^{-10}m^2)
polyester felt	96	1.1	27.3	82.5	3.21	5.89
labyrinth	52.43	38.02	1050	1050	12.67	481.7

ponents, i.e the felt material and the labyrinth inclusion, are modelled as effective acoustic fluids equivalent to rigid materials with open porosity saturated with air.

The well-known Johnson-Champoux-Allard-Lafarge (JCAL) model [1] is employed for both equivalent fluids. This model requires six intrinsic parameters of a porous material to fully describe its acoustic behaviour. These parameters are: porosity (ϕ), tortuosity (α_∞), viscous characteristic length (Λ_v), thermal characteristic length (Λ_th), static viscous permeability ($\mathcal{K}_0$), and static thermal permeability (Θ_0). They are discussed below for both composite components.

Once the six parameters are known for a porous material, its two dynamic permeabilities – viscous and thermal – can be calculated using the scaling functions of the JCAL model. The scaling functions, and therefore both dynamic permeabilities, depend on the frequency f. The dynamic viscous permeability also depends on the kinematic viscosity of the air saturating the pores, while the dynamic thermal permeability depends on the thermal diffusivity of air. The dynamic permeabilities are used to calculate the effective properties of the equivalent fluid: firstly, the effective density and compressibility, and then also the effective speed of sound and characteristic impedance. For this purpose, the ambient mean pressure and some other air properties are also required. Details can be found in Refs. [1, 18].

3.2 Parameters for the conventional acoustic felt

For the acoustic polyester felt, the JCAL parameters were determined experimentally using inverse characterisation combined with gravimetric analysis. The Porosity was estimated directly by the gravimetric analysis, while the remaining five parameters were obtained by fitting theoretical predictions of the surface acoustic impedance and reflection coefficient to the corresponding experimental results measured in an impedance tube on a circular sample of the felt panel. This hybrid procedure ensured correct parameter estimation, enabling precise modelling of the acoustic behaviour of the felt. The parameters characterised for the felt material are given in Table 2.

3.3 Parameters for the labyrinthine inclusion

In contrast to the felt, all six JCAL parameters can be determined analytically for the 3D printed labyrinthine inclusion, because its microstructural geometry is relatively simple and well-defined. It is clearly visible in Figure 3 which shows a cross-section of the composite sample. The inclusion has three identical labyrinthine channels of constant width w, which along with the remaining two dimensions a and b (see Figure 3) uniquely define the two-dimensional microgeometry of the inclusion. The actual values of all necessary dimensions are given in Table 1. These dimensions allow for a direct calculation or estimation of the required JCAL parameters.

The porosity defined as the volume ratio of air in the three channels to the total volume of the inclusion can be determined from the microstructural geometry of its cross-section (see Figure 3), namely

$$\phi = \frac{3w\ell}{WH}\,, \tag{1}$$

where

$$\ell = 16a + 14b + 14w \tag{2}$$

is the length of each labyrinthine channel (calculated along its centreline with sharp corners at each bend).

Since the channels are identical and have a constant width, the kinematic tortuosity can be estimated using the definition of geometric tortuosity [13, 19, 20], i.e. as the squared ratio of the channel length ℓ to the material thickness H. Zielinski et al. [13] demonstrated that to make this estimation more accurate the channel length should be replaced by the estimated length of the flow path through the channel

$$\widetilde{\ell} \approx \ell - 24w + 24\frac{\pi}{2}\frac{w}{2}\,. \tag{3}$$

Here, the flow path is accurately approximated by the channel centreline with rounded corners (at each of

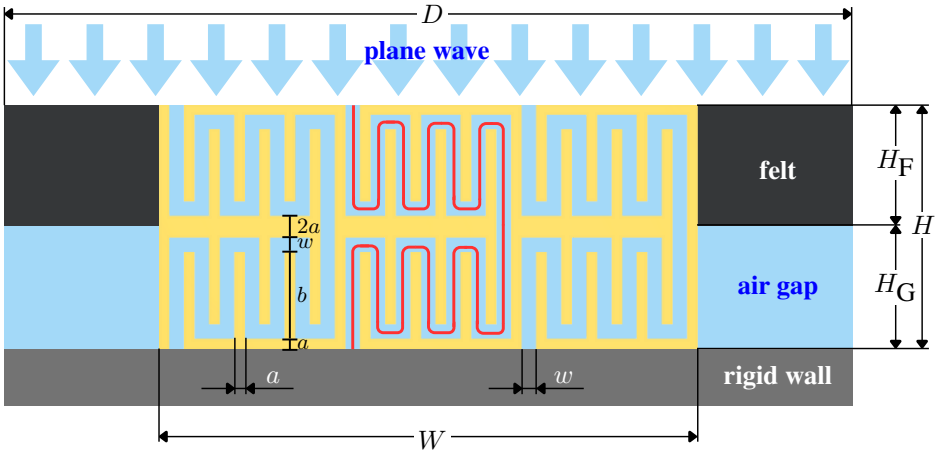

Figure 3. Cross-section of the composite panel (see Table 1 for the actual dimensions).

24 bends), marked with a red curve in Figure 3. Therefore, the tortuosity of the labyrinthine material is calculated as follows

$$\alpha_\infty \approx \left(\widetilde{\ell}/H\right)^2. \tag{4}$$

For a channel with constant width, the thermal characteristic length is equal to its width. This also applies to the characteristic viscous length if the channel is straight. When it is tortuous, as in the case of labyrinthine slits of this work, the channel width is still a very good approximation of the viscous length [1, 13]. Therefore,

$$\Lambda_\mathrm{v} \approx \Lambda_\mathrm{th} = w\,. \tag{5}$$

Based on the determined parameters, the viscous and static thermal permeabilities can be computed for the material with labyrinthine slits, using the following formulae

$$\mathcal{K}_0 \approx \frac{\phi\, w^2}{12\alpha_\infty}\,, \qquad \Theta_0 \approx \frac{\phi\, w^2}{12}\,. \tag{6}$$

The values of JCAL parameters calculated for the labyrinthine inclusion are listed in Table 2, where they can be confronted with those determined for the felt material.

3.4 Surface acoustic impedances

The JCAL parameters determined for the felt matrix and labyrinth inclusion (see Table 2) allowed the calculation of the effective properties for both equivalent fluids that represent these materials in acoustic modelling. In particular, the effective speed of sound for the felt material c_F and for the labyrinth c_L were calculated along with the corresponding characteristic impedances, Z_F and Z_L, respectively. Recall that all these effective properties are complex functions of frequency.

The effective properties can be used to determine sound wave propagation in fluids equivalent to porous materials. Important acoustic indicators such as surface acoustic impedance of a porous layer can be determined. The surface acoustic impedance $\mathcal{Z}_\mathrm{sF}$ of a hard-backed felt panel with thickness H_F and the surface impedance $\mathcal{Z}_\mathrm{sL}$ of a hard-backed labyrinthine material with thickness H_L are calculated as follows

$$\mathcal{Z}_\mathrm{sF} = Z_\mathrm{F} \coth\left(\mathrm{i}\omega H_\mathrm{F}/c_\mathrm{F}\right), \tag{7}$$

$$\mathcal{Z}_\mathrm{sL} = Z_\mathrm{L} \coth\left(\mathrm{i}\omega H/c_\mathrm{L}\right). \tag{8}$$

Here, $\omega = 2\pi f$ is the angular frequency and $\mathrm{i} = \sqrt{-1}$.

Recall that the felt matrix in the composite panel is backed by an air gap of thickness $H_\mathrm{G} = H - H_\mathrm{F}$, see Figure 3. Therefore, the surface acoustic impedance of such a two-layer system is required, i.e.

$$\mathcal{Z}_\mathrm{sFG} = \frac{\mathcal{Z}_\mathrm{sF}^2 + \mathcal{Z}_\mathrm{sF}\mathcal{Z}_\mathrm{sG}}{\mathcal{Z}_\mathrm{sF} + \mathcal{Z}_\mathrm{sG}}\,. \tag{9}$$

In the formula above

$$\mathcal{Z}_\mathrm{sG} = Z_0 \coth\left(\mathrm{i}\omega H_\mathrm{G}/c_0\right) \tag{10}$$

is the surface acoustic impedance of a hard-backed air gap with thickness H_G. Here, Z_0 and c_0 are the characteristic impedance and speed of sound in air, respectively.

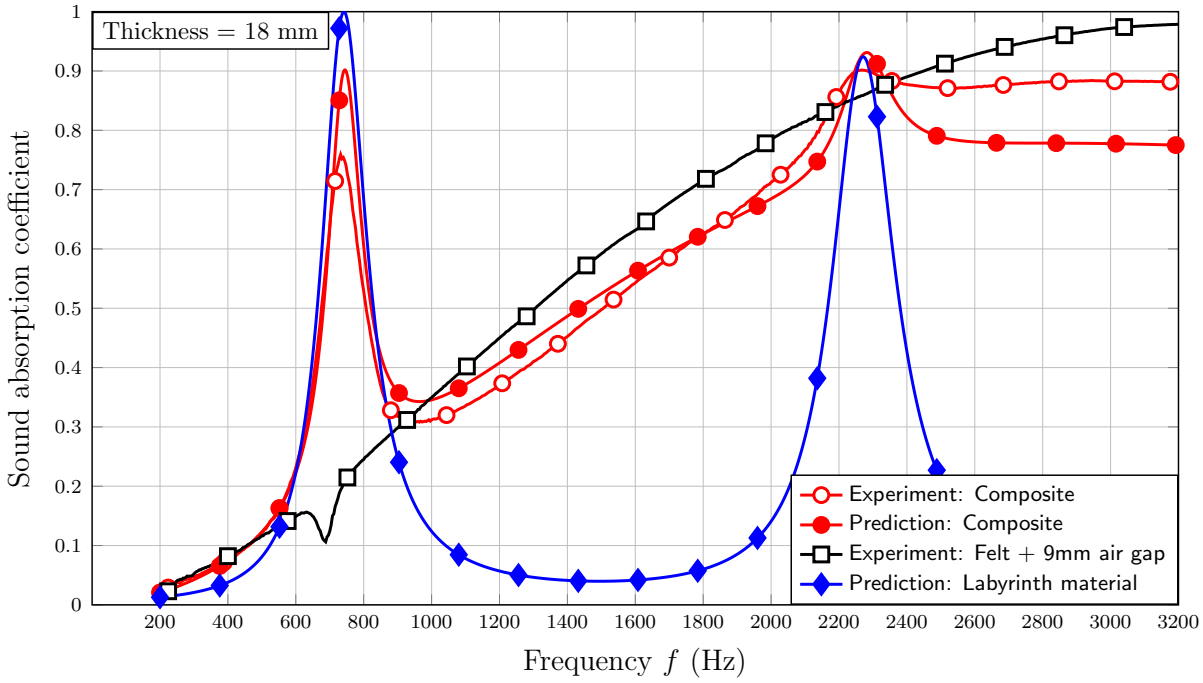

Figure 4. Sound absorption measured and predicted for the acoustic composite sample, measured for the felt panel backed by an air gap, and calculated for the labyrinthine material.

Finally, the surface acoustic impedance of the composite panel can be determined as
